Preparation of [PtS—CH(Me)—CH_2—S$(Ph_3P)_2$]. 1,2-Propanedithiol (1.0 cm^3) was added to a solution of $[Pt(PPh_3)_4]$ in dichloromethane (10 cm^3). The solution immediately turned pale yellow and after 3 min stirring was discontinued. The mixture was triturated with diethylether (30 cm^3) and cooled to −20°C. The product [PtS—CH(Me)—CH_2—S$(Ph_3P)_2$] (**8**) (0.27 g, 76%) was isolated as pale yellow prisms.

^{31}P NMR ($C_6D_5NO_2$): δ (ppm) = 21.4 and 22.1, relative to 85% H_3PO_4 (ext.), J(P–P) (Hz) = 23.8.

NMR spectra

^1H and ^{31}P spectra were recorded on a Brüker AM250 spectrometer operating at 250 and 36.2 MHz, respectively. Measurement of ^1H and ^{195}Pt NMR spectra was also performed for certain compounds at the SERC High Field NMR Service

at Warwick University. Computer simulation of spectra was carried out using previously reported procedures.[4]

X-ray crystallography

All crystallographic measurements were made on a crystal sealed under nitrogen in a glass capillary, using a CAD-4 diffractometer operating in the ω–2θ scan mode with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) as described previously.[11]

Crystal data. $C_{31}H_{39}ClS_2Pt_2P_2 \cdot CHCl_3$, formula weight = 1082.732, monoclinic, $a = 10.298(1)$, $b = 20.189(5)$, $c = 18.209(2)$ Å, $\beta = 92.41(1)°$, $V = 3782.2$ Å^3, space group $P2_1/c$, $Z = 4$, $D_{calc} = 1.87$ g cm^{-3}, μ(Mo-K_α) = 73.6 cm^{-1}. Data were collected in the range $1.5 \leqslant \theta \leqslant 23°$, giving 5612 measured, 5243 unique and 3904 with $I > 1.5\sigma(I)$.

The structure was solved via the heavy-atom method, developed and refined by ΔF syntheses and full-matrix least squares. A disordered molecule of chloroform was found to be present. An absorption correction was applied using DIFABS.[12] Non-hydrogen atoms were refined anisotropically; hydrogens on phenyl rings were freely refined isotropically, those on the CH_2 groups were included with free positional refinement but a common group isotropic U value, whilst methyl hydrogens were inserted in idealized positions and refined as part of a rigid group, with a group U_{iso} for each methyl. The chloroform molecule was represented by one C atom and six half-Cl atoms. The final R and R_ω values were 0.0338 and 0.0342 for 320 parameters. The weighting scheme $\omega = 1/[\sigma^2(F_o) + 0.0002F_o^2]$ was applied. Structure solution and refinement computations were made using SHELX[13] on a VAX 11/780 computer; scattering factor data were taken from Ref. 14. Lists of atomic positional and thermal parameters for all atoms, full lists of bond lengths and angles, and F_o/F_c values have been deposited as supplementary data with the Editor from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

X-ray studies

The structure of [Pt(dppe)(μ_2-SMe)$_2$PtClMe$_3$] has been determined by X-ray crystallography, and is illustrated in Fig. 1, along with selected bond distances and angles in Table 2.

The two platinum atoms have co-ordination numbers of four and six and oxidation states II and IV for Pt(1) and Pt(2), respectively. The platinum–platinum interatomic distance is 3.482 Å which is not indicative of metal–metal bonding. The bond angles S(1)—Pt(1)—S(2) and S(1)—Pt(2)—S(2) are 83.0(2) and 79.2(2)°, respectively, showing the strained nature of the Pt_2S_2 ring. The dihedral angle between the square plane of Pt(1) and the equatorial plane (containing both sulphur atoms) of Pt(2) is approximately 154°. This angle compares with angles between the square planes in the thiolato-bridged Pt(II) dimers [{Pt(PMePh$_2$)(SCH$_2$Ph)(μ_2-SCH$_2$Ph)}$_2$][15] and *cis* - [{Pt(PPr$^n_3$)Cl(μ_2 - SEt)}$_2$][16] of 138.8 and 130°, respectively. In [Pt(dppe)(μ_2-SMe)$_2$PtClMe$_3$] the sulphur atoms are pseudo-tetrahedral in character and the methylthio groups adopt an *anti* configuration, thereby minimizing steric crowding. The Pt(II)—S bonds at 2.358(4) and 2.386(4) Å are notably shorter than the Pt(IV)—S bonds at 2.461(4) and 2.468(4) Å.

Low-temperature NMR studies

The two important relevant structural features of these complexes are the folded nature of the Pt_2S_2 ring and the pyramidal configuration of the bridging sulphur atoms, as revealed by the X-ray diffraction studies. Thus, in principle in solution, a total of eight configurational and conformational isomers are possible, with interconversions occurring by the two processes of ring reversal and pyramidal inversion about sulphur. Ring reversal will convert

exo-methylthio groups to *endo* and vice versa, and independent pyramidal sulphur inversion will exchange *syn* to *anti* configurations of the complex. Both the conformational and configurational changes would be required to fully interconvert all of the possible isomers.

The room-temperature methyl ^{1}H spectral data for all six complexes are collected in Table 3. The ^{1}H spectrum of **1** [Fig. 2(a)] consists of a doublet signal with ^{195}Pt satellites (in addition to a singlet due to a trace of water in the solvent CD_2Cl_2). The doublet splitting is due to four-bond coupling to

the ^{31}P nucleus *trans* to the methylthio group. The ^{195}Pt satellite spectrum shows six of the eight expected signals due to the methylthio protons coupling to one Pt(II) and one Pt(IV) nucleus with different magnitudes. Thus, the total SMe proton absorption clearly shows only one environment for methylthio groups, but on cooling changes occur in all of the spectral regions. At −105°C three signals of approximately equal intensity are observed for the methylthio resonances [Fig. 2(b)]. These changes are interpretable as the slowing down of the pyramidal sulphur inversions on the NMR time-scale; but not unexpectedly ring reversal is still very rapid, and the *endo* and *exo* conformers are not separately observable.

In the solid state complex **1** is in the *anti* con-

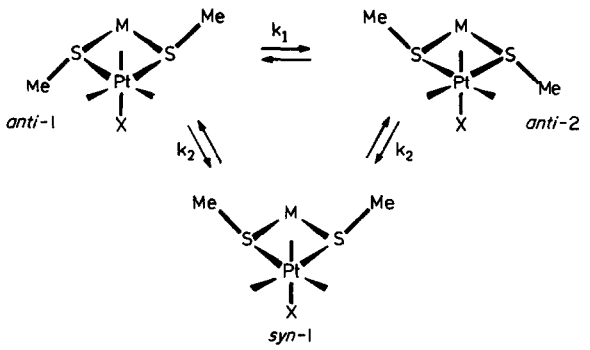

Fig. 3. Interconversion of isomers in complexes **1–6**.

figuration, and the solution spectrum is dominated by the presence of these two diastereoisomers, as illustrated in Fig. 3. These are in equilibrium with the *syn* form, which is thought to be *syn*-1 by virtue of the population dependence of this structure upon halogen type. The populations of these invertomers (Table 4) increase with halogen size, namely Cl < Br < I in accordance with previous findings for the complexes $[PtXMe_3(MeEZEMe)]$ [E = S or Se; X = Cl, Br or I; Z = —CH_2—CH_2— or —CH=CH—).[4]

These conclusions from the ^1H spectra are confirmed by ^{195}Pt NMR spectroscopy (Table 5), which at low temperature shows resonances indicative of only two environments for both Pt(II) and Pt(IV) atoms.[17] For both Pt(II) and Pt(IV) the separate signals are in an intensity ratio of approximately 2:1. The two *anti* isomers are optical antimers and not separately observable by NMR, but from these data we can say that the isomers *anti*-1, *anti*-2 and *syn*-1 in Fig. 3 are all present in approximately equal amounts.

At 25°C the ^{195}Pt spectrum of **1** is averaged to give only one signal each for Pt(II) and Pt(IV) as a result of the onset of rapid sulphur inversion.

The ^{31}P NMR spectra of complexes **1–6** are similar (Table 4), with room-temperature spectra again confirming rapid sulphur inversions. At −80°C "static" spectra are observable with the mirror-image invertomers *anti*(1) and *anti*-(2) producing AB or AX patterns when the two phosphorus environments are anisochronous (complexes **1**, **3** and **6**), and a broad singlet in the other cases (complexes **2**, **4** and **5**). In all cases a singlet due to the *syn*-1 species is additionally observed.

Activation parameters for sulphur inversion

The rate constants in Fig. 3 represent two distinct processes, but the experimental spectra were found

to be virtually insensitive to k_1, the rate constant for a double-site inversion. Only complex **6** exhibited appreciable sensitivity to this parameter, and the experimental and computer synthesized spectra based on the ^{31}P spin problem (Scheme 1) for this complex are illustrated in Fig. 4. The ^{31}P-determined activation parameters for pyramidal inversion about sulphur in compounds **1–6** are noted in Table 6.

Extensive studies of organo-sulphur and organo-selenium ligands co-ordinated to transition metals have demonstrated the dramatic lowering of the barriers to pyramidal inversion.[4] Among many factors recognized, the two that predominate in the current context are metal electronegativity and π-conjugation effects. In the present complexes, the sulphur inversion barriers ΔG^+ are in the range 40–50 kJ mol^{-1}. These represent among the lowest values which have been obtained to date for complexes of the trimethylplatinum halide unit. Such low energies presumably reflect the co-ordination of each inverting sulphur atom to two transition metals.

Complexes **1–6** show two distinctive trends in their values of ΔG^+ for pyramidal inversion, namely:

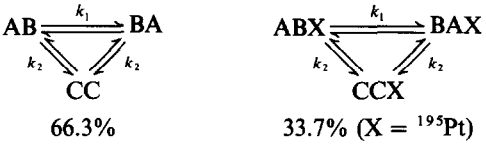
$$\Delta G^+, \text{Pd(II)} > \text{Pt(II)}$$

and

$$\Delta G^+, \text{I} > \text{Br} > \text{Cl}^*$$

Both trends are unusual.

In general,[4] the variation of halogen in trimethylplatinum halide complexes has very little effect upon the barriers to inversions and is attributed to the negligible influence of ligands in the *cis* position with respect to inverting atoms. As evidenced by the direction of halogen dependence of the invertomer populations in these complexes, the steric effect of halogen on the ground state of the complexes is not the major effect, or the order would be reversed. We would therefore consider that the order of energies is possibly due to a halogen-dependent destabilization of the transition states, possibly associated with the special nature of the inversion in the constrained four-membered ring.



Scheme 1.

The lower values of ΔG^+ for sulphur inversion in the Pt(II) complexes compared to the Pd(II) complexes is unexpected and unprecedented, as both on electronegativity and conjugation arguments the reverse order would be predicted.

In the transition state for pyramidal sulphur inversion the M—S—M′ bond angle should become 120°, and it would appear that access to this ideal transition-state geometry is more restricted for the Pd(II)—S—Pt(IV)—S ring than for the corresponding Pt(II)—S—Pt(IV)—S system.

High-temperature ^{1}H *NMR studies*

Platinum–methyl equilibration. Warming solutions of complexes **1–6** in either *d*-chloroform or d_5-nitrobenzene caused the ^{1}H NMR signals of the methyl–platinum protons to broaden and eventually coalesce to a sharp singlet at 100°C, with associated Pt(IV) satellites retained. Further, while these changes were taking place, no alteration of the methyl–sulphur resonances occurred and all ^{195}Pt(IV)–S–C–^{1}H couplings were retained unaltered. These spectral variations are fully temperature-reversible, although some decomposition of **6** does take place at the higher temperatures.

The above changes are indicative of intramolecular scrambling of the platinum methyl groups, and the variable temperature spectra can be simulated using the ^{1}H spin problem described in Scheme 2, where the labels R and S refer to

Scheme 2.

* The ΔG^+ value for complex **4** does not fully accord with this trend, but the large value of ΔS^+ and the low $\log_{10} A$ values quoted for this case suggest that our band-shape fittings were less reliable here.

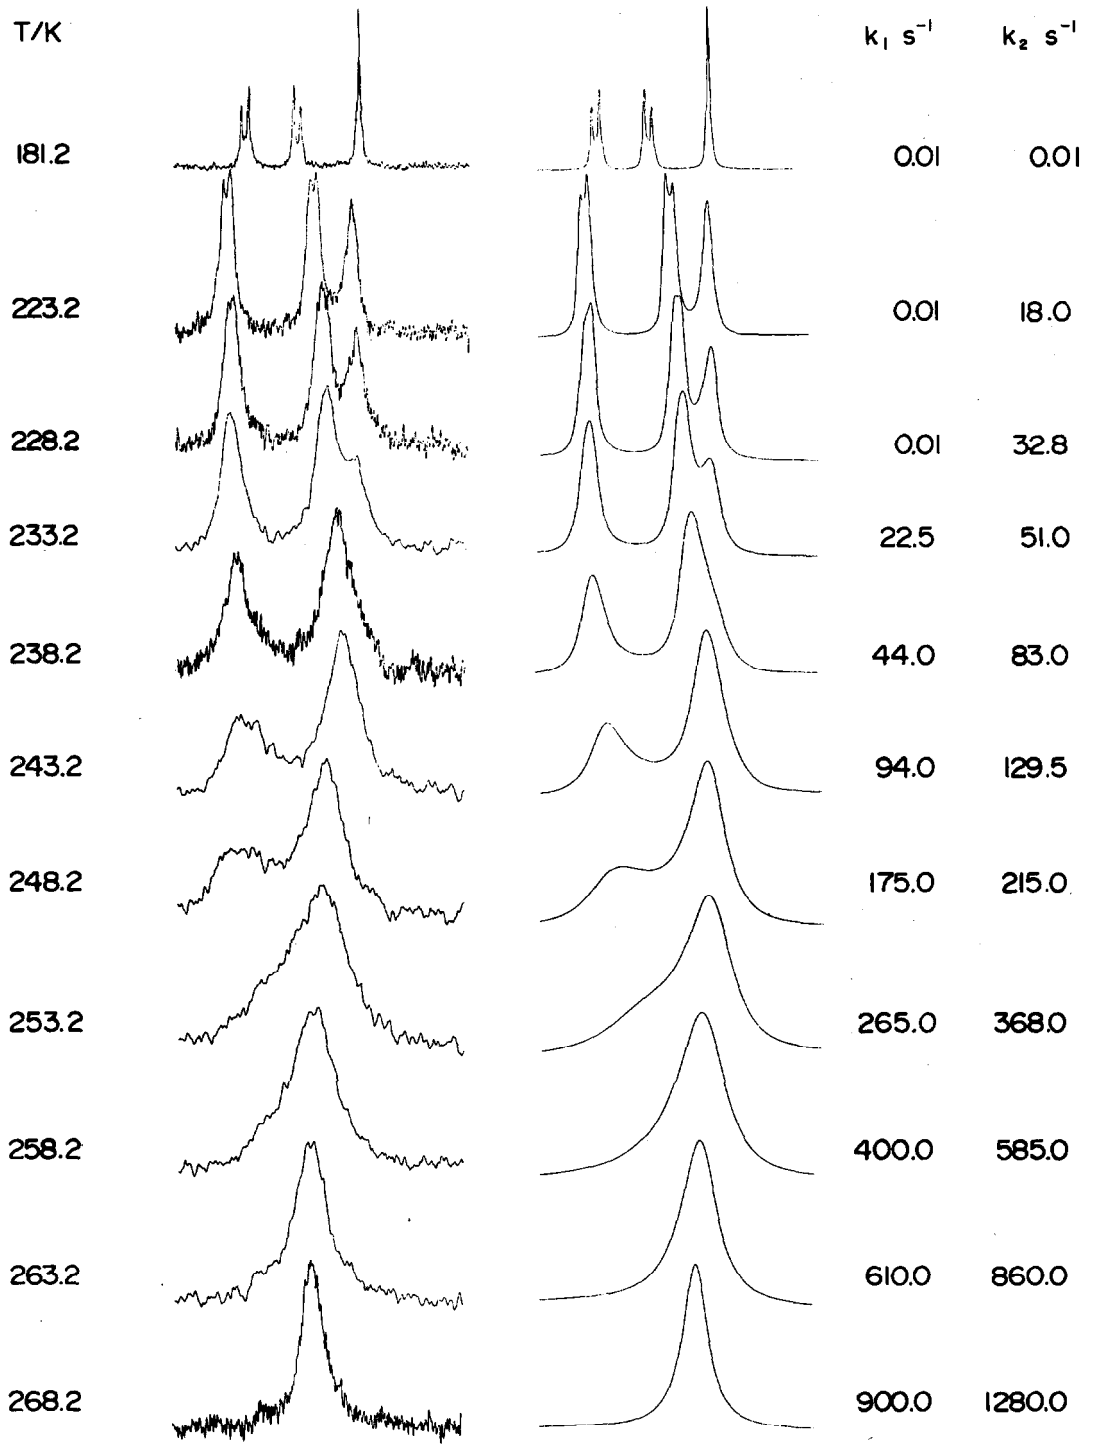


Fig. 4. Variable-temperature experimental and computer-simulated ^{31}P NMR spectra of $[Pd(dppe)(\mu_2\text{-}SMe)_2PtBrMe_3]$ showing the effects of pyramidal sulphur atom inversion.

the axial and equatorial platinum methyls and are population-weighted in a 1 : 2 ratio.

Figure 5 shows the experimental and computer-simulated ^{1}H NMR spectra of **4** in the temperature range of the platinum–methyl fluxions, and the activation parameters for the process are recorded in Table 7. The ΔG^{+} values are of comparable magnitude to those found[18] for other Pt(IV) chelate complexes, e.g. [$PtXMe_3(MeSCH_2SCH_2SMe)$] (X = Cl, Br or I), but unlike the previous study show a small but consistent halogen dependence. In Pt(IV)-chelated thioether complexes[19] the analogous platinum–methyl fluxions are believed to be associated with, in effect, a concurrent 180° rotation of the chelating ligand.[4] The symmetry of complexes **1–6** prevents full evidence of such a movement here, but it seems probable that some such comparable relative motion between the $M(dppe)(\mu_2\text{-}SMe)_2$ moiety and the $PtXMe_3$ unit is taking place in a non-dissociative manner in order to produce such spectral changes.

Palladium thiolato moiety rotation. Whilst the NMR signals for the methylthio hydrogens of Pt(II)–Pt(IV) complexes (**1–3**) remained essentially unchanged over the temperature range 25–150°C, this was not the case for the Pd(II)–Pt(IV) complexes (**4–6**). The bandshape changes of complex **5** are illustrated in Fig. 6 along with computer simulations.

These changes are indicative of an equilibration of the magnetic environments of the two methylthio groups with respect to the phosphorus atoms of the dppe ligand. At ambient temperature each methylthio hydrogen is coupled strongly [^4J(P–Pd–S–C–H) ≃ 14 Hz] to the phosphorus atom mutually *trans*, and only very weakly [^4J(P–Pd–S–C–H) < 1 Hz] to the mutually *cis* phosphorus. At higher temperatures (Fig. 6) the methylthio hydrogens are coupled equally to both of the phosphorus atoms in dppe. The signal essentially changes from a doublet to a triplet, with a halving of the phosphorus–hydrogen coupling, but the full retention of the Pt(IV) satellites.

We perceive two possible processes which could explain these spectral changes in compounds **4–6**. The first would involve successive 180° "rotations" of the dppe ligand about the palladium, whereas the second possibility could involve the entire (dppePd) moiety with respect to the rest of the molecule (Fig. 7). The first of these processes seems unlikely as studies of [$PtClMe_3$dppe] have shown no such rotational process up to 150°C. However, presumably due to the availability of extra lone pairs of electrons on sulphur ligands as opposed to phosphorus ligands, such rotations about metal–sulphur systems have been reported and well characterized.[4] We would therefore propose that these spectral changes occur as a result of a rotation of the (dppePd) moiety through 180° which affects the transposition of the mutually *cis* and *trans* MeS groups with respect to each phosphorus. The activation parameters for this proposed rotation are noted in Table 8.

Complexes **7** and **8** were prepared in order to examine the possibility of comparable rotations in these species. In both complexes the ^{31}P AB quartet was retained up to a temperature of 150°C, indicating an absence of rotation. So it would appear that the rotation of the (dppePd) moiety in complexes **4–6** is aided by the presence of a bimetallic system.

In order to explain the occurrence of methyl scrambling about the Pt(IV) centre, it would appear that both the Pd(II) and Pt(IV) moieties are each undergoing independent "rotations" relative to the central methylthio bridges in complexes **4–6**. In the Pt(II)–Pt(IV) complexes (**1–3**), the unchanged nature of the SMe signal at high temperatures

Complex	E_a (kJ mol^{-1})	$\log_{10}[A\ (s^{-1})]$	ΔG^+ (kJ mol^{-1})	ΔH^+ (kJ mol^{-1})	ΔS^+ (J K^{-1} mol^{-1})
4	75.0±1.2	12.8±0.2	74.9±0.2	72.0±1.2	−9.9±3.2
5	69.3±1.4	11.9±0.2	74.5±0.2	66.4±1.4	−27.2±4.1
6[a]	60.0±3.5	11.4±0.5	68.3±0.5	57.2±3.5	−37.0±10.2

[a] These parameters only approximate, due to the overlap of the sulphur–methyl signal with the H_2O resonance.

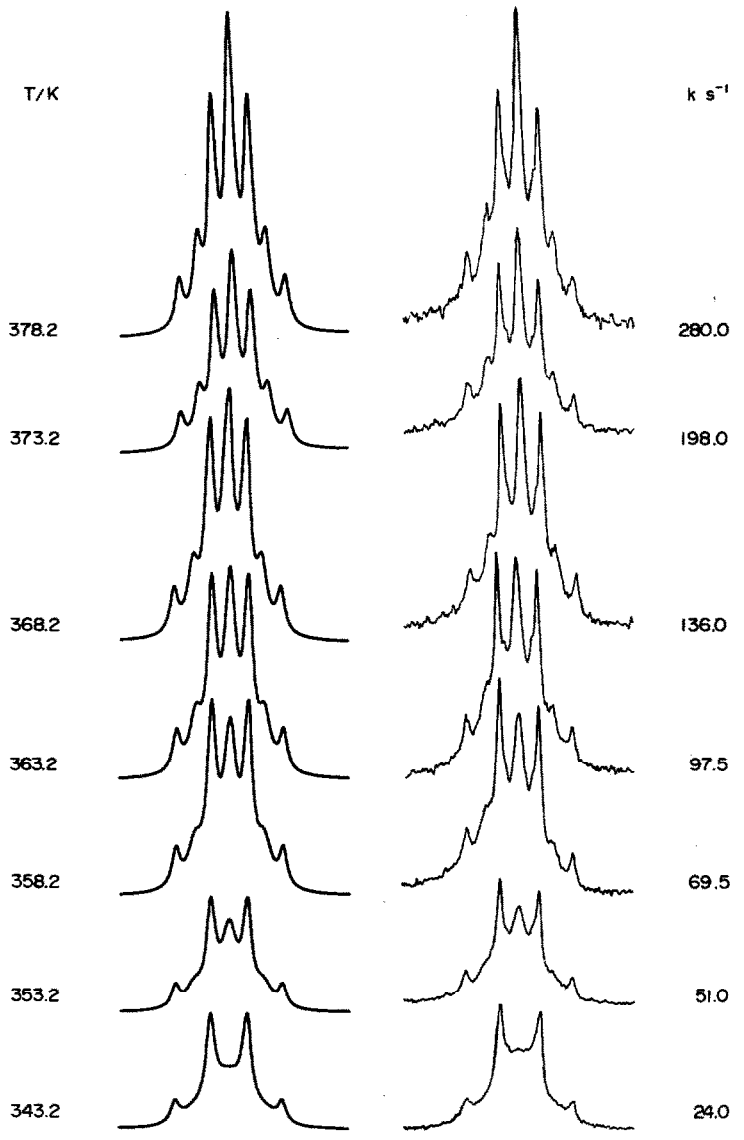

Fig. 6. Variable-temperature experimental and computer-simulated ^{1}H NMR spectra of [Pd(dppe)(μ_2-SMe)$_2$PtClMe$_3$] showing the effects of the rotation of the Pd(dppe) moiety.

implies that any rotation of the [dppePt(II)] fragment is slow on the NMR time scale, even at 150°C. The energies of the ligand rotation fluxion for the Pd(II)–Pt(IV) complex are 8–11 kJ mol^{-1} lower than for the methyl scrambling process, suggesting that the two fluxions are non-concerted and involve different transition states (Fig. 7).

(*Received* 23 *May* 1986; *accepted after revision* 13 *November* 1986)

Abstract—The bis (thiocyanatemercury)tetracarbonyliron, $[Fe(CO)_4(HgSCN)_2]$, was prepared from $[Fe(CO)_5]$ and $Hg(SCN)_2$, and studied by IR spectroscopy and X-ray diffraction. The compound crystallizes in the tetragonal space group $I4_1/a$. The unit cell, with dimensions of $a = 13.778(3)$, $c = 13.234(3)$ Å, $V = 2512.3(9)$ Å^3, contains four molecules. The iron atom is octahedrally coordinated by four carbonyl groups and two mercury atoms in *cis* positions. The coordination of the mercury atoms is distorted square-planar, since, besides mercury–iron and mercury–sulphur bonds, there are also mercury–mercury and mercury-nitrogen interactions. The Fe—Hg distance is 2.506(5) Å and the Hg—Fe—Hg angle is 78.0(1)°.

Reactions of transition-metal complexes with mercury salts have yielded a number of complexes in which there are metal–mercury bonds. Among the first ones described in the chemistry of metal carbonyls are those compounds with Fe—Hg bonds, like $[HgFe(CO)_4]$,[1] a typical example of a cluster. It has been suggested that this compound has a structure analogous to that of $[CdFe(CO)_4]$, which consists of an almost square-planar centrosymmetric eight-membered ring of alternating Cd and $[Fe(CO)_4]$ units.[2] An other important example is given in the series $[Fe(CO)_4(HgX)_2]$ (X = Cl, Br or I), prepared by Hock and Stuhlmann,[3] and subjected to investigations by Lewis,[4,5] who have also shown that these complexes react with amines, without displacement of the CO groups, giving adducts where the nitrogen ligands are coordinated to the mercury atoms. Metal–metal interactions also occur in the series $[Fe(CO)_3L_2HgX_2]$ (L = PPh_3, $AsPh_3$ or $SbPh_3$; X = Cl or Br) obtained from reactions of $[Fe(CO)_3L_2]$ with HgX_2.[6] We are interested in the chemistry of carbonyls containing this type of bonding, and in continuing the studies with compounds that have Fe—M bonds (M = Zn, Cd or Hg)[7–9] we now wish to report our results concerning the synthesis and structure of $[Fe(CO)_4(HgSCN)_2]$. The coordination geometry of the iron atom is *cis*-octahedral, but that of the mercury is not simple because of strong interactions involving the HgSCN groups.

EXPERIMENTAL

Synthesis

All operations involved in the synthesis, except the weighings, were carried out in an atmosphere of purified nitrogen in a Schlenk apparatus. To a solution of 0.236 g (0.745 mmol) of $Hg(SCN)_2$ in 12 cm^3 of H_2O, containing a small amount of NH_4SCN to facilitate the dissolution of the salt, 0.1 cm^3 (0.745 mmol) of $[Fe(CO)_5]$ was added. The mixture was stirred for 3 h at room temperature causing a yellow solid to appear. The insoluble product was filtered off, washed thoroughly with water and diethylether, and then dried *in vacuo*.

* Author to whom correspondence should be addressed.

IR spectrum

The IR spectrum, at room temperature, was recorded as a Nujol mull between CsI plates on a Carl Zeiss Specord 75 IR spectrophotometer.

Determination of the crystal and molecular structure of $[Fe(CO)_4(HgSCN)_2]$

Yellow single crystals, suitable for X-ray analysis, were obtained from acetone solution. They were found to be stable to air and X-ray exposure. The elemental analysis results were in agreement with the formula.

Crystals of $[Fe(CO)_4(HgSCN)_2]$ are tetragonal, $a = 13.778(3)$, $c = 13.234(3)$ Å, $V = 2512.3(9)$ Å^3, space group $I4_1/a$, $Z = 4$, $d_{calc} = 1.812$ Mg m^{-3}.

The cell parameters were determined by least-squares fit from 2θ values of 25 reflexions, using a Nonius CAD-4 diffractometer. Three-dimensional intensity data were collected using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) up to $2\theta = 46°$.

The ω–2θ scanning mode with varying intervals was used. Of the 863 recorded independent reflections, 559 were observed above background [$I \geqslant 3\sigma(I)$, where $\sigma(I)$ was based on counting statistics]. The data were reduced to structure factors with absorption corrections ($\mu = 124.58$ mm^{-1}).

A Patterson map showed the Fe atom to be in the special position (0, $\frac{1}{4}$, z) on the two-fold axis, and the Hg atom in a general position. All the remaining atoms appeared clearly on the difference Fourier map. Refinement was carried out by full-matrix least-squares calculations with anisotropic thermal parameters for all atoms. The function minimized was $\Sigma w_i(k|F_o| - |F_c|)^2$ where $w_i = 1$ for the observed and $w_i = 0$ for the unobserved reflections. The atomic scattering factors used was taken from *International Tables*.[10] The final refinement cycle gave $R = 0.059$ for the observed reflections and $R = 0.076$ with inclusion of the unobserved.

Lists of atomic parameters, observed and calculated structure factors, and anisotropic thermal coefficients for all atoms have been deposited with the Editor as supplementary material.*

RESULTS AND DISCUSSION

The metal–metal-bonded species of general formula $[Fe(CO)_4(MX)_2]$ (X = Cl, Br or I) are well known for M = Hg;[4,5] only one was reported for M = Zn, $[Fe(CO)_4(ZnCl)_2]$,[11] and none containing cadmium have yet been described. In this paper we report our data concerning with the IR and X-ray diffraction studies of $[Fe(CO)_4(HgSCN)_2]$. The CO stretching vibrations are generally the most characteristic ones for the carbonyl compounds and while four IR-active modes ($2A_1 + B_1 + B_2$) are expected on the basis of group theory for the *cis*-$[Fe(CO)_4(HgSCN)_2]$ structure only one (E_u) is expected for the *trans* structure.

The *cis* structure with C_{2v}-symmetry around the iron atom is in agreement with the experimental data, since, as expected, four ν(CO) are observed in the IR spectrum (Fig. 1) of $[Fe(CO)_4(HgSCN)_2]$ at 2083(m-s), 2025(m-s), 2008(m-s) and 1980(sh) cm^{-1} (m = medium, s = strong, sh = shoulder). Taking the average ν(CO) stretching frequencies of the compounds $[Fe(CO)_4(HgSCN)_2]$ (mean 2024 cm^{-1}) and $[Fe(CO)_4(HgI)_2]$ (mean 2042 cm^{-1}) it is shown that the HgSCN group has a lower electronegativity than HgI. The strong band at 595 cm^{-1} in the IR spectrum is assigned to the bending mode δ(FeCO), which in the IR spectrum of $[Fe(CO)_4Hg]$ appears at 599 cm^{-1}.[8]

The three characteristic modes of the thiocyanate[12] were assigned to the bands observed at 2118(m-s) [ν(CN)], 765(w) [ν(CS)] and 495 cm^{-1} (w) [δ(SCN)] (w = weak).

The solid-state structure of $[Fe(CO)_4(HgSCN)_2]$ determined by X-ray diffraction shows that the iron atom is coordinated by the four carbonyl groups and the two mercury atoms in *cis* positions, in a slightly distorted octahedral arrangement. The iron atom lies on a crystallographic two-fold axis and thus the complete molecule has a two-fold symmetry. The structure of the compound with the atom-numbering scheme is shown in Fig. 2. Pertinent bond lengths and angles are given in Table 1.

Within experimental error, average Fe—C [1.85(5) Å] and CO [1.14(5) Å] distances *cis* and *trans* to mercury atoms are identical. The average Fe—C—O angle is 176(1)°.

The Fe—Hg distances are equal to 2.506(5) Å, and it is interesting to compare this value with those of related compounds. In the $[Fe(CO)_4(HgBr)_2]$ molecule two different Fe—Hg bond lengths (2.44 and 2.59 Å) were observed.[13] For the $[Fe(CO)_4(HgCl)_2]$ four independent molecules were observed[14] in the asymmetric unit with different Fe—Hg distances, the average value being 2.49(8) Å. A greater value, 2.552(8) Å, was found in $[Fe(CO)_4(HgCl)_2(py)_2]$, and this may be a consequence of the higher coordination number of the mercury atom in this compound.[15]

The coordination of the mercury atoms is not simple because there are other interactions besides their bonding to the iron and sulphur atoms. The

Fe—Hg—S	168.9(2)		

[a] Symmetry codes: (i) $-x, \frac{1}{2}-y, z$; and (ii) $\frac{3}{4}-y, \frac{1}{4}+x, \frac{1}{4}+z$.

distance between the mercury atoms in the molecule of $[Fe(CO)_4(HgSCN)_2]$ is 3.154(2) Å, which agrees well with the distances observed in other clusters: 3.142 Å in $[Hg_6Rh_4(PMe_3)_{12}]$,[16] and 3.171(4) Å in $[Fe(CO)_4(HgCl)_2(py)_2]$.[15] This suggests a metal–metal bond involving the mercury atoms and is reinforced by the small Hg—Fe—Hg angle [78.0(1)°] in the $[Fe(CO)_4(HgSCN)_2]$ molecule.

In the solid state the molecular packing can allow interactions between atoms of neighbour molecules. In this compound each mercury atom has, at 2.66(3) Å, a nitrogen atom of a thiocyanate group of another molecule ($\frac{3}{4}-y, \frac{1}{4}+x, \frac{1}{4}+z$ symmetry operation). This suggests a Hg—N bond, since this distance is 2.81(1) Å in $Hg(SCN)_2$, where this bond is believed to exist.[17]

Thus the effective coordination number of the mercury atoms is four and its coordination polyhedron is distorted square-planar, as shown in Fig. 3. The mean plane is defined by the constants

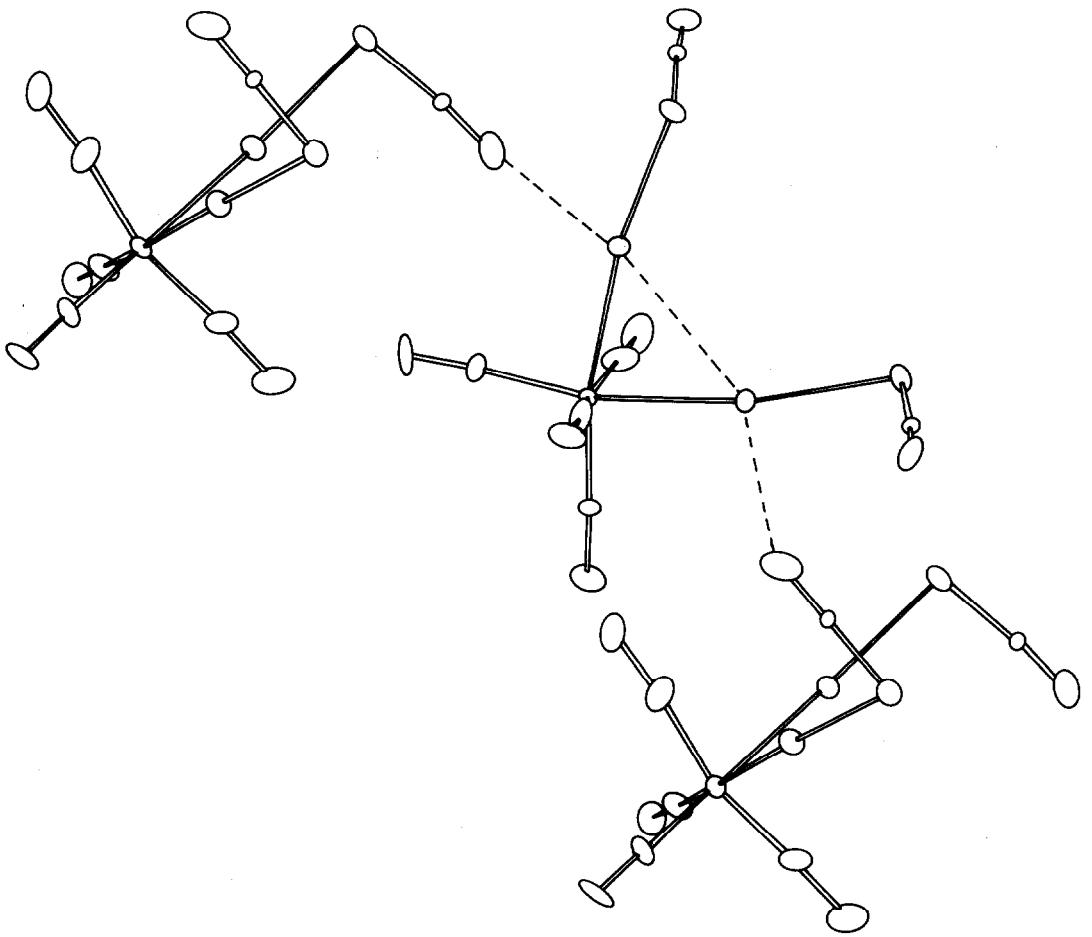

Fig. 3. Coordination of the mercury in the crystal of $[Fe(CO)_4(HgSCN)_2]$.

$A = -0.4940$, $B = 0.8506$, $C = -0.1802$ and $D = 2.1904$, the largest distance to this plane being 0.304(2) Å for the mercury ($\bar{x}$, $\frac{1}{2}-y$, z symmetry operation) atom.

The angle S—C—N is 177.5(13)° in $Hg(SCN)_2$ and 172(1)° in $[Fe(CO)_4(HgSCN)_2]$. The distortion from linearity may be due to the strong intermolecular interactions between mercury and nitrogen atoms. Thus the compound $[Fe(CO)_4(HgSCN)_2]$ can be considered as an infinite polymer due to these Hg—N bonds in the direction of the *c*-axis of the crystal, which is the developed needle axis.

LIGAND COMPLEXES OF Ni(II) WITH ALCOHOLAMINES

J. M. ANTELO, F. ARCE,* F. REY and A. VARELA

Departamento de Quimica Fisica, Facultad de Quimica, E-Santiago de Compostela, Spain

(*Received* 21 *October* 1986; *accepted* 13 *November* 1986)

Abstract—The stability constants of Ni(II) complexes containing alcoholamines were determined by potentiometric titration in aqueous solutions at several ionic strengths. The influence of temperature and ligand substituents are examined.

Studies of the formation of Ni(II)–alcoholamine complexes in aqueous solution have been relatively common.[1–9] The results have nevertheless been contradictory as regards the composition of the complexes, their stability constants, and the effects of variables such as ionic strength, temperature or the nature of the ligand substituents. This article reports the equilibria in aqueous solution of Ni(II) complexes with alcoholamines of form $HOCH_2CH_2NR_1R_2$ (R_1 and $R_2 = CH_3$ or CH_2CH_3).

EXPERIMENTAL

Reagents

Merck p.a. ethanolamine (MEA), *N*-methylethanolamine (NMEA), *N*-ethylethanolamine (EMEA), *N,N*-dimethylethanolamine (NNMEA) and *N,N*-diethylethanolamine (EEMEA) were purified by standard procedures. Alcoholamine solutions were prepared with CO_2-less water and protonated by adding Merck p.a. HCl solution, and their concentration was determined by titration against mercury oxide.

Ni(II) solutions were prepared from the nitrate (Merck p.a.) and their concentration determined by titration against EDTA.

Ionic strength was maintained at 1.0, 0.7, 0.5, 0.3 or 0.2 with Merck p.a. KNO_3 desiccated at 100°C for at least 24 h.

Method

The formation constants of the metal complexes were determined by potentiometric titration in a 250-cm^3 glass cell thermostatted by a Crison Viscobath 54 at 298.0, 305.5 or 313.0 K. Nitrogen purified by Fieser solutions[10] was used to provide an inert atmosphere within the cell and to stir the complex solution during titration. The pH of solution was measured with a Beckman 4500 pH-meter equipped with a Radiometer GK 4501B electrode and calibrated using standard buffers of pH 7.0 and 10.0 (experimental points lay within this range).

The solutions determined contained known quantities of metal ion, alcoholamine, acid (enough to guarantee the total protonation of the alcoholamine) and KNO_3 (to control ionic strength). The ranges of initial concentrations of the various components are listed in Table 1 (solutions with various [Ni(II)]/[alcoholamine] ratios were studied). The titration agent was the same alcoholamine as in the complex being studied, but a concentration some 25–30 times its initial concentration in the cell, and was 0.01 cm^3 added at a time from a Crison 738 microburette equipped with a 1-cm^3 Hamilton syringe accurate to an estimated ± 0.005 cm^3. Each titration was performed at least twice, and the replicate values differed in each case by less than 0.01 pH units. In no case did the fall in ionic strength during titration exceed 2%.

For each ionic strength, the stability constants of the complexes were determined using the program MINIQUAD 75.[11] For each set of curves, various models chosen on the basis of published data for similar systems were tested and refined until total convergence was achieved. Criteria such as minimum χ^2 (chi-square) value, R (crystallographic) factor or sum of square residuals were used to identify the correct model. All calculations were performed on a Univac 1100 computer.

RESULTS AND DISCUSSION

The aim of this study was to establish the stoichiometry of the various Ni(II)–alcoholamine complexes formed, to determine their stability constants, and to investigate the influence of ionic strength, temperature and substituents on these constants. In order to achieve the first of these goals, the experimental results were compared with those predicted by various different stoichiometries considered to be possible *a priori*, i.e. with those expected for various different equilibria of form:

$$pM + qL + rOH \rightleftharpoons M_pL_q(OH)_r, \qquad (1)$$

where M is the metal ion and L the alcoholamine ligand.

For none of the alcoholamines studied were any except mononuclear complexes observed ($p = 1$), hypothetical complexes with $p \geqslant 1$ being rejected by the program, and the stability constants determined separately from each of the pertinent curves were in all cases identical. It was also found that r was in all cases zero. Thus under the conditions of the present study, only simple ML_q complexes are formed, with q depending on the nature of the ligand, the temperature and the ionic strength of the medium.

Table 2 shows that the value of K_1 falls with increasing substitution in alcoholamines, in the order MEA > NMEA ≃ EMEA > NNMEA ≃ EEMEA, which may be attributed to increasing steric hindrance as the space occupied by the ligand grows. For a given degree of substitution, however, stability is not determined by the size of the ligand, but rather by its basicity, as is shown by the fact that whereas the stability constants of NMEA and EMEA are, like their K_{H^+}, very similar, those of NNMEA and EEMEA differ considerably, again like their K_{H^+}.

Table 3. Thermodynamic stability constants of Ni(II)–alcoholamine complexes

	1–1	1–2	1–3	1–4
MEA	2.98	5.59	7.02	8.10
NMEA	2.83	4.80	5.85	
EMEA	2.34	4.89		
NNMEA	(0.50)	2.90		
EEMEA	1.50			

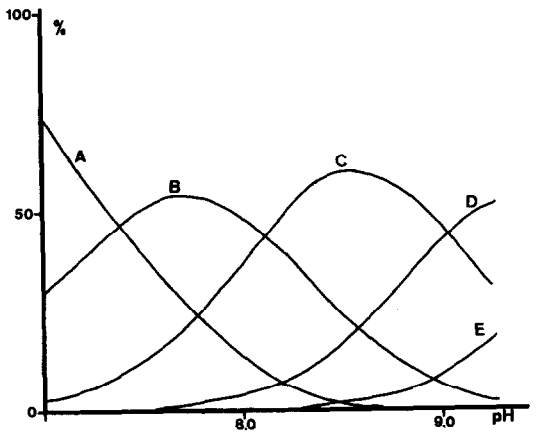

Fig. 1. Variation with pH of the distribution of the several species present in aqueous solution of Ni(II)–MEA $I = 0.70$: (A) Ni(II), (B) Ni–MEA, (C) Ni–$(MEA)_2$, (D) Ni–$(MEA)_3$, (E) Ni–$(MEA)_4$.

In all the systems studied the stability of the complexes increased with the degree of coordination. At the same time, the constants of the successive steps $ML_{n-1} \rightleftharpoons ML_n$ decreased. Thus the increase in steric hindrance with increasing coordination tended increasingly to offset the gain in stability due to the formation of successive metal–ligand bonds.

Reducing the ionic strength of the medium also reduced the stability of the complexes. Although its cause is not known for sure this effect has been observed in various kinds of metal–ligand system.[12] Table 3 lists the thermodynamic constants obtained by extrapolating to $I = 0$ and using the expression $pK = \text{constant} \cdot I^{1/2}$, which is derived from the Debye–Huckel equation and has proved useful in similar systems.[13]

The stability constants of Ni(II)–MEA complexes were calculated at three different temperatures. The differences being within the experimental error, it is not possible to use them to calculate the thermodynamic parameters of the complexation process. This agrees with the results of others,[1,14] and confirms that the potentiometric method is not suitable for determining such parameters for systems like those of the present study.

Figure 1 shows the changing distribution of the various complexes observed as pH varies. As pH rises, the degree of coordination of predominant species increased as the result of the shift in the

equilibrium:

$$LNR_1R_2H^+ \overset{OH^-}{\rightleftharpoons} LNR_1R_2 + OH_2$$
$$\Big\downarrow\uparrow \text{Ni(II)}$$
$$(LNR_1R_2)Ni \rightleftharpoons (LNR_1R_2)_2Ni \rightleftharpoons \cdots$$

THE HYDROLYSIS OF THE La(III) ION IN AQUEOUS PERCHLORATE SOLUTION AT 60°C†‡

LIBERATO CIAVATTA,§ MAURO IULIANO and RAFFAELLA PORTO

Dipartimento di Chimica dell'Università, Via Mezzocannone, 4, 80134 Napoli, Italy

(*Received* 30 *October* 1986; *accepted* 13 *November* 1986)

Abstract—The hydrolysis equilibria of the La(III) ion have been studied at 60°C by measuring, with a glass electrode, the hydrogen ion concentration of a series of lanthanum perchlorate solutions. The [La(III)] of the test solutions, which were made to contain 3 m (molal) ClO_4^- by adding $LiClO_4$, varied from 0.03 to 1 m. Hydrolyzed solutions were prepared by generating OH^- by constant-current coulometry. The potentiometric data, which indicate that at most 3% of the metal ion can be transformed to reaction products without the formation of a precipitate, can be explained by assuming the mononuclear $LaOH^{2+}$ ion and the polynuclear La_2OH^{5+}, $La_2(OH)_3^{3+}$ and $Le_3(OH)_3^{6+}$ ions. Their formation constants in the inert 3 m $LiClO_4$ medium are reported and the effects of medium changes, caused by the replacement of Li^+ with La^{3+}, estimated by the specific interaction theory.

The evidence of numerous, accurate investigations[1,2] on the hydrolysis of Me^{z+} cations suggests the formation of polynuclear $Me_q(OH)_p^{zq-p}$ species with $q > 1$. Though, in principle, the array of (p, q) values may vary in a wide range, in each of the investigated systems the number of polynuclear complexes has been found to be small, usually not greater than 2 or 3, and often the complexes have a high nuclearity: $Bi_6(OH)_{12}^{6+}$, $Pb_4(OH)_4^{4+}$, $Pb_6(OH)_8^{4+}$, $Ce_3(OH)_5^{4+}$ and $Al_{13}(OH)_{32}^{7+}$. Of course we cannot exclude the existence of intermediate species. These are present in undetectable amounts in the solutions studied, most often at 25°C in a 3 M $NaClO_4$ ionic medium; however, they may become important under different experimental conditions of temperature, pressure, or ionic medium.

The objective of the present work was that of exploring at 60°C the intermediate species of the La(III) ion hydrolysis which at 25°C in 3 M $(Li)ClO_4$ has been interpreted[3] in terms of $LaOH^{2+}$, La_2OH^{5+}, $La_5(OH)_9^{6+}$ or $La_6(OH)_{10}^{8+}$. The starting point was Arnerk's[4] systematic investigation on the enthalpies of hydrolytic reactions. For $qMe^{z+} + pOH^- \leftrightarrows Me_q(OH)_p^{zq-p}$ Arnek found $\Delta H_{pq} < 0$ and, moreover, for a given cation $\Delta H_{pq}/p$ is a constant to within $\mp$ 1.7 kJ. It is easily shown by applying the vant'Hoff equation that of two complexes (p', q') and (p'', q'') with $p' < p''$, the (p', q') one is favoured by a temperature increase.

As to the choice of temperature, we were guided by the results of a previous study on the hydrolysis of the Be(II) ion at 60°C.[5] At this temperature we found evidence for $Be_2(OH)_2^{2+}$, a species not detected at 25°C,[6,7] where the predominating complex is $Be_3(OH)_3^{3+}$.

METHOD

To study the hydrolysis equilibria the hydrogen ion concentration of lanthanum perchlorate sol-

† This work is dedicated *in memoriam* of the late Professor Georg Biedermann, K.T.H., Stockholm.

‡ Notation used in this paper: a_w, water activity; A, concentration of Cl^-; B, concentration of La(III); b, concentration of La^{3+}; ${}^*\beta_{pq}$, equilibrium constant for the formation of $La_q(OH)_p^{3q-p}$, regarding H_2O and not OH^- as the reagent; γ_B, γ_H and γ_{pq}, activity coefficients of La^{3+}, H^+ and $La_q(OH)_p^{3q-p}$, respectively; H, proton analytical excess $([ClO_4^-]+A-[Li^+]-3B)$; h, equilibrium concentration of H^+; Δ^*H_{pq}, formation enthalpy of $La_q(OH)_p^{3q-p}$ considering H_2O and not OH^- as the reagent; K_p, formation constant of all species containing p OH^- groups [eqn (8)]; Z, average number of OH^- bound per lanthanum atom. Concentrations and equilibrium constants are expressed on the molal scale {m [mol (kg of water)$^{-1}$]}.

utions was measured with a glass half-cell. The [La(III)] varied between 0.03 and 1 m. At each [La(III)] the acidity was decreased from a level, where the hydrolysis is negligible, to low enough values for solid lanthanum hydroxide to start to form. All of the test solutions were prepared to contain 3 m ClO_4^- by adding $LiClO_4$. This salt has been preferred to the more popular $NaClO_4$ because it is conveniently purified by recrystallization.

As exploratory experiments indicated, the hydrolysis is negligible at $\log h > -5.5$ and less than 3% of B can be transformed into reaction products before precipitation. Thus we were confronted with the problem of investigating poorly buffered solutions, and considerable effort had to be taken to keep protolytic contamination to a minimum. The experience gained in previous studies[3,8,9] on the hydrolysis of cations, which behave as weak acids, was of great value. Test solutions in a state of high purity were prepared by generating OH^- by coulometric methods. Stable and reproducible EMF data could be measured even in solutions where the concentration of OH^- bound to hydrolytic species was as low as 5×10^{-5} m.

The test solutions, abbreviated in the following as TS, had the general composition:

$$B \text{ m La(III)}, H \text{ m } H^+, A \text{ m } Cl^-, (3-3B-H+A) \text{ m } Li^+, 3 \text{ m } ClO_4^-.$$

The auxiliary chloride ion, whose concentration ranged from 5×10^{-3} and 0.05 m, was chosen, first, as a reference in cells without liquid junction for measurements of h and, second, to enable us to decrease the acidity of TS by electrolysis cells using no bridges. It is easily imaginable what sort of experimental difficulties bridges cause when operating at values higher than room temperature.

The hydrogen ion concentration in TS was determined with cell (I):

$$-\text{Ag–AgCl/TS/GE}+ \qquad \text{(I)}$$

where GE denotes glass electrode. At 60°C the EMF of (I) is expressed as:

$$E = E_o' + 66.10 \log (hA) + 66.10 \log \gamma_{HCl}^2, \qquad (1)$$

where E_o' is a constant and γ stands for the activity coefficient. The standard states are so defined that activity coefficients tend to unity as the composition of TS approaches 3 m $LiClO_4$. In each series of measurements, where B was constant, since only low Z values were available, we may neglect variations of γ_{HCl} and calculate h with the simplified form of eqn (1):

$$E = E_o + 66.10 \log (hA). \qquad (2)$$

The value of E_o, which is constant at constant B, must be determined in each experiment, by potentiometric titration, by measuring E in solutions where the hydrolysis is negligible and, consequently, h can be set equal to H. The E_o as well as the H of the starting solution were simultaneously assessed by constructing a Gran diagram.[10] In each case E_o could be calculated to within ± 0.1 mV, while the initial H was evaluated with an uncertainty of less than 0.3%.

The presence of chloride ions enabled us to alkalify TS by constant-current coulometry. For this purpose two additional electrodes were immersed into TS giving rise to the electrolysis circuit (II)

$$-\text{Pt/TS/Ag}+, \qquad \text{(II)}$$

which was connected to a constant-current supply. By electrolysis reaction (3) occurs on the right:

$$\text{Ag(s)} + H_2O + Cl^- \rightarrow \text{AgCl(s)} + OH^- + 0.5H_2\text{(g)}. \qquad (3)$$

Though the test solution contains the redox couples H^+–H_2 and Ag(I)–Ag, no spontaneous reaction seems to take place between H_2 and AgCl as indicated by the constancy within ± 0.1 mV of the EMF of cell (I) for 24 h or more.

The current efficiency was studied by potentiometric acid–base titration of exactly standardized 2×10^{-3} m $HClO_4$. Several analyses, carried out with current intensities between 1 and 5 mA, showed results higher than 1%. After inspection of various factors the origin of the error was identified in the reduction on the cathode of small amounts of silver. These turned out to be nearly proportional to the electrolysis duration but almost independent of chloride in the $5 \times 10^{-3} \leqslant A \leqslant 0.05$ m range.

At the end of each titration, the cathode was withdrawn from TS and the silver deposited on it analysed so that the moles of silver reduced per second (χ) could be ascertained. In experiments with lanthanum two or three platinum gauze electrodes were immersed into TS and each was employed as a cathode in different stages of the electrolysis. In this way the unappreciable influence of acidity on χ could be established.

The χ values were found to fall between 3×10^{-10} and 5×10^{-10} mol s^{-1}. Therefore a 99.9% efficiency can be achieved only with current intensities exceeding 50 mA. On the other hand, high intensities make problematic the avoidance of a local excess of base which might promote the premature precipitation of lanthanum hydroxide. As a compromise, we employed current intensities between 2 and 10 mA,

and corrected the moles of electrons, passed during the electrolysis time t, as χt. For χ we assumed the value found in the same experiment. The results of $HClO_4$ analyses coincided, then, to 0.3% or better with the values calculated from dilution of the stock solution.

The lanthanum titrations hitherto presented were performed by decreasing gradually the acidity of TS. Doubts may, therefore, arise whether a true equilibrium was attained. To answer this essential question a series of measurements was made by acidification of partially hydrolysed solutions: 0.1 m La(III), -1.5×10^{-3} m H^+, 5×10^{-3} m Ag^+, 2.697 m Li^+, 3 m ClO_4^-. Acid was generated coulometrically according to the electrolysis reaction (4):

$$2Ag^+ + H_2O \rightarrow 2Ag(s) + 0.5O_2(g) + 2H^+. \quad (4)$$

The results (back titration in Table 1) are seen in Fig. 1 to agree, within the limits of experimental uncertainty, with data obtained by alkalification. This fact also demonstrates, besides a real equilibrium, the negligible effect of chloride ions on the hydrolysis reaction.

EXPERIMENTAL

Materials and analysis

Lanthanum perchlorate solutions were prepared from lanthanum oxide (99.99% purity), furnished by K.E.K., and $HClO_4$ (p.a. Merck). The oxide was added in a slight excess to a concentrated (3.2 M) $HClO_4$ solution and the pH of the resulting suspension was adjusted to 7. Consequently, the heavy metal ions present in $HClO_4$ precipitated as a

hydroxide or silicate. The excess La_2O_3 was removed by filtration and the acidity was regulated at 10^{-2} m to minimize absorption of CO_2. The exact hydrogen ion concentration was analysed by coulometric titration, the end-point being determined by potentiometry with a glass electrode.

The [La(III)] was established both by titration with EDTA, using xylenol orange as visual indicator,[11] and by precipitating the oxalate which then was oxidized with $KMnO_4$.[12] The results coincided to 0.1%.

Perchloric acid solutions were standardized against $KHCO_3$ and Tl_2CO_3 which are considered primary standards in this laboratory. The analyses, performed with methyl red, agreed better than 0.1%.

Lithium chloride was obtained as described previously.[13]

To prepare *lithium perchlorate* the method described earlier[9] was employed with the modification that small amounts of protolytic impurities, contaminating the final product, were determined with the following potentiometric procedure. Solutions of composition 10^{-2} m H_3BO_3, H m H^+, A m Cl^-, $(3-H+A)$ m Li^+, 3 m ClO_4^-, were alkalified at 60°C with cell (II) while h was measured with cell (I). From data with $h > 10^{-4.5}$ m, E_o and H_o, the initial H, were established as usual on the basis of Gran plots. The data in the $10^{-6} \geqslant h \geqslant 10^{-7.5}$ m interval were employed to get a preliminary value of the dissociation constant of H_3BO_3 (K_a) and, then, to construct the graph $1/(h+K_a)$ vs moles of OH^- generated. Since the result is linear for all the h available, it was concluded that weak acids (HB) present as impurities are almost completely protolyzed at $h < 10^{-6}$ m. Extrapolation to $1/(h+K_a) \to 0$ gave $H_o+[HB]_{tot}$, and consequently $[HB]_{tot}$. The impurities in 3 m $LiClO_4$ amounted to $(34\pm3)\times10^{-6}$ m, in substantial agreement with previous preparations.[14]

The $Z(\log h)_B$ data in lanthanum solutions were corrected for the impurity by assuming its complete protolysis in solutions with $\log h < -6$. This correction makes the Z values of the lowest B uncertain to $\pm10^{-4}$ units.

Experimental details

The EMF measurements were carried out in a silicone oil thermostat at 60.00 ± 0.05°C. The Ag–AgCl electrodes were prepared according to Brown.[15] Pt gauze electrodes (2 × 2 cm) were boiled in 1 : 1 HNO_3 and ignited in alcohol flame. Ag-coated Pt nets, used for electrolysis with cell (II), were prepared by cathodic reduction from 0.03 m AgCl in 16 m LiCl. The silver layers were washed with concentrated ammonia and then they were soaked for several days with water. Glass electrodes, manufactured by Jenaer Glasswerk, were employed. The E values were read with a precision of 0.01 mV with a Keithley 195 System DMM multimeter. To measure the potential of the membrane electrode a preamplifier (Analog Device 309K) had to be used. The constant-current source was a 220 Programable Current Source (Keithley). This instrument furnished intensities constant and accurate to within 0.02%.

Prior to each experiment with cell (I) a stream of

purified and presaturated nitrogen gas was passed overnight through TS, kept at room temperature, to purge it of dissolved oxygen. Throughout the measurements at 60°C the solution was protected by atmospheric contamination by placing it in a six-necked vessel fitted with high-vacuum ground glass stoppers. If the vessel is not hermetically closed, oxygen from the atmosphere may cause drifts in the potential of the Ag–AgCl half-cell. With our apparatus the EMFs of cell (I) remained constant to within 0.1 mV for several hours. The reproducibility of $E-E_o$ was within 0.1 mV.

To analyse silver deposited on Pt cathodes of cell (II), it was anodically stripped in 50 cm^3 3 m $LiClO_4$. The Ag^+ that formed was potentiometrically titrated with Ag^+ generated coulometrically, while the end-point was localized on the basis of Gran plots. Metal (1 μmol) was analysed with error of 2%, which is sufficient for our purposes.

DETERMINATION OF THE COMPOSITION OF THE HYDROLYSIS PRODUCTS

The $Z(\log h)_B$ data, which are the basis of the following calculations, are collected in Table 1 and are graphically represented in Fig. 1. Since less than 3% of La(III) can be transformed into reaction products, the determination of the hydrolysis mechanism may be carried out in two steps. In the first [Section (1)] each set of data, pertaining to a particular B level, was treated with the self-medium approach of Hietanen and Sillén.[16] By this method one obtains the number of OH^- (p) bound to the hydrolysis products and the homoligand equilibrium constants (K_p). Subsequently [Section (2)] the number of lanthanum ions in the complexes (q) and the equilibrium constants ($^*\beta_{pq}$) were determined by analysing the $K_p(B)$ functions. Medium changes caused by the replacement of Li^+ with La^{3+} were estimated by the specific interaction theory (SIT).[17]

Finally [Section (3)] in order to check whether any significant error was introduced by a number of approximations in Sections (1) and (2), all the data were treated by numerical procedures founded on the principle of the least-squares method.

(1) *Evaluation of the prevailing* p *values*

When we consider data at constant B and of Z values not exceeding 0.03, then, without introducing an appreciable error, we may simplify the preliminary calculations by putting:

$$[La^{3+}] = b \sim B. \tag{5}$$

Assuming the formation of a series of hydrolysis products, $La_q(OH)_p^{3q-p}$, the concentration of hydrogen ions set free by hydrolysis (BZ) is expressed by:

$$BZ = h - H = \Sigma p[La_q(OH)_p^{3q-p}]$$
$$= \Sigma p^*\beta_{pq} b^q h^{-p} \gamma_B^q \gamma_H^{-p} \gamma_{pq}^{-1} a_w^{4p}, \tag{6}$$

where the exponent $4p$, to which a_w is elevated, stems from the assumption that H^+ in solution is solvated by $4H_2O$, as suggested by experimental[18,19] as well as theoretical[20] evidence, and that La^{3+} maintains its coordination unchanged in the hydrolysis complexes. At constant B the activity coefficients and water activity may be regarded as constant; consequently, eqns (5) and (6) can be written as:

$$BZ = \Sigma p K_p h^{-p}, \tag{7}$$

where for brevity:

$$K_p = \Sigma B^q {}^*\beta_{pq} \gamma_B^q \gamma_H^{-p} \gamma_{pq}^{-1} a_w^{4p}. \tag{8}$$

We attempted, first, to explain the data in the simplest way by assuming a single p value. This hypothesis was tested by comparing the experimental $BZ(\log h)$ data with model functions calculated on the basis of eqn (7). In the entire BZ range no satisfactory agreement was found with any p between 1 and 5. The shape of the $BZ(\log h)$ graphs was intermediate between model curves calculated with $p = 1$ and 3. Then the family of $Y(\log u)_P$ curves [eqns (9) and (10)] was calculated for $P = 2$, 3 and 4:

$$Y = \log(BZh) - \log K_1 = \log(1 + Pu^{P-1}), \tag{9}$$

$$\log u = [1/(P-1)]\log(K_P/K_1) - \log h. \tag{10}$$

The experimental data could satisfactorily be fitted to the model function with $P = 3$, whereas systematic deviations were found with both $P = 2$ and 4. Therefore data of the present level of accuracy can be explained by the complexes $(1, q)$ and $(3, q')$.

The K_1 and K_3 values, given in Table 2, were calculated from the $\log h + \log u$ and $\log(BZh) - Y$ differences read off in the position of best agreement. The errors represent maximum deviations from mean values.

The results so far presented rest on the validity of eqn (5). To gain an idea of the uncertainty introduced by this approximation the computations were repeated putting $p = q$, hence:

$$b = B(1 - Z). \tag{11}$$

It is evident from Table 2 that the constants evaluated using eqn (5) or (11) are very similar. The

values obtained from eqn (11) were selected for the following treatment.

(2) *Estimation of the most probable* q *values*

To evaluate q in the hydrolysis products the dependence on B of K_1 and K_3 was examined. Clearly, correct conclusions on q and ${}^*\beta_{pq}$ depend on the estimation of changes in the activity coefficients as well as of the water activity caused by the substitution of Li^+ with La^{3+}. Corrections for medium effects were based on SIT.[17] According to the theory, since all participants to the hydrolytic equilibria are positively charged and the anionic composition of the medium remains essentially unchanged, the activity coefficient of a species "i" of charge z_i, defined so that $\gamma_i \to 1$ as $[i] \to 0$ in 3 m $LiClO_4$, may be expressed as a function of the ionic strength (I) as:

$$\log \gamma_i = -z_i^2[0.5452I^{0.5}/(1+1.5I^{0.5})-0.2624] = -z_i^2 D. \quad (12)$$

Concerning the water activity the theory predicts a linear variation between the values relevant in 3 m $LiClO_4$ and 1 m $La(ClO_4)_3$ at 60°C. On the medium scale $a_w \to 1$ as the composition of TS tends to 3 m $LiClO_4$. We estimate from data published by Pitzer[21] that:

$$\log a_w = 0.0199B. \quad (13)$$

With these assumptions eqn (8) for $p = 1$ may be written as eqn (14):

$$K_1 = {}^*\beta_{11}B \times 10^{-4D}a_w^4 + {}^*\beta_{12}B^2 \times 10^{8D}a_w^4. \quad (14)$$

We consider improbable the species with 3 La^{3+} so that no higher terms were included in the series (14). The plot $K_1 \times 10^{4D}B^{-1}a_w^{-4}$ against $B \times 10^{12D}$ is shown in Fig. 2. It is seen that the points lie, within the limits of experimental error, on a straight line. This means that the $LaOH^{2+}$ and La_2OH^{5+} ions are formed with equilibrium constants given in Table 3.

Equation (8) for $p = 3$ can be rearranged to:

$$K_3 = {}^*\beta_{32}B^2 \times 10^{-6D}a_w^{12} + {}^*\beta_{33}B^3 \times 10^{12D}a_w^{12} + \cdots \quad (15)$$

In writing eqn (15) the formation of $La(OH)_3$ was assumed to be negligible. From the plot of $K_3 \times 10^{6D}$

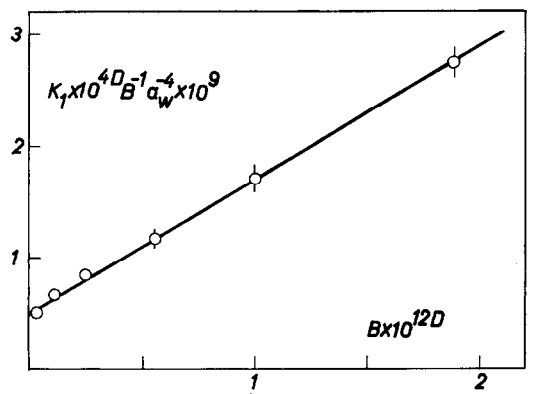

Fig. 2. $K_1B^{-1}a_w^{-4} \times 10^{4D}$ [eqn (14)] as a function of $B \times 10^{12D}$. The line represents: $5.13 \times 10^{-10} + 1.17 \times 10^{-9}B \times 10^{18D}$.

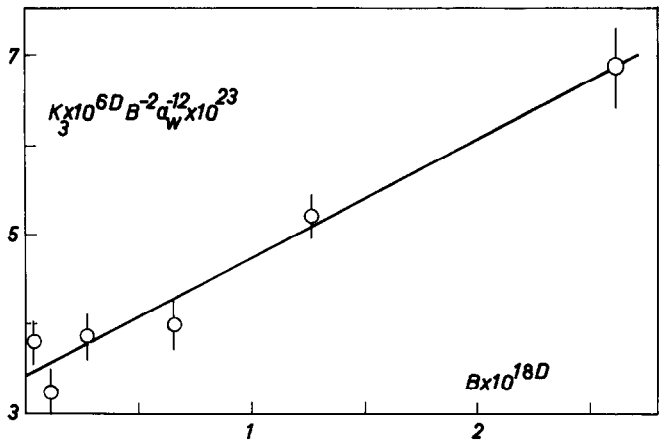

Fig. 3. $K_3 B^{-2} a_w^{-12} \times 10^{6D}$ [eqn (15)] as a function of $B \times 10^{18D}$. The straight line was calculated with: $3.39 \times 10^{-23} + 1.26 \times 10^{-23} B \times 10^{18D}$.

$a_w^{-12} B^{-2}$ against $B \times 10^{18D}$, shown graphically in Fig. 3, it appears that the points fall, within the limits of estimated error, on a straight line, indicating the presence of $La_2(OH)_3^{3+}$ and $La_3(OH)_3^{6+}$. The intercept and slope of the best line through the points gave the constants in Table 3. The error of the slope is fairly large due to the fact that $La_3(OH)_3^{6+}$ is a minor species.

(3) *Refinement of the equilibrium constants*

The calculations of the previous sections have furnished evidence for the formation of $LaOH^{2+}$, La_3OH^{5+}, $La_2(OH)_3^{3+}$ and $La_3(OH)_3^{6+}$. The results were attained by methods based on eqns (5) and (11) which are of approximate validity. It was therefore desirable to refine the constants with more exact procedures.

The experimental data were treated by numerical approaches founded on the principle of least squares. The computation consisted in the minimization of the sum:

$$U = \Sigma (((BZ)_i - (BZ)_{ic})/(BZ)_i)^2, \qquad (16)$$

where $(BZ)_i$ denotes an experimental datum and $(BZ)_{ic}$ a calculated value with a certain set of $*\beta_{pq}$. Medium effects were accounted for by eqns (12) and (13).

The minimum was found with the constants given in Table 3. These are seen to agree well with the graphical evaluation. The uncertainty represents 3 times the standard deviation, as defined by the D-boundary,[22] and is lower than the maximum error estimated by curve fitting.

As a measure of the fit between experimental data and the proposed model we may consider the distribution of the relative error $[1-(BZ)_{ic}/(BZ)_i]$. From a total 103 points 50 are found to have a positive deviation while 53 have a negative deviation. The average of the positive ones amounts to 4.1%, the average of the negative ones to 3.5%. The magnitude and sign of the deviations do not exhibit an appreciable trend with B and Z.

DISCUSSION

We may summarize the results of this work by saying that the La^{3+} hydrolysis at 60°C is explainable in terms of La_2OH^{5+}, $La_2(OH)_3^{3+}$, $La_3(OH)_3^{6+}$ and $LaOH^{2+}$ which link the simple La^{3+} ion with the final hydrolysis products, colloidal lanthanum hydroxide. According to expectation the intermediate species $La_2(OH)_3^{3+}$ and $La_3(OH)_3^{6+}$, that escaped detection at 25°C, are present. The absence of $La_5(OH)_9^{6+}$ or $La_6(OH)_{10}^{8+}$ is readily understood on the basis of the arguments that follow.

From the $*\beta_{11}$ and $*\beta_{12}$ of Table 3 and those determined at 25°C in 3 M $LiClO_4$[3] we estimate the heats associated with the formation of $LaOH^{2+}$ and La_2OH^{5+}, $\Delta^*H_{11} = 40.6 \pm 7.1$ kJ mol^{-1} and $\Delta^*H_{12} = 56 \pm 8$ kJ mol^{-1}. If the mentioned hypothesis, namely Δ^*H_{pq}/p is constant for a given cation, is valid we calculate $\Delta^*H_{95} = 377$ kJ mol^{-1}, which gives at 60°C $\log *\beta_{95} = -64.2$. $La_5(OH)_9^{6+}$ with such an equilibrium constant would reach, at the highest Z studied, a concentration influencing BZ by less than 1%.

The formation of polynuclear complexes may be easier to visualize when it is expressed in terms of polymerization from the mononuclear species. We obtain:

$$LaOH^{2+} + La^{3+} \leftrightarrows La_2OH^{5+}$$

$$[\log(*\beta_{12} \times *\beta_{11}^{-1}) = 0.4 \pm 0.1],$$

$$3LaOH^{2+} \leftrightarrows La_2(OH)_3^{3+} + La^{3+}$$

$$[\log(*\beta_{32} \times *\beta_{11}^{-3}) = 5.37 \pm 0.15],$$

$$3LaOH^{2+} \leftrightarrows La_3(OH)_3^{6+}$$

$$[\log(*\beta_{33} \times *\beta_{11}^{-3}) = 4.9 \pm 0.3].$$

From comparison of these with values of various cations[1,2] it may be inferred that, within the large limits of error, $*\beta_{pq} \times *\beta_{1}^{-p}$ is approximately constant, independent of the nature of the metal. Therefore polymerization is primarily a property of the oxygen atom and the hydroxide ion.

In any case, the question arises why $Me_2(OH)_2^{4+}$ is readily formed by cations of the same 3a group, Sc^{3+} and Y^{3+}, but not by La^{3+}. Presumably the greater stability of $La_2(OH)_3^{3+}$ than of $La_2(OH)_2^{4+}$ is attributable to the effect of charge distribution. Pauling's postulate of the essential neutrality of atoms[23] suggests that charges on atoms in stable substances are generally near zero or at least between $-\frac{1}{2}$ and $+\frac{1}{2}$. Therefore the La^{3+} ion would not reach in $La_2(OH)_2^{4+}$ a sufficient electrical neutrality for stability as, on the contrary, the more electronegative Y^{3+} ion does. Obviously, the introduction of another OH^- bridge in $La_2(OH)_2^{4+}$ further neutralizes charges on the metal and, consequently, causes the resulting $La_2(OH)_3^{3+}$ to be stable. On the other hand, in the attempt to make $Y_2(OH)_3^{3+}$, a more negative charge will pass to Y(III) which is apparently more than required for stability.

The tendency to electrical neutrality may also account for the higher stability of La_2OH^{5+} than of Y_2OH^{5+}. If one tries to replace in La_3OH^{5+} the more electronegative Y^{3+}, in the attempt to render less negative the oxygen atom, more charge will be transferred to Y(III). This, evidently, is more than can be accepted for Y_2OH^{5+} to be stable.

MACROCYCLIC TETRAAMINES FROM REACTION OF THE (1,10-DIAMINO-4,7-DIAZADECANE)COPPER(II) CATION WITH FORMALDEHYDE AND THE CARBON ACIDS NITROETHANE AND DIETHYLMALONATE: VARIABILITY IN REACTIVITY

GEOFFREY A. LAWRANCE* and MARGARET A. O'LEARY

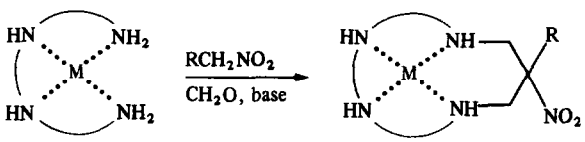
Department of Chemistry, The University of Newcastle, New South Wales 2308, Australia

(*Received* 13 *October* 1986; *accepted* 13 *November* 1986)

Abstract—Reaction of (1,10-diamino-4,7-diazadecane)copper(II) in basic methanol with formaldehyde and the carbon acid nitroethane leads to the facile and high-yielding synthesis of the (10-methyl-10-nitro-1,4,8,12-tetraazacyclopentadecane)copper(II) cation. The similar reaction with diethylmalonate, a weaker carbon acid, yields the (10,10-dicarboxyethyl-1,4,8,12-tetraazacyclopentadecane)copper(II) cation in only low yield.

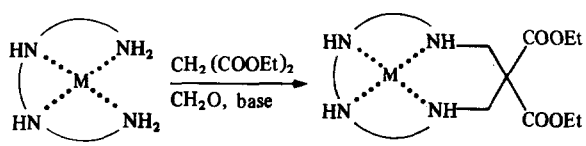
Recently, metal-directed syntheses of multidentate and macrocyclic ligands employing formaldehyde and nitroalkane carbon acids around labile metal ions have been developed.[1,2] These studies supplement earlier studies of inert octahedral amine complexes, where similar reactions have led to the development of a range of macrobicyclic hexaamine ligands.[3–5] In each case, the nitro group introduced into the new ligand from the nitroalkane carbon acid can be chemically or electrochemically reduced to a pendant amine. This produces a new class of macromonocyclic amine ligands, some of which are capable of penta- or hexa-coordination by employing the pendant primary amine group(s) as donor atoms.[2,6] In addition to the chemistry based on nitroalkanes, it was of some interest to us to investigate similar condensation reactions with other carbon acids. While nitroethane is a strong carbon acid ($pK_a \sim 8.6$),[7] it is apparent that other simple organic molecules may be sufficiently acidic to participate in similar reactions. We have noted that diethylmalonate is acidic ($pK_a \sim 13.3$),[7] and may be reactive. With the latter carbon acid, there is the prospect of forming cyclic molecules with pendant acid groups.

The general reaction with nitroalkanes [eqn (1)] is currently being explored in detail for a range of chelate ring sizes and metal ions, and one particular example is described here.



(1)

With diethylmalonate, there is the initial opportunity for macrocyclization [eqn (2)] although hydrolysis and decarboxylation reactions involving the formed *gem* diester, as well as alternate initial reactions, suggest that the reaction may be complicated. Details of this reaction are described and compared with the nitroethane reaction.



(2)

EXPERIMENTAL

Syntheses

$[Cu(L_1)](NO_3)_2$. The tetraamine 1,10-diamino-4,7-diazadecane (35 g, 0.2 mol) was added to $Cu(NO_3)_2 \cdot 3H_2O$ (48 g, 0.2 mol) in methanol (1.5 l). The resulting dark blue solution was warmed, and triethylamine (22 g, 0.22 mol), nitroethane (37 g, 0.49 mol) and formaldehyde (100 cm^3, 37% aq,

* Author to whom correspondence should be addressed.

1.34 mol) were added. After heating at ~ 55°C for 30 min, the solution was left to crystallize at room temperature overnight. Filtration gave glistening blue crystals of the complex (68 g, 74%). Found: C, 31.1; H, 6.0; N, 21.0. Calc. for $C_{12}H_{27}CuN_7O_8$: C, 31.3; H, 5.9; N, 21.3%. IR (KBr disc): $\nu_{as}(NO_2)$ 1530 cm^{-1}, $\nu_s(NO_2)$ 1340 cm^{-1}. Electronic spectrum (water): λ_{max} 572 nm (ε 99 M^{-1} cm^{-1}), 263 (ε 7440). The complex can be readily recrystallized from water as perchlorate or chloride salts. Found (chloride salt): C, 32.8; H, 7.2; N, 16.3. Calc. for $C_{12}H_{27}Cl_2CuN_5O_2 \cdot 1\frac{1}{2}H_2O$: C, 33.1; H, 6.9; N, 16.1%.

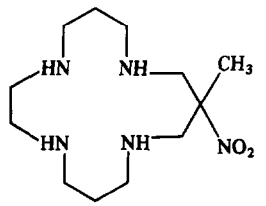
$[Cu(L_2)](ClO_4)_2$. The tetraamine 1,10-diamino-4,7-diazadecane (3.5 g, 0.02 mol) was added to $Cu(NO_3)_2 \cdot 3H_2O$ (4.8 g, 0.02 mol) in methanol (200 cm^3). The resulting dark blue solution was warmed, then diethylmalonate (3.2 g, 0.02 mol), triethylamine (3 cm^3, 0.02 mol) and formaldehyde (10 cm^3, 37% aq, 0.13 mol) were added. After heating for a further 1 h, the solution was left at room temperature overnight. The solution was diluted with water, sorbed onto SP Sephadex C-25 resin (25 cm × 4 cm column) and eluted with 0.25 M $NaClO_4$ adjusted to pH ~ 3. Three significant blue bands were collected. The first failed to crystallize readily, proved to be acid-sensitive and hence non-cyclic, and was discarded. The third band on concentration and standing gave a blue powder (1.44 g). Rapid and essentially complete loss of colour of a solution of this material on acid addition is indicative of a non-cyclic product; the diester macrocycle does not decolourize readily in aqueous acid. Spectroscopy (IR and UV–vis) indicated a similarity to the precursor, and the microanalysis indicated a C : N ratio of 9 : 4, although an acceptable fit for all elements to presumed structures was not forthcoming. Clearly, this material does not arise from a condensate involving diethylmalonate, and complete identification was not pursued. The second band, on concentration, gave blue needles which were collected, washed with alcohol and ether, and air dried to give the diester product (40 mg, < 2%). Found: C, 31.9; H, 5.4; N, 8.9. Calc. for $C_{17}H_{34}Cl_2CuN_4O_{12} \cdot H_2O$: C, 31.9; H, 5.7; N, 8.8%. IR (KBr disc): 1726 cm^{-1} (ester). Electronic spectrum (water): λ_{max} 568 nm (ε 105 M^{-1} cm^{-1}), 268 (ε 7030).

Physical methods

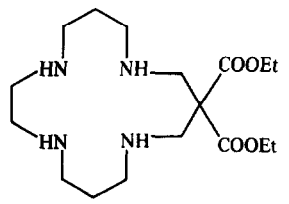
Electronic spectra were recorded in aqueous solution using a Hitachi 220A spectrophotometer. IR spectra were recorded on complexes dispersed in KBr discs using a Nicholet MX-1 Fourier-transform spectrometer. Electrochemical measurements were performed with either a Bioanalytical Systems Inc. CV-27 controller and a glassy carbon working electrode, or with an AMEL Model 473 controller linked to an EG&G PAR Model 303A static mercury drop electrode. A conventional three-electrode system, with Ag–AgCl reference electrode and argon or nitrogen purge gas was employed.

RESULTS AND DISCUSSION

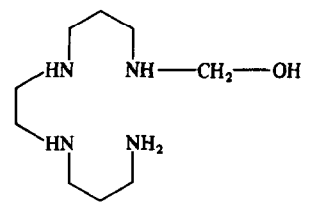
Reaction of copper(II) nitrate, 1,10-diamino-4,7-diazadecane, formaldehyde and nitroethane proceeds readily in warm methanol containing triethylamine as a non-coordinating base, with the product macrocycle 10-methyl-10-nitro-1,4,8,12-tetraazacyclopentadecane (L_1) actually crystallizing as the copper(II) complex during reaction. Without any extensive attempts to refine conditions, yields of the isolated solid of ~ 75% have been obtained routinely. Chromatography of a reaction mixture on SP-Sephadex C-25 cation exchange resin indicated that $[Cu(L_1)]^{2+}$ accounts for ⩾ 90% of copper in the product mixture. The product exhibits characteristic IR vibrations for the nitro group, with ν_{as} at 1530 cm^{-1} and ν_s at 1340 cm^{-1}. Voltammetry in water defined a Cu(II)–(I) couple at −0.67 V (vs Ag–AgCl) and a multielectron irreversible nitro group reduction at −0.94 V. The product is also extremely resistant to dissociation in aqueous acid. Spectroscopic and electrochemical properties are similar to those reported for other well-characterized analogues,[1,2] and preliminary results of an X-ray crystal structure analysis confirm the structure assigned. Evidently, reaction via Scheme 1 proceeds to the essential exclusion of



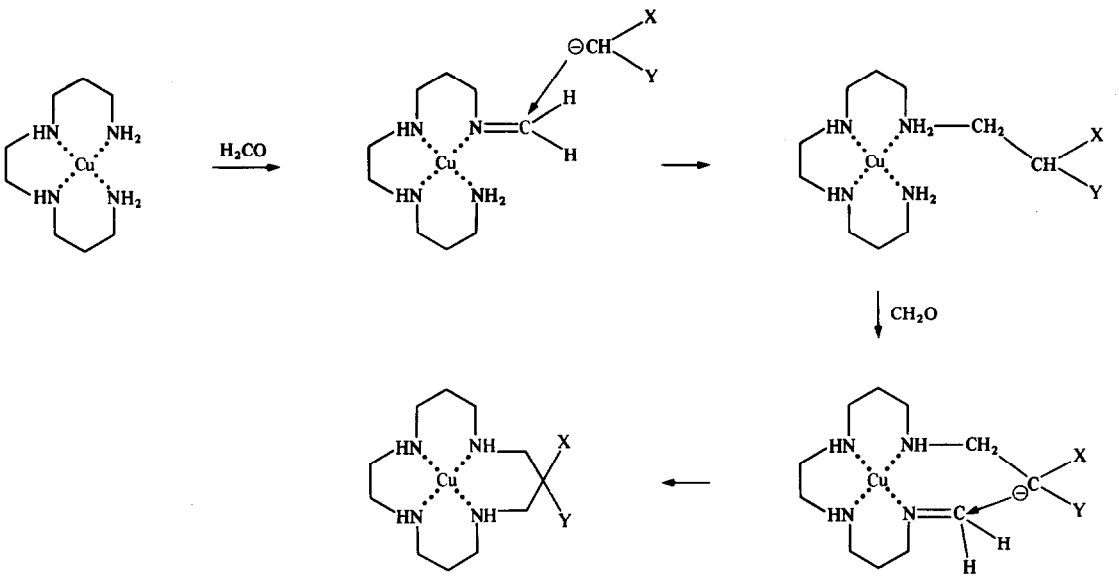
L_1



L_2



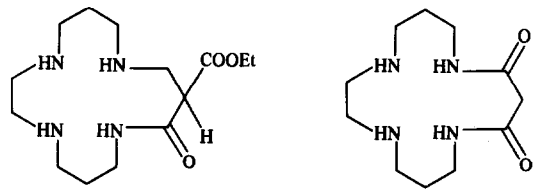
L_3



Scheme 1.

other reactions, the formation of the new six-membered ring being favoured entropically. We are currently pursuing this type of reaction with a range of nitroalkanes and amine complexes, as well as looking at complexes of the pendant amine ligands resulting from nitro group reduction. It is clear that the experimental method represents a facile and probably general route to a new range of macromonocyclic ligands.

When the identical reaction to that described above was performed with diethylmalonate as carbon acid, it was not possible to crystallize any product directly. Chromatography on SP-Sephadex C25 resin indicated that several products were present. The major band, from which a blue solid was crystallized, did not contain a cyclic ligand, decomposing readily in aqueous acid. Spectroscopy and microanalysis best fit a simple structure such as L_3, rather than the required compound L_2. A complex of the latter compound was isolated in low yield from a second band; despite attempts to vary the outcome by altering reaction conditions, the result was always similar. The only macrocyclic complex isolated, which amounted to less than 10% of total copper and was crystallized in no better than 2% yield, proved to contain the macrocycle L_2. The IR spectrum showed a strong band at 1726 cm^{-1} characteristic of an ester. The complex was stable in aqueous acid, indicative of a macrocyclic complex. Voltammetry yielded a well-defined reversible Cu(II)–(I) couple at a potential of −0.82 V, with an irreversible wave at −1.34 V associated with electron addition to the ester substituents and in a similar position to waves assigned to this process in several macrobicyclic cobalt(III) complexes with ester substituents.[8] There was no evidence for any amide species such as L_4, analogues of which have appeared in similar reactions around inert cobalt(III) amines.[9] The diamide L_5 which can form by condensation in the absence of metal ion



L_4 L_5

and formaldehyde[10] was also absent. While decarboxylation or hydrolysis of the *gem* diester isolated had been anticipated, neither apparently occurred under the experimental conditions employed.

The likely reaction of the putative monoimine intermediate (product of the first step in Scheme 1) with hydroxide ion to ultimately form L_3, rather than reaction with the $(EtOOC)_2CH^-$ nucleophile, is not unreasonable since there was no attempt to exclude water from the reaction mixture. The pK_a of $(EtOOC)_2CH_2$ is about 5 units higher than that of $CH_3CH_2NO_2$, strictly limiting the concentration of the anion in the former case. Even assuming like nucleophilicity for the two carbon acid reactants, there will clearly be far greater opportunity for com-

petition by OH^- in the case of the diethylmalonate reaction. Possibly in stringently anhydrous conditions, reactions involving carbon acids with higher pK_a values may prove more successful. We are pursuing this prospect. Evidently nitroalkane carbon acids are far more successful reactants than diester alkane carbon acids under the conditions described.

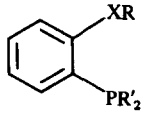
(*Received* 12 *August* 1986; *accepted* 10 *November* 1986)

Abstract—The preparation of the *ortho*-substituted aryldifluorophosphines 2-$MeOC_6H_4PF_2$ and 2-$Me_2NC_6H_4PF_2$ by chlorine–fluorine exchange from the corresponding dichlorophosphines using sodium fluoride in acetonitrile in the presence of a crown ether is described. The *ortho*-substituted aryldichlorophosphines 2-$MeOC_6H_4PCl_2$ and 2-$Me_2NC_6H_4PCl_2$ were prepared from the respective bis(*N*,*N*-dimethylamino)phosphines by cleavage of the P—N bonds with hydrogen chloride. The reaction of 4-fluoroanisole and 2-methoxyphenyllithium with phosphorus trichloride did not yield the expected chlorophosphines, i.e. 2-MeO-5-F-$C_6H_3PCl_2$ and 2-$MeOC_6H_4PCl_2$, but led to formation of 4-fluorophenyldichlorophosphite in the former, and to tris(2-methoxyphenyl)phosphine in the latter case. The difluorophosphine 2-$MeOC_6H_4PF_2$ was found to undergo a spontaneous oxidation–reduction reaction with formation of the tetrafluorophosphorane 2-$MeOC_6H_4PF_4$, and the cyclotetraphosphine (2-$MeOC_6H_4P)_4$. A single-crystal X-ray structure determination of the latter indicated the presence of a strongly puckered four-membered ring with P—P bond lengths ranging between 222 and 223 pm, and endocyclic bond angles of 84°. Vicinal $MeOC_6H_4$ groups were found arranged *trans* to each other. Dichloroplatinum(II) complexes were prepared, involving the two new fluorophosphines, 2-$XC_6H_4PF_2$ (X = MeO or Me_2N), as ligands. In neither case was any evidence found for coordination between platinum and oxygen or nitrogen, and the fluorophosphines were found to function solely as phosphorus donors. The absence of interaction between platinum and the oxygen atom in the *ortho* position of the ligand 2-$MeOC_6H_4PF_2$ was confirmed in a single-crystal X-ray determination of the complex $Cl_2(2\text{-}MeOC_6H_4PF_2)_2Pt$. The compound was found to exist as a planar, *cis*-coordinated species with Pt—Cl bond lengths between 232 and 234 pm, and a Pt—P bond length of 218 pm. All compounds were characterized by NMR spectroscopy (^1H, ^{31}P and ^{19}F, where applicable).

Phosphorus(III) compounds, involving aromatic groups bearing an *ortho* substituent with potential donor atoms, e.g. N, O or Sb, have been known for some time.



X = O, NR, SbR, etc; R, R′ = alkyl or aryl groups.

* Author to whom correspondence should be addressed.

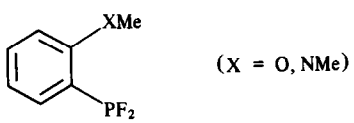
Numerous coordination compounds involving such ligands, displaying interesting catalytic properties in some cases, have been synthesized.[1-4]

Phosphorus(III) compounds of the above type are expected to coordinate, primarily, via the phosphorus atom, but may give rise to chelate formation on account of the potential donor function of the heteroatom. Even though in many cases a proper bond between the metal and the heteroatom may not exist, evidence has been obtained which suggests that, in the course of catalytic reactions, a weak interaction between platinum and the heteroatom may serve to stabilize vacant coordination sites.

In our own previous work concerning the coordinating potential of *ortho*-substituted aryl- and alkyl-phosphines with metals such as Rh(I) or Ir(I),[5] or Pd(II) and Pt(II),[6] such interactions were demonstrated. Thus, it was shown that phosphorus (III) ligands, involving 2-*N*,*N*-dimethylamino substituents in an aromatic group form chelate complexes of composition $(L)PtCl_2$ (M = Pd or Pt), involving coordination of the ligand to the metal via phosphorus as well as nitrogen.[7] In contrast, the related complexes with *ortho*-alkoxy-phenyl groups seem to be bonded to the metal solely via phosphorus. These findings are in agreement with reports by other authors.[2,8] Oxygen does get involved in bonding or interacts strongly with the metal in the case of metallic centres of higher oxidation number.[4(b),9]

The coordinating ability of a heteroatom in the *ortho* position of an aromatic substituent at phosphorus(III) is strongly affected by its basicity, according to the concept of Pearson: nitrogen, as a "softer" atom is expected to coordinate to a "soft" metallic centre, rather than the "hard" oxygen. In addition, the +*I*-effect of a further methyl group at nitrogen was found to be favourable.[5] In an attempt to affect the interaction between the metal and the *ortho* substituent in an aryl group at phosphorus, the following possibilities were considered: (a) Elimination of ligands, e.g. chlorine, using silver salts, generating vacant coordination sites, or coordination sites to which solvent molecules are loosely bound. (b) Increase of the electrophilic character of the metal through the introduction of ligands which reduce the electron density at the metal, e.g. CO, PF_3 or PF_2O^-, isoelectronic to PF_3. (c) Modification of the phosphorus ligand, e.g. through the introduction of fluorine. The considerations listed under (b) also apply.

A ligand of the general type



(X = O, NMe)

on account of the superior back-bounding qualities of the PF_2 grouping is expected to be capable of withdrawing electron density from the metal, in contrast to a PR_2 group (R = alkyl or aryl). Thus, an increase in the electrophilic character will result, facilitating the coordination of a heteroatom. The compounds under discussion are considered to represent novel ligand systems which provide access to a variety of interesting coordination compounds.

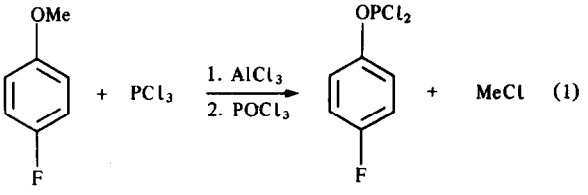
An additional feature of difluorophosphines, RPF_2 (R = alkyl or aryl), is their pronounced tendency to undergo oxidation–reduction reactions, with formation of tetrafluorophosphoranes and cyclopolyphosphines.[10,11] The synthesis of two *ortho*-substituted difluorophosphines, their coordination compounds with platinum(II), and the redox disproportionation of one of the two compounds, $2\text{-}MeOC_6H_4PF_2$, will be described in what follows.

RESULTS AND DISCUSSION

Preparation of substituted aryldichlorophosphines

According to Michaelis,[12] anisole and *N*,*N*-dimethylaniline may be converted to the corresponding *para*-substituted dichlorophosphines under Friedel–Crafts conditions. It is known[13] that, in the case of substituted aryl precursors, mixtures of isomers (predominantly *para*, and some *ortho*) may be formed.

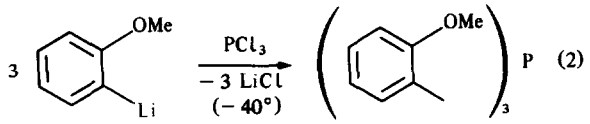
First, the synthesis of 2-methoxy-5-fluorophenyldichlorophosphine was attempted via the reaction of 4-fluoroanisole with phosphorus trichloride in the presence of aluminium chloride. Cleavage of the intermediate complex formed initially with phosphorus oxychloride,[14] however, only furnished 4-fluorophenyldichlorophosphite (**1**) as a result of the cleavage of the ether linkage [eqn (1)], **1** has not previously been described in the literature and was characterized by elemental analysis and NMR spectroscopy.



1

Next, an attempt was made at synthesizing 2-methoxyphenyldichlorophosphine by the reaction of 2-lithioanisole with phosphorus trichloride at low temperature [eqn (2)]. The main reaction product here was the tertiary phosphine, tris(2-methoxy-

phenyl)phosphine, which has previously been reported by Mann and Chaplin.[15]



(2)

The synthesis of 2-methoxyphenyldichlorophosphine in a yield of 10%, using a diazonium intermediate, was first reported by Quin.[16] It was thought that a more efficient route to this dichlorophosphine might be the cleavage of the appropriate bis(*N*,*N*-diethylamino)phosphine with dry hydrogen chloride. A number of *para*-substituted aryldichlorophosphines have previously been obtained by this route.[17] The same principle has been employed by Shaw[18] and, later, by McEwen,[19] in the synthesis of *ortho*-substituted aryldichlorophosphines.

The synthesis of the dichlorophosphines required in the present research was accomplished in accordance with eqns (3) and (4).

The aryl compounds, **2b** and **3b**, react with bis(diethylamino)chlorophosphine according to eqn (3b). The P—N bond in the aminophosphines, **4** and **5**, is cleaved by anhydrous hydrogen chloride with formation of the dichlorophosphines, **6** and **7**, in good yield. The NMR data for compounds **4**–**7** are listed in Table 1.

Preparation of 2-*methoxy- and* 2-N,N-*dimethylaminophenyldifluorophosphine*, **8** *and* **9**

It has been demonstrated that the unsubstituted compound, $C_6H_5PF_2$, may be obtained in good yield by chlorine–fluorine exchange with sodium fluoride from the dichlorophosphine.[20]

It was found that the 2-substituted aryldichlorophosphines, **6** and **7**, may be converted into the corresponding difluorophosphines, **8** and **9**, using sodium fluoride in acetonitrile, in the presence of catalytic quantities of crown ether (15-crown-5), in accordance with eqn (5).

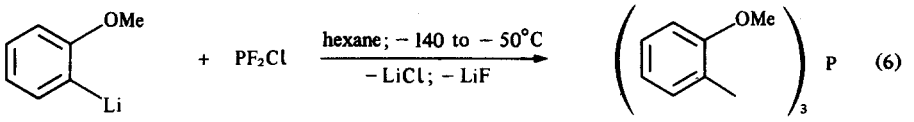
(5)

8 X = O
9 X = NMe

All the compounds are distillable liquids which were characterized by elemental analysis, and by NMR spectroscopy (Table 1).

The possibility was considered that compounds **8** and **9** may result from the direct reaction of PF_2Cl[21] with a suitable aryllithium compound. Thus, 2-methoxyphenyllithium was allowed to react with PF_2Cl at low temperature in a sealed, heavy-wall glass tube [eqn (6)].



(6)

It was found, however, that both P—F bonds and the P—Cl bond in PF_2Cl reacted, with formation of the tertiary phosphine $(2\text{-}MeOC_6H_4)_3P$ as the only product which could be isolated. Chlorodifluorophosphine does not, therefore, react more selectively than phosphorus trichloride [cf. eqn (2)]. Part of the PF_2Cl was recovered unreacted.

Spontaneous oxidation–reduction reaction of 2-*methoxyphenyldifluorophosphine* (**8**)

The difluorophosphine (**8**) could be kept unchanged over periods of several months at −30°C. It was found, however, that a spontaneous disproportionation reaction commences at room temperature, and is accelerated at elevated temperature. Thus, a sample of **8** kept in a sealed NMR

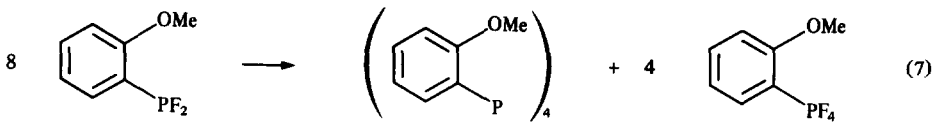
tube for 48 h at 80°C was found to be converted into the corresponding cyclotetraphosphine (**10**) and tetrafluorophosphorane (**11**) in a yield of 90% [eqn (7)].



8 **10** **11**

Oxidation–reduction reactions of the above type have been known for a few years, and were first observed in the case of methyldifluorophosphine.[10,22] Such reactions will be catalytically affected by traces of hydrogen fluoride, formed in the presence of moisture.[23]

Besides tetrafluorophosphoranes, cyclopolyphosphines $[(RP)_n$ (n = usually 4, 5 or 6)] are formed.[24,25] The number n depends on the size and electronegativity of the organic group.[25,26] From mass-spectroscopic (parent ion, m/z 552) and NMR spectroscopic investigations the presence of the four-membered ring $(2\text{-}MeOC_6H_4P)_4$ is clearly indicated. The high-field shift, $\delta_P = -55.6$, in **10** is considered typical of cyclopolyphosphines $(RP)_4$.[25]

The ^1H NMR spectrum of **10** suggests that the state of the compound in solution is not simple. Several δ_H values for the protons of the CH_3O groups ($\delta_H = 3.7$–3.9); besides, unresolved multiplets in the phenyl region are observed. It is assumed, therefore, that the orientation of the phenyl rings (and the methoxy groups connected to them) is different, and/or that the molecule dissociates or rearranges in solution.

The second product, formed during the disproportionation of the difluorophosphine **8**, 2-methoxyphenyltetrafluorophosphorane (**11**) was also formed in the oxidative fluorination reaction of the dichlorophosphine **6** with antimony trifluoride, in analogy to the unsubstituted parent compound, $C_6H_5PF_4$.[27]

The separation of **11** from $SbCl_3$ by distillation proved difficult, and **11** could not be obtained in a pure state. It was, however, characterized unambiguously by its NMR data. Further evidence for its identity has been provided by the hydrolysis of **11** [eqn (9)].

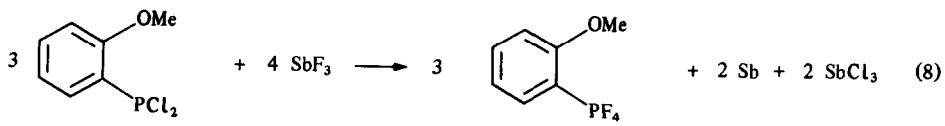
The phosphonic acid, previously reported in the literature,[28] has been characterized by analysis and by its melting point. NMR data could not be obtained, on account of its poor solubility.

Syntheses of the platinum(II) *complexes*, **13** *and* **14**

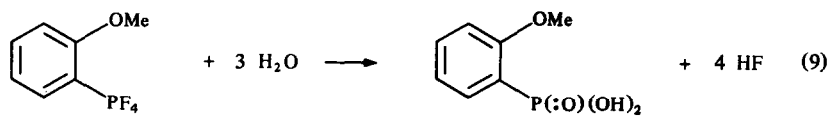
Dichloro-(1,5-cyclooctadiene)platinum(II)[29] was found to react in dichloromethane solution with two equivalents of the difluorophosphines **8** and **9** with displacement of the cyclooctadiene ligand. The complexes *cis*-dichloro-bis{(2-methoxyphenyl) difluorophosphine}platinum(II) (**13**) and *cis*-dichloro - bis{(2 - dimethylaminophenyl)difluoro - phosphine}platinum(II) (**14**) are thus readily obtained.

The *cis* structure of complexes **13** and **14** is suggested by their IR and NMR spectra; it has also been established by a single-crystal X-ray diffraction study of **13** (*vide infra*).

In the IR spectra of both complexes, **13** and **14**, a weak absorption due to ν_{Pt-Cl} is observed at 280 and 335 cm^{-1}, respectively; this is typical of *cis*-chlorine substitution at platinum.[30] Furthermore,



6 **11**



11 **12**

14 X = NMe

cod = cyclooctadiene - 1.5

two characteristic strong bands for ν_{P-F}[31] at 770 and 845–865 cm^{-1} are observed.

The NMR spectra (cf. Table 2) display symmetrical higher-order spin systems of type $A_2XA'_2X'M$ (A and A′ = ^{19}F, X and X′ = ^{31}P, M = Pt). In the ^1H NMR spectra single lines are observed for the $-OCH_3$ and $-N(CH_3)_2$ groups *ortho* to phosphorus. This confirms that the heteroatom, O or N, is not coordinated with platinum, as otherwise platinum satellites should be observed. The platinum–phosphorus coupling constants ^1J(PPt) (5268 Hz for **13** and 5613 Hz for **14**) are of a magnitude expected for PF ligands bonded to platinum.[32] They indicate the presence of *cis* compounds, the Pt–P coupling constants of *trans* complexes being smaller, because of the larger *trans* effect of phosphine ligands compared to chloride. From the ^{19}F and ^{31}P NMR spectra only the sum of the PF coupling constants [$|^1J(PF)+{}^3J(PF)| = 1136$ for **13** and 1117 for **14**] can be obtained directly. The situation in these spin systems involving ^{19}F and ^{31}P nuclei, of which "virtual coupling"[33] is characteristic, is different than for systems with ^1H and ^{31}P nuclei. In the *cis* complexes which are under investigation here the coupling constant ^2J(PP′) is large, because of the very large coupling constant ^1J(PPt). Further, the "virtual coupling" between fluorine of one of the PF ligands to the phosphorus of the second (*cis*) ligand [^3J(FP′)] must be rather large. A simulation of this spectrum should be informative but could not be realized, thus far, because of the difficulty of assigning the coupling constants.

Single-crystal X-ray structure determination of compounds **10** *and* **13**

The cyclotetraphosphine **10** has a geometry very similar to that of the other cyclotetraphosphine derivatives that can be found in the literature. The P—P bond lengths (mean 222.5 pm) compare well with 221.7 pm in $(t\text{-BuP})_4$,[34] 222.4 pm in $(H_{11}C_6P)_4$,[35] 222.2 pm in $(F_3CP)_4$,[36] and 223.4 pm in $(F_5C_6P)_4$.[37] As in these compounds the four-membered ring in **10** is not planar. This is reflected in the mean P—P—P bond angle of 84.1°. While

the lengths of the P—C_{sp^3} bonds in these compounds are around 187 pm the P—C_{sp^2} bond lengths in **10**, and in the pentafluorophenyl derivative, $(F_5C_6P)_4$[37] are near 183 pm (mean value of the P—C bond length in **10**, 183.0 pm).

The bonding geometry at the platinum atom in **13** is distorted square planar with bond angles between 85° (P—Pt—Cl) and 99° (P—Pt—P) (sum of the angles between *cis* bonds 359.9°). The observed distances between platinum and the methoxy-oxygen atoms (347 and 349 pm) prove that there is no increase in the coordination number of platinum.

Whereas the Pt—Cl bond distances of 232 and 234 pm in **13** are very close to similar values found in the literature[36] (e.g. terminal Pt—Cl in $[Pt(Cl)\{P(:O)F_2\}(PEt_3)]_2$, the Pt—P bonds in the molecule are amongst the shortest such bonds described in the literature. Very short bond lengths between phosphorus and the transition metal are generally found in complexes of fluoro-substituted phosphines with transition metals. In the complex $[Pt(Cl)\{P(:O)F_2\}(PEt_3)]_2$ the Pt—$P(Et)_3$ bond length is 225.7 pm whereas the Pt–$P(:O)F_2$ bond length is only 216.8 pm.[39]

The *ortho* substitution at the phenyl ring causes rather short non-bonded distances between the methoxy oxygen and the phosphorus atoms in both compounds (276–283 pm). These values are about 50 pm shorter than the sum of the van der Waals' radii (332 pm). The fact that such a short non-bonding distance is possible is probably due to a certain degree of acceptor character of the phosphorus atom. This interaction causes changes in the bonding geometry around phosphorus. The equivalence of the P—P—C_{sp^2} angles which is found in the other cyclotetraphosphines is lost in **10** where two groups of such angles can be found, one with a mean value of 104.7(7)°, the other with a mean

value of 101.3(9)°. A similar observation can be made in the platinum complex where two groups of C—P—F and C—P—Pt angles are found. The O···P—P angles involving the phosphorus atoms most nearly *trans* to O···P are all between 153 and 158°, whereas to the *cis*-P—P bonds they are between 84 and 90°.

These values can be explained by the fact that the bonding geometry at phosphorus is between the normal pyramid and a pseudo-trigonal bipyramid where one of the equatorial positions is occupied by the non-bonding electron pair and the oxygen donor atom is at an axial position. Similarly the O···P—F angles in **13** are 156.0 and 156.4°. The

geometry around the phosphorus atom is between tetrahedral and trigonal bipyramidal, with axial P—O and P—F bonds, where the bond angles between the pseudo-equatorial Pt—P and C—P bonds, respectively, and the pseudo-equatorial P—F bond [to F(12) and F(22)] are about 3–4° larger than those to the pseudo-axial P—F bond.

EXPERIMENTAL

All manipulations were carried out in an atmosphere of dry oxygen-free nitrogen, using standard techniques. Magnetic stirring was employed throughout. Literature procedures were employed for the synthesis of 2-bromo-*N*,*N*-dimethylaniline,[40] bis(diethylamino)chlorophosphine[41] and dichloro-1,5-cyclooctadieneplatinum.[29]

NMR spectra were recorded using the following instruments and conditions:

JEOL JNMR-60 HL: ^1H (60 MHz), ^{19}F (56.4 MHz), ^{31}P (24.3 MHz);
Varian EM 390: ^{19}F (84.6 MHz);
Bruker WM 400: ^1H (400 MHz), ^{31}P (162.0 MHz);
Bruker AM 300: ^1H (300 MHz).
References: TMS internal (^1H), CCl_3F external (^{19}F), 85% H_3PO_4 external (^{31}P).
Mass spectra: A.E.I. instruments MS 9 and MS 902 S at 70 eV.

Attempts directed at the synthesis of 2-methoxyphenyldichlorophosphine

Reaction of 4-fluoroanisole with phosphorus trichloride: formation of 4-fluorophenyldichlorophosphite (**1**). 4-Fluoroanisole (26 g, 0.2 mol) was added to 30 g (0.23 mol) of aluminium trichloride at such a rate that the temperature of the mixture was kept below 90°C (4 h). Over a period of 30 min, 30 g (0.23 mol) of phosphorus trichloride was then added, so that the temperature was kept between 60 and 100°C, and that the mixture remained liquid. Stirring was continued for 5 h at 60°C and for 12 h at room temperature. A white solid was precipitated upon addition of 51 g (0.33 mol) of phosphorus oxychloride. The mixture was subsequently kept for 1 h at 100–110°C. Upon cooling and addition of 100 cm^3 of petroleum ether (40–60) the mixture was refluxed for 2 h. Fractional distillation of the liquid product remaining after removal of the solid yielded 11.5 g (27%) of **1** [b.p. 70°C (0.5 mm)].

NMR spectra: ^1H, $\delta_{C_6H_3} = 6.7–7.1$ (m, 3H); CH_2Cl_2 as an internal reference. δ ^1H (TMS) = δ ^1H (CH_2Cl_2) -5.35; ^{19}F, $\delta = -111.5$ (s), $CFCl_3$ as an external reference; ^{31}P, $\delta = 178.2$ (s).

Analysis: $C_6H_3Cl_2FOP$ (211.97). Found: C, 34.0; H, 1.9; P, 14.8. Calc.: C, 34.0; H, 1.4; P, 14.6%.

Reaction of 2-methoxyphenyllithium with phosphorus trichloride: preparation of tris(2-methoxyphenyl)phosphine.[15] A solution of *n*-butyllithium (0.134 mol as 57.3 g of a 1.38 M solution in hexane) was added to 25 g (0.134 mol) of 2-bromoanisole. After the mixture had been stirred at room temperature for 8 h, it was cooled to −78°C and stirred for 2 h at this temperature, after addition of 18.3 g (0.134 mol) of phosphorus trichloride. After the mixture had been allowed to warm up to room temperature the lithium chloride precipitated was removed by filtration. Tris(2-methoxyphenyl) phosphine was precipitated upon slow evaporation of the remaining liquid *in vacuo* (12 mm). The product was recrystallized from dichloromethane. Yield 9.8 g (71%) (m.p. 186°C).

NMR spectra: ^1H, $\delta_{OMe} = 3.85$ (s, 9H); $\delta_{Ar} = 6.8–7.5$ (m, 12H) in $CDCl_3$; CH_2Cl_2 as an internal reference; ^{31}P, δ P = −36.5 (CH_2Cl_2 as solvent).

Preparation of 2-methoxyphenyl-bis(N,N-diethylamino)phosphine (**4**)

A Grignard reagent was prepared from 28.1 g (0.15 mol) of 2-bromoanisole (**2a**) and 3.65 g (0.15 mol) of magnesium in 50 cm^3 of diethylether. After 2 h reflux bis(diethylamino)chlorophosphine (31.6 g; 0.15 mol) was added over a period of 0.5 h at −15°C. The mixture was refluxed for 6 h, and the magnesium halide mixture formed was separated by filtration. Distillation of the liquid product furnished 24.9 g (59%) of **4** [b.p. 115°C (0.2 mm)].

Analysis: $C_{15}H_{27}N_2OP$ (282.36). Found: C, 63.8; H, 9.7. Calc.: C, 63.8; H, 9.6%.

Preparation of 2-N,N-dimethylaminophenyl-bis(diethylamino)phosphine (**5**)

A mixture of 0.115 mol of *n*-butyllithium (as 60 g of a 1.38 M solution in hexane) and 23.1 g (0.115 mol) of 2-bromo-*N,N*-dimethylaniline (**3a**) was prepared at −10°C, and was stirred for 12 h at room temperature. Upon cooling to −30°C 24 g (0.115 mol) of bis(diethylamino)chlorophosphine in 20 cm^3 of hexane was added over a period of 0.5 h. The mixture was subsequently refluxed for 5 h. The lithium chloride was removed by centrifugation at room temperature, and the supernatant liquid was fractionally distilled. The product (**5**) was obtained in a yield of 21.8 g (64%) [b.p. 138–140°C (1.0 mm)].

Analysis: $C_{16}H_{30}N_3OP$ (295.41). Found: C, 65.1; H, 10.5. Calc.: C, 65.0; H, 10.2%.

Preparation of 2-methoxyphenyldichlorophosphine (**6**)

A solution of 14.5 g (0.05 mol) of 2-methoxyphenyl-bis(*N,N*-diethylamino)phosphine (**4**) in 40 cm^3 of petroleum ether (40–60) was placed in a 200-cm^3 heavy wall glass tube, fitted with a TEFLON® stopcock, and was cooled to −196°C. Anhydrous hydrogen chloride (7.8 g, 0.21 mol) was than condensed onto the mixture via a vacuum line. The sealed reaction tube was allowed to reach room temperature with continuous shaking over a period of 1 h. The tube was opened in an atmosphere of nitrogen, and the diethylammonium chloride precipitated was filtered off, using a sintered glass disc, and was washed repeatedly with small portions of petroleum ether (40–60), totalling 50 cm^3. The clear liquid product was fractionally distilled, and **6** was obtained in a yield of 8.69 g (82%) [b.p. 83–85°C (0.3 mm)].

Analysis: $C_7H_7Cl_2OP$ (290.01). Found: C, 40.2; H, 3.4. Calc.: C, 40.2; H, 3.4%.

Preparation of 2-N,N-dimethylaminophenyldichlorophosphine (**7**)

As described in the preceding experiment, a mixture of 18.8 g (0.064 mol) of the aminophosphine **5** and 9.65 g (0.265 mol) of dry hydrogen chloride was allowed to react, yielding 10.5 g (74%) of **7** [b.p. 71°C (0.1 mm)].

Analysis: $C_8H_{10}Cl_2NP$ (222.05). Found: C, 43.1; H, 4.6. Calc.: C, 43.3; H, 4.5%.

Preparation of 2-methoxyphenyldifluorophosphine (**8**)

A suspension of 3.8 g (0.09 mol) of carefully dried sodium fluoride in 30 cm^3 of acetonitrile and 8.0 g (0.038 mol) of the chlorophosphine **6** to which two drops of the crown ether 15-crown-5 had been added, was stirred for 24 h at room temperature. The solids were removed by filtration, using a sintered glass disc, and were washed with 5 cm^3 of acetonitrile. Fractional distillation of the liquid product furnished the fluorophosphine **8** in a yield of 5.1 g (76%) [b.p. 62–64°C (1.5 mm)].

Analysis: $C_7H_7F_2OP$ (176.10). Found: C, 46.1; H, 3.9; F, 22.6. Calc.: C, 47.7; H, 4.0; F, 21.6%.

The deviation of the analytical data from the calculated values may be accounted for as a result of the presence of some 2-methoxyphenyltetrafluorophosphorane (**11**) resulting from the disproportionation of **8**.

Preparation of 2-N,N-*dimethylamino-phenyldifluorophosphine* (**9**)

As described in the preceding experiment, 6.0 g (0.027 mol) of the dichlorophosphine **7** were fluorinated during a reaction time of 3 days, employing 3.0 g (0.073 mol) of sodium fluoride, in the presence of two drops of the crown ether 15-crown-5. Distillation furnished **9** as a colourless liquid of b.p. 63–66°C (2.0 mm). Yield 4.2 g (82%).

Analysis: $C_8H_{10}F_2NP$ (189.14). Found: C, 50.6; H, 5.4; P, 16.6. Calc.: C, 50.8; H, 5.3; P, 16.4%.

Oxidation–reduction reaction of **8**

NMR experiment. A mixture of 0.53 (0.003 mol) of **8** with *ca* the same amount of $CDCl_3$ was sealed into a 5-mm NMR tube, and was maintained at 80°C for 2 days. Inspection of the ^{31}P NMR spectrum revealed that **8** had been transformed to a mixture of the cyclotetraphosphine **10** and the tetrafluorophosphorane **11**.

On a preparative scale, the reaction was conducted as follows. A sample of *ca* 1.3 g of the difluorophosphine **8** was found to change to a crystalline solid on standing at room temperature over a period of 3–4 weeks. The crude product was first washed with small amounts of dichloromethane, followed by recrystallization from acetonitrile [solubility of **10** *ca* 1 mg (1 cm^3 of acetonitrile)$^{-1}$]. M.p. 253–255°C.

Analysis: $(C_7H_7OP)_n$ (552.42 for $n = 4$). Found: C, 59.4; H, 5.1; P, 22.4. Calc.: C, 60.9; H, 5.1; P, 22.4%.

Mass spectrum: M^+, 552; base peak 107 ($C_6H_4OMe^+$).

Preparation of 2-*methoxyphenyltetrafluorophosphorane* (**11**)

A mixture of 7.3 g (0.035 mol) of the dichlorophosphine **6** and 9.8 g (0.055 mol) of carefully dried antimony trifluoride was stirred for 3 h at 50°C. The liquid product thus formed was collected by pumping *in vacuo* (*ca* 20 mm), and was subsequently redistilled to give 4.5 g (60%) of the tetrafluorophosphorane [b.p. 84°C (15 mm)]. Elemental analysis (C, H, Cl and P) revealed that the sample contained *ca* 12% of antimony trichloride which proved unseparable by fractionation from **11**. It may be assumed that, as an alternative, AsF_3 should be the reagent to be preferred over SbF_3.

Hydrolysis of **11**: *preparation of* 2-*methoxyphenylphosphonic acid* (**12**)

A mixture of 1.5 g (0.007 mol) of **11** and 1.0 g (0.056 mol) of water was stirred for 1 h. The resulting white solid was dried *in vacuo* (1 mm) and 10 cm^3 of hot water was added. After 2 days at room temperature the product (**12**) crystallized as needles from the filtered solution (m.p. 207°C).

No NMR data were obtained because of the poor solubility of the product.

Analysis: $C_7H_9O_4P$ (188.12). Found: C, 43.5; H, 4.7; P, 16.3. Calc.: C, 44.7; H, 4.8; P, 16.5%.

Preparation of cis-*dichloro-bis*(2-*methoxyphenyldifluorophosphino*)*platinum*(II) (**13**)

To a solution of 0.722 g (0.0019 mol) of the complex, dichlorobis-(1,5-cyclooctadiene)platinum in 8 cm^3 of dichloromethane was added a solution of 0.680 g (0.0039 mol) of **8** in 2 cm^3 of dichloromethane. The mixture was stirred at room tem perature for 10 min. A white precipitate was formed which was removed by filtration and was repeatedly washed with 5-cm^3 portions of ether and pentane. The precipitate was dissolved in *ca* 30 cm^3 of dichloromethane. Subsequently, a 1:1 mixture of toluene and methylcyclohexane was added until the solution remained clear (*ca* 10 cm^3). During a period of 5 days the formation of a crystalline product was observed when a gentle stream of nitrogen was passed over the solution at room temperature. Upon further evaporation of the solid–liquid mixture, a total of 1.04 g (87%) of **13** was obtained (m.p. 221–223°C).

Analysis: $C_{14}H_{14}Cl_2F_4O_2P_2Pt$ (618.20). Found: C, 27.6; H, 2.4; P, 10.4. Calc.: C, 27.2; H, 2.3; P, 10.0%.

Preparation of cis-*dichloro-bis*(2-N,N-*dimethylaminophenyldifluorophosphine*)*platinum*(II) (**14**)

As described in the preceding experiment 0.680 g (0.0018 mol) of dichloro-(1,5-cyclooctadiene) platinum was dissolved in 5 cm^3 of dichloromethane. To this solution a solution of 0.690 g (0.0037 mol) of the fluorophosphine **7** in 4 cm^3 of dichloromethane was added. The solid product formed after 15 min of stirring at room temperature was collected and washed with *ca* 10 cm^3 of pentane. A total of 1.13 g (96%) of complex **13** (m.p. 185–187°C) was obtained.

Analysis: $C_{16}H_{20}Cl_2F_4N_2P_2Pt$ (644.28). Found: C, 29.6; H, 3.3; P, 9.9. Calc.: C, 29.8; H, 3.1; P, 9.6%.

X-ray analysis

Crystals of **13** obtained by recrystallization from CH_2Cl_2–toluene–methylcyclohexane have triclinic symmetry, space group $P\bar{1}$. The unit cell which has the parameters $a = 765.1(2)$, $b = 1037.0(2)$, $c = 1242.5(2)$ pm, $\alpha = 93.32(3)$, $\beta = 92.67(3)$, $\gamma = 104.02(2)°$ contains two molecules, yielding a calculated density of 2.154 g cm^{-3}.

Crystals of **10** obtained by recrystallization from CH_3CN have monoclinic symmetry, space group $P2_1/n$. The unit cell which has the parameters $a = 1192.27(11)$, $b = 1517.16(13)$, $c = 1541.74(16)$ pm, $\beta = 100.303(13)°$ contains four molecules, yielding a calculated density of 1.337 g cm^{-3}.

The data were collected at room temperature on a Syntex $P2_1$ diffractometer using graphite-monochromated Cu-K_α radiation ($\lambda = 154.178$ pm) in the θ–2θ mode in the range $3° \leqslant 2\theta \leqslant 135$, at a scan speed between 2.93 and 29.30° min^{-1}, depending on the intensity of the reflection.

The data were corrected for Lorentz, polarization and absorption effects [$\mu = 18.47(2.675)$ mm^{-1}].* The structures were solved by direct methods and difference-Fourier syntheses. The refinement using 3070 (3389) out of 3411 (4247) measured independent reflections [$I \geqslant 2.0\sigma(I)$] converged at $R = 0.075$ (0.049). A final difference map displayed no electron density higher than 0.36 (0.98) $\times 10^6$ e pm^{-3}. The program SHELX-76[37] and our own programs were used. Complex atom-scattering factors[43] were employed.†

SYNTHESIS AND PROPERTIES OF TETRAGONAL SILVER(I,III) OXIDE, AgO

P. TISSOT

Département de Chimie Minérale, Analytique et Appliquée, Université de Genève, 30, quai E. Ansermet, 1211 Genève 4, Suisse

(*Received* 26 *September* 1986; *accepted* 10 *November* 1986)

Abstract—The pure tetragonal AgO modification was obtained by ozonation of a suspension of Ag_2O or Ag in stirred water. The oxidation proceeds in two steps from Ag, with the intermediary formation of Ag_2O. An oxygen content corresponding to the formula $AgO_{1.15}$ is obtained when the bubbling of ozone is maintained for a long time. The thermal decomposition of tetragonal AgO is complex and has been studied by thermogravimetry and differential thermal analysis.

In a previous article[1] we have described the synthesis of monoclinic AgO by oxidation with ozone of a suspension of Ag or Ag_2O in an aqueous solution of sodium hydroxide. The same procedure, using a suspension of Ag or Ag_2O in pure water instead of a sodium hydroxide solution, affords an other form of AgO. The structure of this silver(I,III) oxide has been determined by neutron powder diffraction;[2] all reflexions could be indexed on a body-centered tetragonal cell with $a = 6.833$ Å and $c = 9.122$ Å.

The existence of a second AgO modification was a matter of controversy for a long time. Early X-ray diffraction data on samples which were synthesized by oxidation of Ag by ozone[3] were interpreted in terms of a tetragonal structure built up by an unusual combination of Ag(I), Ag(II), O_2^{2-} and O^{2-} atoms.[4] Its existence was questioned by some workers[5] but confirmed by others on samples obtained by electrochemical oxidation of silver with asymmetrical current.[6–8] Its structure and properties, however, were never investigated in detail, presumably because of difficulties to obtain samples of sufficient quantity and quality.

EXPERIMENTAL

The experimental details of the synthesis and the analytical methods have been described previously.[1] As already mentioned, the only difference consists in the substitution of the 2 N sodium hydroxide solution by distilled water.

RESULTS AND DISCUSSION

Figure 1 shows the evolution of the concentration of Ag, Ag_2O and AgO as a function of time during the synthesis. From the outset of the oxidation, the tetragonal modification of AgO is formed; only traces of the monoclinic form (less than 3%) have been detected by X-ray analysis at the end of the synthesis. Figure 1 clearly demonstrates that the oxidation proceeds in two successive steps. The maximum concentration of Ag_2O reached is about 18%; this is much less than the 50% obtained in the case of the monoclinic form.[1]

After 22 h, all the silver is oxidized in AgO, but the oxygen content of the product increases slowly when the bubbling of ozone is continued; after 40 h, a maximum excess of oxygen of 10–15% with respect to the stoichiometry of AgO is reached. The thermogravimetry of the compound obtained after 40 h is shown in Fig. 2, and is compared with the monoclinic AgO. The tetragonal AgO decomposes to Ag_2O at a lower temperature than the monoclinic form. All the oxygen in excess is released during this first step, which correspond to a complex reaction as shown in Fig. 3. The DTA curves seems to correspond to the superposition of an endothermic reaction over the exothermic decomposition of AgO to Ag_2O. This endotherm could be due to the decomposition of an oxygen-rich phase, since it increases with the oxygen content; however, diffraction methods have not allowed to see an impurity phase, and this point remains to be clari-

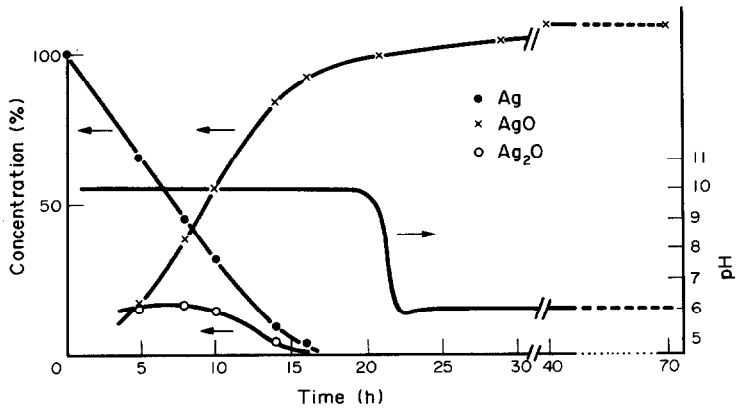

Fig. 1. Evolution of the concentrations and pH during the synthesis. Total flow (O_2+O_3), 150 l h^{-1}; flow of O_3, 2.6 g h^{-1}; temperature, 20°C; reaction mixture, 100 g of Ag in 10 l of water.

fied. The small endothermic effect at 190–200°C is due to the decomposition of Ag_2CO_3 which is formed progressively with the CO_2 contained in the air.

Figure 4 shows a scanning electron microphotograph of the tetragonal AgO; it appears as homogeneous small crystals of 1–3 μm, and is completely different from the large flakes obtained in the sodium hydroxide solution.[1] The poor stability of the tetragonal AgO in hot 7 N KOH solution is probably due to the small size of the particles.

The comparison of the structure of the two modifications of AgO shows that no single shear operation appears to exist which allow to transform one structure into the other;[2] as a matter of fact, we have not observed a transformation after 1 week at 60°C and 1 b, nor after 2 h at 25°C and 10 kb.

CONCLUSIONS

The oxidation of several silver salts in aqueous solution with ozone has been studied by Selbin and Usategui,[9] who obtained either pure monoclinic AgO or a complex compound which decomposes to monoclinic AgO in water. The oxidation by ozone of a suspension of silver in an aqueous solution of sodium hydroxide leads also to monoclinic AgO.[1] On the other hand, this work shows that pure tetragonal AgO is obtained when water is used instead of an alkaline solution. In both cases the oxidation takes place in two steps, with the intermediary formation of Ag_2O. Now this compound is amphoteric; it is slightly soluble as Ag^+ below pH = 12 and as AgO^- above pH = 12.[10] The pH of water saturated with Ag_2O is 10.1 (see Fig. 1), so that the

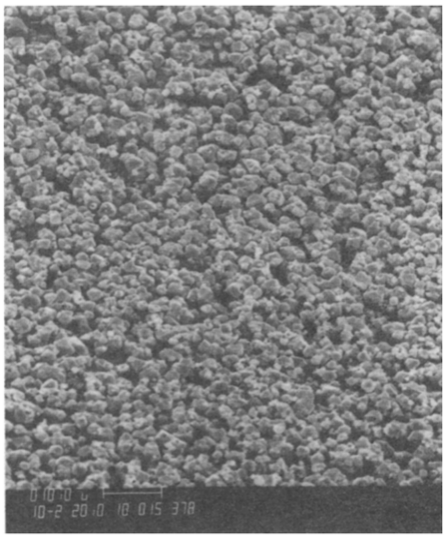

Fig. 4. Scanning electron microscope photography of tetragonal AgO.

main species present in these conditions is Ag^+. Though the mechanism of formation of both modifications of AgO is not known, the two following equations can be written:

$$Ag^+ \xrightarrow{O_3} \text{tetragonal AgO},$$

$$AgO^- \xrightarrow{O_3} \text{monoclinic AgO}.$$

From the low concentration of Ag_2O (Fig. 1) one can deduce that the first reaction is faster than the second.

DIALKYL SULFOXIDES COMPLEXES WITH NICKEL(II) NITRATE AND PERCHLORATE

DENISE DE OLIVEIRA and VIKTORIA K. LAKATOS OSORIO*

Instituto de Química, Universidade de São Paulo, Caixa Postal 20.780, São Paulo, Brasil

(*Received* 12 *August* 1986; *accepted after revision* 10 *November* 1986)

Abstract—Nickel(II) perchlorate and nitrate complexes containing dimethyl, di-*n*-propyl, di-*n*-butyl, di-*i*-butyl and di-*t*-butyl sulfoxides have been synthesized and characterized by IR and electronic spectroscopies, magnetic-susceptibility and electrolytic-conductance measurements. In the complexes containing perchlorate, the metal : sulfoxide molar ratio is 1 : 6 and the perchlorate groups are ionic. In the nitrate compounds, the molar ratio decreases from 1 : 6 to 1 : 2 according to the increase in the steric bulk of the alkyl group from methyl to *t*-butyl. The nitrate group may either be non-coordinating or behave as a monodentate or bidentate ligand. All the complexes contain O-bonded sulfoxide molecules and are characterized as high-spin, with an octahedral or distorted octahedral geometry. The dialkyl sulfoxides studied in this work fall in the same position as dimethyl sulfoxide in the spectrochemical and nephelauxetic series. Electrolytic conductivities suggest that the compounds containing ionic nitrate exhibit sulfoxide–nitrate exchange in nitromethane solutions.

Reports of nickel(II) dimethyl sulfoxide (Me_2SO) complexes are extremely numerous.[1] Little attention, however, has been focused in nickel(II) coordination by dialkyl sulfoxides different from Me_2SO. Currier and Weber[2] have synthesized complexes of type $[NiL_6](ClO_4)_2$, where L = di-*n*-propyl or di-*n*-butyl sulfoxide, while Kolosnitsyn *et al.*[3] have obtained the compounds $Ni(NO_3)_2 \cdot xL$, where L = di-*n*-hexyl sulfoxide and $x = 2$ or 4.

This paper deals with nickel(II) nitrate complexes of the sulfoxides R_2SO, where R = methyl, *n*-propyl, *n*-butyl, *i*-butyl or *t*-butyl. These sulfoxides were selected for study owing to their different basicities and stereochemistries. A nickel(II) perchlorate complex of *i*-Bu_2SO was obtained for the first time and the corresponding compounds with *n*-Pr_2SO and *n*-Bu_2SO, described by Currier and Weber,[2] were prepared in order to determine the ligand field spectroscopic parameters.

EXPERIMENTAL

Chemicals

Me_2SO (Carlo Erba) was dried over 4 Å molecular sieves. Me_2SO-d_6 (Aldrich, isotopic purity 99.5%), *n*-Pr_2SO and *n*-Bu_2SO (K & K Laboratories) were used as such. *t*-Bu_2SO was prepared by oxidation of the corresponding sulfide with H_2O_2 in methanol,[4] the reaction time being 15 h.

The hydrated nickel nitrate was obtained from Merck and nickel perchlorate was prepared from the metal carbonate (Carlo Erba) and perchloric acid.

Nitromethane and diethyl ether were purified by conventional procedures.

Preparation of the complexes

All the complexes were prepared by dissolving the hydrated nickel salt in triethylorthoformate (molar ratio 1 : 10 or more) and adding the sulfoxide in slight excess (neat when liquid or dissolved in a minimum amount of triethylorthoformate and ethanol when solid). The nickel perchlorate complexes with Me_2SO and *n*-Pr_2SO precipitated at room temperature. In the other cases, crystallization was achieved by adding anhydrous diethyl ether and cooling off or by concentrating the solution in a rotatory evaporator, adding anhydrous ether and cooling. The solid obtained after a few days was collected, washed with anhydrous ether and dried at room temperature over silica gel and paraffin, until constant weight. Typical yields ranged from 70 to 90%.

* Author to whom correspondence should be addressed.

Analysis

The Ni content was estimated by titration with EDTA.[5] Analyses for C and H were carried out by the Microanalytical laboratory at this Institute.

Instrumentation

The IR spectra were recorded with a Perkin–Elmer model 180 spectrophotometer, using Nujol mulls of all the solid compounds, films of the liquid ligands between KBr and polyethylene plates and Fluorolube mulls of the nitrate complexes between NaCl plates. The electronic spectra were obtained as described in an earlier paper.[6]

The magnetic-susceptibility measurements (solid samples) were carried out at room temperature, $25 \pm 5°C$, by Gouy's method.

Conductance measurements were carried out on 10^{-3} M solutions of the complexes in nitromethane, at $25.0 \pm 0.5°C$, with a bridge composed of a resistance box No. 4760 and an A.C. galvanometer No. 2370, both from Leeds and Northrup Co., and a conventional cell calibrated with aqueous KCl solution.

The compounds were handled in a dry box, owing to their hygroscopic nature.

RESULTS AND DISCUSSION

Perchlorate compounds

As can be seen from Table 1, the metal–sulfoxide molar ratio is 1:6 for these compounds. The IR spectral features associated with the perchlorate group (unsplitted bands at 620 and 1090 cm^{-1}) as well as the electrolytic-conductance data in nitromethane solutions (Table 1) are indicative of the ionic nature of the complexed nickel–perchlorate bond. The lower frequencies of ν_{SO} (Table 2) relative to the corresponding free sulfoxide indicate the coordination of sulfinyl group to Ni(II) ion by the oxygen atom. The observed magnetic moments and electronic spectra (Table 2) are typical of Ni(II) compounds in high-spin octahedral stereochemistries. The ligand field parameters (Table 2) were calculated[8] from the σ_2-band (at about 13,000 cm^{-1}) and the σ_3-band (at about 24,000 cm^{-1}). The σ_1-band, which gives directly the $10Dq$ value, was hampered by ligand overtones. In spite of the different basicities and stereochemical requirements of the sulfoxides investigated, they are placed at about the same position in the spectrochemical and nephelauxetic series. During the synthesis of the complexes, however, sterical hindrance plays an important role. The general procedure described in Experimental gave products with *n*-Bu_2SO/Ni and *i*-Bu_2SO/Ni ratios of about 5.5. Only after recrystallization in the presence of a 10-fold excess of R_2SO (Table 1) could the hexakis(sulfoxide)nickel complexes be obtained. In the case of Me_2SO and *n*-Pr_2SO, the use of a slight excess of R_2SO (5–15%) in the synthesis was enough to produce directly the stoichiometric 1:6 complexes. Moreover, all the attempts to obtain nickel perchlorate complexes with the bulkier di-*i*-propyl, di-*s*-butyl and di-*t*-butyl sulfoxides were unsuccessful.

Fredrick and Johnson[9] reported perchlorate compounds with Me_2SO/metal ratios > 6, which they attributed to the incorporation of additional quantities of Me_2SO and $HClO_4$. We did not observe such incorporation even by intentionally adding $HClO_4$ to the reaction medium. We could neither obtain an adduct between Me_2SO and $HClO_4$. The protonated Me_2SO cation, $[(Me_2SO)_2H]^+$, is known[10–12] to form compounds with anions such as $[AuCl_4]^-$, $[RhCl_4(Me_2SO)_2]^-$ and $[ClHCl]^-$, but none with ClO_4^-. However, excess of Me_2SO can be held, as solvation molecules, in complexes. In fact, the compound $Ni(ClO_4)_2 \cdot 8Me_2SO$ has been known since 1960,[13] the same year of the publication of Cotton's systematic study of Me_2SO complexes,[14] reporting the compound $Ni(ClO_4)_2 \cdot 6Me_2SO$. By heating the 1 : 8 compound *in vacuo*, at 50°C, the 1 : 6 complex can be obtained.[15]

Nitrate compounds

In the case of these compounds, a variety of stoichiometries were observed (Table 1) as a result of the competitive ligand abilities of the neutral sulfoxide molecules and the nitrate ions. In some instances, products with no integer R_2SO/Ni ratios were obtained and recrystallization was necessary in order to obtain compounds of definite composition.

The decreasing of the steric bulk of the alkyl radical from t-Bu_2SO to Me_2SO promotes an increase of the Ni : R_2SO molar ratio from 1 : 2 to 1 : 6.

Complexes with Ni : Me_2SO ratios of 1 : 8[13,15] and 1 : 4[16] have already been synthesized, as well as the compounds with 1 : 6[17] and 1 : 3[15,18] ratios, which were obtained by decomposition of the 1 : 8 compound, *in vacuo*, instead of by a direct crystallization as reported here.

The results of magnetic measurements and electronic spectra (Table 3) indicate that octahedral symmetry is closely approximated in all the compounds. IR spectral data (Table 3) show that the sulfoxide molecules are O-bonded to the Ni(II) ion. The NO_3 bands are not easily assigned, since IR spectra of these complexes are highly complicated. Table 3 shows some fundamental bands while Table 4 gives the combination bands in the 1700–1800-cm^{-1} region, useful as a criterion of the mode of coordination of the nitrate group.[19]

The nitrate complexes with Ni : sulfoxide molar ratios of 1 : 2 and 1 : 3 are non-conducting in nitromethane (Table 1) and contain bidentate nitrate and both mono- and bidentate nitrate, respectively, as evidenced by IR data (Tables 3 and 4).

The Me_2SO complex of 1 : 4 stoichiometry contains both ionic and bidentate nitrate, instead of only monodentate groups as previously suggested,[16] and can be formulated as $[Ni(Me_2SO)_4(NO_3)]NO_3$. The non-conducting nature of this compound and of $[Ni(Me_2SO)_6](NO_3)_2$ in nitromethane (Table 1) is, therefore, anomalous

and most likely arises as a result of sulfoxide–nitrate exchange. The exchange reaction can be reversed by adding Me_2SO to the solution. The molar conductances of mM solutions of both complexes in 90:10 (v/v) $MeNO_2$–Me_2SO rise to 150–160 S cm^2 mol^{-1}, falling therefore in the accepted range for 2:1 electrolytes in nitromethane.[20] Electronic spectra (Table 5) give further support for the above hypothesis. The spectrum of the nitrate complex in Me_2SO solution approaches those of the perchlorate complex in Me_2SO and $MeNO_2$ solutions, which contain the $[Ni(Me_2SO)_6]^{2+}$ species, while the nitrate complexes in $MeNO_2$ solution exhibit higher values of extinction coefficients, in accordance with the decrease in symmetry accomplished by the presence of Me_2SO and nitrate groups in the Ni(II) coordination sphere. The replacement of monodentate ligands by ionic nitrate, in solution, has already been observed with other ligands.[21,22]

CONCLUSIONS

One can conclude that the ease of formation of non-stoichiometric products in the synthesis of sulfoxide complexes is a general characteristic of the coordination chemistry of this class of ligand. This feature has been more emphasized in the literature about 4*f* metal complexes,[23,24] but it also occurs with O-bonded sulfoxide complexes with 3*d* metals. Several factors can contribute to it, e.g. the weak-

ness of the metal–ligand interaction, the competition between sulfoxide and anions or solvent molecules in the coordination sphere of the metal, the incorporation of sulfoxide as solvation molecules, the possibility of sulfoxide molecules acting as bridging ligands, or the possibility of crystallization of a mixture of complexed species. The synthetic procedure plays, therefore, an important role in obtaining well-defined compounds.

Abstract—The reactions of salicylaldehyde with a suspension of cyanoacetylhydrazine and/or malonic acid amido-hydrazide complexes in aqueous ethanolic solutions afford novel complexes. The structures of the isolated complexes have been elucidated by conventional physical and chemical measurements. The absence of the cyano group band at 2270 cm^{-1} in the IR spectra of all complexes, except those of Co(II) and Ni(II) complexes, suggests the promotion of H_2O to the cyano group (C≡N) forming amido group. Several structures have been proposed in which salicylaldehyde behaves differently toward the cyanoacetylhydrazine complexes. Also, 1-salicylhydrazo-3-imino-3-(*o*-formyl) phenoxy propionic acid hydrazide is synthesized either by extraction from the isolated solid complexes using disodium ethylene-diaminetetraacetate or during refluxing of Co(II) and/or Fe(II) complexes with salicylaldehyde. This novel compound is confirmed by elemental analysis, spectra (IR and ^1H NMR) and mass spectra.

The synthesis and characterization of some metal complexes derived from cyanoacetylhydrazine and some divalent metal ions have been reported earlier.[1] Also, the role of metal ions and salicylaldehyde on the promotion of water to the cyano group was discussed.[1–5] As a consequence of our interest in the complexes containing cyano group, we report herein some studies on cyanoacetylhydrazine and/or malonic acid amido-hydrazide complexes with salicylaldehyde in aqueous ethanolic solution. Also, the action of salicylaldehyde on the promotion process was studied. Moreover, the condensating products of salicylaldehyde with cyanoacetylhydrazine and/or malonic acid amidohydrazide complexes were isolated and elucidated. Accordingly, several structures have been proposed and discussed in which salicylaldehyde behaves differently.

EXPERIMENTAL

The starting complexes of cyanoacetylhydrazine and malonic acid amido-hydrazide are described in Ref. 1. The complexes under investigation were synthesized by refluxing a suspension of the starting complexes in aqueous ethanol solution with excess salicylaldehyde for 2 h. The reaction mixture was dissolved completely at the beginning of reflux and the new solid complexes started to precipitate at the end of the reaction. The structures of the isolated solid complexes depend on the type of starting compound, the preparation conditions and the type of metal ion present. Analytical data, together with colours and magnetic moments, are given in Table 1. Different structures of complexes were isolated according to the following procedures:

(i) The complexes with formulae $[Ni(H_2L)_2(H_2L'')]Ac_2 \cdot H_2O$ and $[Co(HL^+)_2(H_2L'')]$ (H_2L = cyanoacetylhydrazine, HL^+ = malonic acid amido-hydrazide, H_2L'' = salicylaldehyde) were isolated from the reactions of $[Ni(H_2L)_2(Ac)_2]H_2O^1$ and/or $[Co(HL)_2(H_2O)_2]H_2O^1$ with salicylaldehyde in ethanol. Salicylaldehyde

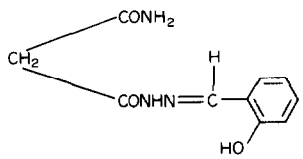
[c] In DMF.

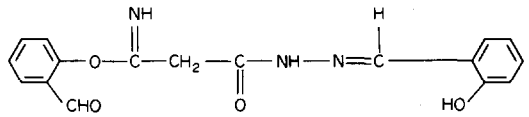
behaves as a mixed ligand towards Co(II) and Ni(II) complexes together with cyanoacetylhydrazine. Also, salicylaldehyde affords an amido group in the case of the Co(II) complex only.

(ii) The reactions of salicylaldehyde with the complexes of Zn(II), $[Zn(HL)_2(H_2O)_2]H_2O$,[1] and U(VI)O_2, $[UO_2(HL)_2]$,[1] gave complexes with formulae $[Zn(HL^*)_2]$ and $[UO_2(HL^*)_2C_2H_5OH]$ [H_2L^* = malonic acid amido-salicoylhydrazone (**1**)]. The analyses of those two complexes showed that salicylaldehyde has been condensed with the amino graoup of the hydrazide moiety together with the promotion of H_2O to the cyano-forming amido group.



1 (H_2L^*)

(iii) 1-Salicylhydrazo-3-imino-3-(*o*-formyl) phenoxy propionic acid hydrazide (**2**) was obtained from the reaction of $[Co(H_2L)_2(H_2O)_2]Cl_2$[1] and/or $[Fe(H_2L)_2(H_2O)_2]Cl_2$[1] with excess salicylaldehyde. The yellow shiny crystals (m.p. = 236°C) were isolated in a very pure state (structure **2**). The analysis and spectral measurements (IR and ^{1}H NMR) confirm structure **2**.



2 (H_2L^{**})

(iv) The Cd(II) complex, $[Cd(H_2L^{**})_4Cl_2]$, was obtained from the reaction of $[Cd(H_2L)_2)Cl_2]$[1] with excess salicyaldehyde in ethanol. On mixing $[Cd(H_2L^{**})_4Cl_2]$ with a suspension of disodium ethylenediaminetetraacetate in water, a yellow precipitate was formed on the surface of the reaction mixture. The product was filtered off and crystallized from acetonitrile. All physicochemical analyses indicate that the yellow material is similar to compound **2** synthesized by method (iii).

(v) The reaction of $[Cu(H_2L^+)Cl]$ (H_2L^+ = malonic acid amido-hydrazide) with salicylaldehyde gave a new solid complex with formula $[Cu(H_2L^*)H_2O]Cl$ in which the coordinated ligand (H_2L^*) is similar to those obtained from method(II) but differs in its mode of complexation. On the other hand, the complex with formula $[Cu_2(L^*)H_2O\cdot\frac{1}{2}C_2H_5OH]Br_2$ was obtained from

the reaction of $[Cu(H_2L)Br]$[1] with excess salicylaldehyde. The reaction of the Cu(I) chloride and bromide complexes with salicylaldehyde is followed by oxidation to Cu(II). The existence of Cu(II) is confirmed from the values of magnetic moments and the appearance of a *d–d* transition band.

All the isolated solid complexes were filtered hot, washed several times with hot ethanol, and dried in a vacuum desiccator over anhydrous calcium chloride.

Physical measurements

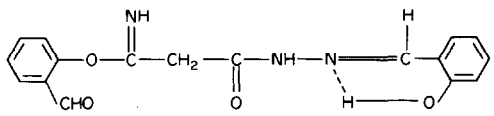
The preparative techniques of the starting compounds as well as the instruments used in this study were identical to our previous work.[1]

RESULTS AND DISCUSSION

The new solids prepared in this study are shown in Table 1. The complexes are microcrystalline or powder-like, and stable in atmospheric conditions. They are insoluble in common organic solvents but quite soluble in DMF and DMSO. The molar conductivities of the complexes in DMF at 25°C are in the 1–20 Ω^{-1} cm^2 mol^{-1} range, indicating a non-electrolytic nature[6] for all complexes except $[Cu(HL^*)H_2O]Cl$ and $[Cu_2L^*H_2O \cdot \frac{1}{2}C_2H_5OH]Br_2$, which have values of 35 and 90 Ω^{-1} cm^2 mol^{-1}, suggesting 1 : 1 and 1 : 2 electrolytes,[6] respectively.

1-Salicylhydrazo-3-imino-3-(*o*-formyl) phenoxy propionic acid hydrazide (structure **2**, H_2L^{**}, m.p. = 236°C) has not been reported before. This novel compound was synthesized during the attempt to prepare the hydrazone complexes of $[Co(H_2L)_2(H_2O)_2]Cl_2$[1] or $[Fe(H_2L)_2(H_2O)_2]Cl_2$[1] with salicylaldehyde. Also, compound **2** was obtained by warming the Cd(II) complex $[Cd(H_2L^{**})_4Cl_2]$ with a suspension of disodium ethylenediaminetetraacetate in water. The solution became yellow and a yellow precipitate appeared on the surface of the reaction mixture. The yellow compound was filtered off, washed with hot ethanol, crystallized from acetonitrile and preserved in a vacuum desiccator over anhydrous $CaCl_2$. The products (compound **2**) from both methods are identical and have the same melting point (236°C) and IR spectra.

The IR spectrum of compound **2** shows characteristic bands at 1615, 1580 and 1320 cm^{-1} assignable to the azomethine (C=N) of imidate[7] and hydrazone, and C—O—C moieties,[8,9] respectively. The observation of a broad band centred at 3440 cm^{-1} indicates the existence of the OH of salicylaldehyde group. Also, the broadness of this band suggests the presence of a hydrogen bond between the azomethine nitrogen of the hydrazone and the OH groups (structure **3**). Moreover, the two strong bands at 1710 and 1685 cm^{-1} were assigned to the carbonyl oxygen of the hydrazide and salicylaldehyde groups, respectively. Those two bands are strong enough to suggest that the carbonyl groups are free from hydrogen bonding (structure **3**).



3

The ligand H_2L^{**} contains several coordination sites but the IR spectrum of the Cd(II) complex indicates that the ligand behaves as a monodentate via the carbonyl oxygen of the hydrazide moiety. Undoubtedly the negative shift (20 cm^{-1}) of the carbonyl group of the hydrazide moiety indicates the participation of this group in bonding. All of the other bands remain more or less unchanged. The presence of only one band at 330 cm^{-1}, due to Cd—Cl,[10] suggests that the two chloride ions are *trans* to each other.

The IR spectra of the Co(II), $[Co(HL^*)_2(H_2L'')]$, and Ni(II), $[Ni(H_2L)_2(H_2L'')]Ac_2 \cdot H_2O$, complexes show that both the carbonyl and the OH groups of salicylaldehyde are coordinated to the metal ion beside the bidentate nature of H_2L and HL^+ in the Co(II) and Ni(II) complexes as reported in Ref. 1. The appearance of new bands at 1720, 1240 and 1155 cm^{-1}, attributable to ν(C=O), ν(C—O)[11] and δ(OH)[11] vibrations, respectively, can be taken as evidence for the participation of salicylaldehyde in bonding. The existence of the OH (phenolic) was checked qualitatively using fresh $FeCl_3$ solution which gives a brown colouration. Salicylaldehyde replaces two water molecules in the original Co(II) complex,[1] but it replaces two acetate ions in the Ni(II) complex.[1]

The stereochemistries of those two complexes, $[Co(HL^+)_2(H_2L'')]$ and $[Ni(H_2L)_2(H_2L'')]Ac_2 \cdot H_2O$, are identical to the original complexes which were prepared from them[1] but different from each other. The differences between the two structures are that the Ni(II) complex exists in the keto form and the Co(II) complex in the enol form. Also, the former shows the cyano group which has disappeared in the latter.

The electronic spectrum of the Co(II) complex $[Co(HL^+)_2(H_2L'')]$ in Nujol mulls shows two bands at 18,900 and 16,900 cm^{-1}, assigned to $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ and $^4T_{1g} \rightarrow {}^4A_{2g}$, suggesting an octahedral structure around the cobalt ion.[12] The magnetic-moment value (3.27 BM) is lower than those

reported for the octahedral structure but similar to $[Co(PBI)_2]I_2$[13,14] [PBI = pyridine-2,6-dialdehyde bis(benzylimine)] which is reported as an octahedral structure with an anomalous magnetic moment (3.72 BM). The spectrum of the Ni(II) complex $[Ni(H_2L)_2(H_2L'')]Ac_2 \cdot H_2O$ in Nujol mulls shows two bands at 26,300 and 18,500 cm^{-1}, assigned to $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$, respectively, in an octahedral symmetry.[15] Also, the band at 20,800 cm^{-1} may be assigned to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition in a square planar geometry.[12] The anomalous magnetic moment (2.12 BM) is also reported for Ni(II) complexes with a mixed stereochemistry.[16,17]

The reaction of salicylaldehyde with the Zn(II) and U(VI)O_2 complexes, $[Zn(HL)_2(H_2O)_2]H_2O$[1] and $[UO_2(HL)_2]$[1], affords new complexes with formulae $[Zn(HL^*)_2]$ and $[(UO_2(HL^*)_2]C_2H_5OH$, respectively, with promotion of water to the cyano group, forming an amido group. Also salicylaldehyde condensed to the NH_2 hydrazide group forming hydrazone. The condensation product (H_2L^*) coordinates to the Zn(II) and U(VI)O_2 ions in a tridentate manner via the azomethine nitrogen, the carbonyl oxygen of the amide group and the enolized carbonyl oxygen of the hydrazide moiety with displacement of a proton from the latter group.

The IR spectra of those two complexes are identical and show no bands at 2270 cm^{-1}, indicating the promotion of water to the cyano group. The new bands at 1710 and 1615 cm^{-1} were assigned to the ν(CO) and $\beta(NH_2)$ vibrations of the amide group formed from the promotion of water to the cyano group. Also, the existence of a broad band centred at 3480 cm^{-1} due to the ν(OH) vibration of salicylaldehyde may indicate the presence of hydrogen-bonded structure between the azomethine of the hydrazone and the OH groups. Moreover, the new bands at 1445, 1410 and 1240 cm^{-1} are assigned to ν_{as}(C—O),[18] ν_s(C—O)[18] and δ(OH) vibrations, respectively.

The band at 930 cm^{-1} assigned to the asymmetric stretching frequency (ν_3) of the dioxouranium ion[19] in the U(VI)O_2 complex before condensation, $[UO_2(HL)_2]$, is shifted to a lower wavenumber (900 cm^{-1}) after condensation, $[UO_2(HL^*)_2]C_2H_5OH$, with salicylaldehyde. The negative shifts (30 cm^{-1}) may suggest the participation of a third coordination site in the bonding in the latter case and coordination via N, O and O instead of N and O before condensation. Also, it suggests the formation of coordination number 8 around the uranium in the case of $[UO_2(HL^*)_2]C_2H_5OH$ but 6 in the case of $[UO_2(HL)_2]$.

The ^{1}H NMR spectrum of the U(VI)O_2 complex $[UO_2(HL^*)_2]C_2H_5OH$ shows signals at δ 10.25, 9.35, 8.65 and 3.4 ppm (downfield of TMS) in d_6-DMSO at room temperature (25°C). These signals are assigned to the protons of OH (phenolic), NH, CH and OH (ethanolic), respectively. Also, the existence of ethanol is confirmed by the observation of the characteristic ethyl resonances.

Finally, the reaction of salicylaldehyde with the diamagnetic Cu(I) complexes, $[Cu(H_2L')Cl]$[1] and $[Cu(H_2L')Br]$, affords new complexes in which Cu(I) is oxidized to Cu(II), and at the same time the condensation of salicylaldehyde on the amino group of the hydrazide group occurs.

The IR spectrum of the Cu(II) complex $[Cu(HL^*)H_2O]Cl$ suggests that HL* coordinates in a tridentate manner via OH (phenolic), azomethine nitrogen (C=N) and the enolized carbonyl oxygen with displacement of a hydrogen atom from the latter group. The observation of a very strong broad band centred at 3350 cm^{-1} suggests the existence of strong hydrogen bonding, probably between the coordinated water and the carbonyl oxygen of the amide and/or the OH phenolic. The bands at 1540, 1460, 1445, 1290, 710, 550, 470 and 340 cm^{-1} are assigned to ν(C=N), ν_{asy}(C—O), ν_s(C—O), δ(OH), ν(Cu—O)[18] (H_2O), ν(Cu—O)[11] (phenol), (Cu—O) (carbonyl) and ν(M—N),[10] respectively. The electronic spectrum in Nujol mulls shows two bands at 18,800 and 13,600 cm^{-1}, indicating a pseudo-tetrahedral geometry[20] around the Cu(II) ion. The bands at 23,800 and 21,700 cm^{-1} are assigned to d–π^* and Cl–Cu charge transfer.[21,22] The magnetic moment (1.72 BM) is in a good agreement with those reported for a d^9-configuration[23] and shows no Cu–Cu interaction. The molar-conductance value (35.0 Ω^{-1} cm^2 mol^{-1}) for the complex $[Cu(HL^*)H_2O]Cl$ in DMF at room temperature (25°C) indicates a 1 : 1 electrolyte.[6]

The electronic spectrum of the Cu(II) bromide complex $[Cu_2L^* \cdot H_2O \cdot \frac{1}{2}C_2H_5OH]Br_2$ in a Nujol mull shows two bands at 18,200 and 15,600 cm^{-1}, indicating a pseudo-tetrahedral geometry around the Cu(II) ion. The subnormal magnetic moment (0.78 BM) is accounted for by assuming the existence of a polymeric structure in the solid state and considerable interaction between the Cu(II) due to spin exchange.[23] Also, the low magnetic moment of the complexes containing the bromide ion compared with the chloride has been reported earlier.[23] Finally, the molar conductivity in DMF is 90.0 Ω^{-1} cm^2 mol^{-1}, suggesting a 1 : 2 electrolyte.[6]

CHEMISTRY OF IRON COMPLEXES—VII. SPECTROSCOPIC (IR AND UV–VIS), MAGNETIC AND OTHER STUDIES OF IRON(II) COMPLEXES WITH BIS(TERTIARYPHOSPHINE/ARSINE OXIDES)

T. S. LOBANA* and S. S. BHATTI

Department of Chemistry, Guru Nanak Dev University, Amritsar 143005, India

(*Received* 21 *July* 1986; *accepted after revision November* 1986)

Abstract—A series of iron(II) complexes with bis(tertiaryphosphine/arsine oxides), $Ph_2E(O)(CH_2)_nE(O)Ph_2$, of general formula $[FeX_2(L–L)(H_2O)_2]\cdot mH_2O$ [X = Cl, Br or SCN; m = 0 or 1; E, n, L–L: P, 1, mdpo; P(As), 2, edpo (edao); P(As), 4, bdpo (bdao); P, 6, hdpo] have been studied using analytical, spectroscopic (IR, far-IR and UV–VIS), magnetic, TGA, conductance and molecular-weight data. All of these compounds have been assigned octahedral structures and are high-spin.

Bis(tertiaryphosphine/arsine oxides) (L–L) (**I**), $Ph_2E(O)(CH_2)_nE(O)Ph_2$ (E = P or As; n = 1, 2, 4 or 6) are known to interact with iron(III) salts forming ionic complexes, $[Fe(L–L)_2X_2][FeX_4]$ (X = Cl or Br), or neutral complexes, $[Fe(L–L)(NCS)_3]$.[1–9] In the case of iron(II), there is one paper dealing with the interaction of iron(II) iodide and iron(II) tetracarbonyl iodide with the above ligands.[10]

In this paper, the reactions of these ligands (**I**) have been extended to iron(II) chloride, bromide and isothiocyanate. In order to overcome the possibility of air oxidation of iron(II), the iron(II) salt solution was obtained from an iron(III) salt by reducing with the minimum amount of ascorbic acid in ethyl alcohol/isopropyl alcohol followed by its interaction with a suitable ligand. The complex once formed was stable and remained unaffected even when exposed to air for several hours.

EXPERIMENTAL

Ligands

The ligands were prepared by the oxidation of bis(tertiaryphosphines/arsines) using 30% H_2O_2 or $KMnO_4$ as the oxidants.[1,11]

Preparation of complexes

Iron(II) chloride solution was refluxed with a ligand solution in a 1 : 1 mole ratio for a period of 15–30 min to ensure completion of the reaction. It was then filtered and washed several times with isopropyl alcohol. Iron(II) bromide complexes were obtained similarly: the refluxing time was 2 h. The volume was reduced to nearly one-half its original volume and the solid complex separated on cooling was filtered and washed with isopropyl alcohol.

Iron(II) isothiocyanate solution [obtained from treatment of iron(II) chloride with KSCN in a 1:2 mole ratio in ethyl alcohol/isopropyl alcohol] and the ligand solution in ethyl alcohol were refluxed for about 2 h. and the volume reduced to nearly one-half its original volume. The complex was separated either on cooling or after the addition of diethyl ether. It was filtered and washed with an ethyl alcohol–diethyl ether mixture.

All the complexes were dried *in vacuo*. An inert atmosphere was maintained during synthesis.

Analytical data and spectroscopic techniques

Carbon, hydrogen and nitrogen analyses were obtained from the University College of Science, Calcutta, India. Iron was estimated by the phenanthroline method.[12] The halogens were estimated by Volhard's method. The techniques used for molar conductivities (nitrobenzene), reflectance spectra (MgO as the standard reflector), thermogravimetric analysis and magnetic-susceptibility measurements were the same as described earlier.[1–8,10] The IR and far-IR spectra of the complexes (as KBr pellets) were recorded in the

* Author to whom correspondence should be addressed.

range 4000–200 cm^{-1} with a Pye–Unicam SP-300 spectrophotometer. The molecular weights of some of the iron(II) isothiocyanate complexes (in nitrobenzene) were determined cryoscopically using a Beckmann thermometer.

RESULTS AND DISCUSSION

The analysis shows that the complexes have a metal : ligand ratio of 1 : 1 (Table 1). The colour of the complexes varies from green to red or brown. The melting or decomposition points of the complexes lie in the range 128–296°C. The complexes are soluble in many common organic solvents.

In the IR spectra of the complexes, the ν(PO) and ν(AsO) decrease on complexation by 25–67 and 38–53 cm^{-1}, respectively. Usually, ν(PO) peaks appear as two peaks while ν(AsO) appears as single peak. The low-energy shifts support coordination by both (EO) groups of the bidentate ligands.[1,7] The ν(E–C_{Phenyl}) (E = P or As) peaks remain essentially unchanged. It is interesting to note that the analogous high-spin iron(III) complexes, $[Fe(L–L)_2X_2][FeX_4]$ (X = Cl, Br, L–L = mdpo, edpo, etc.), showed downward shifts in ν(E–C_{Phenyl}) on coordination.[1,7] Further all these iron(II) halides

Table 1. Analytical data, magnetic moments and other physical data[a–k]

	Complex	Found (calc.) (%) C	H	Fe	N/X	μ_{eff} (BM)

[f] Light brown.

[g] Intense red.

[h] Maroon.

[i] Reddish brown.

[j] Yellowish brown.

[k] Molecular weights found (required) for **7**, **9**, **10** and **12** are: 534 (624), 564 (684), 737 (712) and 766 (754).

complexes show different line positions with respect to ν(EO) compared to those shown by the iron(III) halide complexes, $[Fe(L\text{–}L)_2X_2][FeX_4]$.[1,7]

In the far-IR region, the chloride complexes show medium to strong peaks in the range 355–370 cm^{-1}, while the bromide complexes show similar peaks in the range 270–285 cm^{-1}.[13–15] The presence of H_2O is shown by the elemental analysis and IR spectral bands [ν(OH) (3400–3440 cm^{-1}) and δ(HOH) (1635–1660 cm^{-1})]. The rocking mode of coordinated H_2O at 790 cm^{-1} was detected in the complexes of bdpo only.[16] Tentative assignments to ν(FeO) peaks (weak) have been made in the range 350–428 cm^{-1}.

In the thiocyanate complexes, the ν(CN) peaks (sharp and single) lie in the range 2010–2055 cm^{-1}, indicating the formation of Fe(II)–NCS instead of Fe(II)–SCN or Fe(II)–NCS–Fe(II) bonds. The S-bonded or bridged SCN groups show absorptions for ν(CN) in the 2090–2110- and 2110–2175-cm^{-1} regions, respectively.[17] It is significant to note that the analogous complexes $[Fe(NCS)_3(L\text{–}L)]$ (L–L = edpo, bdpo etc.] and $[Fe(mdpo)_2(NCS)_2](NCS)\cdot 3H_2O$ showed $\nu(C{\equiv}N)$ peaks at a somewhat higher energy [2040–2058 cm^{-1}] and the peaks were broad.[8] The bending modes, δ(NCS), occur in the range 462–492 cm^{-1} in the Fe(II) complexes. The edpo and hdpo complexes show ν(CS) peaks at 840 and 855 cm^{-1}, respectively, and this peak in other complexes has either been obscured (ligand bands) or merged with ν(AsO) peaks (835–840 cm^{-1}). The low-energy ν(Fe–NCS) bands of weak to medium intensity occur in the 245–300-cm^{-1} region.[17] The range for ν(Fe–O) in the isothiocyanate complexes is 380–385 cm^{-1}. The presence of H_2O is shown by IR and elemental analysis.

The molar conductance values (Table 1) suggest the formulation $[FeX(L\text{–}L)(H_2O)_2]^+X^-$ for the halide complexes, but, in view of considerable conductance values of isothiocyanate complexes (< than for a 1 : 1 electrolyte), it is believed that the conductance values are due to possible ionization of the complexes in the solution phase, the halide complexes registering greater values than isothiocyanate complexes [eqn (1)]:

$$[FeX_2(L\text{–}L)H_2O)_2] \rightleftharpoons [FeX(L\text{–}L)(H_2O)_2]^+X^- \quad (X = Cl, Br \text{ or } NCS). \quad (1)$$

Magnetic moments (μ_{eff}) of the complexes (5.20–5.66 BM) are characteristic of high-spin iron(II) complexes (Table 1).[18] The complex $[FeBr_2(bdao)(H_2O)_2]\cdot H_2O$, however, showed a lower value of 4.90 BM which may be attributed to the quenching of the orbital contribution, possibly due to a lower site symmetry. It may be noted that the analogous iron(III) complexes, $[Fe(NCS)_3(L\text{–}L)]$ (L–L = mdpo etc.), reported earlier showed lower μ_{eff} values (5.34–5.58 BM).[8] This lends support to the earlier observation that the FeN_3O_2 chromophores in the iron(III) complexes have a relatively larger ligand field effect due to three nitrogen atoms. The FeN_2O_4 chromophores in iron(II) complexes, however, show a normal magnetic behaviour.[17] The molecular weights of some of the isothiocyanate complexes show their monomeric nature (Table 1).

The solid-phase electronic spectra of the complexes show *d–d* and charge-transfer transitions in the range 12,000–28,000 cm^{-1} supporting octahedral structures.[17] The TGA of the complexes containing coordinated and uncoordinated H_2O molecules showed loss of H_2O in the range 100–180°C; the range was 130–170°C in the case of the complexes containing only coordinated H_2O.

PREPARATION AND CATALYTIC ACTIVITY OF CATIONIC RHODIUM(I) AND IRIDIUM(I) COMPLEXES WITH PHOSPHINE SULPHIDE LIGANDS

C. CLAVER,* F. GILI, J. VIÑAS and A. RUIZ

Departamento de Química, Facultad de Ciencias Químicas, Universidad de Barcelona, Pl. Imperial Tarraco 1, 43005 Tarragona, Spain

(*Received* 2 *October* 1986; *accepted* 17 *November* 1986)

Abstract—The preparation and properties of cationic rhodium and iridium complexes of types $[M(diolefin)L_2](ClO_4)$ and $[M(diolefin)L(PPh_3)](ClO_4)$ [M = Rh, diolefin = 1,5-cyclooctadiene (COD) or 2,5-norbornadiene; M = Ir, diolefin = COD; L = phosphine sulphide] are described. The complexes have been characterized by IR, ^1H NMR and ^{31}P NMR spectroscopy. The use of $[M(diolefin)L_2](ClO_4)$ as catalyst precursors in homogeneous hydrogenation of olefins has been studied.

Studies conducted in this laboratory have focused on the synthesis, characterization and reactivity of rhodium and iridium complexes containing S-donor ligands, thioethers and dithioethers.[1–6] In this paper synthetic details and characterization data for several rhodium(I) and iridium(I) cationic complexes with phosphine sulphide as ligands are presented. Although some related neutral and cationic rhodium and iridium complexes with phosphine sulphide have been previously reported[7] different synthetic methods to those reported here were used.

Single-crystal X-ray studies on different complexes have indicated that tertiary phosphine sulphides are moderate σ-donors with minimal π-acceptor properties.[7–9] We have studied the ability of the phosphine sulphide to displace a diolefin in $[M(diolefin)_2]^+$ complexes as well as the stability and reactivity of the isolated complexes.

In the other hand, there have been many studies of the homogeneous hydrogenation of olefins catalyzed by rhodium cationic complexes, and the catalytic activity of some iridium(I) cationic complexes is also known. $[Rh(COD)(PR_3)_2]^+$ and $[Ir(COD)(PR_3)_2]^+$ (COD = 1,5-cyclooctadiene) are active precursors in homogeneous hydrogenation of olefins.[10–13] Nevertheless, the catalytic activity of complexes with sulphur ligands has been studied to a much lesser extent. Recently Kalck *et al.* have shown that hydrogenation and hydroformylation of olefins and other substrates are catalyzed at low pressure and temperature (5 bar, 80°C) by dinuclear complexes of rhodium(I) with a thiolato ligand.[14–16] In this paper we describe the catalytic activity of some cationic complexes with phosphine sulphide in the homogeneous hydrogenation of 1-heptene.

RESULTS AND DISCUSSION

$[Rh(diolefin)L_2](ClO_4)$ *and* $[(diolefin)Rh\{\mu\text{-}(L\text{–}L)\}_2Rh(diolefin)](ClO_4)_2$ *complexes* (L *and* L–L = *phosphine sulphide*)

The addition to dichloromethane solutions of $[Rh(diolefin)_2](ClO_4)$ [diolefin = COD[17] or 2,5-norbornadiene (NBD)[18]] of a stoichiometric amount (or a slight excess) of L gives the $[Rh(diolefin)L_2](ClO_4)$ derivatives:

$$[Rh(diolefin)_2](ClO_4) + 2L \rightarrow [Rh(diolefin)L_2](ClO_4) + diolefin, \quad (1)$$

where diolefin = COD or NBD, and L = Me_3PS, Et_3PS or Ph_3PS.

When an equimolecular amount of the bidentate ligand $Me_2P(S)(S)PMe_2$ was added to dichloromethane solutions of $[Rh(diolefin)_2](ClO_4)$, the C, H and S elemental analyses of the complexes obtained correspond to the formulation $[Rh(COD)(L\text{–}L)]_n(ClO_4)_n$.

* Author to whom correspondence should be addressed.

Measurements of the equivalent conductivities of the complexes with this ligand at different concentrations in nitromethane solutions gave plots of the Onsager equation $\Lambda_e = \Lambda_o - A\sqrt{c}$, for which A values are characteristic of 2:1 electrolytes,[19] in accordance with the formation of dinuclear complexes [Rh(diolefin)Rh{μ-(L–L)}$_2$Rh(diolefin)] $(ClO_4)_2$, where the ligand is bidentate, bonding two metal atoms.[1,2]

The analytical results, conductivities values,[19,20] IR data and melting points for the complexes are listed in Table 1.

The nuclearity of the complexes [Rh(diolefin)L]$_n(ClO_4)_n$ was found to be n = 1 in the cases of L = Me_3PS, Et_3PS or Ph_3PS, according to the sulfur elemental analyses, in accordance with the behaviour of the phosphine sulphides as monodentate ligands.

The complexes are yellow and moderately air-stable solids. IR spectra show the P=S stretching frequencies to have decreased in the usual manner on coordination,[7] together with those due to the coordinated diolefins, and uncoordinated perchlorate anion (1100s and 620s cm^{-1}).[21]

The ^1H NMR data are given in Table 2. For [Rh(COD)L_2](ClO_4) (L = Me_2PS or Ph_2PS) the spectra in $CDCl_3$ show the resonances corresponding to coordinated COD and the corresponding at sulphur ligand. In the spectrum of the complex with L = Me_3PS, the signal corresponding to Me–P shows a doublet at 2.10 ppm downfield compared to the free ligand (1.79d ppm), with ^2J(P–H) = 13 Hz.

The complex [Rh(COD)$(Me_3PS)_2$](BPh_4) has been previously published by Ainscough *et al.*, but NMR data were not reported.[7]

[Rh(diolefin)L(PPh_3)](ClO_4) *complexes* (L = Me_3PS *or* Ph_3PS)

The addition of a stoichiometric amount of sulphur phosphine ligand and triphenylphosphine

Table 1. Analytical results, conductivity data, melting points and IR data for complexes [Rh(diolefin)L_2](ClO_4), [(diolefin)Rh{μ-(L–L)}$_2$Rh(diolefin)]$(ClO_4)_2$ and [Rh(diolefin)L(PPh_3)](ClO_4)

Table 2. ^{1}H NMR data [δ (ppm)] for complexes [Rh(COD)L_2](ClO_4), [Ir(COD)L_2](ClO_4) and [Ir(COD)(Me_3PS)(PPh_3)](ClO_4)

Complex[a]	COD		PPh_3	Ph_3PS	Me_3PS
	HC=CH	CH_2—C			
[Rh(COD)(Ph_3PS)$_2$](ClO_4)	5.40	3.12	—	7.80–7.20	—
[Rh(COD)(Me_3PS)$_2$](ClO_4)	4.46	2.85	—	—	2.10(d)
[Ir(COD)(Ph_3PS)$_2$](ClO_4)	4.18	2.35	—	7.80–7.20	—
[Ir(COD)(Me_3PS)$_2$](ClO_4)	4.10	3.30	—	—	1.95(d)
[Ir(COD)(Me_3PS)(PPh_3)](ClO_4)	4.22	3.30	7.80–7.30	—	1.96(d)

[a] $CDCl_3$ as solvent, T^a = 20°C, external reference TMS.

(PPh_3) to dichloromethane solutions of [Rh(diolefin)$_2$](ClO_4) (diolefin = COD or NBD)[17,18] gives derivatives of formula [M(diolefin)L(PPh_3)](ClO_4). The complexes can also be prepared by adding a stoichiometric amount of triphenylphosphine to a dichloromethane solution of [Rh(diolefin)L_2](ClO_4) (L = Me_3PS or Ph_3PS):

$$[Rh(diolefin)_2](ClO_4) + L + PPh_3 \rightarrow [Rh(diolefin)L(PPh_3)](ClO_4), \quad (2)$$

$$[Rh(diolefin)L_2](ClO_4) + PPh_3 \rightarrow [Rh(diolefin)L(PPh_3)](ClO_4), \quad (3)$$

where diolefin = COD or NBD, and L = Me_2PS or Ph_3PS.

The isolated yellow or orange complexes are air-stable. The C, H and S elemental analyses, molar conductivities in acetone, melting points and IR data are listed in Table 1. The IR spectra show bands due to the sulphur ligand and coordinated triphenylphosphine, and bands corresponding to the uncoordinated perchlorate ion.[21]

The ^{1}H NMR spectrum of [Rh(COD)(Ph_3PS)(PPh_3)](ClO_4) shows two signals corresponding to the olefinic proton CH=C resonance and two signals corresponding to the methylenic CH_2—C from the COD, together with a large signal from the aromatic protons at 7.80–7.20 ppm. These data suggest redistribution reactions in solution for [Rh(COD)(Ph_3PS)(PPh_3)](ClO_4). The ^{31}P NMR (Table 3) spectrum of $CDCl_3$ solutions of this complex shows a doublet at 26.1 ppm [^1J(Rh–P) = 147 Hz], together with two signals at 28.15 and 29.85 ppm corresponding to coordinated Ph_3PS. The doublet characteristic of square-planar rhodium(I) complexes[22] is coincident with the signal from the [Rh(COD)(PPh_3)$_2$]$^+$ complex, suggesting redistribution reactions in solution:

$$2[Rh(COD)L(PPh_3)](ClO_4) \rightleftarrows [Rh(COD)(PPh_3)_2](ClO_4) + [Rh(COD)L_2](ClO_4). \quad (4)$$

In contrast, the ^{31}P NMR spectrum of a $CDCl_3$ solution of [Rh(COD)(Me_3PS)(PPh_3)](ClO_4) shows a doublet at 29.5 ppm [^1J(Rh–P) = 147 Hz], charac-

Table 3. ^{31}P NMR data [δ (ppm)] for complexes [Ir(COD)L_2](ClO_4) and [Rh(COD)L(PPh_3)](ClO_4)

Compound[a]	Ph_3PS	PPh_3	^1J(Rh–P) (Hz)
Ph_3PS	43.4	—	—
[Rh(COD)(Ph_3PS)(PPh_3)](ClO_4)	28.15, 29.85	26.1	147
[Rh(COD)(Me_3PS)(PPh_3)](ClO_4)	39.14	29.5	147
[Ir(COD)(Ph_3PS)$_2$](ClO_4)	31.7	—	—

[a] $CDCl_3$ as solvent, T^a = 20°C, external reference H_3PO_4.

teristic of square-planar rhodium(I) complexes and a resonance at 39.14 ppm that could be attributed to coordinated Me_3PS, in accordance with the stability of the complex in solution. The ^{31}P NMR data published for the complex $[Rh(COD)(PPh_3)(Ph_3PO)](ClO_4)$ present similar resonances and $^2J(Rh–P)$ is not observed.[23]

Iridium complexes

The reaction in dichloromethane of $[Ir(COD)_2](ClO_4)$[24] with a stoichiometric amount or a slight excess of phosphine sulphide ligand (L = Me_3PS or Ph_3PS) gave derivatives whose C, H and S elemental analyses, conductivity and IR data are in accordance with the formulation $[Ir(COD)L_2](ClO_4)$:

$$[Ir(COD)_2](ClO_4)+2L \rightarrow [Ir(COD)L_2](ClO_4]+COD. \quad (5)$$

When, under the same conditions, the ligand used was $Me_2P(S)(S)PMe_2$, the equivalent conductivities measured at different concentrations in nitromethane solutions of the complex obtained, gave values of A in Onsager's equation $\Lambda_e = \Lambda_o - A\sqrt{c}$[19,20] characteristic of 2:1 electrolytes (Table 4) in accordance with eqn (6):

$$2[Ir(COD)_2](ClO_4)+2L–L \rightarrow [(COD)Ir\{\mu\text{-}(L–L)\}_2Ir(COD)](ClO_4)_2 +2COD. \quad (6)$$

As in the case of rhodium complexes the reactivity of $[Ir(COD)L_2](ClO_4)$ towards PPh_3 gives mixed complexes, $[Ir(COD)L(PPh_3)](ClO_4)$:

$$[Ir(COD)L_2](ClO_4)+PPh_3 \rightarrow [Ir(COD)L(PPh_3)](ClO_4)+L, \quad (7)$$

where L = Ph_3PS or Me_3PS.

The same reaction for the iridium complexes $[Ir(COD)L_2](ClO_4)$ (L = thioether, tetrahydrothiophen or trimethylene sulphide gave pentacoordinated iridium(I) complexes, $[Ir(COD)L_2(PPh_3)](ClO_4)$[2], and no pentacoordinated mixed complexes were obtained with phosphine sulphide ligands.

All the isolated complexes are moderately stable in the solid state but decompose in solutions exposed to air. The C, H and S elemental analyses, conductivity data and melting points of the complexes are listed in Table 4.

The ^1H NMR spectrum of $[Ir(COD)(Ph_3PS)_2](ClO_4)$ in $CDCl_3$ shows the signal at 7.80–7.20 ppm corresponding to Ph_3PS, together with several signals in the region corresponding to COD. However when excess Ph_3PS was added to the $CDCl_3$ solution, the spectrum showed only single signals characteristic of the coordinated COD at 4.18 ppm for olefinic protons, and at 2.35 ppm for methylenic protons.[25–27] The results described could be attributed to the displacement of the Ph_3PS ligand in solution (Table 2).

In order to obtain further information the ^{31}P spectrum in $CDCl_3$ was obtained, showing a major single signal at 31.7 ppm attributed to the coor-

Table 4. Analytical results, conductivity data, melting points and IR data for complexes $[Ir(COD)L_2](ClO_4)$, $[(COD)Ir\{\mu\text{-}(L–L)\}_2Ir(COD)](ClO_4)_2$ and $[Ir(COD)L(PPh_3)](ClO_4)$

Complex	Analysis: Found (Calc.) (%)			Conductivity data		M.p.[d] (°C)	IR data ν(P=S) (cm^{-1})
	C	H	S	Λ_M[a]	A[b]		
$[Ir(COD)(Ph_3PS)_2](ClO_4)$	53.1 (53.4)	4.3 (4.2)	6.1 (6.4)	148	—	96–99	586(m)
$[Ir(COD)(Me_3PS)_2](ClO_4)$	26.0 (27.3)	4.9 (4.8)	9.8 (10.4)	125	—	100–104	520(d)
$[(COD)Ir\{\mu\text{-}(L–L)\}_2Ir(COD)](ClO_4)_2$	24.5 (24.6)	4.2 (4.1)	13.0 (10.9)	225	622[d]	111–114	575(m)

[c] Decomposes.
[d] Measured in nitromethane solution.

dinated Ph_3PS and a minor single signal at 44.0 ppm corresponding to uncoordinated Ph_3PS (Table 3).

For the $[Ir(COD)(Me_3PS)_2](ClO_4)$ complex the ^1H NMR spectrum in $CDCl_3$ indicated the stability of the complex in solution, showing single signals for coordinated COD at 4.10 ppm (CH=C) and 3.30 ppm (CH_2—C), together with the signal assigned to coordinated Me_3PS at 1.95 ppm with $^2J(P–H) = 13$ Hz, characteristic of this ligand, and downfield compared to the free ligand (Table 2).

The ^1H NMR spectrum of $[Ir(COD)(Me_3PS)(PPh_3)](ClO_4)$ in $CDCl_3$ shows the signal corresponding to PPh_3 at 7.80–7.30 ppm, those due to the coordinated COD, 4.22 ppm (CH=C) and 3.30 ppm (CH_2—C), characteristic of this type of complex and a doublet signal at 1.96 ppm [$^2J(P–H) = 11$ Hz] assigned to the coordinated Me_3PS ligand, in accordance with the stability of the complex in solution (Table 2).

Catalytic activity

During recent years a number of rhodium(I) and iridium(I) complexes have proved to be effective hydrogenation catalysts for multiple carbon–carbon bonds. Osborn *et al.* have studied the catalytic activity of cationic $[M(diolefin)L_2]^+$ species (M = Rh or Ir, L = PR_3) in coordinating solvents such as ethanol, acetone or tetrahydrofuran.[10,11,28,29] On the other hand, Crabtree *et al.* have shown that dichloromethane solutions of cationic diolefin iridium(I) complexes in the presence of an olefin constitute hydrogenation catalysts of unprecedented activity for iridium(I) complexes.[12,30] Oro *et al.* have studied the catalytic activity of different cationic rhodium(I) and iridium(I) complexes, $[M(diolefin)L_2]^+$, with different donor ligands and different diolefins.[31,32] The catalytic activities of complexes with sulfur ligands have not been studied. It is known that rhodium(III) complexes containing SEt_2 are active in homogeneous hydrogenation[33,34] and Maitlis *et al.* prepared some complexes with thioethers, but, when 2,5-dimethylthiophene or tetramethylthiophene were used as ligands, the isolated complexes were of type $[Rh(diolefin)(\eta^5\text{-}L)](PF_6)$. The latter complexes are the only ones studied showing catalytic activity for hydrogenation of olefins, but they rapidly deposited rhodium metal.[35] Simultaneously with this work, the catalytic activity of the related $[M(diolefin)L_2](ClO_4)$ and $[(diolefin)M(\mu\text{-}L)_2M(diolefin)](ClO_4)_2$ complexes (L = thioether or dithioether ligand) are being studied in our laboratory.

The $[Rh(diolefin)(Ph_3PS)_2](ClO_4)$ complexes (diolefin = COD or NBD) dissolve in ethanol at 25°C under 1 atm of hydrogen to give catalytically active solutions for the hydrogenation of 1-heptene. In the same way dichloromethane solutions of $[Ir(COD)(Ph_3PS)_2](ClO_4)$ containing 1-heptene react with hydrogen at atmospheric pressure to form species which catalyze the homogeneous hydrogenation of this substrate.

The molar catalyst : 1-heptene ratio was 1 : 100 and isomerization to *cis*-2-heptene was observed in all cases. The $[Rh(COD)(Ph_3PS)_2](ClO_4)$ complexes provide higher conversion rates of 1-heptene than the $[Rh(NBD)(Ph_3PS)_2](ClO_4)$ complex, probably due to the π-acceptor character[36] of NBD in comparison with 1,5-COD (Table 5).

It is noteworthy that in this type of complex the Ir(I) complex provides higher activities than the corresponding Rh(I) complexes (Table 5 and Fig. 1). Figure 1 shows a faster initial rate for the Ir(I) compound, probably due to the rapid formation of active species in this case. The reactivity of the complexes toward molecular hydrogen was studied by bubbling H_2 through solutions of the complexes, and no reaction was found for $[Rh(diolefin)(Ph_3PS)_2](ClO_4)$ complexes (1 atm, 25°C). In contrast, the $[Ir(COD)(Ph_3PS)_2](ClO_4)$ complex reacts rapidly with molecular hydrogen under the

Table 5. Hydrogenation of 1-heptene[a]

Catalyst precursor	Reaction time (min)	% heptane	% 1-heptene	% *cis*-2-heptene	Turnover rate (min^{-1})[b]
$[Rh(COD)(Ph_3PS)_2](ClO_4)$	500	54.2	35.7	10.1	0.90
$[Rh(NBD)(Ph_3PS)_2](ClO_4)$	450	19.7	67.1	13.2	0.15
$[Ir(COD)(Ph_3PS)_2](ClO_4)$	500	68.2	26.5	5.3	7.00

[a] Reaction conditions : [1-heptene] : [Rh] = 100 : 1, pH_2 = 1 atm, T^a = 25°C, solvent = 20 cm^3.

[b] Turnover rate is defined as the ratio of the number of moles of 1-heptene converted to the number of moles of species per time unit.

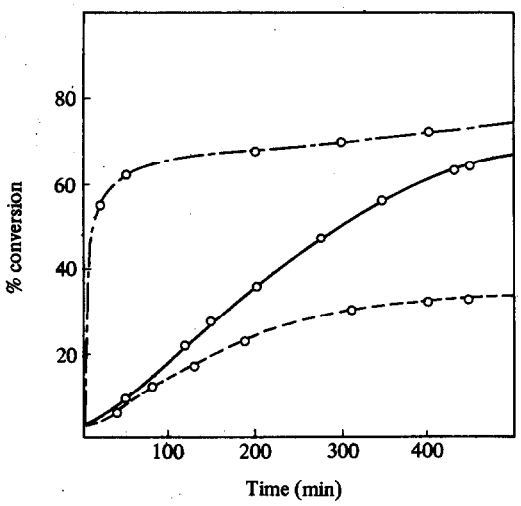

Fig. 1. Conversion of 1-heptene as function of the time catalyzed by $[Rh(COD)(Ph_3PS)_2](ClO_4)$ (O——O), $[Rh(NBD)(Ph_3PS)_2](ClO_4)$ (O---O) and $[Ir(COD)(Ph_3PS)_2](ClO_4)$ (O-·-·-O).

same conditions. The ^1H NMR spectra of $CDCl_3$ solutions show signals at -13 and -20 ppm characteristic of Ir—H protons, in accordance with the Ir(I) tendency to undergo oxidative addition.[5,12,26] This reactivity probably contributes to the easy formation of active hydride species.

EXPERIMENTAL

All preparations were carried out under a nitrogen atmosphere using Schlenk techniques. All the solvents were distilled and deoxygenated before use. The elemental analyses were carried out with a Perkin–Elmer 240 B microanalyzer. The IR spectra were recorded on a Beckman IR 4260 spectrophotometer, using Nujol mulls between polyethylene sheets. Conductivities were measured in acetone or nitromethane solutions in the concentration range *ca* 1×10^{-4}–5×10^{-4} M, with a Radiometer CDM 3 conductimeter. Values of A were determined from Onsager's equation $\Lambda_c = \Lambda_o - A\sqrt{c}$, using several concentrations in nitromethane solutions in the 10^{-3}–10^{-5} M range. The ^1H NMR and ^{31}P NMR spectra were measured on an XL-200 Varian spectrometer using $CDCl_3$ as solvent, and $SiMe_4$ and H_3PO_4 as references. Melting points were determined with a Buchi 510 Melting Point apparatus. The starting materials were prepared as previously reported.[17,18,24] $RhCl_3\cdot xH_2O$ was obtained from Johnson Matthey and phosphine sulphide ligands were purchased from Maybridge Co.

Catalytic activity experiments were performed in a conventional hydrogenation apparatus. The order of introduction of reactants into the hydrogenation flask was: 0.03 mmol of the catalyst precursor, 3 mmol of the substrate in 15 cm^3 of ethanol or dichloromethane, freshly distilled and dried, and finally hydrogen. The mixture was stirred in a thermostat bath at 25°C. The hydrogenation rate were determined by analyzing the products with a Hewlett–Packard 5840 A chromatograph. The peak areas were obtained with a Hewlett–Packard 5840A GC computing integrator.

Preparation of $[Rh(diolefin)L_2](ClO_4)$ (L = Ph_3PS, Me_3PS *or* Et_3PS) *and* $[(diolefin)Rh\{\mu\text{-}(L\text{–}L)\}_2Rh(diolefin)](ClO_4)_2$ [L–L = $Me_2P(S)(S)PMe_2$]

Upon addition of slightly more than the stoichiometric amount of ligand (0.18 mmol L, 0.09 mmol L–L) to dichloromethane solutions of $[Rh(COD)_2](ClO_4)$ or $[Rh(NBD)_2](ClO_4)$ (0.08 mmol) an immediate reaction was observed. The resulting complexes were precipitated by adding ether, and were filtered off, washed with ether and vacuum dried. Yields 85–90%.

Preparation of $[Ir(COD)L_2](ClO_4)$ (L = Ph_3PS *or* Me_3PS) *and* $[(COD)Ir\{\mu\text{-}(L\text{–}L)\}_2Ir(COD)](ClO_4)_2$ [L–L = $Me_2P(S)(S)PMe_2$]

The phosphine sulphide ligand (0.15 mmol L, 0.075 mmol L–L) was added to a dichloromethane solution of $[Ir(COD)_2](ClO_4)$ (0.07 mmol) and an immediate reaction was observed. Subsequent addition of ether precipitated out the complexes, which were filtered off, washed with cold ether, and vacuum dried. Yields 70–75%.

Preparation of $[M(diolefin)L(PPh_3)](ClO_4)$ *complexes* (M = Rh, diolefin = COD *or* NBD; M = Ir, diolefin = COD; L = Ph_3PS *or* Me_3PS)

The compounds were prepared by two routes as described below:

(i) The addition of a slight excess of ligand (0.065 mmol L) and a stoichiometric amount of PPh_3 (0.06 mmol) to dichloromethane solutions of $[M(diolefin)_2](ClO_4)$ (0.06 mmol) produced an immediate reaction. The resulting complex was precipitated out by adding ether and then filtered off, washed with ether, and vacuum dried. Yields *ca* 80%.

(ii) The addition of a stoichiometric amount of PPh_3 (0.06 mmol) to dichloromethane solutions of $[M(diolefin)L_2](ClO_4)$, previously prepared, produced an immediate reaction. The resulting complexes were precipitated by adding ether, and were filtered off, washed with ether, and vacuum dried. Yields 70–80%.

Chemistry Department, University of Sarajevo, Sarajevo, Yugoslavia

(*Received* 21 *October* 1986; *accepted* 17 *November* 1986)

Abstract—The composition of the solvent cage of chloropentaamminechromium(III) ion was determined in water–dimethyl sulfoxide media using proton NMR line-broadening methods and the approach of Covington and coworkers. The number of solvent molecules in the solvent cage was found to be 10. The stepwise formation constants for the substitution of 10 water molecules by 10 dimethylsulfoxide molecules in this solvent cage were calculated. After the first such substitution each successive substitution becomes 1027 J mol^{-1} more difficult, exclusive of statistical factors, than the preceding substitution. The solvent cage composition was assumed to apply to the chloropentaamminecobalt(III) ion. Mercury(II)-assisted removal of chloride ion from the latter complex gave $[Co(NH_3)_5\{OSMe_2\}]^{3+}$/$[Co(NH_3)_5(H_2O)]^{3+}$ product ratios which did not correlate with either the solvent cage composition or the activity ratio of the two solvent components in the bulk phase of the solvent.

The solvent cage of a metal complex ML_p which has a well-defined first coordination shell of ligands L occupying p coordination sites, may be thought of as a more labile and less well-ordered second coordination shell around the ion. The number, n_o, of solvent molecules in, and the composition of, the solvent cage in binary solvent mixtures is known for a few complexes but this information is important in the interpretation of the properties and reactions of the complexes. The Covington[1] theory provides a means of determining n_o and the composition by treating the solvent cage as a coordination shell in which substitution of one solvent by a second occurs in a stepwise manner, as shown in reaction (1), with a stepwise formation constant given by eqn (2):

$$ML_p \cdot W_{n_o-i+1}D_{i-1} + D \overset{K_{iD}}{\rightleftharpoons} ML_p \cdot W_{n_o-i}D_i + W, \quad (1)$$

$$K_{iD} = \frac{[ML_p \cdot W_{n_o-i}D_i]a_W}{[ML_p \cdot W_{n_o-i+1}D_{i-1}]a_D}. \quad (2)$$

Reynolds *et al.*[2,3] have applied this theory to proton magnetic resonance line broadenings measured in water–dimethyl sulfoxide solutions of $[Cr(NH_3)_5\{OSMe_2\}]^{3+}$ and $[Cr(NH_3)_5(H_2O)]^{3+}$. For the former complex ion $n_o = 10$ and for the latter $n_o = 12$. Values of the stepwise constants for both complexes were also reported. The compositions of the solvent cages were quantiatively and simply related to the first-order rate constants

* Author to whom correspondence should be addressed.

for solvent interchange in reaction (3):

$$[Co(NH_3)_5(H_2O)]^{3+} + OSMe_2 \underset{k_w}{\overset{k_s}{\rightleftharpoons}} [Co(NH_3)_5\{OSMe_2\}]^{3+} + H_2O. \quad (3)$$

Frankel *et al.*[4] had previously shown that Cr(III) and Co(III) complexes with like first coordination shells had like solvent cages within experimental error.

Langford and coworkers[5-10] have determined compositions of solvent cages of a number of Cr(III) and Co(III) complexes by NMR techniques and found that frequently the solvent cages were considerably richer in one solvent component than was the solution as a whole. The term "preferential solvation" has been used in the literature to describe this situation; if no "preferential solvation" occurred the fraction of the solvent cage sites occupied by a solvent component would be the same as the mole fraction X_s of that component in the solution as a whole. It would be more accurate when ascertaining whether a solvent is preferentially solvating a complex to compare the ratio n_1/n_2, where n_1 is the number of solvent cages sites around a complex occupied by component 1 and n_2 is the number of these sites occupied by component 2, with the ratio a_1/a_2 of the activities of the two solvent components. When there are large deviations from Raoult's law it may be that:

$$\frac{a_1}{a_2} > \frac{n_1}{n_2} > \frac{X_1}{X_2}$$

or that

$$\frac{a_1}{a_2} < \frac{n_1}{n_2} < \frac{X_1}{X_2}.$$

In the former case the solvent cage is richer in component 1 than is the solution as a whole but not as rich as it should be given the high activity of 1 relative to 2; in this case it is incorrect to regard the complex as preferentially selecting component 1 to occupy solvent cage sites. In the second case the solvent cage is richer in component 2 than is the solution as a whole but not as rich as it should be given the high activity of 2 relative to 1; again it is incorrect to regard the complex as preferentially selecting component 2 for solvent cage sites. However there is frequently a lack of quantitative data concerning the activities of components in solvent mixtures and the only comparison which can be made is of n_1/n_2 with respect to X_1/X_2.

The water (W)–dimethyl sulfoxide (D) mixture exhibits very non-ideal behaviour. At $X_D \leqslant 0.3$ the activities, a_D, of dimethyl sulfoxide show large negative deviations from ideal behavior and $a_D/a_W < X_D/X_W$ but $n_D/n_W > X_D/X_W$ for the solvent cages of aquo- and (dimethyl sulfoxide)pentaamminechromium(III) ions. Also the mole ratio (n_D/n_W) remained greater than the activity ratio (a_D/a_W) up to $X_D = 0.9$. The complexes preferred dimethyl sulfoxide in the solvent cage and, in effect, extracted dimethyl sulfoxide from its low activity state in the bulk solvent phase into the solvent cage. This result is consistent with the view that a complex ion has a second coordination shell in which one ligand (dimethyl sulfoxide) can replace another ligand (water).

Here we report on the solvation number and the solvent cage composition of $Cr(NH_3)_5Cl^{2+}$ in water–dimethyl sulfoxide solvents and compare the results with the ratio of the products formed from the Hg^{2+}-assisted removal of Cl^- from $Co(NH_3)_5Cl^{2+}$ in the same media.

EXPERIMENTAL

Chemicals

Aquo-,[11] (dimethyl sulfoxide)-[12] and chloropentaamminecobalt(III)[13] perchlorates were prepared by literature methods. Chloro- and bromopentaamminechromium(III) dihalides were synthesized from $[Cr(NH_3)_5(OH_2)](NO_3)_3 \cdot NH_4NO_3$ by the method of Zinato *et al.*[14] The dihalides were converted to the perchlorates by precipitation from aqueous solution with concentrated $HClO_4$. All the other chemicals were reagent grade and were used as supplied.

Solvent cage studies

These studies were made as described in detail[3] previously only $[Cr(NH_3)_5Cl](ClO_4)_2$ and $[Cr(NH_3)_5Br](ClO_4)_2$ were used in place of the corresponding aquo and dimethyl sulfoxide complexes. Line widths were obtained by magnifying the lines many times on a screen and then measuring the screen image with a millimeter scale.

The viscosities of the solvent mixtures at 40°C were used to correct the measured line broadenings as previously described.[3] The viscosity-corrected increases in line width were then used to calculate the ratio n_i/n_o for solvent i from eqn (4):

$$\frac{n_i}{n_o} = \frac{\Delta\nu_i}{\Delta\nu_{oi}} \times \frac{N_i}{N_{oi}}. \quad (4)$$

In eqn (4) n_i is the number of molecules of solvent i in a total of n_o solvent molecules in a solvent cage, N_i and N_{oi} are the total number of molecules of the same solvent in the solvent mixture and in the

neat solvent, respectively, and $\Delta\nu_i$ and $\Delta\nu_{oi}$ are the proton line broadenings (corrected for viscosity effect) of solvent i in the mixture and in the neat solvent, respectively. The ratio n_i/n_o is the fraction of the solvent cage sites occupied by solvent i.

Kinetic studies

A known amount of the halo complex (usually 0.150 mmol) was dissolved in a predetermined volume of water–dimethyl sulfoxide solvent mixture of predetermined ionic strength thermostatted at a desired temperature. An excess of concentrated $Hg(ClO_4)_2$ was added quickly by syringe and the assisted removal of the halide ion allowed to go to completion. The reaction mixture was treated as described previously[15] and, as then, the reaction mixture was analysed sometimes by chromatographic separation of the aquo and dimethyl sulfoxide complexes, and sometimes by spectrophotometric methods. Only these two products were formed in the studies reported here.

RESULTS AND DISCUSSION

The solvent cage of $[Cr(NH_3)_5X]^{2+}$

The fractions of the solvent cage sites occupied by dimethyl sulfoxide (n_D/n_o) and water (n_W/n_o) were calculated from eqn (4) and are given in Table 1 along with the activities of dimethyl sulfoxide and water, the activity ratio $Y = a_D/a_W$, and the excess free energy of mixing (ΔG^E).

The enthalpies of mixing and the excess entropies of mixing water and dimethyl sulfoxide at 25 and 70°C measured by Kenttamaa and Lindberg[16] are nearly independent of temperature. Their averages were used to calculate values of ΔG^E at 40°C which were then fit to eqn (5) used by Scott *et al.*[17] by the method of least squares:

$$\Delta G^E = RTX_DX_W(\ln 10)[A + B(2X_D - 1) + C(2X_D - 1)^2] \quad (5)$$

The values of A–C determined from the least-squares fit were used to calculate ΔG^E values for the many solvent mixtures of interest; a few of these are listed in Table 1.

The activities of water and dimethyl sulfoxide at 0.001 mole fraction intervals were calculated from the excess free energies given by eqn (5) and the Duhem–Margules equation. The successive approximations to the correct activities of the two solvents at each mole fraction were repeated until the activities were constant to 16 significant figures to reduce accumulation of error. Previously[3] the successive approximations had been repeated until constancy to 10 significant figures had been achieved. Comparison of the Y values in Table 1 with those previously obtained[3] shows that, with the exception of $X_D = 0.1$, the activity ratios were changed by much less than 1% by the increased rigour of the calculations. It cannot be stressed too strongly that good values of this ratio are needed; Y varies by a factor (29.706/0.0176) = 1688 from $X_D = 0.1$ to $X_D = 0.9$ and, when $n_o = 10$, Y^{10} can range over a factor of 2×10^{32} and other powers of Y over a lesser, but still large, range. Poor Y values

Table 1. Values of the activities of dimethyl sulfoxide (a_D) and water (a_W), the activity ratio $Y = a_D/a_W$, the excess free energy of mixing (ΔG^E), the fractions of the solvent cage sites occupied by dimethyl sulfoxide (n_D/n_o) and water (n_D/n_o), and the stepwise formation constants for replacing water by dimethyl sulfoxide in the solvent cage of $Cr(NH_3)_5Cl^{2+}$

[a] Mole fraction of dimethyl sulfoxide based on solvents only.
[b] For $n_o = 10$, $k = 0.66092$.

would make it impossible to fit the experimental data with one value of K' in eqn (6) over the whole solvent composition range. In eqn (6) the powers of Y appear as coefficients in terms involving K', the first stepwise equilibrium constant for $i = 1$ in eqn (2) with the statistical factor removed, and k, a constant related to the incremental free energy increase in the stepwise substitutions. Equation (6) relates chemical-shift or line-broadening data to the solvent cage parameters n_o, K' and k. The final equation derived by Covington and Thain [eqn (6) in Ref. 1] contains a typographical error; the power of k should read $i(i-n)/2$, not $(i(i-1)/2)-((n-1)/2)$ (the expression given).[1] When the correct power of k is used the equation is readily converted to a more convenient form, namely:

$$\frac{\delta_j}{\delta_{oj}} = \frac{\sum_{i=1}^{n_o} \frac{(n_o-1)!}{(n_o-i)!(i-1)!} Y^i (K')^i k^{i(i-1)/2}}{1+\sum_{i=1}^{n_o} \frac{(n_o!}{(n_o-i)!i!} Y^i (K')^i k^{i(i-1)/2}}. \tag{6}$$

Here $\delta_j/\delta_{oj} = n_j/n_{oj}$ for solvent j.

The solvent cage parameters in eqn (6) are fitted to the n_j/n_{oj} ratios obtained from line-broadening data in the following manner. It is assumed that n_o, K' and k are constant over the whole range of solvent compositions. For a given solvent composition the value of Y is inserted into eqn (6) for (say) dimethyl sulfoxide and an equation of the form given in eqn (7a) is obtained:

$$\frac{n_D}{n_o} = \frac{A'}{B} \quad \text{or} \quad 1 = \frac{A}{B}, \tag{7a}$$

where $A = n_o A'/n_D$. For the other solvent component (say water) there is an analogous equation related to n_W/n_o and insertion of the Y value gives an equation of the form:

$$\frac{n_W}{n_o} = \frac{C'}{D} \quad \text{or} \quad 1 = \frac{C}{D}, \tag{7b}$$

where $C = n_o C'/n_W$. For a given value of n_o the denominators B and D are, and must be, equal. Therefore $A = C$ or, as given in eqn (8):

$$A - C = 0. \tag{8}$$

For a given n_o and solvent composition there are an infinite number of sets of (k, K') values which will satisfy eqn (8). Most of these sets do not remotely satisfy eqn (8) when applied to other compositions with other Y values; the large range in the values of the Y^i coefficients can rapidly make $A-C$ unequal to zero when the (k, K') set of values does not fit that solvent composition. One (k, K') set should fit eqn (8) for *all* solvent compositions. However, because of experimental error one (k, K') set will not be found which satisfies eqn (8) exactly for all solvent compositions. Instead a (k, K') set is found which will minimize the sum of the squared residuals given in eqn (9) for the solvent compositions studied:

$$\sum (A_i - C_i)^2 = \sum \rho_i^2. \tag{9}$$

The smallest sum indicates the best fit of the parameters (k, K') for the assumed n_o. The process is repeated for other n_o values until the best set of (n_o, k, K') values giving the best fit is found.

For 40°C, the ambient temperature at which the NMR spectra were taken, the best set of values was:

$$n_o = 10, \; k = 0.66092, \; K' = 29.8931.$$

When $k = 0.66092$ was used in eqn (8) for $n_o = 10$ and eqn (8) solved for the value of K' for each of nine solutions the K' values given in Table 1 were obtained. The average value of K' and the standard deviation for determination of K' from a single solution are 29.6 ± 3.4. Thus the standard deviation in the solvent range $0.1 \leqslant X_D \leqslant 0.9$ is 11.5%, which is very good considering the very large range covered by the coefficients of k and K' in eqn (6). From Table 1 it is seen that there is no trend in the K' values with change of solvent composition; this result supports the assumption that n_o and k do not change significantly over the solvent range studied.

It can also be seen from Table 1 that the sum of n_D/n_o and n_W/n_o is unity or slightly greater, but does not indicate any significant trend. This result supports the assumption that n_o is constant over the solvent range studied. The tendency for the sum to be somewhat greater than unity may result from the viscosity corrections but the deviation is not serious.

The k and K' values obtained can be used[1] to give the stepwise equilibrium constants defined in eqn (2). For dimethyl sulfoxide replacing water these are: $K_{D1} = 296$, $K_{D2} = 88.1$, $K_{D3} = 34.5$, $K_{D4} = 15.0$, $K_{D5} = 6.79$, $K_{D6} = 3.11$, $K_{D7} = 1.4$, $K_{D8} = 0.612$, $K_{D9} = 0.240$, and $K_{D10} = 0.0713$.

The value $k = 0.66092$ means that on average it becomes more difficult by 1027 J mol^{-1} to replace a water molecule by a dimethyl sulfoxide molecule after each such substitution occurs.

It is seen from Table 1 that at $X_D = 0.1(n_D/n_W) > (X_D/X_W) > (a_D/a_W)$. Because $a_D \ll X_D$ the dimethyl sulfoxide appears to be bonded in the bulk solvent phase in a manner that greatly lowers its activity from that expected on the basis of ideal behavior. Despite this decrease in a_D the mole ratio n_D/n_W for the solvent cage is considerably greater than X_D/X_W

and much greater then a_D/a_W. We can conclude that $Cr(NH_3)_5Cl^{2+}$ is strongly preferentially solvated by dimethyl sulfoxide. The data of Table 1 show that n_D/n_W remains greater than a_D/a_W up to approximately $X_D = 0.8$ and that thereafter the ratio of the solvents in the solvent cage approximately parallels the activity ratio of the solvent in the bulk phase.

A few line-broadening measurements for $Cr(NH_3)_5Br^{2+}$ at $X_D = 0.20$, 0.50 and 0.80 showed that this complex closely paralleled the chloro complex in the composition of the solvent cage. The studies were discontinued and it was concluded that dimethyl sulfoxide preferentially solvated this complex also at $X_D \leqslant 0.5$.

The composition of the solvent cage of the chloro complex can be related to the solvent composition X_D by the following equation:

$$\frac{n_D}{n_o} = \sum_{i=0}^{8} C_i X_D^i,$$

where $C_0 = -8.7646 \times 10^{-6}$, $C_1 = 1.79640$, $C_2 = 17.3356$, $C_3 = -209.2838$, $C_4 = 1021.5398$, $C_5 = -2563.0867$, $C_6 = 3451.8270$, $C_7 = -2368.6495$, and $C_8 = 649.5212$. We are not aware that other equations exist in the literature giving the composition of a solvent cage in terms of mole fractions of solvents.

Hg^{2+}-assisted substitution of $Cr(NH_3)_5X^{2+}$ in water–dimethyl sulfoxide solutions

The Hg^{2+}-assisted release of X^- ($X^- = Cl^-$ or Br^-) from the first coordination shell of $Co(NH_3)_5X^{2+}$ in water–dimethyl sulfoxide solutions leads to formation of $Co(NH_3)_5S^{3+}$ (S = water or dimethyl sulfoxide) as in reaction (10):

$$Co(NH_3)_5X^{2+} + Hg^{2+} + S \rightarrow Co(NH_3)_5S^{3+} + HgX^+. \quad (10)$$

It was of interest in the mechanism of substitution of S for X^- to determine whether the product ratio $[Co(NH_3)_5\{OSMe_2\}^{3+}]/[Co(NH_3)_5(H_2O)]^{3+}$ formed was the same as the n_D/n_W ratio in the solvent cage around the reactant halo complexes. [It was assumed that the $Cr(NH_3)_5X^{2+}$ and $Co(NH_3)_5X^{2+}$ complexes have very similar solvent cages.] In the solvent interchange reaction (3) it has been found[3] that k_S is strictly second-order in n_D/n_o, and that k_W is strictly first-order in n_W/n_o where n_D/n_o and n_W/n_o were for the aquo- and (dimethyl sulfoxide)pentaamminechromium(III) complexes, respectively. This finding strongly supports the I_d mechanism[18] which has previously been assigned to the unassisted thermal substitution reactions of pentaamminecobalt(III) complexes. The mechanism of the assisted substitution reactions of these complexes is less certain and a comparison of the product ratios with solvent cage compositions is desirable.

Table 2. Percentages of $[Co(NH_3)_5OSMe_2]^{3+}$ (p_D) and $[Co(NH_3)_5(H_2O)]^{3+}$ (p_W) formed in the Hg^{2+}-assisted removal of Cl^- and Br^- from $Co(NH_3)_5X^{2+}$ in water–dimethyl sulfoxide solutions as functions of the mole fraction (X_D) of dimethyl sulfoxide: 20.0°C < t < 60.0°C

	0.8	79.0±0.7	20.0±0.7	3.93	
	0.9	87.7±0.8	10.6±0.6	8.24	

The percentages of the dimethyl sulfoxide (p_D) and aquo (p_W) complexes formed in reaction (10) are given in Table 2 for 20, 40 and 60°C for the solvent range $0.1 \leqslant X_D \leqslant 0.9$ for $X^- = Cl^-$ or Br^-. The percentages listed in Table 2 were determined 4 times each at each of the three temperatures at each solvent composition. The percentage of each product at each solvent composition remained the same within the experimental error of less than 3% in the 20–60°C temperature range so that only the average and the standard deviation for a single determination are listed.

When the values of the product ratio p_D/p_W for Cl^- in Table 2 are compared with the solvent cage ratios (n_D/n_W) in the last column of Table 2 it is readily seen that the composition of the solvent cage of $Co(NH_3)_5Cl^{2+}$ does not determine the product ratio of reaction (10). Likewise when the product ratios for Cl^- are compared with the corresponding Y values in Table 1 it is readily seen that the solvent activity ratio does not determine the product ratio. A possible explanation of these results is that formation of a dinuclear complex such as $(NH_3)_5Co\,ClHg^{4+}$ prior to the rate-determining loss of Cl^-

very markedly changes the composition of the solvent cage or at least makes water more available near the departing $HgCl^+$ group. It is very unlikely that the five-coordinate intermediate $Co(NH_3)_5^{3+}$ was formed in the major pathway of reaction (10). Firstly, if it were formed and if it reacted in a first-order step with the solvent in its solvent cage then the product ratio p_D/p_W values would be expected to parallel the n_D/n_W values. This is because the chloro-, bromo-, aquo- and (dimethyl sulfoxide) pentaamminechromium(III) complexes are all strongly preferentially solvated by dimethyl sulfoxide, and it seems likely that the five-coordinate pentaammine complex would be also if it existed.

Secondly, if $Co(NH_3)_5^{3+}$ were formed as an intermediate which reacted in a second-order (but pseudo first-order) step with the bulk solvent components then the p_D/p_W values would be expected to parallel the Y values. This is because the rate of formation of the dimethyl sulfoxide product would be proportional to the product $a_{Co(NH_3)_5^{3+}} \times a_D$, the rate of formation of the aquo product would be proportional to the product $a_{Co(NH_3)_5^{3+}} \times a_W$, and the product ratio would be approximately proportional to a_D/a_W. But this proportionality was not observed.

Likewise the product ratios for Br^- in Table 2 show that they are not determined by n_D/n_W or a_D/a_W. Again these results are readily explained by a dinuclear complex as in the case of Cl^- but not by the formation of the five-coordinate intermediate $Co(NH_3)_5^{3+}$.

It is concluded that the results of the product ratio and solvent cage studies furnish rather strong evidence against the formation of $Co(NH_3)_5^{3+}$ as an intermediate with a lifetime sufficiently long to equilibrate its solvent cage and to undergo diffusional collisions with the major solvent components in a major pathway in reaction (10).

SYNTHESIS OF Co(III) MOLYBDOHETEROPOLYANIONS USING CARBONATO-AMMINE Co(III) COMPLEXES AS STARTING MATERIALS

KENJI NOMIYA, MINORU WADA, HIROYUKI MURASAKI and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 8 *September* 1986; *accepted* 19 *November* 1986)

Abstract—The preparation of two cobalt(III) molybdoheteropolyanions, $[CoMo_6O_{24}H_6]^{3-}$ and $[Co_2Mo_{10}O_{38}H_4]^{6-}$, was systematically studied using some carbonato-ammine cobalt(III) complexes as starting materials. The selectivity and yields of products were significantly influenced by the number of ammine ligands and the charge on the complexes.

Two molybdoheteropolyanions containing a Co(III) ion as the heteroatom, Anderson-type $[CoMo_6O_{24}H_6]^{3-}$ and Evans-Showell-type $[Co_2MO_{10}O_{38}H_4]^{6-}$ polyanions, are well-known.[1] The former, with D_{3d}-symmetry, has also been called a 1:6 salt and the Co(III) ion is located in an octahedral cavity of a crown of six MoO_6 octahedra formed by edge sharing.[2] The latter, with D_2-symmetry, has appeared as a by-product in the preparation of the former and has the dimeric nature of the former.[3] Polyhedral models of them are shown in Fig. 1. These compounds have been directly prepared from reaction of a boiling solution of ammonium heptamolybdate with an aqueous mixture of the Co(II) salt and hydrogen peroxide (the direct method).[4] On the other hand, there are only a few examples of the preparation of such polyanions using Co(III) complexes as a source of the heteroatom. For instance, there are the preparation from $[CoCO_3(NH_3)_4]^+$ reported by Baker *et al.*[5] and Shibata's method using a cold green solution containing the $[Co(CO_3)_3]^{3-}$ complex.[6] We have been interested in the preparation of heteropoly compounds using a transition-metal complex as the starting material.[7] In this work, we have systematically studied the preparation of two Co(III) molybdoheteropolyanions from carbonato-ammine Co(III) complexes such as $[CoCO_3(NH_3)_4]^+$ (**1**), $[CoCO_3(NH_3)_5]^+$ (**2**) and $[Co(CO_3)_2(NH_3)_2]^-$ (**3**), and compared them with the results by the direct method and Shibata's method.

RESULTS AND DISCUSSION

The yields of the two heteropolymolybdates by the preparations studied are shown in Table 1. From complex **2** with five ammine ligands, neither of the two polymolybdates are obtained. In this case, pink undissolved precipitates only are produced, which are probably due to an adduct between the complex cation and the heptamolybdate anion. On the other hand, from complex **1** with four ammines two polymolybdates are obtained with higher yields than by the direct method. Moreover, by prolonging the boiling after the addition of the complex solution to the boiled solution of heptamolybdate, only an Evans–Showell-type molybdate can be isolated.

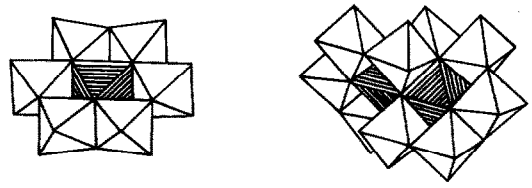

Fig. 1. Polyhedral models of Anderson- (left) and Evans–Showell-type (right) heteropolyanions. Striped octahedra represent the Co(III) ion as a heteroatom.

Table 1. Yields of two Co(III) heteropolymolybdates

Starting materials	Yields (%)[a] Anderson-type	Evans–Showell-type
$[CoCO_3(NH_3)_4]^+$ (1)	16.8[b]	Trace[b]
	Trace[c]	42.4[c]
$[CoCO_3(NH_3)_5]^+$ (2)	—	—
$[Co(CO_3)_2(NH_3)_2]^-$ (3)	—	20.8
$CoSO_4 \cdot 7H_2O + 30\%\ H_2O_2$[d]	14.4	11.8
$[Co(CO_3)_3]^{3-}$[e]	33.5	17.2

[a] Yields with respect to the molar number of starting Co(III) ion.

[b] The boiling time after the final drop was less than 2 min.

[c] The boiling time was more than 20 min.

[d] The direct method.

[e] Shibata's method.

These facts imply that carbonato-ammine complexes containing a lower number of ammine ligands are more reactive. In fact, complex **3** with two ammines produces only an Evans–Showell-type molybdate in a very short reaction time. An Anderson-type molybdate is not obtained from complex **3** even if the solution of heptamolybdate is mildly heated. Shibata's method is a preparation using a tricarbonato Co(III) complex without an ammine ligand. As a matter of fact, this complex is so active and unstable even at room temperature that the starting solution should be ice-cooled. The preparation from complex **1** takes a relatively long time. It is likely that the decomposition of an adduct between a complex cation and the heptamolybdate anion takes extra time.

From a synthetic point of view, it should be noted that yields and selectivity of desired heteropoly compounds can be changed by choosing the ligand in the starting complex.

EXPERIMENTAL

Electronic absorption and IR spectra were recorded with a Hitachi 340 spectrophotometer and a JASCO IR-G spectrophotometer, respectively.

Matrials

The starting complexes $[CoCO_3(NH_3)_4]NO_3 \cdot \frac{1}{2}H_2O$ (**1**), $[CoCO_3(NH_3)_5]NO_3 \cdot \frac{1}{2}H_2O$ (**2**) and $K[Co(CO_3)_2(NH_3)_2] \cdot 3H_2O$ (**3**) were prepared according to the literature, and identified by IR and absorption spectra.[6,8,9] All reagents were of analytical grade.

Preparations

An aqueous solution of complex **1** (6 g, 0.023 mol in 1000 cm^3 of water) was added through a dropping funnel into a boiling solution of ammonium heptamolybdate (28.8 g, 0.023 mol in 200 cm^3 of water). The dropping rate was balanced between the loss of water by evaporation and addition from the funnel. If the dropping rate was fast, reddish precipitates were formed and the reaction was inhibited. The colour of the solution became purple via reddish purple during the first 30 min of dropping and deep green until after 1 h of dropping. The whole addition took about 5 h. After the final drop, the solution was boiled further for a few minutes. Insoluble material was filtered and solid ammonium chloride (3.7 g) was added to the filtrate. On standing the solution overnight at room temperature, bluish green crystals of the Anderson-type heteropolymolybdate $(NH_4)_3[CoMo_6O_{24}H_6] \cdot 7H_2O$ were deposited. From the filtrate, dark olive green crystals of an Evans–Showell-type polymolybdate, $(NH_4)_6\ [Co_2Mo_{10}O_{38}H_4] \cdot 7H_2O$, were obtained. The two polymolybdates were recrystallized twice from water.

The boiling time after the final drop in the above procedure significantly influenced the yields of the two polymolybdates. When the boiling time was prolonged, the yield of the Anderson-type molybdate was lowered and that of the Evans–Showell-type molybdate was raised. From the solution boiled for more than 20 min, only the Evans–Showell-type molybdate was formed.

The two polymolybdates were characterized by IR and electronic absorption spectra.[10–13] The first and second *d–d* absorption bands of the Anderson-type molybdate were measured at 16,500 ($\varepsilon = 18.9$) and 24,300 cm^{-1} ($\varepsilon = 19.4$), respectively. The first *d–d* absorption band of the Evans–Showell-type molybdate was observed at 16,600 cm^{-1} ($\varepsilon = 89.1$). IR bands were measured at 937(s), 920(m), 880(vs), 830(sh), 680(sh), 665(sh), 640(vs), 580(m), 550(br m) and 445(m) cm^{-1} for the Anderson-type molybdate, and at 940(vs), 900(vs), 850(s), 735(sh), 675(s), 665(s), 650(s), 620(m), 600(vs), 560–550(br) and 520(m) cm^{-1} for the Evans–Showell-type compound.

From an aqueous solution of complex **2**, only a pink undissolved solid was produced and neither of the desired polymolybdates were obtained. IR spectra suggested that the pink solid was an adduct of a complex cation with the heptemolybdate anion.

From a dark blue solution of complex **3**, only the Evans–Showell-type polymolybdate was obtained. An aqueous solution of complex **3** (3.14 g, 0.01 mol in 100 cm^3 of water) was added dropwise to a boiling solution of ammonium heptamolybdate (12.6 g, 0.01 mol in 100 cm^3 of water). On dropping, it became effervescent and the dark blue of the complex solution changed to green. The reaction was over within 30 min. The resulting solution was evaporated to a volume of about 30 cm^3 on a steam bath and insoluble material was filtered. By cooling the filtrate to room temperature, dark olive green crystals were produced.

The direct method. An aqueous mixture of $CoSO_4 \cdot 7H_2O$ (4.2 g, 0.015 mol in 30 cm^3 of water) and 30% hydrogen peroxide (2 cm^3) was added to a boiling solution of ammonium heptamolybdate (30.9 g, 0.025 mol in 260 cm^3 of water). The hot solution was filtered once and cooled to room temperature. Bluish green crystals were deposited in the solution. By evaporating the filtrate on a steam bath, dark olive green crystals were obtained.

Shibata's method.[6] A cold mixture of an aqueous solution (4 cm^3) containing $CoCl_2 \cdot 6H_2O$ (6 g, 0.025 mol) and 30% hydrogen peroxide (9 cm^3) was added dropwise to an ice-cooled slurry of potassium hydrogen carbonate (18 g, 0.18 mol in 18 cm^3 of water), and the resulting green solution was filtered quickly. The filtrate was again cooled in an ice bath and used as a starting solution.

The starting solution was added dropwise to an aqueous solution of ammonium heptamolybdate (60 g, 0.049 mol in 200 cm^3 of water) with stirring at room temperature. The resulting mixture was further stirred for 2 h. Bluish green crystals of the Anderson-type molybdate were produced and recrystallized twice from water. To the filtrate the starting solution was added, the pH of the solution was quickly adjusted to 4 with glacial acetic acid, and the solution was stirred for 1 h. After filtration, the dark green filtrate was concentrated to half volume at 60–65°C. On standing at room temperature, the Anderson-type molybdate as a by-product was removed and ammonium chloride (5 g) was added to the filtrate. Dark olive green crystals were produced and recrystallized twice from water.

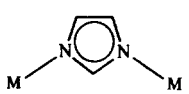
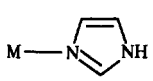
(*Received* 5 *November* 1986; *accepted* 28 *November* 1986)

Abstract—The $[M(NH_3)_5(imidH)]^{3+}$ complex ions (M = Co, Rh or Ir; imidH = imidazole) can be readily prepared by reaction of $[M(NH_3)_5(OSO_2CF_3)]^{2+}$ ions with imidazole in sulfolane. Subsequent reaction of $[M'(NH_3)_5(OSO_2CF_3)]^{2+}$ with $[M(NH_3)_5(imidH)]^{3+}$ in sulfolane in the presence of a non-coordinating base permits synthesis of the binuclear imidazolate-bridged complexes $[(NH_3)_5M(imid)M'(NH_3)_5]^{5+}$ (M = M′ = Co or Rh; M = Co, M′ = Rh), characterized by spectroscopic, chromatographic and voltammetric methods, and by reactivity.

Imidazole is a biologically important heterocycle which is known as the anion to bridge Cu(II) and Zn(II) in bovine erythrocyte superoxide dismutase,[1] for example. Bridging through the two equivalent heteroatoms in the anion has also been achieved in several model complexes.[2] Crystal structure analysis has defined a "bent" geometry (**I**) in the dimers.[3] Imidazole, as a neutral molecule, is also well known as a monodentate ligand (**II**).



I



II

The simple (imidazole)pentaammines of the inert metal ions Co(III), Cr(III) and Ru(III), as well as impure Rh(III) and Ir(III) species, are now known.[4–6] We have found that all of the triad $[M(NH_3)_5(imidH)]^{3+}$ (M = Co, Rh or Ir; imidH = imidazole) can be prepared simply and in high purity from the $[M(NH_3)_5(OSO_2CF_3)]^{2+}$ ions by displacing the labile $CF_3SO_3^-$ group by imidazole. Further, these labile precursors have permitted us to explore the synthesis of the dimers $[(NH_3)_5M(imid)M'(NH_3)_5]^{5+}$ by reaction of $[M(NH_3)_5(imid)]^{2+}$ with $[M'(NH_3)_5(OSO_2CF_3)]^{2+}$, and the results of these investigations are reported herein. Routes to the simple decaamminedimetal(III) species have not been explored much previously. During the course of this work, synthesis of the dicobalt(III) dimer was reported.[7] However, the reaction conditions employed led also to the formation of a trinuclear complex with two bridging imidazolates and to the hexaamminecobalt(III) ion. The different conditions reported here appear to permit synthesis without ligand rearrangement, and can be extended to permit formation of a range of dimetal and mixed-metal compounds.

EXPERIMENTAL

Syntheses

$[Ir(NH_3)_5(imidH)](ClO_4)_3 \cdot H_2O$. A solution of $[Ir(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$[8] (3.0 g) and imidazole (1.5 g) in dry sulfolane (20 cm^3) was heated at 90°C for 4 h. The colourless solution was cooled and washed into a flask with ~ 20 cm^3 of ethanol. Slow addition of diethyl ether (~ 900 cm^3), with stirring, produced a precipitate which was collected and dried. The product was dissolved in 10 cm^3 of water at ~ 40°C, filtered, and a solution of 5 g of $LiClO_4$ in 10 cm^3 of ethanol added. A precipitate began to form near the end of the addition. After refrigeration overnight the product was collected, washed with 1 : 1 ethanol–water (2 × 20 cm^3) and ether (20 cm^3), and dried *in vacuo* (2.0 g, 75%). Found: C, 5.2; H, 3.3; N, 14.6; S, 0.0. Calc. for $C_3H_{21}Cl_3IrN_7O_{13}$: C, 5.5; H, 3.2; N, 14.8; S, 0.0%.

$[Rh(NH_3)_5(imidH)](ClO_4)_3$. A solution of $[Rh(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$[8] (5.0 g) and imidazole (2.5 g) in dry sulfolane (50 cm^3) was heated at 80°C for 2 h. The solution was cooled and washed into a flask with ethanol (50 cm^3), from which a white precipitate was isolated following ether addition (~ 900 cm^3) with stirring. The product was dissolved in water (20 cm^3), filtered, warmed to ~ 40°C and a solution of 10 g of $LiClO_4$ in 20 cm^3 of ethanol added slowly. The absence of any initial precipitate when commencing $LiClO_4$ addition indicates the absence of any hexaamminerhodium(III), which is very insoluble as a perchlorate salt. The solution was refrigerated overnight, and the white powder collected, washed with 1 : 1 ethanol–ether (2 × 20 cm^3), then ether (20 cm^3), and dried *in vacuo* (3.25 g, 75%). Found: C, 6.6; H, 3.6; N, 17.3. Calc. for $C_3H_{19}Cl_3N_7O_{13}Rh$: C, 6.5; H, 3.6; N, 17.7%.

$[Co(NH_3)_5(imidH)](ClO_4)_3$. This compound was prepared from $(Co(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$ and imidazole in sulfolane essentially as described for the rhodium analogue above. This complex has been reported before.[4]

$\{[Co(NH_3)_5]_2(imid)\}(ClO_4)_5 \cdot 3H_2O$. A solution of $[Co(NH_3)_5(imidH)](ClO_4)_3$ (1.02 g) and $[Co(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$[8] (1.18 g) in 20 cm^3 of dry sulfolane was treated with triethylamine (0.5 g), and stirred at 80°C for 1 h. After cooling, the reaction mixture was treated with ethanol (100 cm^3) and ether (200 cm^3) to precipitate a brown solid. This was dissolved in water (20 cm^3) and $NaClO_4$ (2.5 g) added. On standing in a refrigerator for 2 days, an orange powder was obtained (0.4 g, 25%). Found: C, 3.8; H, 4.1; N, 18.3; Cl, 19.3. Calc. for $C_3H_{39}Cl_5Co_2N_{12}O_{23}$: C, 4.0; H, 4.4; N, 18.6; Cl, 19.6%. The reaction mixture may also be chromatographed on Dowex 50W × 2 H^+-form resin. Dilution of the reaction mixture with water (~ 500 cm^3) prior to loading onto the column was required. Elution with 1.0 and 3.0 M HCl removed chloro- and imidazolepentaammine monomers, with the orange dimer being removed with 5.0 M HCl. Evaporation under reduced pressure to ~ 20 cm^3, followed by ethanol addition (~ 50 cm^3), precipitated a brown-orange product (0.7 g, 65%) which can be recrystallized as the perchlorate salt as described above. Electronic spectrum (water), λ_{max} (nm) [ε_{max} (M^{-1} cm^{-1})]: 475 (157), 335 (220).

$[(NH_3)_5Co(imid)Rh(NH_3)_5](ClO_4)_5 \cdot 3H_2O$. A solution of $[Rh(NH_3)_5(imidH)](ClO_4)_3$ (1.1 g) and $[Co(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$[8] (1.2 g) in 20 cm^3 of dry sulfonate was treated with triethylamine (0.5 cm^3), and stirred at 80°C for 3 h. The solution was cooled, 1 g of $LiClO_4$ was added, followed by ethanol (~ 100 cm^3). Refrigeration overnight separated an oil. The solvent was decanted, and the oil dissolved in water (25 cm^3), with warming. A solution of $LiClO_4$ (2 g) in ethanol (25 cm^3) was added slowly, and a precipitate formed on chilling overnight. This was collected, washed with ethanol (2 × 10 cm^3) and ether (10 cm^3), and air dried. It was recrystallized from water (20 cm^3) by addition of $LiClO_4$ (2 g) in ethanol (25 cm^3), followed by chilling overnight, and isolated as above (0.9 g, 50%). Found: C, 3.7; H, 3.7; N, 17.2; Cl, 18.4. Calc. for $C_3H_{39}Cl_5CoN_{12}O_{23}Rh$: C, 3.8; H, 4.1; N, 17.7; Cl, 18.7%. Electronic spectrum (water), λ_{max} (nm) [ε_{max} (M^{-1} cm^{-1})]: 475 (50), 340 (100).

$\{[Rh(NH_3)_5]_2(imid)\}(ClO_4)_5 \cdot C_2H_5OH$. A solution of $[Rh(NH_3)_5(imidH)](ClO_4)_3$ (1.0 g) and $[Rh(NH_3)_5(OSO_2CF_3)](CF_3SO_3)_2$ (1.2 g) in 20 cm^3 of dry sulfolane with triethylamine (0.5 cm^3) added was stirred at 80°C for 3 h. After cooling, ethanol (10 cm^3) and ether (~ 500 cm^3) were added to precipitate an oily white solid. The supernatant was decanted, the oil dried in a desiccator, then redissolved in water (25 cm^3) and filtered. Following addition of 1 g of $LiClO_4$ and 25 cm^3 of ethanol, the solution was chilled overnight and the near white powder was collected, washed with ethanol (5 × 20 cm^3) and ether (20 cm^3), and air dried (1.0 g, 60%). Found: C, 5.4; H, 3.8; N, 16.1; Cl, 16.6. Calc. for $C_5H_{44}Cl_5N_{12}O_{24}Rh_2$: C, 5.8; H, 4.2; N, 16.2; Cl, 17.0%. Electronic spectrum (water), λ_{max} (nm) [ε_{max} (M^{-1} cm^{-1})]: 300 (420), 230sh (2650).

Physical methods

Electronic spectra were recorded using an Hitachi 220A spectrophotometer. IR spectra of compounds dispersed in KBr discs were recorded using a Nic-

olet MX-1 FT-IR. NMR spectra were collected using a JEOL FNM FX200 spectrometer in D_2O solution. Voltammetry was performed using an AMEL Model 473 or PAR Model 170 controller linked to an EG&G PAR Model 303A static mercury drop electrode or conventional dropping mercury electrode, and a three-electrode configuration with a platinum wire auxiliary electrode and an Ag–AgCl or saturated calomel reference electrode, with argon as purge gas. Measurements were made on 10^{-3} M solutions of complex in 0.1 M $NaClO_4$ or $NaCF_3SO_3$ as supporting electrolyte.

RESULTS AND DISCUSSION

The value of trifluoromethanesulfonato complexes as synthetic precursors for a range of inert mononuclear complexes has been established earlier.[9] However, few examples employing such compounds in the synthesis of simple binuclear complexes have appeared. In view of the known role of imidazolate as a bridging ligand, it was appropriate to pursue molecules with this anion linking the metal ions, and this has now been achieved for several decaamminedimetal(III) complexes.

The synthetic route developed required the prior synthesis of imidazolepentaamminemetal(III) complexes, and this was achieved from the trifluoromethanesulfonatopentaamminemetal (III) precursors. The complete triad $[M(NH_3)_5(OSO_2CF_3)]^{2+}$ (M = Co, Rh or Ir) were simply prepared in high yield and purity. While Cr(III) and Co(III) complexes were previously known,[4,5] the Ir(III) and Rh(III) complexes had been prepared before only as impure mixtures of imidazole and aqua pentaammines, with as much as 35% aqua complex present.[6] The pure complexes of the cobalt triad are best characterized by their ^1H NMR spectra in d_6-dimethylsufoxide. Apart from the single broad signal from the ammine protons at δ 3.59 (Co), 3.80 (Rh), and 4.39 (Ir), three separate signals from the non-equivalent imidazole ring carbon protons occur at δ 7.31, 7.69 and 8.28 (Co), δ 7.20, 7.52 and 8.14 (Rh), and δ 7.17, 7.45 and 8.05 (Ir). As has been reported previously,[7] the signal changes to two peaks (ratio 1 : 2) on forming a symmetric dimer.

Characterization of the apparently binuclear complexes is conveniently performed initially by ion chromatography. Mixtures of the binuclear complexes and imidazolepentaamminemetal(III) precursors elute from SP Sephadex C-25 (Na^+-form) or Dowex 50W × 2 (H^+-form) cation exchange resin as two separate bands, with the higher charged binuclear complex eluting more slowly than its precursor. Chromatography can permit convenient separation on a synthetic scale. Further, the symmetric dimer $\{[Co(NH_3)_5]_2(imid)\}^{5+}$ exhibits a ^1H NMR spectrum in 0.1 M DCl [δ 3.6 (broad, NH), 7.08, 7.54 (2 : 1, imidazolate)] like that reported earlier for this molecule.[7] The IR spectra of the molecules also provide evidence for the structural assignments of the molecule as $[(NH_3)_5M(imid)M'(NH_3)_5]^{5+}$ complexes. All monomer precursors and binuclear products show weak but characteristic bands for imidazole throughout the 3000–450-cm^{-1} region, and characteristic ammine vibrations. Further, certain multiplicities absent in the symmetric dimers $\{[M(NH_3)_5]_2(imid)\}^{5+}$ (M = Co or Rh) appear in the mixed complex $[(NH_3)_5Co(imid)Rh(NH_3)_5]^{5+}$; apparent M–N stretching vibrations at 315 and 279 cm^{-1} for the dicobalt and dirhodium complexes, respectively, are replaced by two vibrations at 313 and 282 cm^{-1} in the mixed-metal molecule, whereas ammine resonances at 1350 cm^{-1} (dicobalt) and 1385 cm^{-1} (dirhodium) are replaced by overlapping bands at 1340 and 1390 cm^{-1} in the mixed-metal species. These physical characterizations, in composite, define the existence of binuclear complexes synthesized from imidazolepentaammine and trifluoromethanesulfonatopentaammine precursors in combination.

Further characterization comes from the kinetic behaviour of the binuclear complexes. The $[(NH_3)_5Co(imid)Rh(NH_3)_5]^{5+}$ molecule is stable in 0.01 M OH^-, with no change in optical spectrum observed after 3 h at 25°C, but in 12 M HCl it undergoes slow decomposition ($k_{obs} = 3.5 \times 10^{-5}$ s^{-1}). The rate of electron transfer of this molecule when reacted with VO^{2+} in 0.5 M base at 25°C ($k = 0.020$ M^{-1} s^{-1}) is markedly slower than that reported for $[Co(NH_3)_5(imid)]^{2+}$ under identical conditions ($k = 1.3$ M^{-1} s^{-1}),[10] and presumably results partly from electrostatic considerations in briging together the cationic reductant and the cationic oxidants of different charge and size.

The voltammetry of the complexes is also indicative of the binuclear nature of the products. Metal-centred reduction potentials for complexes determined polarographically are collected in Table 1. The $[M(NH_3)_5(imidH)]^{3+}$ precursors exhibit a single irreversible reduction with $E_{1/2}$ pH-dependent as a consequence of protonation/deprotonation of the imidazole ligand.[11] The dimers display a complex pattern of two sequential one-electron irreversible reductions. No reversible character is shown even at scan rates of 50 V s^{-1} in cyclic voltammograms at a hanging mercury drop electrode. Reduction waves in the mixed cobalt–rhodium molecule are well-separated, but sequential

Table 1. Reduction potentials determined by polarography in aqueous solution at ambient temperature of imidazolepentaammine complexes

Complex	$E_{1/2}$ [V (vs SCE)]
$[(NH_3)_5Co(imid)]^{2+}$	−0.47
$[(NH_3)_5Co(imidH)]^{3+}$	−0.30
$[(NH_3)_5Rh(imid)]^{2+}$	−1.17
$[(NH_3)_5Rh(imidH)]^{3+}$	−1.10
$[(NH_3)_5Co(imid)Co(NH_3)_5]^{5+}$	−0.12, −0.40
$[(NH_3)_5Co(imid)Rh(NH_3)_5]^{5+}$	−0.11, −1.20
$[(NH_3)_5Rh(imid)Rh(NH_3)_5]^{5+}$	−1.02, −1.20

processes can even be distinguished in the d.c. polarograms of the dicobalt and dirhodium complexes. Further, a.c. polarography of the complexes clearly defines two sequential reduction steps in each case. It is notable that the first reduction, assigned to electron addition to one metal ion of the binuclear compound, occurs at a potential of up to 350 mV more positive than in the deprotonated imidazole monomer complex, and some 200 mV more positive than in the protonated monomer complex. Clearly, the reduction potential is shifted to a more positive value as the charge on the opposite side of the imidazole ring increases. While imidazole is apparently not a good mediator of electronic influences,[12] these shifts may be related most simply to overall complex charge. The appearance of two waves in the dimers is probably a consequence of the known rapid dissociation of pentaamminemetal(II) complexes;[11] if reduction and the following dissociation in the first step are very fast, then the second reduction step in the double layer may approximate that of the deprotonated monomer. The observed potentials for the second process (Table 1) do approach those of definitive monomers closely, in support of this view.

It is presumed that the synthetic approach developed here for formation of μ-imidazolato complexes may have general applicability when linking inert metal ions is involved. We are pursuing other reactions employing trifluoromethanesulfonato complexes as synthons with a view to forming other small polymeric metal complexes.

SYNTHESIS AND REACTIONS OF *TRANS*-DICARBONYL BIS-[1,2-BIS(DIMETHYLPHOSPHINO)ETHANE] VANADIUM(0): X-RAY CRYSTAL STRUCTURES OF *TRANS*-$V(CO)_2(dmpe)_2$ [*CIS*-$V(CO)_2(dmpe)_2(CH_3CN)]BPh_4$ AND *CIS*-$V(CO)_2(dmpe)_2(O_2CEt)$

(*Received* 10 *November* 1986; *accepted* 28 *November* 1986)

Abstract—Interaction of *trans*-$VCl_2(dmpe)_2$ with sodium amalgam in tetrahydrofuran under CO gives *trans*-$V(CO)_2(dmpe)_2$. The latter is oxidized by Ag^+ in acetonitrile to give [*cis*-$V(CO)_2(dmpe)_2(CH_3CN)]^+$, isolated as the tetraphenylborate. Interactions with acids (HX) gives neutral complexes of the type $V(CO)_2(dmpe)_2X$ (X = Cl, $MeCO_2$, $EtCO_2$, CF_3CO_2, $PhPO_2H$ or NH_2SO_3); the chloride can be exchanged with N_3^- or CN^- in methanol. X-ray structural studies confirm the *trans* stereochemistry for $V(CO)_2(dmpe)_2$ and the seven-coordination of V^I in both $[V(CO)_2(dmpe)_2(CH_3CN)][BPh_4]$ and $V(CO)_2(dmpe)_2(O_2CEt)$, which have a pseudo octahedral geometry with the two carbonyls occupying a "split" axial site. ^{51}V NMR and other spectra are reported.

Phosphine-substituted carbonyls of vanadium[1] have commonly been prepared from $V(CO)_6$ or $[V(CO)_6]^-$ but for dicarbonyls with bidentate chelating phosphines, only $V(CO)_2(dppe)_2$ [dppe = 1,2-bis(diphenylphosphino)ethane] is known. The characterization of *trans*-$VCl_2(dmpe)_2$[2] now allows the synthesis of *trans*-$V(CO)_2(dmpe)_2$ by the same method used for the preparation of *cis*-$Cr(CO)_2(dmpe)_2$.[3] Some reactions of *trans*-$V(CO)_2(dmpe)_2$ are discussed. Analytical data for new compounds are given in Table 1, and IR and NMR data in Tables 2 and 3.

RESULTS AND DISCUSSION

Synthesis of trans-$V(CO)_2(dmpe)_2$

The interaction of *trans*-$VCl_2(dmpe)_2$ in tetrahydrofuran with excess sodium amalgam under CO (5 atm) gives an orange solution from which air-sensitive crystals of the dicarbonyl complex can be isolated. Although the IR spectrum in hexane shows only a single band at 1763 cm^{-1} as expected for a *trans* stereochemistry, the solid-state spectrum (Nujol mull) shows two bands, which are presumably due to solid-state splitting. The *trans* structure is confirmed by the X-ray crystal structure analysis.

A diagram of the molecule is given in Fig. 1; selected bond lengths and angles are given in Table 4. The V—C distances are *ca* 0.1 Å longer than the Cr—C distances in *cis*-$Cr(CO)_2(dmpe)_2$ and the V—P bonds are also *ca* 0.1Å longer than the two mutually *trans* Cr—P bonds in that complex,[3] and the Cr—P bonds in the analogous Cr^0 complex, $Cr(N_2)_2(dmpe)_2$.[3] However, the V—C distances are only 0.05 Å greater than the Cr—N distances, an indication of the greater π-acceptor capability of the carbonyl ligand. Interestingly, the volume per molecule of this vanadium compound is *ca* 20 $Å^3$ *less* than that of the dinitrogen complex. Although

[a] Found (required).

the thermal ellipsoids for atoms of the dmpe ligands indicate considerable thermal motion or disorder in the vanadium compound, it would seem that the crystal packing in this monoclinic structure is better than that for the dinitrogen chromium structure which is triclinic.

The difference between the *trans* dicarbonyl structure found here and *cis*-$Cr(CO)_2(dmpe)_2$ can be rationalized by MO calculations[4] which suggest that for 18e species such as the chromium complex the *cis* isomer is more stable but for 17e complexes the *trans* isomer is thermodynamically preferred.

The compound is a paramagnetic, low-spin d^5-species ($\mu_{eff} = 1.5$ BM*) from magnetic-sus-

ceptibility measurements by Evans' NMR method.[5] The ESR spectrum (X-band) appears to be an overlapping of three sets of eight lines (^{51}V, $I = \frac{7}{2}$, 100%) corresponding to the interaction of the single electron spin with the nuclear spin of ^{51}V.

By contrast with *trans*-$CrCl_2(dmpe)_2$,[3] reduction of *trans*-$VCl_2(dmpe)_2$ under either dihydrogen or dinitrogen does not give isolatable complexes.

Reactions of trans-$V(CO)_2(dmpe)_2$

Oxidation by Ag^+. Interaction of the complex in acetonitrile at −30°C with $AgSO_3CF_3$ leads to the formation of the cation [*cis*-$V(CO)_2(dmpe)_2(MeCN)]^+$, which can be readily isolated as the orange tetraphenylborate salt, a 1 : 1 electrolyte in MeCN. The spectroscopic properties of the complex (Table 2) are in accordance with the structure determined by X-ray crystallography (see below).

Attempts to isolate an ion $[V(CO)_2(dmpe)_2]^+$ comparable to octahedral *trans*-$[Cr(CO)_2(dmpe)_2]^+$[6] by other types of oxidation were unsuccessful. The coordination of acetonitrile to give the seven-coordinate cation gives an 18e complex which is obviously more stable than an unsolvated 16e species.

Oxidation by HX. *trans*-$V(CO)_2(dmpe)_2$ reacts with HX (X = Cl, $MeCO_2$, $EtCO_2$, CF_3CO_2, $PhPO_2H$ or NH_2SO_3) in diethylether, tetrahydrofuran or toluene to give hydrogen and neutral non-conducting V^I complexes of form *cis*-$V(CO)_2(dmpe)_2X$. These can be recrystallized from hexane or diethylether as red needles. The spectroscopic data are collected in Tables 2 and 3.

The structure of the molecule $[V(CO)_2(dmpe)_2(O_2CEt)]$ and the cation $[V(CO)_2(dmpe)_2(NCMe)]^+$ are essentially analogous, and may be described as "pseudo octahedral", with "equatorial" *bis* -dmpe groups and one axial site occupied by the acetonitrile or unidentate propionate ligands and the other being "split" and accommodating the two carbonyls. Diagrams of the two structures are given in Figs 2 and 3; selected bond lengths and angles are in Tables 5 and 6. The near equality of the C—V—N and C—V—O angles between the "axial" sites preclude the possibility of using a capped octahedral description. One particular feature of this bonding of the two carbonyls is the very narrow C—V—C angle in both structures (*ca* 68°) and the resulting very close non-bonded approach of the two carbon atoms (*ca* 2.1 Å).

The V—C and V—P distances are very similar in both complexes. The former are *ca* 0.05 Å smaller than in the *trans* V^0 dicarbonyl described above, but the V—P distances are *ca* 0.1 Å greater. This difference again probably reflects the greater π-acceptor activity of the carbonyls, especially in a non-*trans* arrangement and bonded to an 18e metal

centre. The V—N and V—O distances are very similar at 2.15 Å.

Azido and cyano complexes can be made from *cis*-$V(CO)_2(dmpe)_2Cl$ by interaction of NaN_3 or KCN in methanol. The azido compound is also formed when *trans*-$V(CO)_2(dmpe)_2$ is treated with Me_3SiN_3 in hexane.

The IR spectra of the complexes are as expected—all showing two strong CO stretching frequencies for the *cis* carbonyls and appropriate bands for the other ligands (Table 2). The carboxylates show the asymmetric and symmetric $\nu(CO_2)$ stretches and the $\Delta\nu$ value (301 cm^{-1}) for the acetate indicates η^1-binding.[7] The ^{31}P–$\{^1H\}$ NMR spectra all show an octet resulting from the coupling of the equivalent phosphorus atoms to the ^{51}V nucleus (Table 3).

The ^{51}V NMR spectra (Table 3) of the $V(CO)_2(dmpe)_2X$ complexes all show a quintet due to the splitting of the ^{51}V resonance by the four equivalent P atoms. The resonances lie between −906 and −1248 ppm in the region expected for V^I

compounds (−870 to −1540 ppm).[8] The observed resonances lie towards the high-frequency end of this range because of the electron-donating ability of the methyl groups on the dmpe ligands. There is indeed a tendency for an increase in ^{51}V deshielding as the bulk of the phosphine increases and the electronegativities of the substituent groups on phosphorus decrease.[9] The small $^1J(V-P)$ values (*ca* 160 Hz) are also in accord with those for vanadium alkyl-phosphine complexes.[10] Finally the ^{51}V shielding increases in the order $X = CN > N_3 > Cl > EtCO_2 > MeCO_2 > CF_3CO_2 > PhPO_2H > NH_2SO_3$; this agrees with Rehder's magnetochemical series of ligands.[11]

Protonation to hydrido species. Interaction of *trans*-$V(CO)_2(dmpe)_2$ with 1 equivalent of tetrafluoroboric acid in methanol at −78°C gives a red solution; on warming to room temperature, an orange solution is obtained from which orange crystals can be isolated. Analytical and spectroscopic data for the BF_4^- and $PhC(SO_2CF_3)_2^-$ salts given in Table 7 indicate that the cation has $[HV(CO)_2(dmpe)]^+$ stoichiometry. The conductivity corresponds to that of a 1 : 1 electrolyte.

The mull IR spectrum shows two strong bands at 1865 and 1827 cm^{-1} attributable to *cis* carbonyls. A relatively weak, sharp band is also observed at 1952 cm^{-1} which is assigned to ν(V—H). However

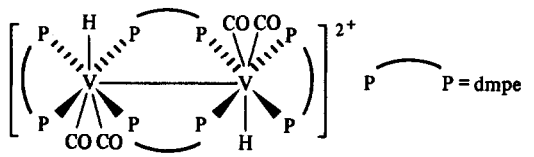
in CH_2Cl_2 solution two bands are observed in the terminal hydride stretching region at 1960 and 1942 cm^{-1}, although the number of ν(CO) bands does not change. The presence of V—H bands is confirmed by essentially quantitative formation (GLC) of $CHCl_3$ on refluxing the compound with CCl_4.

However, magnetic-susceptibility and ESR measurements show that the cation is diamagnetic, thus eliminating the possibility that the ion is analogous to $[MH(CO)_2(dmpe)_2]^+$ (M = Cr,[6] Mo or W[12]). The ^{31}P–{^1H} and ^{51}V–{^1H} NMR spectra in CD_2Cl_2 do not provide any useful structural information, showing only broad resonances at +55.8 ppm and −1311 ppm, respectively. This broadening of the resonances can be ascribed to quadrupolar relaxation caused by the presence of the vanadium nucleus, and thus cooling the NMR sample merely broadens the signals. This quadrupolar relaxation probably also accounts for the fact that no resonance for the hydride proton can be seen in the ^1H NMR.

The diamagnetism of the cation suggests that dimerization of a paramagnetic $VVH(CO)_2(dmpe)_2^+$ species has occurred, presumably with the formation of a V—V bond. The IR spectra shows that there are no bridging CO or hydrido groups; since there are two V—H stretches in solution spectra, this could indicate isomers or some lack of symmetry in solution.

Despite repeated attempts to obtain X-ray quality crystals with different anions, none were obtained; the crystals form as thin mica-like platelets. In the absence of structural data we can only speculate on the structure on the basis of the above data and a reasonable possibility is I shown as the "*trans*" isomer where there is a supported metal–metal bond. V—V bonds have been discussed;[13] there is a precedent for bridging dmpe in the compound $Rh_2(CH_2SiMe_3)_2dmpe_3$[14] which has a single dmpe bridge.



I

EXPERIMENTAL

Microanalyses were performed by Pascher (Bonn) and Imperial College Laboratories.

Instruments

IR: Perkin–Elmer 683, spectra in Nujol mulls unless otherwise stated. NMR: JEOL FX90Q and Bruker WM 250; δ values in ppm relative to Me_4Si (^1H), 85% H_3PO_4 external (^{31}P) and $VOCl_3$ external (^{51}V). ESR: Varian E-12 (X-band). Mass: VG Micromass 7070 and MS9. Conductivities: Data Scientific PT1-18, data in $\Omega^{-1}\,cm^2\,mol^{-1}$. Magnetic

susceptibilities in solution were determined using a modification of Evans' method. Melting points (uncorrected) were determined in sealed capillaries. All manipulations were carried out under argon or nitrogen, and all solvents were dried, distilled and degassed before use.

trans-*Dicarbonyl bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(0)

A pressure bottle containing sodium amalgam (5 equivalents of Na per V) and *trans*-$VCl_2(dmpe)_2$ (0.5 g, 1.23 mmol), in tetrahydrofuran (70 cm^3) at −78°C, was pressurized with CO to 5 atm. The mixture was vigorously stirred and allowed to warm to room temperature. The initial purple solution became red and finally orange. The solution was filtered, evaporated and the residue extracted with hexane (40 cm^3). Filtration, concentration to *ca* 10 cm^3 and cooling to −20°C gave small orange-red prisms which were collected, and dried *in vacuo*. Yield 0.25 g (50%).

ESR (toluene, 97 K): $g_x = 2.1563$, $g_y = 2.0523$, $g_z = 1.8379$. Magnetic susceptibility (CH_2Cl_2, 25°C): $\mu_{eff} = 1.53$ BM.

cis-*Dicarbonyl bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *acetonitrile vanadium*(I) *tetraphenylborate*

To *trans*-$V(CO)_2(dmpe)_2$ (0.4 g, 0.98 mmol), in acetonitrile (30 cm^3) at −30°C, was added $AgSO_3CF_3$ (1 equivalent, 0.98 mmol) in the dark. After *ca* 15 min. the resultant red-brown solution was filtered and the solvent removed *in vacuo*. Addition of a methanolic solution of $NaBPh_4$ gave an orange precipitate which was collected, washed with methanol (2 × 10 cm^3) and dried. Subsequent extraction into acetonitrile (30 cm^3) gave an orange-brown solution, which was stirred with a small amount of mercury to collect the finely-divided silver suspended in solution. After several minutes the orange solution was filtered, concentrated and cooled to −20°C yielding orange-red prisms. Yield 0.5 g (50%).

NMR [^1H (CD_2Cl_2)]: 7.3s, 7.0s, 6.9s (phenyl); 1.95 (CH_2). 1.5 (CH_3). Conductivity (MeCN, 25°C): $\Lambda_M = 61\ \Omega^{-1}\ cm^2\ mol^{-1}$.

cis-*Dicarbonylchloro bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.3 g, 0.74 mmol), in diethylether (40 cm^3) at 78°C, was added HCl (1.47 mmol, 0.9 M in Et_2O). After stirring for *ca* 1 h at room temperature, the red solution was evaporated and the residue extracted into diethylether. Filtration, concentration and cooling to −20°C gave red needles which were collected and dried *in vacuo*. Yield 0.2 g (60%).

NMR [^1H (C_6D_6)]: 1.32s (dmpe).

cis-*Dicarbonyltrifluoroacetato bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.26 g, 0.64 mmol), in tetrahydrofuran (50 cm^3) at −78°C, was added CF_3CO_2H (1.28 mmol, 1.5 M in Et_2O). The mixture was stirred and allowed to warm to room temperature. Removal of the solvent and extraction of the residue into hexane (50 cm^3) gave a red solution. Filtration, concentration and cooling to −20°C yielded small red crystals. Yield 0.17 g (50%).

NMR [^1H (C_6D_6)]: 1.26s (dmpe).

cis-*Dicarbonylacetato bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.34 g, 0.84 mmol), in tetrahydrofuran (50 cm^3) at −78°C, was added CH_3CO_2H (3.95 mmol, 2.6 M in Et_2O). After stirring for 24 h at room temperature, the solvent was removed *in vacuo*, and the residue extracted and crystallized from diethylether, yielding red crystals. Yield 0.2 g (50%).

NMR [^1H (C_6D_6)]: 1.69s (CH_3), 1.32s (dmpe).

cis-*Dicarbonylpropionato bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.48 g, 1.18 mmol), in diethylether (50 cm^3) at −78°C, was added $EtCO_2H$ (2.5 mmol, 1.8 M in Et_2O). After stirring for 24 h at room temperature, the solvent was removed *in vacuo*, and the residue extracted and crystallized from hexane, yielding red needles. Yield 0.28 g (50%).

NMR [^1H (C_6D_6)]: 1.88q (CH_2), 1.13s (dmpe), 1.08t (CH_3).

cis-*Dicarbonylcyano bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

(i) To *trans*-$V(CO)_2(dmpe)_2$ (0.47 g, 1.15 mmol), in hexane (50 cm^3) at −78°C, was added Me_3SiN_3 (3 mmol, 0.5 M in hexane). After stirring at room temperature for 24 h, the resulting yellow precipitate was collected, washed with hexane (2 × 10 cm^3), filtered and dried. Subsequent extraction into diethylether (50 cm^3), filtration and cooling to −20°C gave orange needles which were collected and dried *in vacuo*. Yield 0.2 g (40%).

(ii) A methanolic solution of NaN_3 (0.1 g, 1.54

mmol) was added to *cis*-$V(CO)_2(dmpe)_2Cl$ (0.31 g, 0.7 mmol) in methanol (30 cm^3) at −78°C. After stirring for 24 h at room temperature, the solvent was removed and the residue extracted into diethylether (50 cm^3). Crystallization as above gave orange needles. Yield 0.25 g (80%).

NMR [^1H (C_6D_6)]: 1.25s (dmpe).

cis-*Dicarbonylcyano bis*-[1,2-*bis*(*dimethylphosphino*) *ethane*] *vanadium*(I)

A methanolic solution of KCN (0.084 g, 1.29 mmol) was added to *cis*-$V(CO)_2(dmpe)_2Cl$ (0.15 g, 1.15 mmol) in methanol (50 cm^3) at −78°C. After stirring at room temperature for 24 h, the solvent was removed and the residue extracted into acetonitrile (60 cm^3). Subsequent filtration, concentration and cooling to −20°C gave yellow needles. Yield 0.37 g (75%).

NMR [^1H (C_6D_6)]: 1.28s (dmpe).

cis-*Dicarbonylphenylphosphinato bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.16 g, 0.39 mmol), in toluene (40 cm^3) at −78°C, was added $PhPO_2H_2$ (56.6 mg, 0.4 mmol). After stirring for 24 h at room temperature, the solvent was removed *in vacuo* and the residue extracted and recrystallized from diethylether, yielding red crystals. Yield 0.13 g (65%).

NMR [^1H (C_6D_6)]: 1.34s (dmpe).

cis-*Dicarbonylsulphamato bis*-[1,2-*bis*(*dimethylphosphino*)*ethane*] *vanadium*(I)

To *trans*-$V(CO)_2(dmpe)_2$ (0.39 g, 0.96 mmol), in thf (60 cm^3) at room temperature, was added NH_2SO_3H (97.4 mg, 1 mmol). After stirring for 24 h, the solvent was evaporated and the residue extracted into toluene (40 cm^3). Concentration and cooling to −20°C of the solution gave red needles. Yield 0.35 g (70%).

Salts of the cation $[HV(CO)_2(dmpe)_2]_2^{2+}$

(a) To *trans*-$V(CO)_2(dmpe)_2$ (0.24 g, 0.59 mmol), in methanol (40 cm^3) at −78°C, was added tetrafluoroboric acid (0.67 M in Et_2O, 0.6 mmol). After allowing the red solution to warm with stirring at room temperature for 24 h the final orange solutions was filtered, concentrated and cooled to −20°C, yielding orange crystals of the tetrafluoroborate as methanol solvate. Yield 0.25 g (42%), m.p. 135°C(d). Conductivity (MeOH, 25°C): $\Lambda_M = 90\ \Omega^{-1}\ cm^2\ mol^{-1}$.

(b) To *trans*-$V(CO)_2(dmpe)_2$ (0.22 g, 0.54 mmol), in toluene (40 cm^3) at room temperature, was added a toluene solution of $HCPh(SO_2CF_3)_2$ (0.19 g, 0.54 mmol) giving an orange precipitate. The reaction mixture was stirred for about 2 h and the solid collected, washed with toluene (2×20 cm^3), and dried *in vacuo*. Yield 0.6 g (79%). $\Lambda_M = 79\ \Omega^{-1}\ cm^2\ mol^{-1}$.

(c) The tetrafluoroborate can be converted to the tetraphenylborate by the addition of $NaBPh_4$ in methanol. However, attempts to recrystallize this salt from acetonitrile lead to the isolation of $[V(CO)_2(dmpe)_2(MeCN)][BPh_4]$.

It has also been noted that on standing in dichloromethane the hydrido species slowly gives $V(CO)_2(dmpe)_2Cl$ as shown by IR.

Crystallography

Crystals were sealed under argon in thin-walled-glass capillaries. All crystallographic measurements were made using a CAD4 diffractometer, operating in the ω–2θ scan mode with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) in a manner described previously.[15] Details are given in Table 8. The structures were solved using routine heavy-atom methods and refined by full-matrix least squares, non-hydrogen atoms anisotropically, hydrogens isotropically. One of the bridging methylenes in the unique dmpe ligands of $V(CO)_2(dmpe)_2$ is disordered over two sites which refine to have 47/53 occupancies. Details of the crystal data, intensity measurement and refinement are given in Table 8.

Sources of scattering factor data and computer programs used are given in Ref. 15; all calculations were made on a DEC VAX 11/750 computer.

Acknowledgements—We thank the SERC for a studentship (F.J.W.) and for X-ray facilities. We also thank Dr A.R. Siedle of Minnesota Mining and Manufacturing for a generous gift of fluoro acids.

KINETIC STUDY OF THE REACTION OF *meso*-TETRAKIS(*p*-TRIMETHYLAMMONIUMPHENYLPORPHINATO)DIAQUOCHROMATE(III) WITH THIOCYANATE IONS

J. G. LEIPOLDT* and H. MEYER

Department of Chemistry, University of the Orange Free State, Bloemfontein, Republic of South Africa

(*Received* 2 *January* 1985; *accepted* 1 *December* 1986)

Abstract—The reaction of *meso*-tetrakis(*p*-trimethylammoniumphenylporphinato)-diaquochromate(III), $[CrTAPP(H_2O)_2]^{5+}$, with NCS^-, has been studied at 15, 25 and 35°C in 0.1 M H^+ with $\mu = 1.00$ M ($NaNO_3$). The reaction is first-order in anion concentration up to 0.9 M. The value of the second-order rate constant at 25°C is 4.2×10^{-3} $M^{-1}\,s^{-1}$ with $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ having values of 16.2 kcal mol^{-1} and -15.3 cal (deg mol)$^{-1}$, respectively. The porphine ligand greatly labilizes the chromium(III) toward substitution. High-pressure kinetic data ($\Delta V^{\ddagger}_{exp} = 9.2$ cm^3 mol^{-1}) indicate that the reaction proceeds via an I_d-mechanism.

It is well-known that the porphine ligand labilizes the axial positions in complexes of cobalt(III), rhodium(III) and chromium(III).[1–7] The extent of labilization is dependent upon the other metal complex to which it is being compared. If the reactivity of the porphine complex is compared with the reactivity of the pentaammineaquo complexes, it is found that the labilization is about 10^9, 10^3 and 10^2 for the TPPS [TPPS = *meso*-tetra(*p*-sulphonatophenyl)porphine] complexes of cobalt(III),[3,8] rhodium(III)[4,8] and chromium(III),[5,8] respectively.

The extent of labilization depends not only on the particular central metal ion, but also on the particular porphine. The anation reactions of $[CoTPPS(H_2O)_2]^{3-}$ are, for example, about 100 times faster than those of $[CoTMPP(H_2O)_2]^{5+}$ [TMPP = *meso*-tetra(4-*N*-methylpyridyl)porphine],[1,3] while the anation reactions of $[CrTPPS(H_2O)_2]^{3-}$ are only about 6 times faster than those of $[CrTMPP(H_2O)_2]^{5+}$.[5,6]

It has been suggested that the anation reactions of $[CrTPPS(H_2O)_2]^{3-}$ and $[CrTMPP(H_2O)_2]^{5+}$ proceed via an I_d-mechanism.[5,6] Strong support for this view was recently obtained from a high-pressure kinetic study of the reaction between $[CrTPPS(H_2O)_2]^{3-}$ and NCS^-.[9]

In an effort to gain more insight into the mechanism of the substitution reactions of chromium(III) porphines, we have decided to extend this work to the anation reactions of another water-soluble porphine, the [*meso*-tetrakis(*N*-trimethylammoniumphenyl)porphine (TAPP)] complex of chromium(III).

EXPERIMENTAL AND RESULTS

The iodide salt of TAPP was synthesized as described by Krishnamurthy.[10] The chromium complex of this porphine was synthesized in the same way as $[CrTPPS(H_2O)_2]_3^{3-}$: 100 mg of the iodide salt of TAPP was dissolved in 100 cm^3 dimethylformamide. While the solution was refluxed and purged with nitrogen gas, about 200 mg of chromium hexacarbonyl (an excess) was added in small portions over a period of about 2 h, until all the free porphine were converted into the chromium complex as indicated by the visible spectrum. The solution was allowed to cool to room temperature and 500 cm^3 of diethylether was added to precipitate the chromium(III) complex. The precipitate $\{[CrTAPP(H_2O)_2]I_5\}$ was washed with ether and allowed to dry in the atmosphere at room temperature.

The wavelength of the Soret band for this complex in an acidic medium is at 444 nm with a molar

* Author to whom correspondence should be addressed.

absorptivity of 1.59×10^4 M^{-1} cm^{-1}, and in an alkaline medium at 445 nm with a molar absorptivity of 1.053×10^4 M^{-1} cm^{-1}.

The acid dissociation constants were determined by means of a pH titration. Taking into account the mass balance, Beer's law, and the definition of K_{a1} and K_{a2}, we can write the following equation:

$$A = \frac{A_b K_a + A_a[H^+]}{K_a + [H^+]}, \quad (1)$$

where A is the absorbance at a particular pH, A_b the absorbance of the deprotonated form, A_a the absorbance of the protonated form, and K_a is either K_{a1} or K_{a2} in Scheme 1. K_{a1} was obtained by fitting the absorbance vs $[H^+]$ data, by using a nonlinear least-squares program,[11] to eqn (1). The value of K_{a1} was determined as $4.68\ (\pm 0.76) \times 10^{-8}$ M at 25°C and $\mu = 1.00$ M ($NaNO_3$). This value is a good agreement with the corresponding value for $[CrTPPS(H_2O)_2]^{3-}$,[5] and significantly lower than K_{a1} for $[CrTMPP(H_2O)_2]^{5+}$.[6] We were unable to determine the value of K_{a2} due to the small change in the absorbance with pH in the pH region of the expected value for K_{a2}.

It was not possible to determine the equilibrium constant for the reaction of this complex with NCS^- due to the formation of a precipitate during the reaction. One would expect a value of about 2 M^{-1} for K_1 (Scheme 1) as was the case for the complexes $[CrTPPS(H_2O)_2]^{3-}$ and $[CrTMPP(H_2O)_2]^{5+}$.[5,6]

The anation reactions of $[CrTAPP(H_2O)_2]^{5+}$ by NCS^- were studied at 15, 25 and 35°C in 0.1 M HNO_3 and $\mu = 1.00$ M ($NaNO_3$). It was established that the reaction rates are $[H^+]$-independent at $[H^+] > 10^{-3}$ M. This clearly indicates that $[CrTAPP(H_2O)_2]^{5+}$ is the only reactive species under the experimental conditions.

The rate law for the anation reactions at low pH values is

$$-\frac{d[CrTAPP(H_2O)_2^{5+}]}{dt} = (k_1[NCS^-] + k_{-1})[CrTAPP(H_2O)_2^{5+}]. \quad (2)$$

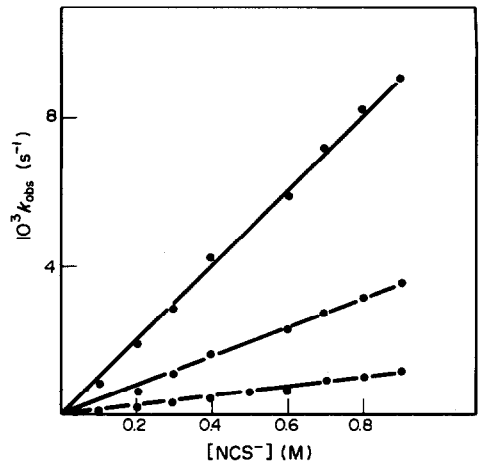

Fig. 1. Plot of k_{obs} vs $[NCS^-]$ at $[H^+] = 0.1$ M ($\mu = 1.0$ M).

All kinetic studies were performed under pseudo-first-order conditions with:

$$k_{obs} = k_1[NCS^-] + k_{-1}. \quad (3)$$

Figure 1 is a plot of k_{obs} vs $[NCS^-]$. The values of k_1 are reported in Table 1. The values of k_1, and particularly those of k_{-1}, were not as accurate as one would like as a result of the formation of a precipitate near the completion of the reaction. The activation parameters (ΔH^+ and ΔS^+) were calculated by means of a nonlinear least-squares fit[11] of the values of k_1 vs temperature to the Eyring–Polanyi equation. These values are given in Table 1.

The high-pressure kinetic data were obtained in a thermostated (± 0.1°C) high-pressure cell[12] coupled to a Zeiss PMQ II spectrophotometer. The results are summarized in Tables 1 and 2.

DISCUSSION

The data in Table 1 clearly indicate that labilization of the chromium(III) ion has been effected by the porphine. The extent of labilization due to TAPP is dependent on the comparison reaction and is, for example, 2700 and 100 compared to $[Cr(H_2O)_6]^{3+}$[13] and $[Cr(NH_3)_5H_2O]^{3+}$,[14] respect-

$$[CrTAPP(H_2O)_2]^{5+} + NCS^- \underset{k_{-1}}{\overset{K_1, k_1}{\rightleftharpoons}} [CrTAPP(H_2O)(NCS)]^{4+} + H_2O$$

$$K_{a1}, -H^+ \Big\| \Big\uparrow +H^+$$

$$[CrTAPP(H_2O)(OH)]^{4+}$$

$$K_{a2}, -H^+ \Big\| \Big\uparrow +H^+$$

$$[CrTAPP(OH)_2]^{3+}$$

ively. This is clearly not as great as the labilization effect in the case of the cobalt(III) complexes.[3,8]

The anation reaction rate constant for the reaction between $[CrTAPP(H_2O)_2]^{5+}$ and NCS^- is about the same as for the corresponding reaction of $[CrTPPS(H_2O)_2]^{3-}$,[5] and about 6 times faster than the corresponding reaction of $[CrTMPP(H_2O)_2]^{5+}$ [6] (see Table 1). The overall charge on the complex thus plays a minor role in the reaction process. In this respect it is important to note that the overall charge is spread over a large planar surface area, and that the negatively charged sulphonato groups and the positively charged trimethylammonium groups are removed far from the reaction metal centre. The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are about the same for the three different porphine complexes of chromium(III). The similarity of the activation parameters and the rate constants for the three porphine complexes (see Table 1) clearly indicate a common reaction mode.

The value of the volume of activation for the reaction between $[CrTAPP(H_2O)_2]^{5+}$ and NCS^- (9.2 cm^3 mol^{-1}) is also about the same as for the corresponding reaction of $[CrTPPS(H_2O)_2]^{3-}$, and may be interpreted as evidence for a dissociative interchange mechanism. This reaction mechanism may be represented as follows:

$$[CrTAPP(H_2O)_2]^{5+} + NCS^- \underset{}{\overset{K}{\rightleftharpoons}} [CrTAPP(H_2O)_2^{5+}, NCS^-], \quad (4)$$

$$[CrTAPP(H_2O)_2^{5+}, NCS^-] \xrightarrow{k_2} [CrTAPP(H_2O)(NCS)]^{4+} + H_2O.$$

The pseudo-first-order reaction rate constant for this mechanism is given by eqn (5):

$$k_{obs} = k_2K[NCS^-]/(1+K[NCS^-]). \quad (5)$$

This relationship between k_{obs} and NCS^- simplifies to:

$$k_{obs} = k_2K[NCS^-] \quad (6)$$

because no curvature in the k_{obs} vs $[NCS^-]$ plot was observed (see Fig. 1) and K is expected to be small.

It follows from eqns (3) and (6) that:

$$k_1 = k_2K.$$

According to this equation:

$$\Delta V^{\neq}_{exp} = \Delta V^{\neq}(k_2) + \Delta V(K)$$

$\Delta V(K)$ is expected to be close to zero: although there is an overall reduction of charges, the positive charges are very far removed from the negative charge on the NCS^- ligand, so that it is not expected that this formal overall reduction of charges would have a significant influence on $\Delta V(K)$. This charge reduction during the pre-equilibrium, in contrast to the charge concentration in the case of the $[CrTPPS(H_2O)_2]^{3-}$ reaction, may be used to explain the slightly higher value of $\Delta V^{\neq}_{exp}$ for the $[CrTAPP(H_2O)_2]^{5+}$ reaction.

The activation volume for the reaction between $[Cr(NH_3)_5H_2O]^{3+}$ and NCS^- [8] points to {in contrast to the activation volume for the anation reaction of $[CrTAPP(H_2O)_2]^{5+}$} an associative acti-

Table 2. k_{obs} as a function of pressure for the anation of $[CrTAPP(H_2O)_2]^{5+}$ by NCS^- at 15°C, $[H^+] = 0.1$ M and $[NCS^-] = 0.9$ M

vation (see Table 1). These results indicate that the labilization of the axial water molecules is accompanied by promoting a dissociative activation. The labilization effect of the porphine ligand, and its capability to promote a dissociative activation, may be explained by its capability to donate electron density to the central metal ion making the chromium(III) d^3, more like a labile d^4 chromium(II) ion, and also stabilizes the five-coordinate intermediate in a dissociative reaction mode.

This phenomenon of promoting a dissociative mechanism (with the corresponding labilization) was also observed in the case of the rhodium(III) and cobalt(III) complexes of TPPS.[9] The high-pressure kinetic data clearly point to a D- and a I_d-mechanism for the anation reactions of $[CoTPPS(H_2O)_2]^{3-}$ and $[RhTPPS(H_2O)_2]^{3-}$, respectively, while an I_d- and an I_a-mechanism were proposed for the anation reaction of the penta-ammineaquo complexes of cobalt(III) and rhodium(III), respectively.[8,9,15]

(*Received* 28 *October* 1986; *accepted* 1 *December* 1986)

Abstract—The complex species formed in aqueous solution between Be(II) and nitrilotriacetic acid (NTA), methyl-*C*-nitrilotriacetic acid (MNTA), nitrilodiaceticpropionic acid (NDAP), nitriloaceticdipropionic acid (NADP) and nitrilotripropionic acid (NTP) were studied at 25°C and ionic strength 0.5 M in $NaClO_4$. The application of the calculus program LETAGROP to the experimental potentiometric data, taking into account hydrolysis of the ion Be(II), indicates that, upon varying the ligand–metal relationships, the following complex species are formed (H_3C ligands): NTA($[BeC]^-$, $\log K = 6.84$); MNTA ($[BeC]^-$, $\log K = 7.39$; BeHC, $\log K = 1.79$); NDAP ($[BeC]^-$, $\log K = 8.10$; BeHC, $\log K = 1.96$; $[BeH_2C]^+$, $\log K = 1.37$); NADP ($[BeC]^-$, $\log K = 9.25$; BeHC, $\log K = 2.37$); and NTP ($[BeC]^-$, $\log K = 9.23$). The values of the stability constants ($[BeC]^-$, $\log K$) indicate the following order of coordinating capacity: NTA < MNTA < NDAP < NADP ≃ NTP. This order is attributed to the increase in propionic groups. It has been confirmed that six-membered ring chelates are the most stable for Be(II), in a similar manner to other elements of the first short period, such as boron and carbon, while Cu(II), Ni(II), lanthanides and other heavier elements prefer five-membered ring chelates.

In our studies in aqueous solution of the EDTA–Be(II)[1,2] (EDTA = ethylenediaminetetraacetic acid) and IDA–Be(II)[3] (IDA = iminodiacetic acid) systems we have found upon analysing the experimental potentiometric data by means of the NERNST/LETA/GRAFICA[4] version of the LETAGROP[5] program, that the species resulting from the hydrolysis of Be(II) must be taken into consideration in the calculations in order to determine the complex species present in the solution and to obtain correct values of the stability constants. Otherwise, the values obtained are higher than the true ones, since the acidity due to hydrolysis of the non-complexed Be(II) is included in the value of the stability constants obtained.

Be(II) tends to tetracoordination.[6] EDTA,[1,2] a potentially hexadentate ligand, forms the complexes $[BeHC]^-$ and $[BeC]^{2-}$ (H_4C ligand). IDA,[3] a potentially tridentate ligand, only forms the monohydroxide complex $[Be(OH)C]^-$ (H_2C ligand) in significant amounts, OH^- occupying the fourth place in coordination. Nitrilotriacetic acid (NTA), a potentially tetradentate ligand, fulfils the coor-

* Author to whom correspondence should be addressed.

dination requirements of Be(II). However, the data available in the literature are contradictory: Dyatlova *et al.*[7,8] affirm that the species BeHC, $[BeC]^-$ and $[BeC(HC)]^{3-}$ (H_3C ligand) are formed with NTA. Stary,[9] by extraction with oxine in $CHCl_3$, found $\log K = 7.11$, at $I = 0.1$ M in $NaClO_4$ and 20°C, for the stability constants of the complex $[BeC]^-$. Other authors[10–12] also determined the stability constant of the complex $[BeC]^-$ from potentiometric measurements in aqueous solution, but the results are contradictory and no reference is made to whether or not the hydrolysis of Be(II) was taken into account in the calculations involved. Votava and Bartušek[10] also studied the NTP–Be(II) (NTP = nitrilotripropionic acid) system and found that the complex $[BeC]^-$ is slightly more stable with NTP than with NTA, contrary to the general belief,[13] still upheld,[14] that five-membered chelate rings provide greater stability than any other size of chelate ring.

It therefore seemed worthwhile to study the influence of the length of the chelate rings on the stability of complexes with Be(II). As well as re-examining the NTA–Be(II) and NTP–Be(II) systems, the MNTA–Be(II) (MNTA = methyl-*C*-nitrilotriacetic acid), NDAP–Be(II) (NDAP- = nitrilodiaceticpropionic acid), and NADP–Be(II) (NADP = nitriloaceticdipropionic acid) systems were also studied. The studies were carried out in aqueous solution at 25°C and $I = 0.5$ M in $NaClO_4$. The only work known on the NTP–Be(II) system is the above-mentioned report of Votava and Bartušek.[10] No reference was found in the literature to the MNTA–Be(II) and NADP–Be(II) systems.

Be(II) is perhaps the most toxic of metallic cations[15] and ligands containing propionic groups may be better sequestering agents.

EXPERIMENTAL

Reagents

NTA. The product used was supplied by Merck, of analytical grade and previously recrystallized.

MNTA. The method of preparation by Irving and Miles[16] was very slow and gave a low yield. It was therefore modified as follows: a solution of α-alanine in a small amount of water was made to react with previously neutralized chloroacetic acid, by heating to 90°C and maintaining the pH between 8 and 9 with NaOH. After addition of NaOH, magnetic stirring was continued for 4 h and the Cd(II) salt was precipitated by adding a theoretical amount of $Cd(NO_3)_2$, aided by ethanol. The Cd(II) salt was filtered and washed with a 50% water–ethanol mixture, suspended in a small amount of water and through this a current of H_2S was then passed. The CdS was separated by filtration. The solution was concentrated in a steam bath, through which a current of argon was passed in order to remove the excess of H_2S, concentrated in a rotavaporator and left to crystallize. The acid was purified by recrystallization in water–ethanol mixtures. This procedure afforded the acid in a high state of purity and within a short period (3–4 days), although the yields were also low.

NDAP. The method of Pratt and Smith[17] was modified in order to obtain the acid in a high degree of purity, following the method employed by Souchay *et al.*[18] in the preparation of some derivatives of iminodiacetic acid: β-alanine was made to react with previously neutralized chloroacetic acid. After formation of the Ba(II) salt, the acid was obtained with conc. H_2SO_4 in good yield.

NTP. This was prepared by reacting β-alanine with β-chloropropionic acid, according to the procedure indicated by Chaberek and Martell,[19] adapted by Votava and Bartušek.[10] The yield was good.

NADP. This acid was prepared analogously to NTP, by reacting glycine with β-chloropropionic acid, again with a good yield.

The acids were identified by their potentiometric equivalents, ^1H NMR and mass spectra.

The solution of $Be(ClO_4)_2$ was prepared by reacting metallic Be (Spex Industries Inc.) with an excess of $HClO_4$ (Merck, analytical grade), its free acidity[20] being determined, as well as the concentration of Be(II) in aqueous solution which was evaluated gravimetrically.[21,22] A carbonate-free sodium hydroxide solution was prepared according to the School of Sillén[23] and standardized against potassium hydrogen phthalate. $NaClO_4$ was prepared by recrystallization of $NaClO_4$ (Merck, analytical grade).

Apparatus and titration procedures

The potentiometric titrations were carried out in inert argon atmosphere, at 25±0.05°C, $I = 0.5$ M in $NaClO_4$, using a Radiometer Type PHM-64 potentiometer, a Radiometer G 202 B glass electrode and a K 401 calomel electrode. The cell constants were determined according to the method of Biedermann and Sillén,[24] the liquid junction potentials being found to be negligible within the margins of $[H^+]$ studied. It was found that $pK_w = 13.72$, in excellent agreement with reported data.[25]

Measurements were taken of the ligands alone at the following concentrations: NTA ($C_L = 5$ mM), MNTA($C_L = 3.7$ and 4.7 mM), NDAP ($C_L = 10$

and 20 mM), NADP (C_L = 4.7 and 5.2. mmM), and NTP (C_L = 2.1 and 2.5 mM); and the ligands in the presence of Be(II) at the following concentrations and ligand : metal ratios : C_M = 0.8 and 1.2 mM, ratios 1 : 1, 2 : 1, 4 : 1 and 6 : 1, for NTA; C_M = 1.5, 3.2 and 12.0 mM, ratios 2 : 1, 1 : 1 and 1 : 2, for MNTA; C_M = 10, 15 and 20 mM, ratios 2 : 1, 1 : 1 and 1 : 2, for NDAP; C_M = 2.0, 5.0 and 9.7 mM, ratios 2 : 1, 1 : 1 and 1 : 2, for NADP; and C_M = 2.3 mM, ratios 2 : 1 and 1 : 1, for NTP.

The normal titration procedure could not be employed for the potentiometric titrations of NTP acid in the presence of Be(II) because of the long time required to reach the equilibria (up to 3 h between two consecutive additions of NaOH). This problem was overcome by preparing individual beakers with solutions of the NTP–Be(II) system at different pH values (25°C and I = 0.5 M in $NaClO_4$), shaking each solution for 24 h and then measuring the potentials when equilibrium was reached in each titration cell.

Data treatment

The experimental potentiometric data were analysed by means of the NERNST/LETA/GRAFICA version[4] of the LETAGROP program,[5] based on a generalized form of the least-squares method that establishes the best model and best values of the β_{pqr} constants, minimizing the function $U = \Sigma(Z_{exp} - Z_{calc})^2$, Z being the average number of dissociated protons for the concentration of ligand (Z_C) or for the total concentration of metal (Z_B). The LETAGROP calculations also give standard deviations $\sigma(Z)$ and $\sigma(\log \beta_{pqr})$.[26] The computations were performed on a Burroughs 6700 computer (Facultad de Ciencias, Universidad Central de Venezuela, Caracas).

Hydrolysis of Be(II) was previously studied under the same experimental conditions.[3]

RESULTS

Ionization constants of the acids

From the values obtained for the constants β_{pr} corresponding to equilibrium (1):

$$pH^+ + rH_3C \rightleftharpoons [H_p(H_3C)_r]^{p+}, \qquad (1)$$

the ionization constants of the acids (K_i) given in Table 1 could readily be determined.

The values of pK_1, pK_2 and pK_3 are in good agreement with those found for NTA at 25°C and I = 0.5 M,[27–29] and with those found for MNTA at 25[30] and 20°C,[16,31] and I = 0.1 M; for NDAP at 25,[30,32] 20[33] and 30°C,[19] and I = 0.1 M; for NADP at 30°C and I = 0.1 M;[19] and NTP at 25,[34] 20[10] and 30°C,[19] and I = 0.1 M. The value of pK_0

(H_4C^+–H_3C equilibrium) is in good agreement with that for NTP.[34] For NDAP and NADP the values of pK_0 are obtained for the first time. For NTA at 20°C and $I = 0.1$ M in KCl, $pK_0 = 0.8 \pm 0.2$.[35]

The order of basicity NTA < NDAP < NADP < NTP is in agreement with the substitution of acetic groups by propionic groups having a greater inductive electron donor effect because of another CH_2 group.[18] The values of pK_0, pK_1 and pK_2 correspond to fundamentally carboxylic protons.[19] The values of pK_3 (HC^{2-}–C^{3-} equilibrium) for all the ligands are in agreement with the protonation of the N atom in aqueous solution.[36] The order of basicity for pK_3 (MNTA > NTA) is explained by the inductive electron donor effect of the methyl radical on the N atom in MNTA. The diagrams of the distribution of species as a function of $-\log[H^+]$, calculated in accordance with the values of $-\log\beta_{pr}$ given in Table 1, show that the monoprotonated species HC^{2-}, with a betaine structure, is the most stable species and occupies the greatest field, and also that the species containing protonated carboxylic groups improve the stability as the number of propionic groups increases. The diagram corresponding to NDAP is represented in Fig. 1.

Stability constants of the complexes formed

The analysis of the experimental data of the Be–ligand systems studied by the NERNST/LETA/GRAFICA version[4] of the LETAGROP program[5] allowed us to calculate the β_{pqr} constants for the complex species formed for each ligand, defined by means of equilibrium (2):

$$pH^+ + qBe^{2+} + rH_3C \rightleftharpoons [H_pBe_q(H_3C)_r]^{(p+2q)+}. \quad (2)$$

Taking into account the species resulting from the massive ionizations of the ligand (H_4C^+, H_3C, H_2C^-, HC^{2-} and C^{3-}) as well as the hydrolytic species of Be(II) existing in the area of calculus, i.e. $[Be_2(OH)]^{3+}$ and $[Be_3(OH)_3]^{3+}$ (whose formation constants at this temperature and ionic strength have been calculated by us in a previous work[3]), the results that best fit the experimental results are those given in Table 2. Although models were tested that included the possible presence of the hydroxy complex $[Be(OH)C]^{2-}$, and complex species with excess of ligand and excess of metal, the results indicate that they are not present in significant amounts. The validity of this analysis can be checked in Fig. 2 for the NDAP–Be(II) system, where an excellent fit can be observed between the experimental Z_B vs $-\log[H^+]$ curves and those calculated from the values of β_{pqr} given in Table 2. Analogous curves are obtained for the other four systems. In Fig. 2 it can be observed that the limit values of Z_B ($Z_B \rightarrow$ 5, 3 and 2, respectively, for ligand : metal ratios of 2 : 1, 1 : 1 and 1 : 2) are those expected for the formation of the complex $[BeC]^-$ and the non-formation of the complex $[Be(OH)C]^{2-}$.

The values of $\log K$ corresponding to the stability constants of the complex species found for the different ligands studied are also given in Table 2, being readily obtained from the values of the β_{pqr} in Table 2, and taking into account the values of the β_{pr} constants of the acids presented in Table 1.

The data in tables 1 and 2 also readily afford the

pK $[BeH_2C]^+$		3.06	

The values found in the literature for log K of the complex $[BeC]^-$ in the case of NTA and NTP are also given in Table 2. The values obtained for NTA by Votava and Bartušek,[10] Fraústo da Silva[11] and Dubey *et al.*[12] are approximately one unit of log K greater than those found by us, probably attributable to the fact that the hydrolysis of Be(II) was not taken into account by these authors. The value found by Stary,[9] although somewhat greater, is the closest to our own, which is explained perfectly by the lower ionic strength (0.1 M in $NaClO_4$) and temperature (20°C). Moreover, the method used by Stary was extraction in oxine with $CHCl_3$, operating at pH ≃ 6, taking care that hydrolysis of Be(II) exerted a negligible influence. For NTP, the value found by Votava and Bartušek[10] is much smaller than that obtained by us. These authors did not take into account the hydrolysis of Be(II) in their calculations and affirm that the constant of the complex $[BeC]^-$ was calculated within a very small range of pH values. However, we consider that the much lower value of log K found by Votava and Bartušek[10] is due to the kinetic process that takes place in the NTP–Be(II) system in aqueous solution, which compelled us to operate in a different manner in order to achieve the equilibria, as indicated in Experimental. Votava and Bartušek do not report in their work[10] that the kinetic process takes place and probably performed the potentiometric measurements without the equilibrium having been reached.

DISCUSSION

In comparison with IDA and analogues[3] (tridentate coordinating agents) that form the

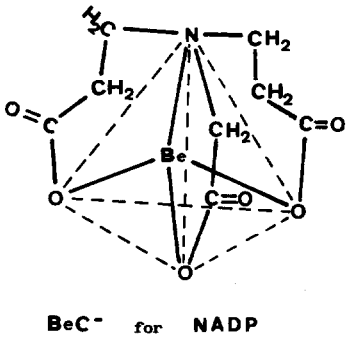

Fig. 3. Structure proposed for the complex $[BeC]^-$ with NADP.

monohydroxycomplex $[Be(OH)C]^-$ (H_2C ligands) as the most stable species, the formation of the species $[BeC]^-$ as the most stable in NTA and analogues (H_3C ligands) implies that these ligands act vs Be(II) as tetradentate coordinating agents, coordinating the N atom and the three carboxylate groups. The tendency of Be(II) to attain tetrahedral coordination[6] is totally fulfilled. The complex $[BeC]^-$ for NADP acid is represented in Fig. 3. Tetrahedrons are analogous for the other ligands. The coordination of the N atom of NTA acid to Be(II) has been manifested by Grigor'ev[37] upon analysing the IR spectrum of the complex $BeHC \cdot 2H_2O$, obtained in a crystalline state.

The following order of stability (Table 2), NTA < MNTA < NDAP < NADP ≃ NTP, is found for the complex $[BeC]^-$. The order NTA < MNTA is explained in that the electron donor nature of the radical CH_3 exerts a positive inductive effect that is superimposed on the steric repulsion exerted by the same radical on the coordinated Be(II), thus strengthening the N—Be bond in an overall manner. The sequence that follows implies an increase in the stability of the complex $[BeC]^-$ as the number of propionic groups coordinated to Be(II) increases, and is analysed below.

The diagrams of the distribution of species of Be(II) as a function of $-\log[H^+]$ was calculated from the values of β_{pr} given in Table 1, β_{pqr} in Table 2, and β_{pq} presented in an earlier work.[3]

The distributions of species of Be(II) as a function of $-\log[H^+]$ are presented in Figs 4–6 for NTA, NDAP and NADP, respectively ($C_{Be} = 1$ mM, ligand : metal ratios 1 : 1 and 3 : 1). The diagram corresponding to MNTA is analogous to that of NTA, with the sole difference that the monoprotonated species BeHC is present in a small amount. The diagram corresponding to NTP is identical with that of NADP, with the exception of the negligible formation of the species BeHC for NTP.

An analysis of the diagrams shows that the complex species are formed directly from the $[Be(H_2O)_4]^{2+}$, which is the non-hydrolysed species present in aqueous solution.[6,38,39] If these diagrams are compared with those of the acids alone (Fig. 1) it is found that the complex species are fundamentally

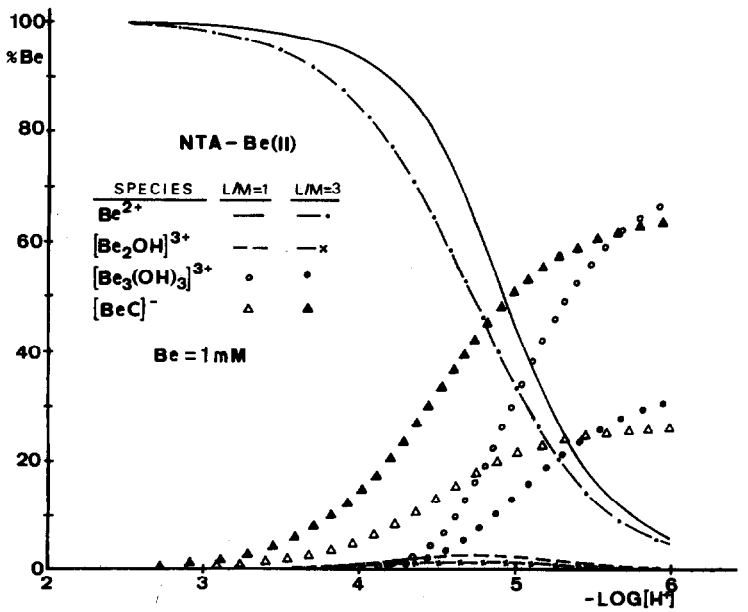

Fig. 4. Species distribution as a function of $-\log[H^+]$ for the NTA–Be(II) system.

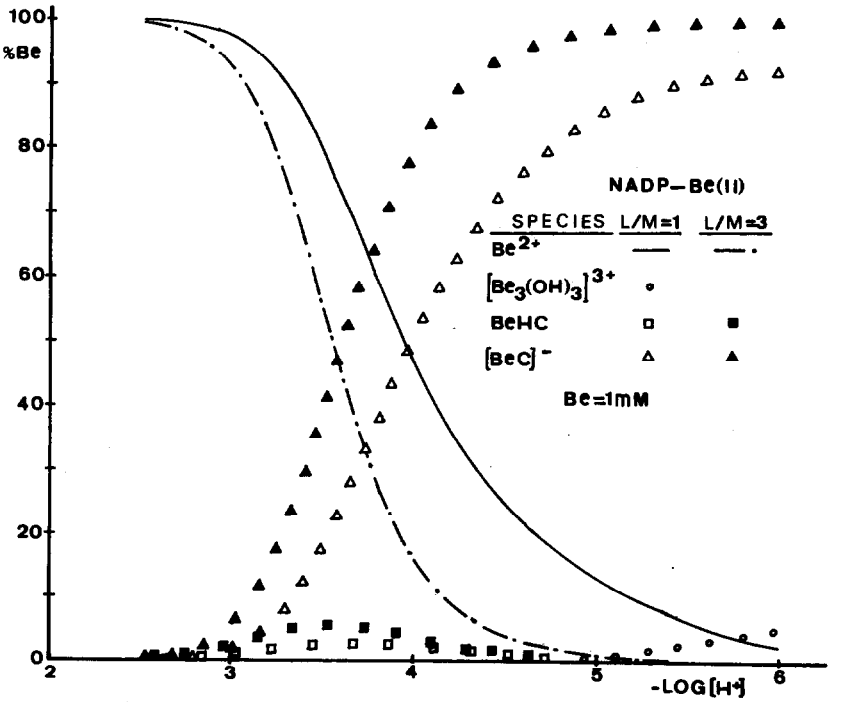

Fig. 6. Species distribution as a function of $-\log[H^+]$ for the NADP–Be(II) system.

formed from the equilibria:

$$[Be(H_2O)_4]^{2+} + H_3C \rightleftharpoons [Be(H_2C)(H_2O)_2]^{+} + H^{+} + 2H_2O, \quad (3)$$

$$[Be(H_2O)_4]^{2+} + H_2C^{-} \rightleftharpoons Be(HC)(H_2O) + H^{+} + 3H_2O, \quad (4)$$

$$[Be(H_2O)_4]^{2+} + HC^{-} \rightleftharpoons [BeC]^{-} + H^{+} + 4H_2O. \quad (5)$$

Equilibrium (5) gives $Z \rightarrow 3$ when the complex $[BeC]^{-}$ is formed (Fig. 2), implying also the coordination of the N atom upon displacement by Be of the betaine proton of the most stable protonated species of the ligand HC^{2-}, accounting in turn for the much greater stability of the complex species $[BeC]^{-}$. In the species $[BeH_2C]^{+}$ and BeHC, the ligand is bidentate and tridentate, respectively, bonding only carboxylate groups to the metal and maintaining the betaine proton, which explains the low stability of these protonated species and the fact also that these are practically not formed by the more symmetric ligands NTA and NTP. Upon raising the pH, of course, the species $[BeH_2C]^{+}$ is transformed into BeHC and the latter into $[BeC]^{-}$.

The species distribution diagrams (Figs 4–6) explain the order of stability of the species $[BeC]^{-}$ in more detail: at a 1 mM concentration of Be(II) and in a ligand: metal ratio of 1:1 for NTA only 25% is complexed at pH 5–6, reaching 65% at a 3:1 ratio. Figure 4 thus justifies the study of the NTA–Be(II) system in Experimental, with ligand: metal ratios of up to 6:1. For NDAP (Fig. 5), under the same experimental conditions, 70% of Be(II) is complexed at pH 5–6 at a ratio of 1:1, attaining almost 100% at a ratio of 3:1. These percentages rise for NADP (Fig. 6) to 90% at a ratio of 1:1, and 100% at a ratio of 3:1. NTP behaves in an identical manner. The non-complexed Be(II) undergoes hydrolysis to form mainly the species $[Be_3(OH)_3]^{3+}$. The practical disappearance of this species at a ligand: metal ratio of 3:1 can be observed in Figs 5 and 6.

The stability sequence found in this work for Be(II), NTA < MNTA < NDAP < NADP ~ NTP, is precisely the opposite of that generally found for other heavier cations such as Cu(II) and Ni(II), as manifested by the data given in Table 3.

These and other results for 3*d* transition and alkaline earth cations led to the conclusion that the decrease in stability upon passing from five- to six-membered chelate rings was a general phenomenon for all metals and polydentate ligands,[13] a belief which is still widespread.[14] This phenomenon was also found to take place in the case of lanthanide chelates with NTA, MNTA and NDAP,[43] as well as in other polyaminocarboxylic acids.[44]

However, contrary to general belief, this phenomenon whereby five-membered chelate rings are more stable than six-membered ones is not common. Indeed, it seems to hold true for central atoms with atomic numbers greater than 10, in which coordination numbers greater than 4 predominate. It has been found that first short period elements, among which Be and B readily form complexes, prefer six-membered chelate rings, in a similar manner to organic compounds having a tetrahedral carbon. Evidence of this phenomenon has been found for complexes of B(III)[45,46] and Be(II).[10,47,48] The present work confirms that for Be(II) six-membered chelate rings are more stable than five-membered ones, analogously to B and C. With regard to the small central atom belonging to the first short period, which is coordinated with a tetrahedral geometry, six-membered chelate rings are puckered with tetrahedral links, and are submitted to fewer strains than five-membered rings. The opposite occurs for larger atoms, such as Ni: structural and ^1H NMR studies indicate that six-membered rings are puckered much more and are submitted to more steric strains than five-membered rings.[17] The step from a tetrahedral to an octahedral geometry, when the volume of the central cation increases, must exert an influence on this change in the stability of the chelate rings. The results obtained in this work show that the stability of the complex $[BeC]^{-}$ is practically the same for NADP and NTP. That is, the third six-membered ring no longer increases

Table 3. Stability constants of the complexes of NTA, NDAP, NADP and NTP with Cu(II) and Ni(II)

	NTA[a]	NDAP[a]	NADP[b]	NTP[b]	NTP[c]
Log *K*, Cu(II)	13.1	12.6	11.9	9.1	8.83
Log *K*, Ni(II)	11.5	11.4	9.1	5.8	5.64

[a] 25°C, $I = 0.1$ M.[27,40 42]
[b] 30°C, $I = 0.1$ M in KCl.[19]
[c] 25°C, $I = 0.1$ M in KNO_3.[34]

the stability with respect to the five-membered ring (Fig. 3, complex $[BeC]^-$ with NADP). This must be attributed to the fact that the third ethylene group (CH_2—CH_2) in the case of NTP undergoes steric repulsion on the part of the other two, that compensate the increase in stability which would correspond to the third six-membered ring. In the case of a ligand : metal ratio of 1 : 1 with NTA, models show that when all three carboxylate groups are bonded (the rings are now five-membered), the three chelate rings are not all equivalent, and one at least is strained.[17]

(*Received* 1 *September* 1986; *accepted* 5 *December* 1986)

Abstract—*N*-nitroso-*N*-alkylhydroxylamines have been prepared by hydrolysis of the mixture obtained by reaction of nitric oxide with Grignard reagents, and stabilized as their copper(II) or iron(III) complexes, $Cu(RN_2O_2)_2$ and $Fe(RN_2O_2)_3$, where R is, for example, Me, Et, Pr^i, Bu^{iso}, Ph, n-C_8H_{17} or n-$C_{12}H_{25}$. The complexes have been characterized by analytical, magnetic and spectroscopic measurements. By single-crystal X-ray methods $Cu(Pr^iN_2O_2)_2$ has been found to be *trans*-planar and $Fe(Pr^nN_2O_2)_3$ has a facial octahedral structure; in each complex the N—O bond lengths are equal with no significant variation between the copper and iron complexes.

The action of nitric oxide on alkyl compounds of diamagnetic metal atoms usually yields[1–16] the corresponding *N*-nitroso-*N*-alkylhydroxylamine derivative [eqn (1)]:

$$R—M+2NO \rightarrow (RN_2O_2)M. \quad (1)$$

As with cupferron (R = phenyl) complexes,[17–19] the hydroxylamate ligand is chelated and coordinates through the two oxygen atoms in the X-ray crystallographic structures reported[8,10,11,13,16–19] to date. Diamagnetic metals in eqn (1) include zinc,[1,2,12] magnesium,[2–6] cadmium,[2] boron,[2] aluminium,[2,7,8] gallium,[8] zirconium,[9,10] tungsten,[11,12] copper(I),[12] niobium,[13,14] tantalum,[13,14] titanium,[9,15] rhenium(III)[16] and rhodium(I).[12] For some paramagnetic metal ions, for example, vanadium(IV),[14] and titanium(III),[14] the *N*-nitroso-*N*-alkylhydroxylamine derivatives cannot be prepared directly through eqn (1) while the reaction[20] of a low-valent cobalt nitrosyl with an alkyl halide afforded the nitrosoalkane complex.

Chemical identification of the products in eqn (1) was first carried out by Sand and Singer.[3] They showed that the action of nitric oxide on phenylmagnesium bromide followed by hydrolysis gave the free acid *N*-nitroso-*N*-phenylhydroxylamine (cupferron), identified because its reactions were the same as those of the product[21] obtained by the action of nitrous acid on *N*-phenylhydroxylamine. The free acid could not be isolated on hydrolysis of the nitric oxide–methylmagnesium iodide reaction mixture, but Sand and Singer[3] did obtain a copper(II) complex, $Cu(MeN_2O_2)_2$, on treatment of the product with copper(II) oxide. There are scattered references to copper(II) complexes of various other *N*-nitroso-*N*-alkylhydroxylamines, but little other than their preparation[1,3,5,9,12] and fungicidal properties[22] have been reported.

We present here a convenient route to *N*-nitroso-*N*-alkylhydroxylamine derivatives of copper(II) and iron(III) which is based on the early work of Sand and Singer.[3] As far as we know complexes of iron(III) have not been characterized previously.

EXPERIMENTAL

Preparation of the complexes

The ligands were first isolated as the magnesium complexes from the appropriate Grignard reagent.

* Authors to whom correspondence should be addressed.

For example, magnesium turnings (1.25 g, 0.051 mol) were converted into the methyl Grignard by the slow addition of methyl iodide (7.1 g, 0.05 mol) in dry ether (80 cm^3). When the ethereal solution had been added the contents of the flask were refluxed for 1 h, the flask cooled in ice, evacuated, and nitric oxide admitted. The solution was stirred in nitric oxide until gas uptake ceased (gas burette). The solvent was removed under reduced pressure, and the resulting pale yellow and hygroscopic *N*-nitroso Grignard complex was stored over calcium chloride.

To prepare the copper(II) complex, half by weight of the product was suspended in water (100 cm^3), cooled, and acidified with dilute sulphuric acid to give the free *N*-nitroso-*N*-methylhydroxylamine which was then extracted into ether (5×20 cm^3 portions). Copper(II) oxide in excess was stirred with the combined extract for several hours, and the suspension left to stand overnight. The deep blue liquor was filtered from the copper(II) oxide which was washed with acetone. The ether and acetone solutions were evaporated to dryness, and the solid recrystallized from methylated spirits. The blue crystals were dried in vacuum.

To prepare the iron(III) complex, iron(III) alum in excess was added to a cooled aqueous suspension of the remaining *N*-nitroso Grignard complex and after stirring for half an hour the iron(III) complex was extracted into chloroform (6×20-cm^3 portions). The extract was dried with calcium chloride, filtered, and taken to dryness. The solid was recrystallized from methylated spirits and the orange crystals dried *in vacuo*.

Complexes of other *N*-nitroso-*N*-substituted hydroxylamines were similarly prepared (Table 1). They were obtained in 20–40% yield based on the mass of magnesium.

The *N*-methyl derivatives were also prepared from *N*-methyl hydroxylamine hydrochloride. This was dissolved in water, acidified with hydrochloric acid, cooled to 0°C, and iron(III) alum and sodium nitrite added with stirring. The iron(III) complex was extracted with chloroform as above. The copper(II) complex was prepared by continuous extraction of the *N*-nitroso-*N*-methylhydroxylamine into a suspension of the oxide in ether. The *N*-phenyl-substituted complexes were also prepared from cupferron in aqueous solution. These methods gave 80–90% yields.

Physical measurements

Diffuse-reflectance electronic spectra were recorded using powdered samples with lithium fluoride as reference material on a Beckman Acta MIV spectrophotometer. Relative molecular masses were measured using a calibrated Mechrolab vapour phase osmometer model 301A (solvent chloroform).

Crystallography

Crystals of $Fe(Pr^nN_2O_2)_3$ and $Cu(Pr^iN_2O_2)_2$ suitable for X-ray investigation were obtained from methylated spirits.

Crystal data. $C_9H_{21}N_6O_6Fe$(**I**), $M = 365.15$, orthorhombic, $a = 9.059(1)$, $b = 11.492(1)$, $c = 15.988(2)$ Å, $U = 1664.5$ Å^3, space group $P2_12_12_1$, $Z = 4$, $D_c = 1.457$ g cm^{-3}, $F(000) = 764$, μ(Mo-K_α) = 9.4 cm^{-1}.

$C_6H_{14}N_4O_4Cu$(**II**), $M = 269.74$, monoclinic, $a = 22.789(2)$, $b = 4.865(1)$, $c = 11.400(1)$ Å, $U = 1106.6$ Å^3, space group $C2/c$, $Z = 4$, $D_c = 1.619$ g cm^{-3}, $F(000) = 556$, μ(Mo-K_α) = 19.8 cm^{-1}.

Data collection and processing. Numbers in brackets refer to structure **II**. Intensity data were collected using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) on an Enraf–Nonius CAD4 four-circle diffractometer in a ω–2θ scan mode. 1896 (1253) reflexions were measured [$\sin\theta/\lambda \leqslant 0.62$], which reduced to 1875 (1111) unique reflexions with 1537 (926) reflexions having $I \geqslant 3\sigma(I)$. Following Lp correction, analysis of a standard reflexion showed no significant decay.

Structure analysis and refinement. The heavy-atom method was used to solve and develop the structures. In structure **II** it was noted that $(k+l)$ and $(h+l)$ even were systematically strong and the volume indicated four molecules per unit cell implying that copper is on a centre of symmetry, at ($\frac{1}{4}$, $\frac{1}{4}$, 0) and related positions. When phased on copper alone the $(k+l)$, l = odd reflexions will have zero calculated F_cs causing two peaks per atom on the F_o map. Correct selection of atom positions overcame this. Full-matrix least-squares refinement was carried out using isotropic thermal parameters and an empirical absorption correction, DIFABS[23] was applied [1768 (1039) reflexions corrected, minimum absorption correction 0.822 (0.851), maximum 1.168 (1.256), average 0.987 (0.989)] prior to refinement with anisotropic thermal parameters. The positions of hydrogen atoms were calculated geometrically and the weighting scheme $w = 1/[\sigma^2(F_o)+0.05(F_o)^2]$ gave satisfactory agreement analysis. Final R and R_w values are 0.043 (0.025) and 0.056 (0.034). All crystallographic programs used were from the SDP package.[24]

Selected bond lengths and angles are given in Table 2. Fractional atomic coordinates, anisotropic temperature factor coefficients and F_o/F_c values

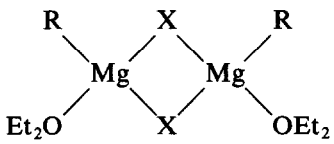
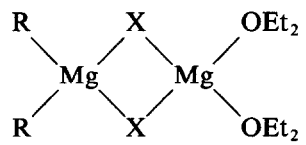
RESULTS AND DISCUSSION

The three methods of preparation of the copper(II) and iron(III) complexes are outlined in Schemes 1–3.

The *N*-methyl-substituted copper(II) and iron(III) complexes whether prepared by Scheme 1 or 2 had identical melting points and IR and mass spectra. The same is true for the *N*-phenyl derivatives from Schemes 1 and 3. The constitution of the complexes is therefore clearly established although the structure of the *N*-nitroso Grignard intermediate remains uncertain. Although alkylmagnesium bromides and iodides are monomeric in ether at low concentration (less than about 3×10^{-2} mol dm^{-3}),[25,26] at concentrations used in preparative studies they are mostly dimeric and exist either as **III** or **IV**.[26]



III



IV

It is possible that the action of nitric oxide on **III** or **IV** in ether would initially yield species **I** or **II**, respectively, but in either case hydrolysis will give RN(NO)OH and complex formation with, e.g. Cu^{2+} will give $[Rn(NO)O]_2Cu$. Since neither the active species in the Grignard reagent nor the initial

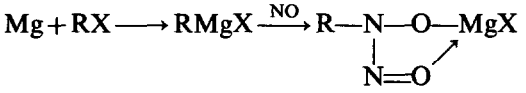
magnesium complex produced is known, the simplest schematic formulation that is stoichiometrically correct is given below:



I

Molecular structures

The molecular structure and the atom-numbering scheme for $Cu(Pr^iN_2O_2)_2$ are shown in Fig. 1. The molecule excluding the alkyl substituents is planar, and the ligands are *trans* as in the *N*-phenyl analogue.[17] The Cu—O bond distances are equal (Table 2) within experimental error but the small bite of the ligand leads to angles significantly below 90° subtended at the metal atom (O(1)—Cu—O(2) = 81.99°). The nearest neighbours axially to the copper(II) ion are N(2) atoms at 3.2 Å, which is much greater than the sum of the radii of Cu^{2+} and nitrogen (*ca* 2.3 Å). Thus there is no intermolecular interaction and the copper(II) ions are in essentially planar coordination.

The atom-numbering scheme and the molecular structure of $Fe(Pr^nN_2O_2)_3$ are presented in Fig. 2. The six O atoms form a distorted octahedron around the iron(III) ion, and the Fe—O distances (Table 2) are the same (2.00 Å) as in the phenyl derivative.[18] The ligands are in a facial arrangement. As in the copper(II) complex, the ligands

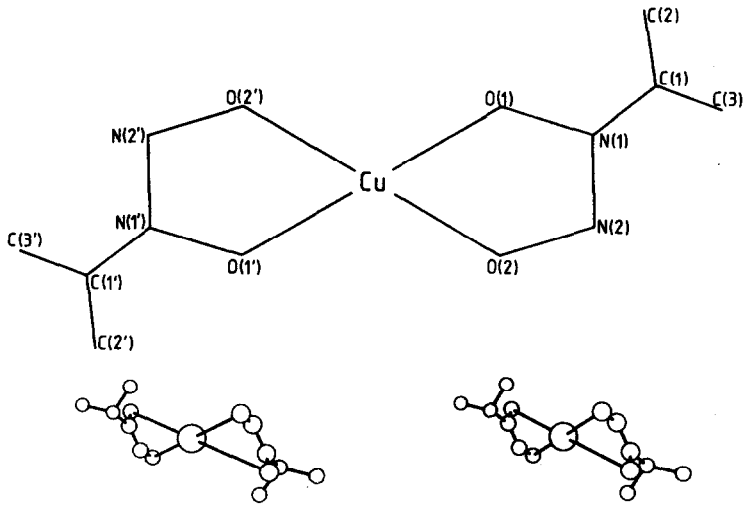


Fig. 1. Atom-numbering scheme, structure, and stereoscopic view of $Cu(Pr^iN_2O_2)_2$.

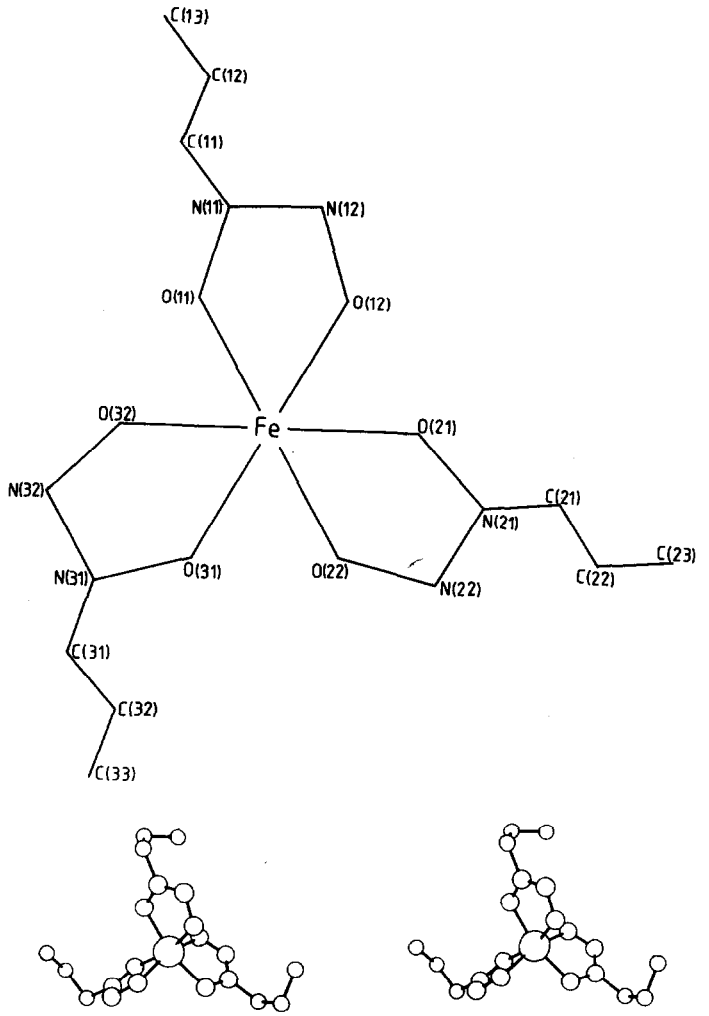

Fig. 2. Atom-numbering scheme, structure, and stereoscopic view of $Fe(Pr^nN_2O_2)_3$.

subtend small angles at the metal ion (76.2°). The ligand dimensions are the same in the two complexes within the stated standard deviations. The N—O bond lengths in the copper(II) and iron(III) complexes are almost equal [Cu, 1.316(4) Å; and Fe, 1.313(11) Å]. Those for Cu(II) are much better refined than any [8,10,11,13,16–19] previously reported. On reviewing the available structures of *N*-nitroso-*N*-alkyl- or *N*-nitroso-*N*-arylhydroxylaminato complexes we find no compelling evidence, as judged by the reported standard deviations in the N—O bond lengths, to support the claim[10] that significantly different N—O bond lengths occur within a single ligand in any given complex. Our values are intermediate between those expected[10] for single (*ca* 1.37 Å) and double (*ca* 1.23 Å) bonds. Our N–N bond lengths are short[10] and invariant with clear evidence for significant double-bond character. The C—N bond distances are normal for single bonds (Table 2).

Magnetic measurements

The effective magnetic moments (μ_{eff}) of the copper(II) complexes (Table 1) are a little above the spin-only value (1.73 BM) as expected for planar or tetragonally-distorted, six-coordinate complexes; and the moments of $Cu(Pr^iN_2O_2)_2$ and $Cu(n\text{-}C_8H_{17}N_2O_2)_2$ are almost independent of temperature (Table 1) as expected for monomeric complexes. The iron(III) complexes are high-spin (for the $t_{2g}^3e_g^2$ configuration moments close to the spin-only value of 5.92 BM are expected); thus the *N*-nitroso-*N*-alkylhydroxylamines are weak field ligands.

Electronic spectroscopic measurements on the copper(II) complexes

The electronic spectra of copper(II) complexes have been extensively reviewed.[27,28] Potentially π-bonding ligands such as acetylacetonate (acac) and

its derivatives appear to favour square planar CuO_4 geometry. The electronic spectra of this chromophore, recorded by diffuse reflectance from powdered samples or by polarized measurements from single crystals, exhibit three or four bands in the visible region with no absorption maxima below 10,000 cm^{-1}. The polarized spectrum of Cu(3-ϕacac)$_2$ is typical with maxima at 15,400, 16,900, 19,000 and 20,600 cm^{-1}, while in other cases, e.g. $CaCuSi_4O_{10}$ and Cu(3-Meacac)$_2$, the spectrum is shifted to lower energy by 2500–1000 cm^{-1}.

These complexes have T (a corrected ratio of the in-plane bond lengths to axial contacts) in the range 0.56–0.66. Semi-coordination need not be considered. If the in-plane bond lengths are about 2 Å then the close contacts in the axial directions are at least 2.8–3 Å for true square planar CuO_4 chromophores. The bond lengths in the solid state are not temperature-dependent.

The diffuse-reflectance spectra of powdered samples of our blue/violet copper(II) complexes (Table 1) are all very similar. A broad envelope centred near 16,700 cm^{-1} has two ill-resolved maxima near 15,600 and 17,800 cm^{-1}, with a low-energy shoulder at about 13,200 cm^{-1}. The complex Cu(Pr^{i}N$_2$O$_2$)$_2$ is square planar with T (uncorrected) = 0.59 as determined by the in-plane Cu—O distances and the closest contacts to Cu from N(2) above and below the plane at 3.205 Å. The spectra show that all of the copper(II) complexes reported here are square planar and confirm the established structure–spectral correlations for such chromophores. It would appear that the olefinic function in Cu(allylN$_2$O$_2$)$_2$ does not interact with the copper(II) atom.

SUBSTITUTION REACTION OF η^5-CYCLOPENTADIENYLRUTHENIUM(II) COMPLEXES WITH NITROGEN, OXYGEN AND SULFUR DONOR LIGANDS

KOLLIPARA MOHAN RAO, LALLAN MISHRA* and UMESH CHANDRA AGARWALA†

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 15 *July* 1986; *accepted after revision* 8 *December* 1986)

Abstract—The heterocycles pyridine, γ-picoline, 2,2′-bipyridine and 1,10-phenanthroline react with $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2X]$ (M = P, As or Sb) and $[(\eta^5\text{-}C_5H_5)Ru(AsPh_3)(PPh_3)X]$ (X = Cl, Br, I, CN, NCS or $SnCl_3$) to form complexes of types $[(\eta^5\text{-}C_5H_5)(MPh_3)(L\text{–}L)^+X^-$ (L–L = 2,2′-bipyridine or 1,10-phenanthroline; X = Cl, Br, I, CN, NCS or $SnCl_3$) and $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)LX]$ (M = As or Sb; L = pyridine or γ-picoline; X = Cl, Br, I, CN, NCS or $SnCl_3$). Interactions of dithiocarbamate (DTC) with $[(\eta^5\text{-}C_5H_5)Ru(SbPh_3)_2X]$ (X = Cl, Br or I) and acetylacetonate (acac) with parent compounds $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)_2X$ (M = P or Sb; X = Cl, Br or I) yielded $[(\eta^5\text{-}C_5H_5)Ru(MPh_3)L]$ (where L = DTC or acac). The reaction products have been characterized by magnetic, spectral and microanalytical data.

The unusual chemistry of cyclopentadienyl ruthenium complexes, $[(Cp)Ru(MR_3)_2X]$ (Cp = η^5-C_5H_5; M = P, As or Sb; R = Ph, Me or OPh), have captured the attention of many investigators for several years.[1–12] In continuation of our previous work[10] we wished to examine the reactions of $[(Cp)Ru(MPh_3)_2X]$ (M = As or Sb) and $[(Cp)Ru(AsPh_3)(PPh_3)X]$ (X = Cl, Br, I, CN, NCS or $SnCl_3$) towards heterocyclic bases like pyridine (py), γ-picoline (γ-pic), 2,2′-bipyridine (bipy) and 1,10-phenanthroline (1,10-phen) and towards sodium diethyl-dithiocarbamate (DTC) and acetylacetone (acac). This paper reports the results of such a study.

EXPERIMENTAL

All of the chemicals used were chemically pure or Analar grade. Solvents were distilled and dried before use. The complexes $[(Cp)Ru(AsPh_3)(PPh_3)X]$ and $[Ru(Cp)(MPh_3)_2X]$ (M = As or Sb; X = Cl, Br, I, CN, NCS or $SnCl_3$) were prepared by the literature procedures.[11,12]

Typical methods of synthesizing the complexes

Preparation of the complexes $[(Cp)Ru(MPh_3)LX]$ (M = As *or* Sb) *and* $[(Cp)Ru(MPh_3)L\text{-}L]^+X^-$ (M = P, As *or* Sb) (X = Cl, Br, I, CN, NCS, $SnCl_3$, DTC *or* acac). The complexes were synthesized by refluxing $[(Cp)Ru(MPh_3)_2X]$ (*ca* 1.2×10^{-4} mol) in 20 cm^3 ethanol with the corresponding substrate for several hours. After concentrating the resulting solution to nearly 5 cm^3‡ a slight excess of diethyl ether (*ca* 20 cm^3) was added yielding a microcrystalline product. It was separated by centrifugation and recrystallized from the appropriate solvent. The recrystallized product was washed with light petroleum, and air dried.

Attempts to synthesize the corresponding arsine complexes having DTC or acac as coligands were unsuccessful.

Preparation of $[(Cp)Ru(MPh_3)L\text{–}L]^+Y^-$ (L = As *or* Sb; Y = BPh_4, BF_4, ClO_4^-, $HgCl_3$ *or* $\frac{1}{2}$ Zn_2Cl_6). These were synthesized by metathesis reactions. The complex $[(Cp)Ru(MPh_3)L\text{–}L]^+X^-$ (*ca* 1.0×10^{-4} mol) in 15 cm^3 of ethanol on mixing with equimolar quantity of Y^- in ethanol (5 cm^3) yielded an immediate orange red precipitate. (Perchlorates of these cations could also be isolated by the addition of a few drops of perchloric acid to their alcoholic solutions. **CAUTION:** One should be careful in their syntheses because of their highly explosive nature.) The precipitated residue was

‡ The solution was concentrated to get a better yield of the complex. It also appeared without concentration, but the yield was poor.

separated by filtration, washed with diethyl ether and recrystallized from a chloroform–methanol mixture.

Using ethanol as solvent no stable product was obtained by the reaction of bipy or 1,10-phen with $[(Cp)Ru(MPh_3)_2H]$ (M = As or Sb). However, in the presence of the anions BPh_4^-, BF_4^-, ClO_4^-, $HgCl_3^-$ and $Zn_2Cl_6^{2-}$ the same reaction mixture yielded the stable cationic salts $[(Cp)Ru(MPh_3)L–L]^+$ (M = As or Sb, L–L = bipy or 1,10-phen). The same reactions carried out in halohydrocarbons such as CH_2Cl_2, CHX_3 etc. gave the corresponding halide salts $[(Cp)Ru(MPh_3)L–L]^+X^-$ (X = Cl or Br) which in the presence of a large anion (Y^-) afforded the corresponding salt of Y^-.

Physical measurements

Carbon, hydrogen and nitrogen analyses were carried out by the Microanalytical laboratory of the Indian Institute of Technology, Kanpur, India. The percentages of halides and sulfur in the complexes were determined by the standard methods[13] in the filtrate obtained after fusing the sample with the fusion mixture (1 : 8 $NaNO_3$–NaOH), extracting it with distilled water and filtering it. IR, UV and visible, ^1H NMR spectroscopic and magnetic measurements were carried out by the methods described elsehwere.[10,11] The results are given in Table 1.

The specific reaction conditions, the analytical data, and other physical properties are given in Table 1.

RESULTS AND DISCUSSION

The empirical formulae of the complexes formed by the substitution reactions of *N*-heterocyclic bases, $[Na(C_2H_5)_2NCS_2]$, or acac with the complexes $[(Cp)Ru(MPh_3)_2X]$ (M = As or Sb; X = Cl, Br, I, CN, NCS or $SnCl_3$) are listed in Table 1. These are air-stable, highly soluble in organic polar solvents like CH_2Cl_2, $CHCl_3$ etc., and relatively less soluble in methanol and ethanol.

The formation of identical substitution products from both $[(Cp)Ru(AsPh_3)_2X]$ with heterocyclic bases is not surprising, because of the substitution of a larger molecule (PPh_3, cone angle 145°) in the latter by a smaller one ($AsPH_3$ cone angle)[14] due to steric hindrance.

An interesting aspect of these reactions is the formation of cationic complexes with bipy and 1,10-phen while py and γ-pic gave neutral ones. Under our reaction conditions we were not able to isolate the cationic complexes with py or γ-pic similar to those reported by Uson *et al.*[15] Although one could have anticipated the formation of the cationic complexes $[(Cp)RuL_2(MPh_3)]^+X^-$ (M = As or Sb; L = py or γ-pic), in the case of py and γ-pic also, seemingly the chelate effect of the ligands L–L plays a significant role in stabilizing the cationic complexes. The cationic nature of the complexes has been confirmed: (a) by exchange reactions using cationic and anionic exchangers (Dowex 50W-XB and Dowex 1-XB), and (b) by synthesizing various salts of the cations with a number of large anions (Table 1). It has been shown here that the bipy and 1,10-phen complexes are cationic $\{[(Cp)Ru(MPh_3)L–L]^+$ (M = As or Sb)$\}$. Although it was previously reported[10] that the corresponding triphenylphosphine complexes have the formula $[(Cp)Ru(PPh_3)L–L_{0.5}X]$, it was later shown that even the PPh_3 complexes gave $[(Cp)Ru(PPh_3)L–L]^+$ on prolonged refluxing (24 h), while on refluxing for a shorter time a mixture of the latter with the starting material was obtained.

The complexes $[(Cp)Ru(MPh_3)L–L]^+Cl^-$ (M = As or Sb) were converted to $[(Cp)Ru(MPh_3)L–L]^+X^-$ (X = Br, I, NCS, CN or $SnCl_3$) by refluxing in methanol with a molar excess of KBr, KI, KCN, KNCS and $SnCl_2$, respectively, with the intermediate $[(Cp)Ru(MPh_3)(MeOH)L–L]^+$ probably being formed during these reactions.[16]

The IR spectra of all the complexes exhibited sharp bands of medium intensity in the 840–850-cm^{-1} region and relatively broader bands at 420 cm^{-1}. These bands have been assigned to the out-of-plane bending and skeletal modes of the C_5H_5 ring, respectively. In addition to these, the characteristic bands of triphenylarsine and triphenylstibine (530s, 1100s, 1440 and 1490 cm^{-1}), together with those of the heterocyclic bases pyridine (1590 and 735 cm^{-1}), γ-picoline (1600, 1505 and 720–730 cm^{-1}), 2,2′-bipyridine (720–740, 840, 1430–1435 and 1600–1590 cm^{-1}) were also observed.[17–20] Further, in all the spectra the characteristic pattern of three bands of decreasing intensity lying in the 540–500-cm^{-1} region suggested the presence of only one coordinated triphenylarsine or triphenylstibine analogue.[15]

The presence of medium-intensity bands due to ν(CS) around 1000 cm^{-1} in the spectra of the DTC complexes,[5] and broad and intense bands around 1600 cm^{-1}, assigned to the mixed vibration having contributions from ν(C═O) and ν(C═C) in the acac complexes[21] suggested the presence of the respective ligands in their complexes.

The cyanide and thiocyanato complexes showed absorption bands at 2050 and 2100 cm^{-1}, respectively, indicating the presence of CN and NCS group.[22–24] The spectra of the cationic complexes having BF_4^- (1050 cm^{-1}), BPh_4^- (1100 cm^{-1})

[a] Melting points (uncorrected).
[b] R = red, Y = yellow, O = orange, YG = yellowish green, OR = orange-red, BO = brownish orange.
[c] A/B = method, S = substrate, T = time, R′ = recrystallization of complex.
[d] Solvent $CDCl_3$. Aromatic protons of the other coligands appeared in the δ-7.0–8.5 region as broad multiplets, and in the case of γ-picoline, dithiocarbamate and acetylacetonate complexes additional signal in the δ-1.8–2.5 region were observed due to methyl protons.
[e] d = decomposed.
[f] Found: mass 922, required: 924 (mass spectrometry FD).

ClO_4^- (1100 cm^{-1}), $HgCl_3^-$ (292 cm^{-1}) and $Zn_2Cl_6^{2-}$ (335 and 300 cm^{-1}) exhibited the characteristic bands of the anions.[2,7] The zinc complex showed no bands attributable to the ν(ZnCl) of $ZnCl_3^-$.[2]

^{1}H *NMR spectra*

^{1}H NMR spectra of all the complexes showed sharp resonance in the δ-4.4–5.0 region. In the spectra of the cationic stibine complexes $[(Cp)Ru(SbPh_3)L\text{–}L]^+X^-$ (L–L = bipy or 1,10-phen) three resonances (1:2:2) were observed, whereas for the $[(Cp)Ru(SbPh_3)LX]$ (L = py or γ-pic) complexes a sharp singlet was observed. The aromatic protons of the triphenylarsine, triphenylstibine and the *N*-donor ligands exhibited broad resonances in the range δ 7.0–8.5. The complexes having γ-pic also showed a resonance due to methyl protons around δ 1.8–2.0. DTC- and acac-containing complexes exhibited additional signals in the δ 3.5 (CH_2), δ 2.0 (methyl) region and δ 5.7 (—CH), δ 2.23 (methyl) region, respectively.[5,20] The interesting aspect of these spectra is that the C_5H_5 proton resonances in the complexes having bases as coligands were shifted downfield compared to their parent species (δ 4.2), viz. $[(Cp)Ru(MPh_3)_2X]$ (M = As or Sb). Furthermore, the downfield shift is larger in the cationic species in conformity with those previously observed for other Ru–Cp cationic complexes.[1-10]

The downfield shift in the position of C_5H_5 protons in all the complexes (neutral or cationic) compared to that in the spectra of the complexes having two molecules of MPh_3 linked to the ruthenium could possibly be due to the difference in the π-accepting behaviour of the heterocyclic bases and triphenylarsine or triphenylstibine.[25]

Electronic spectra

The electronic spectra of the complexes showed a fairly intense band around 450 nm, which could be assigned to a metal to ligand charge-transfer (M → L) transition.[26,27] The variation in the position of the (M → L) charge-transfer bands with the nature of the heterocyclic bases was not regular.

On the basis of the results discussed in the preceding paragraphs and on the basis of the previous studies[1-12] a distorted octahedral structure has been assigned to all the complexes.

PALLADIUM COMPLEXES WITH BIOLOGICAL LIGANDS—III.* KINETICS AND REACTION MECHANISM OF THE INTERACTION OF Pd(II) WITH METHIONINE AND *S*-METHYL-L-CYSTEINE

HAYAT M. MARAFIE, NADYAH SHUAIB and MOHAMED S. EL-EZABY†

(*Received* 22 *September* 1986; *accepted after revision* 8 *December* 1986)

Abstract—Two rate steps have been observed when excess Pd(II) was reacted with methionine (Meth) and *S*-methyl-L-cysteine (SMC) in the pH range 1–3.5. The fast step in both systems was attributed to the formation of a mononuclear chelated complex, and the slow step may be due to the effect of hydrolysis and/or polymerization processes. The mechanism of the fast reaction was discussed in terms of the species $PdCl_4^{2-}$, $[PdCl_3(OH)]^{2-}$, H_2L^+ and HL (L = Meth or SMC). It was concluded that $[PdCl_3(OH)]^{2-}$ was the more reactive species in the complex formation reaction. It was also found that substitution reactions involving Meth were more labile than those involving SMC.

Recent discoveries of the anticarcinogenic properties of some platinum complexes have drawn attention to palladium complexes which in general are chemically similar.[2,3] Although platinum complexes have been shown to be more effective in the treatment of some cancer cases than palladium complexes,[4] yet the latter complexes offer a chemical advantage over the former due to the fact that they are kinetically more labile. This allows a better understanding of the platinum complexes.

In order to study the role of some platinum and palladium complexes in cancer chemotherapy; the interaction of these metal ions should be carefully investigated with ligands commonly found in the biological systems. In this work L-methionine (Meth) and *S*-methyl-L-cysteine (SMC) have been selected as the ligands. Preparative work on Pd(II) complexes with Meth have been reported.[5–8] Among the synthesized complexes are those corresponding to the formulae $[PdCl_2(Meth)]^-$, $[Pd(Meth\text{-}H)_2]^{2+}$, $[Pd(Meth)_2]$, $[Pd(Meth\text{-}H)Cl_2]$ and $[Pd(Meth)H_2O]^+$ {Meth = $[CH_3S(CH_2)_2CH(NH_2)COO]^-$}. The formation constants of $[Pd(Meth)]^+$ and $[Pd(Meth)_2]$ were calculated ($\log\beta_1 = 9.14$ and $\log\beta_2 = 17.00$).[9,10] SMC also interacts with Pd(II) to form several complexes[11–13] having the following formulae $[Pd(SMC\text{-}H)Cl_2]$, $[Pd(SMC)_2]$ and $[Pd_2(SMC\text{-}H)_2Cl_2]^{2+}$ {SMC = $[CH_3SCH_2CH(NH_2)COO]^-$}. The log formation constant of $[Pd(SMC)]^+$ is 9.38.[9]

EXPERIMENTAL

Materials

Meth (Fluka, 99%) and SMC (Fluka, ⩾ 98%) were used without purification. Stock solutions (taken by weight) of the ligands were kept in a dark cool place. A stock solution of Pd(II) chloride (Pierce) was prepared in HCl [which was 10 times the concentration of the Pd(II)]. The concentration of the metal ion was determined by gravimetric methods as Pd(dimethylglyoxime)$_2$.[14]

The kinetic measurements were done using a Union Giken stopped-flow apparatus as previously described.[15] The optical path of the cuvette was 10.0 mm, thermostated at 25°C. The observed rate constants were calculated by a program using the Guggenheim method.

The absorption spectra were obtained using Pye–Unicam SP8-100 and Schimadzu-160 spec-

* For Part II see Ref. 1.

† Author to whom correspondence should be addressed.

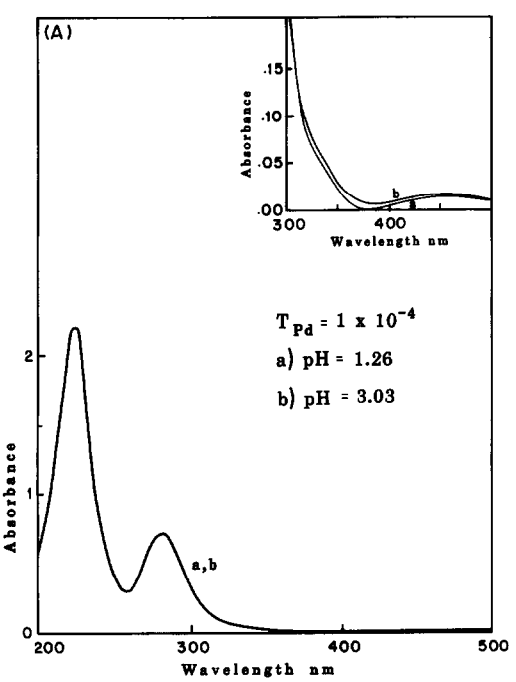
trophotometers in the wavelength range 200–500 nm. The pH measurements were obtained by using a Radiometer pH-meter type 62 equipped with a combined glass electrode (GK 2301C). The pH meter was calibrated before use with two buffers at 2.0 and 4.0.

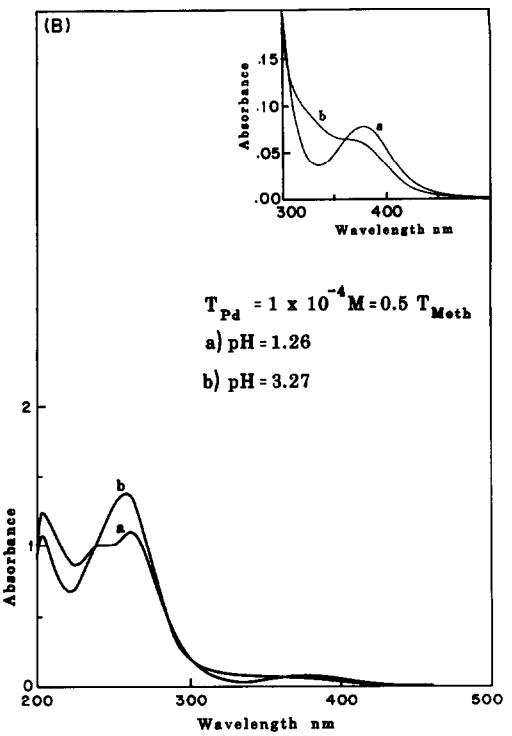
In all measurements, the ionic strength was kept constant at 0.15 M. The Pd(II) concentration (T_{Pd}) ranges from 10^{-3} to 10^{-2} M, and the ligand concentration (T_{Meth} or T_{SMC}) was fixed at 1×10^{-4} M.

RESULTS AND DISCUSSION

The addition of the solution of Meth or SMC to that of Pd(II) almost decolourized it in the pH range 1–5 (when the concentration of ligand is greater than the metal). The spectra show considerable changes where the bands of Pd(II) chloro complexes are shifted to shorter wavelengths with an increase in intensity in the wavelength range 600–200 nm. The ligands themselves have no absorption at wavelengths longer than ~ 220 nm Fig. 1(A)–(C). The spectra are pH-dependent in the pH range used while those of Pd(II) chloro complexes show only a minor change in the intensity with increase in the pH of the solution.

The kinetic runs were monitored at $\lambda_{380\,nm}$ under pseudo-first-order conditions with the con-





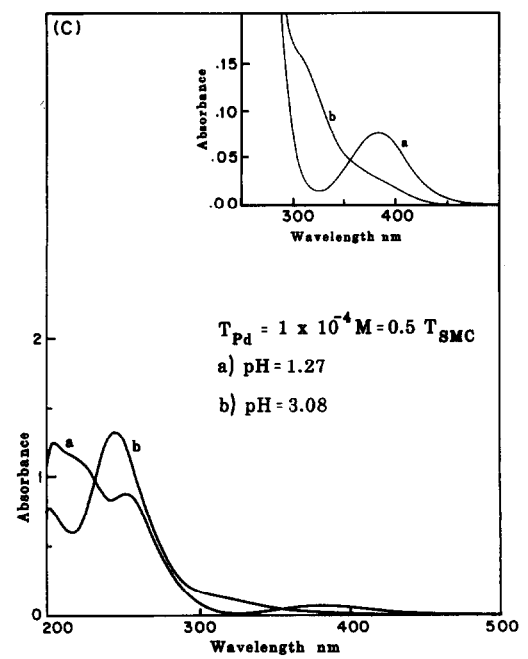


Fig. 1. Spectra of Pd(II)–Meth and Pd(II)–SMC systems at representative pH values. (A) Spectra of Pd(II) at the indicated pH values. (B) Spectra of Pd(II)–Meth at the indicated pH values. (C) Spectra of Pd(II)–SMC at the indicated pH values.

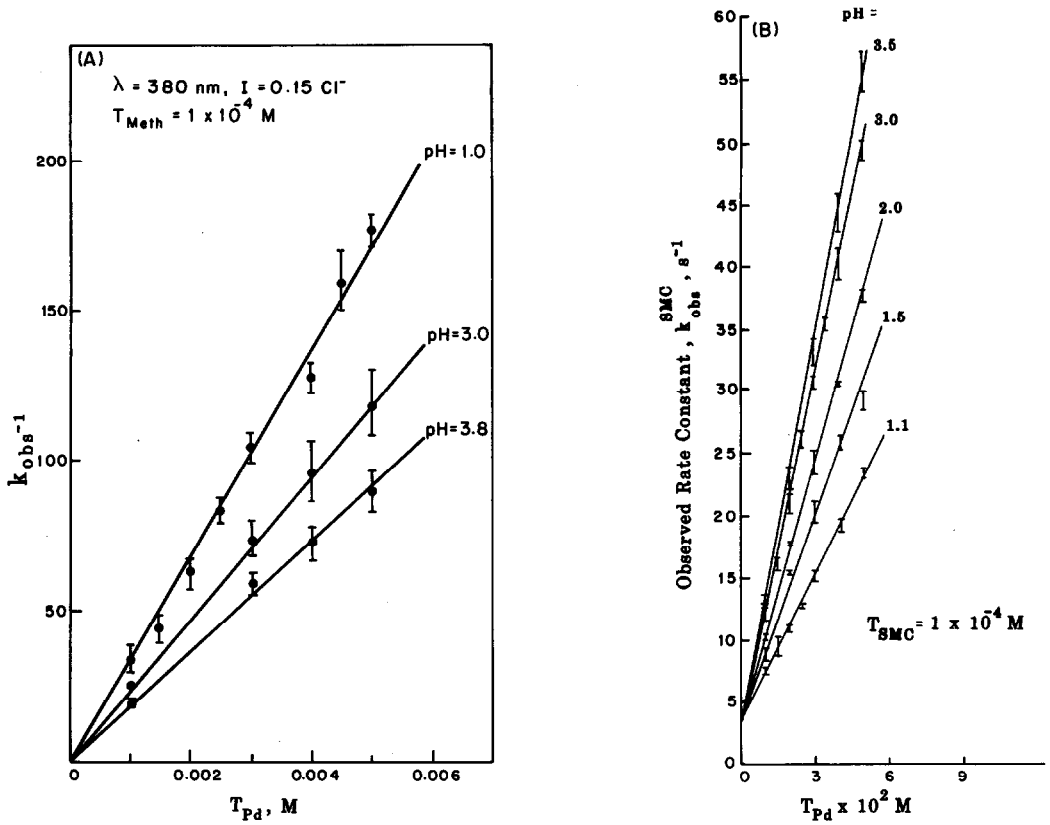

Fig. 2. Dependence of the observed rate constants on pH for: (A) the Pd(II)–Meth system, and (B) the Pd(II)–SMC system.

centration of Pd(II) much greater than that of the ligands. Two rate steps were observed, one in the millisecond range and the other in the second range. The change in absorbance with time for the first fast step was much greater than that for the second slow step which allows a better determination of the first step than the second one. The fast step may be attributed to mononuclear-complex formation, and only that step will be considered, while the slow step may be due to the formation of a polymeric and/or hydrolytic processes. The pseudo-first-order rate constants (k_{obs}) are linearly dependent on the T_{Pd} at constant T_{Meth} or T_{SMC}, and constant pH, Figs 2(A) and (B). These linear relationships are empirically expressed as follows:

$$k_{obs}^{L} = m_i^{L} + m_j^{L} T_{Pd}, \quad (1)$$

where L = Meth or SMC, and m_i^L and m_j^L are the intercepts and slopes at various pH values for both systems. In the Pd(II)–Meth and Pd(II)–SMC systems the intercepts have constant values within experimental errors, in the former the value is 3.5 s^{-1} and in the latter it is zero. On the other hand m_j^{Meth} is inversely proportional to the pH and m_j^{SMC} is directly proportional to the pH. Table 1 records the values of m_j for both systems at various pH values, interpolated from their plots against experimental pH values.

The possible ligand species which may primarily exist in the pH range used (1–3.5) are the protonated and dipolar species since the pK values are 2.24 and 9.17 for Meth,[16] and ~ 2.2* and 8.75 for SMC.[17] The metal species, on the other hand, are the tetrachloro complex of Pd(II) ($PdCl_4^{2-}$, $\log \beta_4 = 11.11$[18]) and likely the species $[PdCl_3(OH)]^{2-}$ ($\log \beta_{1OH} = \log K_{1OH} + \log \beta_{4Cl} = 16.81$[18]†).

The interaction of Pd(II) species with the ligand species may be described by the following reaction

* Estimated value.

† K_{1OH} (= $10^{5.7}$) stands for the equilibrium reaction:

$$PdCl_4^{2-} + OH^- \rightleftarrows [PdCl_3(OH)]^{2-} + Cl^-,$$

and β_{4Cl} stands for the equilibrium reaction:

$$Pd^{2+} + 4Cl^- \rightleftarrows PdCl_4^{2-}.$$

mechanism:

Scheme 1.

where k_i and k_{-i} are the forward and backward micro-rate constants, and K_{1CH} and K_{1OH} are the deprotonation constant of $PdCl_2LH$ and the mixed chloro hydroxo complex of Pd(II) $\{PdCl_4^{2+} + OH^- \rightleftarrows [PdCl_3(OH)]^{2-} + Cl^-\}$, respectively. In this mechanism the polymerization processes are ignored if one considers only the fast rate step. The formation of other mononuclear complexes was also neglected due to the presence of excess metal concentration with respect to the ligands.

The rate equation describing the mechanism in

[a] L = Meth, and L′ = SMC.

Scheme 1 is as follows:

$$\frac{dC_2}{dt} = \frac{T_{Pd}}{Q_3 Q_2}\left(\frac{T_{Meth} - C_2 Q_3}{Q_1}\right) \times \left(Q_6 + \frac{[OH^-]K_{1OH}Q_7}{[Cl^-]}\right) - \frac{C_2 Q_8}{Q_3}, \quad (2)$$

where:

$C_1 = [PdCl_2LH]$,

$C_2 = [PdCl_2L^-]$,

$$Q_1 = 1 + \frac{[H^+]}{K_{2h}} + \frac{[H^+]^2}{K_{1h}K_{2h}}$$

(K_{1h} and K_{2h} are the deprotonation constants of the ligands),

$$Q_2 = 1 + \frac{K_{1OH}[OH^-]}{[Cl^-]},$$

$$Q_3 = (K_{1CH} + [H^+])/K_{1CH},$$

$$Q_4 = k_{-1}[Cl^-]^2[H^+] + k_{-3}[Cl^-]^2 + k_{-5}[Cl^-] + k_{-7}[Cl^-][OH^-],$$

$$Q_5 = k_{-2}[Cl^-]^2[H^+]^2 + k_{-4}[Cl^-]^2[H^+] + k_{-6}[H^+][Cl^-] + k_{-8}[Cl^-],$$

$$Q_6 = (k_1 + k_2)\frac{[H^+]^2}{K_{1h}K_{2h}} + (k_3 + k_4)\frac{[H^+]}{K_{2h}},$$

$$Q_7 = (k_5 + k_6)\frac{[H^+]^2}{K_{1h}K_{2h}} + (k_7 + k_8)\frac{[H^+]}{K_{2h}},$$

and

$$Q_8 = \frac{[H^+]Q_4}{K_{1CH}} + Q_5.$$

The integrated form of eqn (2)* is:

$$\ln\frac{(C_2)_\infty}{(C_2)_\infty - (C_2)_t} = \ln\frac{A_{s_\infty}}{A_{s_\infty} - A_{s_t}} = k_{obs}^L t \quad (3)$$

where:

$$k_{obs}^L = Q_8/Q_3 + Q_9 T_{Pd}/Q_1 Q_2. \quad (4)$$

The terms Q_8/Q_3 and Q_9/Q_1Q_2 stand for the intercepts and slopes expressed in eqn (1) for the Pd(II)–Meth and Pd(II)–SMC systems.

The intercepts are zero in the Pd(II)–Meth system. Figure 2(A) indicates that the Meth complex of Pd(II) has a large value for the formation constant since it represents the backward rate constant. On the other hand, the intercepts have constant values independent of the pH in the Pd(II)–SMC system. In another way:

$$m_i^{SMC} = Q_8/Q_3 \simeq Q_4 \simeq (k_{-3} + k_{-4}K_{1CH})[Cl^-]^2 + (k_{-5} + k_{-6}K_{1CH})[Cl^-]. \quad (5)$$

Equation (5) is correct if $K_{1CH} \leqslant [H^+]$ and m_i is independent of pH. If one accepts the approximations that $k_{-4}K_{1CH}$ and $k_{-6}K_{1CH}$ are much less than k_{-3} and k_{-5}, respectively ($K_{1CH} \leqslant k_{-4}$ and $K_{1CH} \leqslant k_{-6}$), then:

$$m_i^{SMC} = k_{-3}[Cl^-]^2 + k_{-5}[Cl^-] = 3.5\,s^{-1}.$$

If the term corresponding to the slopes is rearranged, one gets the following equation:

$$m_j Q_1 Q_2 = (k_1 + k_2)[H^+]^2/K_{1h}K_{2h} + \{(k_3 + k_4)/K_{2h} + (k_5 + k_6) \times K_w K_{1OH}/K_{1h}K_{2h}[Cl^-]\}[H^+] + (k_7 + k_8)K_w K_{1OH}/K_{2h}[Cl^-], \quad (6)$$

where K_w is the ionic product of water ($= 10^{-13.78}$ at 25°C) and $Q_1 \simeq 1$.

Table 1 shows the values of $m_j Q_1 Q_2$ at interpolated values of pH for the Pd(II)–Meth and Pd(II)–SMC systems. The plots of this dependence are shown in Fig. 3(A) and (B) for both systems. The dependence on H^+ follows a quadratic relationship, specially in the pH range 1–2.5. The coefficients of eqn (6) are equal to $(8.19 \pm 4.17) \times 10^{10}$, $(9.88 \pm 3.26) \times 10^{12}$ and $(9.11 \pm 0.03) \times 10^{15}$ for the Pd(II)–Meth system, and ~ zero, $(1.08 \pm 0.08) \times 10^{12}$ and $(2.93 \pm 0.1) \times 10^{13}$ for the Pd(II)–SMC system. Table 2 shows a numerical comparison of the rate constants of both systems. It seems from Table 2 that the interactions of Pd(II) with Meth or SMC are identical in the sense that most of the reactions in Scheme 1 are significant

Table 2. Micro-rate constants obtained in this work for the Pd(II)–Meth and Pd(II)–SMC system

Rate constants	Pd(II)–Meth	Pd(II)–SMC
$k_1 + k_2$	3.6×10^4	3.0×10^2
$k_3 + k_4$[a]	6.7×10^3	1.9×10^3
$k_5 + k_6$[a]	6.95×10^8	7.6×10^7
$k_7 + k_8$	1.0×10^9	≈ Zero

*Where A_{s_∞}, A_{s_t}, C_∞ and C_t are the absorbances at infinite time t and time t, concentration at infinite time t and time t, respectively.

[a] In determining these constants, the assumption has been made that either the term $(k_7 + k_8)K_w K_{1OH}/K_{2h}[Cl^-]$ or the term $(k_5 + k_6)K_w K_{1OH}/K_{1h}K_{2h}[Cl^-]$ is equal to zero.

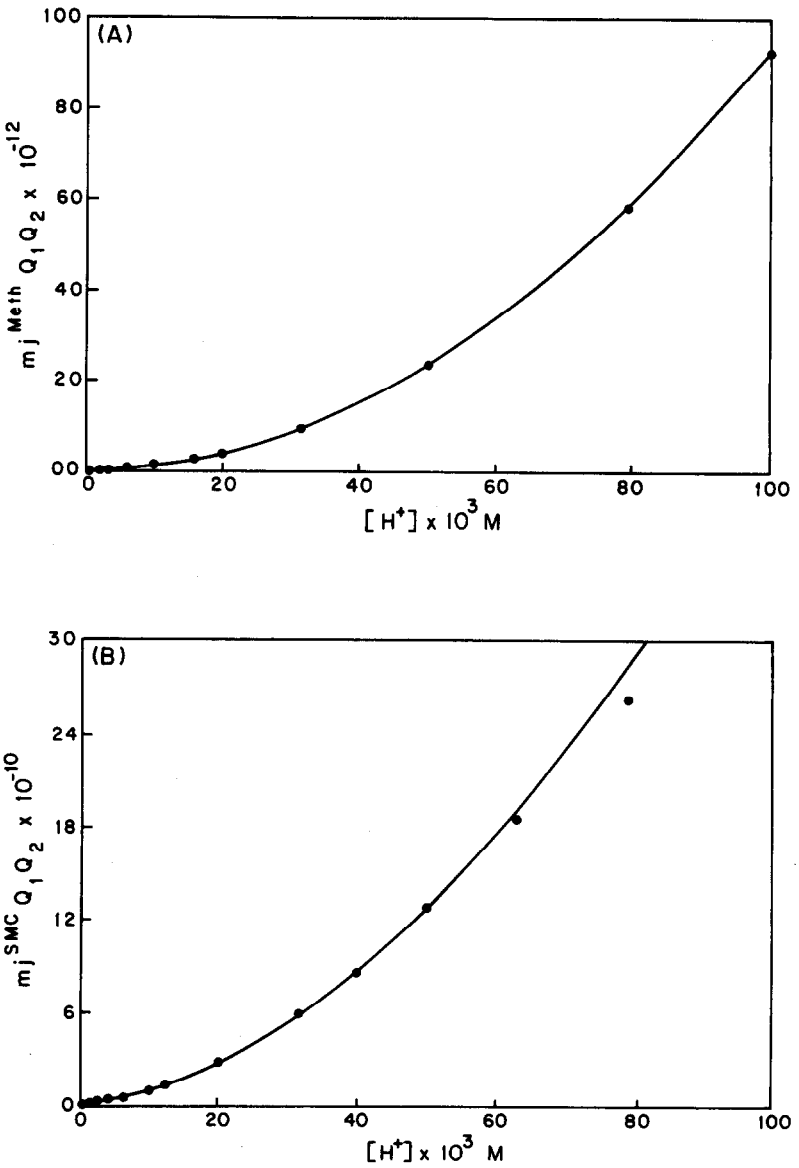

Fig. 3. Dependence of $m_j^L Q_1 Q_2$ on hydrogen ion concentration for: (A) the Pd(II)–Meth system, and (B) the Pd(II)–SMC system.

in the formation of the mononuclear complexes. However, the Pd(II)–Meth system is more labile than the Pd(II)–SMC system despite the fact that a six-membered metal complex is formed in the former and a five-membered complex in the latter, assuming that the amino nitrogen and etherial sulfur are the sites of the ligation. In addition, the substitution reactions involving $[PdCl_3OH]^{2-}$ are more labile than those involving $PdCl_4^{2-}$.

SPECTROPHOTOMETRIC AND CONDUCTOMETRIC STUDY OF COPPER(II) BROMIDE–*N*,*N*-DIMETHYLFORMAMIDE SOLUTIONS

MICHAŁ PILARCZYK,* WACŁAW GRZYBKOWSKI and LUCYNA KLINSZPORN

(*Received* 19 *November* 1986; *accepted* 7 *December* 1986)

Abstract—Visible absorption spectra and the molar-conductance curve for $CuBr_2$ in *N*,*N*-dimethylformamide (DMF) as well as the spectra for the $Cu(ClO_4)_2$–Et_4NBr–DMF and $CuBr_2$–DMF–chlorobenzene systems have been studied. The results indicate the formation of the $CuBr_3(DMF)^-$ complex being the predominating bromo complex of copper(II) in the most concentrated solutions of $CuBr_2$ in DMF. The stability constants of the individual bromo complexes of copper(II) have been determined: $\log\beta_1 = 3.35$, $\log\beta_2 = 5.4$, and $\log\beta_3 = 8.8$.

The nonaqueous copper(II) chloride systems have been extensively studied spectrophotometrically by Vierling and coworkers,[1] and the solvent effect on the stability, the electronic spectra, and the structure of copper(II) chloro complexes was discussed. Their results provided quantitative evidence of the well-known facts that the complexes of copper(II) are less stable in better solvating solvents and the solvation of the anion is an effect of minor importance. However, their opinion concerning the exclusive existence of uncomplexed copper(II) in the form of the four-coordinate $Cu(solvent)_4^{2+}$ cations seems to be questionable.

We report here the copper(II) bromide ($CuBr_2$) system in *N*,*N*-dimethylformamide (DMF). The copper(II) chloride complexes in DMF were studied spectrophotometrically by Gutmann,[2] Vierling,[3] and spectrophotometrically and calorimetrically by Ohtaki,[4] providing the experimental evidence for the existence of four chloro complexes of copper(II) in the system. However, there is a lack of quantitative data of non-aqueous $CuBr_2$ solutions. Chmurzyński *et al.*[5] investigated the DMSO–$CuBr_2$ system and identified four consecutive bromo complexes of copper(II) from spectrophotometric data. The corresponding acetonitrile system was studied by Barnes and Hume,[6] who have shown that $CuBr_2$ undergoes reduction, producing CuBr.

The present work was undertaken in order to determine the nature and stability of complexes formed in DMF solutions of $CuBr_2$. In previous papers we reported the study of ionization equilibria of $CoBr_2$ and $NiBr_2$ in this solvent. It has been shown that the most important factor controlling the electrolytic properties of the DMF solutions of $CoBr_2$ is the high stability of the tetrahedral $CoBr_3(DMF)^-$ complex,[7] while the octahedral $NiBr(DMF)_5^+$ complex is the predominating species in DMF solutions of $NiBr_2$.[8]

EXPERIMENTAL

DMF (analytical grade) was dried using a 4A molecular sieve and distilled under reduced pressure at 45–50°C. The specific conductivity of the purified solvent was in the range $3.0–5.0 \times 10^{-8}$ S cm^{-1}.

DMF-solvated $CuBr_2$ and $Cu(ClO_4)_2$ were prepared from the respective hydrates by dissolving them in DMF, followed by removing any excess of the solvent under reduced pressure at *ca* 65°C. The crystalline solids were recrystallized twice from anhydrous DMF. The products were used to prepare the stock solutions immediately before measurements.

The reagent grade tetraethylammonium bromide

* Author to whom correspondence should be addressed.

(Et_4NBr) was recrystallized twice from anhydrous acetonitrile and dried *in vacuo* at elevated temperature.

The stock solutions of $CuBr_2$ and $Cu(ClO_4)_2$ were analysed for copper(II) by standard EDTA titrations. Solutions for measurements were prepared by weighed dilutions, and the concentrations were calculated using the known densities determined independently.

Absorption spectra were measured using a Beckman UV 5270 spectrophotometer. A conductance bridge Beckman RC 18A was used. Details of the procedures for measuring values were identical to those described previously.[5,7,9,13]

RESULTS AND DISCUSSION

It is convenient to start a discussion of the results obtained for DMF solutions of $CuBr_2$ from an analysis of the spectrophotometric results obtained for the three-component $Cu(ClO_4)_2$–Et_4NBr (variable concentration)–DMF solutions. The study of the spectral effects generated by an increasing concentration of Et_4NBr provides the possibility of the identification of consecutive bromo complexes of copper(II) formed.

Our spectrophotometric and conductometric studies[9] have shown six-coordinated $Cu(DMF)_6^{2+}$ to be the only detectable species in DMF solutions of $Cu(ClO_4)_2$. This conclusion is consistent with that derived from X-ray diffraction measurements on the solution of $Cu(ClO_4)_2$ in DMF reported by Ishiguro and Ohtaki.[11] However, four of the six DMF molecules have a shorter Cu—O bond length. This observation explains the behaviour of the solvated Cu^{2+} within the Mn^{2+}–Zn^{2+} series.[9]

Figure 1 shows the electronic absorption spectra (500–1500 nm) of a series of solutions containing $Cu(ClO_4)_2$ at an approximately constant concentration of 0.0050 mol dm^{-3}, and Et_4NBr at a number of different concentrations not exceeding a 3:1 Et_4NBr:$Cu(ClO_4)_2$ mole ratio. The spectrum of copper(II) for pure $Cu(ClO_4)_2$ in DMF is indicated by curve 1. The position and intensity of the band are characteristic of tetragonally distorted octahedral copper(II) complexes.[12] As is seen, addition of Et_4NBr brings about a rapid increase in the intensity of the band accompanied by a regular shift of the maximum from 790 nm towards longer wavelengths. Further changes in the spectrum of copper(II) induced by an addition of Et_4NBr consist in a development of an absorption band with a maximum at 592 nm. The band is observed at $Et_4NBr/Cu(ClO_4)_2$ ratios exceeding 1.0. With increasing Et_4NBr concentration the band changes in intensity only, indicating the presence of one bromo complex of copper(II) absorbing light in this spectral range, while the changes in the long-wavelength range are due to the consecutive bromo complexes of copper(II).

The changes in the spectrum of copper(II) caused

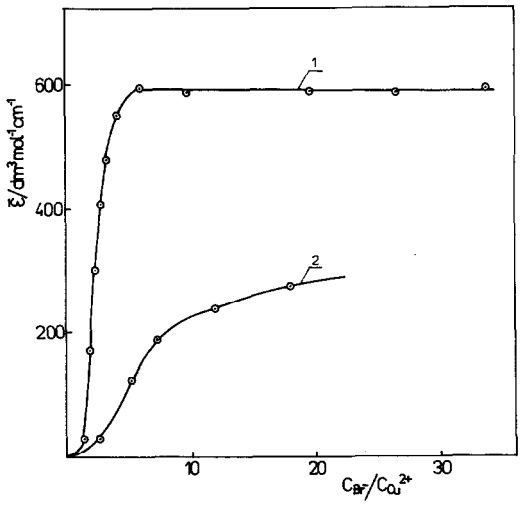

Fig. 3. Plots of the mean absorption coefficient of copper(II) against the $C_{Et_4NBr}/C_{Cu(ClO_4)_2}$ ratio for $Cu(ClO_4)_2$–Et_4NBr solutions in DMF at 25°C for the isosbestic point at 587 nm. (1) $C_{Cu(ClO_4)_2} = 0.005$ mol dm^{-3}, (2) $C_{Cu(ClO_4)_2} = 0.00034$.

by an increasing Et_4NBr concentration are illustrated in Fig. 2 (showing the 592-nm band only). This band seems to be due to the higher bromo complex of copper(II). Moreover, the drastic difference in shape and position suggests a corresponding change in the geometry of the complex. We infer that the band is associated with the presence of a four-coordinate bromo complex of copper(II). At $Et_4NBr/Cu(ClO_4)_2$ ratios from *ca* 1.3 to 4.1 an increase in Et_4NBr concentration results in the gradual growth of this band. When the $Et_4NBr/Cu(ClO_4)_2$ ratio amounts to 19.5 a distinct change in the spectrum of copper(II) is observed. The effect consists in the development of a new band with the maximum shifted toward shorter wavelengths. Subsequently, two well-defined isosbestic points can be observed on the spectra at 504 and 587 nm. Their appearance indicates a two-species equilibrium established within the 19–34 range of the Br^-/Cu^{2+} ratio. Due to the high excess of bromide ion we infer that one of the complexes is the $CuBr_4^{2-}$ complex. The effect of increasing the Et_4NBr concentration becomes more clear when the mean molar absorption coefficient of copper(II) at the wavelength of the isosbestic point is plotted against the Br^-/Cu^{2+} ratio. Figure 3 shows the corresponding plots for the isosbestic point at 587 nm obtained for two series of $Cu(ClO_4)_2$–Et_4NBr solutions markedly differing in $Cu(ClO_4)_2$ concentration. Curve 1 represents the results obtained for the series of solutions containing $Cu(ClO_4)_2$ at a constant concentration of 0.0050 mol dm^{-3}, while curve 2 shows the results obtained in the same range of $Et_4NBr/Cu(ClO_4)_2$ ratios for a lower concentration of $Cu(ClO_4)_2$ (0.00034 mol dm^{-3}). As is seen, the isosbestic point may be observed for the set of spectra corresponding to curve 1, as is indicated by the horizontal section of the plot. Moreover, this fact indicates clearly that the isosbestic points can be observed for more concentrated solutions only. This observation seems to be of practical importance for a study of the analogous systems.

The spectra of a series of solutions of $CuBr_2$ within the concentration range 0.0005–0.06 mol dm^{-3} at 25°C are shown in Fig. 4. The most characteristic feature of the presented set of spectra of copper(II) is the presence of the absorption band with a maximum at 592 nm observed previously for $Et_4NBr/Cu(ClO_4)_2$ ratios exceeding 1.0, but lower than 19.5 (Figs 1 and 2). Inspection of Fig. 4 shows that the band position is independent of salt concentration, while a variation in the intensity with the increase in $CuBr_2$ concentration is observed. The effect of concentration becomes more evident when the mean molar absorption coefficient of copper(II) is plotted against the $CuBr_2$ concentration for the isosbestic point at 587 nm (Fig. 5). The most characteristic feature of this dependence is the sharp increase in the intensity with the increase in $CuBr_2$ concentration below 0.01 mol dm^{-3}, while a further increase in the salt concentration affects the spectrum to a lesser extent.

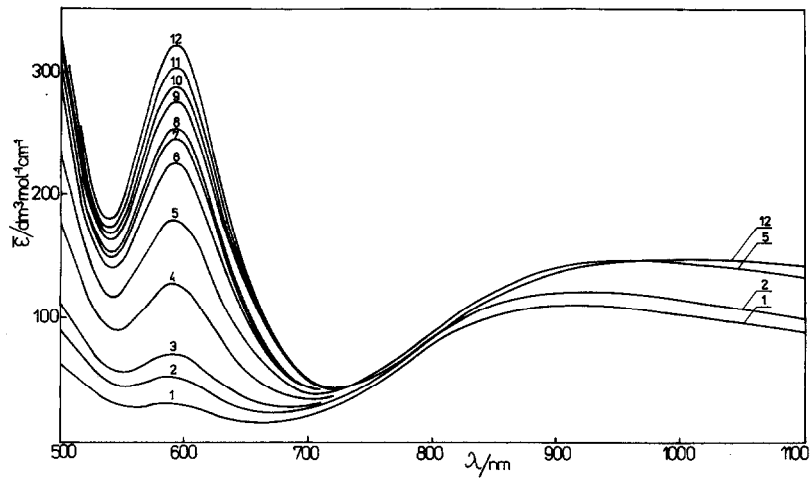

Fig. 4. Visible absorption spectra of $CuBr_2$ solutions in DMF at 25°C. The molar concentrations of $CuBr_2$ are: (1) 0.0004834, (2) 0.0007023, (3) 0.0009793, (4) 0.001953, (5) 0.003644, (6) 0.007327, (7) 0.01022, (8) 0.01319, (9) 0.02021, (10) 0.02682, (11) 0.04020, (12) 0.05536.

This fact may be interpreted in terms of replacing the six-coordinated complexes with the four-coordinated one. The independence of the band position and shape of $CuBr_2$ concentration suggests that only one four-coordinated complex of copper(II) exists in solution. Moreover, an increase in the $CuBr_2$ concentration in the solution brings about an increase in its relative content.

Figure 6 shows the molar-conductance curve of $CuBr_2$ in DMF at 25°C, while the experimental values are listed in Table 1. We may note that the limiting molar conductance of $CuBr_2$ would have

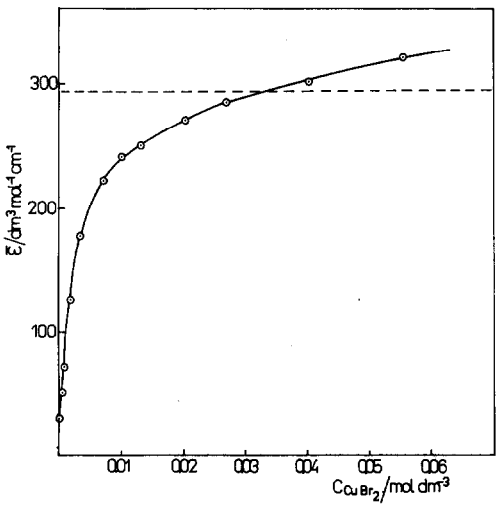

Fig. 5. Plot of the mean molar absorption coefficient of copper(II) for DMF solutions of $CuBr_2$ at 25°C for the isosbestic point at 587 nm. The broken line corresponds to 50% of copper(II) in the form of the $CuBr_3DMF^-$ complex.

the value 187.3 S cm^2 mol^{-1}, calculated from known ionic conductances,[9,10] and this value is significantly higher than the value obtained for the most dilute solution. The solid line in Fig. 6 indicates a fragment of the molar-conductance curve predicted for $CuBr_2$ with the assumption that the solute exists in DMF as a 1 : 1-type electrolyte, i.e. the $CuBr(DMF)_5^+ \cdot Br^-$ complex electrolyte. It becomes clear that extensive complex formation must occur already in the lowest concentration range. Moreover, it can be seen from Fig. 6 that the molar-conductance curve runs almost horizontally at higher $CuBr_2$ concentrations. Such behaviour was found to be characteristic of the formation of ionic species in solution.[7,13] This range of higher concentrations corresponds to the appearance of the band with a maximum at 592 nm in the spectrum of the $CuBr_2$ solution. Thus, we infer that the band is due to the presence of the $CuBr_3(DMF)^-$ complex anion. Formation of this tribromo complex of copper(II) is responsible for the low molar-conductance values. A qualitative confirmation of this conclusion is provided by the effect which the addition of a non-coordinating diluent of low polarity (chlorobenzene) exerts on the spectrum of $CuBr_2$ dissolved in DMF. The spectra of copper(II) observed at a high chlorobenzene content are shown in Fig. 7 along with the spectrum of $CuBr_2$ in pure DMF. As is seen, the addition of diluent results in the disappearance of the band with a maximum at 592 nm. However, this effect is accompanied by the development of a new absorption band with a maximum at *ca* 652 nm (curve 4, 95 mol % of chlorobenzene). It may be expected that the decrease in the dielectric constant of the medium

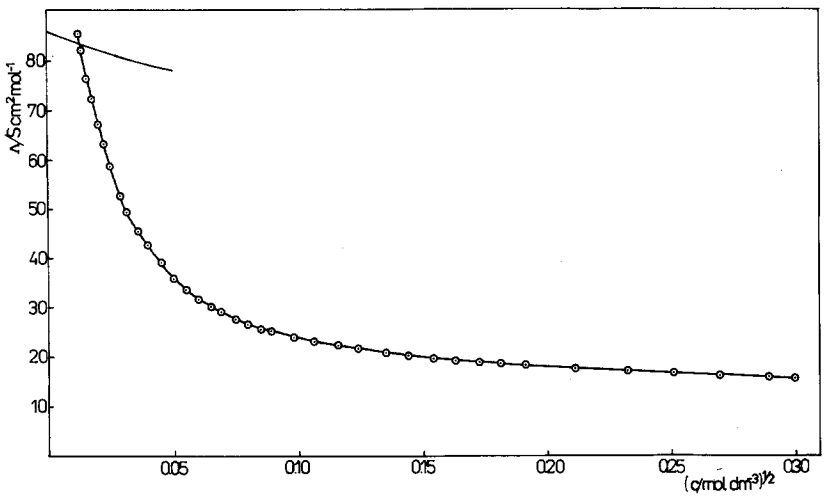

Fig. 6. Plot of the molar conductance of $CuBr_2$ in DMF solutions against the square of concentration at 25°C. The solid line represents the conductometric curve predicted for the 1 : 1-type $CuBr^+ \cdot Br^-$ complex electrolyte.

favours the formation of a neutral species. Thus, it seems to be evident that the light-absorbing complex of copper(II) existing in a DMF solution of $CuBr_2$ is the $CuBr_3(DMF)^-$ complex anion, while the species responsible for the absorption band at 652 nm is a neutral dibromo complex of copper(II), i.e. the pseudotetrahedral $CuBr_2(DMF)_2$ complex. Further conformation of this conclusion arises from the influence of temperature on the intensity of the band at 652 nm. Figure 8 shows the spectra of the $CuBr_2$–DMF–chlorobenzene (95 mol %) solution determined at three different temperatures. As is seen, an increase in the temperature brings about a distinct increase in the band intensity. This temperature variation of the spectrum is consistent with the conclusion mentioned above. The increase in temperature results in a liberation of the coordinatively active solvent from the six-coordinated

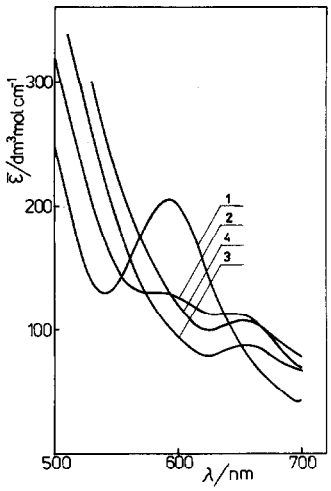

Fig. 7. Absorption spectra of copper(II) for $CuBr_2$–DMF–chlorobenzene solutions at 25°C for constant $CuBr_2$ concentration (0.00512 mol dm^{-3}) and variable chlorobenzene mole fraction: (1) 0.0, (2) 0.638, (3) 0.862, (4) 0.945.

species and the non-ionic $CuBr_2(DMF)_2$ complex is formed. Additional manifestations of this process are the changes observed at longer wavelengths consisting of a decrease in intensity and a blue-shift of the broad band with a maximum between 920 and 940 nm.

The most important feature of the spectra obtained at 25°C for the DMF solutions of $CuBr_2$ is the band due to the presence of the $CuBr_3(DMF)^-$ complex located in the spectral range where absorption due to the six-coordinate species can be ignored. Thus, the band intensity is directly related to the mole fraction of copper(II) existing as the tribromo complex. Figure 5 shows the concentration dependence of the mean molar absorption coefficient of copper(II) in DMF solutions of $CuBr_2$ ($\bar{\varepsilon}$) at the isosbestic point at 587 nm where the molar absorption coefficients of $CuBr_3(DMF)^-$ and $CuBr_4^{2-}$ have a common value of $\varepsilon_{34} = 588$ dm^3 mol^{-1} cm^{-1}. The above results permit the calculation of the equilibrium concentration of the $CuBr_3(DMF)^-$ complex. Thus, ignoring absorption due to other species, the mole fraction of the tribromo complex may be calculated as:

$$\frac{C_3}{C} = \frac{\bar{\varepsilon}}{\varepsilon_{34}}. \tag{1}$$

Inspection of the plot presented in Fig. 5 shows that the value of $\bar{\varepsilon}$ approaches 320 dm^3 mol^{-1} cm^{-1} in the more concentrated solution. Taking into account the value of ε_{34} the mole fraction of $CuBr_3(DMF)^-$ amounts to 0.54. It means that more than 50% of the copper(II) exists as the $CuBr_3(DMF)^-$ complex in more concentrated solutions of $CuBr_2$. It should be noted that the value of 0.54 is lower than the value of $\frac{2}{3}$ expected for complete binding of bromide to the $CuBr_3(DMF)^-$ complex. However, we infer that such a situation is possible for the most concentrated solutions of $CuBr_2$. It corresponds to the formation of a complex electrolyte of type $ML_6^{2+} \cdot 2MX_3L^-$ (L denotes the solvent molecule) known to be one of the most common coordination forms of the transition-metal halides in donor solvents.[7,13,14]

The results presented above provide the possibility of calculating stability constants of all the complexes assumed to be formed in DMF solutions of $CuBr_2$. In the computer analysis performed we assumed the formation of the $CuBr^+$, $CuBr_2$ and $CuBr_3^-$ formal complexes, the corresponding formation constants being defined as:

$$K_n = \frac{C_n}{C_{n-1}[Br^-]} Y_n, \tag{2}$$

where $n = 1$, 2 or 3, and Y_n is the quotient of the respective activity coefficients. Variations in the activity coefficients were assumed to follow the Debye–Hückel equation involving the ion-size parameter *Bå*, the latter being estimated from conductance data[9] as 3.3. Taking into account the equations

$$C = C_0 + C_1 + C_2 + C_3, \tag{3}$$

$$2C = C_1 + 2C_2 + 3C_3 + [Br^-], \tag{4}$$

arising from the material balance for the cation and anion we attempted to find the best values of K_n describing the properties of the DMF solutions of $CuBr_2$ for the range of concentrations in which the absorption due to $CuBr_3(DMF)^-$ was measured. The resulting values of the logarithms of the formation constants are: $\log K_1 = 3.35$ (± 0.10), $\log K_2 = 2.05$ (± 0.05) and $\log K_3 = 3.40$ (± 0.05). The equilibrium concentrations of the single com-

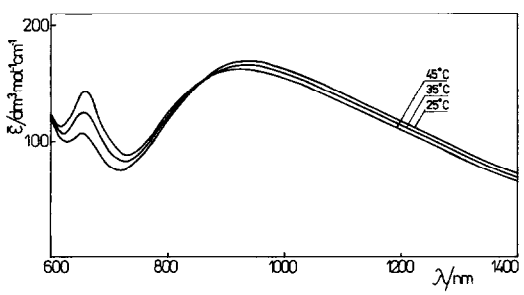

Fig. 8. The influence of temperature on the absorption spectrum of copper(II) for $CuBr_2$–DMF–chlorobenzene solution ($C_{CuBr_2} = 0.0051$, $X_{chlorobenzene} = 0.945$).

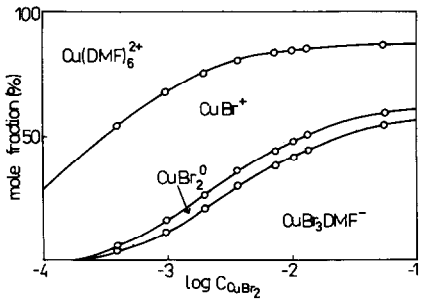

Fig. 9. Formation diagram for the copper(II) complexes in DMF solutions of $CuBr_2$ at 25°C.

plexes found for different concentrations of the solute have been used for preparing the distribution diagram shown in Fig. 9. As is seen, the dominating bromo complexes of copper(II) are the mono- and tribromo species while the formation of the dibromo complexes is an effect of minor importance for the $CuBr_2$–DMF system as well as for the $CuBr_2$–DMF–chlorobenzene solutions. The established sequence of the formation constants, $K_1 > K_2 < K_3$, reflects properly the change in the coordination number of the central metal atom upon coordinating the third bromide anion.

It seems to be of interest to compare the data obtained with results reported by Vierling for the chloro complexes of copper(II) in DMF.[1] The formation constants obtained correspond to values of 3.35, 5.40 and 8.8 for the logarithms of the stability constants of the mono-, di- and tribromo complexes of copper(II), respectively, while the values for the corresponding chloro complexes are 4.4, 9.0 and 12.0. It seems to be obvious that the higher stability of the chloro complexes is a consequence of the better donicity of chloride anion. The order of donor strength found by Gutmann[15] is as follows: $\ldots I^- < Br^- < DMF \leqslant Cl^- < DMSO \ldots$

(*Received* 19 *August* 1986; *accepted* 22 *December* 1986)

Abstract—Methylphosphinediacetic acid (H_2G) is coordinated to nickel(II) in two different ways, depending on whether its carboxyl groups are protonated or dissociated. The acid behaves as a monodentate tertiary phosphine in that it yields a series of *trans*-square planar $NiX_2(H_2G)_2$ complexes (X = Cl, Br, NCS or CN) which are stable in the solid state and as solutions in polar non-aqueous solvents. In neutral aqueous solution the NiG_2^{2-} complex is the predominant species ($\log\beta_2 = 8.24$ at 25°C and $I = 0.1$) even in excess nickel(II). Solid $NiG \cdot 4H_2O$ is the nickel salt of this anion, $Ni[NiG_2] \cdot 8H_2O$. The X-ray structural determination of the barium salt, $BaNiG_2 \cdot NaClO_4 \cdot 5H_2O$, revealed the uncommon *cis*-square planar arrangement around nickel with the G^{2-} anions acting as chelating P,O-bidentate to nickel and as O-monodentate to barium. Sodium and perchlorate ions are located between the complex units and, surprisingly, cannot be removed on recrystallization.

Phosphineacetic acids belong to the class of functionalized phosphines which are capable of coordinating metal ions through the soft or hard donor or through both donors simultaneously as chelating or bridging ligands. Depending on the metal ion type and the structure of the particular phosphineacetate, all these coordination modes have been demonstrated for complexes studied in this laboratory.[1] From the ligands investigated, those with the general formula $RP(CH_2CO_2H)_2$ represent a series which offers a possibility of studying the influence of the R substituent on the coordination properties of the potentially terdentate $-P(CH_2CO_2)^{2-}$ group. As expected, the coordination behaviour has been shown to change drastically from $R = C_6H_5$[2] to $R = C_2H_5$.[3] Hence, a program was developed to synthesize and study several ligands containing R groups with very different steric and/or electronic parameters. The present paper describes nickel(II) complexes of methylphosphinediacetic acid[4] (H_2G) as the ligand involving the sterically undemanding methyl substituent with a marked $+I$ effect.

EXPERIMENTAL

The synthesis of the ligand[4] and most of the experimental techniques[3–5] have been described. All manipulations with solutions were carried out in a dry argon atmosphere; the solids are air-stable.

Preparation of the complexes

$NiCl_2(H_2G)_2$: 1 mmol $NiCl_2 \cdot 6H_2O$ and 2 mmol $H_2G \cdot HCl$ were dissolved in a small amount of water and repeatedly evaporated *in vacuo* to dryness with excess acetic acid–benzene (1 : 1 vol.) until a red crystalline material separated. This was dissolved in hot acetic acid, filtered and allowed to cool slowly. Recrystallization from acetic acid and drying at 80°C/0.2 kPa gave the product in 55% yield.

$NiX_2(H_2G)_2$ (X = Br, NCS or CN) were obtained by metathesis of the chlorocomplex with stoichiometric amounts of KX in acetic acid, filtration of KCl and crystallization (for X = CN, crystallization was induced by addition of benzene). Yields of the recrystallized (acetic acid) and dried complexes varied between 40 and 70%. The iodo complex could not be obtained pure because of irreversible precipitation of anhydrous NiI_2. For measurements in solution, the complex was freshly prepared by metathesis and removal of KCl by filtration where necessary.

† Anorganisch-Chemisches Institut der Universität Bonn. Present address: Institut für anorganische Chemie II, Egerlandstrasse 1, 8520 Erlangen, F.R.G.

$NiG \cdot 4H_2O$: 1 mmol $H_2G \cdot HCl$ was dissolved in 4 cm^3 water, neutralized by 1.5 mmol Li_2CO_3 and mixed with 1.02 mmol hydrated nickel(II) perchlorate. The product was precipitated by slow addition of excess ethanol. After washing with ethanol and drying at 25°/0.2 kPa the yield was 85%.

$BaNiG_2 \cdot NaClO_4 \cdot 5H_2O$: 4.00 mmol $H_2G \cdot HCl$, 2.00 mmol hydrated nickel(II) perchlorate and 2.00 mmol hydrated barium(II) perchlorate were dissolved in 6.00 cm^3 2.00 M NaOH. After addition of 6 cm^3 ethanol at 60°C and cooling, the product suddenly crystallized out. It was recrystallized twice from 50% (vol.) aqueous ethanol and dried at 25°C/0.2 kPa with an overall yield of 65%.

CAUTION: the compound detonates violently on heating above 230°C.

Numerous attempts to obtain a product of this type in the absence of sodium and/or perchlorate ions failed.

The samples containing ^{64}Ni were prepared from ^{64}NiO (Tekhsnabeksport, U.S.S.R.) by scaling down the procedures outlined.

Analytical data for all the new compounds (C, H, Ni, P, halogens, N, Na, Ba and H_2O where appropriate) agreed with the calculated values within ± 0.5 relative %.

Crystal structure determination

The preparation of single crystals of $BaNiG_2 \cdot NaClO_4 \cdot 5H_2O$ involved considerable difficulty, mainly because of the notorious tendency of needle-like crystals to aggregate along the needle axis. Finally, 0.2 mmol $NiBr_2(H_2G)_2$ dissolved in 1 cm^3 water was neutralized with 0.4 cm^3 2 M NaOH, and the solution was poured into a long 5-mm internal diameter test tube and mixed with 1.4 cm^3 of a freshly prepared 5% gelatine solution in 50 vol. % aqueous ethanol. After formation of the gel, a solution of 0.2 mmol $Ba(ClO_4)_2 \cdot 3H_2O$ in 2 cm^3 ethanol was carefully layered on the top, the tube was sealed and left undisturbed for 2 weeks at room temperature. Crystals which formed in the gel layer were isolated by thorough decantation with 70 vol. % and then absolute ethanol. Their identity and quality was confirmed by Weissenberg photographs. The sample chosen for X-ray measurement was about $1.0 \times 0.15 \times 0.04$ mm^3. 6898 reflections were collected for $3° < 2\theta < 54°$. 5244 asymmetric data yielded a final number of 4386 strong reflections with $F > 4\sigma$. The symmetry is triclinic, space group $P\bar{1}$, $a = 6.991(2)$, $b = 11.470(3)$, $c = 15.341(3)$ Å, $\alpha = 102.09(2)°$, $\beta = 91.60(2)°$, $\gamma = 90.47(2)°$, $V = 1202.2(5)$ $Å^3$, $d_m = 1.99$ (flotation in bromoform–benzene), $d_x = 2.02$ g cm^{-3}, $Z = 2$, $R = 0.045$, $R_w = 0.040$, and the number of refined parameters is 331. The measurement was carried out on a Nicolet R3m diffractometer. The radiation was Mo-K_α, the unit cell was refined using 16 reflections, and the Wykoff scan from 2.0 to 29.3° min^{-1}, scan width 1.0°. Structure determination using direct methods (SHELXTL), anisotropic refinement of non-hydrogen atoms, the hydrogen atoms were calculated for ideal tetrahedra and refined in rigid groups. Isotropic hydrogens, water hydrogen atoms with a fixed temperature factor of 0.1. The last refinement used a weighting scheme with $w = 1/\sigma^2[R_w]$. Final atomic coordinates, thermal parameters and a list of bond lengths and angles have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The properties of the complexes are summarized in Table 1.

H_2G as the ligand

Analogously to other monophosphineacetic acids, H_2G in non-aqueous solvents of medium polarity coordinates to nickel(II) as a monodentate phosphine forming complexes of the $NiX_2(H_2G)_2$ type. Their properties in the solid state and in solution are consistent[6] with the familiar *trans*-square planar structure and with uncoordinated, strongly hydrogen-bonded ligand carboxyl groups. The *trans* geometry follows unambiguously from the number of isotope-substitution-sensitive bands in the far-IR spectra.[5,7] As is usual for nickel(II) complexes, the thiocyanate is N-bonded.[8]

With the exception of the cyano complex, all members of the series decompose instantaneously in water to yield H_2G and NiX_2. The solutions in non-aqueous solvents contain monomeric molecules of the complexes, are non-conducting, and their UV–VIS spectra are identical with the solid-state spectra. The conductivity of the aqueous solution of $Ni(CN)_2(H_2G)_2$ can be explained by a partial dissociation of carboxyl protons as indicated[9] by the solution IR spectrum. In contrast, the Ni—CN bond persists even in a strong acid. All the complexes are kinetically labile as indicated by their NMR spectra consisting of broad bands. The spectra become sharper on cooling but remain unresolved at −40°C which is the temperature where the solubility of the samples becomes impractically low. Hence, the only information from the NMR spectra is the coordination shifts which exhibit usual trends suggesting a strong P → Niσ-interaction.

G^{2-} as the ligand

In aqueous solution, the G^{2-} anion coordinates to nickel(II) with the formation of the NiG_2^{2-} complex anion. The $Ni(ClO_4)_2$–G^{2-}–H^+ system was studied potentiometrically with a glass electrode at 25°C, $I = 0.1$(Na)ClO_4, total G = 0.002 and 0.003 M, 0.0004 < total Ni < 0.006 M, 1.8 < log H^+ < 12.5, and the stability constants obtained by the standard data treatment[10] are:

$$\log \beta_{120} = \log [NiG_2]/([Ni][G]^2) = 8.24(6),$$

$$\log \beta_{121} = \log [NiHG_2]/([Ni][H][G]^2) = 12.5(2),$$

$$\log \beta_{122} = \log [NiH_2G_2]/([Ni][H]^2[G]^2) = 16.1(2)$$

(charges omitted). Interestingly, no detectable amounts of 1 : 1 complexes are formed in the system under the given experimental conditions.

The properties of the complexes containing the NiG_2^{2-} anion suggest a square-planar arrangement involving the ligand as bidentate P,O-chelating with one carboxylate group free and thus easily protonated. Further protonation destroys the NiG_2 core completely. The formally 1 : 1 solid compound, $NiG \cdot 4H_2O$, should be certainly formulated as $Ni[NiG_2] \cdot 8H_2O$: the nickel(II) ion outside the NiG_2 core seems to be coordinated by water molecules and/or intra- and intermolecular carboxyl oxygens in a pseudo-octahedral arrangement, analogous to dinickel(II) ethylenediphosphinetetraacetate.[1(e),5] The structure of the barium salt of the complex anion represents a problem of special interest. Firstly, the compound contains the stoichiometric amount of sodium perchlorate which cannot be removed on recrystallization from aqueous ethanol. The IR spectrum indicates that the perchlorate is present as the ionic species. Secondly, the geometry of the (presumably planar) nickel coordination environment remains unclear on the basis of the spectral data: down to the temperature where measurements in aqueous methanol are possible, the complex is NMR-labile and the spectra thus yield no information about the P–CH_2 virtual coupling;[11] further, the IR spectrum is obscured by ligand bands in the region where the isotopic shifts of ν(Ni—O) should be of diagnostic value. However, the solution IR spectrum clearly shows the presence of two types of COO groups.[9] Consequently, an X-ray structural determination was undertaken.

The perspective view of the structure together with the atom numbering is depicted in Fig. 1 and the stereoview of the unit cell in Fig. 2. Table 2 summarizes the important distances and angles. The structure consists of NiG_2^{2-} complex anions with P,O-chelating ligands; the uncoordinated carboxyls form ionic bonds to barium(II). Hence, the G^{2-} anion should be formally considered as a simultaneously chelating and bridging terdentate ligand, which is a novel bonding type among phosphineacetates. The interspace available permits almost exact accommodation of perchlorate and sodium ions, thus probably explaining why analogous compounds without sodium perchlorate could not be prepared.

The conformation of the chelate rings and, consequently, the pertinent bonding distances and angles differ from one ring to another but are all unexceptional. As usual,[1] the main distortion of the ligand resulting from its coordination is located on the phosphorus atom with bonding angles varying between 97.4 and 125.8°. For the carboxylate

[b] Not assumed to be hydrogen bonding.

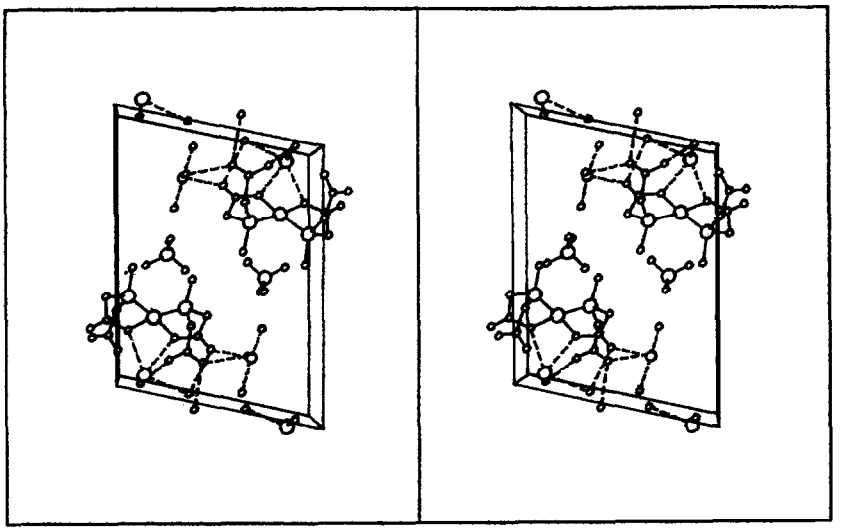

Fig. 2. Stereoview of the unit cell down the *a*-axis.

groups bonded to nickel, the carbonyl and hydroxyl C—O distances can be safely distinguished (1.218, 1.206, 1.306, 1.317 Å, respectively), suggesting a high degree of covalency of the Ni—O bond. In contrast, the carboxylate bonds to barium are ionic with a mean C—O distance of 1.238(7) Å.

The environments of all three cations are more or less unusual. The nickel(II) coordination polyhedron represents a rare example of the *cis*-square planar monophosphine complex for which, to our knowledge, only one other representative has been safely authenticated.[12] The NiP_2O_2 moiety is planar within ± 0.04 Å and the distortion of the angles from an ideal square is attributable to the bulkiness of phosphorus. The available data suggest that there is a general tendency for P,O-chelating phosphineacetates to assume the P,P-*cis* arrangement in complexes of Group VIII metals,[1(b),(c),(e)] forming chelate rings of very similar envelope conformations irrespective of the metal ion type.

The environment of barium(II) includes nine oxygen atoms from water molecules and intra- and intermolecular carboxylate groups. As expected, the intramolecular bonding distances to O(14) and O(23) are considerably shorter than the remaining Ba–O contacts; consequently, the geometrical arrangement is distorted and does not seem to be simply related to any of the ideal polyhedrons calculated for the hard-sphere model.[13] Roughly stated, the BaO_9 moiety can be approximated as a pentagonal bipyramid with doubled axial positions and barium in the centre: the O(14) and O(23) atoms together with three water molecules constitute an approximate equatorial plane (within ± 0.34 Å including barium) yielding, probably by chance, the exact theoretical O—Ba—O angle of 72(6)°. Four intermolecular carboxylate oxygens arranged as two couples, $O(13)^{iii}+O(14)^{iii}$ and $O(12)^{v}+O(22)^{v}$, complete the arrangement at the two doubled axial positions. The straight line connecting the centers of gravity of the two couples of oxygen atoms intersects the mean equatorial plane at an acceptable angle of 85.7° and at a distance of only 0.25 Å from barium. The two pairs of axial oxygens adopt a staggered conformation with a dihedral angle of 45.8° between the Ba–$O(13)^{iii}$–$O(14)^{iii}$ and Ba–$O(12)^{v}$–$O(22)^{v}$ planes.

The environment of sodium(I) is a distorted trigonal bipyramid with three water molecules forming an equatorial plane (within ± 0.03 Å including sodium) and with two intermolecular carboxylate oxygens at the axial positions.

The water molecules are coordinated at barium and sodium; W(1) acts as a bridge between two adjacent barium ions. The hydrogen atoms of the water molecules could not be located precisely but, according to the geometry of O...O contacts,[14] are likely to be involved in hydrogen bonding to carboxylate oxygens (Table 2). The various degrees of participation of the water molecules in coordination and hydrogen bonding conform to the temperature factors of the water oxygen atoms.

STABILITY CONSTANTS OF BORATE COMPLEXES OF OLIGOSACCHARIDES

J. F. VERCHERE* and M. HLAIBI

Laboratoire de Chimie Macromoléculaire, U.A. 500 du C.N.R.S., Faculté des Sciences de Rouen, B.P. 67, 76130 Mont-Saint-Aignan, France

(*Received* 28 *November* 1986; *accepted* 22 *December* 1986)

Abstract—The formation of borate complexes of several mono-, di- and trisaccharides in aqueous solution [$t = 25°C$, $I = 0.1$ M (KCl)] was studied by the potentiometric method. Values of the stability constants β_1 and β_2 of the 1 : 1 and 1 : 2 species were calculated for all compounds, using an extended version of the Antikainen equation. Raffinose, melezitose, saccharose and other fructose-containing oligosaccharides gave complexes of low stability, whereas lactulose and fructose gave very stable complexes. It is concluded that fructose moieties in oligosaccharides complex the borate anion by their 2- and 3-OH groups, in agreement with recent work by ^{11}B NMR.

The complexation of borate ion by polyhydroxy compounds has been widely studied, most of all for analytical purposes, and many polyols and sugars have been tested for the potentiometric determination of boric acid. Another interest of this reaction can be found in the field of bioinorganic chemistry, since many biological molecules contain hydroxyl groups in positions favourable for complexation. As a result, many sugars can be separated as borate complexes on anion-exchange resins,[1,2] and the use of a boric acid solution as an eluent permits the determination of several carbohydrates by HPLC with conductimetric detection.[3] We had begun the determination of the stability constants of the species involved in such experiments when a preliminary paper[4] by Lajunen *et al.* appeared on the same subject. These authors published stability constants for several borate–sugar complexes, most of which were assigned 1 : 1 stoichiometries. However, we have detected both 1 : 1 and 1 : 2 borate–sugar ratios for all the sugars we have studied. Examination of earlier literature revealed other discrepancies of the same type. For example, two papers[5,6] reported that all the sugars investigated formed 1 : 1 as well as 1 : 2 species, while the 1 : 1 complex was claimed[7] to be absent in the case of arabinose.

This prompted us to publish this account of our work in progress, using a modified treatment of the data obtained by the classical potentiometric method. Numerical calculations (assisted by a micro-computer) were performed instead of the traditional graphical methods, in order to avoid the problems encountered when the 1 : 1 and 1 : 2 complexes are of similar stabilities. It allowed the first determination of the stability constants of the complexes of two trisaccharides.

Principle

The principle of the potentiometric determination of the stability constants of borate–polyol complexes has been widely described.[4–10] It is well known that the acidity of boric acid, according to eqn (1), increases when complexation by a polyol occurs, as represented in eqn (2). One can therefore consider the new ionization equilibrium (3) of acidity constant $K'a$:

$$HB \rightleftharpoons B^- + H^+, \quad (1)$$

$$B^- + nL \rightleftharpoons BL_n^-, \quad (2)$$

$$HB + nL \rightleftharpoons BL_n^- + H^+, \quad (3)$$

where HB stands for boric acid, B^- for the borate ion, and BL_n^- for the 1 : n complex formed with the neutral ligand L. The acidity constants are K_a for boric acid alone and K'_a in the presence of ligand at concentration [L].

The values of pK'_a can easily be obtained by titrat-

* Author to whom correspondence should be addressed.

ing HB+L mixtures with a strong base. A more convenient method has been described[8] in which the ligand is added to a solution of borax. Attention must be paid to avoid: (i) the formation of polyborates, by using a low total boron concentration; and (ii) the protonation of the complexes, by working in neutral or slightly acidic media. Using these assumptions, Antikainen[9] derived the relationship known as the "Antikainen equation":

$$K'_a = k_n[L]^n + K_a, \quad (4)$$

in which k_n, the equilibrium constant for eqn (3), can be related to the stability constant β_n:

$$\beta_n = [BL_n^-]/[B^-][L]^n = k_n/K_a. \quad (5)$$

Subsequent studies have developed various formulations of this equation. When the complex is unique, a graphical treatment leads to a straight line, the slope and intercept of which determine the values of n and k_n. The intervention of a second species causes a curvature of the graphs, which are then treated anew so as to show two segments of slopes 1 and 2, respectively.

This method was found of little accuracy when applied to sugars which form two complexes of comparable stabilities. It made us look for a method which would not rest on the assumption of only one predominant species, but would take into account the simultaneous formation of several complexes. As a matter of fact, an extensive study[10] of the well-known borate–mannitol system[8] showed that, although small contributions of several other complexes could be demonstrated, a satisfactory description of the system in neutral media was possible by considering only the anionic 1:1 and 1:2 complexes. This conclusion was assumed to be true in every borate–sugar system, allowing us to write thus the analytical borate concentration:

$$c_B = [B^-] + [BL^-] + [BL_2^-]. \quad (6)$$

The concentrations of complexes BL^- and BL_2^- can be calculated as a function of $[B^-]$ using the stability constants β_1 and β_2:

$$c_B = [B^-](1 + \beta_1[L] + \beta_2[L]^2). \quad (7)$$

Using the notion of the conditional stability constant[11] which is basically identical to the apparent acidity constant K'_a used by Antikainen, we can write:

$$K'_a = c_B[H^+]/[HB]. \quad (8)$$

Finally, combining eqns (7) and (8) yields eqn (9):

$$K'_a = K_a(1 + \beta_1[L] + \beta_2[L]^2), \quad (9)$$

which is a more general form of the Antikainen equation.

EXPERIMENTAL

Chemicals

All the sugars, of the highest available commercial grade (Aldrich or Fluka), were used without further purification. The borax solutions were prepared from disodium tetraborate (Prolabo) and their concentrations were checked by titration with sodium hydroxide in the presence of sorbitol.[12] The borax concentration was kept very low to avoid any formation of polyborate ions (50 mg in 100 cm^3, corresponding to $c_B = 2.62 \times 10^{-3}$ M). The ionic strength was always 0.1 M (KCl).

In order to prevent any chemical or microbial degradation, the sugars were added in solid form in the borax solutions. It had the further advantage of minimizing the dilution effect of their introduction.

Apparatus

The measurements were made in a cell thermostated at 25°C by a water bath. The pH-metre was a Metrohm E 632, fitted with a Metrohm combined glass electrode, calibrated with commercial buffers (Prolabo Normadose). With some sugars, it was necessary to wait about 15 min before the stabilization of the pH values. However, we verified in several runs that the final values were reproducible.

Calculations

The experimental pH values of the borax–sugar mixtures (equivalent to pK'_a values) were compared to values calculated from eqn (9) on a micro-computer, using a laboratory-made BASIC routine. An iteration was then performed on the β_1 and β_2 parameters until the observation of the closest agreement between the two sets of values.

RESULTS

The complexes formed by the borate ion and 12 carbohydrates, including mono-, di- and trisaccharides, were studied by the potentiometric method. The values of the conditional acidity constants of boric acid, K'_a, were determined vs the concentration [L] of the ligand. Generally, we used the method[8] based on the measurement of the pH of borax–ligand mixtures, but when the complexation was fast, we checked that identical values of K'_a were obtained from the titration curves of boric acid by a base in the presence of ligand. For most sugars, however, the reaction was slow and the readings of pH were made after complete stabilization. It was

verified by duplicating the runs that the final pH values were highly reproducible, showing the observed pH drifts to be a slow conformational evolution to a definite equilibrium state.

The pK_a value for uncomplexed boric acid in our experimental conditions was checked in each experiment for [L] = 0. The mean value was $pK_a = 9.04 \pm 0.02$.

Typical sets of data and calculations are presented in Tables 1–4. The parameters β_1 and β_2 were adjusted in eqn (9) until complete agreement between calculated and experimental pK'_a values. For a given run, the accuracy on $\log \beta_n$ was ± 0.02. The comparison of several runs showed the values to have a mean standard deviation of ± 0.08. The values of the stability constants are collected in Table 5 and compared with literature values of different origins.

List of di- and trisaccharides[a]

Lactose	4-O-β-D-galactopyranosyl-D-glucose
Maltose	4-O-α-D-glucopyranosyl-D-glucose
Saccharose	α-D-glucopyranosyl-β-D-fructose
Lactulose	4-O-β-D-galactopyranosyl-D-fructose
Melibiose	6-O-α-D-galactopyranosyl-D-fructose
Turanose	3-O-α-D-glucopyranosyl-D-fructose
Raffinose	O-α-D-galactopyranosyl-(1 → 6)-α-D-glucopyranosyl-β-D-fructofuranoside
Melezitose	O-α-D-glucopyranosyl-(1 → 3)-β-D-fructofuranosyl-α-D-glucopyranoside

[a] The formulae are represented in Figs 1 and 2.

DISCUSSION

For all the oligosaccharides studied, we could determine the values of the stability constants β_1 *and* β_2, contrary to the results[4] of Lajunen *et al.*, who generally reported only β_1 values for disaccharides. Nevertheless, all of these β_1 values agreed

well. It is of interest to note that our values for lactose confirm those[6] of Evans *et al.*, who also found evidence for the formation of two complexes. Similarly, our results for arabinose concord with two earlier studies[5,6] on the existence of two complexes, although another paper[7] considered only the 1 : 2 species.

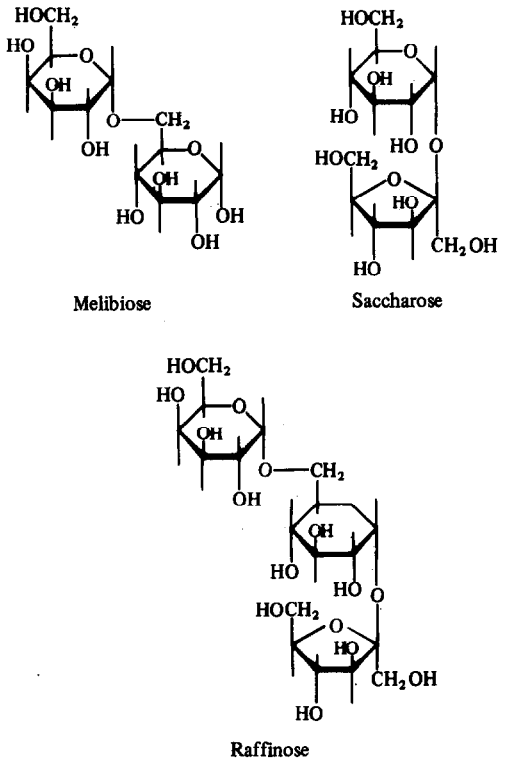

Fig. 1.

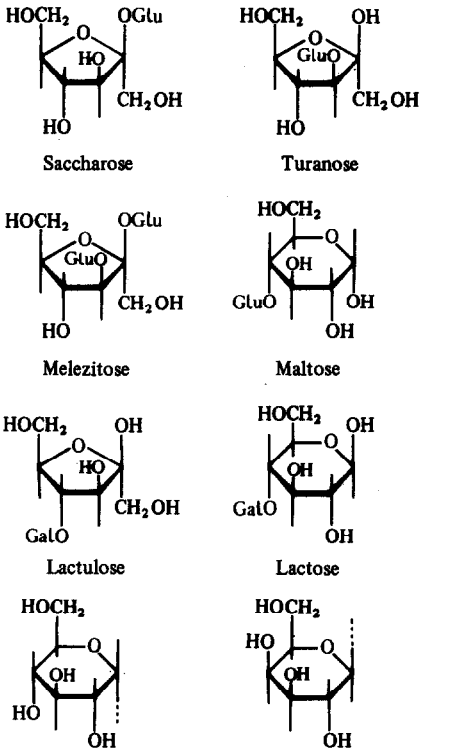

Fig. 2.

We first thought that the method employed by Lajunen *et al.*[4] did not allow the determination of low β_2 values, because this paper did not report values lower than $\log\beta_2 = 2.44$. It would have explained the absence of β_2 for lactose, maltose and saccharose. Besides, it could not account for the discrepancy on erythritol, for which we found $\log\beta_2 = 2.91$, with a β_1 value close to that given by Lajunen *et al.*

Therefore, we decided to check the validity of our method by studying three aldoses, glucose, galactose and mannose, for which the literature values were in good concordance. It can be seen in Table 5 that our results are close to previous ones, and we infer then that our procedure is as reliable as those used earlier. The results for arabinose lead to the same conclusion. Since the complexes of erythritol and arabinose appear to have stabilities comparable to those of the aldoses, there does not seem to exist any fundamental difference in the complexing behaviours of these monosaccharides, and hence any reason for their complexes displaying different stoichiometries. It makes the origin of the discrepancies even more puzzling.

This study allows interesting comparisons of the

stabilities of mono- and disaccharide complexes. The complexes of maltose (made of two glucose moieties) are weaker than those of glucose itself, and the complexes of lactose are weaker than those of its two constituents, glucose and galactose. This loss of complexing ability of glucose and galactose when they are engaged in disaccharides is probably due to the formation of the glycosidic link, which makes one anomeric hydroxyl group no longer available for complexation.

The case of fructose-containing oligosaccharides (Figs 1 and 2) appears much more complicated. Fructose is known[6,13] to give complexes of much higher stability than aldoses. However, saccharose forms complexes which present the lowest stabilities of all those investigated in this work. Moreover, the formation of the 1:2 complex from the 1:1 complex is thermodynamically unfavourable, since $\beta_2 < \beta_1$. In the same way, the complexes of turanose (3-O-α-D-glucopyranosyl-D-fructose) were reported[4] to be much weaker than those of fructose.

The results obtained for the trisaccharides can now be used to rationalize this difference. Raffinose (Fig. 1) can be considered as a combination, either of galactose and saccharose, or of melibiose and fructose. Lajunen *et al*'s results[4] and ours give the following order of stability of the complexes:

fructose ≫ melibiose > raffinose > saccharose.

Thus the addition of galactose to saccharose, to form raffinose, *increases* the complex stability. On the other hand, the addition of fructose to melibiose, to form raffinose, *decreases* the complex stability. It can be concluded that the complexation sites of raffinose and saccharose are not located on the fructose moiety. In the case of raffinose, these facts even suggest that the galactose moiety contains the complexation site.

Similarly, melezitose (Fig. 2) can be considered as a combination, either of saccharose and glucose, or of turanose and glucose. Since the order of stability of the complexes is:

fructose ≫ glucose > turanose

> melezitose > saccharose,

it is clear that the complexation sites of saccharose, turanose and melezitose are not situated on the fructose moiety, but on the glucose moieties. It can be noticed that the addition of glucose to saccharose, which forms melezitose, *increases* the stability of the borate complexes.

By contrast, other fructose-containing disaccharides form complexes as stable as those of fructose. This is the case[13] for isomaltulose (6-O-α-D-glucopyranosyl-D-fructose) and lactulose, as shown in Table 3. It clearly indicates that the borate ion is bound to the fructose moiety of the molecule since

the other moiety, which is an aldose, would form complexes of much lower stability. Further evidence is given by the comparison with lactose, which only differs from lactulose (Fig. 2) by a glucose moiety replacing the fructose moiety. Lactose gives only weak complexes, showing that the presence of a fructose moiety is indeed necessary for the formation of complexes of high stability.

We can conclude that the complexing properties of the fructose moiety in disaccharides dramatically depend on the location of the glycosidic link. This is obviously related to the fact that the complexation with a borate ion requires[14] two adjacent hydroxyl groups in adequate positions. The above discussion revealed that substitution of the 6-OH group (example of isomaltulose) and of the 4-OH group (example of lactulose) had almost no effect on the complexes stabilities. On the other hand, substitution of the 3-OH group (in the case of turanose), of the 2-OH group (in saccharose and raffinose), or of both groups (in melezitose), strongly decreased the affinity of fructose towards the borate ion. These conclusions are in perfect agreement with those of a recent ^{11}B and ^{13}C NMR study,[13] which deduced from the variations of the chemical shifts through complexation that borate was bound to the 2- and 3-OH groups of fructose, either free or combined to glucose in isomaltulose. The present study provides evidence that an extended version of the Antikainen equation allows an accurate calculation of the stability constants of borate–carbohydrate complexes, even with large ligands like di- or trisaccharides. Such determinations offer a basis for the establishment of structure–reactivity correlations, as examplified for a series of fructose-containing oligosaccharides. A demonstration of their usefulness can be found in a recent study[3] devoted to the conductimetric detection of carbohydrates, in which the observed order of sensitivity was exactly the same as the order of complex stability shown in Table 5.

Acknowledgement—We thank Mrs E. Leconte for her assistance in part of the experimental work.

CYCLIC VOLTAMMETRIC STUDIES INTO THE REDUCTION OF A SERIES OF TRIS(1,3-DIKETONATO)IRON(III) COMPOUNDS IN DICHLOROMETHANE AND DIMETHYLSULPHOXIDE

HOLLY J. McCARTHY and DEREK A. TOCHER*

Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(*Received* 5 *December* 1986; *accepted* 22 *December* 1986)

Abstract—A series of seven tris(1,3-diketonato)iron(III) chelates were prepared and studied using cyclic voltammetry in dichloromethane and dimethylsulphoxide. In the former solvent only a single reduction wave is observed and is assigned to the Fe(III)–Fe(II) couple. Despite the metal-based redox chemistry the formal potential is strongly influenced by the substituent groups on the chelating ligands and can be linearly correlated with the sum of the Taft inductive parameters for these substituents. In dimethylsulphoxide the reduced monoanion $[Fe(1,3\text{-diketonate})_3]^-$ undergoes a following chemical reaction which is interpreted as the extrusion of one 1,3-diketonate ligand. That reaction is an equilibrium and the position of the equilibrium is observed to depend upon the electronic effect of the substituent groups on the chelating ligands. For the strongly withdrawing trifluoroacetylacetonate ligand the dissociation of that ligand is essentially quantitative.

Transition-metal 1,3-diketonato complexes have been known for many years and have been subjected to study by numerous techniques.[1,2] Much research effort continues to be devoted to this topic. For example there are several recent literature reports into the catalytic properties of the compound $Ru(acac)_3$.[3–6]

Several years ago the polarographic reduction potentials of extended series of chromium(III) tris(1,3-diketonato) and ruthenium(III) tris(1,3-diketonato) compounds were reported in the literature.[7,8] A significant variation in these half-wave potentials was observed. That variation was rationalized on the basis of the relative electronic effects of the substituent groups on the 1,3-diketonato rings.

For many other transition metals only the parent compound, $M(acac)_2$ or $M(acac)_3$, has been examined electrochemically.[9] A case in point is that the redox chemistry of $Fe(acac)_3$† has been studied by several authors.[9–12] This compound undergoes a reversible reduction, assigned to a metal-based Fe(III)–Fe(II) couple, and an irreversible oxidation.[9] The reduction product, $[Fe(acac)_3]^-$, is observed to undergo a coordinative relaxation reaction with lithium ions in acetonitrile solution.[10]

In the present investigation seven tris(1,3-diketonato)iron(III) chelates were prepared and investigated using cyclic voltammetry in dichloromethane and dimethylsulphoxide.

EXPERIMENTAL

The Fe(III) chelates were prepared by established methods.[13]

Cyclic voltammetric studies were performed in dichloromethane and dimethylsulphoxide solutions, containing 0.2 and 0.1 mol dm^{-3}, respectively, of tetra-*n*-butylammonium tetrafluoroborate as supporting electrolyte, using the instrumentation and cell geometry previously described.[14]

† The following ligand abbreviations are employed: acac, acetylacetonate; tfp, trifluoroacetylacetonate; dbm, dibenzoylmethanide; bzac, benzoylacetonate; paa, 3-phenylacetylacetonate; tmh, tetramethyl-3,5-heptanedionate; maa, 3-methylacetylacetonate.

RESULTS AND DISCUSSION

Iron complexes are particularly suitable for electrochemical studies because of the existence of two well-defined oxidation states (II and III) of the metal ion. It was therefore not unexpected that the Fe(III)tris(1,3-diketonates) exhibited uncomplicated voltammetric behaviour in dichloromethane solution with current–voltage curves indicative of near reversible one-electron transfer reactions:

$$[Fe(R_1COCR_2COR_3)_3]+e^- \rightleftharpoons [Fe(R_1COCR_2COR_3)_3]^-, \quad (1)$$

and half-wave potentials strongly influenced by the nature of the chelate ring substituents. The reversibility of the electrode reactions was investigated in several ways. Plots of $i_p/v^{1/2}$ and $i_{p,c}/i_{p,a}$ vs v are linear in the range 20–500 mV s^{-1}, consistent with reversible electron transfer. The potentials $E_{p,c}$ and $E_{p,a}$ were observed to be independent of scan rate below 200 mV s^{-1}, and the peak-to-peak separations (ΔE_p) to be 60 ± 5 mV at 100 mV s^{-1}. Table 1 contains the voltammetric data on the electroreductions of this series of tris-chelate complexes.

Inspection of the data in Table 1 for the electrode reactions in dichloromethane solution immediately reveals the qualitative behaviour of the half-wave potentials with the nature of the substituent. Potentials become more positive [i.e. increasing ease of reduction of the Fe(III) species] as the number and type of electron-releasing substituents are decreased. Because these complexes can be assumed to possess similar trigonal geometries and a common redox active centre, the mechanism of electron transfer at the electrode surface should be the same, and linear free-energy relationships may be sought. Earlier two groups[7,8] explored such relationships in series of ruthenium and chromium tris(1,3-diketonato) complexes, and arguments were advanced for the use of both σ_m and σ_p Hammett parameters in such correlations. We have chosen to avoid the controversy as to which of Hammett's parameters is more appropriate in these systems by correlating our electrode potentials with the one-ligand sum of the Taft inductive parameters, which are independent of the stereochemical relationship between metal centre and position of the substituent group on the metallocyclic ring.

A plot of the potential for the one-electron reduction of the Fe(1,3-diketonato)$_3$ complexes against the one-ligand sum of Taft's inductive parameters is presented in Fig. 1. Free-energy relationships of this type have previously been described for other metal tris- and bis-chelate complexes,[15] though a firm theoretical justification has frequently been lacking. Thus for the present series of complexes such a relationship is best regarded as an empirical observation on the substituent effects on the Fe(1,3-diketonato)$_3$ $\rightleftharpoons$ [Fe(1,3-diketonato)$_3$]$^-$ redox couples.

It was pointed out several years ago that in order to correlate $E_{1/2}$ of Cu(1,3-diketonates)$_2$ to the electronic effect of the substituent groups on the ligands the chelates must be similarly substituted, i.e. all aliphatic, all aromatic, or all mixed aliphatic–aro-

matic substituents.[16] Correlations between different classes of these Cu(II) chelates are not straightforward. The same is not true, however, for the Cr(III)[7] or Ru(III)[8,17] 1,3-diketonate complexes, or for the Fe(III) 1,3-diketonate complexes discussed in this paper. For each of these three series of compounds strong correlations exist between the reduction potentials and the electronic effect of the substituent group(s), regardless of its identity. The other obvious difference between the copper complexes and those of the other three metals is the geometry of the diketonate ligands about the metal ion. It is likely that the electrode surface can interact more directly with the chelated Cu(II) than with the chelated M(III) ions on simple stereochemical grounds. Although the details of such interactions are unknown the consequences are clearly important in determining the nature of the ligands' influence on reduction potentials.

The potentials which we have obtained for the electroreduction of the Fe(III) tris(1,3-diketonate) compounds can be compared with those obtained earlier for the related ruthenium compounds. The potential range encompassed by the series of compounds described in this paper is some 0.99 V, with $Fe(tfp)_3$ being the easiest to reduce ($E_{1/2} = +0.02$ V), while $Fe(tmh)_3$ is the most difficult to reduce ($E_{1/2} = -0.97$ V). The potential interval for the related ruthenium complexes is 1.03 V (−0.36 to −1.39 V).[17] A detailed comparison of the reduction potentials for pairs of compounds with the same ligating groups clearly shows that in every instance the iron compound is substantially easier to reduce (by *ca* 0.1 V, after having made an appropriate correction for the different reference electrodes employed in the various studies). These observations are in keeping with the higher oxidation state becoming more favourable down the triad. Clearly the MO to which the electron is being added must contain substantial ligand character. Inasmuch as the t_{2g} metal orbitals can mix with the π ligand MOs a variation in substituent group will of necessity alter the energies of these orbitals[18] and hence a degree of substituent dependence of $E_{1/2}$ is expected. The ligand contribution to the redox-active MOs is difficult to quantify solely on the basis of electrochemical measurements. Nevertheless a recent report on the electrochemical properties of a series of Ni, Pd and Pt bis(dithio-1,3-diketonate) compounds[15] reached the conclusion that for these compounds the redox-active MOs are ligand-based, a deduction subsequently confirmed for $[Ni(MeCS \cdot CHCS \cdot Me)_2]^-$ by ESR spectroscopy.[19] Although the ligand participation in the redox-active MOs in this series of compounds is substantial we do not feel, at this time, that there is sufficient evidence to describe the electron-transfer reaction in dichloromethane as anything other than an Fe(III)–Fe(II) couple.

We turn now to the electrochemical behaviour in dimethylsulphoxide solution. Figure 2 illustrates the voltammagrams obtained for the compounds $Fe(acac)_3$ and $Fe(tfp)_3$ in dimethylsulphoxide solution, while Table 1 contains the pertinent data on the potentials for the electron-transfer reactions. The voltammagram for $Fe(acac)_3$ is characterized

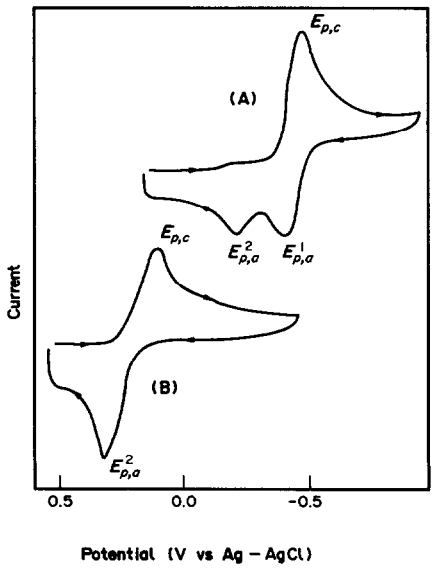

Fig. 2. Cyclic voltammograms of: (A) $Fe(acac)_3$, and (B) $Fe(tfp)_3$, in dimethylsulphoxide solution. Scan rate 100 mV s^{-1}.

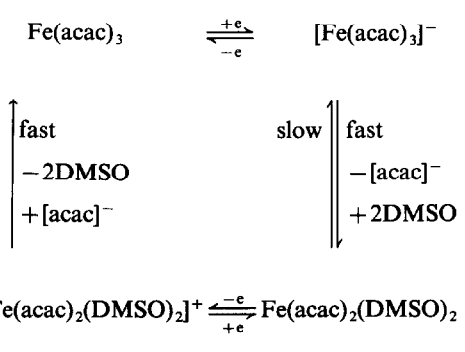
by a clean forward wave at −0.48 V. On reverse scan two responses are observed. The one at more negative potential, −0.38 V, can be attributed to the reoxidation of the $[Fe(acac)_3]^-$ formed initially. The second wave occurs at a significantly less cathodic potential, −0.19 V, and can most likely be assigned to the oxidation of $Fe(acac)_2(DMSO)_2$, as discussed below. At a scan rate of 100 mV s^{-1} the current ratio $I^l_{p,a}/I_{p,c}$ is *ca* 0.66. Surprisingly this current ratio *decreases* with increasing scan rate, and is observed to be a maximum (*ca* 0.90) at the slowest scan rate, 20 mV s^{-1}, which we have employed. At the same time it is observed that the peak attributed to $Fe(acac)_2(DMSO)_2$ is a maximum at fast scan rates. The voltammetric peak at less cathodic potentials, −0.19 V, is completely suppressed by addition of an excess of acac anions, in the form of Na(acac), to the electrochemical cell. This is indicative of the dissociative nature of the chemical reaction coupled to the electron transfer. Thus we believe that reaction to be of the form:

$$[Fe(acac)_3]^- \underset{}{\overset{DMSO}{\rightleftharpoons}} Fe(acac)_2(DMSO)_2 + [acac]^- . \quad (2)$$

There are a number of precedents for the dissociation of the acac ion from a reduced metal acetonate complex, usually, though not always, in the presence of an alkali metal ion.[10,11,17,20–22] The less cathodic oxidative response can be attributed to the removal of an electron from $Fe(acac)_2(DMSO)_2$. As the cation $[Fe(acac)_2(DMSO)_2]^+$ was not detected in subsequent scans that cation must rapidly recombine with the free $[acac]^-$ ion, reforming $Fe(acac)_3$. The unusual current response on varying the scan rate can best be explained by invoking a fast forward reaction and slow back reaction in eqn (2). The mechanism for the electroreduction/electrooxidation and coupled chemical reactions is fully illustrated in Scheme 1. The voltammetric behaviour of $Fe(dbm)_3$, $Fe(bzac)_3$, $Fe(paa)_3$ and $Fe(maa)_3$ is similar to that described for



Scheme 1. A mechanism for the behaviour of $Fe(acac)_3$ in dimethylsulphoxide solution.

$Fe(acac)_3$ although the details of the analysis differ. In particular it would appear that the position of the chemical equilibrium is significantly influenced by the electronic effects of the various substituents on the chelating ligands. The data which we have available suggest that the more electron-withdrawing are the chelating ligands' substituents the further to the right lie the equilibria of the type illustrated in eqn (2) (see Table 1). In the limiting case of $Fe(tfp)_3$ only a single reoxidation wave is observed. When Na[tfp] is added to the electrochemical cell the position of that wave shifts to a value *ca* 100 mV more cathodic and now occurs close to the potential at which we would expect to observe the oxidation of $[Fe(tfp)_3]^-$. Thus the voltammetric peak initially observed at +0.35 V must be due to the oxidation of $Fe(tfp)_2(DMSO)_2$, i.e. the redox behaviour of $Fe(tfp)_3$ in dimethylsulphoxide can also be rationalized on the basis of the scheme described earlier.

CONCLUSIONS

We have shown that the $[Fe(1,3\text{-diketonate})_3]^{0/-}$ couple is strongly influenced by substituent groups on the ligand, yielding an approximately linear plot of $E_{1/2}$ vs Taft inductive parameter (σ^*_R). The substituent dependence is very similar to that for the $[Ru(1,3\text{-diketonate})_3]^{0/-}$ couple, and is interpreted as the redox-active orbital having appreciable ligand character. The assignment from electrochemical studies alone of a redox process as being substantially metal- or ligand-based in character must be treated with caution. However, the systematic shifting in potentials on changing the metal centre from ruthenium to iron argues strongly for metal-based processes.

Measurements in dimethylsulphoxide solutions indicate that the reduced monoanions are activated towards substitution in the strongly coordinating solvent. The ability of the metal ion to participate in such coupled chemical reactions is a function of the substituent groups on the ligand and can be suppressed by addition of the free 1,3-diketonate anion. Parallels have been drawn between these reactions and the coordinative relaxation reactions of reduced metal 1,3-diketonates.

(*Received* 5 *December* 1986; *accepted* 22 *January* 1987)

Abstract—Mono- and dinuclear rhodium(I) complexes of formulae $[Rh(L_2)(bipym)]^+$ and $[\{Rh(L_2)\}_2(\mu\text{-bipym})]^{2+}$ [L_2 = diolefin or $(CO)_2$] have been prepared and their catalytic activity in hydrogen-transfer reactions explored. The heterodinuclear $[Cl_2Pd(\mu\text{-bipym})Rh(tfb)]ClO_4$ complex was obtained by reacting $[Rh(tfb)(bipym)]^+$ with $[PdCl_2(cod)]$ or alternatively from $[Rh(tfb)(acetone)_x]^+$ with $[PdCl_2(bipym)]$. Ion-pair complexes of formulae $[Rh(diolefin)(bipym)]^+[RhCl_2(diolefin)]^-$ (diolefin = cod, nbd or tfb) were prepared by adding bipym to acetone suspensions of $[RhCl(diolefin)]_2$.

The preparation and properties of cationic rhodium(I) complexes with chelating nitrogen donor ligands are of growing interest;[1–3] in particular, some of them, containing diolefins as ancillary ligands, are active catalyst precursors for hydrogen-transfer reactions.[4–7] There is also an increasing interest in the synthesis of mixed-valence or homo- and heterobinuclear complexes with bidentate bridging ligands,[8] due to the possibility of exploring their electronic interactions in a fundamental way and also utilizing such complexes for multielectron transfer catalysis; very recently a cationic ruthenium(II)–palladium(II) binuclear complex, and binuclear platinum(II) complexes bridged by 2,2′-bipyrimidine (bipym) have been reported.[9]

In this paper we describe some neutral and cationic rhodium(I) complexes, as well as a rhodium(I)–palladium(II) complex, with the bipym ligand which can potentially act as a chelate or "bidentate" bridging ligand between two metal centers.

RESULTS AND DISCUSSION

A general route for the synthesis of cationic species of the type $[Rh(L_2)(bipym)]^+$ [L_2 = tetrafluorobenzobicyclo(2,2,2)octatriene (tfb), bicyclo(2,2,1)heptadiene (nbd), 1,5-cyclooctadiene (cod) or $(CO)_2$] (compounds **1–4**) involves the reaction of the solvated $[Rh(L_2)(Me_2CO)_x]ClO_4$ intermediate with bipym, in the stoichiometric ratio 1:1. Compound **4** was also obtained by bubbling carbon monoxide through a dichloromethane solution of any of the $[Rh(diolefin)(bipym)]ClO_4$ complexes, or by reaction of $[Rh(acac)(CO)_2]$ (acac = acetylacetonate) with bipym in the presence of perchloric acid. After working up the compounds were isolated as air-stable microcrystalline solids in good yield; they are 1:1 electrolytes in acetone or nitromethane, and their IR spectra show bands due to the uncoordinated perchlorate anion at *ca* 1100s and 620s cm^{-1}. Complex **4** shows, in dichloromethane solution, two strong $\nu(CO)$ bands at 2105 and 2050 cm^{-1} typical of *cis*-dicarbonyl derivatives,[10] suggesting an electron density on the rhodium atom similar to that found for related 2,2′-bipyridine or 1,10-phenanthroline cationic complexes.[10,11] The coordinated bipym ligand in these complexes has two prominent bands near 1570 and 1550 cm^{-1} assigned to ring-stretching modes, a strong band at *ca* 745–750 cm^{-1}, due to the C—H bending mode, and one near 660 ascribed to the ring-bending mode of the phenyl groups. The low solubility of these compounds, in most solvents, prevented the obtaining of NMR spectra.

Most probably, the mononuclear $[Rh(L_2)(bipym)]^+$ complexes are square-planar with the bipym ligand acting in a bidentate way. Thus, these

* Author to whom correspondence should be addressed.

rhodium complexes have the capability of acting as N-donor ligands for metals, and could be considered as "metalloligands". So, homobinuclear rhodium complexes of formula $[\{Rh(diolefin)\}_2(\mu\text{-bipym})](ClO_4)_2$ (**5–7**) can be prepared by reacting $[Rh(diolefin)(Me_2CO)_x]^+$ species with the mononuclear $[Rh(diolefin)(bipym)]ClO_4$ complexes, or more directly by treating the solvated species with bipym in the ratio 2:1; they are obtained as air-stable black or brown microcrystalline solids, which are insoluble in diethylether or hexane, and only slightly soluble in acetone or dichloromethane. These products are 1:2 electrolytes in acetone and their IR spectra show bands of the uncoordinated perchlorate anion at *ca* 1100s and 620s cm^{-1} which are split, in the solid state, for complex **5**, may be indicating a coordination of the perchlorate anion in the solid state; a possible formulation could be $[Rh(OClO_3)(tfb)(bipym)Rh(tfb)]ClO_4$.* The coordinated bipym in these homobinuclear compounds presents, in the IR spectrum, differences from their monometallic precursors;[12] so, the 1550-cm^{-1} band, assigned to ring-stretching modes in the monometallic complexes is absent in the bimetallic derivatives; there is also an invariable decrease in energy, by *ca* 15–20 cm^{-1}, of the C—H bending mode, and finally the addition of the second metal leads to loss of the band near 600 cm^{-1}.

The mononuclear $[Rh(L_2)(bipym)]^+$ compounds can also act as N-donor ligands for other metals, so, reaction of the "metalloligand" complex **1** with $[PdCl_2(cod)]$, in acetone, gave the heterobinuclear $[Cl_2Pd(\mu\text{-bipym})Rh(tfb)]ClO_4$ (**8**). An alternative synthesis of this heterobinuclear complex was by the reaction of $[PdCl_2(bipym)]$ (**9**) {obtained from $[PdCl_2(cod)]$ or $[PdCl_2(tht)_2]$ (tht = tetrahydrothiophene)} with the solvated species $[Rh(tfb)(Me_2CO)_x]^+$; compound **8** was prepared as a brown, air-stable solid and it is a 1:1 electrolyte in acetone solution. Its IR spectrum shows bands due to the uncoordinated perchlorate anion at 1100s and 625s cm^{-1}; the coordinated bipym bands are similar to that found for the homobinuclear complexes, that is 1580s cm^{-1} (ring-stretching) and 735s cm^{-1} (C—H bending); there are also two ν(Pd—Cl) at 335 and 360 cm^{-1}, corresponding to two chlorine atoms *cis* to the palladium atom.

Attempts at preparing neutral dinuclear rhodium complexes containing the "RhCl(diolefin)" moiety and bipym as a bridging ligand, prompted us to explore the reaction of $[RhCl(diolefin)]_2$ with bipym (Rh : bipym ratio 2 : 1). With the diolefin cod, a red, very insoluble solid was obtained, in acetone (**10a**); analytical results revealed the presence of only one molecule of bipym for two rhodium atoms, and its IR spectrum in the solid state showed an absorption characteristic of a M—Cl terminal band *trans* to a C=C double bond in the species "MCl(cod)L".[19] These data suggested the formulation of the complex as a binuclear square-planar compound of formula $[\{RhCl(COD)\}_2(\mu\text{-bipym})]$. Stirring this red compound in chloroform caused the colour to change to green (**10b**), the 260-cm^{-1} band disappeared, and the product was slightly more soluble than the red solid. An ^1H NMR spectrum of compound **10b** shows two different types of cod: vinyl resonances at 4.27 (br, 8H), aliphatic resonances at 2.50 (br, 2H), 2.40 (br, 2H) and 1.76 (br, 2H), and 1.27 (br, 2H) ppm. This spectrum is characteristic of species of type $[Rh(cod)(bipym)][RhCl_2(cod)]$.[20]

When the diolefin was nbd or tfb, compounds **11** and **12** were obtained; they are dark-green solids, with IR spectra similar to that found for compound **10b**, so we formulated them as ion-pair species.

The reaction of $[RhCl(diolefin)]_2$ with bipym (Rh : bipym ratio 1 : 1) in acetone gave, for the diolefins cod and nbd, compounds **10a** and **11**, while, for tfb, a mononuclear rhodium compound was prepared (**13**). This compound did not show the ν(Rh—Cl) absorption band present in square-planar rhodium(I) chlorine complexes, indicating that the compound is probably five-coordinated, but in acetone solution it shows some conductivity (20 Ω^{-1} cm^2 mol^{-1}) which suggests an equilibrium between neutral five-coordinated and ionic square-planar species, with ionic chlorine.[21]

Finally, we have used the related 2,4,6-tris(2-pyridyl)-s-triazine (tpt) which has six nitrogen atoms and could potentially coordinate to three metallic centers. Thus, reacting this ligand with the solvated species $[Rh(nbd)(Me_2CO)_x]^+$ in the ratio 1:3 gave the cationic trinuclear complex $[\{Rh(nbd)\}_3(tpt)](ClO_4)_3$ (**14**).

Catalytic activity

The above-mentioned similarity of bipym to 2,2′-bipyridine or 1,10-phenanthroline prompted us to explore the ability of the diolefin complexes as catalyst precursors for hydrogen transfer from isopropanol to acetophenone in the presence of potassium hydroxide. Thus, after 1 h of reaction the extent of conversion (%), using 2,5-norbor-

* In this context, it is interesting to mention that, while the pentacoordinated tetrafluorobenzobarrelene complex of formula $[Ir(OClO_3)(tfb)(diolefin)]$ (diolefin = tfb[13] or cod[14]) and $[Rh(OClO_3)(tfb)_2]$[15] have been reported, only square-planar $[M(diolefine)_2]ClO_4$(M = Ir or Rh) compounds were obtained for diolefin = cod,[16] Me_3tfb[17] or nbd.[18]

nadiene rhodium precursors, decreased in the sequence $[\{Rh(nbd)\}_2(bipym)](ClO_4)_2$ (**52**) > $[Rh(nbd)(bipym)][RhCl_2(nbd)]$ (**8**) > $[Rh(nbd)(bipym)]ClO_4$ (**4**), whilst under similar conditions the well-known complex $[Rh(nbd)(phen)]ClO_4$[4] converted 60%. Interestingly 81% conversion was observed using $[\{Rh(nbd)\}_3(tpt)](ClO_4)_3$ as the catalyst precursor.

EXPERIMENTAL

C, H and N analyses were carried out with a Perkin–Elmer 240-B microanalyzer. Conductivities were measured at 20°C in *ca* 5×10^{-4} M acetone or nitromethane solutions using a 9501/01 conductometer. IR spectra were recorded on a Perkin–Elmer 599 spectrophotometer over the range 4000–200 cm^{-1}, using Nujol mulls between polyethylene sheets or in dichloromethane solution between NaCl plates. The GLC analyses were performed on a Perkin–Elmer 3920B chromatograph connected to a Perkin–Elmer M-2 integrator. The starting materials, $[RhCl(cod)]_2$,[22] $[RhCl(nbd)]_2$,[23] $[RhCl(tfb)]_2$,[24] $[Rh(acac)(CO)_2]$[25] and $[PdCl_2(cod)]$[26] were prepared by published methods.

$[Rh(diolefin)(bipym)]ClO_4$ (**1–3**)

An acetone solution (15 cm^3) of $[Rh(diolefin)(OCMe_2)_x]^+$ (diolefin = tfb, cod or nbd) {prepared by treating the appropriate $[RhClL_2]_2$ (0.1 mmol) with $AgClO_4$ (42 mg, 0.2 mmol) in acetone for 30 min and filtering off the AgCl formed} was added to a solution of bipym (32 mg, 0.2 mmol) in acetone. Evaporation of the solution to *ca* 1 cm^3 and addition of diethyl ether (15 cm^3) gave compounds **1–3** as microcrystalline solids which

[b] Nitromethane solvent. ν(CO) for complex **4**: 2105 and 2050 cm^{-1} (in dichloromethane).

were filtered, washed with diethyl ether and dried *in vacuo*.

$[Rh(CO)_2(bipym)]ClO_4$ (**4**)

This complex was prepared by two different routes:

(i) To a solution of $[Rh(acac)(CO)_2]$ (80 mg, 0.31 mmol) in acetone (20 cm^3) were added successively $HClO_4$ (0.31 mmol) and solid bipym (0.31 mmol). A slow precipitation of a yellow solid began immediately. After stirring the suspension for 30 min, diethyl ether (15 cm^3) was added and then the solid was filtered off, washed with diethyl ether and dried *in vacuo*.

(ii) Carbon monoxide was bubbled through a solution of $[Rh(diolefin)(bipym)]ClO_4$ (diolefin = tfb, cod or nbd) (0.10 mmol) in 5 cm^3 dichloromethane for 15 min, at room temperature. The resulting solution was vacuum concentrated to *ca* 0.5 cm^3. Slow addition of diethyl ether led to precipitation of required complex, which was filtered off, washed with diethyl ether, and vacuum dried.

$[\{Rh(diolefin)\}_2(bipym)](ClO_4)_2$ (**5–7**)

An acetone solution (20 cm^3) of $[Rh(diolefin)(OCMe_2)_x]^+$ (diolefin = tfb, cod or nbd) (0.26 mmol) was added to a solution of bipym (20.5 mg, 0.13 mmol) in acetone (5 cm^3). The initial yellow colour of the solution changed immediately to dark red and a black solid was formed. The mixture was stirred for 30 min, and then the solid was filtered off, washed with diethyl ether and air dried.

$[Cl_2Pd(bipym)Rh(tfb)]ClO_4$ (**8**)

This complex was prepared by two different routes:

(i) To an acetone suspension (30 cm^3) of complex **1** (0.15 mmol) solid $[PdCl_2(cod)]$ (0.15 mmol) was added. The mixture was stirred for 24 h giving a brown solid and a brown-reddish solution. After removing part of the acetone and adding diethyl ether, the solid was filtered off, washed with diethyl ether and air dried.

(ii) An acetone solution (20 cm^3) of $[Rh(tfb)(OCMe_2)_x]ClO_4$ (0.14 mmol) was added to a suspension of $[PdCl_2(bipym)]$ (**9**) (0.14 mmol) in acetone (10 cm^3). Precipitation of a brown solid began immediately. The mixture was stirred for 30 min. Diethyl ether was added, and then the solid was filtered off, washed with diethyl ether and air-dried.

$[PdCl_2(bipym)]$ (**9**)

This complex was prepared by two different routes:

(i) To an acetone solution (20 cm^3) of bipym (159 mg, 1.0 mmol) solid $[PdCl_2(cod)]$ (1.0 mmol) was added. The suspension was stirred for 12 h, yielding a light yellow solid which was filtered off, washed with acetone and vacuum dried.

(ii) Slow addition of a solution of $[PdCl_2(tht)_2]$ (353.0 mg, 1.0 mmol) in 10 cm^3 of acetone, to a solution of bipym (170.0 mg, 1.0 mmol) in 10 cm^3 of acetone led to instantaneous precipitation of a yellow solid. After 30 min, the solid was filtered off, washed with acetone and vacuum dried.

$[\{RhCl(cod)\}_2(bipym)]$ (**10a**)

Addition of bipym (35.0 mg, 0.22 mmol) to a suspension of $[RhCl(cod)]_2$ (54 mg, 0.11 mmol) in 20 cm^3 of acetone led to instantaneous precipitation of a red solid, which was filtered off, washed with acetone and vacuum dried.

$[Rh(cod)(bipym)][RhCl_2(cod)]$ (**10b**)

A suspension of $[\{RhCl(cod)\}_2(bipym)]$ (65.1 mg, 0.10 mmol) in 10 cm^3 of chloroform was stirred for 30 min. The green solid formed was filtered off and vacuum dried.

$[Rh(nbd)(bipym)][RhCl_2(nbd)]$ (**11**)

Addition of bipym (37.9 mg, 0.24 mmol) to a suspension of $[RhCl(nbd)]_2$ (55.2 mg, 0.12 mmol) in 20 cm^3 of acetone led to instantaneous precipitation of dark-green solid, which was filtered off, washed with acetone and vacuum dried.

$[Rh(tfb)(bipym)][RhCl_2(tfb)]$ (**12**)

The precedure described for preparation of **11** was used, but starting from $[RhCl(tfb)]_2$ (50.0 mg, 0.07 mmol) and bipym (10.8 mg, 0.07 mmol). A dark-green solid was obtained.

$[RhCl(tfb)(bipym)]$ (**13**)

The procedure described for preparation of **12** was used, but starting from $[RhCl(tfb)]_2$ (100.0 mg, 0.14 mmol) and bipym (48.4 mg, 0.31 mmol). A red solid was obtained.

$[\{Rh(nbd)\}_3(tpt)](ClO_4)_3$ (**14**)

An acetone solution (20 cm^3) of $[Rh(nbd)(OCMe_2)_x]ClO_4$ (0.1 mmol) was added to a sol-

ution of tpt (0.06 mmol) in acetone (10 cm^3). The initial yellow colour of the solution changed immediately to red. The mixture was stirred for 30 min. Evaporation of the solution to *ca* 2 cm^3 and addition of diethyl ether gave a brown solid which was filtered off, washed with diethyl ether and vacuum dried.

Table 1 collects analytical results, conductance and yields for the reported complexes.

Catalytic activity

The hydrogen-transfer reactions were carried out under argon in refluxing isopropanol with magnetic stirring. The equipment consisted of a 50-cm^3 round bottomed flask, fitted with a condenser and provided with a secum cap. The catalysts were prepared by adding potassium hydroxide (0.1 mmol) in isopropanol (1 cm^3) to an isopropanol solution (8 cm^3) of precursor complex (0.02 mmol referred to rhodium). The resulting solution was refluxed for 1 h, and 2 mmol of the substrate in isopropanol (1 cm^3) were injected. Reactions were followed by GLC using FFAP on Chromosorb GHP 80/100 mesh (3.6 m × $\frac{1}{8}$ in.) at 120°C.

(*Received* 6 *October* 1986; *accepted* 7 *January* 1987)

Abstract—Two compounds of the general formula $[L_3V(\mu\text{-}Cl)_3L_3]BPh_4$ [L = tetrahydrofuran (**1**) or 3-methyltetrahydrofuran (**2**)] were prepared and investigated via single-crystal X-ray studies. Compound **1**, tris(μ-chloro)hexakis(tetrahydrofuran)divanadium(II) tetraphenylborate, crystallizes in space group $P2_1/c$ with unit-cell dimensions: a = 16.636(6) Å, b = 16.771(5) Å, c = 19.158(5) Å, β = 110.71(4)°, V = 5000(6) Å^3, Z = 4. Compound **2**, tris(μ-chloro)hexakis(3-methyltetrahydrofuran)divanadium(II) tetraphenylborate, forms monoclinic crystals (space group Cc) with a = 18.376(5) Å, b = 10.843(3) Å, c = 29.317(6) Å, β = 103.02(2)°, V = 5691(5) Å^3, Z = 4. Refinement, by least-squares methods, using a data to parameter ratio of 6.1 for **1** and 9.1 for **2**, converged with an unweighted discrepancy index of 7.46 and 5.31% for **1** and **2**, respectively. The V—V′ distances are: 2.978(3) Å for **1** and 2.976(1) Å for **2**. The use of 3-methyltetrahydrofuran as a supporting ligand is discussed since such substituted THF molecules reduce the tendency to disorder in the $[V_2(\mu\text{-}Cl)_3(THF)_6]^+$ cations.

The reduction of $VCl_3(THF)_3$ in tetrahydrofuran (THF) with Zn or $AlR_2(OR)$ affords novel, vanadium(II), face-sharing bioctahedral complexes, $[V_2(\mu\text{-}Cl)_3(THF)_6]_2Zn_2Cl_6$ or $[V_2(\mu\text{-}Cl)_3(THF)_6]AlR_2Cl_2$, respectively.[1,2] These compounds proved to be useful starting materials for a variety of unusual dinuclear and polynuclear vanadium complexes.[3–7] However, crystallographic studies of $[V_2(\mu\text{-}Cl)_3(THF)_6]_2Zn_2Cl_6$, and in particular those of $[V_2(\mu\text{-}Cl)_3(THF)_6]AlR_2Cl_2$ (R = C_2H_5), were very difficult because of an extensive disorder in the THF ligands at room temperature. For $[V_2(\mu\text{-}Cl)_3(THF)_6]_2Zn_2Cl_6$ the quality of the intensity data was greatly improved by collection at −100°C and the structure was satisfactorily refined (the unweighted discrepancy index was 0.045).[1] Crystals of $[V_2(\mu\text{-}Cl)_3(THF)_6]AlEt_2Cl_2$ diffracted poorly (even at −100°C) and the structure could not be satisfactorily refined because of additional severe disorder in the diethyldichloroaluminate anion.[2]

In order to overcome these problems we decided to substitute 3-methyltetrahydrofuran for THF to see whether such substitution would improve the quality of the intensity data and result in a better crystallographic structure of the $[V_2(\mu\text{-}Cl)_3L_6]^+$ cation.

We report here the preparation of a new compound, $[L_3V(\mu\text{-}Cl)_3L_3]BPh_4$ (**2**) (L = 3-methyltetrahydrofuran), and its complete X-ray analysis. The crystallographic data are further compared with those for the THF analog (**1**), and it is demonstrated that a more accurate and nondisordered structure was obtained for the 3-methyltetrahydrofuran derivatives.

EXPERIMENTAL

All operations were performed under an atmosphere of argon by using standard Schlenk techniques and a double-manifold vacuum line. THF, 3-methyltetrahydrofuran and hexane were freshly

* Author to whom correspondence should be addressed.

distilled from benzophenone ketyl prior to use. Solutions were transferred via stainless steel cannulae and/or syringes. Anhydrous VCl_3 was purchased from Strem Chemicals, Inc. and 3-methyltetrahydrofuran and $AlEt_2(OEt)$ (as a 25 wt % solution in toluene) were purchased from Aldrich Chemical Co. $NaBPh_4$ was deaerated *in vacuo* at room temperature.

$[V_2(\mu\text{-}Cl)_3(THF)_6]BPh_4$ (1)

This compound was prepared from $[V_2(\mu\text{-}Cl)_3(THF)_6]_2(Zn_2Cl_6)$ according to our earlier published procedure.[1(b)] Better X-ray quality crystals were obtained by the following modified procedure. Several solutions of different concentration of **1** in THF were prepared and each of them was carefully covered with hexane at room temperature. The solutions were allowed to stand undisturbed for several weeks, after which period good-quality crystals of **1** were obtained from the most dilute solution.

$[V_2(\mu\text{-}Cl)_3(3\text{-methyltetrahydrofuran})_6]BPh_4$ (2)

A solution of VCl_3 (0.6 g, 0.8 mmol) in 10 cm^3 of freshly distilled 3-methyltetrahydrofuran was refluxed for 12 h under argon in a 50-cm^3 round-bottomed three-neck flask equipped with a magnetic stirrer and a reflux condenser. The solution became clear and red-orange in color. To this solution of $VCl_3(3\text{-methyltetrahydrofuran})_3$ in 3-methyltetrahydrofuran was added 7.5 cm^3 of a 25 wt % solution of $AlEt_2(OEt)$ in toluene via a syringe. The solution was stirred for 7 days at room temperature during which time the color changed to a bright green. This solution of $[V_2(\mu\text{-}Cl)_3(3\text{-methyltetrahydrofuran})_6]AlCl_2Et_2$ was then filtered through Celite 545 (Fisher Scientific Co.) onto 1.0 g (2.9 mmol) of $NaBPh_4$. The solution was stirred for 12 h at room temperature and filtered through Celite to a Schlenk tube. Freshly distilled hexane (25 cm^3) was carefully placed on top of this solution and the Schlenk tube was allowed to stand undisturbed for several days. Green X-ray quality crystals of **2** were isolated by filtration, washed with hexane and dried *in vacuo* [yield 1.5 g, 1.4 mmol (83%)].

X-ray crystallography

General procedures that have already been fully described elsewhere were used to determine the crystal structures.[8] Information about data collection and structure refinement for **1** and **2** is given in Table 1. The intensity data were corrected for Lorentz and polarization effects. The positions of vanadium atoms in the unit cell of **1** (space group $P2_1/c$) and **2** (space group Cc) were determined by direct methods using program MULTAN 84. A series of isotropic least-squares refinements and Fourier syntheses then revealed the rest of the structure. Two THF rings in **1** were assigned a disordered model with a fractional occupancy factor 0.5 for each carbon atom. Taking into account the number of observed reflections for **1** it was reasonable to limit anisotropic refinement to the V, Cl and O atoms only. In the case of **2** all atoms could be refined anisotropically. Since the 3-methyltetrahydrofuran derivative crystallized in a non-centrosymmetric space group the enantiomorph giving lower residuals was chosen for refinement.

Tables of positional and isotropic equivalent thermal parameters, anisotropic thermal parameters, *B*s, observed and calculated structure factors, as well as full lists of bond distances and angles for both compounds have been deposited as supplementary material with the Editor at Queen Mary College.

RESULTS AND DISCUSSION

Figures 1 and 2 show the two divanadium(II) cations, **1** and **2**, respectively, and define the atomic numbering scheme used in the tables and the following discussion. Tables 2 and 3 list important interatomic dimensions for **1** and **2**, respectively.

The structure of tris(μ-chloro)hexakis(tetrahydrofuran)divanadium(II) tetraphenylborate (**1**) has already been described by us in 1985.[1(b)] At that time, however, we were not able to obtain good-quality crystals of this compound so the reported structural determination was not very accurate. Since that time we have learnt more about complexes containing the $[(THF)_3V(\mu\text{-}Cl)_3V(THF)_3]^+$ cation and not only were we able to obtain better-quality single crystals of **1** (which still exhibit disorder in the THF ligands) but we have also prepared a new compound in this area which possesses non-disordered 3-methyltetrahydrofuran ligands, namely tris(μ-chloro)hexakis(3-methyltetrahydrofuran)divanadium(II) tetraphenylborate (**2**).

The immediate coordination sphere of the two vanadium centers in both cations is that of a bioctahedron sharing a face comprised of three chlorine atoms. The V—V distance of 2.978(3) Å in **1** and 2.976(1) Å in **2** is *ca* 3 Å, a value very similar to those in other compounds containing the $V(\mu\text{-}Cl)_3V$ unit which we have reported, e.g. 2.993(1) Å in $[(THF)_3V(\mu\text{-}Cl)_3V(THF)_3]_2Zn_2Cl_6$.[2] As expected the metal–ligand distances are practically the same in both compounds.

[a] Numbers in parentheses are estimated standard deviations in the least significant digits.

As mentioned in the introduction, the disorder in the THF ligands of **1** is extensive. It is associated with the adoption of different conformations by a particular THF ring. In some cases the different carbon atom positions could be resolved and they have been dealt with in a conventional manner by assigning fractional occupancy factors. In general, however, different conformations could not be resolved and the corresponding carbon atoms had relatively high thermal parameters. In contrast, the structure of **2** required no disorder treatment since well-refined carbon atoms of 3-methyltetrahydrofuran ligands were obtained, and this led to a lower unweighted discrepancy index of 5.31%. The estimated standard deviations of the interatomic dimensions are lower, roughly by a factor of 2 in the 3-methyltetrahydrofuran derivative.

The crystallization of **2** in a noncentrosymmetric space group indicates that the introduction of substituted THF leads to the formation and resolution of chiral isomers.

This report clearly shows that substitution of disordered THF ligands by 3-methyltetrahydrofuran results in more accurate X-ray structure determination. We believe that this is an artifice that could profitably be employed in many other cases.

SYNTHESIS AND STRUCTURAL CHARACTERIZATION OF A POLAR Os(II, III) COMPLEX, $Os_2(fhp)_4Cl$

F. ALBERT COTTON* and MAREK MATUSZ

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 26 *October* 1986; *accepted* 23 *January* 1987)

Abstract—The title compound was prepared by prolonged reaction of $Os_2(CH_3COO)_4Cl_2$ with Hfhp (Hfhp = 6-fluoro-2-hydroxypyridine) in refluxing toluene in the presence of LiCl. The product, $Os_2(fhp)_4Cl$ (**1**), is a result of ligand displacement with a concomitant core reduction of Os_2^{6+} to Os_2^{5+}. Crystals were grown by slow diffusion of hexane into a dichloromethane solution of **1**. Crystallographic data are as follows: tetragonal crystal system, space group *I*4*mm* (No. 107), $a = b = 11.000(3)$ Å, $c = 13.142(2)$ Å, $V = 1590(1)$ Å^3, $Z = 2$. The molecule possesses crystallographic 4*mm* symmetry, with the Os—Os bonds lying along the four-fold axes. The four fhp ligands are arranged in a polar fashion around the diosmium core, blocking one axial site. The second axial position is occupied by a chloride ion. The principal distances in **1** are: Os(1)—Os(2) = 2.341(1) Å, Os(1)—N = 2.027(12) Å, Os(2)—O = 2.014(5) Å, Os(2)—Cl = 2.487(7) Å. The title compound was also investigated by several physical methods. The electrochemistry as determined by cyclic voltammetry revealed two processes: a reversible, one-electron reduction at $E_{1/2} = -0.63$ V in dichloromethane and an irreversible oxidation at $E_{ox} = +0.95$ V in dichloromethane vs Ag–AgCl at room temperature. The electronic spectrum shows strong bands at 413 nm ($\varepsilon = 4290$ M^{-1} cm^{-1}), 309 nm ($\varepsilon = 23{,}560$ M^{-1} cm^{-1}) and at 294 nm ($\varepsilon = 26{,}500$ M^{-1} cm^{-1}) as well as shoulders at 334 and 261 nm.

In this laboratory we are continuing our investigation of compounds that contain a multiply-bonded Os_2^{n+} ($n = 4$, 5 or 6) core. Early reports suggested that attempted ligand substitution reactions on $Os_2(CH_3COO)_4Cl_2$ usually afford monomeric products,[1] but further investigations in our laboratory[2–5] and elsewhere[6] since then have provided routes to an array of multiply-bonded diosmium complexes. Our synthetic efforts have been focused on compounds containing 6-substituted oxypyridine anions as ligands. These ligands are generally useful in spanning multiply-bonded dimetallic units.[7] The steric demand of the substituent in the 6-position of the 2-hydroxypyridinato ring plays a crucial role in determining the structure and properties of the product. With the relatively bulky chlorine atom as a substituent two interesting molecules have been synthesized. A polar complex,[8] $Os_2(chp)_4Cl$, containing the Os_2^{5+} core is formed in the reaction of diosmium-tetraacetate dichloride with 6-chloro-2-hydropyridine. In the same reaction, a second product is formed,[9] $Os_2Cl_4(chp)_2 \cdot L$ (L = py or H_2O), an Os(III, III) complex with four terminal chloride ions, two *trans* chp ligands and an axial, neutral ligand.

It has been shown previously that 6-fluoro-2-hydroxypyridine (Hfhp) characteristically prefers to form a polar arrangement (also called a 4:0 arrangement) of the four ligands across the dimetal unit. The complexes $M_2(fhp)_4 \cdot THF$ (M = Cr, Mo or W),[10] $Ru_2(fhp)_4Cl$[11] and $Rh_2(fhp)_4 \cdot DMSO$[12] have previously been synthesized, and all have the 4:0 arrangement. The work reported here was undertaken to determine how the diosmium unit would behave toward the same ligand.

EXPERIMENTAL

Starting materials

$Os_2(CH_3COO)_4Cl_2$ was prepared by a literature procedure.[1] The ligand, Hfhp, was obtained from Dow Chemical Co. Lithium chloride was dried at 110°C overnight. Dry and deoxygenated solvents were freshly distilled before use.

Preparation of $Os_2(fhp)_4Cl$ (**1**)

$Os_2(CH_3COO)_4Cl_2$ (0.1 g, 0.145 mmol), LiCl (0.6 g, 14 mmol), Hfhp (0.6 g, 5.3 mmol) and 10 cm^3 of toluene were refluxed for 3 days under an argon atmosphere. The crystalline diosmium-tetraacetate dichloride gradually disappeared and a brown precipitate was deposited. The reaction mixture was cooled and filtered. The solid residue was washed several times with diethyl ether to remove unreacted ligand. The remaining solids were extracted with CH_2Cl_2 until the washings were almost colorless. The brown-yellow CH_2Cl_2 solution was concentrated and carefully layered with hexane. In a few days a uniform mass of well-formed, block-shaped crystals was deposited. They were filtered, washed with hexane and air dried. The yield is 70 mg (*ca* 56%). The complex is air-stable in the solid state and in solution.

Found: C, 28.2; H, 1.5. Calc. for $Os_2ClF_4O_4N_4C_{20}H_{12}$: C, 27.8; H, 1.4%. Electronic spectrum (850–250 nm, CH_2Cl_2 solvent): λ_{max} = 413 nm (ε = 4300 M^{-1} cm^{-1}), λ = 334 nm (sh), λ_{max} = 309 nm (ε = 23,600 M^{-1} cm^{-1}), λ_{max} = 284 nm (ε = 26,500 M^{-1} cm^{-1}), λ = 261 nm (sh).

Measurements

Elemental analyses were performed by Galbraith Laboratories Inc. The electronic spectra were measured on CH_2Cl_2 solutions (HPLC grade) using a Cary 17D spectrophotometer. Electrochemical measurements were done with a Bioanalytical Systems Inc., model BAS 100 Electrochemical Analyzer in conjunction with a Bausch & Lomb, Houston Model DMP 40 digital plotter. Experiments were carried out in CH_2Cl_2 containing *ca* 0.2 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as a supporting electrolyte. A three-electrode cell configuration was used with a platinum disk and a platinum wire as working and auxiliary electrodes, respectively. All potentials are referenced to the Ag–AgCl electrode at 24±2°C with full positive feedback resistance compensation, and are uncorrected for junction potentials. Magnetic measurements were made at room temperature on CH_2Cl_2 solution by the Evans method on a Varian 390 spectrometer. A correction for the diamagnetism of the ligand was applied. X-band ESR spectra were obtained on CH_2Cl_2 frozen solutions using a Varian E-6S spectrometer.

X-ray crystallographic procedures

The structure of a single crystal of **1** was determined by application of general procedures which have been fully described elsewhere.*[13] The pertinent crystallographic data are summarized in Table 1. Important bond distances and angles are given in Table 2. A regular, block-shaped crystal of approximate dimensions 0.3 × 0.4 × 0.6 mm was mounted in a capillary in mother liquor. The diffraction data were collected on a CAD 4 auto-diffractometer equipped with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. Lorentz, polarization and absorption corrections were applied. There are five possible space group choices consistent with the systematic absences. These are *I*422, *I*4*mm*, *I*$\bar{4}$*m*2, *I*$\bar{4}$2*m* and *I*4/*mmm*. Given the cell volume and the expected molecular formula, $Os_2(fhp)_4Cl$, there must be two molecules in the unit cell. With Z = 2 and an ordered model, the only possible space group is *I*4*mm*, with the molecule on a four-fold axis. One Os atom can be placed at the origin, which than allowed us to determine the position of the other Os atom from the Patterson map. The alternating least-squares and difference Fourier cycles revealed positions of all non-hydrogen atoms. As the refinement progressed it became clear that absorption still affected the calculations, despite an earlier empirical absorption correction based on psi scans. The program DIFABS[14] was applied to the data. Successful refinement confirmed our choice of space group. The largest peaks in the final difference Fourier map were ghosts of heavy atoms. In a final cycle, 497 data were used to refine 57 parameters to give R = 0.028 and R_w = 0.054.

RESULTS AND DISCUSSION

Preparation

The $Os_2(fhp)_4Cl$ compound reported here is formed in good yields (*ca* 60%) in the reaction of $Os_2(CH_3COO)_4Cl_2$ with Hfhp in refluxing toluene

* Calculations were done on the VAX-11/780 computer at the Department of Chemistry, Texas A&M University, College Station, Texas with a VAX-SDP software package.

in the presence of LiCl. Attempts to run the reaction in molten Hfhp in a fashion analogous to the previously described syntheses[8,9] of $Os_2(chp)_4Cl$ and $Os_2Cl_4(chp)_2 \cdot L$ did not yield any identifiable products. The use of stoichiometric amounts of $Os_2(CH_3COO)_4Cl_2$ and Hfhp (1 : 2) in the presence of LiCl, in an attempt to obtain $Os_2Cl_4(fhp)_2$, yielded only **1** in lower yields. We have not, under any conditions, seen evidence of the formation of $Os_2Cl_4(fhp)_2$. Also, use of Me_3SiCl, which has been shown to remove acetate ions and other oxygen-containing ligands from the multiply-bonded dimetallic units, has failed in this case. The role of LiCl is unknown (although its use has been reported[16] before) and we do not wish to speculate on the mechanistic aspects of the reaction since the additional complicating factor is the reduction of the diosmium unit.

The reducing agent is most likely Hfhp, but the possibility of disproportionation cannot be excluded in view of the 60% yield of reaction.

Spectroscopic and magnetic properties

The visible region of the electronic spectrum of **1** in CH_2Cl_2 displays one strong band at 413 nm ($\varepsilon = 4300$ M^{-1} cm^{-1}). This is similar to the previously observed band for the $Os_2(chp)_4Cl$ complex ($\lambda_{max} = 412$ nm, $\varepsilon = 3800$ M^{-1} cm^{-1}).

The ground electronic state for this molecule is most likely a spin-quartet derived from the $\sigma^2\pi^4\delta^2\delta^*\pi^{*2}$ electronic configuration, since it has

a room-temperature magnetic moment in CH_2Cl_2 solution of 3.70 BM. For $Os_2(chp)_4Cl$ a moment of only 2.90 BM was found, and this was taken to mean that there was substantial population of a spin-doublet derived from a $\sigma^2\pi^4\delta^2\sigma^2*\pi*$ or $\sigma^2\pi^4\delta^2\pi*^3$ configuration. In the present case there would appear to be much less thermal access to such a doublet state. The $Os_2(fhp)_4Cl$ compound exhibits an ESR signal at −196°C (in frozen CH_2Cl_2 solution), but it has a different appearance from the one shown by $Os_2(chp)_4Cl$. We are not certain how to interpret this result. In any case, **1** can be added to the list of diosmium complexes, of both the III, III and II, III types whose magnetic properties require more detailed study.

Electrochemistry

The electrochemical properties of the compound were studied by cyclic voltammetry. CH_2Cl_2 solutions with TBAH as a supporting electrolyte were used. A reversible, one-electron reduction at $E_{1/2} = -0.63$ V and an irreversible oxidation at $E_{ox} = +0.90$ V (Fig. 1) were observed. The presumably metal-based reduction represents the following process:

$$Os_2^{5+} + e^- \rightarrow Os_2^{4+}.$$

For the similar $Os_2(chp)_4Cl$ complex this reduction was observed at −0.60 V. To our surprise the oxidation appears to be irreversible, although the above-mentioned $Os_2(chp)_4Cl$ undergoes reversible oxidation at almost the same potential (+0.90 V).

*Molecular structure**

Selected bond distances and angles are presented in Table 2, and Fig. 2 presents an ORTEP view of the molecule with the atoms labeled. The molecular symmetry is rigorously C_{4v} (*4mm*) with Os(1), Os(2) and Cl lying along a four-fold axis. The four fhp ligands are placed on two perpendicular mirror planes. The asymmetric unit consists of Os(1), Os(2), Cl and one fhp ligand.

The molecule has a polar arrangement with the four fhp ligands pointing in one direction. One axial site, which is unoccupied, is encumbered by the four fluorine atoms. The second axial site is occupied by a chlorine atom. The perfect C_{4v}-geometry is possible in this case because the relatively small fluorine atoms do not come in close contact. In contrast, the polar molecules with chp or mhp as ligands are always twisted from the ideal eclipsed conformation to alleviate repulsive X---X interactions.

The Os—Os distance is 2.341(1) Å. This is the same distance, within experimental error, as found earlier in $Os_2(chp)_4Cl$. Additional distances and angles are at about the expected values.

We wish now to compare some experimental results for **1** to those of the isomorphous and isostructural $Ru_2(fhp)_4Cl$, as summarized in Table 3.

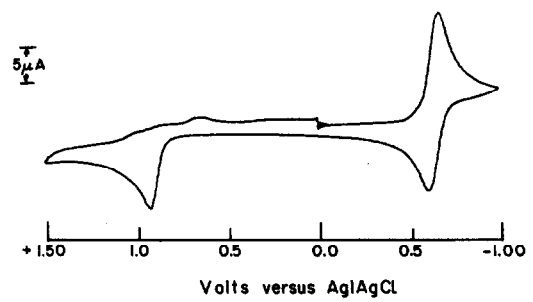

Fig. 1. Cyclic voltammogram of $Os_2(fhp)_4Cl$ (measured at 200 mV s^{-1} in 0.2 M TBAH–CH_2Cl_2 at a Pt-disk electrode).

* *Supplementary material available.* Full listing of bond angles, bond distances, anisotropic displacement parameters and observed and calculated structure factors (6 pages) have been deposited with the Editor. Atomic positional parameters have been deposited with the Cambridge Crystallographic Data Centre.

As far as the structural parameters are concerned, the only difference between these two structures can be attributed to the larger size of Os than Ru. This in turn leads to a longer metal–metal bond (by 0.057 Å). The Os—Cl and Os—O distances are also slightly longer than the corresponding Ru ones, but the Os—N distances are shorter (by about 0.06 Å).

As a part of our investigation of diosmium chemistry we have established the formation of a second polar diosmium complex. **1** is formed in reasonable yield from $Os_2(CH_3COO)_4Cl_2$. Ligand substitution is accompanied by a reduction from an Os_2^{6+} to an Os_2^{5+} dimetallic core.

(*Received* 21 *October* 1986; *accepted* 12 *January* 1987)

Abstract—Reactions of $[Fe_2S_2(CO)_6]^{2-}$ (**3**) with $[Cl_2FeS_2MS_2]^{2-}$ [M = Mo (**4**) or W (**6**)] and $[Cl_2FeS_2VS_2FeCl_2]^{3-}$ (**8**) in acetonitrile–THF solutions afford the new clusters $[MFe_3S_6(CO)_6]^{2-}$ (M = Mo (**5**) or W (**7**)] and $[VFe_6S_8(CO)_{12}]^{3-}$ (**9**). $(Et_4N)_2$ (**5**) crystallizes in orthorhombic space group *Pbcn* with $a = 15.314(7)$ Å, $b = 16.627(6)$ Å, $c = 29.971(13)$ Å, and $Z = 8$. Cluster **5** is formed by displacement of chloride from **4** by **3** to yield a species with the $[Fe_2(\mu_3\text{-}S)_2Fe(\mu_2\text{-}S)_2MoS_2]^{2-}$ core arrangement containing one Fe(II) and Mo(VI) in distorted tetrahedral sites. Similar structures are proposed for **7** and **9**, with the latter containing two **3** ligands bound to the $[VFe_2S_4]^{1+}$ core of **8**. Treatment of **5** with RSSR results in oxidative decarbonylation and formation of $[Mo_2Fe_6S_8(S_2)_2(SR)_6]^{4-}$ (**10**) (R = *p*-C_6H_4Cl or *p*-C_6H_4Br), which consists of two $[MoFe_3(\mu_3\text{-}S)_4]^{3+}$ cubane-type subclusters bridged by two $\mu_2\text{-}\eta^3\text{-}S_2^{2-}$ groups. Cluster **10** was also obtained in a direct-assembly system consisting of $[MoS_4]^{2-} + 3FeCl_3 + S_2^{2-} + 7RS^-$ in methanol. Evidence is presented that the solid-state structure of **10** is maintained in solution. The redox change $[MoFe_3(\mu_2\text{-}S)_2(\mu_3\text{-}S)_2S_2]^{2-}$ (**5**) → $[MoFe_3(\mu_3\text{-}S)_4(S_2)]^{1+}$ (**10**) is described as an oxidatively induced core internal conversion in which there is net Fe and S oxidation and Mo reduction. It is argued that the reduction of tetrahedral Mo(VI) to or near Mo(III), stabilized in a six-coordinate site, is a significant factor in the formation of the cubane structure. The formation of the cubane cluster $[VFe_3S_4Cl_3(DMF)_3]^{1-}$ from **8** and $FeCl_2$ is similarly promoted by the reduction of tetrahedral V(V) to or near V(III). The syntheses of **5**, **7**, **9** and **10** illustrate the utility of **3** as a cluster precursor.

At present, the synthetic cluster species most closely related to the native cluster which is the FeMo-cofactor of nitrogenase are those containing one or two cubane-type $MoFe_3(\mu_3\text{-}S)_4$ cores. The leading aspects of these clusters have recently been summarized.[1] Their synthesis is usually achieved by direct cluster assumbly involving the simple reactants $[MoS_4]^{2-}$, $FeCl_3$ and thiolate in an alcohol solvent. In this way the double-cubane clusters $[Mo_2Fe_6S_8(SR)_9]^{3-}$ [2–4] (**1**) and $[Mo_2Fe_7S_8(SR)_{12}]^{3-}$ [5] (**2**), containing the indicated bridge units, have been prepared in good yield. Single cubanes of general types $[MoFe_3S_4(SR)_3(cat)L]^{2-,3-}$ [6–8] [cat = 3,6-disubstituted catecholate(2−)] and $[MoFe_3S_4(SR)_4(dmpe)]^{1-}$ [9] [dmpe = 1,2-bis(dimethylphosphino) ethane] are accessible by bridge cleavage of **2**. The single cubanes exhibit certain electronic features[10] and possess Mo site structural properties[1,11] that bear an apparent resemblance to corresponding aspects of the cofactor.

Recently we have been exploring other routes to Mo–Fe–S and other heterometal Fe–S clusters of possible biological relevance. Noting the chelating ability[12,13] of the Seyferth anion $[Fe_2S_2(CO)_6]^{2-}$ [12] and the possibility of oxidative decarbonylation[14] of reaction products by disulfides leading to new clusters, we have examined the reactions of this anion with Fe(II) complexes derived from the thiometalates of Mo, W and V. Among the results

presented are the synthesis and structure of a new cluster type exemplified by $[MoFe_3S_6(CO)_6]^{2-}$, and the identity of its decarbonylation product. The information provided here augments earlier brief reports[15,16] of some of the principal findings of this research.

EXPERIMENTAL

Preparation of compounds

All operations were performed under a pure dinitrogen atmosphere. Acetonitrile was purified by distillation from CaH_2 and stored over 3-Å molecular sieves. Methanol and THF were distilled from $Mg(OMe)_2$ and Na–K alloy, respectively. $Fe_2S_2(CO)_6$,[12] Na_2S_2,[17] $(NH_4)_2[MoS_4]$,[18] $(Et_4N)_2[MFeS_4Cl_2]$ (M = Mo[19] or W[20]), and $(Et_4N)_3[VFe_2S_4Cl_4]$[21] were prepared as described. Bis (*p*-chlorophenyl)disulfide was obtained as a white crystalline solid by the iodine oxidation of *p*-ClC_6H_4SH in methanol. Solutions of $Li_2[FeS_2(CO)_6]$ in THF were prepared by the method of Seyferth *et al.*[12]

$(Et_4N)_2[MoFe_3S_6(CO)_6]$ (**5**). A freshly prepared, bright green solution of 5.8 mmol of $Li_2[Fe_2S_2(CO)_6]$ (**3**) in 100 cm^3 of THF at −78°C was treated with an equimolar, red-brown solution of $(Et_4N)_2[MoFeS_4Cl_2]$ (**4**) in 400 cm^3 of acetonitrile. The reaction mixture was slowly warmed over 5 h to ambient temperature, stirred overnight, and filtered to remove LiCl and a black insoluble solid. Ether (~ 200 cm^3) was added to the dark purple filtrate to afford 2.21 g (43%) of crude product as a purple-brown microcrystalline solid. Recrystallization of this material from acetonitrile–ether [3 : 1 (v/v)] afforded 1.80 g (35%) of pure product as purple-brown microcrystals. Found: C, 29.9; H, 4.7; Fe, 18.6; Mo, 10.7; N, 3.2; S, 21.6. Calc. for $C_{22}H_{40}Fe_3MoN_2O_6S_6$: C, 29.9; H, 4.6; Fe, 18.9; Mo, 10.8; N, 3.2; S, 21.7%. IR (MeCN): ν_{CO} 2042 (m), 2004 (s), and 1960 (vs) cm^{-1}. Absorption spectrum (MeCN): λ_{max} (ε_M) 331 (23,600), 410 (sh), and 470 (8960) nm.

$(Et_4N)_2[WFe_3S_6(CO)_6]$ (**7**). A freshly prepared solution of 1.86 mmol of $Li_2[Fe_2S_2(CO)_6]$ in 50 cm^3 of THF at −78°C was treated with an equimolar, bright orange solution of $(Et_4N)_2[WFeS_4Cl_2]$ (**6**) in 200 cm^3 of acetonitrile. Following slow warming over about 12 h to room temperature, the reaction mixture was filtered to remove LiCl and a black insoluble solid. The volume of the orange-brown filtrate was reduced to ~ 75 cm^3, 30 cm^3 of ether were added, and the solution was cooled to −20°C to afford 1.3 g (72%) of crude product as a gold-brown microcrystalline solid. Recrystallization of this material from acetonitrile–ether [2 : 1 (v/v)] gave 1.1 g (61%) of pure product as gold-brown microcrystals. IR (MeCN): ν_{CO} 2043 (m), 2004 (s), and 1959 (vs) cm^{-1}. Absorption spectrum (MeCN): λ_{max} (ε_M) 272 (19,700), 360 (14,800), 415 (8810), 464 (5570), and 524 (5100) nm.

$(Et_4N)_3[VFe_6S_8(CO)_{12}]$ (**9**). To a solution of 2.90 mmol of $Li_2[Fe_2S_2(CO)_6]$ in 100 cm^3 of THF at −78°C was added a solution of 1.19 g (1.45 mmol) of $(Et_4N)_3[VFe_2S_4Cl_4]$ (**8**) in 250 cm^3 of acetonitrile. After the reaction mixture was warmed to room temperature over ~ 12 h, it was filtered to remove LiCl. The volume of the purple filtrate was reduced to ~ 80 cm^3. The solution was cooled to −20°C and filtered to remove additional LiCl. Addition of ether (~ 80 cm^3) to the filtrate caused the separation of 1.1 g (54%) of crude product as a purple-black microcrystalline solid. Recrystallization of this material from acetonitrile–ether [1 : 1 (v/v)] afforded 0.62 g of pure product as a black crystalline solid. Found: C, 31.3; H, 4.5; Fe, 24.8; N, 3.1; S, 18.5; V, 3.8. Calc. for $C_{36}H_{60}Fe_6N_3O_{12}S_8V$: C, 31.6; H, 4.4; Fe, 24.5; N, 3.1; S, 18.7; V, 3.7%. IR (MeCN): ν_{CO} 2035 (m), 1998 (s), and 1955 (vs) cm^{-1}. Absorption spectrum (MeCN): λ_{max} (ε_M) 316 (26,500), 416 (11,500), 526 (sh), and 560 (12,100) nm.

$(Et_4N)_4[Mo_2Fe_6S_8(S_2)_2(S\text{-}p\text{-}C_6H_4Cl)_6]$ (**10**). (i) *By oxidative decarbonylation of* **5**. A solution of 0.65 g (2.26 mmol) of bis(*p*-chlorophenyl)disulfide in 20 cm^3 of ether was added to a stirred solution of 1.00 g (1.13 mmol) of **5** in 100 cm^3 of acetonitrile. The reaction mixture gradually changed from a purple-brown to a yellow-brown color over a period of 1 day. The mixture was stirred at ambient temperature for 4 days, or at 50°C for 10 h, after which no bound CO was detectable (IR). Following reduction of the solvent volume to ~ 40 cm^3, the mixture was filtered to remove disulfide. THF (~ 50 cm^3) was added to the yellow-brown filtrate, the

solution was cooled at −20°C for ~ 4 h, and then filtered to give 0.80 g of crude product as a black microcrystalline solid. The product was separated from the more soluble salts of $[Fe_nS_n(S\text{-}p\text{-}C_6H_4Cl)_4]^{2-}$ ($n = 2$ or 4[14]) by thorough washing with acetone–acetonitrile [3:1 (v/v)]. This procedure afforded 0.48 g (37%) of pure product as a black microcrystalline solid. Found: C, 34.9; H, 4.4; Cl, 9.1; Fe, 15.0; Mo, 8.6; N, 2.4; S, 25.0. Calc. for $C_{66}H_{104}Cl_6Fe_6Mo_2N_4S_{18}$: C, 35.6; H, 4.6; Cl, 9.3; Fe, 14.6; Mo, 8.4; N, 2.4; S, 25.1%. Absorption spectrum (MeCN): λ_{max} (ε_M) 348 (sh), and 437 (30,600) nm. The *p*-bromobenzenethiolate derivative was prepared analogously with use of bis(*p*-bromophenyl)disulfide.

(ii) *Direct synthesis.* A slurry of 2.0 g (7.7 mmol) of $(NH_4)_2[MoS_4]$ in 50 cm^3 of methanol was added to 0.85 g (7.7 mmol) of Na_2S_2 to produce a bright red solution. This was treated with a mixture of NaOMe (5.4 mmol) and *p*-ClC_6H_4SNa (54 mmol) (from 59.4 mmol of NaOMe and 54.0 mmol of the thiol) in 300 cm^3 of methanol. A filtered solution of 3.7 g (23 mmol) of $FeCl_3$ in 100 cm^3 of methanol was added dropwise to the bright red reaction mixture over a period of 30 min. The resultant purple-brown reaction mixture was stirred for 16 h to afford an intense yellow-brown solution. Addition of 2.6 g (15 mmol) of Et_4NCl caused separation of a brown amorphous solid, which was collected by filtration. This material was extracted with 1 l of acetonitrile to effect separation from chloride salts, the extract was filtered, and the solvent was removed *in vacuo*. The solid residue was washed with 5 × 100 cm^3 of acetone, leaving 1.2 g of crude product as a brown amorphous solid. Recrystallization of this material from acetonitrile–THF afforded 1.0 g (11%) of pure product as a black microcrystalline solid. Found: C, 34.9; H, 4.4; Cl, 9.1; Fe, 15.0; Mo, 8.6; N, 2.4; S, 25.0%. The product was spectroscopically identical with that prepared by method (i). The *p*-bromobenzenethiolate derivative was prepared analogously with use of *p*-BrC_6H_4SNa.

Structure determination of $(Et_4N)_2[MoFe_3S_6(CO)_6]$

Collection and reduction of data. Single crystals of **5** were obtained by ether diffusion into a propionitrile solution. A crystal was mounted in glass capillary which was sealed under dinitrogen. Diffraction experiments were performed with a Nicolet R3M four-circle automated diffractometer equipped with a Mo X-ray tube and a graphite monochromator. Data collection parameters are summarized in Table 1. The final orientation matrix and unit-cell parameters were obtained from the least-squares refinement of 25 machine-centered reflections having $20° \leqslant 2\theta \leqslant 25°$. Selected omega scans were symmetrical and exhibited full widths at half-height of 0.37–0.45°. Three standard reflections examined after every 63 observations showed no signs of decay over the course of data collection. The data were corrected for Lorentz and polarization effects and an empirical absorption correction was applied with the programs XTAPE and XEMP of the SHELXTL structure determination package (Nicolet XRD Corporation, Madison, WI). The systematic absences $0k0$ ($k = 2n+1$), $h0l$ ($l = 2n+1$), and $hk0$ ($h+k = 2n+1$) uniquely define the space group as *Pbcn* (No. 60).

Solution and refinement of the structure. The structure was solved by a combination of direct methods (MULTAN) and Fourier techniques. Trial positions of the Mo and Fe atoms were taken from the E-map derived from the phase set with the highest combined figures of merit. The remaining non-hydrogen atoms were located in subsequent Fourier refinement cycles by using the program CRYSTALS. Atom-scattering factors were taken from a standard source.[22] Isotropic refinement converged at 20%. The asymmetric unit consists of two cations and one anion. Both cations displayed thermal parameters sufficiently large to indicate disorder, which was not successfully modeled. The anion and the cation nitrogen atoms were anisotropically refined by using blocked-cascade least-squares refinement. The cation carbon atoms were refined isotropically by using the method of additional observational equations.[23] Several carbonyl groups also have thermal parameters suggestive of disorder. In the final stages of refinement, hydrogen atoms were placed at a distance of 0.98 Å from bonded carbon atoms and assigned an isotropic thermal parameter of 0.05 $Å^2$. Unique data used in the refinement and final R values are given in Table 1. Tables of atom coordinates, thermal parameters, and structure factors have been deposited as supplementary data with the Editor, from whom copies are available on request.*

Other physical measurements

All measurements were performed under strictly anaerobic conditions. ^1H NMR spectra were recorded on a Brüker WM-300 spectrometer. CD_3CN was purified by distillation from CaH_2 and was stored over 3-Å molecular sieves. UV–visible and IR spectra were recorded on a Cary Model 219 and a Perkin–Elmer Model 599B spectrophotometer,

*Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Table 1. Summary of crystal data, intensity collection and structure refinement parameters for $(Et_4N)_2[MoFe_3S_6(CO)_6]$

Formula	$C_{22}H_{40}Fe_3MoN_2O_6S_6$
Molecular weight	884.43
a (Å)	15.314(7)
b (Å)	16.627(6)
c (Å)	29.971(13)
Crystal system	Orthorhombic
V (Å^3)	7631(5)
Z	8
d_{calc} (g cm^{-3})	1.64
Space group	*Pbcn*
Crystal dimensions (mm)	$0.12 \times 0.46 \times 0.70$
Radiation	Mo-K_{α_1} ($\lambda = 0.71069$)
Absorption coefficient (μ) (cm^{-1})	18.1
Transmission factors (max/min)	0.94/0.54
Scan speed (deg min^{-1})	2.00–29.3 (θ–2θ scan)
Scan range (°)	$1.25+(2\theta_{K\alpha_1}-2\theta_{K\alpha_2})$
Background/scan time ratio	0.25
Data collected	5–45° ($+h$, $+k$, $+l$)
Total reflections	5820
R_{merge}[a] (%)	2.8
Unique data [$F_o^2 > 3.0\sigma(F_o^2)$]	3220
Number of variables	282
R[b] (%)	8.3
R_w[c] (%)	9.5[d]

[a] R_{merge} is defined by:

$$R_{merge} = \left[\frac{\sum N_i \sum_{j=1}^{N_i} (\bar{F}_j - F_j)^2}{\sum (N_i - 1) \sum_{j=1}^{N_i} F_j^2} \right]^{1/2},$$

where N_i is the number of reflections in a given set, F_j is one member of the set, and $\bar{F}_j$ is the mean.

[b] $R = [\Sigma (|F_o| - |F_c|)/\Sigma |F_o|]$.

[c] $R_w = [\Sigma w(|F_o|^2 - |F_c|^2)/\Sigma w|F_o|^2]^{1/2}$.

[d] Weighting scheme for least-squares refinement: $w = 1/\sigma(F_o)$.

respectively. Solution magnetic moments were determined by the usual NMR method.[24] Electrochemical measurements were made with standard PAR instrumentation; other details are given in a figure legend.

RESULTS AND DISCUSSION

Synthesis and properties of derivatives of $[Fe_2S_2(CO)_6]^{2-}$

Reduction of persulfide-bridged $Fe_2S_2(CO)_6$ affords the highly reactive dianion $[Fe_2S_2(CO)_6]^{2-}$ [12] (**3**). Recent work has shown that the LUMOs of the isostructural compounds $Fe_2E_2(CO)_6$ (E = S[25] or Se[26]) are mainly E–E antibonding in character and that the Se—Se bond is broken upon reduction (EXAFS determination).[27] With its demonstrated ability to chelate a variety of main-group and transition-element halides to form species containing $MFe_2(\mu_3\text{-}S)_2$ and $MFe_4(\mu_3\text{-}S)_4$ cores,[12,13] **3** is a potentially useful precursor in cluster synthesis. The reactions of **3** carried out in this study are shown in Fig. 1. The clusters $[MFe_3S_6(CO)_6]^{2-}$ [M = Mo (**5**) or W (**7**)] were prepared according to reaction (1):

$$[Fe_2S_2(CO)_6]^{2-} + [MFeS_4Cl_2]^{2-} \rightarrow [MFe_3S_6(CO)_6]^{2-} + 2Cl^-, \quad (1)$$

which involves displacement of chloride from the tetrahedral Fe(II) centres of $[MFeS_4Cl_2]^{2-}$ [M = Mo (**4**) or W (**6**)]. These ligands had been shown earlier to be susceptible to substitution by

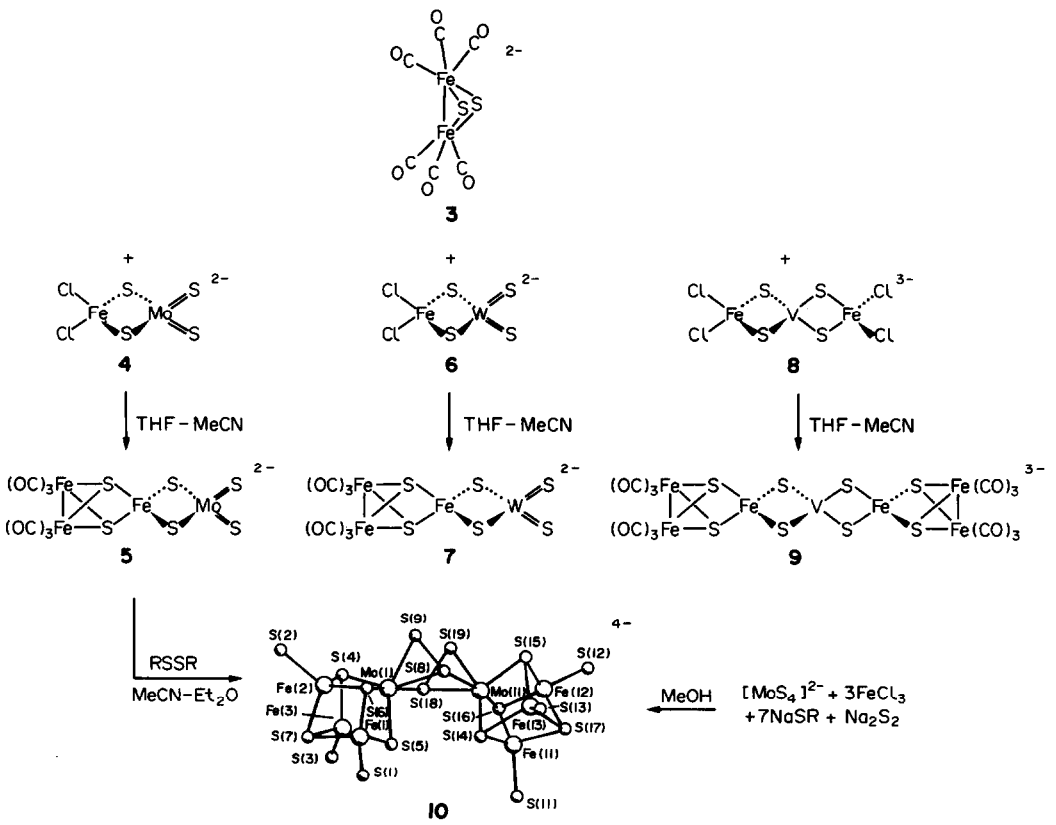

Fig. 1. Scheme showing the synthesis of clusters **5**, **7**, **9** and **10** from the common precursor $[Fe_2S_2(CO)_6]^{2-}$ (**3**) and their established (**5** and **10**) or probable (**7** and **9**) structures.

thiolate.[19] In the related reaction (2):

$$2[Fe_2S_2(CO)_6]^{2-} + [VFe_2S_4Cl_4]^{3-} \rightarrow [VFe_6S_8(CO)_{12}]^{3-} + 4Cl^- \quad (2)$$

the heptanuclear cluster $[VFe_6S_8(CO)_{12}]^{3-}$ (**9**) was derived from the "linear" precursor $[VFe_2S_4Cl_4]^{3-}$ (**8**), whose VFe_2S_4 core is nonlabile.[21] In contrast, the isoelectronic and isostructural clusters $[MFe_2S_4Cl_4]^{2-}$ (M = Mo or W) form an equilibrium mixture with **4**/**6** and $FeCl_2$ in DMF solution. Presumably because of core lability, all attempts to prepare $[MoFe_6S_8(CO)_{12}]^{2-}$ even in acetonitrile–THF solution yielded only **5**.

Clusters **5**, **7** and **9** are most simply recognized by their characteristic LMCT visible spectra, which are shown in Fig. 2. These are perturbed versions of the spectra of the parent $[MS_4]^{2-,3-}$ ions[21] and indicate retention of the M(VI or V) oxidation state. IR spectra in the carbonyl region are nearly identical for the three clusters. The three-band patterns are similar in intensity to that of $Fe_2S_2(CO)_6$ (ν_{CO} 2080, 2038 and 1998 cm^{-1}) but are shifted to lower frequencies by about 40 cm^{-1}, a consistent feature of metal derivatives containing the intact $Fe_2S_2(CO)_6$ group.[12,13,28-30] Diffraction quality crystals of only **5** were obtained. Cluster **7** was not analyzed inasmuch as its preparation, purification and IR spectrum were strictly analogous to those of **5**. The indicated structure of **9** is entirely probable and follows from its composition and IR spectrum, and the structure of **5**.

Structure of $[MoFe_3S_6(CO)_6]^{2-}$

The crystal structure of the Et_4N^+ salt of cluster **5** consists of well-separated anions and cations. The latter are unexceptional and are not further considered. Two perspectives of the structure of **5** are shown in Fig. 3. Selected interatomic distances and angles are collected in Table 2. In addition to $Fe_2S_2(CO)_6$[25] itself, there are other species whose structures are pertinent to a consideration of that of **5**. These formally contain the dianion **3** and include a variety of $Fe_2(\mu_2\text{-}SR)_2(CO)_6$ compounds with $Fe_2(SEt)_2(CO)_6$[31] prototypical, $Fe_2(\mu_2\text{-}SR)(\mu_2\text{-}SHgR)(CO)_6$[32] (R = Me or Et), $Ge[S_2Fe_2(CO)_6]_2$[33] (**11**), $[Fe_6S_6(CO)_{12}]^{2-}$[30] (**12**), and $[MoOFe_5S_6(CO)_{12}]^{2-}$[29] (**13**). The only other structurally characterized derivative of **3** is $[Fe_4S_4(CO)_{12}]^{2-}$, which contains two

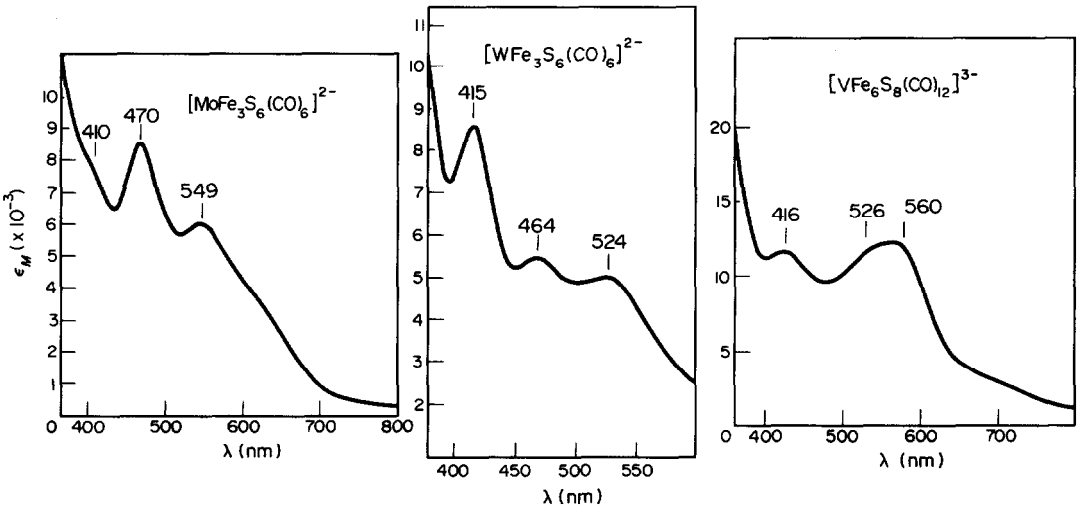

Fig. 2. Visible-absorption spectra of $[MoFe_3S_6(CO)_6]^{2-}$ (**5**), $[WFe_3S_6(CO)_6]^{2-}$ (**7**), and $[VFe_6S_8(CO)_{12}]^{3-}$ (**9**) in acetonitrile solutions.

$[Fe_2S_2(CO)_6]^{1-}$ groups joined by a disulfide bond.[34]

The configuration of cluster **5** approaches C_{2v}-symmetry, with the C_2-axis containing Mo and Fe(1), and is immediately recognizable as a combination of **3** and **4** (Fig. 1) with the anticipated chloride displacement. The $[MoFe_3(\mu_2\text{-}S)_2(\mu_3\text{-}S)_2]^{2+}$ core contains a roughly planar $Mo(\mu_2\text{-}S)_2Fe_3$ portion with atom displacements of ≤ 0.06 Å from

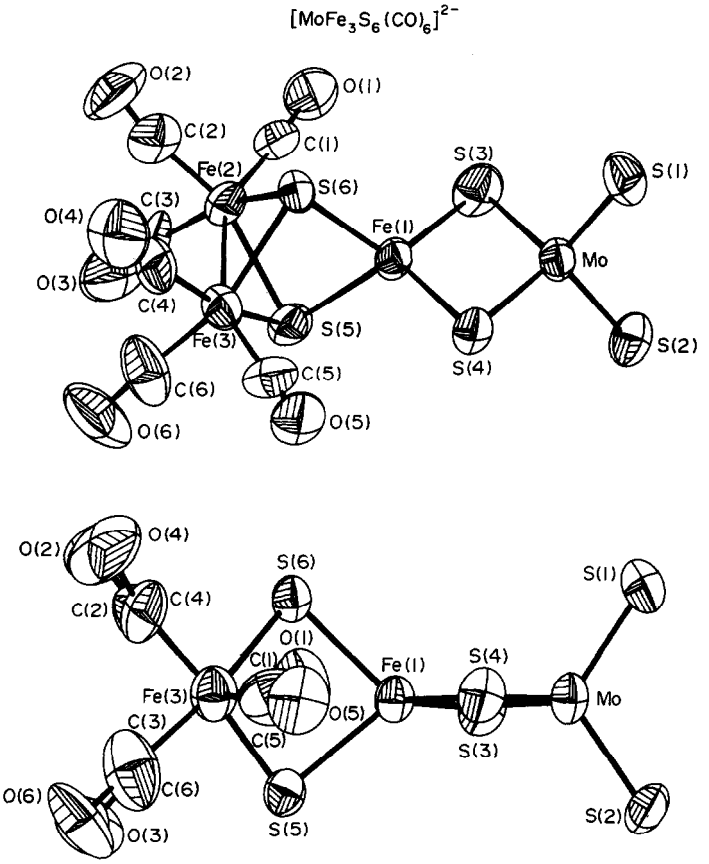

Fig. 3. Two views of the structure of $[MoFe_3S_6(CO)_6]^{2-}$ (**5**) showing 50% probability ellipsoids and the atom-labeling scheme. The views are related by a 45° rotation around the idealized C_2-axis.

the MoS(3,4)Fe(1–3) plane.* The $Fe_3(\mu_3\text{-}S)_2$ fragment consists of two triply bridging atoms S(5,6) equidistant (± 1.55 Å) from the Fe_3 plane. In this sense, the fragment is similar to the $[Fe_3S_2]^{2+}$ core of $[Fe_3S_2(WS_4)_3]^{4-}$,[35] except that the Fe atoms form an isosceles rather than an equilateral triangle. The $S_2Fe(1)S_2MoS_2$ portion consists of two edge-shared irregular MoS_4 and FeS_4 tetrahedra. The dihedral angle MoS(1,2)/MoS(3,4) = 89.6° and Fe(1)S(3,4)/Fe(1)S(5,6) = 92.8°. Chelation of Fe(1) by atoms S(5,6) of subunit **3** is anticipated in **11**–**13**.

The Mo and Fe(1) atoms occupy sites which approach local C_{2v}-symmetry. The expanded terminal S(1)—Mo—S(2) [111.9(2)°] and compressed bridging S(3)—Mo—S(4) angles [104.7(2)°], and the shorter Mo—S terminal (mean 2.16 Å) than bridging distances (mean 2.262 Å), are typical of μ_2-η^2 binding to $[MoS_4]^{2-}$.[1] These effects are well exemplified by $[(PhS)_2FeS_2MoS_2]^{2-}$ [36] in which, for example, the terminal and bridging Mo—S bond lengths (S—Mo—S bond angles) are 2.149 Å [112.2(1)°] and 2.262 Å [105.5(1)°], respectively. As its NH_4^+ salt, $[MoS_4]^{2-}$ is nearly perfectly tetrahedral,[37] with mean bond distances and angles of 2.178(6) Å and 109.5(7)°. The coordination unit of the unique atom Fe(1) is severely distorted from a tetrahedral arrangement. Bond angles range from 85.6(2) to 119.2(1)°, with the lower limit being the chelate bite angle S(5)—Fe(1)—S(6), which corresponds to an S...S bite distance of 3.107(6) Å. This angle at Ge [86.4(2)° (**11**)] and Fe [86.8(1)° (**12**), and 84.1(5)° (**13**)] in other complexes is nearly the same. However, the bite angle of **3** is not constrained from lower values inasmuch as it is decreased to 70.8(3)° at Mo in **13**.[29]

Carbonyl-ligated atoms Fe(2,3) exhibit distorted square pyramidal coordination with basal planes C(2,3)S(5,6) and C(4,5)S(5,6), disposed at a dihedral angle of 66.8°. Atoms Fe(2) and Fe(3) are displaced 0.31 and 0.32 Å, respectively, from their basal planes toward apical carbonyl groups. Atom S(6) nearly symmetrically bridges Fe(1–3), the mean distance being 2.301(3) Å. Bridging by S(5) is less regular [mean 2.302(22) Å] and is the principal feature that degrades core symmetry below C_{2v}. The Fe—Fe distance of 2.491(4) Å is 0.06 Å shorter than that in $Fe_2S_2(CO)_6$, and reflects the consistent but not necessarily monotonic tendency of the metal–metal bond to decrease as the S···S bite is increased. This effect also appears with $Fe_2S_2(CO)_6$ and **3** in THF solution, where from EXAFS results the two Fe—Fe distances differ by 0.03 Å.[27] (With $[Fe_2Se_2(CO)_6]^{0,2-}$ in THF the Fe—Fe bond length increases by about 0.03 Å upon passing to the dianion.[27]) More information is required to establish any relationship between bite distance or Fe_2S dihedral angle and Fe—Fe bond length in derivatives of **3**. Given that the upper occupied MOs of **3** are mainly sulfur in character and the LUMO has a Fe–Fe antibonding component,[38] measurable differences in Fe—Fe and S···S distances in a more extensive series of compounds can be anticipated. These effects notwithstanding, it is evident that fragment **3** retains its essential geometrical and electronic features in the derivatives **5** and **11**–**13**. The structure of **5** is most consistent with the oxidation state assignment Mo(VI)+Fe(II)+2Fe(I) in the $[MoFe_3S_4]^{2+}$ core. The magnetic moment of $4.90\mu_B$ (acetonitrile, 297 K) is due to tetrahedral Fe(II) and is the same as the value for $[(PhS)_2FeS_2MoS_2]^{2-}$ in the solid state.[36]

Oxidative decarbonylation of $[MoFe_3S_6(CO)_6]^{2-}$

Reaction (3) effects the core oxidation $2[Fe_2S_2]^0 \rightarrow [Fe_4S_4]^{2+} + 2e^-$ and affords the product cluster with R = Ph in 65% isolated yield:[14]

$$2Fe_2S_2(CO)_6 + RSSR + 2RS^- \rightarrow [Fe_4S_4(SR)_4]^{2-} + 12CO. \quad (3)$$

Other than with the simpler metal carbonyls, oxidative decarbonylation reactions using disulfides have been little explored. The compositional identity of the $[MoFe_3S_4]^{2+}$ core of **5** and the $[MoFe_3S_4]^{3+}$ cores of **1**, **2** and other cubane-type clusters[1] suggested the core oxidation $[MoFe_3S_4]^{2+} \rightarrow [MoFe_3S_4]^{3+} + e^-$ with structural

* All planes are unweighted least-squares planes.

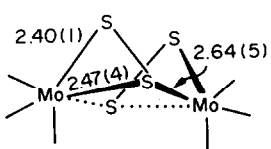
[a] $[Fe_2(\mu_2\text{-}S)_2(CO)_6]^{2-}$ chelate "bite" distance.
[b] $[Fe_2(\mu_2\text{-}S)_2(CO)_6]^{2-}$ chelate "bite" angle.

rearrangement, and probable conversion of terminal sulfide to an oxidized form. After some experimentation, reaction (4) was developed by using excess disulfide (R = *p*-C_6H_4Cl or *p*-C_6H_4Br*):

$$2[MoFe_3S_6(CO)_6]^{2-} + 3RSSR \rightarrow [Mo_2Fe_6S_8(S_2)_2(SR)_6]^{4-} + 12CO. \quad (4)$$

Products were obtained in ~ 40% yields as Et_4N^+ salts. Structure **10** (R = *p*-C_6H_4Br) was established by X-ray analysis and has been described.[15] Relatively poor crystal quality led to insufficient data for precise structural determination of these crystals, which have two formula units per asymmetric unit. However, the configuration of the anion was established as the double cubane **10** whose subclusters are joined by two μ_2-η^3 persulfide bridges in bridge unit **14**. Subcluster dimensions are unexceptional.[1] In **14** nonbridging sulfur atoms are in a *syn* arrangement; their MoS_2 groups are roughly parallel (dihedral angle 17°). The bridge is folded such that the two $Mo(\mu_2\text{-}S)_2$ groups are disposed at a dihedral angle of 22°. Mean values (Å) of certain bond lengths are indicated; the Mo···Mo distance of



14

3.97(7) Å is nonbonding. The μ_2-η^3 mode of persulfide bridging has been less frequently encountered than other arrangements.[39] Three prior examples are known.[40] Of these, the most relevant is $(Me_5C_5)_2Mo_2(\mu_2\text{-}S_2)_3(S_2)_2$,[40(d)] whose corresponding bridge fragment has dimensions within 0.03 Å of those of **14**. In this molecule the bridge structure also includes a μ_2-η^2-S_2^{2-} group. Cluster **10** provides the only case of an $Mo_2(\mu_2\text{-}\eta^3\text{-}S_2^{2-})_2$ bridge unit.

Attempted oxidative decarbonylation of $[WFe_3S_6(CO)_6]^{2-}$ (**7**) did not proceed analogously to reaction (4). $[(RS)_2FeS_2WS_2]^{2-}$ [36] and $[Fe_4S_4(SR)_4]^{2-}$ were the only identifiable products, suggesting that the usual reducibility order W(VI) < Mo(VI) applies to **5** and **7**. A similar reaction of $[VFe_6S_8(CO)_{12}]^{3-}$ (**9**) afforded mainly $[Fe_nS_n(SR)_4]^{2-}$ (n = 2 or 4) detected by ^{1}H NMR together with a lesser amount of unknown products (δ 4.8, 5.2, 15.2 and 17.3). No VFe_3S_4 cubane cluster was detected, but it is available by another route[16] (*vide infra*).

Direct synthesis and properties of $[Mo_2Fe_6S_8(SR)_6(S_2)_2]^{4-}$

The establishment of the structure of **10** raised the possibility of a direct synthesis of the cluster, i.e. a procedure not requiring isolation of an intermediate. Cluster assembly reaction (5) in methanol conducted with the indicated stoichiometry gave the desired cluster in 11% purified yield:

$$2[MoS_4]^{2-} + 6FeCl_3 + 14RS^- + 2S_2^{2-} \rightarrow [Mo_2Fe_6S_8(S_2)_2(SR)_6]^{4-} + 18Cl^- + 4RSSR. \quad (5)$$

Thus, as all other cubane-type $MoFe_3S_4$ clusters,[1-5] **10** can be prepared from simple reactants in a redox-buffered system that produces the $[MoFe_3S_4]^{3+}$ core oxidation level. The low-yield is offset by the use of inexpensive, readily accessible reagents.

In solution, **10** displays an intense absorption band at 437 nm, in the region typical of thiolate-ligand clusters.[2-7] Retention of the solid-state structure in solution is adequately shown by the electrochemical and NMR results in Fig. 4. The coupled one-electron reductions at $E_{1/2}$ = −1.14 and −1.34 V are entirely typical of double cubanes such as **1** and those with $Mo_2(\mu_2\text{-}OR)_3$ bridges.[3-5] Potential separations of about 200 mV are a common feature of clusters with Mo···Mo distances of 3.2–3.8 Å. This feature extends to **10**, whose Mo···Mo is ~ 0.2 Å longer than the previous upper limit. All other cubane-type $MoFe_3S_4$ clusters have either trigonal (e.g. **1** and **2**) or mirror symmetry,[1] properties clearly reflected in their isotropically shifted NMR spectra. While **10** has overall C_{2v}-symmetry, its subclusters lack symmetry owing to the unsymmetrical nature of the bridge **14**. The occurrence of three *m*-H signals is consistent with retention of this bridge structure in solution.

The presence of persulfide and the unsymmetrical nature of the bridge **14** with the long Mo—S bond of 2.64(5) Å suggest possible ligand-induced cleavage with or without persulfide reduction to single cubanes having $MoL(SH)_2$ or $MoL(\eta^2\text{-}S_2)$ coordination. The former group might also afford a sulfido-bridged double cubane. Reduction of coordinated persulfide by thiol or thiolate is documented.[41] Unfortunately, we have thus far been unable to effect regiospecific bridge reactions. Thiols (*p*-ClC_6H_4SH, PhSH and EtSH), $NaBH_4$

* These substituents afforded disulfides of sufficient oxidizing power and by-product clusters $[Fe_nS_n(SR)_4]^{2-}$ (n = 2 or 4) whose salts were separable from **10**. With R = Ph reaction (4) was much slower, and with R = *p*-$C_6H_4NO_2$ the reaction was nearly complete in 10 h at ambient temperature, but by-product clusters were not readily separable.

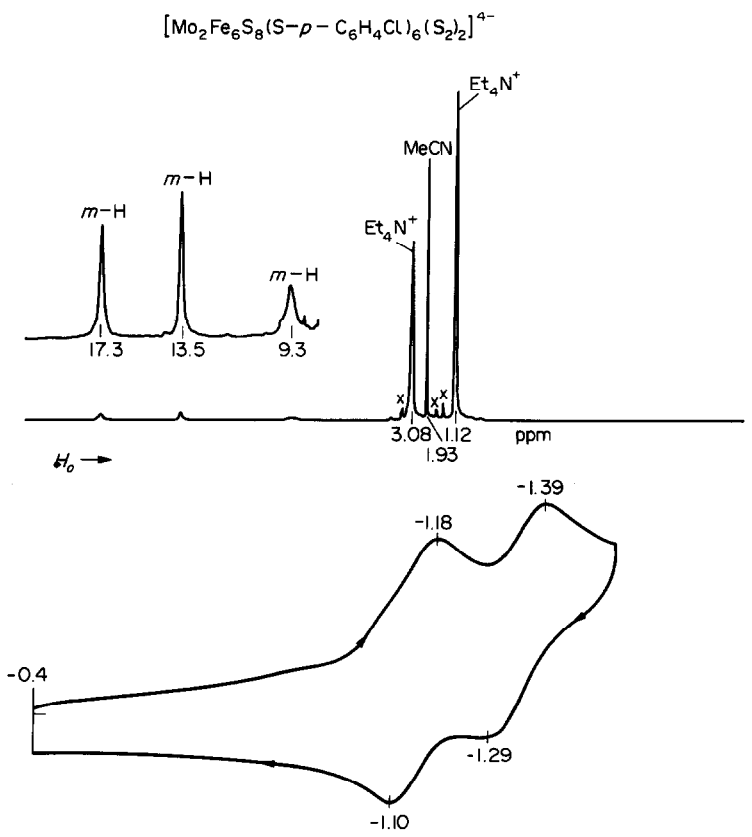


Fig. 4. Upper: ^{1}H NMR spectrum (300 MHz) of $[Mo_2Fe_6S_8(S_2)_2(S\text{-}p\text{-}C_6H_4Cl)_6]^{4-}$ (**10**) in CD_3CN solution at 298 K. Lower: cyclic voltammogram of **10** in acetonitrile solution (0.1 *M* *n*-Bu_4NCl supporting electrolyte, 100 mV s^{-1}, glassy carbon working electrode). Peak potentials vs SCE are given.

and $LiEt_3BH$ proved unreactive, while butane-1,4-dithiol, Et_3P, Et_2PPh and CN^- gave complex mixtures of products usually including $[Fe_4S_4(SR)_4]^{2-}$. Experiments directed toward the attainment of clusters with the above coordination groups are continuing.

Core conversion reactions

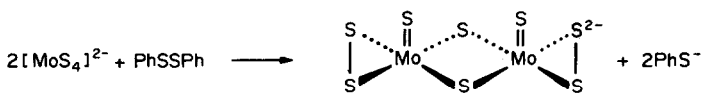
If the core composition of **5** is taken to include the terminal sulfides, the overall redox change of oxidative decarbonylation reaction (4) is given by reaction (6):

$$[MoFe_3(\mu_2\text{-}S)_2(\mu_3\text{-}S)_2S_2]^{2-} \rightarrow [MoFe_3(\mu_3\text{-}S)_4(S_2)]^{1+} + 3e^- \quad (6)$$

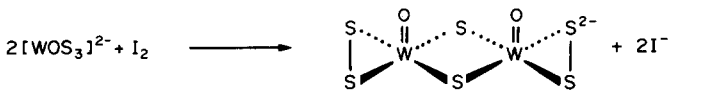
The product core contains $[MoFe_3S_4]^{3+}$* whose oxidation state descriptions as deduced from structural features and ^{57}Fe isomer shifts of isoelectronic delocalized clusters,[1,3,10] is Mo(III)+3$Fe^{2.67+}$. Reaction (6) involves, in effect, a one-electron oxidation of $[MoFe_3S_4]^{2+}$ with concomitant electron redistribution, and the ligand-based oxidation $2S^{2-} \rightarrow S_2^{2-} + 2e^-$. Given an adequate oxidant, reaction (4) succeeds in part because of two interdependent effects: (i) the Fe atoms become sufficiently oxidized to have no affinity for CO and are therefore free to bind thiolate and adopt the stable tetrahedral $FeS_3(SR)$ coordination of cubane clusters;[1] and (ii) internal electron redistribution affords an oxidation state at or near Mo(III), which concertedly drives the structural rearrangement to a stabilized, six-coordinate Mo site. These effects justify description of reaction (6) as an *oxidatively induced core internal conversion.*[15] It is similar to,

*This and following considerations continue the description of (S_2) as persulfide. Given the formation without exception of the 3+ core in synthesis[1] and the numerous cases of authenticated persulfide binding by Mo(III–VI),[39,40(b)(d),42,43] this description is well-founded. However, the X-ray analysis of **10** yields an S—S distance of 2.0(2) Å, which is insufficiently precise to distinguish between coordinated S_2 (1.89 Å[44]) and S_2^{2-} (2.13 Å[45]), whose bond lengths when uncoordinated are indicated.

but not strictly a member of, a small but growing set of reactions in which an external *oxidant* leads to internal *reduction* of a metal center.[43,46-50] Reactions (7)[43] and (8)[50]:



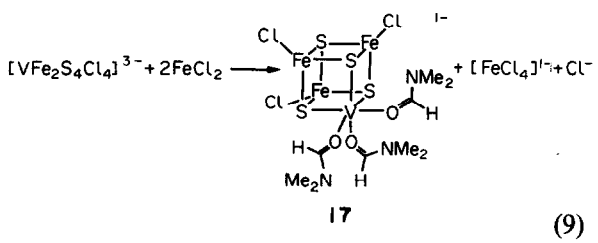
15 (7)



16 (8)

are clear examples, yielding M(V) products **15** and **16**, respectively, with sulfide and persulfide ligands, and no loss of sulfur atoms. These reactions have been termed (without mechanistic implication) *induced internal electron transfers*.[43,46] Reaction (4) differs from them by reason of a net oxidation of the metal atom set. The two reaction types, however, share the characteristics of ligand oxidation, metal atom (partial) reduction, and reduction of the external oxidant, whose reduced form functions as a ligand in reaction (4).

Reduction (or oxidation) of a metal atom to an oxidation state stabilized by a different stereochemistry in product than reactant is a common occurrence. However, in the form of the generalized core component reaction $M_3S_4 + M \rightarrow M_4(\mu_3\text{-}S)_4$, it is an exceptional means of closing metal cluster polyhedra. Indeed, there appear to be only two instances of this type of reaction. One of these, described in (ii) above, is made explicit in reaction (6). The other is reaction (9):[16,51]



17 (9)

Here linear cluster 8[21] undergoes the core conversion $[VFe_2S_4]^{1+} + e^- + Fe^{2+} \rightarrow [VFe_3S_4]^{2+}$ with incorporation of Fe^{2+}, electron redistribution, and *reduction* of V(V) to or near the V(III) level,[51,52] which is stabilized by six-coordination. Presumably, reduction precedes capture of Fe^{2+}. Note that $[MoFe_3S_4]^{3+}$ and the core of product **17** are isoelectronic and are similarly delocalized.[51] In reactions (4) and (9) closure to the cubane core is strongly driven by the instability of the reduced heterometal in its original tetrahedral site. The same point likely applies to reaction (5) and other direct synthesis of $MoFe_3S_4$ clusters, all of which utilize $[MoS_4]^{2-}$. However, the intermediate(s) immediately prior to cubane formation have not been identified. This concept of cluster closure may be applicable in other systems. The scope of reactions analogous to (9) with other reductants and metal sources remains to be established. Lastly, the preparations of **5**, **7**, **9**, **10**, **12**[30] and **13**[29] illustrate the utility of the Seyferth anion **3** as a precursor in cluster synthesis.

NICKEL COMPLEXES OF *N,N,N',N'*-TETRAKIS-(2-BENZIMIDAZOLYLMETHYL)-1,2-DIAMINOETHANE (L) AND THE X-RAY CRYSTAL STRUCTURE OF $\{[NiL]^{2+}[NiCl_2(H_2O)_3(C_2H_5OH)]\}2Cl^-(C_2H_5OH)$

Abstract—The preparation and properties of Ni(II) complexes of the title ligand (L) are described and the X-ray crystal structure of $Ni_2LCl_4(H_2O)_3(C_2H_5OH)_2$ is reported. The crystal structure shows that the two nickel ions are not bridged but exist as two distinct distorted octahedral species. Six coordination about one nickel ion is produced exclusively by L to give the cationic species $[NiL]^{2+}$. The second nickel ion achieves six coordination through an interesting combination of ligands to produce the novel complex $[NiCl_2(H_2O)_3(C_2H_5OH)]$. Since the two remaining chloride ions are hydrogen bonded to two of the water molecules and the ethanol molecule of $[NiCl_2(H_2O)_3(C_2H_5OH)]$ the entire complex can be considered to be formed by the cocrystallization of the large cation $[NiL]^{2+}$ by the "large anion" $\{[NiCl_2(H_2O)_3(C_2H_5OH)]Cl_2\}^{2-}$.

The ligand *N,N,N',N'*-tetrakis-(2-benzimidazolylmethyl)-1,2-diaminoethane (L) reacts with $Cu(H_2O)_6(BF_4)_2$ to give a six-coordinate $[CuL]^{2+}$ ion of unusual geometry.[1] Reaction with an excess of $Cu(NO_3)_2(H_2O)_3$ has given a ligand- and nitrate-bridged dimer $[Cu_2L(NO_3)_3]^+$,[2] whilst $CuClO_4$ gives the Cu(I) dimer $[Cu_2L]^{2+}$.[2] L is also known to react with $Mo(CO)_6$ to give the ligand-bridged dimer $Mo_2(CO)_6L$.[3] We are particularly interested in dimeric nickel complexes, in which the metal atoms are within approximately 6 Å of each other, as potential models for our EXAFS studies of the enzyme urease.[4] In view of this it was decided to investigate the coordination chemistry of L with a series of Ni(II) salts in the hope of generating suitable EXAFS models.

EXPERIMENTAL

L was synthesized as described previously and characterized using NMR and mass spectroscopy.[5] $NiL(ClO_4)_2 \cdot 2H_2O$, $NiL(NO_3)_2$, $NiLCl_2 \cdot 2H_2O$, $NiLBr_2 \cdot 2(C_2H_5OH)$ and $NiL(SCN)_2$ were all prepared by the same general method, viz. the appropriate metal salt was dissolved in hot ethanol and this was added slowly to a hot ethanolic solution of ligand. The crystalline product which formed rapidly was filtered off, and dried *in vacuo*. A metal : ligand ratio of 2 : 1 was used for these preparations.

$Ni_2LCl_4 \cdot 6H_2O$

$NiCl_2 \cdot 6H_2O$ (0.59 g) was dissolved in the minimum volume of hot ethanol and then diluted with acetone (30 cm^3). To this was added dropwise a

solution of L (0.73 g) in acetone (30 cm^3). A pale blue product formed which could not be recrystallized from acetone. This was filtered off and dried *in vacuo*.

$Ni_2LCl_4(H_2O)_3(C_2H_5OH)_2$

To a stirred hot mixture of $NiCl_2 \cdot 6H_2O$ (0.59 g) and nitromethane (30 cm^3) was added sufficient ethanol to give a clear solution. To this was added dropwise a solution of L (0.73 g) in nitromethane (30 cm^3). The resulting dark green solution was heated and stirred for a few minutes, when a pale blue product formed. On cooling the blue product redissolved, and on standing for 2 weeks the solution gave brown microcrystals in low yield. The crystals used in the X-ray study were obtained by successive filtrations of a crystallizing solution until large single crystals formed.

$Ni_2LBr_4 \cdot 2H_2O \cdot C_2H_5OH$

$NiBr_2 \cdot 3H_2O$ (0.45 g) was dissolved in the minimum volume of hot ethanol, and the solution diluted with 30 cm^3 of acetone. To this was added dropwise a solution of L (0.47 g) in acetone (30 cm^3). A purple product formed which turned blue-grey on filtering and vacuum drying at 70°C.

$Ni_2LBr_4 \cdot 3H_2O$

$NiBr_2 \cdot 3H_2O$ (0.45 g) was dissolved in the minimum volume of hot ethanol and then diluted with hot nitromethane (30 cm^3). To this was added dropwise a hot solution of L (0.47 g) in nitromethane (30 cm^3). A blue product formed which was filtered off and air dried, which caused a colour change to grey on the surface and green in the bulk of the material. The green product was separated and dried at 70°C *in vacuo*.

$Ni_2L(SCN)_4$

$Ni(SCN)_2$ was prepared from KSCN (0.97 g) and $Ni(NO_3)_2 \cdot 6H_2O$ (0.73 g) in ethanol. To an ethanolic solution of $Ni(SCN)_2$ was added 30 cm^3 of nitromethane followed by L (0.73 g) in nitromethane (30 cm^3). The grey product that quickly formed was filtered off and dried *in vacuo*.

The analytical results for the above complexes are given in Table 1.

The diffuse-reflectance spectra were recorded on a Beckmann DK2 spectrophotometer and are given in Table 2.

Magnetic measurements (Table 2) were carried out at room temperature on a Gouy balance of conventional design.

X-ray crystallography

The crystal used for the X-ray study was sealed in a thin-walled glass capillary. All crystallographic measurements were made at 293±2 K using a CAD4 diffractometer operating in the ω–2θ scan mode, with Ni-filtered Cu-K_α radiation (λ = 1.54178 Å) as previously described.[6] The structure was solved via the heavy-atom method and refined using full-matrix least-squares using two blocks, one for atoms in each ion, and with scattering factors taken from Ref. 7. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were inserted in idealized positions, allowed

Final $R = 0.0615$, $R_w = 0.0506$, weights = $1/[\sigma^2(F_o) + 0.00002F_o^2]$.

Tables of atomic positional and thermal parameters, bond lengths and angles, and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure of the title compound is shown in Fig. 1 where Cl(3) is hydrogen bonded to hydrogen atoms of water oxygens O(1) and O(2), and Cl(4) is hydrogen bonded to the hydrogen atoms of O(4) (an ethanol molecule) and O(3) (a water molecule). Selected bond lengths and angles are given in Table 3. $[NiCl_2(H_2O)_3(C_2H_5OH)]$ exhibits facial geometry and the interesting feature of the molecule is the unusual combination of ligands utilized to achieve the distorted octahedral stereochemistry. $[NiL]^{2+}$ is also distorted octahedral. The two distances Ni—N(13) (2.051 Å) and Ni—N(33) (2.058 Å) are very similar to the values found for other Ni(II) benzimidazole complexes.[8,9] The other two Ni imino nitrogen distances, Ni—N(23) (2.101 Å) and Ni—N(42) (2.147 Å), are somewhat longer and presumably a consequence of the geometrical requirements of the ligand. The various bond angles centred at Ni range from 78.3 to 122.6° for *cis* groups and from 157.9 to 176.3° for *trans* groups. The most marked deviation from ideal geometry is the N(42)—Ni(1)—N(23) angle of 122.6°, the largest angle less than this being 96.8° for the *cis* N(13)—Ni(1)—N(2).

The complexes of stoichiometry $NiLX_2$ (X^- is ClO_4^-, NO_3^-, Cl^-, Br^- or SCN^-) have electronic spectral and magnetic properties which are consistent with the assignment of a structure similar to that of the cation in the title complex together with the appropriate anion, i.e. $NiL^{2+}2X^-$. The elec-

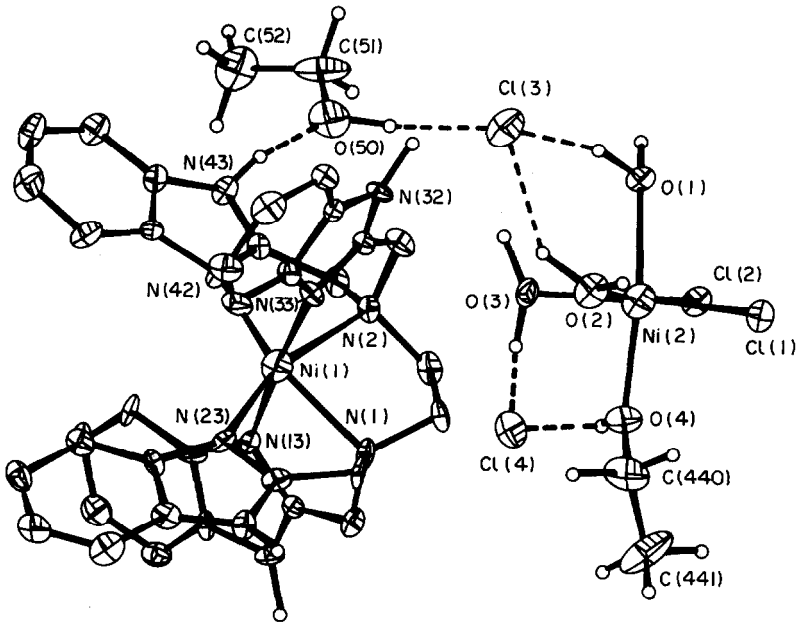

Fig. 1.

tronic spectra of the title complex can be interpreted as the superposition of the spectra due to the two species $[NiL]^{2+}$ and $[NiCl_2(H_2O)_3(C_2H_5OH)]$.

It could be argued that the electronic spectra of $Ni_2LCl_4 \cdot 6H_2O$ and the two forms of Ni_2LBr_4 contain features attributable to Ni(II) ions in octahedral and tetrahedral environments. This would lead to the assignment of the structure $NiX_4^{2-}NiL^{2+}$ to these complexes (X^- is Cl^-, Br^- or SCN^-) but their spectra do not show the relatively high intensity absorption bands associated with tetrahedrally coordinated Ni(II) complexes. In view of this,

assignment of a structure to these complexes will not be attempted. However, because of the possibility that some of these complexes might be of the structural type suitable for our EXAFS studies we are currently trying to grow crystals of them suitable for an X-ray crystallographic investigation.

SYNTHESIS AND STRUCTURAL STUDIES OF METAL(II) 4,9,16,23-PHTHALOCYANINE TETRAAMINES

B. N. ACHAR,* G. M. FOHLEN,† J. A. PARKER‡ and J. KESHAVAYYA

Department of Post-Graduate Studies and Research in Chemistry, Manasagangotri, Mysore 570006, India

(*Received* 27 *August* 1986; *accepted after revision* 21 *January* 1987)

Abstract—Preparation of pure metal(II) 4,9,16,23-phthalocyanine tetraamine 2-hydrates of copper, cobalt, nickel and zinc are reported. Elemental analysis, electronic spectra, FT-IR spectra, powder X-ray diffraction, magnetic-susceptibility measurements, dynamic thermogravimetric MS and GC–MS spectral studies are carried out to check the purity, structural integrity, thermal stability and mode of fragmentation of these complexes. Magnetic-susceptibility measurements showed a variation in the magnetic moments of these complexes with magnetic field strength, indicating the presence of a co-operative intermolecular effect.

Metal phthalocyanines and their derivatives are of great technological importance for the manufacture of blue-green pigments.[1–3] Currently intensive research is going on in producing phthalocyanine compounds useful for applications[1] as catalysts, photoconductors, photosensitizers, electrical conductors, photovoltaic materials, and thermally stable polymers.[1–7] Incorporation of the phthalocyanine structure either in the polymeric backbone or as curing agent to epoxy resins is expected to increase thermal stability, chemical resistance and fire retardance. The polymers prepared from phthalocyanines did not give the thermal stability expected from the stable phthalocyanine structure.[8–13] The use of phthalocyanine carboxylic acids and copper phthalocyanine to cure epoxy resins has been described in the literature.[14,15] However, those phthalocyanine derivatives and copper phthalocyanine are insoluble, react heterogeneously and remained as discrete particles even after curing. Because of this major disadvantage of insolubility, complete realization of their thermal stability and the chemical resistance of phthalocyanines were not seen in the cured resins. This is because phthalocyanine and its metal derivatives are insoluble in water and most common organic solvents. But the solubility can be altered by substituting suitable functional groups in the peripheral benzene rings of the phthalocyanine structure. Among the thermally stable soluble phthalocyanine compounds, amine groups substituted metal phthalocyanine derivatives are found to be promising. The amine derivatives of metal phthalocyanines have been previously synthesized mostly for the preparation of inks, dyes and pigments.[1,16–21] The procedures described often give impure compounds and these compounds have not given clear solutions in aprotic solvents. An efficient method was developed for the synthesis of analytically pure metal(II) 4,9,16,23-phthalocyanine tetraamines with the structure shown in Fig. 1.

The present work describes the synthesis and structural investigations of pure metal phthalocyanine tetraamines (MPTAs). The synthetic procedure has been adapted from the methods outlined to synthesize various other types of metal phthalocyanine derivatives.[16–25]

EXPERIMENTAL

Materials

4-Nitrophthalic acid, ammonium chloride and ammonium molybdate are A.C.S. reagents from Aldrich Chemical Co., U.S.A. All other chemicals were of analytical grade. Metal(II) 4,9,16,23-phthalocyanine tetraamine 2-hydrates of copper, cobalt, nickel and zinc are prepared as follows.

(1) *Copper*(II) 4,9,16,23-*tetranitrophthalocyanine.* 12.0 g copper sulfate pentahydrate, 37.0 g 4-nitrophthalic acid, 4.5 g ammonium chloride, 0.5 g ammonium molybdate and excess urea (50–60 g) were finely ground and placed in a 500-cm^3 three-necked flask containing 25 cm^3 of nitrobenzene. The temperature of the stirred reaction mixture was slowly increased to 185°C and maintained at 185 ± 5°C for 4.5 h. The solid product was finely ground and washed with alcohol until free from nitrobenzene. The product was added to 500 cm^3 of 1.0 N hydrochloric acid saturated with sodium chloride, boiled for about 5 min, cooled to room temperature and filtered. The resulting solid was treated with 500 cm^3 1.0 N sodium hydroxide containing 200 g sodium chloride and heated at 90°C until the evolution of ammonia ceased. The solid product after filtration was treated with 1.0 N hydrochloric acid and separated by centrifugation. Alternate treatment with hydrochloric acid and sodium hydroxide was repeated twice. The copper(II) 4,9,16,23-tetranitrophthalocyanine was washed with water until chloride-free. The blue complex was dried at 125°C.

(2) *Copper*(II) 4,9,16,23 - *tetraaminophthalocyanine 2-hydrate.* About 10 g of finely ground copper(II) 4,9,16,23-tetranitrophthalocyanine was placed in 250 cm^3 water. To this slurry 50 g of sodium sulfide nonahydrate was added and stirred at 50°C for 5 h. The solid product was separated by centrifuging the reaction mixture and treated with 750 cm^3 of 1.0 N hydrochloric acid. The bulky blue precipitate of copper(II) tetraaminophthalocyanine hydrochloride was separated by centrifugation. It was then treated with 500 cm^3 of 1.0 N sodium hydroxide, stirred for 1 h and centrifuged to separate the dark green solid complex. The product was repeatedly treated with water, stirred and centrifuged until the material was free from sodium hydroxide and sodium chloride. The pure copper complex was dried *in vacuo* over P_2O_5.

Metal(II) tetranitrophthalocyanines of cobalt, nickel and zinc were prepared by the same method using cobalt, nickel and zinc salts in place of the copper salt of procedure (1). The corresponding metal phthalocyanine tetraamines are obtained by using procedure (2) as described above.

Methods

Beckman Model DB spectrophotometer with 1-cm silica cells, from Beckman Instruments Inc., U.S.A., was used for UV and visible spectral studies. IR spectra were recorded using a Nicolet MX-1 FT-IR spectrometer. Carbon, hydrogen and nitrogen elemental analyses were done by Huffman Laboratories Inc. Co., U.S.A. The metal contents in the MPTAs were determined by decomposing a known amount of the complex using a sulphuric acid–nitric acid mixture followed by careful evaporation and calcination to constant weight. Thermogravimetric studies were carried out with a Du Pont Model 990 thermal analyzer and a 951 thermogravimetic module. A heating rate of 10°C min^{-1} was used in air and nitrogen atmospheres with a flow rate of 100 cm^3 min^{-1}. The Gouy magnetic balance consisting of a type NP-53 electromagnet with a DC power supply type MP-1053 and a semimicrobalance supplied by Universal Scientific Co., India, was used. A mercury tetrathiocyanato cobaltate(II) complex was used as the calibration standard. The JDX-8P JEOL X-ray diffractometer was used to study the X-ray diffraction pattern of the samples. The spectra were obtained with the following conditions: target Fe (Mn filter), voltage 30 kV, current 30 mA, time constant 4, chart speed 10 mm min^{-1}, channel width 0.7, and channel center 1.0.

A Hewlett–Packard model 5980 mass spectrometer equipped with a data acquisition system provided mass spectra of the individual components of the pyrolysis products at 70 eV. Two direct inlet probes (DIPs) were used. The low-temperature DIP can heat to 470°C at a heating rate of 50–100°C min^{-1} below 350°C and 10–50°C min^{-1} above 350°C. The high-temperature DIP was attached to a solid pyrolizer. The sample was heated for 1 min at each of the following temperatures: 700, 800, 900 and 1000°C. A Hewlett–Packard model 5830A gas chromatograph was used to study the volatile gaseous products formed during the thermal treatment. A sample of 1–2 mg of MPTA was inserted inside the platinum coil of the pyroprobe. The sample was

then kept in the pyrolysis chamber which was kept at 250°C. The sample was pyrolyzed at 900°C for 1 min. The volatile products were flushed with helium carrier gas to the GC separation column. The GC column used was 2 m long with a 2 mm i.d., glass column packed with 3% OV101 on 80/100 supelcoport. During the analyses the column temperature was held at 60–280°C and then maintained at the upper limit for 8 min. The helium gas flow was 20 cm^3 min^{-1}.

RESULTS AND DISCUSSION

The procedures described above are simple, commercially realizable and give pure compounds with almost quantitative yields (≃ 90%) except in the case of the zinc compound where the yield was only 30–40%. In this case the zinc complex seems to undergo degradation when it is heated in the presence of sodium hydroxide solution. These MPTAs have a metallic lustre and a deep greenish black colour. They give clear solutions in aprotic solvents such as dimethylsulphoxide, dimethylformamide and dimethylacetamide. The method of synthesis is applicable to the preparation of MPTAs of metals whose ionic radii[26] are about 0.8 Å. The preferred metals are copper, cobalt, nickel, zinc, iron, platinum, aluminium and vanadium. The most preferred metals are copper, cobalt and nickel. The results of the elemental analyses for carbon, hydrogen, nitrogen and metal agreed fairly well with the calculated values and were consistent with the structures shown in Fig. 1 with two water molecules.

Electronic absorption spectra

Metal(II) 4,9,16,23-tetraaminophthalocyanines of copper, cobalt, nickel and zinc showed absorption bands at 208–218, 288–306 and 732–746 nm in 30 N sulphuric acid (Table 1). In addition, shoulders are observed around 380–384 nm in all the absorption spectra of the complexes. The deep greenish

blue colour of the derivatives may be due to the $e_g \leftarrow a_{2u}$ transitions. A small dependence of the spectrum upon the central metal ion may be due either to the involvement of the $p\pi(a_{2u})$ orbitals in the π-bonding of the phthalocyanine ring system or more probably to the inductive effect.[27] In comparison with the spectra of the corresponding parent phthalocyanines the two peaks in UV regions around 208–218 and 288–306 nm remained almost unaffected in the spectra of the corresponding MPTAs. The peaks in the parent metal phthalocyanines around 424–438 nm appeared as shoulders at 380–384 nm with a blue shift. The peaks in the longer-wavelength region (732–746 nm) showed a bathochromic shift with increasing intensity with respect to the corresponding parent phthalocyanines. This is due to the auxochromic $-NH_2$ group present in the benzene portion of the complexes.

IR spectra

The FT-IR spectral data were recorded in KBr discs and the results are presented in Table 1. Two weak broad absorption bands at 3279–3284 and 3165–3188 cm^{-1} are observed in all the spectra of the MPTAs. These absorptions may be assigned to the ν_{as} and ν_s stretching vibrations of the amino groups. Intense $-NH_2$ group in-plane bending vibrations are observed at 1602–1607 cm^{-1}. Peaks around 1340–1345, 1299–1309 and 1248–1251 cm^{-1} indicated the presence of C—N aromatic stretching. The bands at 1133–1136, 1095–1098, 1045–1060, 936–951, 863–864 and 743–750 cm^{-1} may be assigned to the various phthalocyanine skeletal vibrations.[27]

Dynamic thermogravimetric studies

The nature of the analytical curves (Fig. 2) indicated that these amine derivatives of copper, cobalt, nickel and zinc phthalocyanines are degraded mainly in two steps. The weight loss (5–5.4%) which takes place between 50 and 130°C corresponds to the loss of two water molecules. The second weight loss is very catastrophic in an oxidizing atmosphere and is about 76–77% which is equivalent to the degradation of the unmetallated phthalocyanine structure. The final products in the oxidizing atmospheres are CuO, CoO, NiO and ZnO. The stability of the MPTAs in the oxidizing atmosphere is in the order CoPTA > CuPTA > NiPTA > ZnPTA. The second step of weight loss is very resistant in a nitrogen atmosphere and the weight loss seems to be due to some other mode of degradation. This weight loss is gradual in the temperature range 500–900°C and the char yields vary from 65 to 79%, depending on the MPTA. The stability in the inert atmosphere is found to follow the order NiPTA > CoPTA > CuPTA > ZnPTA.

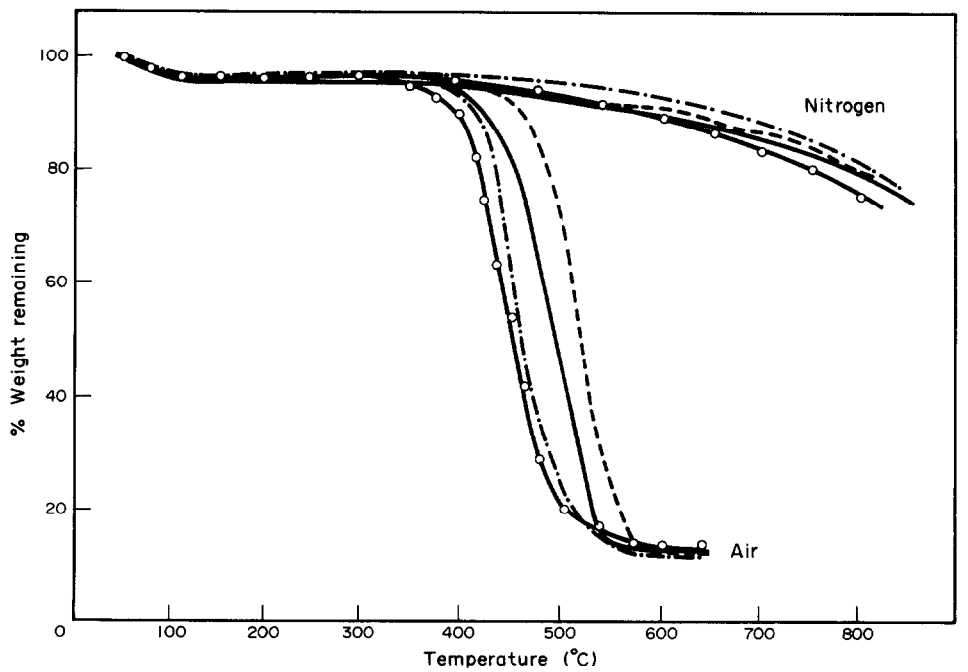

Fig. 2. Dynamic thermogravimetric analytical curves of: (1) $CuPTA \cdot 2H_2O$ (——), (2) $CoPTA \cdot 2H_2O$ (– – – –), (3) $NiPTA \cdot 2H_2O$ (— · — · —), and (4) $ZnPTA \cdot 2H_2O$ (— ○ — ○ —).

Magnetic-susceptibility measurements

The magnetic-susceptibility data for metal(II) 4,9,16,23-phthalocyanine tetraamines of copper, cobalt, nickel and zinc are consistent with the paramagnetic nature of the copper and cobalt complexes and the diamagnetic nature of the nickel and zinc complexes. The complexes are square planar with molecular symmetry D_{4h}. A summary of the magnetic properties over the range of magnetic field strengths 1025–6144 G are reported in Table 1. The magnetic moment parallels that of other spin-paired square planar cobaltous derivatives with a moment considerably above that expected for one unpaired electron. This may be due to the orbital contribution which could arise by mixing the ground state $(b_{2g})^2 (e_g)^4 (a_{1g})^1$ and higher orbitally degenerate states such as $(b_{2g})^2 (e_g)^3 (a_{1g})^2$. CuPTA has a moment corresponding to the spin-only value at a higher magnetic field strength and this value is very close to the 1.9 BM observed in most of the copper complexes. The variation in the magnetic moments with magnetic field strength has also been observed in the case of metal phthalocyanine sulphonic acid and metal phthalocyanine tetracarboxylic acid complexes. The variations in these complexes may also be due to the intermolecular co-operative effect.[25]

Powder X-ray diffraction

X-ray diffraction spectrographs of CuPTA, CoPTA, NiPTA and ZnPTA recorded through a range of angles (5–90°) showed similar patterns. All these complexes showed one broad sufficiently intense diffracted peak and the interplanar spacings calculated based on these data gave values (in Å) of 13.05, 12.32, 12.32 and 12.32 for CuPTA, CoPTA, NiPTA and ZnPTA, respectively.

Mass and GC–mass spectral studies

The mass spectra recorded at various temperatures indicated that the concentrations of the volatile products observed are very low even at a very high temperature. At 500°C, m/z of 18, 14, 64, 91, 118 and 143 appeared in more than 20% relative abundance with $m/z = 118$ being the base peak. At higher temperatures (700–1000°C) m/z of 28, 32, 44, 64, 82, 96, 128, 160, 192 and 256 (base peak) are seen in the mass spectra of the MPTAs. The gas chromatograms of the pyrolysed products of the MPTAs showed only trace quantities of volatile materials. The products identified are N_2, N_2H_4, C_6H_6, $C_6H_5NH_2$, C_6H_5CN, $C_6H_5(CN)_2$ and $C_6H_4(CN)(NH_2)$. The peak corresponding to $m/z = 44$ in mass spectra of MPTAs seems to be unusual. However, this is possible if the tetraamines have the property of adsorbing carbon dioxide gas. The study to support this is under further investigation.

COMPLEXATION OF PROTONS BY MACROCYCLIC POLYETHERS IN ACETONITRILE

HANS-JÜRGEN BUSCHMANN

Physikalische Chemie, Universität-GH Siegen, Postfach 101240, D-5900 Siegen, F.R.G.

(*Received* 19 *November* 1986; *accepted* 21 *January* 1987)

Abstract—The complexation of H^+ by different macrocyclic polyethers in acetonitrile solutions has been studied by means of calorimetric titrations. The most stable complex is observed with 18-crown-6. The measured stability constants decrease when the number of benzo substituents of 18C6 are increased. The stability of the complexes formed with larger macrocyclic polyethers is also smaller in comparison with 18C6. Unfavourable entropic changes during the reaction are responsible. Compared with noncyclic polyethers all ligands studied form more stable complexes. Favourable entropic contributions are mainly responsible.

The interactions of different crown ethers with various cations have been studied very intensively.[1] However, results for the reaction of H^+ with macrocyclic polyethers are very rare.[2] Some stability constants for these reactions have already been reported.[3] Even experimental results for the protonation of noncyclic and macrocyclic polyethers in the gas phase are available from the literature.[4] The gas-phase reactions of H_3O^+ and $CH_3OH_2^+$ with crown ethers have also been studied.[5] These results can not be directly compared with the experimental data obtained in solution due to interactions between solvent molecules and crown ethers.[6]

As a continuation of an earlier work[2] the complexation of H^+ by more crown ethers in acetonitrile solutions is studied to get more information about the factors influencing the experimental results observed.

EXPERIMENTAL

Materials

The different benzo crown ethers shown in Fig. 1 are non-commercial and were provided by Prof. E. Weber (Bonn).[7] All other crown ethers (see Fig. 2) like 21-crown-7 (21C7, Parish), dibenzo-21-crown-7 (DB21C7, Parish), dicyclohexano-27-crown-9 (DC27C9, Parish), dibenzo-30-crown-10 (DB30C10, Parish) and dicyclohexano-30-crown-10 (DC30C10, Parish) were used without further purification.

Trifluoromethanesulfonic acid (Ega) was used as purchased. The dissociation of trifluoromethanesulfonic acid can be considered as complete under experimental conditions.[8] The water content of the solvent acetonitrile (Merck) was less than 0.3%.

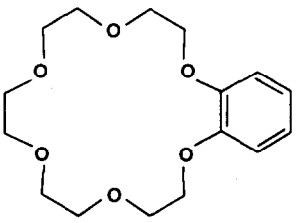
Procedure

All stability constants smaller than $10^5\ M^{-1}$ and reaction enthalpies were determined by titration calorimetry using a Tronac Model 450 calorimeter. The procedure used to calculate the stability of the complex formed from the thermogram and the corresponding reaction enthalpy has already been described elsewhere.[9] It has already been shown that even the large crown ethers only form 1:1 complexes:[2]

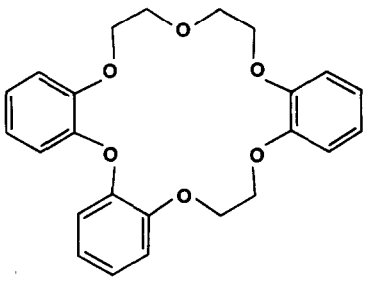
$$L + H^+ \rightleftharpoons LH^+, \quad K = \frac{[LH^+]}{[L][H^+]}.$$

Therefore it is possible to titrate a solution of trifluoromethanesulfonic acid (0.06–0.08 M) into a ligand solution (5×10^{-3} M). The heat (Q) produced during titration is related to the reaction enthalpy (ΔH) after correction for all non-chemical heat effects as shown by the following equation:

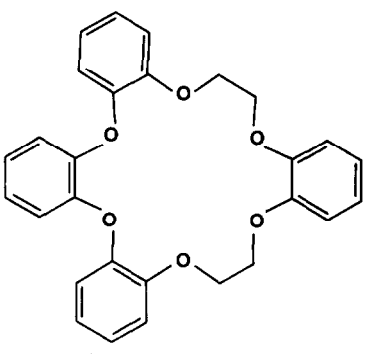
$$Q_t = \Delta H \Delta n_t$$



B18C6



TB18C6



TeB18C6

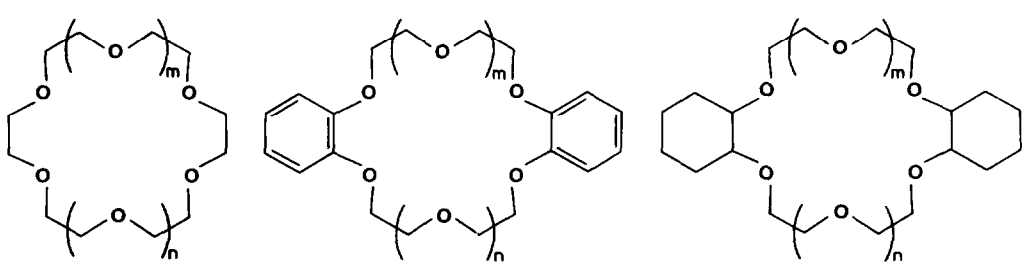
Fig. 1. Benzo-crown ethers.

where Δn_t is the number of mol of complex formed at time t. For stability constants smaller than 10^5 M^{-1} Δn_t is not constant during titration but is a function of the stability constant of the reaction observed. Also from the experimental data in this investigation no evidence is found of the existence of complexes with compositions other than 1 : 1. The electrostatic repulsion between two protons complexed by one ligand molecule obviously prevents the formation of such complexes in acetonitrile solutions.

RESULTS AND DISCUSSION

The values of $\log K$, ΔH and $T\Delta S$ for the reaction of H^+ with different 18-crown-6 ligands are given in Table 1. With an increasing number of benzo groups attached to 18-crown-6 decreasing values are measured for the reaction enthalpies. These data clearly demonstrate an electron withdrawal effect of the benzo groups. Thus, the electron density at the neighbouring oxygen donor atoms is reduced, directly influencing the reaction enthalpies measured. However, the reaction enthalpies measured for the reaction of 18C6 and B18C6 are almost identical.

Reaction entropies obtained for both ligands differ considerably. This observation is based on several factors. It is known that the ligand 18C6 forms complexes with the solvent acetonitrile.[6] No such information is obtainable for B18C6. If both ligands are not equally solvated in acetonitrile solutions the reaction entropies observed should reflect this situation. Assuming stronger interactions between 18C6 and acetonitrile than between B18C6 and this solvent more solvent molecules are liberated during the complex formation of 18C6 with H^+ compared to B18C6. As a result the com-



m = 1, n = 1 : 18C6

[b] From Ref. 2.

plexation of H^+ by 18C6 is favoured by entropic contributions.

The reaction entropies increase from B18C6 with an increasing number of the ligand's benzo groups. The structural flexibility of these ligands during the formation of the H^+ complexes is reduced and an increasing number of donor atoms already possess a fixed position in the ligand. The proton complex formed with the ligand DC18C6 is much stronger in comparison with all other 18-crown-6 ligands. Only enthalpic factors are responsible for this observation which may result from the different solvation of these ligands. This interpretation is also supported by further experimental results measured for the reaction of different 18-crown-6 ligands with alkali ions in acetonitrile solutions.[10]

In Table 2 more results for the reaction of H^+ with crown ethers larger than 18-crown-6 are summarized. Comparing the reaction enthalpies of the unsubstituted crown ethers 18C and 21C7 with one another and also their dibenzo derivatives one finds that they are identical in both cases. The additional oxygen donor atom does not influence the values of the reaction enthalpies. The differences in complex stabilities are only caused by minor entropic changes.

On increasing the size of the macrocyclic ligands further, an enhancement of the measured reaction enthalpies is observed in nearly all cases. The values of the reaction enthalpies for the reaction of all dibenzo-crown ethers are smaller than for the dicyclohexano-crown ethers. These results are in agreement with the influence of the electron withdrawal effect of benzo groups already discussed. This effect vanishes with an increasing number of oxygen donor atoms not attached to benzo groups of the crown ether. Thus, there is the possibility of the complexed proton increasing to interact with "normal" oxygen donor atoms. In contrast, the enhancement of the flexibility of the ligand is responsible for more unfavourable entropic changes during the reaction.

The dicyclohexano-crown ethers show much smaller changes in the reaction enthalpies with a number of donor atoms. The basicity of all oxygen donor atoms is nearly equal. Sterical reasons may therefore be responsible for the observed changes in the reaction enthalpies. Compared with the results for the corresponding dibenzo-crown ethers more of the observed reaction entropies for dicyclohexano-crown ethers are negative. When the size of the ligand increases, all thermodynamic values for the different ligands substituted obviously approach one another. This behaviour is not surprising because the individuality of all crown ethers is expected to vanish if the ligands are large enough.

The values of the reaction enthalpy measured for the reaction of large crown ethers decrease in the

following order as far as experimental data are available:

dicyclohexano-crown ether > crown ether

> dibenzo-crown ether.

An identical sequence was found for different ligands.[2] However, reaction entropies cannot be arranged in a similar way. The values for the reaction of unsubstituted and dibenzo-crown ethers are rather similar. Only larger unfavourable entropic contributions are observed for the complexation reaction of the large dicyclohexano-crown ethers.

The values of the reaction enthalpies measured for the complexation of H^+ by different non-cyclic polyethers are smaller when compared with the values obtained for the dicyclohexano-crown ethers estimated in this work.[2] In methanol solution it was found that the values of the reaction enthalpy for the complexation of alkali ions by non-cyclic polyethers increase with an increasing number of ether oxygen donor atoms.[11] Until further data are published the same behaviour may be presumed for the complexation of H^+.

All crown ether ligands studied in this work form more stable complexes compared with their non-cyclic analogues.[2] With the restriction given above entropic factors are responsible for this observation.

Acknowledgement—The ligands B18C6, TB18C6 and TeB18C6 were kindly donated by Prof. E. Weber. Financial support by the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

DINUCLEAR COPPER(II) COMPLEX MEDIATED REGIOSELECTIVE ALDOL-TYPE CONDENSATION OF 2-HYDROXY-5-METHYLBENZENE-1,3-DICARBALDEHYDE*

BIBHUTOSH ADHIKARY, AMAL K. BISWAS and KAMALAKSHA NAG†

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India

(*Received* 1 *December* 1986; *accepted* 21 *January* 1987)

Abstract—An aldol-type reaction of one of the carbaldehyde moieties of 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde (HL) takes place with ketones containing α-methyl and/or α-methylene groups through an *in situ* generated dicopper(II) complex, $Cu_2L_2(ClO_4)_2 \cdot 2H_2O$. The metal-free condensation products are 2-hydroxy-3-formyl-5-methyl-1-benzal ketones. No such reaction takes place with the mononuclear complex $CuL_2 \cdot H_2O$. The ligand (HL) itself undergoes uncontrolled self-condensation and polycondensation.

Although aldol condensation[1] is a versatile method in organic chemistry, its application suffers from the drawback of self-condensation and polycondensation, especially when a cross-coupling reaction is carried out with conventional base or acid catalysts. In recent years considerable attention has been focussed on directed coupling of two carbonyl compounds in a regioselective manner.[2–4] A very useful approach has been the reaction of a carbonyl compound with a suitably reactive metal enolate or enol-ether that is derived regioselectively from the other carbonyl compound. Of the various metal derivatives, boron enolates are found to react most selectively with aldehydes.[5–7] In several cases the desired aldol condensation products have also been obtained by using some transition-metal complexes as catalysts.[8] The present study is concerned with the regioselective addition of α-methyl and/or α-methylene ketones to one of the carbonyl groups of the symmetric molecule 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde (HL) through its dinuclear copper(II) complex, $Cu_2L_2(ClO_4)_2 \cdot 2H_2O$.

During the course of our studies[9] on the dinuclear metal complexes $M_2L_2(ClO_4)_2 \cdot 2H_2O$ (**1**) (M = Cu, Ni, Co or Mn), we noted that the two metal atoms are not equally strongly bound to the ligand. These complexes are formed when the mononuclear complex species $ML_2 \cdot H_2O$ are reacted with their corresponding metal perchlorate salts in dry EtOH. However, the phenoxo bridge of the dinuclear complexes undergoes hydrolytic cleavage in a wet solvent to regenerate $ML_2 \cdot H_2O$. The IR spectra of **1** show[9(b)] the presence of two C=O stretchings, which are separated by *ca* 20 cm^{-1}. The rationale for these observations is that, since in a dinuclear chelate the drainage of electron density occurs through the phenoxo bridge, the metal atom that was originally bound to the ligand draws more electronic charge from the formyl oxygen co-ordinated to it in order to retain its greater stability, and as a result the C=O stretching vibration of this carbonyl group appears at a lower frequency relative to the other one. We considered that in this situation the activated carbonyl group should be more susceptible to nucleophilic attack, and complex **1** may be directed to undergo regioselective aldol type condensation. We find that such a reaction indeed takes place with ketones containing α-methyl and/or α-methylene groups, and offers a route to the synthesis of 2-hydroxy-3-formyl-5-methyl-1-benzal ketones (**2**). To our knowledge no straightforward method exists for the preparation of compounds of type **2**.

RESULTS AND DISCUSSION

Preliminary studies showed that all the dinuclear complexes react in the same way. However, the

* Part 6 of the series: Dinuclear metal complexes. Part 5 is Ref. 9(b).

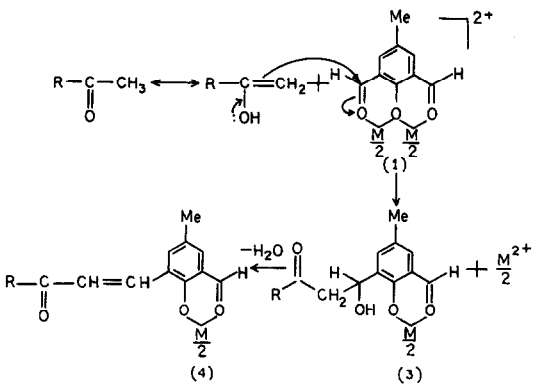
† Author to whom correspondence should be addressed.

reactions of **1** with acetone, acetophenone, 2-butanone, 4-methyl-2-pentanone and *trans*-4-phenyl-3-butene-2-one, as reported here, involve the use of the dicopper(II) complex for the sake of convenience.

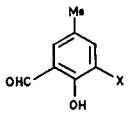
Typically, the reactions were carried out by heating a mixture of $CuL_2 \cdot H_2O$, $Cu(ClO_4)_2 \cdot 6H_2O$ and a ketone in a molar ratio of 1 : 1.5 : 6 in dry EtOH. The condensation products were isolated and characterized as the mononuclear complex species (**4**), which are the derivatives of α,β-unsaturated ketones rather than those of aldols (**3**). It appears that the dehydration of **3** to **4** is caused by the effect of heat. Although aldol condensation is normally carried at ambient or subambient temperature, in the present study the application of heat was necessary due to the poor solubility of the precursor complex. The removal of the metal from the condensation products yield 2-hydroxy-3-formyl-5-methyl-1-benzal ketones (**2a–f**). It may be noted that, when the condensation is carried out with 2-butanone, two isomeric products, viz. **2c** and **d**, are obtained in a ratio of 5 : 1. In the case of 4-methyl-2-pentanone, however, the reaction takes place only through the α-methyl group.

The overall yield of **2** lies in the range 70–50%. About 10–15% of the parent dialdehyde (HL) is recovered unchanged. Other reaction product(s) obtained as an intractable viscous material remains uncharacterized.

It is important to mention that all these reactions take place with $Cu_2L_2(ClO_4)_2 \cdot 2H_2O$ generated *in situ*, but *not* with a preformed material. This indicates that the aldol condensation taking place here is catalyzed by the trace of free $HClO_4$ present in the perchlorate salt. In fact the pH of an aqueous solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.2 M) was found to be *ca* 3.9. It is also important to note that the use of a dry solvent is a prerequisite, and the use of aqueous $HClO_4$ is forbidden on the ground of hydrolytic cleavage of **1**. The aldol type reaction *does not* take place with the mononuclear complex $CuL_2 \cdot H_2O$ under a variety of conditions, including the use of acid and base catalysts. The failure of $CuL_2 \cdot H_2O$ to bring about a cross-coupling reaction underscores the specific role of the dinuclear species (Scheme 1). The free ligand, on the other hand, undergoes uncontrolled self-condensation and poly-condensation in the presence of aqueous NaOH.



Scheme 1



Scheme 1. (**2a**) X = CH=CHCOCH$_3$, (**2b**) X = CH=CHCOC$_6$H$_5$, (**2c**) X = CH=CHCOCH$_2$CH$_3$, (**2d**) X = CH=C(CH$_3$)COCH$_3$, (**2e**) X = CH=CHCOCH$_2$CH(CH$_3$)$_2$, (**2f**) X = CH=CHCOCH=CHC$_6$H$_5$, (**4a**) R = CH$_3$, (**4b**) R = C$_6$H$_5$.

EXPERIMENTAL

Melting points were measured in open capillary tubes and are uncorrected. C and H analyses were performed on a Perkin–Elmer model 240C elemental analyzer. IR spectra were recorded on a Perkin–Elmer model 783 IR spectrophotometer with KBr pellets. UV spectra in $CHCl_3$ solutions were obtained with a Pye–Unicam SP8-150 spectrophotometer. ^{1}H NMR spectra [δ (ppm)] were recorded at 200 MHz on a Varian Associates XL-200 spectrometer in $CDCl_3$ with Me_4Si as an internal standard.

HL was prepared by a method described in the literature.[10] Mono- and dinuclear copper(II) complexes of HL were prepared as described earlier.[9(a)]

Preparation of 2a–f

2a. A mixture of $CuL_2 \cdot H_2O$ (4.08 g, 10 mmol), $Cu(ClO_4)_2 \cdot 6H_2O$ (5.55 g, 15 mmol) and dry Me_2CO (100 cm^3) was heated under reflux. Within a few minutes, bright-green crystals of $Cu_2L_2(ClO_4)_2 \cdot 2H_2O$ deposited, which began to dissolve with the passage of time, and a dark-brown solution was obtained over a period of 10 h. The solution was filtered and slowly added with stirring to 500 cm^3 of water, when a brown precipitate was obtained. This was collected by filtration and dried. The crude complex (**4a**)* thus obtained was dis-

* The crude complex (**4a**) was recrystallized twice from a $CHCl_3$–*n*–hexane mixture and gave satisfactory analytical data for the composition $C_{24}H_{22}O_6Cu \cdot H_2O$. The IR spectra of **4a** and the product obtained by reacting **2a** with $Cu(OAc)_2 \cdot H_2O$ were identical.

solved in $CHCl_3$ (50 cm^3) and shaken with 2 M HCl (3 × 20 cm^3). The organic layer after washing with water was dried over Na_2SO_4. The $CHCl_3$ solution was evaporated to dryness and the residue was repeatedly extracted with light petroleum (b.p. 40–60°C). The combined extracts on concentration gave long light-yellow needles of **2a**, which was further recrystallized from light petroleum (65%) (m.p. 101°C). (Found: C, 70.4; H, 6.0. $C_{12}H_{12}O_3$ requires: C, 70.6; H, 5.9%.) ^{1}H NMR: 2.37 (s, 3H, $ArCH_3$), 2.41 (s, 3H, $COCH_3$), 6.87, 7.83 (q, 2H, J_{AB} = 16.0 Hz, *trans*-CH=CH), 7.42 [d, 1H, J = 2.0 Hz, 3-CH(phenyl)], 7.62 [d, 1H, J = 1.6 Hz, 5-CH(phenyl)], 9.85 (s, 1H, CHO), 11.51 (s, 1H, OH). IR (cm^{-1}): 1675(s), 1645(s), 1625(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)]: 370 (7100), 300 (8850), 260 (22,300).

2b. A mixture of $CuL_2 \cdot H_2O$ (3.66 g, 9 mmol), $Cu(ClO_4)_2 \cdot 6H_2O$ (5.0 g, 13.5 mmol) and PhCOMe (6.48 g, 54 mmol) in dry EtOH (100 cm^3) was refluxed for 16 h. A brown solid (**4b**)* formed was collected by filtration and washed with MeOH and $CHCl_3$. This was suspended in MeOH (100 cm^3) and stirred with 4 M HCl (25 cm^3) when it changed to a yellow material. The product was collected by filtration and recrystallized from $CHCl_3$–MeOH (1:2) mixture. Further recrystallization from light petroleum afforded yellow needles of **2b** (70%) (m.p. 106°C). (Found: C, 76.9; H, 5.2. $C_{17}H_{14}O_3$ requires: C, 76.7; H, 5.3%.) ^{1}H NMR: 2.39 (s, 3H, $ArCH_3$), 7.54 (m, 5H, COC_6H_5), 7.86, 7.96 (q, 2H, J_{AB} = 16.7 Hz, *trans*-CH=CH), 8.03 [d, 1H, J = 2.6 Hz, 3-CH(phenyl)], 8.07 [d, 1H, J = 2.4 Hz, 5-CH(phenyl)], 9.84 (s, 1H, CHO), 11.67 (s, 1H, OH). IR (cm^{-1}): 1660(s), 1645(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)]: 370 (11,100), 310 (13,600), 270 (26,400).

2c *and* **d**. To a suspension of $CuL_2 \cdot H_2O$ (5.3 g, 13 mmol) in dry EtOH (150 cm^3), $Cu(ClO_4)_2 \cdot 6H_2O$ (7.22 g, 19.5 mmol) and MeCOEt (4.68 g, 65 mmol) were added. A dark brown solution obtained after a 36-h reflux was filtered and evaporated to dryness on a rotary evaporator. The residue dissolved in MeOH (50 cm^3) was poured into water (1 dm^3), when a brown precipitate was obtained. This was collected by filtration, dissolved in $CHCl_3$ and decomposed with HCl (2 M). The $CHCl_3$ layer after drying was evaporated to dryness. The residue was extracted repeatedly with boiling light petroleum and the combined extract was subjected to column chromatography (silica gel, 60–120 mesh). The first fraction separated on elution with light petroleum was HL (10%). The second fraction obtained with a 2:98 (v/v) mixture of $MeCO_2Et$–light petroleum was **2c** (50%). The third fraction (**2d**) (10%) was collected by eluting with the same solvent mixture in a ratio of 5:95.

2c: m.p. 101–102°C. (Found: C, 71.3: H, 6.5. $C_{13}H_{14}O_3$ requires: C, 71.6: H, 6.4%.) ^{1}H NMR: 1.18 (t, 3H, CH_2CH_3), 2.36 (s, 3H, $ArCH_3$), 2.73 (q, 2H, CH_2CH_3), 6.90, 7.80 (q, 2H, J_{AB} = 16.5 Hz, 2H), 7.39 [d, 1H, J = 1.4 Hz, 3-CH(phenyl)], 7.58 [s, 1H, 5-CH(phenyl)], 9.86 (s, 1H, CHO), 11.55 (s, 1H, OH). IR (cm^{-1}): 1690(s), 1660(s), 1635(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)]: 370 (8000), 290 (11,500), 260 (25,800).

2d: m.p. 122°C. (Found: C, 71.5: H, 6.3. $C_{13}H_{14}O_3$ requires: C, 71.6: H, 6.4%.) ^{1}H NMR: 1.99 [s, 3H, CH=C(CH_3)], 2.38 (s, 3H, $ArCH_3$), 2.49 (s, 3H, $COCH_3$), 7.41 [s, 1H, 3-CH(phenyl)], 7.46 [s, 1H, CH=C(CH_3)], 7.67 [s, 1H, 5-CH(phenyl)], 9.88 (s, 1H, CHO), 11.32 (s, 1H, OH). IR (cm^{-1}): 1660(s), 1650(s), 1630(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)]: 360 (7500), 290 (8200), 260 (26,500).

2e. The reaction was carried out in the same way as described above using 2-methylpentanone. Chromatographic separation of the crude product by eluting with light petroleum [to remove HL (15%)], followed by a 98:2 mixture of light petroleum and $MeCO_2Et$ afforded **2e** (50%) (m.p. 59°C). No further isomer could be separated by increasing the polarity of the solvent mixture. (Found: C, 73.4; H, 7.2. $C_{15}H_{18}O_3$ requires: C, 73.2; H, 7.3%.) ^{1}H NMR: 0.99 [d, 6H, $CH(CH_3)_2$], 2.26 [m, 1H, $CH(CH_3)_2$], 2.36 (s, 3H, $ArCH_3$), 2.56 (d, 2H, CH_2CO), 6.90, 7.78 (q, 2H, J_{AB} = 16.4 Hz, *trans*-CH=CH), 7.39 [d, 1H, J = 1.5 Hz, 3-CH(phenyl)], 7.59 [d, 1H, J = 1.7 Hz, 5-CH(phenyl)], 9.87 (s, 1H, CHO), 11.56 (s, 1H, OH). IR (cm^{-1}): 1680(s), 1645(s), 1625(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)]: 370 (8700), 290 (12,300), 260 (28,000).

2f. By using PhCH=CH COMe as the reactant, **2f** was obtained (50%) in the same way as described above (m.p. 96°C). (Found: C, 77.8; H, 5.4. $C_{19}H_{16}O_3$ requires: C, 78.1; H, 5.5%.) ^{1}H NMR: 2.38 (s, 3H, $ArCH_3$), 7.12, 7.94 (q, 2H, J_{AB} = 16.1 Hz, ArCH=CH), 7.33, 7.75 (q, 2H, J_{AB} = 16.0 Hz, PhCH=CH), 7.44, 7.72 (m, 7H, aromatic), 9.89 (s, 1H, CHO), 11.67 (s, 1H, OH). IR (cm^{-1}): 1665(s), 1640(s), 1615(s). UV (nm) [ε ($dm^3 mol^{-1} cm^{-1}$)] 370 (15,500), 325 (24,000), 270 (18,500).

* The analytical data of the crude product showed that it was substantially pure and had desired IR spectral features.

(*Received* 22 *December* 1986; *accepted* 21 *January* 1987)

Abstract—The formation constants of ternary and quaternary complexes containing the ligands pyridoxamine, glycylglycine and imidazole with Co(II), Ni(II), Zn(II) and Cd(II) were determined by pH-metric titration in 0.15 M $NaNO_3$ at 37°C using the MINIQUAD-75 program. It has been shown that the logarithms of the ternary formation constants are linear increasing functions of the sum of the logarithms of the first protonation constants of the ligands, but the $\log K^1$ ($MLH_m + ML'H_m \rightleftharpoons^{K^1} MLL'H_s$) are linear decreasing functions. It has been shown that deprotonation of the peptidic group is prohibited in ternary and quaternary metal complexes. It is also found that the imidazole moiety favourably ligates the ternary complexes rather than the bare metal ions.

The present investigation is a continuation of our efforts to study ternary and quaternary metal complexes of vitamin B_6 compounds and other biological ligands.[2,3] The importance of this study is firstly to prove that ternary and quaternary metal complexes may exist in biological systems in addition to the binary complexes. Secondly, supplementation of trace metal concentrations in nutritive mixtures should take into consideration the interaction between different ligands and metal ions not only to form binary metal complexes but also to form ternary and quaternary metal complexes. Thirdly, the complex equilibria may serve as models for vitamin B_6 dependent enzymatic reactions.

EXPERIMENTAL

Materials

The ligands glycylglycine (Glycyl) (> 99%, BDH) and pyridoxamine dihydrochloride [$Pm(HCl)_2$] (> 99%; Merck) were used without further purification. Imidazole (Imd) (Aldrich) was crystallized from benzene and dried under reduced pressure. Nickel(II), cobalt(II), zinc(II) and cadmium(II) nitrates (> 99%, BDH) were used without purification. Stock solutions of the ligands (L^-) were kept at ~ 5°C in dark. The concentration of stock solutions of the metal ions (M^{2+}) were checked by EDTA complexiometric methods. Potentiometric approaches were used utilizing a Radiometer pH meter model pH M62 provided with a Radiometer cupric selectrode type F1112 Cu as indicator electrode and a Radiometer calomel electrode type K 401 as a reference electrode.[4]

Measurements

The titrimetric data were acquired using a Orion Research Microprocessor Ionalyzer type 901 using a Radiometer combined glass electrode type GK 2301C. The ionalyzer in the pH mode was calibrated using two Radiometer buffers at pH values of 6.98 and 4.03 at 37°C. All pH-metric titrations were carried out as previously described.[2] The ionic strength was kept constant at 0.15 M $NaNO_3$ and the temperature at 37°C. In ternary systems, the concentrations of each ligand were not more than twice the concentration of the metal ions. In the quaternary systems, the concentration of each ligand was identical to that of the metal ions except for Imd where its concentration was not more than 4 times that of the metal ions. The metal ion concentration was in the range $(0.6–2.0) \times 10^{-3}$ M. The hydrogen ion concentration was taken as 10^{-pH}.

Precipitation usually occurs above pH 7 in most of the titrations when the composition ratio was 1:1 (L:M) in the case of binary systems and above 8 when the ratio was $\geqslant 2:1$. In the ternary and quaternary systems the precipitation occurs at pH not greater than 8.5 in some systems, the Zn(II) and Cd(II) systems in particular.

Methods

Titration data were analyzed by using the MINIQUAD-75 program.[5] Several equilibrium models were tested. The results were assessed as previously described.[2] The pK_w used in the computation is 13.38.[2]

RESULTS AND DISCUSSION

Binary complexes of Ni(II), Co(II), Zn(II) *and* Cd(II)

The formation constants of the binary complexes of Ni(II), Co(II), Zn(II) and Cd(II) with Pm and Imd have been recently studied.[4] Although some of the formation constants of the binary complexes of these metal ions with Glygly have been previously reported,[6] yet they have been reevaluated under the experimental conditions used in this work (Table 1). It is noted that Co(II) and Ni(II) form $1:1:-1$ species ($Glygly^-:M^{2+}:H^+$) similarly to Cu(II) in which the peptidic proton has probably been lost, forming a tridentate ligand.[3] Besides, Ni(II) can also form a $2:1:-2$ species with Glygly which is

Table 1. Formation constants of binary complexes of Glygly with Co(II), Ni(II), Zn(II) and Cd(II) at $I = 0.15$ M ($NaNO_3$) and $T = 37$°C: p, r and s stand for the stoichiometric coefficients of Glygly, M^{2+} and H^+, n is number of titration data points

(i) M. K. Kim and A. E. Martell, *J. Am. Chem. Soc.* 1967, **89**, 5138; (ii) S. Pelletier, *J. Chim. Phys.* 1972, **69**, 751; (iii) N. C. Li and M. C. M. Chen, *J. Am. Chem. Soc.* 1958, **80**, 5678; (iv) E. V. Sklenskaya and M. Kh. Karapetyants, *Russ J. Inorg. Chem.* 1966, **11**, 1102.

not formed with Co(II) and Cu(II). This has been attributed to the possible formation of stable hexacoordinated species. Zn(II) and Cd(II), similarly to Co(II), Ni(II) and Cu(II), form regular 1 : 1 : 0 and 2 : 1 : 0 species where Glygly is bidentate. These complexes are less stable than the corresponding glycine metal complexes.[4] However, the inability of Zn(II) and Cd(II) to deprotonate the peptidic proton may possibly be due to the precipitation encountered in these systems at pH ~ 8.5.

When $\log\beta_1^{ML}$ of the binary metal complexes (1 : 1 : 0 species) of Glygly, Gly,[4] Pm and Imd were plotted against the log of the first protonation constant of the ligands ($\log\beta_1^{HL}$), linear relationships were obtained (Fig. 1). These linear relationships can be understood on the basis of the following equation:[7]

$$\log\beta_1^{ML} = \log\beta_1^{HL} + \frac{1}{2.303RT}\{[G^o(M) - G^o(H)] + [G^o(HL) - G^o(ML)]\}. \quad (1)$$

This equation implies that the slope should be 1 if the second term on the right is constant. From Fig. 1 all the binary systems studied have slopes of approximately 1 except for the Cu(II) system where the slope was ~ 2. A non-unity slope means that the term $[G^o(HL) - G^o(ML)]$ must also be a linear function of $\log\beta_{1LH}$ since the term $[G^o(M) - G^o(H)]$ is a constant.

Similarly, the plots of $\log\beta_2^{ML_2}$ (for 2 : 1 : 0 species) vs $\log\beta_1^{HL}$ were linear with non-unity slopes. The slopes are greater than 1 with the exception of Cd(II) where it is less than 1. Equation (1) is usually useful in predicting unknown values of the formation constants.

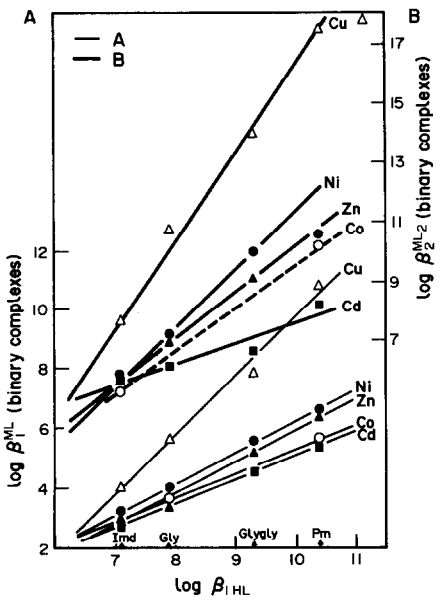

Fig. 1. Dependence of $\log\beta_1^{ML}$ (scale A) and $\log\beta_2^{ML_2}$ (scale B) on the basicity of the ligand exemplified by $\log\beta_{1HL}$ for Co(II), Ni(II), Zn(II) and Cd(II) metal ions.

Ternary and quaternary complexes of Co(II), Ni(II), Zn(II) *and* Cd(II)

The formation constants of the ternary and quaternary complexes of Co(II), Ni(II), Zn(II) and Cd(II) are for the following equilibrium reaction:

$$l\mathrm{Pm}^- + p\mathrm{Glygly}^- + q\mathrm{Imd}^- + r\mathrm{M}^{2+} + s\mathrm{H}^+ \rightleftharpoons (\mathrm{Pm}_l\mathrm{Glygly}_p\mathrm{Imd}_q\mathrm{M}_r\mathrm{H}_s)^z, \quad (2)$$

where l, p, q, r and s are the stoichiometric coefficients, and $z = (2r+s)-(l+p)$.

Many equilibrium models (at least 20 models) have been tried using the MINIQUAD-75 program. The accepted models were based on the values of chi square $[(xi)^2]$, reliability factor (R) and sum of the squared residuals (S) whenever they were the smallest and when the calculated values of the constants had the smallest standard deviations. Furthermore, the effect of variations in the values of protonation constants and binary formation constants of the chosen ternary model (and also ternary formation constants in the case of the chosen quaternary model) were tested. The selected equilibrium models depicted in Tables 2–4 were adopted in which the values of the formation constants did not change on testing within their standard deviations.

Ternary complexes of Co(II), Ni(II), Zn(II) *and* Cd(II). The ternary complexes of Co(II), Ni(II), Zn(II) and Cd(II) involving Pm–Imd have been previously reported.[4] Only the systems involving Pm–Glygly and Glygly–Imd will be discussed in this work. It seems from Tables 2 and 3 that the metal ions under consideration are incapable of deprotonating the peptidic proton in the presence of Pm and Imd contrary to the systems involving Cu(II).[3] This finding may be understood in the cases of the Zn(II) and Cd(II) systems due to early precipitation but not in the cases of the Co(II) and Ni(II) systems. However, it may be rationalized on the basis of ionic potential where the electrostatic interaction between different ligands is greater in the Cu(II) system than in the Co(II) and Ni(II) systems. Another feature can be extracted from Tables 2 and 3, that a number of protonated species appear in the Pm–Glygly systems, similar to the Pm–Imd systems,[4] while none of these complexes appear in the Glygly–Imd system. One should expect that protons are located on the Pm moiety presumably on the pyridinic nitrogen (Pm acts as a bidentate ligand)

and on the amino group (Pm acts as a monodentate ligand).

The application of an equation similar to eqn (1) on the ternary Pm–Glygly and Glygly–Imd complex systems:

$$\log \beta_{1MLL'H_s} = (\log \beta_1^{HL} + \log \beta_1^{HL'}) + \frac{1}{2.303RT}[G^o(M)2G^o(H)] + [G^o(HL) + G^o(HL')] + G^o(MLL'H_s), \quad (3)$$

where L and L′ are two different ligands, together with the systems previously studied[3,4] reveals a linear relationship between the ternary formation constants (log $\beta_{1MLL'H_s}$) and (log β_1^{HL} + log $\beta_1^{HL'}$) (Fig. 2).

However, the slope is not 1 but less than 1 in the Co(II), Ni(II), Zn(II) and Cd(II) systems, and surprisingly is 1 in the case of the Cu(II) systems. In addition, the plots of log K^1 ($K^1 = \beta_{1MLL'H_s}/\beta_{1MLH_m}\beta_{1ML'H_m}$) vs the sum (log β_1^{HL} + log $\beta_1^{HL'}$) are also linear for the 1 : 1 : 1 : 0 spec-

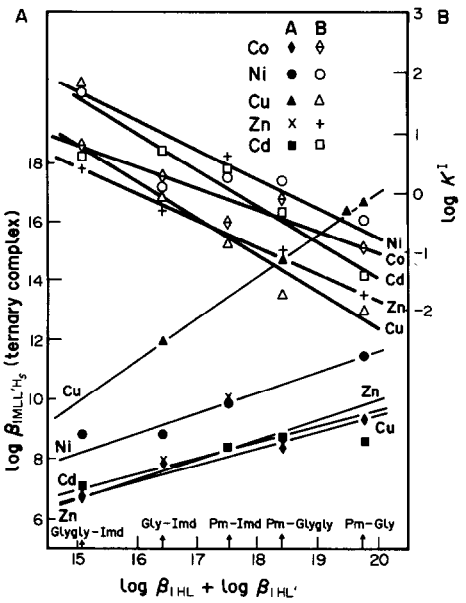

Fig. 2. Dependence of $\log \beta_{1MLL'H_s}$ (scale A) and $\log K^1$ (scale B) for ternary complexes on ($\log \beta_{1HL} + \log \beta_{1HL'}$) of Co(II), Ni(II), Zn(II) and Cd(II) metal ions.

ies (Fig. 2) with negative slopes. This linear dependence may show the bonding strength and, in particular, the extent of the contribution of π-bonding character. It should be kept firmly in mind that the magnitudes of $\log K^1$ is strongly influenced by statistical differences in the formation of each complex as well as differences in bonding. The statistical values of $\log K^1$ depend on the coordination number of the metal ion and denticity of the ligands,[8,9] e.g. for the tetragonal complexes of Cu(II) with bidentate ligands the statistical value is $-\log 4$ (-0.6). For other geometries the statistical values may be less but are always negative. Values of $\log K^1$ greater than -0.6 indicate that ternary metal complex formation is more favored over that of binary metal complexes and reasons other than statistics should be considered. Although $\log K^1$ may be evidence for the formation of the ternary complexes, other approaches may also be considered to indicate its formation in solution.[2]

Quaternary complexes of Co(II), Ni(II), Zn(II) *and* Cd(II). Table 4 shows the formation constants of the quaternary complexes of the Pm–Glygly–Imd system with Co(II), Ni(II), Zn(II) and Cd(II). They are less by one log unit than the Pm–Gly–Imd systems.[4] This may be ascribed to the more steric hindrance exerted by Glygly-containing quaternary complexes over the Pm–Gly–Imd systems. The complexes are mostly protonated: where possible the protons are located on Pm and Glygly (e.g. in the case of 1:1:1:1:2 and 1:1:1:1:3 species).

0	0	1	1	0	3.03	3.20	4.02	2.98	2.74					
0	0	1	2	0	5.60	5.25	7.55	5.63	—					

Some of the values of the formation constants have been estimated on the assumption that the differences in the log forms of the formation constants, e.g. 1:1:1:1:0 and 1:1:1:1:1 species, are independent of the type of metal ion [Cu(II) systems are exceptions] or the type of ligand system under consideration, i.e. Gly[3] or Glygly quaternary complex systems. This was found to be true to a great extent in these systems.

It is interesting to notice that the metal ions can acquire up to two molecules of Imd in the presence of Pm and Glygly or Gly.[4] In fact, the chelation of these metal ions with Pm and Gly or Glygly facilitates the ligation with Imd. This may be verified by comparing the formation constants of the equilibrium reactions:

$$\text{M(Pm)(Gly)H [or M(Pm)(Glygly)H]} + \text{Imd} \rightleftharpoons \text{M(Pm)(Gly)(Imd)H [or M(Pm)(Glygly)(Imd)H]},$$

$$K' = \beta_{1QH}/\beta_{1TH}; \quad (4)$$

$$\text{M(Pm)(Gly)H [or M(Pm)(Glygly)H]} + 2\text{Imd} \rightleftharpoons \text{M(Pm)(Gly)(Imd)H [or M(Pm)(Glygly)(Imd)}_2\text{H]},$$

$$K'' = \beta_{2QH}/\beta_{1TH} \quad (5)$$

[where β_{1QH} and β_{2QH} are the formation constants of the quaternary 1:1:1:1:*s* and 1:1:2:1:*s* complexes (Pm:Gly or Glygly:Imd:M^{2+}:H^+) and β_{1TH} is the formation constant of the ternary species] with those of the binary complexes of these metal ions with Imd (Table 5).

It it clear from Table 4 that the peptidic proton of Glygly is not dissociated in the quaternary complexes of the metal ions under investigation in contrast to the Cu(II) system previously reported.[1]

CONCLUSION

The aforementioned results may indicate that not only binary and/or ternary complexes could be formed but quaternary complexes may also be formed specially in the pH range 6.5–8.5. Generally, the presence of Pm (specially the protonated forms) in the vicinity of metal ions allows the attack of other nucleophilic ligands leading to the formation of ternary and quaternary species. These complexes are positively charged in most cases, which facilitates their transport in biological fluids but prohibits their transfer through cell membranes since neutral species are preferred.

THE ISOLATION AND CHARACTERIZATION OF THE FIRST EXAMPLES OF PAIRS OF α- AND β-ISOMERS OF DIRHENIUM(II) OF TYPE $Re_2X_4(LL)_2$ (X = Cl OR Br, LL = BIDENTATE PHOSPHINE LIGAND)

LORI BETH ANDERSON, MOHAMMED BAKIR and RICHARD A. WALTON*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 28 *November* 1986; *accepted* 23 *January* 1987)

Abstract—The complexes $Re_2Br_4(depe)_2$ and $Re_2X_4(dppee)_2$ (X = Cl or Br, depe = $Et_2PCH_2CH_2PEt_2$, dppee = *cis*-$Ph_2PCH{=}CHPPh_2$) have been prepared in their α- (eclipsed rotational geometry, chelating phosphine ligands) and β- (staggered rotational geometry, bridging phosphine ligands) isomeric forms. The chloro complex β-$Re_2Cl_4(depe)_2$ has also been isolated. In the case of α- and β- $Re_2Br_4(depe)_2$, the preparations involve the reactions of $Re_2Br_4(P\text{-}n\text{-}Pr_3)_4$ with depe in toluene–ethanol. While α-$Re_2X_4(dppee)_2$ are prepared from the reactions of $(n\text{-}Bu_4N)_2Re_2X_8$ with dppee in various solvents, the β-isomers are obtained upon reacting $Re_2X_4(PR_3)_4$ (R = Et or *n*-Pr) with dppee in benzene. These are the first examples of triply bonded dirhenium(II) complexes that have been isolated in both their α- and β-forms. β-$Re_2X_4(dppee)_2$ (X = Cl or Br) constitute the first examples of complexes of this structural type which contain both C=C and M≡M units within the same fused decalin-like ring system. The isomers β-$Re_2Cl_4(depe)_2$ and β-$Re_2X_4(dppee)_2$ (X = Cl or Br) are oxidized by $NOPF_6$ in acetonitrile to give paramagnetic β-$[Re_2Cl_4(depe)_2]PF_6$ and β-$[Re_2X_4(dppee)_2]PF_6$. These oxidized complexes in turn react with CH_3CN in the presence of $TlPF_6$ to afford β-$[Re_2Cl_3(depe)_2(NCMe)](PF_6)_2$ and β-$[Re_2X_3(dppee)_2(NCMe)](PF_6)_2$, respectively. The cleavage of the Re≡Re bonds of α- and β-$Re_2Cl_4(dppee)_2$ occurs upon their reaction with CCl_4–CH_2Cl_2 to give *cis*-$ReCl_4(dppee)$. The related bromo complex *cis*-$ReBr_4(dppee)$ is formed when β-$Re_2Br_4(dppee)_2$ is reacted with CH_2Cl_2–Br_2.

The existence of the complexes β-$M_2X_4[R_2P(CH_2)_2PR_2]_2$ (M = Mo, W, or Re; X = Cl, Br or I; R = Me, Et or Ph) which contain intramolecular bridging phosphine ligands has sparked considerable interest.[1–4] This bonding mode leads to the formation of two stable six-membered rings that are fused about a common metal–metal quadruple (M = Mo or W) or triple (M = Re) bond. These compounds have proved to be of significance in metal–metal multiple bond chemistry from the point of view of the ring conformations that are present, the rotational geometry (eclipsed or staggered) about the metal–metal multiple bond, and their chirality.[1–3,5] In the case of the complexes where M = Mo or W, the related α-isomers, in which the phosphine ligands are chelating and there is an eclipsed rotational geometry, have also been isolated in some instances.[1–3]

We now report the first cases of dirhenium(II) complexes of this type which have been isolated in both their α- and β-isomeric forms [the phosphine ligands are $Et_2PCH_2CH_2PEt_2$(depe) and *cis*-$Ph_2PCH{=}CHPPh_2$(dppee)]. In the case of β-$Re_2X_4(Ph_2PCH{=}CHPPh_2)_2$ (X = Cl or Br), these complexes constitute the first examples of complexes of this type which contain both C=C and M≡M units within the same fused decaline-like ring system.

EXPERIMENTAL

Starting materials

Samples of the complexes $Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2$,[6] $Re_2Cl_4(PEt_3)_4$,[7] $Re_2X_4(P\text{-}n\text{-}Pr_3)_4$ (X = Cl or Br)[7]

and α-$Re_2Cl_4(dmpe)_2$[8] were prepared, according to the literature methods, from $(n\text{-}Bu_4N)_2Re_2X_8$ (X = Cl or Br)[9,10] and the appropriate phosphine in alcohol solution. The $Me_2PCH_2CH_2PMe_2$(dmpe), depe and dppee ligands were purchased from Strem Chemicals. In the case of depe, a 0.606 M solution in toluene was used. The $LiBEt_3H$ reagent was obtained from Aldrich as a 1.0 M solution in THF. Solvents used in the preparation of the complexes were of commercial grade and were thoroughly deoxygenated prior to use.

Reaction procedures

All reactions were performed in a nitrogen atmosphere using standard vacuum line techniques. Chromatographic separations were performed on a silica gel column (60–200-mesh, Davidson Grade 62).

(A) *Preparation of* $Re_2X_4(depe)_2$. (i) β-$Re_2Cl_4(depe)_2$. A quantity of $Re_2Cl_4(P\text{-}n\text{-}Pr_3)_4$ (0.30 g, 0.26 mmol) was suspended in 20 cm^3 of a 1 : 1 mixture (by volume) of toluene and ethanol, and then treated with depe (1.29 cm^3, 0.78 mmol). This reaction mixture was refluxed for 20 h, cooled to room temperature, and ethanol (~ 15 cm^3) was added. The purple crystalline product which precipitated from the purple-brown solution was collected by filtration, washed with ethanol and hexane, then dried *in vacuo*: yield 0.140 g (70%). Found: C, 25.8; H, 5.3. Calc. for $C_{20}H_{48}Cl_4P_4Re_2$: C, 25.9; H, 5.2%.

(ii) α-$Re_2Br_4(depe)_2$. The preparation of this complex involved refluxing a mixture of $Re_2Br_4(P\text{-}n\text{-}Pr_3)_4$ (0.465 g, 0.35 mmol) and depe (1.75 cm^3, 1.1 mmol) in 20 cm^3 of a 1 : 1 mixture (by volume) of toluene and ethanol for 24 h. The reaction mixture was cooled, filtered, and the dark green crystalline solid collected. The purple-brown filtrate was set aside [see A(iii)]. The green product was washed with ethanol and hexane and dried *in vacuo*; yield 0.262 g (68%). Found: C, 22.0; H, 4.4. Calc. for $C_{20}H_{48}Br_4P_4Re_2$: C, 21.7; H, 4.4%.

(iii) β-$Re_2Br_4(depe)_2$. Addition of 20 cm^3 of ethanol to the purple-brown filtrate obtained from A(ii) yielded a purple solid. This was collected, washed with ethanol and hexane and dried *in vacuo*; yield 0.032 g (8%). The identity of this product was based upon its electrochemical and spectroscopic properties (*vide infra*).

(B) *Preparation of* $Re_2X_4(dppee)_2$. (i) α-$Re_2Cl_4(dppee)_2$. A mixture comprising $(n\text{-}Bu_4N)_2Re_2Cl_8$ (0.20 g, 0.175 mmol), dppee (0.60 g, 1.51 mmol), and 10 cm^3 of methanol, to which eight drops of conc. HCl had been added, was refluxed for 24 h. The resulting reaction mixture was cooled to room temperature and filtered to give a green solid and yellow filtrate. The solid was washed with methanol until the washings were colorless, and then with hexanes and finally diethyl ether. It was purified by chromatography (silica gel column with CH_2Cl_2 as eluent) and recrystallized from CH_2Cl_2–diethyl ether; yield 0.035 g (15%). Found: C, 47.9; H, 3.7; Cl, 11.0. Calc. for $C_{52}H_{44}Cl_4P_4Re_2$: C, 47.8; H, 3.4; Cl, 10.8%.

The reaction between $(n\text{-}Bu_4N)_2Re_2Cl_8$ and dppee in refluxing ethanol (4 days) likewise gave α-$Re_2Cl_4(dppee)_2$ in low yield. Work-up of the yellow filtrate from this reaction, and that from the analogous reaction in methanol–conc. HCl (*vide supra*), gave *trans*-$[ReCl_2(dppee)_2]Cl \cdot nH_2O$ as a second product.[11] The reaction of $Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2$ (0.10 g, 0.10 mmol) with dppee (0.26 g, 0.67 mmol) in refluxing ethanol (10 cm^3) for 4 days gave a green-yellow solid which was filtered off, washed with hexanes and diethyl ether, and dried. This product was washed with CH_2Cl_2 to give a green extract [shown to be α-$Re_2Cl_4(dppee)_2$]; the remaining orange-yellow solid was shown to be *trans*-$ReCl_2(dppee)_2$.*

(ii) β-$Re_2Cl_4(dppee)_2$. A mixture of $Re_2Cl_4(PEt_3)_4$ (0.15 g, 0.152 mmol), dppee (0.18 g, 0.454 mmol) and 10 cm^3 of benzene was refluxed for 2 days. The reaction mixture was cooled to room temperature and filtered. A light brown solid was collected, and washed with benzene, methanol, hexanes and diethyl ether. The product was purified by chromatography (silica gel column with CH_2Cl_2 as eluent) and recrystallized from CH_2Cl_2–diethyl ether: yield 0.09 g (45%). Found: C, 47.7; H, 3.4. Calc. for $C_{52}H_{44}Cl_4P_4Re_2$: C, 47.8; H, 3.4%.

β-$Re_2Cl_4(dppee)_2$ was isolated in 35% yield when $Re_2Cl_4(P\text{-}n\text{-}Pr_3)_4$ was used in place of $Re_2Cl_4(PEt_3)_4$ in the above procedure.

(iii) α-$Re_2Br_4(dppee)_2$. The reaction between $(n\text{-}Bu_4N)_2Re_2Br_8$ (0.10 g, 0.067 mmol) and dppee (0.23 g, 0.580 mmol) in 10 cm^3 of methanol that contained eight drops of conc. HBr (48%) was carried out with a procedure similar to that described in B(i) and a reaction time of 2 days. The green insoluble product was found to be the bis-CH_2Cl_2 solvate: yield 0.02 g (20%). Found: C, 39.1; H, 2.9. Calc. for $C_{54}H_{48}Br_4Cl_4P_4Re_2$: C, 39.2; H, 2.9%. The presence and amount of CH_2Cl_2 was confirmed by ^1H NMR spectroscopy in $(CD_3)_2SO$ ($\delta = +5.76$).

The filtrate from this reaction was evaporated to low volume to afford orange crystals of $[ReBr_2(dppee)_2]Br \cdot H_2O$: yield 0.036 g (22%).[11]

* The identity of *trans*-$ReCl_2(dppee)_2$ has been established by an X-ray structure analysis[11] and its independent preparation from the one-electron reduction of *trans*$[ReCl_2(dppee)_2]Cl$.

(iv) β-$Re_2Br_4(dppee)_2$. The reaction between $Re_2Br_4(PR)_3)_4$ (R = Et or *n*-Pr) and dppee in refluxing benzene gave brown β-$Re_2Br_4(dppee)_2$ in yields of 35–50% when a procedure similar to B(ii) was used. Purification was affected by chromatography (silica gel column with CH_2Cl_2 as eluent) and recrystallization from CH_2Cl_2–diethyl ether. Found: C, 42.2; H, 3.2. Calc. for $C_{52}H_{44}Br_4P_4Re_2$: C, 42.1; H, 3.0%.

(C) *Reactions of the* $Re_2X_4(depe)_2$ *complexes.* (i) β-$[Re_2Cl_4(depe)_2]PF_6$. The neutral species β-$Re_2Cl_4(depe)_2$ was oxidized by suspending a quantity of it (0.10 g, 0.11 mmol) in 4 cm^3 of CH_3CN. The suspension was chilled, and a stoichiometric quantity of $NOPF_6$ (0.021 g, 0.12 mmol) added. Following the addition of $NOPF_6$, all of the solid dissolved to yield a red-violet solution. The solution was warmed to room temperature and stirred for 30 min. It was filtered to remove any trace amounts of unreacted $NOPF_6$ and diethyl ether was added to the filtrate. The resulting red-violet solid was collected by filtration, washed with diethyl ether and dried *in vacuo*: yield 0.085 g (74%). Found: C, 22.3; H, 4.7. Calc. for $C_{20}H_{48}Cl_4F_6P_5Re_2$: C, 22.4; H, 4.5%. Addition of an excess of $NOPF_6$ produced the dark purple, air-sensitive dication $[Re_2Cl_4(depe)_2](PF_6)_2$ as evidenced by its electrochemical properties.

(ii) β-$[Re_2Cl_3(depe)_2(NCMe)](PF_6)_2$. The preparation of this complex involved dissolving β-$[Re_2Cl_4(depe)_2]PF_6$ [see C(i)] (0.10 g, 0.093 mmol) and $TlPF_6$ (0.032 g, 0.093 mmol) in 5 cm^3 of acetone and adding 1 cm^3 of CH_3CN. When the reaction mixture was stirred for 12 h, a white precipitate of TlCl formed in the purple-colored reaction medium. This mixture was filtered to remove the TlCl, and diethyl ether was added to the filtrate to precipitate a purple-brown solid. This was collected, washed with diethyl ether and dried *in vacuo*: yield 0.085 g (75%). Found: C, 22.0; H, 4.7. Calc. for $C_{22}H_{51}Cl_3F_{12}NP_6Re_2$: C, 21.6; H, 4.2%.

(iii) β-$[Re_2Cl_3(depe)_2(NCMe)]PF_6$. The reduction of $[Re_2Cl_3(depe)_2(NCMe)](PF_6)_2$ [C(ii)] was accomplished by placing a quantity of it (0.075 g, 0.061 mmol) in 5 cm^3 of THF and adding a solution of $LiBEt_3H$ in THF (0.10 cm^3). The violet suspension turned green-brown within 5 min of stirring the reaction mixture at room temperature. Stirring was continued for a total of 30 min, and diethyl ether added to the green-brown solution to precipitate a light green solid. This solid was collected and recrystallized from CH_2Cl_2–diethyl ether and dried *in vacuo*: yield 0.048 g (73%). Found: C, 24.7; H, 4.8. Calc. for $C_{22}H_{51}Cl_3F_6NP_5Re_2$: C, 24.5; H, 4.8%.

(D) *Reactions of the* $Re_2X_4(dppee)_2$ *complexes.* (i) β-$[Re_2Cl_4(dppee)_2]PF_6$. A mixture of β-$Re_2Cl_4(dppee)_2$ (0.15 g, 0.115 mmol) and $NOPF_6$ (0.022 g, 0.125 mmol) was dissolved in 10 cm^3 of CH_3CN and then stirred for 30 min at room temperature. The solution was reduced in volume and diethyl ether was added to precipitate the product. A pale blue solid was filtered off, washed with hexanes and diethyl ether, and dried *in vacuo*: yield 0.14 g (84%). Found: C, 43.4; H, 3.2. Calc. for $C_{52}H_{44}Cl_4F_6P_5Re_2$: C, 43.0; H, 3.0%.

(ii) $[Re_2Br_4(dppee)_2]PF_6$. A procedure similar to D(i) produced a purple solid; yield 97%. Found: C, 39.0; H, 3.0. Calc. for $C_{52}H_{44}Br_4F_6P_5Re_2$: C, 38.3; H, 2.7%.

(iii) β-$[Re_2Cl_3(dppee)_2(NCMe)](PF_6)_2$. A mixture of β-$[Re_2Cl_4(dppee)_2]PF_6$ (0.09 g, 0.062 mmol) and $TlPF_6$ (0.02 g, 0.06 mmol) was dissolved in 10 cm^3 of CH_3CN. The reaction mixture was stirred at room temperature for 4 h and then evaporated to dryness. The residue was dissolved in CH_2Cl_2 and filtered into a flask containing diethyl ether. The purple insoluble product was filtered off, washed with hexanes and diethyl ether, and dried *in vacuo*: yield 0.075 g (81%). Found: C, 41.9; H, 3.4; Cl, 5.9. Calc. for $C_{54}H_{47}Cl_3F_{12}P_6Re_2$: C, 40.5; H, 3.0; Cl, 6.6%.

(iv) β-$[Re_2Br_3(dppee)_2(NCMe)](PF_6)_2$. A procedure identical to D(iii) produced a purple solid: yield 93%. Found: C, 38.1; H, 3.0. Calc. for $C_{54}H_{47}Br_3F_{12}P_6Re_2$: C, 37.4; H, 2.7%.

(v) *cis*-$ReCl_4(dppee)$. α-$Re_2Cl_4(dppee)_2$ (0.05 g, 0.038 mmol), 5 cm^3 of CH_2Cl_2, and 10 cm^3 of CCl_4 were refluxed for 2 days. The reaction mixture was cooled to room temperature, the solvent evaporated, and the resulting orange residue was extracted into CH_2Cl_2, filtered, and diethyl ether added to the filtrate to crystallize *cis*-$ReCl_4(dppee)$: yield 0.03 g (54%). Found: C, 42.8; H, 3.2; Cl, 19.2. Calc. for $C_{26}H_{22}Cl_4P_2Re$: C, 43.1; H, 3.1; Cl, 19.6%.

When β-$Re_2Cl_4(dppee)_2$ was used in place of the α-isomer, this same mononuclear Re(IV) complex *cis*-$ReCl_4(dppee)$ was isolated in 88% yield.

(vi) *cis*-$ReBr_4(dppee)$. A quantity of β-$Re_2Br_4(dppee)_2$ (0.05 g, 0.034 mmol), was suspended in 10 cm^3 of CH_2Cl_2 and treated with 2 drops of liquid Br_2. This mixture was then stirred at room temperature for 18 h. The solvent was evaporated and the resulting dark red residue was worked-up as described in D(v): yield 0.06 g (98%). Found: C, 34.9; H, 2.7. Calc. for $C_{26}H_{22}Br_4P_2Re$: C, 34.6; H, 2.5%.

Physical measurements

IR spectra were recorded as Nujol mulls using an IBM IR/32 Fourier transform spectrometer (4000–

400 cm^{-1}). Electronic absorption spectra were recorded as CH_2Cl_2 solutions on Cary 17D and IBM 9420 spectrophotometers. Electrochemical experiments were performed by using a Bioanalytical Systems, Inc., Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035B x–y recorder. CH_2Cl_2 solutions containing 0.1 *M* tetra-*n*-butylammonium hexafluorophosphate (TBAH) as a supporting electrolyte were utilized. $E_{1/2}$ values $[(E_{p,a}+E_{p,c})/2]$ were referenced against an Ag-AgCl electrode at room temperature and were uncorrected for junction potentials. ^{31}P NMR and ^{1}H NMR spectra were recorded with use of a Varian XL-200 spectrometer. The ^{31}P NMR spectra were referenced to H_3PO_4 as an internal standard while for the ^{1}H NMR spectra resonances were referenced internally to the residual protons of the incompletely deuterated solvents.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University microanalytical laboratory.

RESULTS AND DISCUSSION

Preparation and characterization of $Re_2X_4(depe)_2$ (X = Cl *or* Br)

The complex β-$Re_2Cl_4(depe)_2$ was first prepared and structurally characterized by Cotton and coworkers.[12] However, the reported method for its synthesis produced the desired compound in 20% yield. In order to explore the reaction chemistry of this complex, an improved synthetic route was desirable. We found that by using $Re_2Cl_4(P\text{-}n\text{-}Pr_3)_4$ in place of $(n\text{-}Bu_4N)_2Re_2Cl_8$ and refluxing this, in the presence of depe, in a mixed-solvent system (to enhance the solubility of the starting dirhenium complex), the yield of β-$Re_2Cl_4(depe)_2$ was increased to *ca* 70%. The bromide analogue β-$Re_2Br_4(depe)_2$ could also be isolated using reaction conditions similar to those employed in the preparation of the chloride derivative. The β-isomer, however, was formed in very low yield (< 10%), while the major product of the reaction was α-$Re_2Br_4(depe)_2$. The α-form is insoluble in the reaction mixture and crystallizes during the course of the reaction. This is the first time that α- and β-isomers of a dirhenium(II) complex of this type have been isolated although both isomers are known for certain dimolybdenum(II) and ditungsten(II) species.[1-4]

The identification of the new species α- and β-$Re_2Br_4(depe)_2$* was based upon a comparison of their electrochemical and spectroscopic properties (Table 1) with the related behavior of the structurally characterized complexes α-$Re_2Cl_4(dmpe)_2$,[8] α-$Re_2Cl_4(dppp)_2$ [dppp = $Ph_2P(CH_2)_3PPh_2$],[13] β-$Re_2Cl_4(depe)_2$[12] and β-$Re_2Cl_4(dppe)_2$[dppe = $Ph_2P(CH_2)_2PPh_2$].[14-16] In the case of α-$Re_2Cl_4(dmpe)_2$ and β-$Re_2Cl_4(depe)_2$, these data have not been reported previously and so are included here for the first time (see Table 1). The cyclic voltammograms (CVs) of solutions of these complexes in 0.1 M TBAH–CH_2Cl_2 revealed the presence of two accessible one-electron oxidations (Fig. 1); this property is characteristic of the triply bonded Re_2^{4+} core.[2,17] Oxidation of β-$Re_2Cl_4(depe)_2$ to the paramagnetic monocation was achieved by using 1 equivalent of $NOPF_6$ as the oxidizing agent. Attempts to carry out the analogous oxidation of α-$Re_2Br_4(depe)_2$ led to its decomposition. The oxidized species β-$[Re_2Cl_4(depe)_2]PF_6$ possesses electrochemical processes at $E_{1/2}$ = +0.08 V(red) and $E_{1/2}$ = +0.88 V(ox) vs Ag–AgCl (Fig. 1). The X-band ESR spectrum of the monocation, as measured at −160°C in CH_2Cl_2,

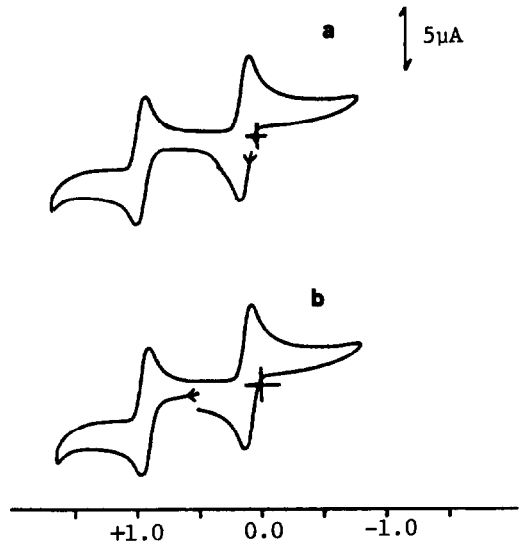

Fig. 1. Cyclic voltammograms (recorded at v = 200 mV s^{-1} using a Pt-bead electrode) for 0.1 M TBAH–CH_2Cl_2 solutions of: (a) β-$Re_2Cl_4(depe)_2$, and (b) β-$[Re_2Cl_4(depe)_2]PF_6$.

* The structure of α-$Re_2Br_4(depe)_2$ has recently been confirmed by a single-crystal X-ray structure analysis with data collected at −150°C. The structure [space group $I4_1/acd$, with a = 13.466(2) Å and c = 36.619(7) Å] is disordered and the Re—Re distance is 2.202(6) Å (L. F. Falvello, unpublished results).

Table 1. Electrochemical properties and electronic absorption spectra

Complex	Half-wave potentials[a]		Electronic absorption spectrum[b]

[a] In V vs Ag–AgCl for 0.1 m TBAH–CH_2Cl_2 solutions recorded at $v = 200$ mV s^{-1}. In the case of the reversible couples, the ΔE_p values ($= E_{p,a} - E_{p,c}$) are in the range 90–130 mV.

[b] Spectra recorded in CH_2Cl_2 unless otherwise stated; ε values are given in parentheses.

[c] $E_{p,a}$ value.

[d] Approximate value since for $E_{p,a} = +1.08$ V and $E_{p,c} = +0.90$ V, $i_{p,a} > i_{p,c}$.

[e] Recorded as Nujol mull. Relative intensities of bands are signified by w = weak, m = medium and s = strong.

[f] This work.

displayed a broad signal between 1000 and 4000 G which is centered at $g = 2.1$. In the presence of an excess of $NOPF_6$, the second oxidation can be accessed to yield the dark purple air-sensitive dication. This species was characterized by cyclic voltammetry in 0.1 M TBAH–CH_2Cl_2 solution; the processes at $E_{1/2} = +0.08$ V and $E_{1/2} = +0.88$ V correspond to reductions.

While β-$Re_2Cl_4(depe)_2$ did not react with CH_3CN, its oxidized congener β-[$Re_2Cl_4(depe)_2$]PF_6 did so to give [$Re_2Cl_3(depe)_2(NCMe)$]$(PF_6)_2$ when $TlPF_6$ was present. This behavior resembles that observed in the case of the formation of the dppe analogues [$Re_2X_3(dppe)_2(NCMe)$]$(PF_6)_2$ (X = Cl or Br).[18] The CV of the paramagnetic dication exhibits $E_{1/2} = +0.35$ V(red) and $E_{p,a} = +1.55$ V vs Ag–AgCl. In this depe-bridged system, the potentials are shifted by at least 1 V to more positive values compared to the dppe analogue.[18] Thus, while the irreversible reduction at ~ −1.5 V in the CV of [$Re_2X_3(dppe)_2(NCMe)$]$(PF_6)_2$ is apparently shifted to a potential below the solvent limit in the CV of [$Re_2Cl_3(depe)_2(NCMe)$]$(PF_6)_2$, an additional oxidation is not accessible (at +1.55 V). These differences presumably reflect the greater σ-donor ability of depe compared to dppe. The complex behaves as a 2:1 electrolyte in acetone ($\Lambda_M = 170$ Ω^{-1} cm^2 mol^{-1}), in accord with its formulation as a dication. The paramagnetism of this species is evidenced by its ESR spectrum measured at −160°C in CH_2Cl_2 ($g \simeq 2.1$). The electronic absorption spectrum of [$Re_2Cl_3(depe)_2(NCMe)$]$(PF_6)_2$ in CH_2Cl_2 has λ_{max} at 1275 nm (ε = 150), 640 nm(sh), 486 nm (ε = 700) and 424 nm (ε = 900).

The dication [$Re_2Cl_3(depe)_2(NCMe)$]$(PF_6)_2$ could be reduced chemically to [$Re_2Cl_3(depe)_2$ (NCMe)]PF_6 by the use of $LiBEt_3H$ in THF solution. The electrochemistry of the resulting monocation displays $E_{1/2} = +0.35$ V(ox), as well as $E_{p,a} = +1.55$ V vs Ag–AgCl. The conductivity of a 1×10^{-3} M acetone solution is consistent with the formulation as a 1:1 salt ($\Lambda_M = 120$ Ω^{-1} cm^2 mol^{-1}). Its electronic absorption spectrum, recorded in CH_2Cl_2 solution exhibits λ_{max} at 645 nm (ε = 120), 506 nm (ε = 200) and a shoulder at 400 nm, while the IR spectrum (Nujol mull) possesses a weak ν(CN) mode at 2269 cm^{-1} due to the coordinated MeCN ligand. Its $^{31}P-\{^1H\}$ NMR spectrum, measured in $(CD_3)_2CO$ solution, is similar to that of [$Re_2X_3(dppe)_2(NCMe)$]PF_6,[18] namely two apparent triplets at δ −4.81 and −5.02 which are the components of an AA′BB′ pattern.

Preparation and characterization of $Re_2X_4(dppee)_2$ (X = Cl *or* Br)

The phosphine ligand dppee reacts with $(n\text{-}Bu_4N)_2Re_2Cl_8$ in refluxing methanol–conc. HCl or ethanol, and with $Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2$ in refluxing ethanol,

to give the green isomer α-$Re_2Cl_4(dppee)_2$ in yields of *ca* 15%. Work-up of the yellow filtrate and washings from the reactions of $(n\text{-}Bu_4N)_2Re_2Cl_8$ with dppee gave *trans*-$[ReCl_2(dppee)_2]Cl \cdot nH_2O$ as an additional reaction product, while *trans*-$ReCl_2(dppee)_2$ is a by-product of the reaction of $Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2$ with dppee. The green bromo analogue α-$Re_2Br_4(dppee)_2$ was formed (yield *ca* 20%) upon heating $(n\text{-}Bu_4N)_2Re_2Br_8$ with an excess of dppee in methanol–conc. HBr (48%) for 2 days. Orange crystalline *trans*-$[ReBr_2(dppee)_2]Br$ was isolated from this reaction filtrate. Upon heating the dirhenium(II) species $Re_2X_4(PR_3)_4$ (X = Cl or Br, R = Et or *n*-Pr) with dppee in benzene, the brown β-isomers of $Re_2X_4(dppee)_2$ precipitated and were isolated in yields of 35–50%.

As shown in Table 1, the distinction between the α- and β-isomers is best seen in the differences between their electronic absorption spectra. The most prominent lowest-energy band is either at ~ 850 nm (α-forms) or at ~ 500 nm (β-forms), with weak lower-energy shoulders also apparent in some of the latter spectra. A further difference is apparent in the case of the low-frequency Nujol mull IR spectra of the chloride complexes in which α-$Re_2Cl_4(dppee)_2$ has ν(Re—Cl) modes at 314s, 282s and 260w cm^{-1}, while for β-$Re_2Cl_4(dppee)_2$ the corresponding bands are at 333s, 320m and 304m cm^{-1}. These data can be compared with that reported for α-$Re_2Cl_4(dppp)_2$ [ν(Re—Cl) at 307s, 292sh and 270m cm^{-1}][13] and β-$Re_2Cl_4(dppe)_2$ [ν(Re—Cl) at 333vs and 303m-s cm^{-1}].[15] These conclusions are further substantiated by differences in the $^{31}P\text{-}\{^1H\}$ NMR spectra of the pairs of α- and β-$Re_2X_4(dppee)_2$ compounds. For the α-isomers, a singlet is observed at δ +29.6 (CD_2Cl_2 solvent) for X = Cl, and at δ +25.9 ($(CD_3)_2SO$ solvent) for X = Br; these chemical shifts are characteristic of five-membered rings formed by chelating phosphines.[5,19] On the other hand, the β-isomers display singlets which are shifted upfield to δ +5.6 (CD_2Cl_2 solvent) and δ −0.2 (CD_2Cl_2 solvent) for X = Cl and Br, respectively. This shift is typical of the greater shielding associated with six-membered rings compared to their five-membered analogues.[19] The ^1H NMR spectra [recorded in CD_2Cl_2 or $(CD_3)_2SO$] showed the expected phenyl resonances along with an AA′XX′ pattern centered between δ +8.2 and +8.8 for the olefinic protons of the dppee ligand.

Although we were able to grow single crystals of β-$Re_2Cl_4(dppee)_2$ for an X-ray structure analysis, a satisfactory structure solution was thwarted by poor crystal quality. While we have not yet been able to obtain better crystals, the preliminary structure analysis is sufficient to clearly define the major structural details of this molecule.*

The reactivity of β-$Re_2X_4(dppee)_2$ towards $NOPF_6$ in CH_3CN resembled that found for β-$Re_2X_4(depe)_2$ (*vide supra*). Oxidation occurred to give β-$[Re_2X_4(dppee)_2]PF_6$ which displayed the expected electrochemical properties (see Table 1), with a one-electron oxidation at $E_{1/2} \simeq +1.1$ V and a one-electron reduction at $E_{1/2} \simeq +0.3$ V vs Ag–AgCl. These complexes behaved as 1 : 1 electrolytes in CH_3CN ($\Lambda_M \sim 125\ \Omega^{-1}\ cm^2\ mol^{-1}$ for $C_M = 1.5 \times 10^{-4}$ M) and had Nujol mull IR spectra with ν(P—F) of PF_6^- at *ca* 850 cm^{-1}. Like their depe analogues, these salts react with acetonitrile in the presence of $TlPF_6$ to give $[Re_2X_3(dppee)_2(NCMe)](PF_6)_2$ whose properties resemble closely those of $[Re_2X_3(depe)_2(NCMe)](PF_6)_2$ (*vide supra*) and $[Re_2X_3(dppe)_2(NCMe)](PF_6)_2$.[18]†

Cleavage of β-$Re_2X_4(dppee)_2$ to give the mononuclear rhenium(IV) complexes *cis*-$ReX_4(dppee)$ occurred upon reaction with CCl_4 (X = Cl) or Br_2 (X = Br). These orange (X = Cl) or dark red (X = Br) colored complexes are almost certainly close structural analogues of *cis*-$ReCl_4(dppe)$.[20] In the case of *cis*-$ReCl_4(dppee)$, its low-frequency IR spectrum showed a pattern for the ν(Re—Cl) modes at 345m, 326s and 305s cm^{-1} that is very characteristic of a *cis*-MCl_4L_2 geometry [i.e. *cis*-$ReCl_4(dppe)$ has ν(Re—Cl) at 346m, 331s and 305s cm^{-1}].[20] Like other complexes of type *cis*-$ReCl_4(LL)$, where LL = dppe, dppm or arphos,[17]

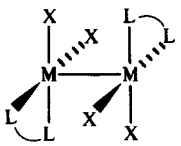
* Crystal data for β-$Re_2Cl_4(dppee)_2$ at 22°C: monoclinic space group $P2_1/n$, $a = 16.684(7)$, $b = 12.869(7)$, $c = 9.766(3)$ Å; $\beta = 106.69(3)°$, $V = 4706(7)$ Å^3, $Z = 4$, $\rho_{calc.} = 1.843$ g cm^{-3}. A preliminary structure analysis was based upon 6458 reflections of which 5431 have $F_o^2 > 5\sigma(F_o^2)$. Like the crystal structures of other multiply bonded dimetal complexes, β-$Re_2Cl_4(dppee)_2$ exhibits a disorder in which there are two orientations of the M_2 unit within the polyhedron defined by the eight donor atoms. The Re—Re distance of 2.24(1) Å (for the major orientation, 76%) is typical of that seen in other complexes that contain Re≡Re bonds.[9,12–14] The staggered rotational geometry about the Re—Re bond is similar to that in β-$Re_2Cl_4(dppe)_2$. In the case of β-$Re_2Cl_4(dppee)_2$ the pairs of Cl—Re—Re—Cl and P—Re—Re—P torsional angles average to approximately 62 and 59°, respectively, while for β-$Re_2Cl_4(dppe)_2$ the corresponding values are 59.6 and 52.4°.[14]

† For example, the CVs of solutions of $[Re_2X_3(dppee)_2(NCMe)](PF_6)_2$ in 0.1 M TBAH–CH_2Cl_2 are as follows: X = Cl, $E_{1/2}(red) = +0.58$ V and $E_{p,c} = -1.67$ V vs Ag–AgCl; X = Br, $E_{1/2}(red) = +0.67$ V and $E_{p,c} \simeq -1.55$ V vs Ag–AgCl. Solutions of these complexes in CH_3CN had $\Lambda_M \simeq 230\ \Omega^{-1}\ cm^2\ mol^{-1}$ for $C_M = 1.2 \times 10^{-4}$ M.

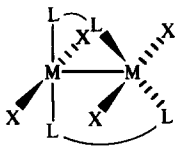
cis-ReX_4(dppee) display a very accessible one-electron reduction in the CVs of their solutions in 0.1 M TBAH–CH_2Cl_2 with $E_{1/2} = +0.13$ V (X = Cl) and $E_{1/2} = +0.21$ V (X = Br) vs Ag–AgCl.

Concluding remarks

The preparation of $Re_2X_4(depe)_2$ and $Re_2X_4(dppee)_2$ is the first time that the α- and β-pairs of the type $M_2X_4(bidentate)_2$ (see **I** and **II**) have been isolated for dirhenium(II), although such pairs are known in the case of the isostructural (but



I



II

not isoelectronic) dimolybdenum(II) and ditungsten(II) cores.[1-4] In contrast to the much studied dimolybdenum(II) complexes of this type,[1,2] we find no evidence for α-⇌β-isomerization in CH_2Cl_2 solutions of these complexes. This surprising result is under further investigation in view of the facility with which this isomerization occurs in the case of α- and β-isomers of $Mo_2X_4(LL)_2$ and the current interest in the mechanism of such transformations.[21,22]

The complexes β-$Re_2X_4(dppee)_2$ are of special interest for they establish the stability of the fused ring system depicted below, and point to the existence of other complexes of this class.*

(*Received* 12 *December* 1986; *accepted* 9 *January* 1987)

Abstract—The fast atom bombardment mass spectra of a series of ionic compounds of formula [(triphos)M(η^3-E_2X)]Y (triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane; M = Ni, E = X = P, Y = BF_4 or PF_6; M = Co, E = P, X = S or Se; E = As, X = S, Se or Te; Y = BF_4) are reported. The cations contain a homo- or hetero-atomic trimembered inorganic ring *trihapto* bonded to a metal–triphos unit. Both in glycerol and thioglycerol the complexes exhibit a characteristic fragmentation which involves the stepwise loss of the three atoms of the inorganic ring and the ejection of organic radicals from the triphos ligand. Adduct ions with sulphur atoms or sulphur organic radicals are, furthermore, observed in thioglycerol. Such adducts infer interactions of the matrix with: (a) the atoms of the inorganic ring of the complex cations, and (b) the metal atom of the (triphos)M moiety.

In recent years desorption mass spectrometric methods have been increasingly applied to the characterization of metal-containing compounds of low volatility.[1–16] Field desorption mass spectrometry usually shows only the molecular ion, but fast atom bombardment (FAB) mass spectrometry yields also fragment ions which supply significant information on the structures of the metal complexes.[1–13] Recently the comparison of the solution chemistry of transition-metal compounds and their behaviour when dissolved in appropriate matrices under FAB has provided a powerful new tool for the study of solution dynamics and reactivity.[17]

This paper reports the FAB mass spectra of the following cationic compounds: [(triphos)Ni(η^3-P_3)]BF_4 (**1**), [(triphos(Ni(η^3-P_3)]PF_6 (**2**), [(triphos)Co(η^3-P_2S)]BF_4 (**3**), [(triphos)Co(η^3-P_2Se)]BF_4 (**4**), [(triphos)Co(η^3-As_2S)]BF_4 (**5**), [(triphos)Co(η^3-As_2Se)]BF_4 (**6**), and [(triphos)Co(η^3-As_2Te)]BF_4 (**7**).

This isostructural and isoelectronic series of compounds contain a (triphos)M unit η^3-bound to the homocyclic P_3 ring (M = Ni) or to the heterocyclic triatomic E_2X (E = P; X = S or Se: E = As; X = S, Se or Te) ring (M = Co). The metal and the three unsubstituted main group atoms form a pseudotetrahedral core and the general structure of the cation of the compounds is shown in Fig. 1.

compounds crystallize with a molecule of solvent (ethanol for **6** and benzene for the other complexes) which has been omitted for it is not relevant in the present study.

The mass spectra were obtained on a Kratos MS 80 mass spectrometer equipped with a FAB source. Primary argon atoms at an energy of 6–7 keV were generated in an Ion Tech Ltd gun. The samples were dissolved in a small amount of chloroform and one droplet of the solutions was mixed with the matrix (glycerol or thioglycerol) on the copper tip of the FAB probe.

RESULTS AND DISCUSSION

The FAB mass spectra of all compounds have been obtained using glycerol and thioglycerol as matrices. The abundances of the ions are rather low for the samples dissolved in glycerol and the overall ionic yield is significantly lower than in thioglycerol.

FAB spectra with glycerol as matrix

The cations $[C]^+$ display a characteristic fragmentation pathway (Table 1) with stepwise loss of the three phosphorus atoms in compounds **1** and **2** (E = X = P), or of the two pnicogen atoms followed by the chalcogen atom in all the other compounds. $[(triphos)M]^+$ (M = Co or Ni) is the base peak in the spectra of all compounds; it undergoes further breakdown with ejection of organic radicals. In the spectra of **1** and **2** these fragmentation processes give the ions at *m/z* 497, $[(triphos)Ni-PPh_2]^+$; *m/z* 442, $[(triphos)Ni-CH_3CCH_2CH_2PPh_2]^+$; and *m/z* 420, $[(triphos)Ni-Ph-PPh_2]^+$.

Such ions exhibit the typical pattern due to the nickel isotopes. The cobalt complexes present the corresponding peaks at *m/z* 498, 443 and 421. No other ion containing metal are formed.

A comparison of the spectra obtained from $[(triphos)Ni(P_3)]BF_4$ (**1**) and $[(triphos)Ni(P_3)]PF_6$ (**2**) shows that the different anions (Table 1) do not affect appreciably the nature and the relative abundances of the positive ions.

FAB spectra with thioglycerol as matrix

The FAB mass spectra of complexes **1**–**7** in thioglycerol exhibit a higher number of abundant ions and are more complicated than those with glycerol as matrix; such behaviour has to be ascribed to the interactions that occur between the samples and the matrix containing the thio group.

Two remarkable features distinguish the spectra run in thioglycerol from those in glycerol: (a) the intact $[C]^+$ cation is the base peak (Table 2) for all the compounds at variance with glycerol where the most abundant ion is $[(triphos)M]^+$, and (b) several hydrogenated peaks are observed whilst no protonated ion is detected in glycerol.

Table 1. Relative abundances of the most significant ions in the FAB mass spectra of $[(triphos)M(\eta^3\text{-}E_2X)]Y$ complexes[a] with glycerol as matrix

[b] $[C+S]^+$, $[C-As+RS]^+$ and $[(triphos)Co+2RS]^+$ show the same nominal mass at *m/z* 897.

[c] $[C-As]^+$ and $[(triphos)Co+RS]^+$ show the same nominal mass at *m/z* 790.

The spectra of the nickel compounds **1** and **2** (Table 2) which have different counterions (BF_4^- for **1** and PF_6^- for **2**, respectively) are practically identical, showing that the nature of the anion does not affect the fragmentation of the compounds when they are dissolved in thioglycerol. The metal-retaining ions have been identified through the typical isotopic pattern for the two nickel derivatives. The composition of the fragments which contain cobalt has been assigned by their mass and by comparison to the corresponding species of the nickel compounds **1** and **2**.

The several ions found in the FAB spectra of compounds **1–7** may be divided into three distinct groups. The largest one consists of ions which do not contain sulphur atoms or RS (RS is the $CH_2OHCHOHCH_2S^{\cdot}$ radical that originates from thioglycerol). Such ions show a mass that ranges between $[C+H]^+$ and $[triphos-PPh_2]^+$ and are present also in the spectra in glycerol (except the

hydrogenated ones). This indicates that a portion of the cations undergo in thioglycerol the same fragmentation pathway as in glycerol.

The second group of ions consists of species, in which one S or RS group is linked to the intact cation, namely $[C+H+RS]^+$, $[C+RS]^+$, $[C+S+2H]^+$, $[C+S+H]^+$ and $[C+S]^+$, or to fragments originating by loss of one or two pnicogen atoms. The peaks due to these ions, which are not very strong and whose intensity changes for the different compounds **1–7**, show an interaction between the complex cation and the matrix. The $[C+S]^+$ and the protonated $[C+H+S]^+$ species suggest that also in the ions formed from $[C]^+$ and the RS radical the interaction between the cation and the matrix occurs through the sulphur atom. It is likely that the sulphur atom and the sulphur-containing radicals bind the inorganic triatomic unit of the complex cations. The metal ions of compounds **1–7** are actually in a six-coordinate environment (Fig. 1) and hence coordinatively saturated; the spectral data furthermore do not contain fragments which originate from thiophilic attack on the triphos ligand. Taking into account that the major decomposition pathway of the cations in glycerol goes through the stepwise loss of pnicogen atoms, the heavier ions, $[C-E+2RS+H]^+$, $[C-E+2RS]^+$, $[C-E+RS+H]^+$, $[C-E+RS]^+$ and $[C-2E+RS]^-$ (Table 2), likely originate from the substitution of a pnicogen atom from the cyclic E_2X unit of the intact cation with sulphur-containing species.

The remaining sulphur- or thioradical-containing ions, namely $[(triphos)M+S+2RS]^+$, $[(triphos)M+2RS]^+$, $[(triphos)M+RS]^+$, $[(triphos)M+2S+H]^+$, $[(triphos)M+2S]^+$, $[(triphos)M+S+H]^+$ and $[(triphos)M+S]^+$ have lost the cyclic triatomic ring P_3 or E_2X. Their presence provides evidence for the ability of the metal–ligand system to interact with thio species of the matrix. This is supported by the following points: the $[(triphos)M]^+$ species is the base peak in glycerol, which does not yield any interaction with metal-containing fragments; the hemioctahedral (triphos)M moiety provides a fragment which has orbitals whose energy and symmetry are well suited to stabilize a wide class of complexes with unsubstituted or substituted sulphur atoms.[22]

All the reactions of these complex ions in thioglycerol (yielding ions which contain RS radicals or other sulphur species) appear to take place at high rate under the fast argon atom beam. The ionic abundances, in fact, do not change noticeably in spectra run at different times after the beginning of the atom bombardment.

The FAB mass spectra of the cations $[(triphos)M(\eta^3\text{-}E_2X)]^+$, which contain the new triatomic units E_2X (E = X = P; M = Ni; E = As; X = S, Se or Te: E = P; X = S or Se; M = Co), in glycerol and thioglycerol provide interesting information on the behavior of the pseudo-tetrahedral ME_2X core which undergoes a demolition by a stepwise loss of the pnicogen and chalcogen atoms.

By comparing the spectra of the cations in glycerol and thioglycerol it appears that in the latter matrix two different kinds of interactions occur at the cations and the related fragments. The sulphur atom and the thio groups from thioglycerol are suggested to bind to: (a) the inorganic units of the intact complex cations, and (b) the (triphos)M fragment. It has been recently found that the (triphos)M (M = Co or Ni) moieties in the presence of the appropriate sulphur species yield a wide group of monomeric and oligomeric complexes in which they are bound to unsubstituted or substituted sulphur atoms.[22] Such behaviour shows a parallelism between the reactivity of (triphos)M both in solution and under FAB.

According to such considerations the presence in the FAB spectra of the ions that originate from the cations and the sulphur-containing species may suggest a reactivity in solution of the intact cations with sulphur-containing species provided that the appropriate reagents and conditions are employed.

ESR STUDIES ON THE INTERMOLECULAR INTERACTIONS OF THE MONONITROSYL CHELATE COMPLEXES OF IRON

V. I. ILIEV* and D. SHOPOV

Institute of Kinetics and Catalysis, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

(*Received* 18 *February* 1986; *accepted after revision* 12 *January* 1987)

Abstract—Using ESR the exchange of ligands was studied between mononitrosyl chelate complexes of iron and chelate complexes of nickel with the following ligands: dithiocarbamate (dtc), dithiophosphate (dtp), dithiocarbonate (xant), 8-quinolinethiolate, 8-hydroxyquinoline, acetylacetonate and *o*-hydroxy-benzylideneaniline. For some mixed-ligand complexes the exchange of the covalency of the metal–ligand bond was evaluated. The interaction of the mononitrosyl complexes with Lewis acids (I_2 and Br_2) and bases (pyridine, DMFA and DMSO) was studied in the cases of $Fe(NO)(dtc)_2$, $Fe(NO)(dtp)_2$ and $Fe(NO)(xant)_2$. In both of the latter cases the interactions with Lewis acids and bases led to the formation of paramagnetic dinitrosyl complexes, while with $Fe(NO)(dtc)_2$ hexacoordinated mononitrosyl complexes were formed. A reaction pathway is suggested and discussed for the formation of the dinitrosyl complexes and their composition.

In our previous studies[1] it was shown that the interaction of the tris-chelates of Fe(III) with NO and NO_2 is connected with the splitting of one chelate ligand and the formation of iron nitrosyl complexes. The continuous treatment with NO_2 leads to complete destruction of the nitrosyl complexes.

Although there exists a considerable interest in the mononitrosyl chelate complexes, we have not found data in the literature concerning the possibility of exchange of ligands in the non-charged mononitrosyl chelate complexes and the formation of thermodynamically stable complexes with mixed ligands. Some aspects of the interaction were studied[2,3] for iron mononitrosyl dithiocarbamate complexes with Lewis acids (X), where hexacoordinated complexes are obtained of type $Fe(NO)\cdot X\cdot(dtc)_2$ (dtc = dithiocarbamate) therefore changes occur only in the coordination polyhedron, but the chelate encirclement is not changed.

The purpose of the present investigations was to study the changes in the ligands in iron mononitrosyl chelate complexes with other chelate ligands. The changes taking place in the first coordination sphere during the interactions with some monodentate organic Lewis bases and acids were also studied.

The investigations were carried out with the following mononitrosyl complexes of iron: $Fe(NO)(R_2dtp)_2$, $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$, $Fe(NO)(tox)_2$ (R_2dtp = dialkyldithiophosphato, Et_2dtc = diethyldithiocarbamato). The basic method of our investigations was ESR spectroscopy.

EXPERIMENTAL

The sodium salt of *O*,*O*-diisopropyldithiophosphoric acid was synthesized according to methods described in the literature.[4] The same applies to *o*-hydroxy-benzylideneaniline (SchB).[5] The rest of the ligands used, $Me_2dtp\cdot NH_4$, $Et_2dtc\cdot Na$, $tox\cdot HCl$ and $ox\cdot H_2SO_4$ (8-hydroxyquinolinesulphate) (Fluka), and Et-xant·K (Merck) were used after filtration of their water solutions.

The mononitrosyl complexes $Fe(NO)L_2$ were obtained according to Ref. 6, from the respective ligands, $FeSO_4$ and $NaNO_2$, with argon bubbled through the solution. The complexes $Fe(NO)(Et\text{-}xant)_2$ and $Ni(SchB)_2$ were obtained by extraction of the aqueous solutions of the respective ligands, and $NiCl_2$ with $CHCl_3$. After that they were recry-

* Author to whom correspondence should be addressed.

stallized from $CHCl_3$ or a $CHCl_3$–toluene mixture in a 1 : 1 ratio. $Ni(acac)_2$ was from Fluka.

$Fe \cdot I \cdot (NO)_2 \cdot H_2O$ was synthesized according to Ref. 7 with the use of NO gas (Merck–Schuhardt).

The ESR spectra were measured on a Brucker ER 200D-SRC spectrometer in the *X*-band. The g factors are determined using diphenylpicrylhydrazyl as a reference.

RESULTS

Exchange of ligands in nitrosyl complexes of iron

Because the mononitrosyl complexes studied gave too similar ESR parameters the exchange of ligands was carried out as follows: (1) between iron mononitrosyl complexes with ligands of one type and diamagnetic chelate complexes of nickel with ligands of the other type (see Table 1); and (2) an exchange at lower temperature (240 K), where the observed bands were considerably narrower. The ESR spectra were registered for 5 min, and after the initial mixing of the starting solutions no change was detected in the ESR parameters and the intensity of the spectra for 2 h.

When solutions of $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$ and $Fe(NO)(tox)_2$ in chloroform were mixed with $Ni(i\text{-}prdtp)_2$ and the concentration of the latter increased, the ESR spectra of the initial nitrosyl complexes decreased in intensity, and the spectra of new complexes were obtained (Fig. 1). Only in the case when $Fe(NO)(Et_2dtc)_2$ interacted with $Ni(i\text{-}prdtp)_2$ (in 1 : 1 molar ratio of the starting complexes) was formation of $Fe(NO)(i\text{-}prdtp)(Et_2dtc)$ observed as proved by the ESR spectra [Fig. 1(a) and (b)]. The ESR parameters of $Fe(NO)(i\text{-}prdtp)(Et_2dtc)$ in frozen chloroform–toluene solution (volume ratio 1 : 3) were as follows: $g_\parallel = 2.026, g_\perp = 2.043$; ${}^{N}A_\parallel = 15.7$ G; ${}^{N}A_\perp = 12.5$ G, ${}^{P}A = 7.3$ G.

In both of the other cases under the same experimental conditions and ratio of reagents as for the initial $Fe(NO)(Et\text{-}xant)_2$ or $Fe(NO)(tox)_2$, the parameters of the newly formed $Fe(NO)(i\text{-}prdtp)(Et\text{-}xant)$ or $Fe(NO)(i\text{-}prdtp)(tox)$ were observed [see Fig. 1(c) and (d)]. In frozen solutions (mixture of toluene–chloroform) and a $Fe(NO)L_2/Ni(i\text{-}prdtp)_2$ ratio of 1 : 1 in all three cases the presence of $Fe(NO)(i\text{-}prdtp)_2$ was detected. In solution (298 and 240 K) the ESR spectrum of $Fe(NO)(dtp)_2$ was not observed, most probably because the bands are very much expanded.[8]

When solutions in chloroform of $Fe(NO)(tox)_2$ with $Ni(Et\text{-}xant)_2$ or $Ni(Et_2dtc)_2$ were mixed (molar ratio of the initial complexes 1 : 2) the ESR spectra (see Fig. 2) of the initial $Fe(NO)(tox)_2$ were detected, formed as a result of the exchange between $Fe(NO)(tox)(Et\text{-}xant)$ and $Fe(NO)(Et\text{-}xant)_2$ or $Fe(NO)(tox)(Et_2dtc)$ and $Fe(NO)(Et_2dtc)$ mononitrosyl complexes (see Table 1).

During the interaction of $Fe(NO)(Et_2dtc)_2$ with $Ni(Et\text{-}xant)_2$ in chloroform (molar ratio of the complexes from 1 : 1 to 1 : 4) the ESR spectra showed only the formation of $Fe(NO)(Et\text{-}xant)_2$.

When solutions in chloroform–toluene (volume ratio 1 : 3) of $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$ or $Fe(NO)(tox)_2$ with $Ni(ox)_2$, $Ni(SchB)_2$ or $Ni(acac)_2$ (at molar ratio from 1 : 2 to 4 : 1) were mixed at 298, 240 and 140 K only a decrease in the intensity of the ESR spectra of the initial nitrosyl complexes was observed.

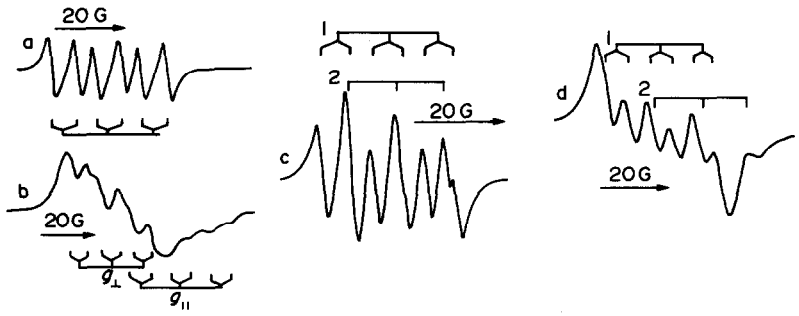

Fig. 1. ESR spectra of mixed-ligand complexes: (a) Fe(NO)(*i*-prdtp)(Et_2dtc) (240 K in chloroform); (b) Fe(NO)(*i*-prdtp)(Et_2dtc) (140 K in toluene–chloroform); (c) (1) Fe(NO)(*i*-prdtp)(Et-xant) and, (2) Fe(NO)(Et-xant)$_2$ (240 K in chloroform); and (d) (1) Fe(NO)(*i*-prdtp)(tox), and (2) Fe(NO)(tox)$_2$ (240 K in chloroform).

thylsuphoxide (DMSO) at ambient temperature, the characteristic triplet ESR spectrum of the mononitrosyl complex was preserved. Only a slight change in the ESR parameters was observed, compared with those in chloroform (Table 2).

The addition at ambient temperature of pyridine, DMFA or DMSO (1–10% by volume) to the solutions in chloroform–toluene of Fe(NO)(Me_2dtp)$_2$ or Fe(NO)(Et-xant)$_2$ led to a decrease in intensity and to the complete disappearance of the ESR spectra of the mononitrosyl complexes after a period of 10–15 min. The ESR spectra were not observed in frozen solutions ($T = 140$ K). The addition of the same amounts of the bases to the solutions of both complexes in *i*-amyl alcohol showed that the decrease in intensity of the ESR spectra of the mononitrosyl complexes is accompanied by the observation of dinitrosyl complexes—Fe(NO)$_2$(Me_2dtp) or Fe(NO)$_2$(Et-xant) (Fig. 3). The solutions of Fe(NO)(Me_2dtp)$_2$ and Fe(NO)(Et-xant)$_2$ in *i*-amyl alcohol gave ESR spectra characteristic only of the mononitrosyl complexes. The addition of Ni(Et_2dtc)$_2$ to the Fe(NO)$_2$(Me_2dtp) or Fe(NO)$_2$(Et-xant) obtained (even in the cases when pure pyridine and DMFA were used as solvents) led to the formation of Fe(NO)(Et_2dtc)$_2$ which was identified by its ESR spectrum (Fig. 3). The addition of Ni(Et-xant)$_2$ under the same conditions, to the Fe(NO)$_2$(Et-xant) did not cause destruction of the dinitrosyl complexes, but only a weak broadening of the lines is observed for the hyperfine splitting from ^{14}N.

When Fe(NO)(Et-xant)$_2$ was dissolved in nitrobenzene, a solvent where no coordination is observed, but which has a dielectric constant ($\varepsilon = 34.8$) close to that of DMFA ($\varepsilon = 36.7$), the ESR spectrum showed that the structure of the mononitrosyl complex was preserved.

The addition of I_2 or Br_2 to the solution of Fe(NO)(Et_2dtc)$_2$ in ethanol (molar ratio 3 : 1) led to a complete disappearance of its spectrum after several minutes. Under the same conditions for Fe(NO)(Me_2dtp)$_2$ or Fe(NO)(Et-xant)$_2$ together

with the disappearance of the ESR spectra new signals attributed to new complexes were observed (Fig. 4). An ESR spectrum with the same parameters was obtained when thiocarbamide was added to $Fe\cdot I\cdot (NO)_2\cdot H_2O$ (Table 3).

DISCUSSION

Exchange of ligands in the mononitrosyl complexes of iron

In all the cases studied by us, it was found that complete ligand exchange proceeded between the respective $Fe(NO)\cdot L'_2$ and NiL''_2. This fact was confirmed by the observation of ESR spectra of mononitrosyl complexes with composition $Fe(NO)L''_2$. The decrease in the intensity of the ESR spectra of $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$ and $Fe(NO)(tox)_2$ during the interaction with $Ni(ox)_2$, $Ni(SchB)_2$ and $Ni(acac)_2$ can also be considered as a result of the exchange of ligands between these complexes and the formation of the respective nitrosyl species, for some of which it was supposed[8] that they are high-spin complexes.

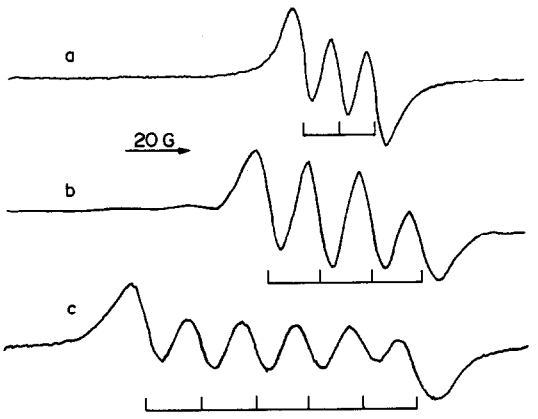

Fig. 4. Typical ESR spectra obtained during the interaction of $Fe(NO)\cdot L_2$ with Lewis acids in ethanol at 298 K: (a) $Fe(NO)(Et\text{-}xant)_2$, (b) $Fe(NO)_2\cdot Br\cdot L$, and (c) $Fe(NO)_2\cdot I\cdot L$. L is coordinated Et-xant.

The ESR spectra obtained during the interaction of $Ni(i\text{-}prdtp)_2$ with $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$, and $Fe(NO)(tox)_2$, and of the latter with $Ni(Et_2dtc)_2$ and $Ni(Et\text{-}xant)_2$, have different parameters from those of the complexes studied of type $Fe(NO)\cdot L_2$. This fact can be attributed to the formation of mixed-ligand mononitrosyl complexes of the following type—$Fe(NO)\cdot L'\cdot L''$. A synonymous proof for the formation of mixed-ligand complexes with composition $Fe(NO)(i\text{-}prdtp)(Et_2dtc)$, $Fe(NO)(i\text{-}prdtp)(Et\text{-}xant)$ and $Fe(NO)(i\text{-}prdtp)(tox)$ was the superhyperfine structure observed in all three cases due to the interaction of the unpaired electron with one phosphorus nucleus.

An additional indication of the formation of mixed-ligand complexes was the fact that their ESR parameters satisfy the following inequalities: $g^{Fe(NO)\cdot L'_2} \leqslant g^{Fe(NO)\cdot L'\cdot L''} \leqslant g^{Fe(NO)\cdot L''_2}$ and $A^{Fe(NO)\cdot L'_2} \leqslant A^{Fe(NO)\cdot L'\cdot L''} \leqslant A^{Fe(NO)\cdot L''_2}$ (Table 1). A similar dependence was observed for the ESR parameters of the mixed-ligand chelate complexes of copper.[9,10]

For the complexes $Fe(NO)(tox)_2$[1,8] and for its mixed-ligand complexes obtained during the interaction of $Ni(Et\text{-}xant)_2$ and $Ni(Et_2dtc)_2$ the superhyperfine structure from the ^{14}N nuclei of the thiooxine ligands was not observed. However, the fact that the ESR parameters of the complexes obtained fulfil the condition above, i.e. that they are approximately average values of the respective

[b] X = Br or I.

initial nitrosyl complexes (Table 1), gives us reason to assign them to mixed-ligand complexes having the following compositions: $Fe(NO)(tox)(Et_2dtc)$ and Fe(NO)(tox)(Et-xant).

Most probably, the exchange of ligands between $Fe(NO)(Et_2dtc)_2$ and $Ni(Et\text{-}xant)_2$ proceeds also through the formation of mixed-ligand complexes but, because of the too similar ESR parameters of $Fe(NO)(Et_2dtc)_2$ and $Fe(NO)(Et\text{-}xant)_2$, the latter were not resolved. Mixed-ligand complexes are formed probably during the exchange of ligands between $Fe(NO)(Et_2dtc)_2$, $Fe(NO)(Et\text{-}xant)_2$ and $Fe(NO)(tox)_2$ with $Ni(Ox)_2$, $Ni(SchB)_2$ and $Ni(acac)_2$. The absence of ESR spectra of mixed-ligand complexes can arise as a result of the low equilibrium concentration and/or because they are high-spin complexes.

The formation of mixed-ligand complexes is not thermodynamically favoured in all of the cases we have studied. For example, for a $Fe(NO)\cdot L_2'/Ni\cdot L_2''$ ratio of 1:1 only Fe(NO)(*i*-prdtp)(Et_2dtc) was obtained. In the other cases that we have studied the ratio of the complexes and the equilibrium process of exchange of ligands is drawn in different extent towards the initial complexes. In our previous papers[9,10] a 100% yield of mixed-ligand complexes during the interaction of $Cu(R_2dtc)_2$ with $Cu(R_2dtp)_2$ was observed.

Qualitatively, the same results are obtained when the exchange of ligands is studied between the respective mononitrosyl chelate complexes of iron.

Taking into account the low polarity of the solvents, favouring the exchange of ligands according to an association mechanism,[9] the following most probable scheme for the exchange of ligands in mononitrosyl complexes can be proposed:

$$Fe(NO)\cdot L_2' + Ni\cdot L_2''\,[Fe(NO)\cdot L_2''] \rightleftharpoons$$
$$Fe(NO)\cdot L_2'\ldots No\cdot L_2'', \rightleftharpoons$$
$$Fe(NO)\cdot L'\cdot L'' + Ni\cdot L'\cdot L'' \rightleftharpoons$$
$$Fe(NO)\cdot L_2'' + Ni\cdot L_2'.$$

In our previous study,[1] on the basis of the analysis of $^{57Fe}A_o$ it was found that the covalency of the Fe—L bonds changes in the following order:

$$Fe(NO)(dtp)_2 < Fe(NO)(xant)_2$$
$$< Fe(NO)(dtc)_2 < Fe(NO)(tox)_2.$$

However, in the cases of the mixed-ligand complexes of $Fe(NO)\cdot L\cdot(dtp)$ just the opposite order of covalency change of the dithiophosphate bonds depending on L was observed:

$$tox < Et\text{-}xant \leqslant Et_2dtc < i\text{-}prdtp.$$

The latter is determined by the spin density on the 3*s* orbital of ^{31}P (Table 1). Therefore, the covalency of the bonds of the ligands giving more covalent bonds in $Fe(NO)\cdot L_2$ gets stronger in mixed-ligand complexes and, on the contrary, with the less covalent bonds it gets weaker. The results obtained are in agreement with the theoretical treatment of the question concerning the formation of mixed-ligand complexes of this kind.[11]

In all the other cases that we have studied, the changes in g_o and ^{N}A values were similar within experimental error, and conclusions such as those above can not be drawn.

Interaction of mononitrosyl complexes of iron with Lewis acids and bases

The disappearance of the ESR spectra of Fe(NO)(Me_2dtp)$_2$ and Fe(NO)(Et-xant)$_2$(in chloroform–toluene mixture) when small amounts of pyridine, DMFA or DMSO are added is a result of the low solubility of the dinitrosyl chelate complexes of iron in non-polar solvents. The absence of a dinitrosyl complex when pyridine or DMFA is added to Fe(NO)(Et_2dtc)$_2$ can be explained by its greater stability. This is confirmed by the results of the interaction of Fe(NO)$_2$(Ex-xant) or Fe(NO)$_2$(Me_2dtp) (obtained in the presence of bases) with Ni(Et_2dtc)$_2$, where the formation of Fe(NO)(Et_2dtc)$_2$ was found. At the same time the addition of Ni(Ex-xant)$_2$ did not lead to the destruction of the Fe(NO)$_2$(Et-xant) complex. It should be noted that a dinitrosyldithiocarbamate complex of iron has not been described in the literature.[3]

Although DMFA and nitrobenzene have approximately equal permeativity values (35), the dinitrosyl complex is obtained only in the presence of DMFA which expresses weak coordination properties as a Lewis base. Taking into account this fact, one can draw the conclusion that the coordination properties of the solvents influence this process. One can suggest that the coordination of pyridine, DMFA or DMSO to Fe(NO)(Et-xant)$_2$ and Fe(NO)(Me_2dtp)$_2$ helps the opening of the chelate ring, leading to redistribution of the nitrosyl groups and ligands among the molecules, when Fe(NO)$_2$·L, FeL$_2$·2B and disulphide are obtained from the ligands. The following reasons confirm the possibility of the formation of dinitrosyl complexes in such a way:

(1) It has been shown[12] that the interaction of Fe(III)(xant)$_3$ and Fe(III)(dtp)$_3$ (dithiophosphinato complex) with pyridine leads to splitting of chelate ligands from the complex, when Fe(II)(chel)$_2$·2Py and disulphide are obtained from the ligands.

(2) It was shown that an exchange proceeds in solution between Fe^{15}(NO)(dtc)$_2$ and ^{14}NO.[3]

It is known that when the Fe(NO)(dtc)$_2$ complex interacts with I_2 and Br_2 hexacoordinated diamagnetic nitrosyl complexes [*cis*-I·Fe(NO)(dtc)$_2$ and *cis*-Br·Fe(NO)dtc$_2$] are formed.[2,3] However, during the interaction of Fe(NO)(Et-xant)$_2$ and Fe(NO)(Me_2dtp)$_2$ with I_2 and Br_2 we found the formation of paramagnetic species giving the superhyperfine structure of one iodine or bromine nucleus. The ESR spectra show similar parameters to those described in our experiments and given in[7] for the following species: Fe(NO)$_2$·X_2^- and Fe(NO)$_2$·X·H_2O (X = I or Br) (Table 3). The constants of superhyperfine interaction obtained by us have lower values than those given in the literature (Table 3). The reason for this can be the difference of the ligands from the first coordination sphere of the metallic ion. The observation of an ESR spectrum with the same parameters during the interaction of Fe(NO)·I·H_2O with thiocarbamate suggests that the complexes obtained have the structure described, but in their first coordinate sphere a monodendate-bonded sulphur-containing ligand can be found. Therefore, the interaction of Fe(NO)(Et-xant)$_2$ and Fe(NO)(Me_2dtp)$_2$ with I_2 and Br_2 leads to full destruction of the chelate encirclement of the initial mononitrosyl complexes, and then dinitrosyl complexes are obtained.

Abstract—The pentacoordinate rhodium nitrosyl complexes $[RhBr_2(NO)L_2]$ [L = $P(OPh)_2Ph$, $P(OMe)Ph_2$ or $P(OPr^i)Ph_2$] have been synthesized and the structures of $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ and $[RhBr_2(NO)\{P(OPr^i)Ph_2\}_2]$ have been determined X-ray crystallographically. Both of these latter compounds are tetragonal pyramidal with the nitrosyl group apical. The methoxydiphenylphosphine ligands in $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ are *cis*-disposed whereas the larger *cis*-propoxydiphenylphosphine ligands in $[RhBr_2(NO)\{P(OPr^i)Ph_2\}_2]$ are mutually *trans*. The nitrosyl group in *trans*-$[RhBr_2(NO)\{P(OPr^i)Ph_2\}_2]$ eclipses an Rh-P axis but in *cis*-$[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ it is staggered with respect to the P–Rh–P linkage. The isomeric behaviour of nitrosyl complexes of type $[RhX_2(NO)L_2]$ (X = halogen, L = phosphorus donor ligand) is rationalized in terms of the size of the ligand L.

It has been established that the pentacoordinate nitrosyl complexes $[MCl_2(NO)(PPh_3)_2]$ (M = Rh or Ir) adopt tetragonal pyramidal geometries with the nitrosyl group in the apical position and the triphenylphosphine ligands *trans*-disposed with respect to each other.[1,2] The nitrosyl bends rather unexpectedly in the more sterically crowded P–M–P plane. We subsequently synthesized the rhodium triphenylphosphite nitrosyl complex $[RhBr_2(NO)\{P(OPh)_3\}_2]$ and established that this compound assumes a related structure but with the triphenylphosphite ligands mutually *cis*.[3] The nitrosyl group again bends towards the phosphorus ligands but is staggered in relation to the P–Rh–P linkage. Hoffman *et al.*,[4] by considering the relative energies of the metal orbitals and those on the nitrosyl group for pentaccordinate nitrosyl complexes, have postulated a set of rules dictating the conditions under which the NO ligand will bend in these complexes

* Present address: Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K. Author to whom correspondence should be addressed.

and, if it does, in which direction it will do so. In particular the bending of the NO group along the P–M–P axis in $[MCl_2(NO)(PPh_3)_2]$ (M = Rh or Ir) was rationalized but at the time of publication compounds of type *cis*-$[MX_2(NO)L_2]$ (M = Rh or Ir, X = halogen, L = phosphorus donor ligand) were not known, and as a consequence reference was not made to them.

With the object of elucidating the factors governing the isomeric behaviour of compounds of type $[MX_2(NO)L_2]$, we have synthesized a number of complexes of formula $[RhBr_2(NO)L_2]$ where L has been systematically varied. This paper describes the synthesis and molecular structures of two closely related complexes, $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ (**1**) and $[RhBr_2(NO)\{P(OPr^i)Ph_2\}_2]$ (**2**), as well as the investigation of the synthesis of $[RhBr_2(NO)\{P(OPh)_2Ph\}_2]$ (**3**) and $[RhBr_2(NO)\{P(OPh)Ph_2\}_2]$ (**4**) containing phosphorus ligands intermediate between PPh_3 and $P(OPh)_3$.

EXPERIMENTAL

Complexes **1**–**3** were synthesized by treatment of $[\{Rh(NO)Br_2\}_n]$[5] with the appropriate phosphorus ligand following the procedure described in the literature.[6] Compound **1** crystallized as air-sensitive, olive-green platelets [ν(N—O) 1680 cm^{-1}, in Nujol] from methanol at −15°C: yield *ca* 65%. (Found: C, 43.4; H, 3.7; N, 1.9. $C_{26}H_{26}Br_2NO_3P_2Rh$ requires C, 43.1; H, 3.6; N, 1.9.) **2** was obtained as dark red, air-stable chunky crystals [ν(N—O) 1620 cm^{-1}, in Nujol] from acetone–ethanol at −15°C: yield *ca* 30% (the reason for this low yield has been discussed[6]). (Found: C, 46.0; H, 4.3; N, 1.9. $C_{30}H_{34}Br_2NO_3P_2Rh$ requires C, 46.1; H, 4.4; N, 1.8.) Compound **3** was crystallized as air-sensitive, green microcrystals [ν(N—O) 1740 cm^{-1}, in Nujol] from dichloromethane–methanol at 0°C: yield *ca* 65%. (Found: C, 50.3; H, 3.8; N, 1.3. $C_{36}H_{30}Br_2NO_5P_2Rh$ requires C, 49.1; H, 3.4; N, 1.6.) Compounds **1** and **3** decomposed after a few days to oils which were nitrosyl-free according to the IR spectroscopic evidence.

X-ray crystallographic studies

Data collection, structure solution and refinement details have been described previously.[6] In the case of compound **1** all atoms except the phenyl carbons were refined anisotropically, while only the Rh, Br and P atoms of **2** were given anisotropic temperature factors. Anisotropic refinement of the nitrosyl atoms in **2** resulted in improbable temperature factors. The high final value of R (and R_W) in the case of compound **2** is probably a consequence of thermal effects: the average volume per non-hydrogen atom is 21.3 $Å^3$, compared with 19.8 $Å^3$ for **1**.

Crystal data, data collection and refinement details are summarized in Table 1, and selected bond lengths and angles are given in Table 2.

RESULTS AND DISCUSSION

While **1**–**3** were readily synthesized from $[\{Rh(NO)Br_2\}_n]$, attempts to prepare **4** proved unsuccessful. Reaction of $[\{Rh(NO)Br_2\}_n]$ with $P(OPh)Ph_2$ resulted in the formation of $[\{RhBr(NO)\{(Ph_2PO)_2H\}\}_2]$,[6] or intractable oils with no N—O stretching bonds in their IR spectra, depending on whether or not traces of water were present in the reaction mixture. Exchange of the $AsPh_3$ ligands in $[RhBr_2(NO)(AsPh_3)_2]$, another possible route to **4**, was also unsuccessful: stirring of a suspension of the triphenylarsine complex in dry ethanol in the presence of a twice molar excess of $P(OPh)Ph_2$ did not result in ligand substitution (indicated by monitoring by means of IR spectroscopy).

Single crystals suitable for X-ray diffraction studies could only be obtained for two of the three compounds synthesised, viz. **1** and **2**. The molecular structures of these two compounds, as established crystallographically, are illustrated in Figs 1 and 2, respectively. Both compounds are tetragonal pyramidal with bent apical nitrosyl groups. The two phosphorus ligands and the two bromine atoms are mutually *cis* in compound **1** whereas in compound **2**, which exhibits crystallographic two-fold symmetry, they are mutually *trans*. As such the two compounds are structurally analogous to $[RhBr_2(NO)\{P(OPh)_3\}_2]$[3] and $[RhCl_2(NO)(PPh_3)_2]$,[1] respectively.

The σ-donor–π-acceptor properties of $P(OMe)Ph_2$ and $P(OPr^i)Ph_2$ may be assumed to be very similar, so that the different isomeric forms adopted by compounds **1** and **2** are best rationalized in terms of the difference in the steric size of the two ligands. A simple geometrical parameter which is used extensively to rank the steric influence of phosphorus donor ligands is the ligand cone angle.[7] This angle, which is essentially the apical angle of the cone whose apex is the metal atom and which envelopes the van der Waals' volume of the strain-free ligand, has been used to rank ligands in the correct order of the degree of dissociation of $[NiL_4]$ (L = ligand) complexes in solution. The cone angles for those ligands corresponding with crystallographically established structures for the nitrosyl complexes of type $[RhX_2(NO)L_2]$ (X = halogen, L = phosphorus donor ligand) are: $P(OPh)_3$ 121(10)° (the large uncertainty in this cone angle reflects the considerable flexibility of this ligand arising from the P–O–C linkages), $P(OMe)Ph_2$ 132(2)°, $P(OPr^i)Ph_2$ 140°, and PPh_3 145(2)°; the cone angle for $P(OPr^i)Ph_2$ has been estimated by taking the weighted arithmetic mean of the cone angles for $P(OPr^i)_3$ and PPh_3. Although it is accepted that the two phosphorus ligands in the *cis* isomers, $[RhBr_2(NO)L_2]$, may be considerably intermeshed and that the ligand cone angle is not necessarily the sole parameter for ranking ligands in the order of their steric influence it is proposed, nevertheless, that the critical ligand cone angle representing the crossover point between a preferred *cis* and a preferred *trans* configuration for

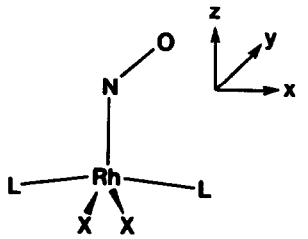
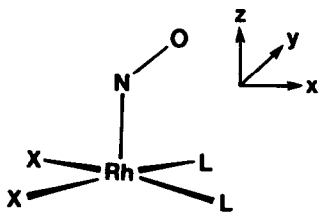
$[RhBr_2(NO)L_2]$ lies somewhere between 132 and 140° on the basis of the above angles. The structure of **3** could not be established unequivocally by crystallographic methods (*vide supra*) but on the basis that the compound has the same colour (green) as $[RhBr_2(NO)\{P(OPh)_3\}_2]$ (green) and $[RhBr_2(NO)\{P(OMe)Ph_2\}_2]$ (olive green) it is assumed that it adopts the *cis* configuration. The estimated cone angle for $P(OPh)_2Ph$ (129°) is less than 132°, and thus the structure of **3** is consistent with this cone angle proposal.

Similar to that in $[RhCl_2(NO)(PPh_3)_2]$,[1] the nitrosyl group in compound **2** adopts a bent geometry [Rh—N—O(1) 133(4)°] (*vide supra*) and in so doing eclipses the P–Rh–P axis. As described above, Hoffmann *et al.* have explained[4] this bending in terms of a general molecular orbital scheme for pentacoordinate metal nitrosyl complexes. In particular they showed that the metal d_{xz}- and d_{yz}-orbitals which are degenerate for compounds of the type $[Rh(NO)L_4]$ with C_{4v}-symmetry, are not of the same energy in *trans*-$[RhX_2(NO)L_2]$ as a consequence of the *trans* arrangement of the basal ligands, and that the orbital lying in the same plane as the weaker donor ligands (d_{xz}) is lower in energy. The π^*(NO) orbitals will interact differently with the two *d*-orbitals with the interaction involving d_{yz} being the stronger. Bending will thus take place in the plane of the weaker donor ligands. Extending the proposals of Hoffmann *et al.* it is suggested that the metal d_{xz}- and d_{yz}-orbitals in **1** and $[RhBr_2(NO)\{P(OPh)_3\}_2]$ (see below) will also interact differently with the π^*-orbitals of the NO group with the interaction involving d_{yz} again being the





stronger such that bending occurs towards the phosphorus ligands but in a plane (*xz*) which bisects the P—Rh—P angle. Bending in this plane will also minimize steric repulsions.

A more simplistic picture is that the nitrosyl group, free to rotate about the Rh–N vector, will orient itself so that its dipole moment opposes the dipole moment of the rest of the complex. The positive end of the dipole of the *cis*-$RhBr_2L_2$ moiety lies in a direction bisecting the P—Rh—P angle and it is in this direction that the negative end of the NO dipole will orient itself. However the *trans*-RhX_2L_2 moiety has a very small resultant dipole moment, and in this situation one could expect the NO group to orient itself so that the Br...O distances are maximized as indeed observed. Significantly the NO group in the compound $[Rh(O_2CCF_3)_2(NO)(PPh_3)_2]$[8] which has a *trans* structure analogous to $[RhCl_2(NO)(PPh_3)_2]$,[1] is oriented so that it bends in a plane approximately bisecting one of the P—Rh—O angles. An interpretation of this observation is that, for this particular *trans* complex, the steric repulsion effects of the two sets of basal ligands, i.e. the triphenyl phosphines and the trifluoroacetate groups, are very similar, and that as a consequence the nitrosyl group bends in the plane where steric effects are least. Alternatively, in terms of the proposals[4] of Hoffmann *et al.* it could be argued that the powerful electron-withdrawing effect of the CF_3 groups reduces the donor strength of the trifluoroacetate ligands such that the donor properties of the PPh_3 and CF_3COO ligands are similar, and that, as a consequence, steric effects will govern the direction of bending of the nitrosyl group.

A further feature of the nitrosyl complexes under discussion which warrants some comment is that concerning their stability. Whereas the *trans* derivatives $[RhCl_2(NO)(PPh_3)_2]$ and $[RhBr_2(NO)\{P(OPr^i)Ph_2\}_2]$ are stable in solution at ambient temperature the *cis* species $[RhBr_2(NO)L_2]$ [L = $P(OPh)_3$, $P(OMe)Ph_2$ or $P(OPh)_2Ph$] are unstable under similar conditions. It is suggested that although *cis* products are only isolated for the less bulky phosphorus ligands, the steric repulsion between these ligands when *cis*-disposed is sufficient to cause the instability of their complexes. The inability to isolate $[RhBr_2(NO)\{P(OPh)Ph_2\}_2]$ may be attributed to the formation of the *cis* isomer and its inherent instability. The reason as to why the *cis* compounds do not rearrange to the more sterically stable *trans* isomers is not however clear.*

(*Received* 21 *October* 1986; *accepted* 23 *January* 1987)

Abstract—The complexes $M(1\text{-nqo})_3$ (M = Rh or Ir, 1-nqoH = 1,2-naphthoquinone 1-oxime) and $M(2\text{-nqo})_3$ (M = Rh or Ir, 2-nqoH = 1,2-naphthoquinone 2-oxime) were prepared by the interaction of the quinone oxime with hydrated rhodium(III) chloride or chloroiridic(III) acid. The mixture resulting from the reaction of chloroiridic(III) acid and 1,2-naphthoquinone 1-oxime on treatment with pyridine afforded [pyH][Ir(1-nqo)(py)Cl_3] which was characterized by X-ray crystallography. The complexes $Rh(1\text{-nqo})_3$ and $Rh(2\text{-nqo})_3$ were also obtained by the nitrosation of the respective naphthol in the presence of hydrated rhodium(III) chloride. None of the trischelates showed any tendency to react with pyridine, triphenylphosphine or aqueous hydrochloric acid.

RESULTS AND DISCUSSION

Recently several papers dealing with metal complexes of 1,2-quinone mono-oximes and their structures have been published.[1–3] These complexes have been concerned mainly with first-row transition metals. Complexes of other metals have attracted attention for analytical or extraction purposes, but apart from studies of uranyl,[4] ruthenium,[5] and related platinum[6] complexes, the routes leading to them and their properties and structures have not been investigated. Here we report on the synthesis and properties of the complexes $M(1\text{-nqo})_3$ (M = Rh or Ir, 1-nqoH = 1,2-naphthoquinone 1-oxime), $M(2\text{-nqo})_3$ (M = Rh or Ir, 2-nqoH = 1,2-naphthoquinone 2-oxime) and [pyH][Ir(1-nqo)$pyCl_3$], and on the X-ray crystallographic characterization of the latter.

The complexes $Rh(1\text{-nqo})_3$ and $Rh(2\text{-nqo})_3$ were obtained from the reaction of rhodium(III) chloride with the appropriate 1,2-naphthoquinone mono-oxime or its sodium salt, in buffered aqueous acetone at pH 5–6 under reflux. All reactions afforded mixtures of products from which the trischelates were separated by using column chromatography. Thin-layer chromatographic examination of the trischelates, however, showed the presence of two components suggesting that each product is a mixture of two isomers. The formation of isomers is not unexpected in view of the ambidentate and asymmetric nature of the ligands which can give rise to linkage and/or geometrical isomerism. Similar behaviour has been reported for the analogous cobalt(III) complexes.[7]

The iridium trischelates $Ir(1\text{-nqo})_3$ and $Ir(2\text{-nqo})_3$ were prepared by reacting a solution of chloroiridic(III) acid with the sodium salt of the mono-oxime in buffered aqueous acetone at pH 4–5 under reflux. As in the case of the corresponding rhodium complexes these were separated as mixtures of isomers chromatographically. The reaction of chlo-

* Author to whom correspondence should be addressed.

roiridic(III) acid with either of the 1,2-naphthoquinone mono-oximes in unbuffered aqueous methanol under reflux afforded very complex mixtures which contained some of the respective trischelate. Addition of pyridine to the mixture arising from the reaction of 1,2-naphthoquinone 1-oxime with chloroiridic(III) acid led to the isolation of the complex [pyH][Ir(1-nqo)(py)Cl_3] in low yield.

Mixtures of isomers of Rh(1-nqo)$_3$ and Rh(2-nqo)$_3$ were also obtained from the nitrosation of the appropriate naphthol in the presence of rhodium(III) chloride. However, the yield of the products were lower than those obtained from the direct reaction of the oximes with rhodium(III) chloride. No iridium trischelates resulted from the nitrosation of either of the naphthols in the presence of chloroiridic(III) acid. In both cases the main product was the respective 1,2-naphthoquinone monooxime.

Neither the rhodium nor the iridium trischelates showed any tendency to react with pyridine or triphenylphosphine. This behaviour contrasts with that of the corresponding iron(III), cobalt(III) and chromium(III) complexes which undergo internal redox and/or deoxygenation reactions on treatment with these Lewis bases.[5] All the trischelates showed passivity towards hydrochloric acid, a feature which again contrasts with that of analogous complexes of first transition series metals.

Both the rhodium and iridium trischelates, and the complex [pyH][Ir(nqo)(py)Cl_3] were found to be diamagnetic, which reflects the tendency of both rhodium(III) and iridium(III) to adopt a low-spin t_{2g}^6 arrangement. The IR spectra of all the complexes include strong absorptions in the 1500–1620 cm^{-1} region assignable to ν(C=O) and ν(C=N) stretching vibrations, and which are indicative of the quinone oximic character of the ligand. Evidence for the quinone oximic character is also provided by the X-ray study of the pyridinium trichloro(1,2-naphthoquinone 1-oximato)(pyridine)-iridate(III).

Crystal and molecular structure of [pyH][Ir(1-nqo)(py)Cl_3]

Crystal data. $C_{20}H_{17}IrN_3Cl_3$, monoclinic, $P2_1/c$, $a = 11.403(3)$, $b = 11.977(4)$, $c = 15.155(5)$ Å, $U = 2062.87$ Å^3, $D_c = 1.810$ g cm^{-3}, $Z = 4$. Intensity data were collected on a Phillips PW1100 four-circle diffractometer using graphite-monochromated Mo-K_α radiation. The structure was solved and refined using 2816 unique reflections [$I > 3\sigma(I)$] to a final R factor of 0.0366.* Anisotropic thermal parameters were used for the Ir, N, the carbonyl O and all the Cl atoms. All hydrogen atoms for the compound were found from a subsequent difference map and included in the calculation of the structure factors, but were not refined. The bond lengths and the bond angles are listed in Tables 1 and 2, and the atomic numbering is explained in Fig. 1.

As with other 1,2-quinone oximato-complexes of *d*-block metals the chelate ring in the trichloro(1,2-naphthoquinone 1-oximato)(pyridine)iridate(III) anion is five-membered. The bond lengths in the chelate ring agree well with results for other 1,2-naphthoquinone oximato complexes and the short C_3—C_4 bond length provide additional evidence for the quinone oximic character.[8–10] The Cl—Ir—Cl bond angles [89.5°(av.)] are close to the idealized value of 90° for octahedral complexes. The pyridine molecule completes the distorted octahedral arrangement around Ir.

EXPERIMENTAL

IR spectra were recorded with a Pye–Unicam SP2000 spectrophotometer. Magnetic measurements were made at room temperature using a Gouy balance equipped with a permanent magnet of 3600 Oe. The absorbent used in the chromatography columns was Merk Kieselgel 60 (70–230-mesh) and TLC was carried out using precoated Merck Kieselgel 60 F_{254} plates. Chloroiridic(III) acid was prepared from chloroiridic(IV) acid as described earlier.[11] Hydrated rhodium(III) chloride of 39.0% Rh content was used.

Reaction of hydrated rhodium(III) *chloride with* 1,2-*naphthoquinone* 1-*oxime or its sodium salt*

A solution of hydrated rhodium(III) chloride (2.09 g, 7.9 mmol) in water (50 cm^3) was added to a solution of 1,2-naphthoquinone 1-oxime (5.24 g, 30.3 mmol) in acetone (100 cm^3) in a sodium acetate–acetic acid buffered medium at pH 5–6, and the mixture was heated under reflux for 2 h. Filtration gave a solid which was washed with water, dried at 60°C/30 mmHg and chromatographed. Elution with toluene gave a mixture of purple isomers of *tris*(1,2-*naphthoquinone* 1-*oximato*)*rhodium*(III) (3.25 g, 67%). (Found: C, 57.8; H, 3.4; N, 6.2; Rh, 16.0%. $C_{30}H_{18}N_3O_6Rh$ requires: C, 58.2; H, 2.9; N, 6.8; Rh, 16.6%.)

Similarly, hydrated rhodium(III) chloride (2.00 g, 7.6 mmol) and sodium 1,2-naphthoquinone 1-oximate (5.50 g, 28.2 mmol) gave tris(1,2-naphthoquinone 1-oximato)rhodium(III) (3.01 g, 64%) (identified by TLC and IR).

Reaction of hydrated rhodium(III) *chloride with* 1,2-*naphthoquinone* 2-*oxime or its sodium salt*

A solution of hydrated rhodium(III) chloride (2.00 g, 7.6 mmol) in water (50 cm^3) was added to a solution of the 1,2-naphthoquinone 2-oxime (5.29 g, 30.8 mmol) in acetone (100 cm^3) in a sodium acetate–acetic acid buffered medium at pH 5–6 and the mixture was heated under reflux for 2 h. Filtration gave a solid which was washed with water, dried at 60°C/30 mmHg and chromatographed. Elution with toluene gave a mixture of isomers of *tris*(1,2-*naphthoquinone* 2-*oximato*)*rhodium*(III) (3.25 g, 69%). (Found: C, 59.0; H, 3.2; N, 6.9; Rh, 16.3. $C_{30}H_{18}N_3O_6Rh$ requires: C, 58.2; H, 2.9; N, 6.8; Rh, 16.6%.)

Similarly, hydrated rhodium(III) chloride (2.00 g, 7.6 mmol) and sodium 1,2-naphthoquinone 2-oximate (5.4 g, 27.7 mmol) gave tris(1,2-naphthoquinone 2-oximato)rhodium(III) (3.15 g, 67%) (identified by TLC and IR).

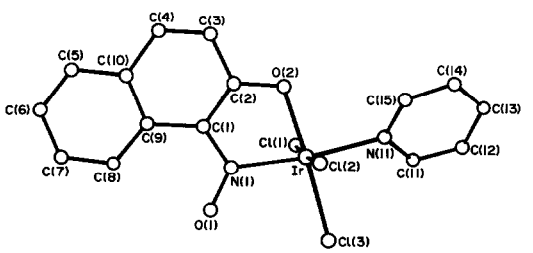

Fig. 1. Structure of the anion of [pyH][Ir($C_{10}H_6NO_2$](py)Cl_3].

Reaction of chloroiridic(III) *acid with the mono-oximes of* 1,2-*naphthoquinone*

Chloroiridic(III) acid (3.00 cm^3, containing 0.40 g Ir, 2.2 mmol) was added to a solution of 1,2-naphthoquinone 1-oxime (5.8 g, 33.5 mmol) in methanol (150 cm^3) and heated under reflux for 3 days. Removal of solvent gave a brown solid (4.93 g) (multicomponent by TLC). A portion of the solid (0.51 g) was stirred with pyridine (100 cm^3) for 2 days. Filtration gave a purple solid which was recrystallized from methanol to give needle-like crystals of pyridinium trichloro(1,2-naphthoquinone 1-oximato)(pyridine)iridate(III) (0.05 g, 4%) (characterized by X-ray crystallography).

Similarly chloroiridic(III) acid (3.00 cm^3, containing 0.40 g Ir, 2.2 mmol) and 1,2-naphthoquinone 2-oxime (5.8 g, 33.5 mmol) gave a brown solid which was shown by TLC to be multicomponent.

Reaction of chloroiridic(III) *acid with sodium* 1,2-*naphthoquinone mono-oximates*

Chloroiridic(III) acid (4.00 cm^3, containing 0.54 g of Ir) was added to a solution of sodium 1,2-

naphthoquinone 1-oximate (7.5 g, 38.5 mmol) in 1 : 1 water–acetone (200 cm^3) buffered at pH 4–5 with sodium acetate–acetic acid and heated under reflux for 5 days. The mixture was filtered to give a dark brown solid (4.28 g) which was dried at 60°C/30 mmHg and chromatographed. Elution with toluene gave *tris*(1,2-*naphthoquinone* 1-*oximato*) *iridium*(III) (0.41 g, 20%). (Found: C, 49.6; H, 3.7; N, 5.4; Ir, 26.7. $C_{30}H_{18}IrN_3O_6$ requires: C, 50.8; H, 3.3; N, 5.9; Ir, 27.1%.)

Similarly *tris*(1,2-*naphthoquinone* 2-*oximato*)*iridium*(III) (18%) (Found: C, 49.3; H, 3.8; N, 5.3; I, 27.5. $C_{30}H_{18}IrN_3O_6$ requires C, 50.8; H, 3.3; N, 5.9; Ir, 27.1%) was obtained when sodium 1,2-naphthoquinone 2-oximate was used.

Nitrosation of 1-*naphthol or* 2-*naphthol in the presence of hydrated rhodium*(III) *chloride*

A solution of sodium nitrite (5.13 g, 74.3 mmol) in water (50 cm^3) was added to a stirred solution of 1-naphthol (4.01 g, 29.9 mmol), hydrated rhodium(III) chloride (1.98 g, 7.5 mmol), acetic acid (10 cm^3) and sodium acetate (10.00 g) in 2 : 1 methanol–water mixture (300 cm^3). After 20 h the mixture was filtered to give a dark purple solid which was washed with water and dried at 60°C/35 mmHg and chromatographed. Elution with toluene gave tris(1,2-naphthoquinone 2-oximato)rhodium(III) (1.9 g, 39%) (identified by TLC and IR).

Similarly, nitrosation of 2-naphthol gave tris(1,2-naphthoquinone 1-oximato)rhodium(III) (1.6 g, 32%) (identified by TLC and IR).

Nitrosation of 1- *or* 2-*naphthol in the presence of chloroiridic*(III) *acid*

Nitrosation of 1-naphthol (3.00 g, 20.8 mmol) in the presence of chloroiridic(III) acid, (3.00 cm^3, containing 0.41 g of Ir, 2.2 mmol) carried out as above, gave unreacted 1-naphthol (32%) and 1,2-naphthoquinone 1-oxime (41%) (identical TLC, IR with an authentic sample). TLC of the filtrate indicated a multicomponent mixture which did not contain $Ir(1\text{-nqo})_3$.

Similarly nitrosation of 2-naphthol (3.00 g, 20.8 mmol) gave unreacted 2-naphthol (26%) and 1,2-naphthoquinone 2-oxime (55%) (identical TLC and IR with an authentic sample). TLC of the filtrate indicated a multicomponent mixture which did not contain $Ir(2\text{-nqo})_3$.

Attempted reactions of the $Rh(1\text{-nqo})_3$, $Rh(2\text{-nqo})_3$, $Ir(1\text{-nqo})_3$ *or* $Ir(2\text{-nqo})_3$ *with concentrated hydrochloric acid, triphenylphosphine or pyridine*

$M(1\text{-nqo})_3$ or $M(2\text{-nqo})_3$ (M = Rh or Ir) (*ca* 0.50 g) was recovered in *ca* 95% yield after being: (i) heated under reflux with pyridine (30 cm^3) for 7 days, or (ii) stirred with triphenylphosphine (1.00 g) in toluene (30 cm^3) for 7 days under reflux, or (iii) heated with concentrated aqueous hydrochloric acid (20 cm^3) for 3 days.

A NOVEL PREPARATION OF KEGGIN-TYPE DODECATUNGSTOCOBALTATE(II) USING $[Co(ox)_3]^{3-}$ AND HYDROGEN PEROXIDE AS STARTING MATERIALS

KENJI NOMIYA, TSUNEO OCHIAI and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering,
Seikei University, Musashino, Tokyo 180, Japan

(*Received* 1 *December* 1986; *accepted* 9 *February* 1987)

Abstract—A novel rapid route for the preparation of the Keggin-type $[Co(II)W_{12}O_{40}]^{6-}$ heteropolyanion was found by using the $[Co(ox)_3]^{3-}$ complex and 30% aqueous hydrogen peroxide. The intermediate dicobalt species $[Co(II)Co(II)W_{11}O_{40}H_2]^{8-}$ was directly isolated in high yield and the final product was easily and rapidly derived from it.

Dodecatungstocobaltate(II), $[CoW_{12}O_{40}]^{6-}$, one of the Keggin-structure heteropoly tungstopolyanions with transition-metal ions as a heteroatom, was first prepared by Baker and McCutcheon.[1,2] It has been derived from the acid (HCl) hydrolysis of green crystals of an intermediate dicobalt species, $[Co(II)Co(II)W_{11}O_{40}H_2]^{8-}$, which is formed from a boiling mixture of the aqueous solution of sodium tungstate and aqueous Co(II) acetate. One of the Co(II) ions in the dicobalt species occupies the central tetrahedral cavity and the other an exterior octahedral site of the Keggin structure, the latter being coordinated with one water molecule.[3] In the preparation, the purification process of the dicobalt species, by repeated recrystallizations from the aqueous solution acidified with acetic acid, takes a very long time and seriously influences the yield of the final product.[4] To reduce the total time for preparation, we have previously tried an improved version.[5] By adding ether and 6 M sulpuric acid to the aqueous solution of the dicobalt species, which is still crude, the ether adduct of the free acid of the final product is formed as the third layer. The metatungstate obtained as a byproduct in the ether adduct should be removed. The separation is comparatively easy, because the thermal stabilities of the metatungstate and the desired product are quite different. This purification is surely more convenient than the original one. On the other hand, we have been interested in the preparation of heteropoly compounds using transition-metal complexes as the starting material.[6] In this work, we have devised a greatly improved preparation of the pure dicobalt species in high yield using the $[Co(ox)_3]^{3-}$ complex and 30% aqueous hydrogen peroxide as starting materials. In this method, it is surprising that the starting Co(III) state is completely converted to the Co(II) state in spite of the presence of a strong oxidation reagent.

EXPERIMENTAL

Spectral measurements were performed by previously reported methods.[4,5] All chemicals used were analytical grade.

Preparations

The starting complex, $K_3[Co(ox)_3]\cdot 3H_2O$, was prepared according to the literature,[7] and identified by IR spectroscopy.[8] $Na_3[Co(ox)_3]\cdot 4H_2O$ was synthesized by using $Na_2C_2O_4$ instead of $K_2C_2O_4$ in the preparation of the corresponding potassium salt.

Dicobalt species. $Na_2WO_4\cdot 2H_2O$ (50 g, 0.15 mol) was dissolved in 100 cm^3 water. The pH of the solution was adjusted to *ca* 6 with glacial acetic acid. A separate solution was prepared by dissolving 6.2 g (0.013 mol) of $K_3[Co(ox)_3]\cdot 3H_2O$ in 100 cm^3 water to which 4.5 cm^3 of 30% aqueous hydrogen peroxide

had been added. The tungstate solution was maintained at above 90°C on a steam bath and the cobalt complex solution was added dropwise with stirring. All of the cobalt solution had been added over about 1.5 h and a deep green solution was formed. After the addition of the final drop, the solution was maintained at above 90°C for about 30 min with stirring. By filtering the hot solution, small amounts of a brown precipitate of Co(II) oxalate were removed. The deep green filtrate was kept overnight in the refrigerator and the green crystals of pure dicobalt species which deposited were collected, washed with ethanol and then ether, and dried *in vacuo* (yield 21 g).

The inital $Na_2WO_4 \cdot 2H_2O$ in the preparation cannot be replaced with K_2WO_4 because sparingly soluble precipitates of paratungstate were produced on the pH adjustment with glacial acetic acid.

$K_6[Co(II)W_{12}O_{40}] \cdot nH_2O$ *and* $K_2(TBA)_4[Co(II)W_{12}O_{40}]$. Twenty grams of the green crystals of the dicobalt species were dissolved in 100 cm^3 of 1 M aqueous HCl. The colour of the solution changed immediately from green to blue and insoluble precipitates were formed, while the dicobalt species were converted to the $[Co(II)W_{12}O_{40}]^{6-}$ ion. After filtering the precipitates, the deep blue filtrate was evaporated to dryness on a steam bath. During the process, the metatungstate present as an impurity was decomposed to an insoluble yellow solid (tungsten trioxide).[5] About 50 cm^3 of water was added, the yellow solid was filtered off and the deep blue filtrate was again evaported to dryness on the steam bath. No more yellow solid appeared. This fact shows contamination by less metatungstate as an impurity and that the obtained blue-green solid is the $[Co(II)W_{12}O_{40}]^{6-}$ compound. The potassium salt was isolated by dissolving the residual solid in about 40 cm^3 aqueous solution containing 4 g of KCl, concentrating the solution on a steam bath, cooling and adding equal amounts of ethanol. This compound was contaminated with *ca* 0.2% Na. Yield 4.1 g.

The precipitated $K_2(TBA)_4[CoW_{12}O_{40}]$ (TBA = tetrabutylammonium) was obtained by adding an aqueous solution containing 10 g of TBABr into an aqueous solution of the potassium salt. Sky-blue crystals (1.6 g) were obtained without any solvation by recrystallizing twice from acetronitrile. In this compound, no Na was detected. Found: C, 19.9; H, 4.0; N, 1.4. Calc. for $K_2[(C_4H_9)_4N]_4[CoW_{12}O_{40}]$: C, 19.5; H, 3.7; N, 1.4%. Electronic absorption bands and their intensities in UV–vis and near-IR regions were identical with the previously described data.[5] IR bands (KBr disk) were observed at 1025 (w), 945 (s), 875 (vs), 765 (vs), 520–580 (w, br) and 445 (m) cm^{-1}, which show the W—O vibrations characteristic of the Keggin structure.[4,5,9]

When the corresponding amounts of an $Na_3[Co(ox)_3] \cdot 4H_2O$–$Na_2WO_4 \cdot 2H_2O$–30% H_2O_2 system as starting materials were used, the sodium salt of dicobalt species was formed. However, this compound was highly soluble and cannot be obtained as crystals. By adding ethanol to the once filtered solution, a deep green paste of the dicobalt species was collected at the bottom of the beaker and was separated by decantation. By repeating the procedures described above, $Na_2(TBA)_4[Co-W_{12}O_{40}]$ was finally formed with a yield of 1.5 g. In this case, the purification, which involves the decomposition of the contaminated metatungstate on a steam bath, must be repeated many times.

RESULTS AND DISCUSSION

The method described here provides the potassium salt, the potassium TBA salt and the sodium TBA salt of $[Co(II)W_{12}O_{40}]^{6-}$ in high yields within a few days. The total time for the preparation of final products is markedly shortened and the yield is superior to the previous methods with the purity retained.

The $[Co(ox)_3]^{3-}$ complex reacts with the tungstate ion in aqueous solution at above 90°C without hydrogen peroxide. The visible absorption spectrum of its reaction mixture showed the formation of tetrahedral Co(II) species. Although the hydrogen peroxide was used with the aim of maintaining the starting Co(III) state, the formation of the Co(II) species was unexpectedly promoted. The amount of hydrogen peroxide did not affect the yield and quality of the dicobalt species. It is probable that in the hot solution the oxalato ligand acts as a reducing reagent for the Co(III) ion and the hydrogen peroxide catalytically promotes the reduction reaction. Instead of hydrogen peroxide, other "oxidation reagents", e.g. potassium peroxodisulphate, gave no dicobalt species, but pink-red precipitates as a main product, which is presumably the Co(II)-substituted species in one of the exterior octahedral tungsten sites of the metatungstate.

The $[Co(III)W_{12}O_{40}]^{5-}$ species with a tetrahedral Co(III) ion as a heteroatom can be derived from the isostructural Co(II) species by oxidation with peroxodisulphate.[1,5] Thus, this work is also useful for such a preparation.

(*Received* 7 *April* 1986; *accepted* 16 *September* 1986)

Abstract—Formation constants of Co(II), Ni(II), Cu(II), Zn(II) and Cd(II) complexes with 3-hydroxy-2-naphthalene carboxylic acid have been determined potentiometrically in a 50% (v/v) dioxane–water solution at 25°C and 0.2 M KNO_3. Experimental data are analysed using several computer programs. The obtained values for the log of the formation constant of the first 1 : 1 (metal : ligand) complex with the different metals are: Co 7.9, Ni 7.1, Cu 10.44, Zn 7.8 and Cd 7.3. The log of the formation constant for the 1 : 2 copper complex is 18.20. It is to be noted that Ni(II) yields a 1 : 1 complex weaker than expected from the Irving–Williams series.

Metal complex formation with 3-hydroxy-2-naphthalene carboxylic acid (hnca) has not been previously studied in a conclusive way. Sandhu *et al.*[1] studied it under rather limited conditions (for each metal ion all the experiments were performed at the same concentrations and at a unique ratio of metal to ligand, and the potentiometric cell was calibrated externally using aqueous buffer solutions, whereas measurements were made in a dioxane–water medium). Other studies[2,3] refer mainly to hnca complexes with Cu(II) and Zn(II) including a rough evaluation of the formation constants.

Complexation with hnca cannot be studied in aqueous solution by potentiometric methods because of the low solubility of this ligand at neutral pH. In the present work, dioxane–water mixtures [50% (v/v)] were chosen because of the increased solubility of the ligand in this medium, allowing therefore higher total concentrations of both ligand and metal ion in the potentiometric determinations. However hydrolysis of the metal ions disturbs the complex formation near neutral pH, preventing the formation of binary complexes higher than the 1 : 1, except for Cu(II) ion where the complexation is the strongest.

Salicylate and 5-sulphosalicylate ions have the same donor groups and in the same respective positions as the hnca ligand. Their bivalent metal complexes follow the Irving–Williams series of stabilities, but the increase in stability along the series is rather small, as usual when dealing with ligands with only oxygen-donor groups. In their Ni(II) complexes this increase in stability [relative to the cobalt(II) complex] is unusually low. Comparison of hnca with salycilate complexes will allow the evaluation of the influence of a more extended aromatic system. Comparison with aliphatic β-hydroxycarboxylic acids cannot be made, because of the lower acidity of the hydroxy group in these compounds, which act as monodentate ligands through the carboxylate group, leading to much lower values of the constants. Aromatic ortho-hydroxycarboxylic acids form chelates through both oxygen atoms—carboxylate and phenoxide—whereas related aliphatic hydroxycarboxylic acids do not.

In the present work the stability constants of the Cu(II), Ni(II), Zn(II), Cd(II) and Co(II) complexes with hnca have been evaluated within a rather wide concentration range, and using very different metal to ligand concentration ratios, at 25°C, 0.2 M KNO_3 ionic strength and in 50% (v/v) dioxane–water mixtures. Protonation constants of the 3-hydroxy-2-naphthoate ligand under the conditions of the present work are $\log K_1 = 13.54$ and $\log K_2 = 17.17$.[4]

EXPERIMENTAL

Reagents and solutions

3-Hydroxy-2-naphthalene carboxylic acid (Merck, synthesis) was recrystallized twice in ethanol and treated with activated carbon. Ni(II) stock solutions were prepared from $Ni(NO_3)_2 \cdot 6H_2O$ (Merck, p.a.) and standardized gravimetrically with dimethylglyoxime; Co(II) stock solutions were prepared from $Co(NO_3)_2 \cdot 6H_2O$ (Merck, p.a.) and standardized volumetrically with EDTA [with hexamethylenetetramine (Carlo Erba, RPE) at pH 6 and 40°C, orange xylenol as indicator];[5] Cu(II) stock solutions were prepared from $Cu(NO_3)_2 \cdot 5H_2O$ (Merck, p.a.) and standardized iodometrically; Zn(II) stock solutions were prepared from $Zn(NO_3)_2 \cdot 4H_2O$ (Merck, p.a.) and standardized gravimetrically with phosphate;[5] Cd(II) stock solutions were prepared from $Cd(NO_3)_2 \cdot 4H_2O$ (Merck, p.a.) and standardized volumetrically with EDTA (with hexamethylenetetramine at pH 5 and orange xylenol as indicator). Stock KOH (Merck, p.a.) solutions were prepared with an ionic exchange resin[6] to avoid carbonation, and were standardized volumetrically with biphthalate. HNO_3 solutions were prepared from HNO_3 (Merck, p.a.) and standardized volumetrically with tris(hydroxymethyl)aminomethane. All these solutions were made 50% (v/v) dioxane–water by mixing doubly distilled freshly boiled water and dioxane (Carlo Erba, purified by the Eigenberger method[7]). The ionic strength was kept at 0.2 M with KNO_3 (Probus, p.a.; recrystallized twice). A flow of N_2 (previously purified with vanadous perchlorate and barium hydroxide) bubbled continuously through the potentiometric solutions.

Apparatus

The potentiometric cell was:

Ag/AgCl/KCl(sat)//test solution

(50% dioxane–water)/GE

The value of the emf of the potentiometric cell was taken with an Orion 701A potentiometer (precision 0.1 mV), a reference Ag–AgCl electrode (Orion 9005 keramic junction type), and a glass electrode (GE) (Orion 9101). The potentiometric cell was thermostatted externally at 25°C. Titrant was added with a Metrohm Multidosimat E415 autoburette equipped with an Exchange Unit 10-cm^3 burette cylinder (552) with an antidiffusion burette tip. All the potentiometric assembly is controlled by an HP 9816 microcomputer via an HP 3421A Data Acquisition Control Unit (see later).

Procedure

The potentiometric method previously described[8] has been adapted to a computer-controlled titration procedure. A BASIC program controls both acquisition of emf readings and addition of titrant volumes. Readings are taken every 90 s; when two successive readings differ by less than 0.1 mV a new addition of a prefixed titrant volume is made (if reading stabilization is not reached in 12 min, a new prefixed titrant volume is added anyway and a warning message is stored). Calibration of the potentiometric cell is carried out by a Gran titration of a diluted mineral acid solution in the same ionic medium with a strong base. The calibration parameters (standard potential of the cell and value of the ionic product of the medium[4,8]), are calculated using a multiparametric data-fitting procedure[9] or Grant plots.[10] Additionally, both procedures can be used to test the Nernstian response of the potentiometric cell. Once the calibration parameters are known the ligand and metal ion are added, and the potentiometric titration is performed. The values of the emf readings and added volumes are recorded on both magnetic and paper media ready for their further treatment. The titration is finished either when there is hydrolysis of the metal ion (easily detected from the hydroxide precipitation or from its effect on the emf readings: instability, acid drift...), or at a prefixed pH value. The followings titrations were performed: Eight titrations of solutions containing Co(II) concentrations in the range 5.56×10^{-4}–4.78×10^{-3} M and ligand concentrations in the range 2.29×10^{-3}–1.92×10^{-2} M (covering a range of ligand/metal ratios from 1.1 to 4.5); 13 titrations of solutions containing Ni(II) concentrations in the range 2.98×10^{-4}–7.14×10^{-3} M and ligand concentrations in the range 2.89×10^{-3}–1.92×10^{-2} M (covering a range of ligand/metal ratios from 1.07 to 20); four titrations of solutions containing Cu(II) concentrations in the range 9.57×10^{-4}–2.69×10^{-3} M and the ligand concentrations in the range 6.34×10^{-3}–2.07×10^{-2} M (covering a range of ligand/metal ratios from 6.6 to 8.5); five titrations of solutions containing Zn(II) concentrations in the range 4.48×10^{-4}–2.88×10^{-3} M, and ligand concentrations in the range 2.58×10^{-3}–2.49×10^{-2} M (covering a range of ligand/metal ratios from 1.6 to 19.7); and five titrations of solutions containing Cd(II) concentrations in the range 5.5×10^{-4}–3.29×10^{-3} M and ligand concentrations in the range 2.40×10^{-3}–4.16×10^{-3} M (covering a range of ligand/metal ratios from 1.0 to 4.5).

For the Co(II), Ni(II) and Cu(II) systems, complexation can be detected by the colour changes.

The absorption spectra show a shift in the maximum of the absorption band to shorter wavelengths, which is related to the stronger ligand field produced by the ligand molecules compared to the solvent molecules. Cu(II) solutions change to green, with bands at $\lambda_{max} = 755$ [ε (cm^{-1} mol^{-1} l) = 114] at pH = 4.4, at $\lambda_{max} = 735$ ($\varepsilon = 95$) at pH = 5.12, and at $\lambda_{max} = 640$ ($\varepsilon = 110$) at pH = 12; Co(II) solutions change to red-orange, with bands at $\lambda_{max} = 507$ ($\varepsilon = 146$) and $\lambda_{max} = 1218$ ($\varepsilon = 293$) at pH = 5.3; Ni(II) solutions change to green with bands at $\lambda_{max} = 660$ ($\varepsilon = 145$), $\lambda_{max} = 725$ ($\varepsilon = 158$), $\lambda_{max} = 1150$ ($\varepsilon = 83$) and $\lambda_{max} = 1190$ ($\varepsilon = 76$) at pH = 6.5. Zn(II) and Cd(II) solutions do not absorb.

Solutions which contain high concentrations of copper ion (e.g. 3.0×10^{-3} M) and excess of ligand gave a red precipitate at neutral pH. Elemental analysis shows that the insoluble product is the 1 : 1 complex. Its low solubility is related to the fact that it has no electrical charge.

RESULTS AND DISCUSSION

Cu(II) *complexes*

The values of the formation constants of the Cu(II) complexes with hnca, obtained from the numerical analysis of the experimental potentiometric data using the computer programs MINIGLASS,[9] MINIQUAD[11] and SUPERQUAD,[12] are given in Table 1.

The same experimental data were used to evaluate the formation curves given in Fig. 1. Independently of which is the minimization function defined by each program, the values obtained for the stability constants are similar. For MINIGLASS the standard deviation of the titre residuals is 0.024 cm^3, (compared to an autoburette resolution of 0.01 cm^3, a reproducibility error of 0.005 cm^3 and an absolute error of 0.02 cm^3); for MINIQUAD the standard deviation of the residuals on the total concentrations is 0.88×10^{-5} M (less than 1% of the analytical concentration); and for SUPERQUAD the ratio of the root mean square of the weighted residuals to the estimated error in our working conditions (0.01 cm^3 for the autoburette and 0.1 mV for the emf readings) is sigma = 2.37.[12] In the additional statistical analysis of the residuals performed by MINIQUAD and SUPERQUAD[11,12] the values obtained for the chi-square satistic with both programs are quite high, reflecting[8,12,13] the difficulties in having a normal distribution of residuals in the least-squares analysis of tiration emf data. This fact is more discernible when the different test solutions are prepared from completely independent stock solutions, in accordance with the findings by Braibanti *et al.*[14] As it is known, moreover, for a given model there is a tendency to yield higher chi-square values when the fit is improved through parameter refinement, reflecting that there is a limit in the consideration of the normal distribution of residuals, which is related to the limit of precision attainable in the usual experimental conditions. Some work is made by us at present to analyse this behaviour, which on the other hand has also been recognized by other authors.[14]

Table 1. Formation constants of Cu(II)–hnca complexes[a]

Treatment	Log of the constants[b,c]	No. of curves (No. of points)	s[d]	χ^2[e]
MINIGLASS	10.42(1)	4	0.024	—
	18.20(3)	(184)		
MINIQUAD	10.42(3)	4	0.88×10^{-5}	125.8
	18.20(3)	(184)		
SUPERQUAD	10.44(2)	4	2.37	52.5
	18.20(3)	(184)		

[a] At 25°C, 50% (v/v) dioxane–water and 0.2 M KNO_3.

[b] Value of the log of the global formation constants for the reactions: Cu(II) + hnca = Cu(hnca) and Cu(II) + 2hnca = $Cu(hnca)_2$.

[e] Value of the residual chi-squares defined as in Refs 12, 13 and 8, respectively.

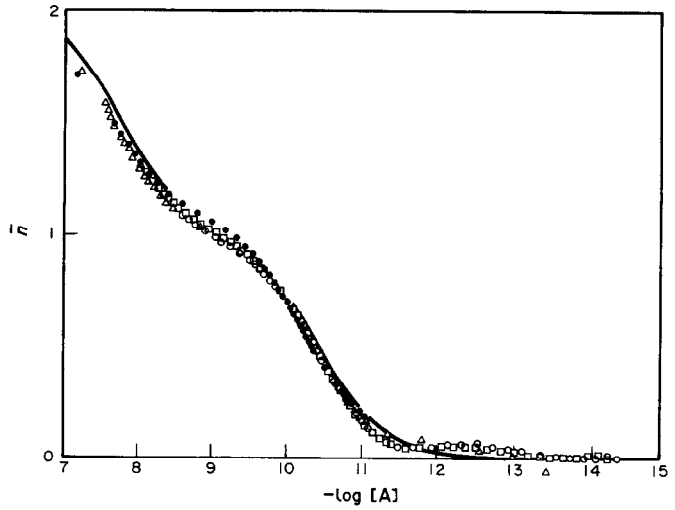

Fig. 1. Complexation of Cu(II) ion with hnca at $I = 0.2$ M KNO_3 and 50% (v/v) dioxane–water medium. In the figure $\bar{n}$ is the average ligand number[8] and $-\log[A]$ is the log of the free ligand concentration. Initial hnca and copper(II) ion concentrations given in millimol: (□) 7.69 and 0.96, (○) 6.34 and 1.06, (△) 8.43 and 0.98, and (●) 20.7 and 2.69. The continuous line is the theoretical curve obtained with the log of the complexation constants (see Table 1) (10.44 and 18.20).

The values obtained for the two formation constants of Cu(II) complexes are of the magnitude to be expected from the values of the Cu(II)–salicylate complexes in aqueous solutions.[8] The second stepwise formation constant ($\log K_2 = 7.76$) is nearly three log units lower than the first one ($\log K_1 = 10.44$), showing the enhancement of the first complexation by neutralization of charge.[15] In Fig. 2 the distribution of species which contain Cu(II) when the pH is changed are given.

Other metal ion complexes

In Table 2 the log values of the first formation constant of the complexes of hnca with Co(II), Ni(II), Zn(II) and Cd(II) are given. As was pointed out (see earlier), for all these metal ions it was only possible to obtain the formation constant of the first complex, since the formation of the second one is disturbed by the hydrolysis and precipitation of the metal ion. Therefore the experimental data including measurements in the pH range where hydrolysis occurs were not taken into account, since data in this pH range would not improve the numerical fit and because, if they are included, the rejection of species becomes arbitrary (e.g. the 1 : 1 complex is discarded by SUPERQUAD when hydroxocomplexes are included in the model). Moreover these data cannot be considered at equilibrium, since the emf readings at this stage showed

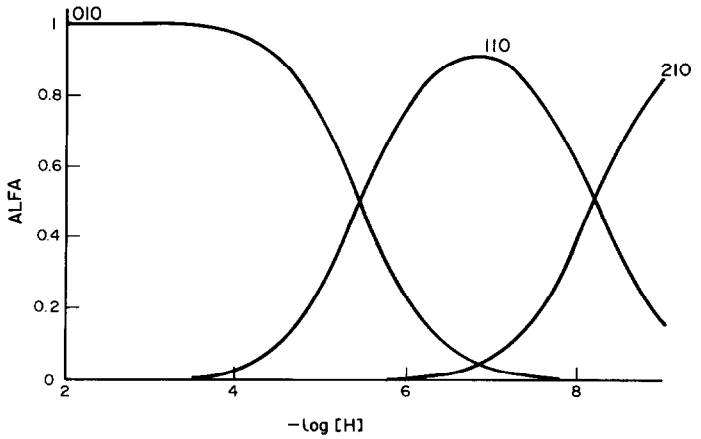

Fig. 2. Distribution plot of the species which contain copper(II). In the figure 010, 110 and 210, refer respectively to Cu(II), Cu(hnca) and $Cu(hnca)_2$. ALFA is the ratio of each species concentration to the total copper(II) concentration.

[e] Value of the residual chi-squares.[12]

a steady drift (see Experimental). The values of sigma shown in Table 2 for the SUPERQUAD treatment[12] are somewhat higher than expected. In any case we have preferred to maintain the results such as they are given in Table 2, since the improvement of the fit produced by the rejection of "queue" titration points does not yield different values of the constants but decreases the formation extent of the first complex, reducing therefore the precision of its constant. High chi-square values are also here related to the not quite Gaussian behaviour of the weighed queue residuals.

DISCUSSION

Comparison of the values given in Tables 1 and 2 confirms[1] that the formation constants for the 1 : 1 complexes of the metal ions studied here do not follow completely the Irving–Williams sequence.[16] The value of the constant for the Ni(II) complex is the lowest obtained, while according to the Irving–Williams series it should lie between the Cu(II) and Co(II) values. As it was pointed out before (see earlier), the increase in stability from Co(II) to Ni(II) in the Irving–Williams series is rather weak in the case of complexes with oxygen-donor groups.[17] Additionally, the greater stability of the Co(II) complex could be partially explained by a high stabilization due to a high Jahn–Teller distortion of the octahedral low-spin Co(II) complex.[3]

(*Received* 17 *June* 1986; *accepted after revision* 27 *October* 1986)

Abstract—The reaction of the $[Mo(NO)_2]^{2+}$ moiety with the (X,Y)-donor ligands (X,Y = dithiocarbamates, xanthates, 2-picolinate, *o*-aminophenoxide, *o*-aminothiophenoxide or dithizone) leads fundamentally to formation of complexes of type $Mo(NO)_2(X,Y)_2$. Sometimes secondary products are also formed, as for example the mononitrosyl heptacoordinated complex $Mo(NO)(2\text{-pic})_3$ (5) (2-pic = 2-picolinate). In the reaction with dithizone a complex of composition $Mo(NO)_2(HDtz)_2(H_2Dtz)$ was isolated. The $Mo(NO)_2(R_2dtc)_2$ (R_2dtc = *N*,*N*-dialkyldithiocarbamates) complexes decompose in $CHCl_3$ or by reaction with CO in CH_2Cl_2 to give the mononitrosyl derivatives $Mo(NO)(R_2dtc)_3$. The reaction of complex 6 with PPh_3 yields $Mo(2\text{-pic})_3 \cdot H_2O$. The crystal structure of $Mo(NO)_2(2\text{-pic})_2$ has been determined. The crystals are orthorhombic, space group *Pbca* with $a = 12.502(3)$, $b = 15.15(4)$, $c = 15.296(6)$ Å, $U = 2897(8)$ Å^3, $z = 8$, $D_c = 1.84\ g\ cm^{-3}$ $\mu(Mo\text{-}K_\alpha) = 9.23\ cm^{-1}$, $F(000) = 1584$. The Mo atom presents a distorted octahedral coordination. The atomic parameters have been refined by least-squares analysis of 1845 observed reflexions to $R = 0.025$.

Several examples of molybdenum dinitrosyl derivatives have been described, such as $Mo(NO)_2(L,L)_2$ [L,L = R_2dtc (R = Me or Et),[1–4] or acac[2]], $Mo(NO)_2X_2L_2$,[3–6] $[Mo(II)(NO)_2(NCS)_4]^{2-}$, $[Mo(II)(NO)_2(NHO)(NCS)_4]^{2-}$ and $Mo(II)(NO)_2(NCS)_2(L,L)$[4] (L,L = bipy or phen). These dinitrosyl derivatives can be obtained by three general methods: (1) oxidation by NO^+ or substitution by NO of molybdenum hexacarbonyl or its derivatives;[1,2,5,6] (2) reduction of $MoCl_5$ by nitric oxide;[7] and (3) reductive dinitroxylation of: (a) ammonium hepamolybdate by hydroxylamine in slightly basic or acidic media,[3] or (b) of MoO_4^{2-} by hydroxylamine in the presence of NCS^-. In case (3b) mono- or dinitrosyl species of molybdenum(II) can be obtained too. To date, mononitrosyl molybdenum(II) complexes of formula $Mo(NO)(R_2dtc)_3$ (R = Me, Et, Pr^n or Bu^n),[1,8] $Mo(NO)(NH_2O)(NCS)_2(L,L)$ (L,L = bipy or phen),[4] $Mo(NO)(NH_2O)(Et_2dtc)_2$[4] and $Mo(NO)(NH_2O)(2\text{-pic})_2$[9] have been described in the literature.

Electrochemical and ESR studies of *cis*-$Mo(R_2dtc)_2(NO)_2$ have been reported,[10] as well as the electronic spectra[11] of a wide variety of six-coordinate complexes containing the cis-$[Mo(NO)_2]^{2+}$ moiety.

Activation of a nitrosyl group to give mononitrosyl complexes occurs by reaction of *cis*-$Mo(NO)_2(Et_2dtc)_2$ with strong Lewis bases such as azide, cyanate, cyanide or diethyldithiocarbamate in hot dimethyl sulfoxide.[12]

The dinitrosyl complexes of type $Mo(NO)_2(L,L)_2$ described contain only (S,S)-donor uninegative ligands such as the *N*,*N*-dialkyldithiocarbamates, or (O,O)-donor ligands such as acetylacetonate or oxalate. This fact prompted us to investigate the synthesis and characterization of new dinitrosyl derivatives, obtained by method (3a), with anionic (X,Y)-donor ligands (X,Y = N, O or S) containing donor atoms of different size and basicity. The ligands used were xanthates (Rxant; R = Me or

* Author to whom correspondence should be addressed.

Et), and *N*-alkyldithiocarbamates (RHdtc, R = Me) [(S,S)-donor ligands]; *o*-aminophenoxide (*o*-AP) and 2-picolinate (2-pic) [(N,O)-donor ligands]; *o*-aminothiphenoxide (*o*-ATP) [(N,S)-donor ligand] and dithizone (H_2Dtz) [(potentially S-(S,S) or (N,S)-donor ligand].

A study of the reactivity of the new complexes towards chloroform or Lewis bases (carbon monoxide or triphenylphosphine) has been carried out.

RESULTS AND DISCUSSION

(*a*) *Reaction of the* $[Mo(NO)_2]^{2+}$ *moiety with the* (X,Y)*-donor ligands*

The new derivatives have been prepared by addition of the alkali salt of ligand or of the ligand in basic medium to the reaction mixture which contains the $[Mo(NO)_2]^{2+}$ moiety. The compounds stable to air and atmospheric moisture have been characterized by elemental analysis, electric-conductance and magnetic-susceptibility measurements, and IR and electronic spectroscopy (in solution and diffuse reflectance). The complexes are non-electrolytes and diamagnetic.

The compounds obtained by this type of reaction are hexacoordinated molybdenum(O) complexes of general formula $Mo(NO)_2(X,Y)_2$, although sometimes secondary products are formed which sometimes could not be characterized. So, in the reaction with 2-picolinate a mixture of $Mo(NO)_2(2\text{-pic})_2$ (**1**) (crystalline green solid) and $Mo(NO)(2\text{-pic})_3$ (**5**) (pale yellow solid) is obtained. These compounds can be separated by successive recrystallizations from dichloromethane. The mononitrosyl derivative with this ligand (**5**) is insoluble in all solvents. The heptacoordinated mononitrosyl derivative, $Mo(NO)(NH_2O)(2\text{-pic})_2$, has been described in the literature.[9] The *o*-aminophenoxide ligand reacts with the $[Mo(NO)_2]^{2+}$ moiety to give the $Mo(NO)_2(o\text{-AP})_2$ complex and a mixture of unidentified products, some of which are ligand condensation products.

The reaction with dithizone leads to the formation of a dark purple solid with metallic lustre of formula $[Mo(NO)_2(HDtz)_2(H_2Dtz)]$ where HDtz is the monoanion of the ligand and H_2Dtz the neutral ligand.

The behaviour of the (S,S)-donor ligands towards $[Mo(NO)_2]^{2+}$ is different. When the ligand used is an *N*,*N*-dialkyldithiocarbamate, the reaction leads to formation of a $Mo(NO)_2(R_2dtc)_2$ complex, as described in the literature[3] for other dithiocarbamates. In the case of *N*-methyldithiocarbamate a mixture of $Mo_2O_3(MeHdtc)_4$ (purple) and a dinitrosyl species is obtained, but if the experiment is carried out in an inert atmosphere an orange solid is isolated although with very low yield. The elemental analysis data of this compound are consistent with a formula of type $Mo(NO)(MeHdtc)_3$, but its IR spectrum presents two $\nu(NO)$ vibrations. The presence of oxocomplexes in the reaction medium has been also previously described.[3,4] On the other hand, the alkali xanthates react instantaneously, but no characterizable products could be isolated because of the formation of unstable oils or oil solids and molybdenum oxides or oxocomplexes.

(*b*) *Reaction of the* $Mo(NO)_2(X,Y)_2$ *complexes with chloroform,* CO *or* PPh_3

The $Mo(NO)_2(R_2dtc)_2$ derivatives (R_2 = 2Et or pyr) react with PPh_3 in chloroform to give a mixture of compounds from which the molybdenum(V) oxocomplex, $Mo_2O_3(R_2dtc)_4$, can be isolated. When these dinitrosyl species are stirred in $CHCl_3$ for a prolonged time in an N_2 atmosphere they decompose giving rise to an oxocomplex $[Mo_2O_4(R_2dtc)_2]$ and the mononitrosyl complexes $Mo(NO)(R_2dtc)_3 \cdot \frac{1}{2}CHCl_3$.

As mentioned above, complexes of this type have been previously described,[1,8] but they do not contain the crystallization solvent. The presence of $CHCl_3$ has been shown by IR spectroscopy and Cl analysis by X-ray fluorescence.

The reaction of the *N*-methyldithiocarbamate complex (**6**) with $CHCl_3$ is not reproducible. Sometimes a solid of composition $Mo(NO)(MeHdtc)_3 \cdot \frac{1}{2}CHCl_3$ is isolated.

$Mo(NO)_2(o\text{-AP})_2$ (**2**) and $Mo(NO)_2(o\text{-ATP})_2$ (**3**) do not react with PPh_3 and are stable in $CHCl_3$. However, when an excess of PPh_3 is added to complex **1** in $CHCl_3$ a relatively quick reaction occurs with formation of a molybdenum(III) complex of composition $Mo(2\text{-pic})_3 \cdot H_2O$. Compounds of this type, with (O,O)-donor ligands have been described.[13]

No reaction was observed on bubbling CO through a solution of $Mo(NO)_2(X,Y)_2$ complexes (X,Y = 2-pic, *o*-AP or *o*-ATP) in CH_2Cl_2 and the recovered solids were spectroscopically (IR) identical with the starting compounds. However the formation of $Mo_2O_4(R_2dtc)_2 \cdot xCH_2Cl_2$ and $Mo(NO)(R_2dtc)_3$ occurs upon treatment with CO of $MO(NO)_2(R_2dtc)_2$ species. This process is analogous to the decomposition in $CHCl_3$, but here the oxo complex is obtained pure.

All these results [(a) and (b)] are summarized in Scheme 1. Table 1 lists analytical, physical and IR data for the new complexes.

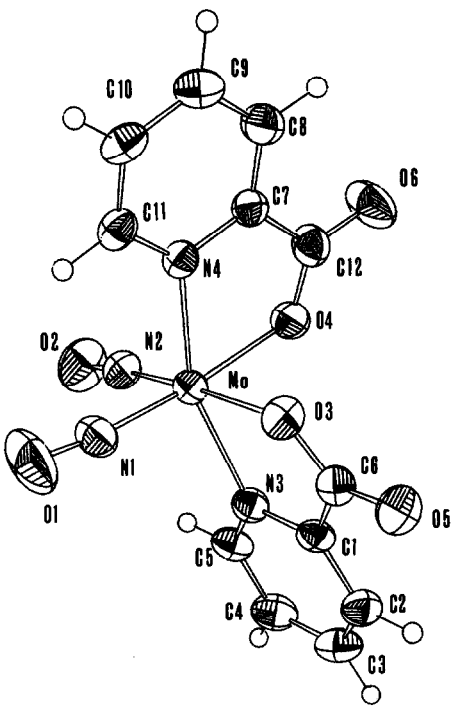

Fig. 1.

Crystal structure of complex 1

Structure. Figure 1 shows the geometry of the structure and the atom labelling.[14] Table 2 lists the bond lengths and angles.

Few X-ray structures are available for $[Mo(NO)_2]^{2+}$ complexes.[15] The present study has confirmed the formation of a new compound, namely $MO(NO)_2(2\text{-pic})_2$. The molybdenum atom is coordinated to two 2-picolinates as (N,O)-donor chelating ligands, and to two NO groups in *cis* positions, forming a distorted octahedron. Both NO groups are almost linear. The ON—Mo—NO angle [87.6(2)] is close to that reported[11] for $Mo(NO)_2(Et_2dtc)_2$ [88.0(4)].

The Mo—N bond lengths are similar to those found by Enemark and Feltham[16] in $Mo(NO)_2Cl_2(PPh_3)_2$. The N—O distances [1.168(6) and 1.173(5) Å] and Mo—N—O angles [173.9(4) and 174.9(4)°] are less than in the above compound but are within the range found for linear nitrosyls in other nitrosyl derivatives.[2,17,18] The bond lengths and bond angles are as expected for the 2-picolinate ligand.[19] The packing of the crystal is determined only by van der Waals' interaction and significative intermolecular interactions have not been observed. This fact is important to explain the magnetic behaviour found in the complex.

IR spectra

In the IR spectra of the dinitrosyl species, two NO stretching frequencies are observed indicating the *cis* coordination of these ligands. The complexes should then exist as optical isomers although these have been not resolved. In all spectra, ν(NO) occurs in the 1783–1630-cm^{-1} region, and, if NO is considered to be coordinated as NO^+, then the $Mo(NO)_2(X,Y)_2$ derivatives could be regarded as hexacoordinated complexes of zerovalent metal ions.

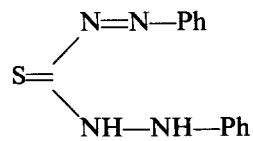
On the basis of observed IR spectra the lower-frequency ν(NO) vibrations have been assigned to $M^{(n+1)+}—N^-=O$ and the higher-frequency vibrations to the $M^{(n-1)+}—N\equiv O^+$ structure, although this rule is misleading because of the great overlap in the ν(NO) frequencies of bent and linear nitrosyls in the 1720–1620-cm^{-1} range.[20]

The NO^+ character of the nitrosyl group in the derivatives can also be deduced from the study of the crystalline structure of complex **1**. The Mo—N—O bond angles (173.9 and 174.9°) are characteristic of octahedral metal linear nitrosyls in which this angle varies from 170 to 180° indicating a straight coordination of the NO^+ group.[20]

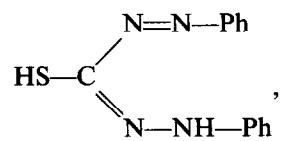
In the $Mo(NO)_2(X,Y)_2$ complexes the values of the ν(NO) frequency vary in the order (N,O) > (S,N) > (S,S) with the nature of the (X,Y) ligand. This variation is consistent with the decrease in the π-contribution to the Mo—NO bond and with the electronegativity of the donor atoms of the (X,Y) group. The same variation can be observed in the mononitrosyl derivatives whose stereochemistry and metal environment are comparable.

In the dinitrosyl complexes the (X,Y) ligand is a uninegative bidentate ligand as can be deduced from its characteristic IR vibrations (see Table 1). As mentioned above, the crystal structure of $Mo(NO)_2(2\text{-pic})_2$ shows that the 2-picolinate ligand acts as an (N,O)-donor chelating group.

The assignment of a possible structure to the dithizone derivative is difficult owing to the different coordination modes of this ligand (H_2Dtz) of resonant formulae:



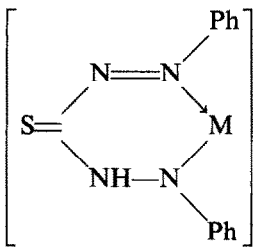
and



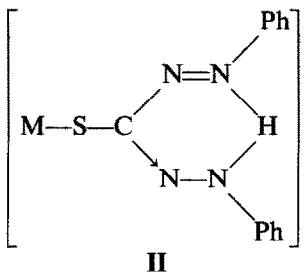
,

which can lose one or two protons behaving as an uninegative group (primary dithizone, HDtz) or binegative group (secondary dithizone, Dtz),

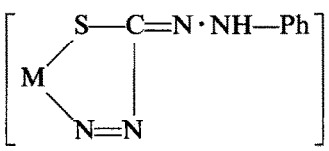
respectively. The primary dithizone can be coordinated by several modes:[21]



I



II



III

The IR spectrum of primary dithizone complexes may be different to the compounds with secondary dithizones because the former present bands are due to the NH, C=N or N=N group, while such vibrations, would disappear in the spectrum of the latter.[22] In our complex, ν(NH) and ν(C=N) bonds are observed so that a formulation of type $Mo(NO)_2(Dtz)_3$ Is discarded. The hydrogen analysis and magnetic moments also do not correspond to this formulation. On the other hand the conductivity measurement and potassium analysis by X-ray fluorescence are not in agreement with a formulation of type $K[Mo(NO)_2(Dtz)_3]$.

According to all the experimental data, the two more possible stereochemistries for the dithizones derivative are $Mo(NO)_2(HDtz)(H_2Dtz)$ or $Mo(II)(NO)_2(Dtz)_2(H_2Dtz)$. The diagmagnetism observed could be consistent with either formula. The ν(NO) values are also in agreement with those corresponding to hexacoordinated molybdenum(O) complexes and with those of heptacoordinated molybdenum(II) complexes of type $Mo(NO)_2(NHO)(NCS)_2(L,L)$ (L,L = bipy or phen) or $[PPh_4][Mo(NO)_2(NHO)(NCS)_4]$,[4] so that it is difficult to distinguish between the possible compounds, although the hydrogen elemental analysis seems to correspond to the molybdenum(O) complex (**4**). The dithizone neutral molecule can act as an S-donor monodentate ligand.

Most metal complexes containing primary dithizonate show an N,S-coordination. In our case the primary dithizone is also probably coordinated as an N,S-ligand (structure **III**).

As mentioned above, the IR spectrum of mononitrosyl complex **4** shows two ν(NO) bands. The separation between the bands of *ca* 120 cm^{-1} can not be attributed to an isomer mixture or to the presence of a symmetrical dimer, but could be due to an asymmetrical dimer with metal atoms in different oxidation states of type $(NO)_2(MeHdtc)Mo(O)(\mu\text{-}MeHdtc)_2Mo(IV)(MeHdtc)_3$. However, in the literature, some examples of monomeric mononitrosyl complexes with two ν(NO) bands have been reported.[23]

The *N*-methyldithiocarbamate derivative $Mo(NO)(MeHdt)_3$ shows a broad ν(NH) band at *ca* 3250 cm^{-1} in the solid-state spectrum, but this vibration appears as a sharp band at higher frequency (*ca* 3450 cm^{-1}) in the solution spectrum (DMSO or acetone). This fact can be attributed to interactions in the solid state between NH groups of different molecules.

The remaining mononitrosyl derivatives show only one NO stretching frequency as expected. The values obtained for this frequency are analogous to those of heptacoordinated molybdenum(II) complexes, $Mo(NO)(R_2dtc)_3$,[1,8] $Mo(NO)(NH_2O)(NCS)_2(L,L)$[4] or $Mo(NO)(NH_2O)(Et_xdtc)_2$.[4]

All nitrosyl complexes prepared of formulae $Mo(NO)_2(X,Y)_2$ and $Mo(NO)(X,Y)_3$ conform to the 18-electron rule, with the NO^+ group and the (X,Y) chelating ligand regarded as a three-electron donor.

The chloroform of crystallization in the $Mo(NO)(X,Y)_3 \cdot \frac{1}{2}CHCl_3$ complexes gives rise to a ν(C—Cl) band at *ca* 750 cm^{-1}.

The ν(C=O) frequencies of all 2-picolinate complexes rule out the existence of interactions through this oxygen atom.

Electronic spectra

Electronic spectra for several products are recorded in DMF or DMSO solution in the 260–900-nm region. Diffuse-reflectance spectra were also measured in the 190–900-nm region. Table 3 summarizes the absorption maxima (λ_{max}), the molar absorptivities values (ε), and a tentative assignment.

We have assigned the spectra on the basis of the data reported by Budge *et al.*[10] and Minelli *et al.*[11] We assign the electronic absorption at 655–800 nm to a transition within the $\{Mo(NO)_2\}^6$ group from the $a_2[d_{xy}, \pi^*(NO)]$ or $b_2[d_{xy}, \pi^*(NO)]$ to the $b_1(\pi^*NO)$ orbital. The more intense absorption at *ca* 450 nm is assigned to a transition from the

$a_1[d_z^2, \pi^*(NO)]$ to the $b_1(\pi^*NO)$ orbital of the $\{Mo(NO)_2\}^6$ group. Our data agree with the results of Minelli *et al.*[11] These authors have emphasized that the ON—Mo—NO angle value is very important so that no interaction between the $b_1(\pi^*NO)$ orbital and the d_{xz} orbital (which also has b_1-symmetry) occurs if this angle is $\simeq 90°$. The value of 87.6(2) found in the case of $Mo(NO)_2(2\text{-pic})_2$ permits the above-mentioned assignment. Likewise the absorption bands at higher energies included $L \leftarrow M$ charge-transfer and/or intraligand transitions.

In the ditizone complexes a high contribution of the ligand bands is present in all maxima observed in the spectrum.

The significant change observed in the solution and solid spectra of complex **3** can be due to the existence of an interaction with the solvent.

Magnetic properties

All the compounds show at room temperature a feeble paramagnetism which can be partially due to a temperature-independent paramagnetism (tip). The corrected molar susceptibilities founded for these compounds are generally higher than those reported for other nitrosyl complexes and are attributed to a tip.[4] However the carbonyl complexes of molybdenum frequently exhibit complicated magnetic properties.[24]

In the case of complex **1**, which exhibits the higher susceptibility values, the susceptibility was measured as a function of field strength at four different temperatures (Table 4) and was found to be dependent of field strength and temperature. However the structural data preclude any spin–spin interaction in this compound.

EXPERIMENTAL

All reagents and solvents required for compound preparation were of analytical grade. Sodium *N*-methyldithiocarbamate was prepared by the method described in the literature.[25] The complexes $Mo(NO)_2(R_2dtc)_2$ (R = Et, R_2 = pyr) were obtained by the method described by Sarkar and Subramanian.[3] C, H and N analysis were carried out by Elemental Microanalysis Ltd Laboratories (Devon, U.K.). Conductance measurements were performed at room temperature using a Philips PW 9506120 conductivity bridge. IR spectra in the 4000–200-cm^{-1} region were recorded on a 325 Perkin–Elmer spectrophotometer, using KBr disks. Electronic spectra were scanned in DMF or DMSO solution on a Kontron Uvikon 820 spectrophotometer. The diffuse-reflectance spectra of the solid compounds were recorded on the same spectrophotometer with the standard Kontron diffuse-reflectance accessory and barium sulfate as reference. Sometimes, the solid samples were slightly diluted with $BaSO_4$. The magnetic susceptibilities were measured by the Faraday method.

Crystal data

$C_{12}H_8MoN_4O_6$, $M = 400.07$, orthorhombic, $a = 12.502(3)$, $b = 15.15(4)$, $c = 15.296(6)$ Å, $U = 2897(8)$ Å^3, $Z = 8$, $D_c = 1.84$ g cm^{-3}, $F(000) = 1584$, space group *Pbca*, μ(Mo-K_α) = 9.23 cm^{-1}.

X-ray data collection

A green prismatic crystal of size $0.3 \times 0.2 \times 0.2$ (**1**) was mounted on a Nonius CAD-4-F diffrac-

tometer. The cell dimensions were refined by least-squares fitting on the θ values of 25 reflexions.

The lower precision achieved in the values of the b parameter could be attributed to a mosaic spread in this direction. The intensities of 2816 unique reflexions with $1 < \theta < 25°$, $hkl(000)$ to (15 18 18), were measured at 295 K with monochromatic Mo-K_α radiation ($\lambda = 0.71069$ Å) and a ω–2θ scan technique. There was no appreciable change in the periodically monitored standard reflexions. The intensities were corrected for Lorentz and polarization effects and 1845 of these were considered as observed by the criterion $I > 2\sigma(I)$. Scattering factors for neutral atoms and anomalous dispersion corrections for atom were taken from *International Tables for X-ray Crystallography* (1974).[26]

Solution and refinement

The heavy atom was located from the three-dimensional Patterson map. The positions of the remaining non-hydrogen atoms were obtained for Fourier synthesis. An empirical absorption[27] and extinction correction was applied at the end of the isotropic refinement. The H atom positions were calculated and included. Final refinement minimizing $\Sigma w[|F_o| - |F_c|]^2$ with fixed isotropic temperature factors and coordinates for H atoms gave $R = 0.025$ and $R_w = 0.027$. No trend in ΔF vs $F_o \sin\theta/\lambda$ was observed. Maximum and average shift/error were 0.59 and 0.07, respectively. Most of the calculations were performed with XRAY76.[28]

Final atomic positional and thermal parameters, bond lengths and angles, and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Preparation of the complexes

$Mo(NO)_2(2\text{-pic})_2$ (**1**) and $Mo(NO)(2\text{-pic})_3$ (**5**). Ammonium heptamolybdate (0.5 g) and hydroxylamine hydrochloride (0.85 g) were heated in 10 cm^3 of DMF at *ca* 90°C for an hour to get a green solution as described in the literature.[3] A suspension of 2-picolinic acid (0.697 g) in 20 cm^3 methanolic KOH (0.65 g) was added and a lemon green solid was formed immediately. The reaction mixture was refluxed in an inert atmosphere for an hour and poured into 100 cm^3 of boiled water. After keeping at *ca* 90°C for 30 min the mixture was allowed to cool, and the precipitate was filtered off. The solid obtained was recrystallized several times from dichloromethane. Two products were obtained, a green solid soluble in CH_2Cl_2, **1**, and a pale yellow solid insoluble in the solvent **5**.

$Mo(NO)_2(o\text{-AP})_2$ (**2**). To the green solution in DMF obtained as described above a solution of *o*-aminophenol (0.68 g) in 30 cm^3 of methanolic KOH (0.65 g) was added and the resulting reddish-brown mixture was refluxed for 1 h in an inert atmosphere. The mixture was allowed to cool and the precipitate formed was filtered off. The filtrate was poured into 150 cm^3 of boiled water saturated with N_2. A green-brown solid appeared after a few minutes. The mixture was stirred as *ca* 90°C for 20 min and then the precipitate was filtered off, washed with water, and dried over P_4O_{10} *in vacuo* for several hours.

$Mo(NO)_2(o\text{-ATP})_2$ (**3**). To the DMF green solution of $[Mo(NO)_2]^{2+}$ obtained as above a solution of *o*-aminothiophenol (0.71 g) in 30 cm^3 of methanolic KOH (0.65 g) was added and the resulting yellow-brown mixture was refluxed for 1 h in an inert atmosphere. Then, it was allowed to cool and the mixture was poured into 150 cm^3 of boiled water saturated with N_2. The brown solid formed was filtered off, washed with water, and dried over P_4O_{10} *in vacuo*. After the addition of $CHCl_3$ (75 cm^3) to the crude product, the mixture was stirred and the solid resulting was filtered off, washed with $CHCl_3$ and MeOH several times, and dried *in vacuo*.

$Mo(NO)_2(HDtz)_2(H_2Dtz)$ (**4**). A solution of dithizone (1.43 g) in 15 cm^3 methanolic KOH (0.65 g) was added to a green solution of $[Mo(NO)_2]^{2+}$. The mixture was refluxed in an inert atmosphere for 1 h and poured into 100 cm^3 of boiled water. A very dark precipitate was formed. After 1 h of stirring at room temperature the violet-purple solid was filtered off, washed with water, and dried over P_4O_{10} *in vacuo*.

$Mo(NO)(MeHdtc)_3$ (**6**). To the green solution containing the $[Mo(NO)_2]^{2+}$ moiety a suspension of $NaMeHdtc \cdot 2.5H_2O$ (0.986 g) in methanol (40 cm^3) was added under N_2. The reddish-brown reaction mixture was refluxed. After 30 min the solvent was partially evaporated at reduced pressure and the mixture was filtered. The filtrate was poured into 150 cm^3 of boiled and degasified water. The orange gel obtained was centrifuged, washed with water, and dried *in vacuo* over P_4O_{10}. The product was recrystallized from MeOH.

$Mo(NO)(pyrdtc)_3 \cdot \frac{1}{2}CHCl_3$ (**7**). The $Mo(NO)_2(pyrdtc)_2$ complex was stirred in $CHCl_3$ and under N_2 for several days. Then the reaction mixture was filtered and the yellow solution obtained was precipitated with light petroleum ether (b.p. 40–60°C). The orange-yellow solid formed was filtered off, washed with light petroleum ether, and dried *in vacuo*.

$Mo(NO)(Et_2dtc)_3 \cdot \frac{1}{2}CHCl_3$ (**8**). The $Mo(NO)_2$

$(Et_2dtc)_2$ complex was stirred in chloroform and under N_2 for 16 h. Then the brown oil and yellow solution formed are separated by decantation. The addition of light petroleum ether (b.p. 40–60°C) gave rise to the formation of a yellow solid, which was filtered off, washed with light petroleum, and dried *in vacuo*. On the other hand, acetone added to the oil gave rise to a brown solid (product mixture) and a yellow solution from which a yellow solid was obtained by precipitation with light petroleum ether. Both the yellow products were identical.

$Mo(2\text{-pic})_3 \cdot H_2O$ (**9**). The reaction was carried out under N_2. Complex **1** and PPh_3 in a 1 : 1 molar ratio were stirred in $CHCl_3$ for 2 days, during which the colour of the solution became topaz. Diethyl ether was added to precipitate an earth-yellow solid, which was filtered off, washed with ether, and dried *in vacuo*. The same reaction in an excess of PPh_3 occurred much more rapidly and the solution became topaz in 1 h.

Reaction of $Mo(NO)_2(pyrdtc)_2$ *with* CO. Carbon monoxide was bubbled through a solution of the complex $Mo(NO)(pyrdtc)_2$ in CH_2Cl_2 at room temperature for 50 min giving rise to the formation of an $Mo_2O_4(pyrdtc)_2 \cdot xCH_2Cl_2$ complex as a crystalline red solid or an orange powder. This solid was filtered off, washed with the CH_2Cl_2, and dried *in vacuo*. The mononitrosyl derivative $Mo(NO)(pyrdtc)_3$ was precipitated from the filtrate by addition of light petroleum ether (b.p. 40–60°C). Sometimes this compound contained traces of the starting dinitrosyl complex.

Abstract—Perchlorate and hexafluorophosphate salts of monomeric [Cu(terpy)(OOCH)(OH_2)]$^+$ and dimeric [Cu(terpy)(OOCR)]$_2^{2+}$ cations (terpy = 2,2′:6′,2″-terpyridine, R = CH_3 or C_2H_5) have been synthesized and characterized by IR, electronic and ESR spectra, and analytical data. Spectroscopic results indicate a five-coordinate, close-to-square pyramidal geometry around the copper(II) ion. The half-field absorption in the $\Delta M_s = 2$ region of powdered X-band ESR spectra has been observed for the dimeric species. The crystal structure of [Cu(terpy)(OOCH)(OH_2)](ClO_4) has been determined by X-ray diffraction methods. The compound crystallizes in the space group $P2_1/c$ with unit-cell dimensions: a = 7.341(3), b = 13.919(2), c = 18.081(3) Å, β = 101.68(3)°, V = 1809(1) Å^3, Z = 4. The structure was refined to R = 0.044, R_w = 0.051.

To design synthetic pathways to systems of desired properties is a growing challenge for inorganic chemists.[1,2] Our current interest in this area is focused on copper(II) chemistry. In addition to understanding the factors determining the conformation around copper(II) in the solid state,[3] we intend to gain insight into the chemical and structural effects that govern exchange-coupling interactions in condensed species.[4] Thus, we have reported the synthesis and characterization of a wide set of pentacoordinated Cu(L_{III})XY complexes (L_{III} = tridentate ligand, X = coordinating anion, Y = coordinating or non-coordinating anion) showing a great structural diversity (including mono-, bi- and polynuclear species). Tridentate rigid "quasi-planar" ligands such as terpy (2,2′:6′,2″-terpyridine),[3–8] paphy (pyridine-2-aldehyde-2′-pyridylhydrazone)[9] and TPT [2,4,6-tris(2-pyridyl)-1,3,5-triazine][10] favour the stacking of [Cu(L_{III})X]$^+$ entities to give dimers or other condensed systems (simple or ladder-like chains), but the ultimate nature of the resulting compound depends mainly not only on the concrete ligand but also on the character of the potentially bridging X anion.

We have now synthesized and characterized a family of carboxylate and terpy-containing copper(II) complexes. The ability and adaptability of simple carboxylates as bridging ligands is well-established.[11]

EXPERIMENTAL

Preparation of the complexes

[Cu(terpy)(OOCH)(OH_2)](ClO_4] (A). Solutions of $CuSO_4 \cdot 5H_2O$ (0.061 g, 0.2 mmol) in water (4

* Author to whom correspondence should be addressed.

cm^3), terpy (0.046 g, 0.2 mmol) in acetone (4 cm^3) and NaOOCH (0.027 g, 0.4 mmol) in water (2 cm^3) were mixed in sequence with stirring. The resulting blue solution was filtered and then $NaClO_4 \cdot H_2O$ (0.12 g, 0.8 mmol) in water (4 cm^3) was added to the filtrate with stirring. Slow evaporation at room temperature yields blue prismatic crystals after several hours. Crystals were separated by filtration, washed with cold water and acetone, and stored in a desiccator over silica gel. Found: C, 42.2; H, 3.1; N, 9.1. Calc. for $C_{16}H_{14}ClCuN_3O_7$: C, 41.8; H, 3.1; N, 9.2%.

[Cu(terpy)(OOCH)(OH_2)](PF_6) (**B**). This blue complex was prepared as described for **A** but using KPF_6 instead of $NaClO_4 \cdot H_2O$. Found: C, 38.1; H, 2.5; N, 8.3. Calc for $C_{16}H_{14}PF_6CuN_3O_3$: C, 38.1; H, 2.8; N, 8.3%.

[Cu(terpy)(OOCMe)]$_2$(ClO_4)$_2 \cdot 2H_2O$ (**C**). A solution of terpy (0.046 g, 0.2 mmol) in acetone (3 cm^3) was added to other of $Cu(OOCMe)_2 \cdot H_2O$ (0.040 g, 0.2 mmol) in water (3 cm^3) with stirring. After filtration of the resulting blue solution, $NaClO_4 \cdot H_2O$ (0.112 g, 0.8 mmol) in water (4 cm^3) was added with stirring and the solution allowed to stand at room temperature. The green-bluish needles which appeared after several hours were separated, washed and stored as above. Found: C, 43.2; H, 3.3; N, 8.8. Calc for $C_{17}H_{16}ClCuN_3O_7$: C, 43.1; H, 3.4; N, 8.9%.

[Cu(terpy)(OOCMe)]$_2$(PF_6)$_2 \cdot 2H_2O$ (**D**). Green-bluish needles of this complex were obtained by the same method as for **C** but using KPF_6 instead of $NaClO_4 \cdot H_2O$. Found: C, 39.6; H, 3.1; N, 8.0. Calc. for $C_{17}H_{16}PF_6CuN_3O_3$: C, 39.4; H, 3.1; N, 8.1%.

[Cu(terpy)(OOCEt)]$_2$(ClO_4)$_2$ (**E**). This anhydrous complex was prepared as described for **A** but using HOOCEt instead of NaOOCH. The resulting blue solution was adjusted to pH = 7 by aqueous NaOH solution and then allowed to stand at 60°C. After several hours, green-bluish needles appeared and were separated from the solution by filtration and treated as above. Found: C, 46.3; H, 3.3; N, 9.0. Calc. for $C_{18}H_{16}ClCuN_3O_6$: C, 46.1; H, 3.4; N, 9.0%.

[Cu(terpy)(OOCEt)]$_2$(PF_6)$_2 \cdot 2H_2O$ (**F**). Green-bluish needles of this complex were obtained in the same way as for **E** but using KPF_6 instead of $NaClO_4 \cdot H_2O$, and allowing to stand the solution at room temperature. Found: C, 40.8; H, 3.3; N, 7.9. Calc. for $C_{18}h_{18}PF_6CuN_3O_3$: C, 40.6; H, 3.4; N, 7.9%.

Physical measurements

IR spectra (KBr pellets) were recorded on a Pye-Unicam SP2000 spectrophotometer. Diffuse-reflectance electronic spectra were registered on a Pye-Unicam SP 180 spectrophotometer. ESR spectra were recorded on a Bruker ER 200D *X*-band spectrometer. Water was determined thermogravimetrically using a Setaram B70 simultaneous TGA-DTA thermobalance.

Crystallographic study

Crystal data of A. Blue prismatic crystals of $C_{16}H_{14}ClCuN_3O_7$, $M = 459.3$, monoclinic, $a = 7.341(3)$, $b = 13.919(2)$, $c = 18.081(3)$ Å, $\beta = 101.68(3)°$, $V = 1809(1)$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.686$ g cm^{-3}, $F(000) = 932$, μ(Mo-K_α) = 14.0 cm^{-1}, λ(Mo-K_α = 0.70926 Å.

Data collection. A well-formed crystal of dimensions $0.14 \times 0.16 \times 0.18$ mm was mounted on an Enraf-Nonius CAD-4 diffractometer equipped with a graphite monochromator. The cell dimensions were obtained by least-squares refinement of 25 well-centered reflections ($22° < 2\theta < 37°$). From systematic absences ($0k0$, k odd; $00l$, l odd; $h0l$, l odd) the space group $P2_1/c$ was assumed. Examination of four standard reflections [(1 7 $\bar{8}$), (0 4 $\bar{10}$), (0 8 0), (0 3 $\bar{9}$)], monitored after each 50 reflections, showed no appreciable intensity decay. 3444 reflections were measured ($2° < 2\theta < 50°$; $-8 < h < 8$, $0 < k < 16$, $0 < l < 21$) with the variable-speed ω-2θ technique, of which 2397 were unique with $I > 2.5\sigma(I)$ and used in the determination of the structure. Lorentz and polarization corrections were applied, but not absorption.

Structure solution and refinement. The position of copper and 15 non-hydrogen atoms were determined by direct methods (MULTAN 11/84).[12] The remaining non-hydrogen atoms were located from successive Fourier syntheses. Refinement of the structure was carried out with the SHELX76 system[13] by weighted anisotropic full-matrix least squares. All hydrogen atoms were located by Fourier difference syntheses and included in the refinement with common fixed isotropic thermal parameters ($U = 0.059$ Å^2). The perchlorate anion is disordered. A difference map calculated at this stage revealed four minor O sites around the central Cl. A model with eight O sites and two sets of complementary occupancies was introduced. The oxygen atoms with minor occupancy factor were isotropically refined and a value of 0.14 was obtained for this parameter. The final R values were $R = 0.044$ and $R_w = 0.051$ (237 parameters refined). $\Sigma w(|F_o| - |F_c|)^2$ minimized with $w = 1/(\sigma^2(F_o) + 0.01455F_o^2)$ with $\sigma^2(F_o)$ from counting statistics. In the final difference map the residual maxima were less than 0.60 e Å^{-3} except for one peak (1.25 e Å^{-3}) around the perchlorate

anion. Atomic scattering factors and corrections for anomalous dispersion for the copper atom were taken from *International Tables for X-ray Crystallography*.[14] The geometrical calculations were performed with XANADU[15] and DISTAN,[16] and molecular illustrations were drawn with PLUTO.[17] Final atomic coordinates, thermal parameters and F_o/F_c values have been deposted with the Editor as supplementary data. Atomic coordinates have also been deposited with the Cambridge Crystallostallographic Data Centre.

RESULTS AND DISCUSSION

Significant aspects guiding the synthetic strategies have been previously reported.[10] Molecular formulae have been written considering all the structural information available (see below). Except for **A**, the thermal dehydration step occurs as a one-stage endothermic process. In the case of **A**, this first step seems more complex, showing an exothermic component. The weight loss involved fits to the evolution of 1 mol CO_2 overlapping with H_2O removal, and the DTA temperature peak is relatively high (see Table 1).

Assignments of the more relevant IR spectral bands in the complexes are listed in Table 1. Bands due to terpy ligand and counterions are not discussed. Notwithstanding, it must be stressed that in no case the bands proper of ClO_4^- and PF_6^- regular groups appear split. We conclude that both anions act as non-coordinating groups.[18] From the data in Table 1 some facts are noteworthy: (1) in both formate complexes, bands assignable to ν_{as}(COO) and ν_s(COO) are located at 1600 and 1330 cm^{-1} ($\Delta\nu = 270$ cm^{-1}), respectively. However, these bands appear around 1580 and 1410 cm^{-1} ($\Delta\nu$ *ca* 170 cm^{-1}) in the remaining complexes spectra (2) Likewise, only the spectra of the formate complexes display a weak band at 425–430 cm^{-1}, which can be associated to Cu—O(water) stretching vibrations.[19] These facts argue in favour of: (1) a different carboxylate coordination mode in formate complexes with respect to the others. Thus, $\Delta\nu$ values are consistent with monodentate formate and bidentate (chelating or bridging) acetate and propionate;[11,20] (2) when considering the anhydrous character of **E**, the lack of ν(Cu—O) in the spectra of **C**, **D** and **F** suggests that water molecule occupies a coordination site only in the formate complexes. However, in all cases, the main component of ν(O—H) band is centered about 3410 cm^{-1}. It can be thought that water is involved in hydrogen bonds of medium strength.[21] This might explain why lattice water removal **C**, **D** and **F** also requires moderately high temperatures (Table 1).

The reflectance electronic spectra of all the solids studied exhibit one broad unresolved band centred around 15,300 cm^{-1} (Table 1). Our previous results on related systems[3–8] indicate that the rigid terpy ligand favours geometries close to square pyramidal around copper(II). This contention is also consistent in the present case and the position of the intensity maximum in the absorption envelope agrees with the Hathaway observations for $[CuN_3O_2]$ chromophores.[22]

X-band ESR spectra of polycrystalline samples show axial-type signals which remain unchanged from room temperature down to 125 K (Fig. 1). The ESR line shapes, leading to $g_\parallel = 2.23$–$2.25 > g_\perp = 2.06$ (Table 1) points towards a mainly copper(II) $d_{x^2-y^2}$ orbital ground state, a result which agrees with the above statements. In addition, it must be noted the appearance at half-field values (i.e. in the $\Delta M_s = 2$ forbidden transition region) of a new weak absorption (Fig. 1, Table 1) in the spectra of the acetate and propionate complexes. This signal implies a magnetic interaction between two copper(II) ions and supports unequivocally the presence of dimeric entities in these complexes (**C**–**F**). IR, visible and ESR spectra data become coherent here, assuming a molecular structure similar to that schematized in Fig. 2 in which the [Cu(terpy)(OOCR)]$^+$ moieties are linked through bidentate bridging carboxylate groups to give the dimeric pentacoordinated unities. Lacking X-ray structural

data (attempts to grow suitable crystals have been not successfully up to date) an *anti–syn* carboxylate coordination mode has been assumed (as the more likely) for pictorial purposes only.

Now, the absence of the $\Delta M_s = 2$ signal in the ESR spectra of the formate complexes may be related to the monodentate character of the carboxylate groups shown by IR. Thus, it has been previously noted that copper(II) formate and its adducts are reluctant to adopt the binuclear copper(II) acetate type structure (which is also found in the higher alkanoates).[11] This behaviour has been associated to the low σ-electron donor efficiency of the $HCOO^-$ group which generally leads to polymeric complex structures.[11] In our case, monodentate formates might yield mononuclear or polymeric (containing mono-oxo-bridging formate anions) species. Although the probable coordination to copper of the water molecule points towards a monomeric formulation for these complexes, the question remains open at this stage. This fact and the availability of single crystals of **A** suitable for X-ray study lead us to approach its structural resolution.

Figure 3 shows a perspective view of the $[Cu(terpy)(OOCH)(OH_2)]^+$ cation with the detailed labelling of the atoms, and Fig. 4 shows a stereoscopic view of the unit cell. Significant bond distances and angles are given in Table 2. The coordination sphere of copper(II) is best described as a square pyramid. The basal positions are occupied by the three nitrogen atoms from the terpy ligand and an oxygen atom of the monodentate formate anion [Cu—N(1) = 2.030(4), Cu—N(2) = 1.947(4),

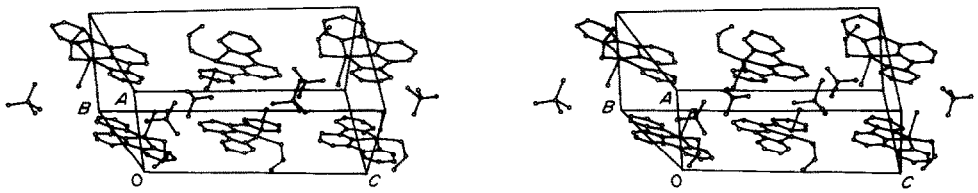

Fig. 4. Stereoscopic view of the unit cell for complex **A**.

Cu—N(3) = 2.056(4), Cu—O(2) = 1.935(3) Å], while the apical site is occupied by the oxygen atom from the water molecule [Cu—O(1) = 2.247(3) Å]. The basal atoms are coplanar within ±0.02 Å and the copper atom is displaced 0.15 Å from the mean plane. The terpy ligand is planar within ±0.13 Å and the plane through the atoms Cu, O(1) and O(2) makes an angle of 87.9° with the basal mean plane. If the second oxygen atom of the formate anion is considered as "semicoordinated"[22] [Cu—O(3) = 2.815(4) Å] the environment of the copper would be described as an elongated and strongly distorted octahedron [the O(2)—Cu—O(3) angle is 51.9(1)°]. This kind of coordination has been also found in other carboxylate, nitro and nitrite copper(II) complexes.[2,22,23]

The interatomic distances and angles in the terpy ligand are in agreement with those found in previously described complexes.[4,7,23,24] As predicted above, the formate group is asymmetric [C(16)—O(2) = 1.266(6) and C(16)—O(3) = 1.237(5) Å] as a consequence of the polarization of the charge density towards the metal-bonded oxygen atom.

The structure of **A** (Fig. 4) consists of double layers which are parallel to the "*bc*" plane. These double layers are built up with pairs of $[Cu(terpy)(OOCH)(OH_2)]^+$ units related by an inversion center; perchlorate anions occupy interlayer empty spaces. Crystal packing of the layers is achieved by intermolecular hydrogen bonding between the water molecule and the "semicoordinated" oxygen atom from the formate anion [O(1)—O(3)′ = 2.699(5) Å, O(1)—H(w2)—O(3)′ = 171(5)°] giving infinite chains $\cdots H_2O—Cu—O—C—O—H_2O—Cu\cdots$ along the (1 0 0) direction [O(3)′ from O(3) after $1+x, y, z$]. The water molecule is also involved in another hydrogen bond with an oxygen atom from the perchlorate anion [O(1)—O(5) = 3.039(4)Å; O(1)—H(w1)—O(5) = 168(3)°].

Based on the results reported, a similar structure can be expected for **B**. Only the hydrogen-bonding scheme must differ from its perchlorate analogue, and this might lay behind the difference observed in the dehydration step.

Lastly, dealing with exchange interactions, we note (Table 1) that the $G = g_{\parallel} - 2/g_{\perp} - 2$ parameter value is near to 4 even for the dimeric species, indicating that exchange interactions are weak.[22] This result is not surprising if the actual geometry of the dimers is that proposed above. The effective overlap between the magnetic orbitals involved in the entity would be very poor.[3–8] Furthermore, bridging carboxylates provide in general a poor support to propagation of the exchange interactions except when the structural function is *syn–syn*, as in the copper(II) acetate.[11]

Accordingly, further structural and magnetic studies could play a key role improving the understanding of the factors controlling exchange-coupling interactions, and are in progress.

THE PREPARATION AND USE OF DISULPHURDINITRIDO COMPLEXES: THE X-RAY STRUCTURE OF $[PPh_4][S_3N_3]$

RAY JONES, PAUL F. KELLY, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

(*Received* 4 *November* 1986; *accepted* 23 *January* 1987)

Abstract—The preparation of $M(S_2N_2)(PR_3)_2$ (M = Pd or Pt) (**1**) complexes by reaction of $MCl_2(PR_3)_2$ with $S_4N_4H_4$ in the presence of diazabicycloundecane is described. A variety of other reagents also give rise to **1**; in particular S_4N_4–BuLi. The reactive intermediate in the latter case appears to be $S_3N_3^-$ which has been characterized by X-ray crystallography as the PPh_4^+ salt: tetragonal, space group $P\bar{4}$, $a = 17.579(5)$, $c = 7.447(2)$ Å. The protonation of **1** to $[M(S_2N_2H)(PR_3)_2]X$ ($X = Cl^-$ or BF_4^-) and the use of **1** in the preparation of S_3N_2O is reported.

Metalla-sulphur–nitrogen chemistry provides access to a number of unusual compounds.[1–3] Apart from the potentially interesting solid-state properties of the stacking compounds[4] many complexes stabilize otherwise unknown anionic sulphur–nitrogen species such as $S_2N_2^{2-}$ and $S_2N_2H^-$. A number of synthetic strategies have been employed in the preparation of $Pt(S_2N_2)(PR_3)_2$ (**1**) and $[Pt(S_2N_2H)(PR_3)_2]X$ ($X = PF_6^-$) complexes. For example, in **1** when $PR_3 = PPh_3$ reaction of $Pt(PPh_3)_3$ with $S_4N_4H_4$ is satisfactory.[5] However this method is not readily extended to other systems. We have successfully used $Na(S_3N_3)$ [eqn (1)]:

$$PtCl_2(PR_3)_2 + 2Na(S_3N_3) \rightarrow Pt(S_2N_2)(PR_3)_2 + S_4N_4 + 2NaCl. \quad (1)$$

but this salt is air-sensitive and **extremely explosive**; clearly an alternative is preferable.

Reaction of $[Me_2Sn(S_2N_2)]_2$ with $PtCl_2(PR_3)_2$ in the presence of $[NH_4][PF_6]$ provides a useful route to **2** but the tin reagent is moderately air-sensitive and probably toxic. We have been investigating alternative routes to **1** and **2**. Here we report on the use of $S_4N_4H_4$–dbu (dbu = diazabicycloundecane) and S_4N_4–RLi as reagents. Both can be reacted with *cis*-$PtCl_2(PR_3)_2$ to give **1**. In the case of S_4N_4–RLi reactions one of the reactive intermediates is the $S_3N_3^-$ anion and the crystal structure of its tetraphenylphosphonium salt is reported. Protonation reactions for the conversion of **1** into **2** are described. The usefulness of **1** as a source of S_2N_2 in ring syntheses has also been studied.

EXPERIMENTAL

General reaction conditions, drying of solvents, preparation of starting materials and spectroscopic measurements were as described previously.[6]

$Pt(S_2N_2)(PMe_2Ph)_2$

To a suspension of $S_4N_4H_4$ (20 mg, 0.1 mmol) in a CH_2Cl_2 (10 cm^3) solution of *cis*-$PtCl_2(PMe_2Ph)_2$ (110 mg, 0.2 mmol) was added excess dbu (six drops). The colourless solution gradually turned pale yellow and the $S_4N_4H_4$ started to dissolve. After 10 min the reaction was a golden yellow colour with only a trace of $S_4N_4H_4$ undissolved. At this point additional dbu (two drops) was added and the reaction was stirred for a further 90 min. The CH_2Cl_2 was removed *in vacuo* leaving an oily pale yellow solid which was washed with degassed water (2×60 cm^3), and then dried *in vacuo*. The final product was obtained as a pale yellow/off white solid by extraction with CH_2Cl_2 followed by precipitation using hexane. Yield 90 mg (79%). The product had indistinguishable IR and ^{31}P NMR properties from those previously reported.[7]

$Pt(S_2N_2)(PEt_3)_2$ *and* $Pt(S_2N_2)(PPh_2Me)_2$

Reactions performed on a ^{31}P NMR scale gave the same products as those previously reported.[7]

* Author to whom correspondence should be addressed.

$Pd(S_2N_2)(PR_3)_2$ (PR_3 = PEt_3, PMe_2Ph, PPh_2Me *or* PPh_3)

Reactions were performed as described for $Pt(S_2N_2)(PMe_2Ph)_2$ but using *trans* or *cis*/*trans* mixtures of the palladium complexes.

For $PR_3 = PMe_2Ph$: Found: C, 40.1; H, 4.5; N, 5.8. Required: C, 40.5; H, 4.7; N, 5.9%. IR: ν(NS) 1070(vs), 605(w) cm^{-1}. $^{31}P-\{^1H\}$: δ −3.8, −9.2 ppm; ^2J = 41.5 Hz.

For $PR_3 = PEt_3$: Found: C, 31.8; H, 6.6; N, 6.6. Required: C, 33.1; N, 6.9; H, 6.4%. IR: ν(NS) 1074(vs), 671(m), 605(w), δ(NS)/ν(PdS) 443(w), 348(w) cm^{-1}. $^{31}P-\{^1H\}$: δ 16.5, 22.5 ppm; ^2J = 37 Hz.

For $PR_3 = PPh_2Me$: $^{31}P-\{^1H\}$: δ 7.9, 11.5 ppm, ^2J = 39 Hz; product not isolated.

For $PR_3 = PPh_3$: reaction did not proceed as for other phosphines. No AX ^{31}P NMR spectrum was observed.

$[Pd(S_2N_2)(PPh_3)]_2$ precipitated out of the reaction mixture.

$[M(S_2N_2H)(PR_3)_2]X$

X = BF_4^-. To a suspension of **1** in thf (0.1 mmol in 10 cm^3) was added $Et_2O \cdot BF_3$ (Aldrich, two drops). Initially **1** dissolved giving an intense green-yellow solution, and after further stirring some precipitate appeared. The volume of thf was reduced *in vacuo* and diethyl ether added to precipitate **2**. The product may be purified by crystallization from Et_2O–CH_2Cl_2. In this way analytically pure $[Pt(S_2N_2H)(PMe_2Ph)_2][BF_4]$ is obtained. In the case of palladium complexes for $PR_3 = PEt_3$: $^{31}P-\{^1H\}$: δ 20.6, 23.9 ppm; ^2J = 29 Hz. $PR_3 = PMe_2Ph$: IR: ν(NH) 3300 cm^{-1}. $^{31}P-\{^1H\}$: δ −3.9, −5.4 ppm; ^2J 34 Hz.

X = Cl^-. To a suspension of $Pt(S_2N_2)(PMe_2Ph)_2$ in thf (0.1 mmol in 10 cm^3) was added a few drops of HCl-saturated CH_2Cl_2. The solvent was removed under *in vacuo* and the gummy solid triturated with hexane. Filtration, extraction of the solid into thf and removal of solvent *in vacuo* gave a green oily solid. The crystalline product was obtained by slow diffusion of hexane into a CH_2Cl_2 solution. Yield 0.08 mmol (80%). Found: C, 29.7; H, 3.5; N, 4.0. Required for $[Pt(S_2N_2H)(PMe_2Ph)_2]Cl \cdot CH_2Cl_2$: C, 29.8; H, 3.7; N, 4.1%. NB: the ^{31}P NMR of the initial crude reaction shows *ca* 20% *cis*-$PtCl_2(PMe_2Ph)_2$ as the side product. No attempt was made to recover this material.

Preparation of S_3N_2O

$Pt(S_2N_2)(PMe_2Ph)_2$ (56 mg, 0.1 mmol) in CH_2Cl_2 (10 cm^3) was treated with excess $SOCl_2$ (two drops) with stirring under N_2. The solution immediately changed from golden yellow to light orange. After stirring for 1 min the solvent was removed *in vacuo*. The resulting red oil was extracted into CH_2Cl_2 (1 cm^3) and this solution chromatographed (Kieselgel 60 Prep. plate) using CH_2Cl_2 as the eluant. The band at R_f = 0.65 was extracted from the silica using CH_2Cl_2 and after removal of this solvent the product was further purified by vacuum sublimation onto a liquid nitrogen cold finger (bath temperature 60°C). Yield 5 mg (35%). IR: 1125(s), 985(m), 912(m), 740(m), 670(m), 510(m) cm^{-1}.

$[PPh_4][S_3N_3]$

A solution of S_4N_4 (0.28 g, 1.5 mmol) in thf (20 cm^3) was treated with ^{n}BuLi [0.56 cm^3, 2.7 M (Aldrich), 1.5 mmol]. The reaction immediately went dark red. The thf solution was reduced *in vacuo* and treated with hexane (50 cm^3) giving an orange-red precipitate. After filtration and drying the remaining solid was extracted into thf and solid $[PPh_4]Cl$ (0.56 g, 1.5 mmol) added. CH_2Cl_2 was added until most of the $[PPh_4]Cl$ had dissolved and the solution was filtered. After standing for a few minutes a yellow solid precipitated. Enough CH_2Cl_2 to dissolve this solid was added and hexane was layered on the resulting red solution. The product was obtained as large orange crystals. Found: C, 59.5; H, 3.4; N, 8.3. Calc. C, 60.4; H, 4.2; N, 8.8%.

X-ray structural analysis of $[PPh_4][S_3N_3]$

Crystal data: $C_{24}H_{20}N_3PS_3$, orange tetragonal sphenoidal crystals, tetragonal, a = 17.579(5), c = 7.447(2) Å, U = 2230 $Å^3$, space group $P\bar{4}$, Z = 4, M = 477.6, D_c = 1.38 g cm^{-3}, μ(Cu-K_α) = 37 cm^{-1}.

Measurements. Crystal dimensions 0.5 × 0.2 × 0.2 mm. Refined unit-cell parameters were obtained by centring 14 reflections on a Nicolet R3m diffractometer, 1807 independent reflections ($\theta \leqslant 58°$) were measured with Cu-K_α radiation (graphite monochromator) using the ω-scan measuring routine. Of these 1652 had $|F_o| > 3\sigma(|F_o|)$, and were considered to be observed. Lorentz, polarization and an analytical absorption correction based on indexed faces were applied.

Structure analysis. The structure was solved by a combination of the heavy-atom method and ΔE map recycling. The positions of the phosphorus atoms, one on the two-fold axis at [(0, $\frac{1}{2}$, z)] and the other two on the $\bar{4}$ special positions [(0, 0, $\frac{1}{2}$) and ($-\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$)] were determined from the Patterson map. The positions of all the other non-hydrogen atoms

were determined by successive ΔE map recycling. The non-hydrogen atoms were refined anisotropically. The hydrogen atom positions were idealized (C—H = 0.96 Å) assigned isotropic thermal parameters [$U(H) = 1.2U_{eq}(C)$] and allowed to ride on their parent carbons.

Refinement was by block cascade full-matrix least squares to $R = 0.063$, $R_w = 0.074$ [$w^{-1} = \sigma^2(F) + 0.0011F^2$]. The chirality of the structure was established by refinement of a free variable (η) which multiplies all f'' values. This variable converged to a value of 1.1(1). Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[8]

Final atomic coordinates, including those of the hydrogen atoms, and thermal parameters have been deposited with the Editor as supplementary data. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

It has been recognized for several years[9] that the S_4N^- anion is in equilibrium with S_7N^- formed by deprotonation of S_7NH [eqn (2)]:

$$S_7N^- = S_4N^- + \tfrac{3}{8}S_8 = S_3N^- + \tfrac{1}{2}S_8. \qquad (2)$$

and we have made use of this equilibrium in the preparation[10] of $AuCl_2(S_3N)$. Surprisingly, reaction of the S_3N^- anion with group VIII metal chlorides gives complexes containing the $S_2N_2H^-$ ligand and this, together with the results of our studies (*vide infra*), suggests the involvement of anions such as $S_2N_2^{2-}$ in solution reactions of a number of sulphur–nitrogen compounds.

Since the deprotonation reaction of S_7NH provides a useful route to M–S–N complexes we have investigated the reactivity of $S_4N_4H_4$ in the presence of the base dbu. Thus treatment of *cis*-$PtCl_2(PR_3)_2$ or *trans*-$PdCl_2(PR_3)_2$ with $S_4N_4H_4$–dbu yields $M(S_2N_2)(PR_3)_2$ (**I**) in good yield [eqn (3)]:

$$2MCl_2(PR_3)_2 + S_4N_4H_4\text{–dbu} \rightarrow 2M(S_2N_2)(PR_3)_2 + 2\text{dbuHCl}. \qquad (3)$$

(NB: only demonstrative examples were isolated; the generality of the reaction was established by ^{31}P NMR). The new palladium complexes gave satisfactory NMR, IR and microanalytical data. An interesting feature of the reaction is the formation of an intermediate compound, observed by ^{31}P NMR (Fig. 1), with $\delta = -13.8$ and -23.0 ppm and $^1J(Pt–P) = 3658$ and 2987 Hz. Attempts to isolate this intermediate were unsuccessful; it is also observed from reaction of dbu with *cis*-$PtCl_2(PR_3)_2$ and the NMR data suggests a complex with two phosphine, one chloro and one dbu ligand. This is somewhat

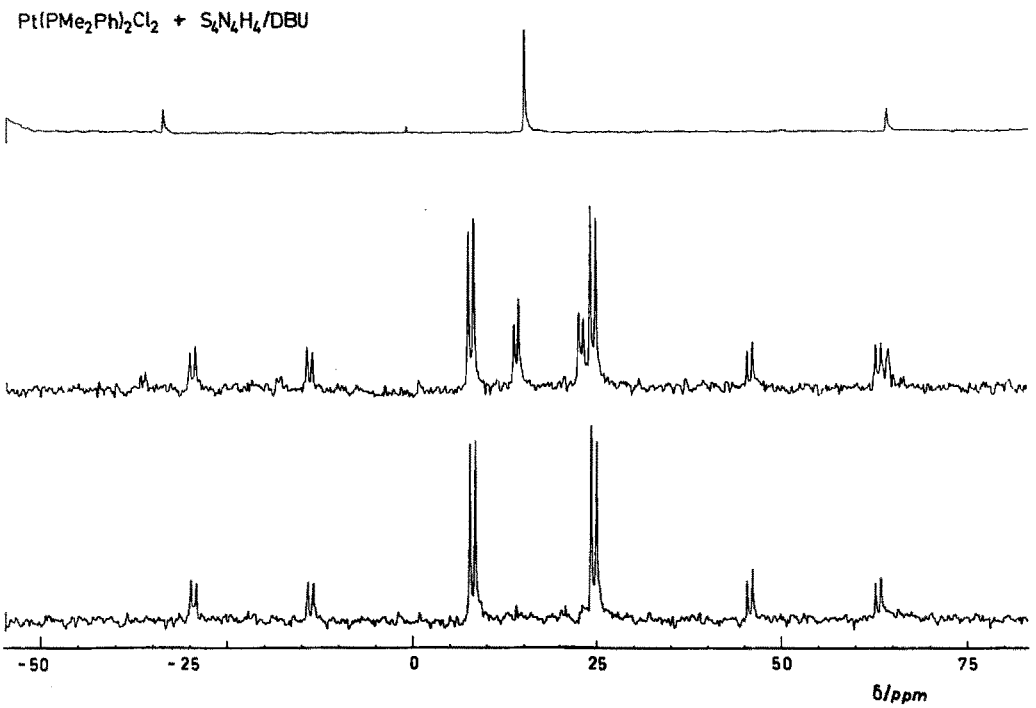

Fig. 1. ^{31}P–{^1H} NMR of the reaction of *cis*-$PtCl_2(PMe_2Ph)_2$ with $S_4N_4H_4$ and dbu. Upper trace shows starting material, middle trace shows $Pt(S_2N_2)(PMe_2Ph)_2$ and intermediate believed to be *cis*-$PtCl(dbu)(PMe_2Ph)_2$, lower trace is after addition of additional dbu.

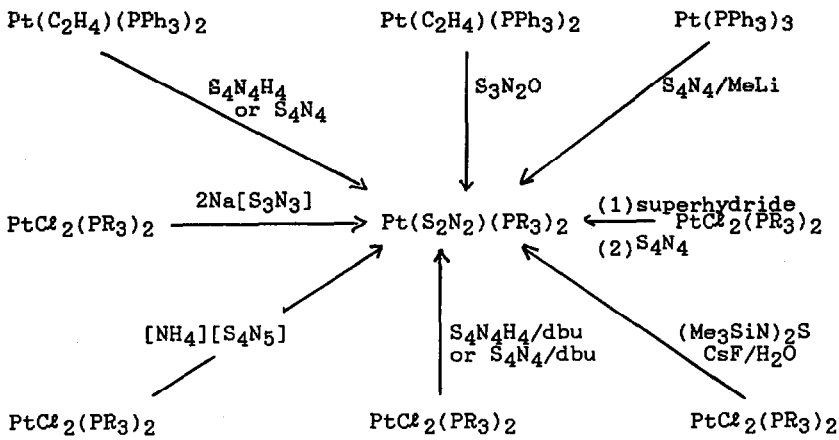

Scheme 1. Reactions in which $Pt(S_2N_2)(PR_3)_2$ is a major product. Note that in some cases the results are from ^{31}P NMR only.

surprising since dbu is considered to be a non-nucleophillic base.

The mechanism of the reaction in eqn (2) is not immediately obvious and two observations appear to rule out a simple equilibrium process involving $S_2N_2^{2-}$. Firstly, the reaction is extremely clean (Fig. 1) with all of the $S_4N_4H_4$ eventually being complexed as $S_2N_2^{2-}$; in other studies[7] on $S_3N_3^-$ we always observed the formation of S_4N_4. Secondly, unlike many of the reactions involving SN species no major colour changes are seen; these would be expected if species such as S_3N^- were involved. It is possible that the reaction proceeds via co-ordination of $S_4N_4H_4$ followed by elimination of HCl to give $Pt(S_4N_4H_2)(PR_3)_2$ which is then attacked by $PtCl(dbu)(PR_3)_2$ to give two molecules of $[Pt(S_2N_2H)(PR_3)]Cl$; this will be deprotonated by dbu to yield **1**.

We have also observed disulphurdinitrido complexes from a number of other routes and these are summarized in Scheme 1. One particularly interesting reaction is that of S_4N_4 with BuLi; a very reactive species is formed. We thought it possible that the intermediate might be $S_2N_2^{2-}$ and thus attempted to crystallize it using $[PPh_4]Cl$. Surprisingly, the product obtained is $[PPh_4][S_3N_3]$, identified by X-ray crystallography, IR and microanalysis. The crystal structure (Fig. 2, Table 1) reveals the expected planar ring for the anion with similar bond distances and angles to those reported for the $[(n\text{-}C_4H_9)_4N]^+$ salt.[11] We do not believe that the variation in S—N bond distances in the ring are a consequence of anion–cation interactions in the solid state as all of the inter-ion distances are con-

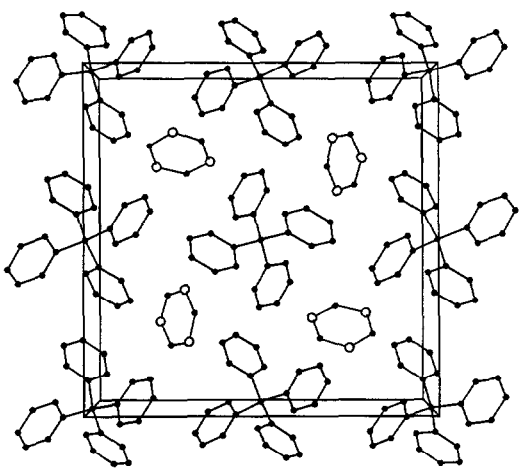

Fig. 2. X-ray structure of $[PPh_4][S_3N_3]$ viewed down the crystallographic *c*-direction. The sulphur atoms are depicted as open circles.

Table 1. Selected bond distance (Å) and angles (°) for $[PPh_4][S_3N_3]$

S(1)—N(1)	1.641(9)	S(1)—N(3)	1.566(8)
S(2)—N(1)	1.601(10)	S(2)—N(2)	1.609(7)

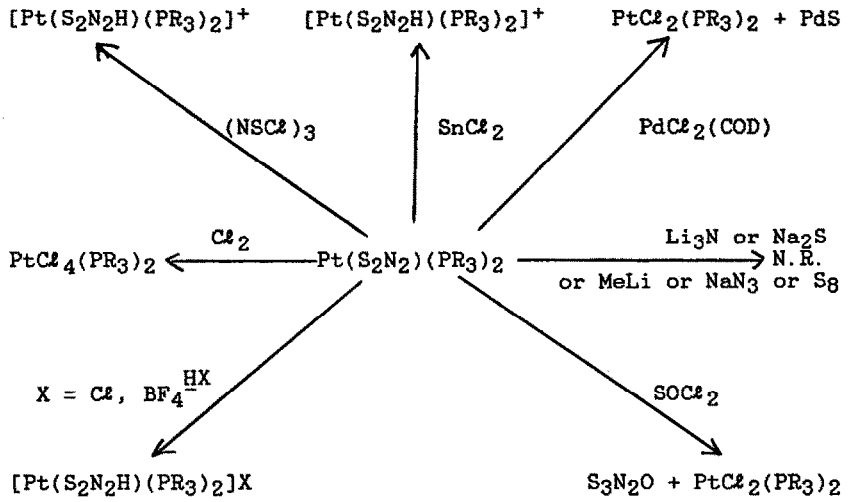
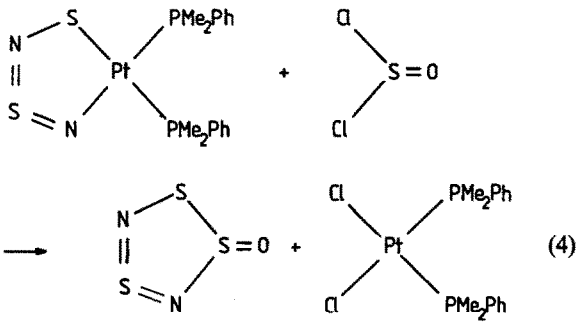


Scheme 2. Reactions of $Pt(S_2N_2)(PR_3)_2$.

sistent with the van der Waals' radii. In contrast to the PPh_4^+ salt reported here and the $[(n\text{-}C_4H_9)_4N]^+$ salt[11] the S—N distances of the $S_3N_3^-$ anion in $Tl_2[S_3N_3][S_4N_5]$[12] show no significant variation.

The wide variety of circumstances in which we have observed $S_2N_2^{2-}$ complexes suggests that this anion is an important species in sulphur–nitrogen chemistry although it may be unstable. The platinum centre appears to be particularly appropriate for trapping and stabilizing the disulphurdinitrido group. The complexes reported here are all reasonably air-stable both as solids and in solution.

The protonation of **1** is readily accomplished using HCl or HBF_4, enabling the isolation of **2** which have stacking structures with columns of cations and anions. Other reactions of **1** are shown in Scheme 2. The majority of the reactions were followed by ^{31}P NMR but we have been able to isolate S_3N_2O by the reaction with $SOCl_2$ [eqn (4)]:



(4)

Reaction of **1** with S_2Cl_2 in attempts to prepare S_4N_2 is less satisfactory; the product decomposing during workup. In the preparation of S_3N_2O the starting *cis*-$PtCl_2(PR_3)_2$ is recyclable and thus **1** appears to have potential as a reagent in the synthesis of sulphur–nitrogen heterocycles.

Acknowledgement—We are grateful to Johnson Matthey for loans of precious metals.

Abstract—Tetraethylammonium bis(1,1-dicyanoethene-2,2-diselenolato)oxotechnetate(V) has been prepared from Tc(V) gluconate and characterized by single-crystal X-ray structural analysis ($R = 0.064$). In the complex the technetium atom is centred in an approximate square pyramid in which the four selenium atoms form the basal plane and the oxygen is at the apex. The Tc—Se distances average 2.471(4) Å, while Tc=O is 1.67(2) Å.

The widespread use of the nuclide ^{99m}Tc (γ-emitter, γ-energy: 140 keV, $t_{1/2} = 6$ h) in the diagnostic nuclear medicine[1–3] has strongly stimulated the development of the coordination chemistry of technetium. Using the long-lived isotope ^{99}Tc (β^--emitter, $E_{max} = 0.29$ MeV, $t_{1/2} = 2.1 \times 10^5$ years) a series of technetium complexes has been prepared and characterized[4] including oxidation states of the metal from "0" up to "+7".

Oxotechnetium(V) complexes have been studied by X-ray analysis with O-, S-, N- and P-donor atom ligands,[5,6] as well as tetrachlorooxotechnetate(V), $TcOCl_4^-$.[7] Here, the first report dealing with the X-ray structure of a technetium complex with selenium coordinated tetraethylammonium bis(1,1-dicyanoethene - 2,2 - diselenolato)oxotechnetate(V) is presented.

EXPERIMENTAL

Potassium 1,1-dicyanoethene-2,2-diselenolate can be prepared from malonitrile and carbon diselenide by literature procedures.[8] All other reagents were analytical grade.

Synthesis of tetraethylammonium bis(1,1-dicyanoethene-2,2-diselenolato)oxotechnetate(V)[9]

A solution of 330 mg (1.1 mmol) potassium salt of the ligand in water (2 cm^3) was added dropwise to a solution of Tc(V) gluconate[10] (0.5 mmol) at pH 6–7. After addition of 0.5 cm^3 of a saturated Et_4NBr solution and cooling, a yellow brown powder was precipitated and collected by suction filtration. Recrystallization from acetone–*i*-propanol gave large brown crystals (175 mg, yield 49% based on Tc). M.p. = 182–184°C. (Found: C, 26.7; H, 2.7; N, 9.3; Se, 44.3; Tc, 13.8. Calc. for $(Et_4N)TcO$-

*Structure determination and crystal data**

The collection of X-ray data was carried out at room temperature on an automatic Philips PW 1100 diffractometer, using Mo-K_α radiation ($\lambda = 0.7107$ Å). A summary of the crystallographic data is given in Table 1. An experimental absorption correction based on Ψ scans[11] of three reflections at $\chi = 90°$ was applied to the intensities. Most of the calculations were carried out in the SHELX-76 system.[12]

Relevant bond lengths and angles are contained in Table 2, and the molecular structure and labelling are reported in Fig. 1.

* Final positional thermal parameters, a list of all bond lengths and angles, a table of some geometrical features (least-square planes, torsion angles and interatomic contacts) and a list of the observed and calculated structure factors have been deposited as supplementary materials with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Preparation and spectroscopical behaviour

Tc(V) gluconate[10] has been shown to be a useful precursor for the preparation of technetium oxo complexes. Reaction with 1,1-dicyanoethene-2,2-diselenolate yields a complex anion of the type $[TcO(ligand)_2]^-$, as previously reported for a series of dithiolato ligands,[10,13] which can be isolated in form of its salts with large cations (e.g. tetraethylammonium).

The complex, which represents the first coordination compound of technetium with a $TcOSe_4$ coordination sphere, yields brown crystals, easily soluble in organic solvents like acetone and dichloromethane. In the IR spectrum the typical Tc=O stretching frequency can be observed as an intense band at 965 cm^{-1}. A comparison with the bands in corresponding Tc=O complexes with the stepwise sulphur substituted ligands 1,1-dicyanoethene-2,2-thioselenolate, $[SSeC{=}C(CN)_2]^{2-}$, and 1,1-dicyanoethene-2,2-dithiolate, $[S_2C{=}C(CN)_2]^{2-}$, shows a bathochromic shift depending on the number of selenium atoms in the coordination sphere (see Table 3).[9] The same holds true for the electronic spectra

as outlined in Table 3, probably caused by the lowering of the ligand field strength by the selenium donors with respect to sulphur. Similar results have been found studying various transition-metal complexes with dichalcogenocarbamates[14] including nitridotechnetium(V) complexes with these ligands[15] and dichalcogenophosphinates.[16]

X-ray analysis

The structure of $(Et_4N)TcO(Se_2C{=}C(CN)_2)_2$ contains well-separated anions and countercations, as shown in Fig. 1. This X-ray analysis confirms the square pyramidal geometry typical of mono-oxo Tc(V) compounds; the tetrahedral tetraethylammonium ion has no unusual features and is not further discussed. In the oxotechnetium anion the four selenium atoms on the base lie roughly in a plane, with the Tc atom 0.88 Å above it, towards the "yl" oxygen atom. The fifth bond, Tc=O, is approximately perpendicular to this plane and its distance of 1.67 Å is similar to that in other mono-oxo technetium complexes.[6] Two features of the structure are worthy of note. Firstly, there appears no prior report of a Tc—Se bond length. The four Tc—Se bond distances are in very close agreement with each other, with a mean value of 2.471 Å. The bond is longer by 0.15 Å than the mean Tc—S value in five-coordinate TcO^{3+} complexes.[17] However, this lengthening is to be expected on the basis of the different covalent radii of Se and S (1.17 and 1.04 Å, respectively).[18] The values for the Se—C bond lie in the narrow range 1.89–1.92 Å, which compares well with the values in the literature,[19] and seems to be normal for a Se—C (sp^2) distance.

Secondly, there is something remarkable about the C=C bond length in the selenolate ligands. In fact, the C(1)—C(2) and C(5)—C(6) lengths [1.32(3) and 1.41(3) Å, respectively] are different and there is no apparent reason for such a difference. A slight mispositioning of C(2) and C(6) atoms could be attributable to anisotropy, but introduction of anisotropic thermal parameters for all the atoms of the anion and/or application of a weighting scheme based on statistics counting did not improve the model (R index lowered to 0.063, but with 199 variables). If we assume the average value (1.36 Å), it parallels those found in $[Ni(Se_2C{=}C(CN)_2)_3]^{3-}$[20] and $[Ni(SeSC{=}C(CN)_2)_2]^{2-}$.[21]

Acknowledgement—We thank Dr W. Dietzsch (Karl-Marx-University, Leipzig) for providing us with the selenium-containing ligands.

SYNTHESIS AND REACTIVITY OF COMPOUNDS OF FORMULA W(S)(OR)$_4$

M. H. CHISHOLM,* J. C. HUFFMAN and J. W. PASTERCZYK

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 5 *January* 1987; *accepted* 23 *January* 1987)

Abstract—In ethereal solutions, $WSCl_4$ and 4 equiv LiOR (R = Bu^t or Pr^i) react to form compounds of formula W(S)(OR)$_4$. A single-crystal X-ray diffraction study of W(S)(OBu^t)$_4$ showed it to have a square-based pyramidal geometry with an apical sulfide ligand. Pertinent bond distances (Å) and angles (°) are: W—S = 2.1396(13), W—O(av.) = 1.886(3), S—W—O(av.) = 105.09(10), W—O—C(av.) = 143.47(27). The tert-butoxide compound is stable toward sulfur atom abstraction by phosphines, and neither compound has shown any tendency to undergo comproportionations with $W_2(OR)_6$ (R = Pr^i or CH_2Bu^t) species to form compounds of formula $W_3(\mu_3\text{-}S)(OR)_{10}$, in direct contrast to analogous molybdenum and tungsten oxo alkoxides.

Soluble transition-metal oxide and sulfide clusters have been the subjects of much research as models for both industrially-important heterogeneous catalysts[1] and active sites in metalloenzymes.[2] Particularly common is the family of trinuclear molybdenum and tungsten oxo and sulfido clusters.[3] Efforts in this area in our group have so far focused on metal oxo, imido and alkylidyne alkoxide clusters. For example the compounds $Mo_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6$ (R = Pr^i or CH_2Bu^t) were recently reported,[4] and the series was extended in further work[5] to include the isostructural species $W_3(O)(OPr^i)_{10}$ and $Mo_2W(O)(OPr^i)_{10}$. Use was made of ligand substitution accompanied by comproportionation in the synthesis of $W_3(\mu_3\text{-}NH)(OPr^i)_{10}$ from $W_2(OPr^i)_6(py)_2$ and $W(N)(OBu^t)_3$ in the presence of isopropanol.[6] Since this synthetic strategy has proven so useful and considering the high affinity that molybdenum and tungsten show for sulfur, we considered the possibility of making sulfido-capped tritungsten decaalkoxide clusters, particularly since the triply-bridging sulfido ligand is such a common entity in both early and late transition metal chemistry.[3,7] This paper describes the synthesis of the necessary monomeric precursors and our efforts to use them in cluster-building reactions.

RESULTS AND DISCUSSION

Syntheses

The reaction between $WSCl_4$ and 4 equiv of LiOR (R = Bu^t or Pr^i) in ethereal solutions at −78°C gives W(S)(OR)$_4$ in good isolated yields [eqn (1)]:

$$W(S)Cl_4 + 4LiOR \xrightarrow[-78°C]{\text{ether}} W(S)(OR)_4 + 4LiCl. \quad (1)$$

This simple ligand exchange route is essentially analogous to that used in preparing $W(O)(OPr^i)_4$[5] and $W(O)(NMe_2)_4$[8] from $WOCl_4$ (though the latter product must be prepared via an intermediate methoxide to minimize side reactions). Direct combination of alcohols with $MoOCl_4$ or $WOCl_4$, however, must occur in the presence of ⩾ 4 equiv of an amine to precipitate the HCl liberated as trialkylammonium chloride. In this manner W(O)(OR)$_4$ (R = Me, Et, Pr^n, Pr^i, Bu^n or benzyl) compounds were first prepared over 25 years ago,[9] and the analogous $Mo(O)(OPr^i)_4$ was obtained more recently,[5] though this latter compound can also be prepared via the lithium alkoxide method.[10] Mononuclear Mo(O)(OR)$_4$ (R = Bu^t, Pr^i or CH_2Bu^t) species also result from direct reaction of O_2 with the appropriate Mo(IV) alkoxide.[4]

Comparison with other mononuclear monosulfide species is provided by $[V(S)(edt)_2]^{2-}$ (edt = ethane-1,2-dithiolate dianion), recently reported by two groups.[11,12] Henkel's synthesis involves either a comproportionation and ligand rearrangement of VS_4^{3-} and $V_2(edt)_4^{2-}$ or reaction of the former with excess edt^{2-}. The Christou synthesis, however, occurs via the direct exchange of sulfur for the oxygen atom of $[V(O)(edt)_2]^{2-}$ using hexamethyldisilthiane, $(Me_3Si)_2S$. Other analogs are the $[Re(S)(edt)_2]^-$ anion[13] and the neutral species V(S)(acen) [acen-*N*,*N*′-ethylenebis(acetylacetonylideneaminato) dianion][14] and V(S)(salen) (salen = bis-salicylaldehydeethylenediimine dianion).[15] The latter two Schiff base complexes are obtained from the vanadyl compounds via S for O exchange using B_2S_3.

Physicochemical properties

The new $W(S)(OR)_4$ compounds are pale colored solids which are soluble in common organic solvents. They are air- and moisture-sensitive, particularly the tert-butoxide. Both are readily sublimable and the tert-butoxide can be crystallized from CH_2Cl_2 or Et_2O. Analytical, IR and ^1H NMR data are given in Experimental.

Solid-state and molecular structure of $W(S)(OBu^t)_4$: *bonding considerations*

The sample of $W(S)(OBu^t)_4$ which was used for the X-ray study crystallized from CH_2Cl_2 in the space group $P\bar{1}$. An ORTEP diagram of this molecule is shown in Fig. 1. Selected bond distances and angles are given in Table 1.

Table 1. Selected bond distances (Å) and angles (°) for $W(S)(OBu^t)_4$ (averaged where appropriate)

W—S	2.1396(13)
W—O	1.886(3)
O—C	1.448(6)
S—W—O	105.09(10)
O—W—O *cis*	86.13(13)
O—W—O *trans*	149.83(13)
W—O—C	143.47(27)

The overall coordination geometry consists of a square-based pyramid with the sulfide ligand occupying the axial site and the four alkoxide oxygen atoms lying in the basal sites. The tungsten atom is 0.49 Å above the mean plane of the oxygen atoms. The molecule has a slight distortion such that the two pairs of *trans* O—W—O angles are inequivalent by 2.85° giving the molecule virtual C_2-symmetry, but the ^1H NMR spectrum shows equivalent methyl resonances. Thus rapid O—C bond rotation and scissoring of the *trans* alkoxides must be occurring at room temperature. The solid-state distortion is likely due to crystal packing forces.

In square pyramidal compounds of formula MXL_4 symmetry considerations dictate that M–X π- and M–L $\pi_\parallel$-bonding (L orbitals parallel to the M–X vector) compete for the same metal orbitals, namely the d_{xz} and d_{yz}. In the present compound the W—S distance is shorter than the sum of standard literature covalent radii (1.37+0.94 Å).[16] The W—O distances are also shorter than the sum of the covalent radii (1.37+0.67 Å)* and at the lower end of the W—OR bond length range.[17] The W—O—C angles are also rather large. These data indicate a large amount of O → W and S → W π-

* See discussion of M—OR π-bonding in Ref. 17 for derivation of the oxygen 0.67-Å single-bond radius.

bonding, and that the oxygen atoms are hybridized in between sp^2 and sp as their filled p-orbitals donate into vacant tungsten orbitals. Furthermore, the lower value of $\bar{\nu}$(W=S) for the tert-butoxide vs the iso-propoxide (518 vs 540 cm^{-1}, respectively) when combined with the former's greater basicity reflects that the same tungsten orbitals are used for π-bonding by both the sulfide and the alkoxide ligands. Table 2 lists a series of compounds in which the terminal sulfide ligands occupy the axial position in a square-based pyramidal geometry. Note that the M=S distances fall within a fairly narrow range as do the $\bar{\nu}$(M=S) values. Comparing the tungsten compounds, there is a rough inverse relationship between d(W=S) and $\bar{\nu}$(W=S), as expected, and the larger d(W=S) values occur for compounds containing good π-donating equatorial ligands, further supporting the contention that the same metal orbitals accept π-electron density from both equatorial and axial ligands. Considering the formal electronic unsaturation of the metal atom in the present compounds, the high degree of ligand → metal π-bonding should be no surprise. In an Xα-SW calculation on $WSCl_4$, S → W π-bonding is in fact predicted giving rise to a high-lying ligand-centered orbital of e symmetry.[24]

Attempted comproportionation reactions to form compounds of formula $W_3(\mu_3\text{-}S)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6$

Synthesis of trinuclear oxo-capped alkoxide clusters proceeds according to eqn (2):[4,5]

$$M_2(OR)_6 + M(O)(OR)_4 \rightarrow M_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6 \quad (2)$$

M = Mo, R = Pr^i or CH_2Bu^t; M = W, R = Pr^i

Synthesis of isoelectronic imido-capped analogs proceeds similarly, possibly via comproportionation of the metal moieties followed by addition of alcohol [eqn (3)]:[6,25]

$$M_2(OR)_6 + M(N)(OBu^t)_3 \xrightarrow{\text{hexane–ROH}} M_3(\mu_3\text{-}NH)(OR)_{10} \quad (3)$$

M = Mo, R = Pr^i or CH_2Bu^t; M = W, R = Pr^i

Sulfur occurs widely as a four-electron donor in a μ_3-coordination mode[7] and the tungsten sulfide monomers described above are formally isolobal to the M(O)(OR)$_4$ species of eqn (2). These facts led us to believe that a sulfur-capped trinuclear alkoxide cluster could be easily accessible via M(S)(OR)$_4$ precursors.

Attempts to synthesize compounds of formula $W_3(\mu_3\text{-}S)(OR)_{10}$ (R = Pr^i or CH_2Bu^t) are summarized in Table 3. In all cases ^{1}H NMR spectroscopy showed no evidence of a 3 : 3 : 3 : 1 pattern for the four types of different OR ligands expected for products of formula $W_3(\mu_3\text{-}S)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6$. Instead W(S)(OR)$_4$ compounds and (in cases where excess alcohol was used) W(OR)$_6$ compounds were observed in the reaction mixtures. The observation of mononuclear hexaalkoxides has precedent in reaction (3) in which addition of alcohol to $(Bu^tO)_3W{\equiv}N$ to form W(OR)$_6$ and ammonia competes with triangle formation.[25] Regardless, it appears that alcoholysis of the starting materials is at least a kinetically favored reaction compared to trimer formation. Unfavourable steric factors arising from the larger sulfido vs oxo ligand could reasonably explain this difference in reactivity. Of note here are the observations that in space-filling diagrams of the related imido-capped complex the imido proton is tightly wedged into the pocket

Table 3. Summary of attempted syntheses of $W_3(\mu_3\text{-}S)(OR)_{10}$ compounds

$W_2(OBu^t)_6 + W(S)(OBu^t)_4 + xsPr^iOH \xrightarrow[2\,days,\,RT]{toluene}$

$W_2(ONe)_6(HNMe_2)_2 + W(S)(OBu^t)_4 \xrightarrow[28\,h,\,RT]{(1)\ toluene} \xrightarrow[1\,day]{(2)\ 4NeOH}$

formed by the adjacent alkoxide ligands, and that no $M_3X(OR)_{10}$ clusters containing alkoxide ligands bulkier than the iso-propoxy group are known.

Attempted desulfurization/aggregation via phosphines

Trialkyl and triaryl phosphines are widely known to be efficient sulfur atom abstractors. It was thought that desulfurization of $W(S)(OBu^t)_4$ using phosphines would yield a highly reactive $W(OBu^t)_4$ fragment which could possibly react with the tungsten starting material forming a confacial bioctahedral $(Bu^tO)_3W(\mu\text{-}S)(\mu\text{-}OBu^t)_2W(OBu^t)_3$ species. However, no reaction occurs between $W(S)(OBu^t)_4$ and either PPh_3 or PBu^n_3 as confirmed by ^1H NMR spectroscopy.

EXPERIMENTAL

All manipulations were performed under a dry-nitrogen atmosphere using standard Schlenk techniques or a Vacuum Atmospheres drybox. Solvents were dried and deoxygenated by standard methods. $WSCl_4$ was prepared by the sealed tube reaction of WCl_6 and S_8.[26] Lithium alkoxides were prepared by reaction of *n*-butyllithium with the corresponding alcohol. ^1H NMR spectra were obtained on a Nicolet 360 MHz spectrometer; shifts are relative to the 7.15-ppm signal of residual protons in d_6-benzene. IR spectra were obtained on a Perkin–Elmer 283 spectrophotometer. Electron impact mass spectra were obtained on a Kratos MS-80 mass spectrometer. Elemental analyses were performed by Alfred Bernhardt Analytical Laboratories (Elbach, F.R.G.).

$W(S)(OBu^t)_4$

$LiOBu^t$ (1.03 g, 12.8 mmol) was placed in a large Schlenk tube equipped with a stirbar. Diethyl ether (60 cm^3) was added and the solution cooled to $-78°C$. $WSCl_4$ (1.15 g, 3.2 mmol) was added via an addition tube over 10 min with stirring. The solution immediately became red, then faded to yellow within 15 min. The solution was left to stir and warm to room temperature over 4 h. After allowing the LiCl precipitate to settle overnight it was filtered off using a medium frit and the solution stripped to dryness leaving a yellow powder. X-ray quality crystals as yellow plates were grown in 54% yield by cooling a concentrated CH_2Cl_2 solution of this powder to $-15°C$. The product also sublimes at 50°C, 10^{-4} torr onto a water-cooled probe. ^1H NMR data (25°C, d_6-benzene): δ 1.51 ppm. IR data (Nujol mull, CsI plates, cm^{-1}): 1359(s), 1230(m), 1170(s), 1024(w), 940(vs), 906(msh), 784(s), 557(s), 518(s), 478(s), 365(m), 288(m). Analysis for $WSO_4C_{16}H_{36}$ (Calc.): C, 37.6 (37.8); H, 7.0 (7.1); S, 6.5 (6.3)%. The mass spectrum showed a weak molecular ion at $m/z = 508$ and a *t*-butyl$^+$ parent ion at $m/z = 57$ as well as numerous other ions.

$W(S)(OPr^i)_4$

$LiOPr^i$ (1.04 g, 15.7 mmol) was placed in a large Schlenk tube equipped with a stirbar. Diethyl ether (40 cm^3) was added and the solution cooled to −78°C. $WSCl_4$ (1.40 g, 3.9 mmol) was added with stirring over 3 h via an addition tube with the solution changing from colorless to yellow to brown. The solution was allowed to stir 6 h and warmed to room temperature. LiCl was filtered off using a medium frit and the solution evaporated to dryness *in vacuo*, leaving an oily red residue. This was taken up in 20 cm^3 of CH_2Cl_2, allowed to stand for an hour, then the solvent removed *in vacuo*, leaving an orange solid. Sublimation at 50°C, 10^{-4} torr onto a water-cooled probe gave the product as a pale orange powder. ^1H NMR data (25°C. d_6-benzene): δ 1.32 ppm (d, $^3J_{H-H} = 6.14$ Hz, 6H), 5.25 ppm (septet, 1H). IR data (Nujol mull, CsI plates, cm^{-1}): 1320(m), 1258(w), 1164(s), 1126(ssh), 1113(vs), 975(vs), 846(s), 598(vs), 465(mbr), 425(msh), 300(mbr). Solution IR (hexane, KBr cavity cell) also shows $\tilde{\nu}$(W=S) at 540(m) cm^{-1}. Analysis for $WSO_4C_{12}H_{28}$ (Calc.): C, 31.6 (31.9); H, 6.1 (6.2); S, 7.0 (7.1)%. This product can also be obtained substituting $NaOPr^i$ in place of $LiOPr^i$ or by reacting $W(S)(OBu^t)_4$ with 4 equiv isopropanol overnight in toluene. The original method, given above, gave the best yields.

Attempted desulfurization and comproportionation reactions involving $W(S)(OBu^t)_4$

(a) $W(S)(OBu^t)_4$ (0.50 g, 0.98 mmol) was placed in a 50-cm^3 Schlenk flask equipped with a stirbar. Toluene (20 cm^3) was added via syringe, stirring commenced, and PPh_3 (0.129 g, 0.49 mmol) was added via a sidearm addition tube over $\frac{1}{2}$ h. The solution was stirred for 24 h, then heated to 50°C and stirred for an additional 24 h. The solvent was then removed *in vacuo*. ^1H NMR spectroscopy of

the residue revealed only unreacted $W(S)(OBu^t)_4$ and PPh_3.

(b) $W(S)(OBu^t)_4$ (0.43 g, 0.84 mmol) was placed in a 50-cm^3 Schlenk flask equipped with a stirbar. Hexane (20 cm^3) was added, followed by PBu^n_3 (105 μl, 0.42 mmol). The solution was stirred for 24 h, and then the solvent was removed *in vacuo*. ^1H NMR spectroscopy of the residue showed unreacted $W(S)(OBu^t)_4$.

Attempted comproportionation reactions involving $W(S)(OR)_4$ *and* $W{\equiv}W^{6+}$ *species*

Reactions performed in attempts to synthesize a compound of the formula $W_3(\mu_3\text{-}S)(OR)_{10}$ (R = Pr^i or CH_2Bu^t) are summarized in Table 3. In no case was there ^1H NMR spectroscopic evidence demonstrating the formation of such a species. The only compounds identified in the reaction mixtures (via ^1H NMR spectroscopy) were $W(S)(OR)_4$* and in cases where excess alcohol was used $W(OR)_6$ (R = Pr^i or CH_2Bu^t).

Crystallographic study of $W(S)(OBu^t)_4$

General operating procedures have been described previously.[28] Crystal data for $W(S)(OBu^t)_4$ are summarized in Table 4.

A suitable equidimensional fragment was cleaved from a large plate and transferred to the goniostat using standard inert atmosphere handling techniques and cooled to $-160°C$ for characterization and data collection. The sample remaining in the glovebag darkened rapidly, indicating extreme sensitivity.

A systematic search of a limited hemisphere of reciprocal space yielded a set of diffraction maxima with no systematic absences or symmetry, and was thus indexed as triclinic. The structure was successfully solved via a Patterson function and refined in the centrosymmetric space group $P\bar{1}$. All atoms including hydrogens were located and refined.

A final difference Fourier was featureless, the largest peak being 1.21 e $Å^{-3}$ located at the metal site, the next largest peak being 0.42 e $Å^{-3}$.

Final atomic parameters, full lists of bond distances and angles and F_o/F_c values have been deposited as supplementary materials with the Editor from whom copies are available upon request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Center.

* Reaction of $W(S)(OBu^t)_4$ and 4 equivalents of neopentanol in toluene gives a very air-sensitive mixture whose major product is believed to be $W(S)(OCH_2Bu^t)_4$ and which displays ^1H NMR resonances at δ = 1.06 and 4.54 ppm, consistent with products obtained in attempted comproportionations using excess neopentanol.[27]

He I PHOTOELECTRON SPECTROSCOPIC STUDY OF *CLOSO*-DICARBADODECABORANES AND THEIR 9-HALOGENO DERIVATIVES

TOMÁŠ VONDRÁK

ESCA Centre, The J. Heyrovský Institute of Physical Chemistry and Electrochemistry, Czechoslovak Academy of Sciences, Vlašská 9, 11840 Prague, Czechoslovakia

(*Received* 5 *December* 1986; *accepted* 28 *January* 1987)

Abstract—He I photoelectron spectra of the *closo*-carboranes 1,2-$C_2B_{10}H_{12}$ and 1,7-$C_2B_{10}H_{12}$, and their 9-halogeno derivatives are reported. The low ionization energy bands are gathered into two groups. The MNDO quantum chemical method provides the same picture and indicates that these bands correspond predominantly to the B—H (C—H) bonding molecular orbitals. Bromine and iodine bring about an almost uniform increase in ionization energies whereas the shape of the low ionization energy features of the chloro derivatives differ from those of the parent compounds. This effect is interpreted by the conjugative interaction of cluster π-type orbitals with the chlorine non-bonding orbitals.

The *closo*-carboranes form a group of polyhedral molecules of particular interest from the viewpoint of multicentre bonding.[1] The interest in the electronic structure of this class of compounds is stimulated by their analogy with transition-metal cluster compounds through the isolobal principle.[2] Numerous quantum chemical calculations on these compounds have been reported.[3–7] The MNDO calculated MO energies are in reasonably good agreement with those obtained by the *ab initio* method[8] and Stone's tensor surface harmonic approach.[9–11]

To our knowledge no attempt has been made to compare the calculated orbital energies with the energies of ionic states accessible by UV photoelectron (PE) spectroscopy. Fehlner *et al.* used the equatorial-apex model[3] for a discussion of the PE spectra of some thiaboranes and the effect of the exo substituent.[12]

We report here the He I PE spectra of the *closo*-carboranes 1,2-$C_2B_{10}H_{12}$ (**1a**) and 1,7-$C_2B_{10}H_{12}$ (**2a**), as well as the spectra of their 9-chloro derivatives (**1b** and **2b**), 9-iodo derivatives (**1d** and **2d**), and 9-Br-1,2-$C_2B_{10}H_{12}$ (**1c**), together with the results of the MNDO calculations on the non-substituted species.

The PE spectra can be divided into three regions labeled A–C (Figs 1 and 2). In region A four overlapping bands (1–4) and a well-resolved band (5) are found in the spectrum of **1a**. Only four bands are observed within this region in the spectrum of **2a**. Four and three ionization events are observed in region B of the spectrum of the *ortho* and the *meta* isomer, respectively. A vibrational fine structure corresponding to a wavenumber of 720 cm^{-1} is observed in region C of the spectrum of **2a**. The *ortho* isomer has only two broad features in this region.

To interpret the spectral bands we apply Koopmans theorem allowing the correlation of the ionic state energies with the orbital energies of the ground state.[13]

The MNDO calculations on **1a** and **2a** provide the 15 outermost occupied levels gathered into two groups (Table 1). For **1a** the HOMO and five levels are within a 0.6-eV interval. The two nearly degenerate MOs are separated by 0.5 eV and the following MO lies 0.6 eV lower (Table 2). Hence we can tentatively assign bands 1–3 to the $6b_1$, $6b_2$, $10a_1$, $3a_2$, $9a_1$ and $5b_2$ MOs, band 4 to the $2a_2$ and $5b_1$ MOs, and band 5 to the $8a_1$ MO. For **2a** the nine outermost MOs lie in a narrower interval and no level is markedly separated from the others. Thus any detailed assignment of region A is not possible since there is no hint how to assign nine levels to the four observed bands. The six MOs lying between -15 and -17 eV correspond to the bands observed in region B. It follows from the composition of the MOs that the ionizations found in

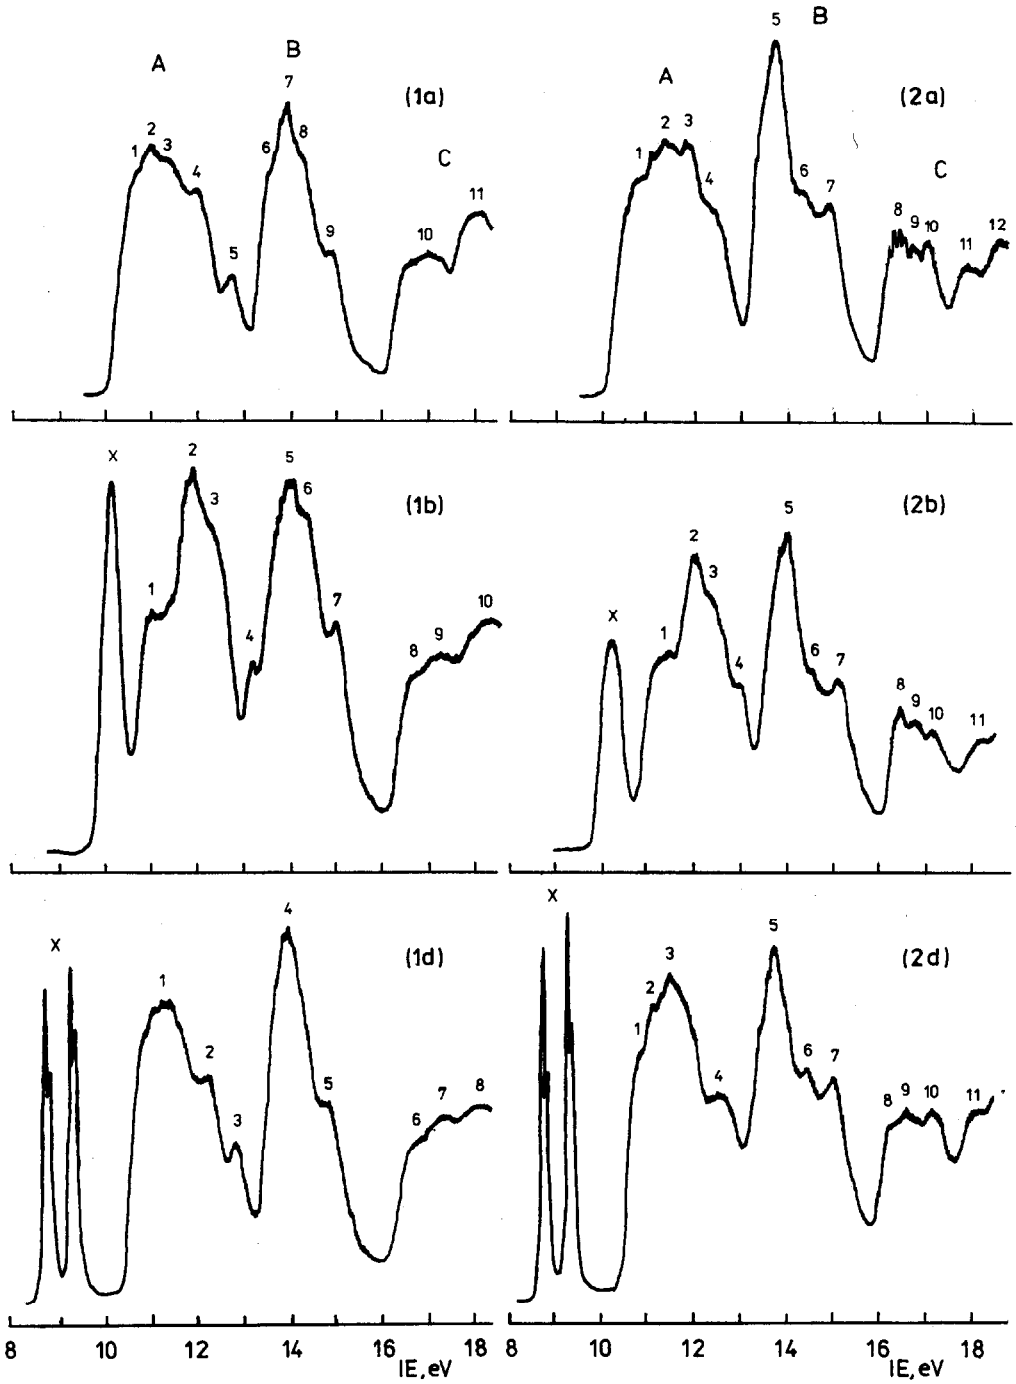

Fig. 1. He I photoelectron spectra of 1,2-$C_2B_{10}H_{12}$ (**1a**), 9-Cl-1,2-$C_2B_{10}H_{11}$ (**1b**), 9-I-1,2-$C_2B_{10}H_{11}$ (**1d**), 1,5-$C_2B_{10}H_{12}$ (**2a**), 9-Cl-1,5-$C_2B_{10}H_{11}$ (**2b**) and 9-I-1,5-$C_2B_{10}H_{11}$ (**2d**).

regions A and B come mainly from the B—H (C—H) bonding MOs. The sharp bands at low ionization energy (IE) which are observed in the spectra of the halogeno derivatives come unambiguously from ionizations of the halogen lone pairs. The spin–orbit splitting of the lone-pair ionization found in the spectra of the iodo derivatives and the bromo derivative amounts to 0.27 and 0.54 eV, respectively. The value of the spin–orbit splitting found for tertiary alkyl iodides is only 0.01 eV higher, and the shape of the peaks is identical. The low IE component of the lone-pair band broadens with increasing conjugative interaction between the halogen and the alkyl.[14] The FWHM of the spin–orbit components in the iodo derivatives are 0.16 and 0.18 eV for the high and the low one, respect-

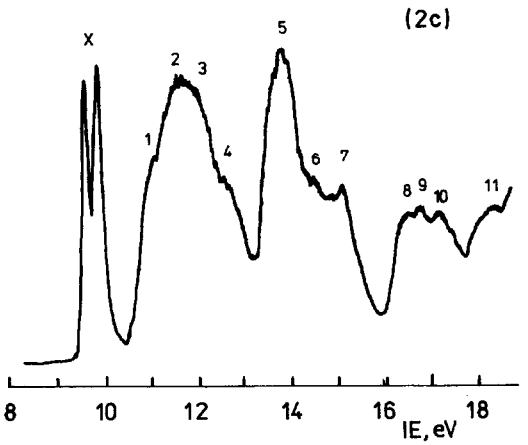

Fig. 2. He I photoelectron spectrum of 9-Br-1,5-$C_2B_{10}H_{11}$ (**2c**).

ively (0.19 and 0.26 eV for tertiary aliphatic alkyl iodides[15]). Hence the degree of conjugation between halogen lone pairs and carborane skeleton π-orbitals* is essentially the same as in the alkyl halogenides. The identical shape of the bands within region A of the spectra of the iodo and bromo derivatives, and an almost uniform shift of all bands to a higher IE, corroborate this conclusion since no carborane MO is markedly stabilized.

Region A of the spectra of the chloro derivatives **1b** and **2b** differs significantly from those of the parent compound. Band 1 is more resolved and band 2 increases in intensity. We believe that this demasking of band 1 is due to the stabilization of the carborane π-orbitals. The HOMO ($6b_1$) and HOMO-3 ($10a_1$) in **1a** and HOMO ($10a_1$) and HOMO-4 ($6b_2$) in **2a** have a significantly higher localization on atom B(9) (Table 1). Thus these MOs can be stabilized by a conjugative interaction. The absence of this effect in the spectra of the bromo and iodo derivatives could be rationalized by a smaller resonance integral and/or by an increase in the energy difference between the interacting orbitals.

For the MNDO calculation the experimental internal coordinates[16] of the heavy atoms have been used and the coordinates for the hydrogen atoms were allowed to relax.

The He I PE spectra were recorded on a VG Scientific UVG 3 spectrometer. The resolution (FWHM) was 30–40 meV through the entire spectrum. An Ar–Xe mixture has been used as the internal calibrant.

* π-Orbitals are composed from the boron *p*-orbitals tangential to the surface of the cluster.

POLYMERIZATION REACTIONS IN $[Co(NH_3)_5(H_2O)][CoX(CN)_5]$ AND *CIS*-$[Co(NH_3)_4(H_2O)_2][CoX(CN)_5]$ (X = Cl, Br, I, NO_2 OR N_3) DOUBLE-COMPLEX SALTS

Abstract—Polymerization reactions of $[Co(NH_3)_5(H_2O)][CoX(CN)_5]$ and *cis*-$[Co(NH_3)_4(H_2O)_2][CoX(CN)_5]$ (X = Cl, Br, I, NO_2 or N_3] have been studied. The compounds undergo aging reactions in the solid state or in solution induced by the ligand X involving solvolytic processes affording polymeric materials with μ-cyano bridges. A mechanistic explanation of these reactions is given and a comparison between both series of compounds together with the parent compound $[Co(NH_3)_6][Co(CN)_6]$ is discussed.

The dehydration–anation reaction of double-complex salts of type:

$$[Co(NH_3)_5(H_2O)][Co(CN)_6] \rightarrow [(NH_3)_5Co—NC—Co(CN)_5]+H_2O \quad (1)$$

is well known.

Many examples of this reaction have been reported in the literature, and a number of μ-CN dinuclear complexes have been synthesized by this method, employing different amminated or aminated cationic aquo complexes and cyanurated anions.[1,2]

The physical and chemical properties of these μ-CN dinuclear complexes have been studied.[3] The kinetic parameters of such reactions have been currently studied in a series of double-complex salts containing different cations but the same anion. The aim of such work is to understand the influence of the varying cation in the kinetic parameters and to propose a realistic mechanism for the reaction.

We have reported a complete kinetic–mechanistic study of the reaction:

$$[Co(NH_3)_5(H_2O)][CoX(CN)_5] \rightarrow [(NH_3]_5Co—NC—CoX(CN)_4]+H_2O$$

in order to understand the influence of the anion.[4] The unit-cell parameters of these double-complex salts are modified by the different X groups; consequently, variation in the lattice free spaces allows a study of their influence in the activation energy and kinetic parameters of the solid-state process, we have proposed an S_N1 mechanism with a Frenkel-type defect and a square-base pyramid as an activated complex according to the House and LeMay nomenclature.[5,6] In the course of these studies, we have observed significant differences in the behaviour of the double-complex salts with the $[CoX(CN)_5]^{3-}$ anions or the simpler one $[Co(CN)_6]^{3-}$, and the $[Co(NH_3)_4(H_2O)_2]^{3+}$ and $[Co(NH_3)_5(H_2O)]^{3+}$ cations. We have, therefore, made a complete comparative study of the corresponding dehydration–anation reaction, the results of which are reported in this paper.

EXPERIMENTAL

Synthesis of the new compounds cis-$[Co(NH_3)_4(H_2O)_2][CoX(CN)_5]$ (X = Cl, Br, I, NO_2, N_3 *or* CN)

Starting materials such as *cis*-$[Co(NH_3)_4(H_2O)_2](ClO_4)_3$,[7] $K_3[CoN_3(CN)_5]$[8] and $K_3[Co(CN)_6]$[9] were prepared by literature methods. Acidopentacyanocobaltates(III) salts of type $K_3[CoX(CN)_5]$ were prepared by a method already reported by us.[10]

Double-complex salts, *cis*-$[Co(NH_3)_4(H_2O)_2]$

* Author to whom correspondence should be addressed.

$[CoX(CN)_5]$ (X = Cl, Br, I, NO_2, N_3 or CN), were synthesized by precipitation from their corresponding compounds. In a typical experiment, $NaClO_4$ (2.0 g) was added to a solution of $K_3[CoCl(CN)_5]$ (1.2 g) in a water–acetic acid mixture (5 : 1, 6 cm^3). $KClO_4$ precipitated immediately and was discarded. To the clear solution *cis*-$[Co(NH_3)_4(H_2O)_2](ClO_4)_3$ (1.2 g) was added in small portions with continuous stirring until all the solid was dissolved. Then glacial acetic acid was added, resulting in the formation of an orange-pink precipitate which was filtered, washed with ethanol, and dried *in vacuo*. Yields were about 65%, and the analytical data were in agreement with the formula proposed in all cases (Table 1).

Synthesis of the compounds $[Co(NH_3)_5(H_2O)][CoX(CN)_5]$ (X = Cl, Br, I, NO_2, N_3 *or* CN)

These compounds were synthesized according to the procedure already reported by us.[4]

Physical measurements

IR spectra were measured on a Beckman IR-20 spectrophotometer as KBr pellets. Electronic spectra were measured in aqueous solution on a Beckman Acta III and a Shimadzu UV-240 spectrophotometer. The electronic spectra of the insoluble compounds were measured as KBr pellets on the Beckman Acta III instrument. Powder X-ray diffraction were done on a Phillips diffractometer. Molar conductivities were measured on a Radiometer CDM-3 conductivitimeter. Thermogravimetric analyses were done on a Perkin–Elmer TGS-2 and a Rigaku Thermoflex system. C, H and N microanalyses were performed on a Perkin–Elmer 240 microanalyzer. Co analyses were done by a complexometric method with EDTA.[12]

RESULTS

Spectral measurements

We have already reported[4] that the compounds $[Co(NH_3)_5(H_2O)][CoX(CN)_5]$ (X = Cl, Br, I, NO_2, N_3 or CN) are isomorphous. The tetrammine series also shows a similar behaviour (Table 2), and both series are isostructural with the parent compound $[Co(NH_3)_6][Co(CN)_6]$, the crystalline structure of which has been resolved by X-ray diffraction method. The latter compound has a trigonally distorted CsCl structure distorted affecting spatial group $R\bar{3}$.[12] The isostructuralism with the aquoammine complexes may be explained assuming a disorder of the water molecules in the coordination sphere of Co(III) ion as has been proved in other cases too.[13]

The electronic spectra of these compounds in aqueous solution are reported in Table 3. All of them show two bands in the visible and near-UV region. The former bands at higher energies are attributed to the first *d–d* transition of the anionic moiety while the latter ones at lower frequencies are assigned to the first *d–d* transition of the cationic moiety. The second band always exhibits less intensity than the first one, and apparently seems to be partially overlapped by this band. It is, therefore, necessary to have a Gaussian analysis of these bands to ascertain the position of the maximum of the less intense band. Both these bands appear to have the same energy as in the simple salts of both anionic and cationic species, showing the presence of the amminated cation and cyanurated anion in the compound without significant interactions between them.

[a] Values for this compound were not found due to fast polymerization.

Table 4 shows the most significant bands in the IR spectra of these compounds. The CN stretching mode is very characteristic, appearing as a strong and narrow band at 2120 cm^{-1}. Sometimes a weak band appearing at slightly higher frequencies is also assigned to the same mode perturbed by hydrogen bonding.[14]

Thermal behaviour of *cis*-$[Co(NH_3)_4(H_2O)_2][CoX(CN)_5]$ (X = Cl, Br, I, NO_2, N_3 *or* CN)

Thermogravimetric measurements show as the first step, for all these compounds, the loss of two water molecules, so a difficulty in isolating dinuclear compounds with a μ-CN ligand of the type indicated in reaction (2) could be expected:

$$[Co(NH_3)_4(H_2O)_2][CoX(CN)_5] \rightarrow [(NH_3)_4(H_2O)Co—NC—CoX(CN)_4] + H_2O. \quad (2)$$

The heating of these double complexed salts in the solid state does not give isolable μ-CN dinuclear compounds, unlike the pentammine series, but insoluble compounds for which IR spectrum displays two bands of equal intensity in the CN stretching mode region. The appearance of two bands in this region is attributed to two different types of CN bonds. Terminal —CN bonds appear at lower frequency while bridging —CN— bonds appear at

higher energies.[1,15] These solids are polymeric materials formulated as $Co_2(NH_3)_4(CN)_5X$.

Reaction (2) in aqueous solution was followed by spectrophotometric methods. As an example, the results for *cis*-$[Co(NH_3)_4(H_2O)_2][CoCl(CN)_5]$ were the following. At first it shows an electronic spectrum with two bands at 505 and 390 nm. The spectrum shifts to higher energies during the heating. When the spectrum remains constant a solid product can be collected by precipitation, showing bands at 490 and 345 nm in the electronic spectra in aqueous solution, and two bands in the CN stretching mode region in the IR spectra.

The first maximum (490 nm) is characteristic of a Co(III) ion in an octahedral environment of five nitrogens and one oxygen as in the $[Co(NH_3)_5(H_2O)]^{3+}$ ion. On the other hand, the second maximum (345 nm) is typical of a Co(III) ion surrounded by five carbons and one nitrogen as is known to occur in $[Co(—NC)(CN)_5]^{3-}$.[16] and $[Co(NH_3)(CN)_5]^{2-}$.[17] These results are identical for all the double salts discussed in this paper.

Solid-state reactions in the $[Co(NH_3)_5(H_2O)][CoX(CN)_5]$ *series*

In an earlier paper[4] we have reported the synthesis of dinuclear compounds with a μ-CN ligand according to the following reaction:

$$[Co(NH_3)_5(H_2O)][CoX(CN)_5] \rightarrow [(NH_3)_5Co—NC—CoX(CN)_4] + H_2O \quad (3)$$

(X = Cl, Br, I, NO_2, N_3 or CN). These dinuclear compounds are fairly stable, permitting to isolate, characterize and study them. However, they undergo reactions in the solid state as well as in solution as we have shown by spectrophotometric and ^{59}Co NMR spectroscopy.[4]

As a typical case, $[(NH_3)_5Co—NC—CoCl(CN)_4]$ was chosen. At first this compound shows bands at 388 and 470 nm. After 2 weeks, the compound was recrystallized by discarding the insoluble part. The compound obtained from the clear solution showed bands at 340–345 and 470 nm in the electronic spectrum in aqueous solution. The amminated Co(III)

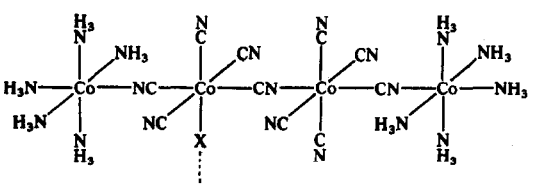
cation does not change its electronic spectrum, while, on the contrary, the cyanurated Co(III) anion changes its spectrum, being finally similar to $[Co(—NC)(CN)_5]^{3-}$ and $[Co(NH_3)(CN)_5]^{2-}$ species.[16,17] Furthermore, chemical analyses showed a C : H : N ratio identical to the freshly prepared dinuclear compound, indicating that no loss of NH_3, $(CN)_2$ or H_2O had occurred. The compound showed an electrical conductivity of 520 Ω^{-1} mol^{-1} cm^2 and the presence of free chlorine. The IR spectrum was similar to the original complex. These results are similar for all pentamminaquocobalt(III) double salts.

DISCUSSION

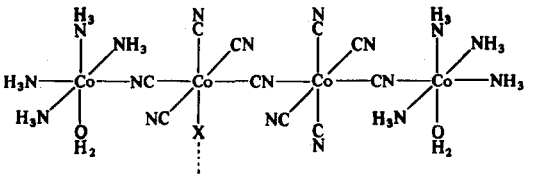
It is known that by heating the double-complex salt $[Co(NH_3)_4(H_2O)_2][Co(CN)_6]$ the μ-CN dinuclear compound $[(NH_3)_4(H_2O)Co—NC—Co(CN)_5]$ is obtained,[18] and there is no report of polymerization problems in this case. A similar observation has been made in the case of the dinuclear compound, $[(NH_3)_5Co—NC—Co(CN)_5]$, obtained by controlled heating of $[Co(NH_3)_5(H_2O)][Co(CN)_6]$.[1] It is clear that the presence of the X ligands favours both the solution and solid-state processes with time shown by these compounds, and hence all mechanisms describing them must be taken into account. On the other hand, it is well known that the easy hydrolysis of the $[CoX(CN)_5]^{3-}$ ions gives $[Co(H_2O)(CN)_5]^{2-}$ species,[16] which undergo polymerization even in solution. The aged solutions of this species exhibit one band at 350 nm in its electronic spectrum.

The nature of the aged dinuclear μ-CN compounds in both the pentammine and tetrammine series may be explained by two alternative mechanisms. In the first step a μ-CN dinuclear compound is formed. Such reactions may follow one of the following mechanisms.

(a) The chloride ligand or any of the X ligands is lost by a hydrolytic process and a new intermolecular μ-CN bond is formed with other dinuclear molecule. This mechanism should give to a polymeric material as indicated in **Ia** and **b**, depending on the starting amminated salt:

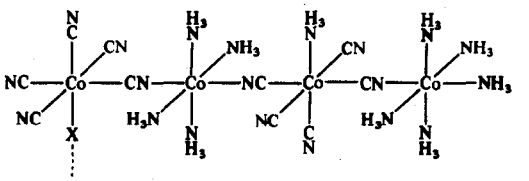


Ia X = Cl^-, Br^- or H_2O

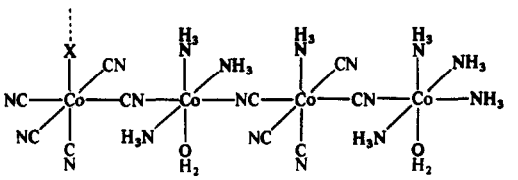


Ib X = Cl^- or H_2O

(b) One X ligand is lost by a migration mechanism of an NH_3 group giving a new intermolecular μ-CN bond, as indicated in **IIa** and **b**. Intramolecular migration of such types in these compounds has been demonstrated to occur by ^{59}Co NMR spectroscopy.[4]



IIa X = Cl^-, Br^- or H_2O



IIb X = Cl^- or H_2O

If the new μ-CN bond formed in the above-mentioned mechanism was intramolecular, dinuclear compounds of formula $[(NH_3)_4Co(NC)_2Co(CN)_3NH_3]X$ or $[(NH_3)_3(H_2O)Co(NC)_2Co(CN)_3NH_3]X$ may be synthesized as reported by several authors.[18,19]

The polymers shown above are similar but with different sequences of the amminated and cyanurated moieties.

CONCLUSIONS

The chemical and spectral characteristics of these polymeric materials are in agreement with the experimental results found. The difference in reactivity between these acidopentacyanocobaltates(III) and the parent hexacyanocobaltate(III) depends on the nature of the ligand X. The easy hydrolysis of these X groups is a critical step in the polymerization process. The rate of polymerization varies in the order Cl < Br < I. The difference between the polymeric materials afforded by aging

of both amminated series of compounds is due only to the presence of coordinated water molecules in the fragments of the polymerization of the tetramminated series as shown in **I** and **II**. The coordinated water molecules are extremely susceptible to polymerization, as has been repeatedly demonstrated in a number of cases involving the synthesis of μ-CN dinuclear compounds.[1,20] Because of this reason, the pentamminated series behaves differently, which permits the isolation of μ-CN dinuclear compounds before undergoing polymerization. On the contrary, the tetramminated series is more sensitive to these processes, and undergoes rapid polymerization, which prevents the isolation of dinuclear complexes.

LIGHT-INDUCED LIGAND-SUBSTITUTION REACTIONS—II. REACTION BETWEEN THE $[CoBr(NH_3)_5]^{2+}$ ION AND ETHYLENEDIAMINETETRAACETATE BY IRRADIATION WITH VISIBLE LIGHT OF AQUEOUS ACID SOLUTION CONTAINING THE TRIS(2,2′-BIPYRIDINE)RUTHENIUM(II) ION

(*Received* 5 *January* 1987; *accepted* 28 *January* 1987)

Abstract—The ligand-substitution reaction of the bromopentaamminecobalt(III) ion, $[CoBr(NH_3)_5]^{2+}$, with ethylenediaminetetraacetate (EDTA) (which denotes all the forms of EDTA, i.e. $edta^{4-}$, $Hedta^{3-}$, H_2edta^{2-} etc.) was induced by irradiation with visible light of aqueous solutions containing the tris(2,2′-bipyridine)ruthenium(II) ion, $[Ru(bpy)_3]^{2+}$. The $[Co(edta)]^-$ ion was efficiently produced in acid solutions at pH 2–3, where $[Ru(bpy)_3]^{2+}$ acts as an inductor and a photocatalyst. The ligand-substitution reaction constitutes a chain reaction composed of a $[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^{3+}$ cycle, where the substitution reaction is initiated by the quenching reaction of the photoexcited complex $[Ru(bpy)_3]^{2+*}$ with $[CoBr(NH_3)_5]^{2+}$. The formation rate of $[Co(edta)]^-$ by the ligand-substitution reaction between EDTA and $[CoBr(NH_3)_5]^{2+}$ decreased with increasing pH (pH > 3) as well as with decreasing pH (pH < 2), and was at a maximum at pH 2–3. Under conditions of pH 2–3, the photo-induced ligand-substitution reaction between EDTA and $[CoBr(NH_3)_5]^{2+}$ was quantitative, i.e. the $[[Co(edta)]^-]_{formed}/[[CoBr(NH_3)_5]^{2+}]_{decomposed}$ ratio = 1. Reaction mechanisms are discussed.

In a previous work,[1] we studied the photo-induced ligand-substitution reaction between ethylenediaminetetraacetate (EDTA) and $[CoCl(NH_3)_5]^{2+}$. Our interest has arisen from comparing $[CoBr(NH_3)_5]^{2+}$ with $[CoCl(NH_3)_5]^{2+}$ in the same photo-induced reaction composed of a $[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^{3+}$ cycle. In the initial stage of the present work, we found that the production of $[Ru(bpy)_3]^{3+}$ {or the disappearance of $[Ru(bpy)_3]^{2+}$} due to the quenching reaction between $[Ru(bpy)_3]^{2+*}$ and $[CoBr(NH_3)_5]^{2+}$ was remarkably different from that in the case of $[CoCl(NH_3)_5]^{2+}$ in the previous work[1] (refer to Fig. 1).

When a solution containing $[Ru(bpy)_3]^{2+}$ and $[CoBr(NH_3)_5]^{2+}$ {or $[CoCl(NH_3)_5]^{2+}$} was irradiated with visible light, the $[Ru(bpy)_3]^{2+}$ ion was oxidized to the $[Ru(bpy)_3]^{3+}$ ion by the bimolecular quenching reaction of $[Ru(bpy)_3]^{2+*}$ with $[CoBr(NH_3)_5]^{2+}$ {or $[CoCl(NH_3)_5]^{2+}$}. The $[Ru(bpy)_3]^{3+}$ ion once formed could react with the solvent water or other reducing species such as the Br^- ion in solution, being reduced to the $[Ru(bpy)_3]^{2+}$ ion. Consequently, the difference in the disappearance of $[Ru(bpy)_3]^{2+}$ { or the production of $[Ru(bpy)_3]^{3+}$} due to the quenching reaction of $[Ru(bpy)_3]^{2+*}$ with $[CoBr(NH_3)_5]^{2+}$ and $[CoCl(NH_3)_5]^{2+}$ is attributable to the Br^- and Cl^- ions, the latter ion not being oxidized by $[Ru(bpy)_3]^{3+}$ but the Br^- ion being oxidized by $[Ru(bpy)_3]^{3+}$: the Br^- or Cl^- ion is liberated by the quenching reaction of $[Ru(bpy)_3]^{2+*}$ with $[CoBr(NH_3)_5]^{2+}$ or $[CoCl(NH_3)_5]^{2+}$. Despite the remarkably different behavior in the quenching reactions of $[CoBr(NH_3)_5]^{2+}$ and $[CoCl(NH_3)_5]^{2+}$, the photo-induced ligand-substitution reaction of both complexes with EDTA was found to proceed similarly.

Conditions: 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$ and 5×10^{-3} mol dm^{-3} $[CoBr(NH_3)_5]Br_2$ for plots △ and ▲, 1×10^{-3} mol dm^{-3} $[CoBr(NH_3)_5](ClO_4)_2$ for plots □ and ■, and 5×10^{-3} mol dm^{-3} $[CoCl(NH_3)_5]Cl_2$ for plots ○ and ●; 0.05 mol dm^{-3} acetic acid and sodium acetate (pH 4.75), nitrogen saturated, 25°C. Plots △, □ and ○ indicate the results with continuous irradiation of visible light by four 100-W tungsten lamps, and plots ▲, ■ and ● indicate the results obtained when the photo-reacted solution stood in the dark after irradiation for 1 h.

EXPERIMENTAL

Chemicals

$[Ru(bpy)_3]Cl_2\cdot6H_2O$[2] and $[CoBr(NH_3)_5](ClO_4)_2$[3] were prepared as described in the literature[2,3] and recrystallized twice. Disodium dihydrogen ethylenediaminetetraacetate ($Na_2[H_2edta]$) and other chemicals used were of guaranteed-reagent grade. Deionized water was further distilled with and without addition of permanganate in a glass still.

Procedure

The procedure is essentially the same as described in the previous paper.[1] The pH of the reaction solution was adjusted with perchloric acid and sodium acetate.

RESULTS AND DISCUSSION

As seen in Fig. 1, when the solution containing $[Ru(bpy)_3]^{2+}$ and $[CoBr(NH_3)_5]^{2+}$ or $[CoCl(NH_3)_5]^{2+}$ in the absence of EDTA was irradiated with visible light the $[Ru(bpy)_3]^{2+}$ ion was oxidized to the $[Ru(bpy)_3]^{3+}$ ion by a bimolecular quenching reaction with the photoexcited species $[Ru(bpy)_3]^{2+*}$, and the $[Ru(bpy)_3]^{3+}$ ion could be reduced rapidly to the $[Ru(bpy)_3]^{2+}$ ion by the Br^- ion (see plot Δ in Fig. 1), and thus the variation curve for the $[Ru(bpy)_3]^{2+}$ ion concentration using $[CoBr(NH_3)_5]^{2+}$ as a quencher was very different from that using the $[CoCl(NH_3)_5]^{2+}$ ion. On the other hand, when a reaction mixture of the same constituents as in Fig. 1 contained some EDTA, the $[Ru(bpy)_3]^{2+}$ ion concentration did not change at all with $[CoBr(NH_3)_5]Br_2$, $[CoBr(NH_3)_5](ClO_4)_2$ and $[CoCl(NH_3)_5]Cl_2$ during irradiation by light, and instead the $[Co(edta)]^-$ complex was produced in proportion to the irradiation time (t), at least for the initial stage of the reaction (see Figs 2 and 3).

This fact indicates that the $[Ru(bpy)_3]^{3+}$ ion once formed is rapidly reduced to the $[Ru(bpy)_3]^{2+}$ ion by the Co(II)EDTA† ion produced by the reaction between EDTA and Co^{2+}_{aq} {or $[CoBr(NH_3)_5]^+$} [see eqn (4)]. The latter species could be formed first by the quenching reaction of the $[Ru(bpy)_3]^{2+*}$ ion with $[CoBr(NH_3)_5]^{2+}$, and dissociates rapidly to Co^{2+}_{aq}, Br^- and NH_3 (or NH_4^+) [see eqn (3)]. It was found that the formation rate of $[Co(edta)]^-$ was indifferent to the Br^- ion over the initial concentration range 0–0.02 mol dm^{-3} in the reaction mixture: the formation rate $d[[Co(edta)]^-]/dt$ was 2.56×10^{-7}, 2.66×10^{-7} and 2.60×10^{-7} mol

† The formula Co(II)EDTA used in the present paper represents a mixture of $[Co(edta)]^{2-}$ and $[Co(Hedta)]^-$; the equilibrium constant $K=[[Co(Hedta)]^-]/\{[[Co(edta)]^{2-}][H^+]\}$ for the reaction $[Co(edta)]^{2-}+H^+\rightleftharpoons[Co(Hedta)]^-$ is $10^{3.1}$ dm^3 mol^{-1} at an ionic strength of 0.10 mol dm^{-3} and 20°C.[4] Thus, the species $[Co(Hedta)]^-$ should be dominant in acid solutions of pH 2–3.

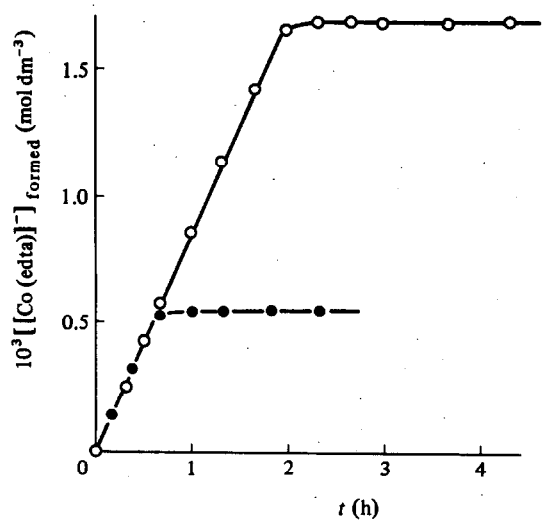

Fig. 2. Examples of $[[Co(edta)]^-]_{formed}$ vs t. Conditions: pH 2.2 (0.02 mol dm^{-3} $HClO_4$), ionic strength 0.21 mol dm^{-3}; initial concentrations are 1×10^{-2} mol dm^{-3} $[CoBr(NH_3)_5](ClO_4)_2$, and 1.7×10^{-3} mol dm^{-3} and 5.4×10^{-4} mol dm^{-3} $Na_2[H_2edta]$ for plots ○ and ●, respectively; and 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$. The other conditions are the same as those in Fig. 1 with irradiation by four lamps (see footnote ‡ on p. 1575).

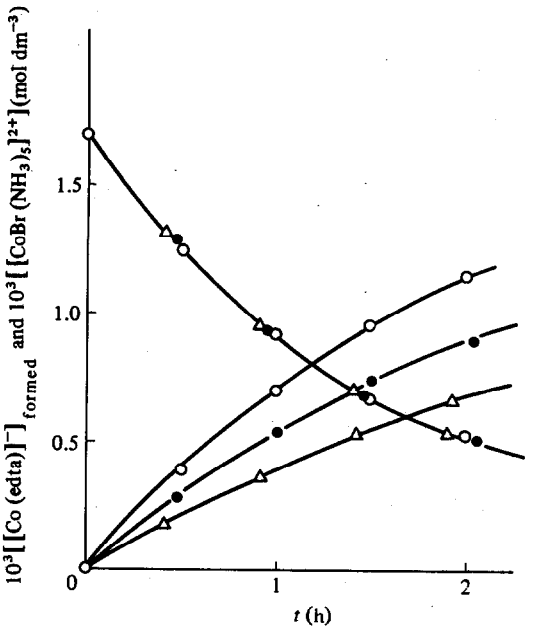

Fig. 3. Variations in the $[[Co(edta)]^-]_{formed}$ and $[[CoBr(NH_3)_5]^{2+}]$ concentrations at pH 4.75. Conditions: 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$, 1.7×10^{-3} mol dm^{-3} $[CoBr(NH_3)_5](ClO_4)_2$, 0.05 mol dm^{-3} acetic acid and sodium acetate (pH 4.75), and 1×10^{-3}, 2×10^{-3} and 4×10^{-3} mol dm^{-3} EDTA for plots ○, ● and △, respectively. Other conditions are the same as in Fig. 2.

dm^{-3} s^{-1} in 0, 0.004 and 0.02 mol dm^{-3} Br^-, respectively.†

Effect of hydrogen ion concentration on the formation rate of $[Co(edta)]^-$

The initial rate of formation of the $[Co(edta)]^-$ ion [V_i in eqn (8)] was determined from plots of $[[Co(edta)]^-]_{formed}$ vs t for various hydrogen ion concentrations. As seen in Fig. 4, the formation rate of $[Co(edta)]^-$ decreased at pH < 2 and pH > 3, and was maximum at pH 2–3.

The decrease in the formation rate of $[Co(edta)]^-$ at pH < 2 would be due to the increase in the protonated species of EDTA, i.e. H_4edta, H_3edta^- etc., and due to the decrease in the equilibrium concentration of $[Co(edta)]^{2-}$ in such acid solutions. While the decrease in the formation rate of $[Co(edta)]^-$ at pH > 3 is caused by the occurrence of a reaction between EDTA and $[Ru(bpy)_3]^{3+}$ which competes with the formation reaction of $[Co(edta)]^-$, i.e. the reaction between Co(II)EDTA and $[Ru(bpy)_3]^{3+}$ [eqn (5)]. At pH 2–3, the formation rate of $[Co(edta)]^-$ was independent of the EDTA concentration in the reaction mixture, and the concentration of the $[Co(edta)]^-$ formed was

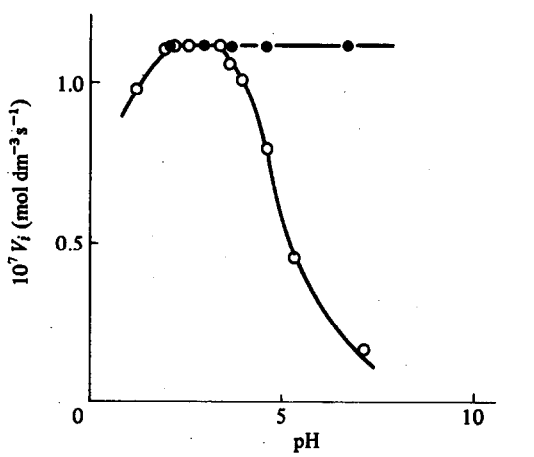

Fig. 4. Effect of pH on the formation rate of $[Co(edta)]^-$. Conditions for plot ○: 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$, 2×10^{-3} mol dm^{-3} $[CoBr(NH_3)_5](ClO_4)_2$, 2×10^{-3} mol dm^{-3} $Na_2[H_2edta]$, and ionic strength 0.09 mol dm^{-3}. Other conditions are as in Fig. 2. Conditions for plot ●: all the conditions are the same as in plot ○, except for 2×10^{-3} mol dm^{-3} $CoSO_4$, which is equivalent to the EDTA concentration added before starting the reaction.

† The rate constants for the oxidation reactions of water (H_2O), Br^- and Co(II)EDTA by the $[Ru(bpy)_3]^{3+}$ ion are 3.2×10^{-4} s^{-1},[1] 0.44 dm^3 mol^{-1} s^{-1}, and $\geqslant 10^4$ dm^3 mol^{-1} s^{-1}, respectively. Thus, the reaction between Co(II)EDTA and $[Ru(bpy)_3]^{3+}$ could occur predominantly in the presence of Br^- in aqueous solutions.

Table 1. Formation of $[Co(edta)]^-$ and decomposition of $[CoBr(NH_3)_5]^{2+}$ by the photo-induced reaction[a]

t (h)	$10^3[[Co(edta)]^-]_{formed}$ (mol dm^{-3})	$10^3[[CoBr(NH_3)_5]^{2+}]_{decomposed}$ (mol dm^{-3})	$\frac{[[Co(edta)]^-]_{formed}}{[[CoBr(NH_3)_5]^{2+}]_{decomposed}}$
0.5	0.39	0.39	1.00
1.0	0.70	0.70	1.00
1.5	0.97	1.01	0.96
2.0	1.14	1.11	1.03
			Av. 1.00 ± 0.02

[a] Conditions are the same as for plot ○ in Fig. 2, except for 2×10^{-3} mol dm^{-3} $[CoBr(NH_3)_5](ClO_4)_2$.

equal to that of the $[CoBr(NH_3)_5]^{2+}$ decomposed due to the photo-induced ligand-substitution reaction (see Table 1).

Therefore, the stoichiometry and overall reaction at pH 2–3 may be written as follows:

$$[CoBr(NH_3)_5]^{2+} + EDTA \xrightarrow[[Ru(bpy)_3]^{2+}]{h\nu} [Co(edta)]^- + Br^- + 5NH_4^+ \quad \text{(at pH 2–3).} \quad (1)$$

When some $CoSO_4$ concentrations were added to the reaction mixture before starting the reaction, and when all the EDTA species existed as Co(II)EDTA,† the formation rate of $[Co(edta)]^-$ was independent of pH over the range 2–7 and was equal to that at pH 2–3 without addition of $CoSO_4$ (see plot ● in Fig. 4). At pH 4.75, the rate of the decrease in the $[CoBr(NH_3)_5]^{2+}$ ion concentration in the photo-induced reaction system was not dependent on the EDTA concentration, but the formation rate of the $[Co(edta)]^-$ ion decreased with increasing EDTA concentration (see Fig. 3), and the $[[Co(edta)]^-]_{formed}/[[CoBr(NH_3)_5]^{2+}]_{decomposed}$ ratio was 0.7, 0.6 and 0.5 at 0.001, 0.002 and 0.004 mol dm^{-3} EDTA, respectively, at the start of the reaction. These ratio values were smaller than unity being quite different from the corresponding value of 1.0 at pH 2–3 (see Table 1). Consequently, the photo-induced ligand-substitution reaction between $[CoBr(NH_3)_5]^{2+}$ and EDTA proceeds most efficiently (at an efficiency of 100%) at pH 2–3, and proceeds less efficiently at the other pH values of the reaction solution. The experiments hereafter will be carried out at pH 2.2 in a solution of 0.02 mol dm^{-3} $HClO_4$.

Dependence of reaction rate on the $[CoBr(NH_3)_5]^{2+}$ *ion concentration*

The initial rate of formation of $[Co(edta)]^-$ [V_i in eqn (8)] was determined from plots as in Fig. 2, and the reciprocal V_i was plotted against the reciprocal $[CoBr(NH_3)_5]^{2+}$ concentrations at the start of the reaction. As seen in Fig. 5, the V_i^{-1} vs $[[CoBr(NH_3)_5]^{2+}]_i^{-1}$ plots showed a straight line with an intercept. The intercept was hardly dependent on the temperature as well as on the ionic strength, but the slope decreased with increasing temperature or ionic strength (see Fig. 5 and Table 2).

Effect of the irradiated-light intensity on formation of $[Co(edta)]^-$

No substitution reaction between EDTA and $[CoBr(NH_3)_5]^{2+}$ and no formation of $[Co(edta)]^-$ were found in the dark, and the rate of formation of $[Co(edta)]^-$ was proportional to the number of lamps used for irradiation. The initial rate of formation of $[Co(edta)]^-$ was 1.78×10^{-8}, 6.07×10^{-8}, 9.72×10^{-8}, 1.29×10^{-7} and 1.56×10^{-7} mol dm^{-3} s^{-1} with room light, one, two, three and four lamps, respectively, under the same conditions as those at pH 2.2 in Fig. 4.

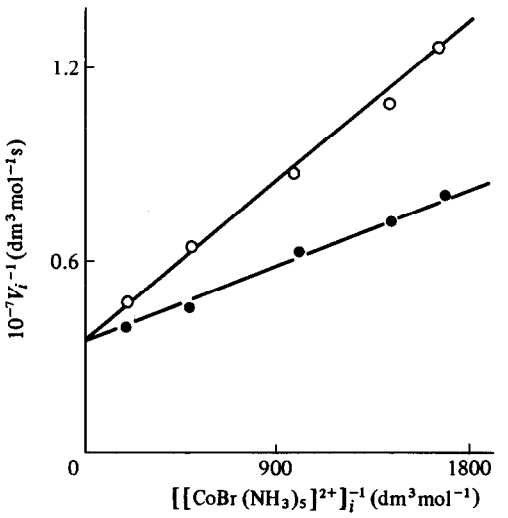

Fig. 5. Plots of V_i^{-1} vs $[[CoBr(NH_3)_5]^{2+}]_i^{-1}$ [eqn (8)]. Conditions: pH 2.2 (0.02 mol dm^{-3} $HClO_4$); other conditions as for plot ○ in Fig. 4. Plots ○ and ● indicate the results obtained at ionic strengths of 0.09 and 0.21 mol dm^{-3}, respectively.

† See footnote † on p. 1572.

[a] Conditions as in Fig. 5.
[b] Value obtained by measurement of the luminsecence of $[Ru(bpy)_3]^{2+*}$ which is quenched by the $[CoBr(NH_3)_5]^{2+}$ ion; the Stern–Volmer constant was 601 dm^3 mol^{-1}.
[c] This value has been obtained from the slope in Fig. 2 [see eqn (7″)].

It was also confirmed that the aquation of the $[CoBr(NH_3)_5]^{2+}$ ion during the occurrence of the photo-induced ligand-substitution reaction was negligible under any conditions employed in the present study and that the concentration of the $[Ru(bpy)_3]^{2+}$ ion remained constant during the photo-induced reaction.

Reaction mechanism

The following reaction mechanism could be proposed to account for the results obtained at pH 2–3:

$$[Ru(bpy)_3]^{2+} + h\nu \xrightarrow{I_a} [Ru(bpy)_3]^{2+*}$$

$$[Ru(bpy)_3]^{2+*} \xrightarrow{k_0} \begin{cases} [Ru(bpy)_3]^{2+} + h\nu' \\ [Ru(bpy)_3]^{2+} + \Delta \end{cases} \quad (2)$$

$$[Ru(bpy)_3]^{2+*} + [CoBr(NH_3)_5]^{2+} \xrightarrow{k_q} [Ru(bpy)_3]^{3+} + [CoBr(NH_3)_5]^{+}$$

$$\xrightarrow{H^+} Co^{2+}_{aq} + 5NH_4^+ + Br^-, \quad (3)$$

$$Co^{2+}_{aq}\ \{\text{or } [CoBr(NH_3)_5]^{+}\} + EDTA \rightleftharpoons Co(II)EDTA, \quad (4)\dagger$$

$$Co(II)EDTA + [Ru(bpy)_3]^{3+} \xrightarrow{k_1} [Co(edta)]^- + [Ru(bpy)_3]^{2+}, \quad (5)\dagger$$

$$[Ru(bpy)_3]^{2+*} + [Co(edta)]^- \xrightarrow{k'_q} [Ru(bpy)_3]^{3+} + Co(II)EDTA. \quad (6)$$

The overall reaction is the same as in the stoichiometric eqn (1). Although the quenching rate constant k'_q is as large as k_q [$k_q = (1.1\text{–}1.7) \times 10^9$ dm^3 mol^{-1} s^{-1} (see Table 2) and $k'_q = 2 \times 10^9$ dm^3 mol^{-1} s^{-1}], the reaction of eqn (3) proceeds predominantly when $[[CoBr(NH_3)_5]^{2+}] \gg [[Co(edta)]^-]$. Such conditions $\{[[CoBr(NH_3)_5]^{2+}] \gg [[Co(edta)]^-]\}$ should be satisfied at least for the initial period of the reaction even if the photoreaction started at a relatively low $[CoBr(NH_3)_5]^{2+}$ ion concentration. When the reaction of eqn (6) is neglected, the following rate law can be derived:

$$\frac{d[[Co(edta)]^-]}{dt} = \frac{I_a\Phi k_q[[CoBr(NH_3)_5]^{2+}]}{k_0 + k_q[[CoBr(NH_3)_5]^{2+}]}, \quad (7)\ddagger$$

where I_a indicates the amount of light absorbed, Φ indicates the quantum yield for the excited species $[Ru(bpy)_3]^{2+*}$, and, thus, $I_a\Phi$ corresponds to the formation rate of the excited species. Thus, the initial rate of formation of the $[Co(edta)]^-$ ion (V_i) is written as follows:

$$V_i^{-1} = \frac{1}{I_a\Phi} + \frac{k_0}{I_a\Phi k_q}[[CoBr(NH_3)_5]^{2+}]_i^{-1}. \quad (8)$$

Plots of V_i^{-1} vs $[[CoBr(NH_3)_5]^{2+}]_i^{-1}$ are illustrated in Fig. 5, and the intercept and slope are $1/(I_a\Phi)$ and $k_0/(I_a\Phi k_q)$, respectively. Consequently, the values of $I_a\Phi$ and k_q/k_0 are obtained from the plots, and these

† See footnote † on p. 1572.

‡ When $k_q[[CoBr(NH_3)_5]^{2+}] \gg k_0$, eqn (7) should be written as follows:

$$d[[Co(edta)]^-]/dt = (I_a\Phi) \quad (7')$$

and

$$[[Co(edta)]^-]_{formed} = (I_a\Phi)t, \quad (7'')$$

where the term $I_a\Phi$ is constant (see text and Table 2), and thus the $[[Co(edta)]^-]_{formed}$ should be proportional only to t, irrespective of the $[[CoBr(NH)_3]_5]^{2+}$ ion as well as the EDTA concentration. This is actually the kind of case given in Fig. 2, in which the value of $k_q[[CoBr(NH_3)_5]^{2+}]_i$ is 10-fold larger than the k_0 of 1.5×10^6 s^{-1},[5] and is also much larger than the $k'_q[[Co(edta)]^-]_{formed}$ values during the formation reaction of the $[Co(edta)]^-$ ion.

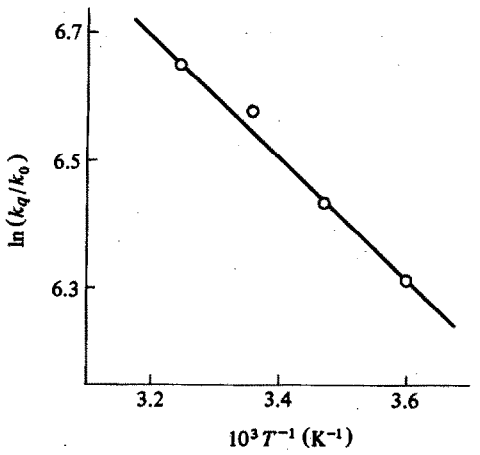

Fig. 6. Arrhenius plots for k_q/k_0. Conditions as in Table 2.

values are given in Table 2. The $I_a\Phi$ values were independent of the temperatures as well as of the ionic strength, while k_q/k_0 values were rather dependent on the temperature as well as on the ionic strength. The plot of $\ln(k_q/k_0)$ vs T^{-1} showed a straight line, giving the activation energy $E_q - E_0 = 8.31$ kJ mol^{-1} (Fig. 6).

We can evaluate the k_q values from k_q/k_0 by using $k_0 = 1.52 \times 10^6$ s^{-1}.[5] The k_q values were obtained under various conditions and are given in Table 2 together with $I_a\Phi$ and k_q/k_0 values. For comparison, the k_q value was determined by measurement of the luminescence of $[Ru(bpy)_3]^{2+*}$ in various $[CoBr(NH_3)_5]^{2+}$ concentrations with determination of the Stern–Volmer constant. The result is given in Table 2 together with values obtained by using eqn (8). They are in good agreement with each other under the given conditions. This also supports the reaction mechanism of eqns (2)–(6), and the rate law of eqns (7) and (8) is practically valid.

At pH > 3, the concentrations $[Co(edta)]^-$ ion which was formed became less than those of the $[CoBr(NH_3)_5]^{2+}$ ion which decomposed to Co^{2+}_{aq}, Br^- and NH_4^+, and the $[[Co(edta)]^-]_{formed}/[[CoBr(NH_3)_5]^{2+}]_{decomposed}$ ratio decreased with increasing EDTA concentration (see Fig. 3). This fact could be attributed to the occurrence of the reaction between EDTA and $[Ru(bpy)_3]^{3+}$. This consideration is reasonable because the reaction rate of $[Ru(bpy)_3]^{3+}$ with EDTA becomes much faster with increasing pH of the solution; e.g. the second-order rate constant for the reaction between $[Ru(bpy)_3]^{3+}$ and EDTA is 8×10^3 and 2×10^6 dm^3 mol^{-1} s^{-1} at pH 4 and pH 7, respectively.[6] The reaction of $[Ru(bpy)_3]^{3+}$ with EDTA competes with that of $[Ru(bpy)_3]^{3+}$ with Co(II)EDTA [eqn (5)], and the reaction rate of the formation of the $[Co(edta)]^-$ ion becomes slower according to the increase in the EDTA concentration at pH > 3 (see Fig. 3).

Abstract—Reaction of $[ReOCl_3(PPh_3)_2]$ with bromophenylhydrazine in methanol yields $[ReCl(N_2C_6H_4Br)_2(PPh_3)_2]$ (**1**). Complex **1** reacts with arylthiolates to give mixtures of $[Re(SAr)(N_2C_6H_4Br)_2(PPh_3)_2]$ (**2**) and $[Re_2(SAr)_7(NNR)_2]^-$. Complexes **1** and **2** display trigonal bipyramidal geometries with the phosphine ligands occupying the axial sites. A significant feature of the structures is the nonequivalence of the rhenium–diazenido moieties, such that for **1** the Re—N(1) and N(1)—N(2) distances are 1.80(2) and 1.24(3) Å, while Re—N(3) and N(3)—N(4) are 1.73(2) and 1.32(3) Å, and for **2** the Re—N distances are 1.73(1) and 1.80(2)° with corresponding N—N distances of 1.32(2) and 1.25(2) Å. Reaction of $(PPh_4)[ReO(SPh)_4]$ (**3**) with unsymmetrically disubstituted hydrazines affords complexes of the type $[ReO(SPh)_3(NMRR')]$ (R = Me, R′ = Ph for **4**). Complexes **3** and **4** display distorted square pyramidal geometries with the oxo groups apical. The significant feature of the structure of **4** is the nonlinear Re—N(1)—N(2) linkage, exhibiting an angle of 145.6(10)°. The angle does not appear to correlate with a significant contribution from a valence form with sp^2 hybridization at the α-nitrogen. *Crystal data*: **1**: monoclinic space group, $P2_1/n$, $a = 12.216(2)$ Å, $b = 19.098(2)$ Å, $c = 20.257(4)$ Å, $\beta = 106.20(1)°$, $V = 4538.3(8)$ Å^3 to give $Z = 4$; structure solution and refinement based on 1905 reflections converged at $R = 0.070$. **2**: monoclinic space group $P2_1/n$, $a = 14.393(2)$ Å, $b = 18.842(3)$ Å, $c = 20.717(4)$Å, $\beta = 110.26(1)°$, $V = 5270.5(8)$ Å^3 to give $Z = 4$ for $D = 1.53$ g cm^{-1}; structure solution and refinement based on 4249 reflections to give $R = 0.070$. **3**: monoclinic space group $P2_1/n$, $a = 12.531(2)$ Å, $b = 24.577(4)$ Å, $c = 16.922(3)$ Å, $\beta = 99.06(1)°$, $V = 5146.2(9)$ Å^3, $D = 1.36$ g cm^{-3} for $Z = 4$, 2912 reflections, $R = 0.050$. **4**: monoclinic space group $p2_1/n$, $a = 16.137(2)$ Å, $b = 9.863(2)$ Å, $c = 16.668(2)$ Å, $\beta = 111.12(1)°$, $V = 2474.7(6)$ Å^3, $D = 1.74$ g cm^{-3} for $Z = 4$, 2940 reflections, $R = 0.066$.

Although there have been extensive recent studies of transition-metal complexes with sulfur ligands,[1] relatively few simple monomeric rhenium thiolato complexes have been reported.[2–4] In particular, examples of rhenium thiolato species incorporating small organic molecules are rare. As part of our studies of the binding of small molecules to metal sulfur sites, we have prepared a number of diazeonido– and hydrazido(2−)–rhenium complexes with aromatic thiolato coligands.

The organodiazenido group $(NNR)^+$ is formally isoelectronic with the nitrosyl ligand NO^+ and chemically related to the diazenide unit, —NNH, a potential intermediate in the reduction of dinitrogen to ammonia. Structural studies have confirmed that the organodiazenido ligand may adopt a variety of geometries: "singly bent",[5] "doubly bent"[6] and bridging.[7]

Unsymmetrically disubstituted organohydrazines may function as hydrazido(2−) ligands, —NNRR′, which arise formally and often in practice, from the protonation of the terminal nitrogen of the organodiazenido ligand. Once again linear[8]

* Author to whom correspondence should be addressed.

and bent[9] M–N–N frameworks have been observed.

In this paper we report the synthesis and structural characterization of the five-coordinate mononuclear rhenium diazenido and hydrazido(2−) complexes $[Re(NNC_6H_4Br\text{-}4)_2(SC_6H_3\text{-}2,5\text{-}Me_2)(PPh_3)_2]$ (**2**) and $[ReO(NNMePh)(SC_6H_5)_3]$ (**4**), respectively. Complex **2** was prepared by the reaction of $[ReCl(NNC_6H_4Br\text{-}4)_2(PPh_3)_2]$ (**1**) with 2,5-dimethylthiophenol. Although the five-coordinate species **1** had been isolated previously,[10] some ambiguity existed with respect to the structural identity, whether mononuclear or chloro-bridged binuclear. This study establishes the mononuclear trigonal bipyramidal structure, analogous to that of $[MoCl(NNMe_2)_2(PPh_3)_2]^+$.[11]

The oxo-hydrazido(2−) species (**4**) was isolated from the reaction of $[ReO(SPh)_4]^-$ (**3**) with the disubstituted hydrazine by replacement of a thiophenolate group. Although the retention of the oxo group was unanticipated, a similar reaction trend has been observed for $[MoO(SPh)_4]^-$ with disubstituted hydrazines.

DISCUSSION

The most frequently employed synthetic routes to aryldiazenido complexes employ oxidative addition of a diazonium salt or insertion into a metal–hydrogen bond to give a diazene complex which is subsequently deprotonated.[12] The silylated diazene Me_3SiN_2Ph has also been shown to provide an efficient method of introducing the aryldiazenido function.[13] Finally, direct reaction of a metal oxo species with an arylhydrazine may proceed by a condensation mechanism, followed by deprotonation, to yield a metal–aryldiazenido complex.[14] Employing the latter methodology, the rhenium(V)–oxo complex $[ReOCl_3(PPh_3)_2]$ reacts with excess *p*-bromophenylhydrazine in methanol to give **1** as a red–orange precipitate in 70–80% yield The complex exhibits a strong IR band at 1520 cm^{-1} assigned to ν(N=N). The X-ray diffraction studies discussed below have established the identity of this species as a mononuclear complex, analogous to the manganese complex $[MnX(N_2Ph)_2(PPh_3)_2]$.[15]

Suspension of **1** in warm benzene or methylene chloride gives a red-maroon material with strong IR bands at 1560 and 1520 cm^{-1}. We suspect the occurrence of a dimerization reaction in aprotic solvents giving a doubly chloro-bridged species (**1a**), implying both linear and bent diazene ligands functioning as three- and one-electron donors.

Complex **1** reacts with excess HCl in methanol to give a red-orange material analyzing for $[ReCl_2(NNHC_6H_4Br\text{-}4)(NNC_6H_4Br\text{-}4)(PPh_3)_2]$ (**1b**). The complex shows strong IR bands at 1625 and 1572 cm^{-1} assigned to ν(N—N) for the hydrazido(2−)- and diazenido-type ligands. Complex **1b** appears to be structurally analogous to the previously reported $[ReBr_2(N_2Ph)(NNHPh)(PPh_3)_2]$ where protonation occurs at the β-nitrogen of the nitrogen ligand.[10]

Addition of an excess of 2,5-dimethylthiophenol to **1** results in a dark red solution from which orange crystals of **2** are observed to form in several hours. The characteristic IR bands at 1545 and 1515 cm^{-1} confirm the presence of the bisorganodiazenido–rhenium unit. In the reaction with unsubstituted phenylthiolate, a second crop of lustrous black crystals separates from the mother liquor after several days. This species has been identified as the formally rhenium(II) complex $[Re_2(SAr)_7(NNC_6H_4Br\text{-}4)_2]^-$, isolated as the triethylammonium salt. The structural and chemical properties of this class of complexes have been discussed previously.[16] Although displacement of the chloro ligand of **1** by thiophenolate occurs readily, under the reaction conditions employed substitution of the phosphine ligands and one organodiazenido group by thiolate ligands occurs only slowly to yield the stable triply thiolato-bridged species $[Re_2(SAr)_7(NNR)_2]^-$.

In contrast to the behavior of **1**, complex **2** reacts with HCl to produce intractable materials, presumably as a result of protonation at the coordinated thiolate sulfur rather than at nitrogen. This preferential protonation at the thiolate site appears to be characteristic of diazenido–thiolate complexes.

Although there are now several examples of molybdenum hydrazido(2−) complexes with thiolate coligands,[17] analogous rhenium complexes have not been reported. In an attempt to isolate rhenium species of this type, $[ReOCl_3(PPh_3)_2]$ was treated with an excess of an unsymmetrically disubstituted organohydrazine, such as $H_2NNMePh$, to yield a crystallizine, light orange material analyzing for $[ReCl(NNMePh)_2(PPh_3)_2]$. Both —$NNR_2$ ligands cannot serve as four-electron donors, since the metal would have a 20-electron count, suggesting that one —NNR_2 group is bent at the α-nitrogen and functions as a two-electron donor.

Reaction of $[ReCl(NNMePh)_2(PPh_3)_2]$ with excess thiophenol in benzene yields **4** in low yield as a diamagnetic bright red crystalline material. The presence of the oxo group is confirmed by a strong IR band at 945 cm^{-1}, while the band at 1545 cm^{-1} is attributed to the hydrazido(2−) ligand. The oxo ligand is apparently introduced from residual oxygen in the reaction solvent, and yields may be considerably improved by carrying out the synthesis in

oxygenated solvents. The oxo–hydrazido complex (**4**) may also be prepared by reaction of $[ReO(SPh)_4]^-$ (**3**) with $H_2NNMePh$. Although we anticipated the replacement of the oxo group of **3** by a hydrazido(2−) ligand, **3** reacted with the 1,1-disubstituted hydrazine with retention of the oxo group and replacement of a thiophenolate group by the hydrazido(2−) ligand to give **4**. This is not a simple methathesis reaction as concomitant oxidation of the metal from Re^{V} to Re^{VII} occurs. A hydrazido(1−) species such as $[Re(NHNMePh)O(SPh)_3]^-$ may be an intermediate. The formation of a rhenium–nitrogen multiple bond may provide the driving force for oxidative elimination of the hydrogen on the α-nitrogen.

DESCRIPTION OF THE STRUCTURES

Relevant bond lengths and angles are tabulated in Tables 1 and 2, and ORTEP views of the structures are presented in Figs 1–4.

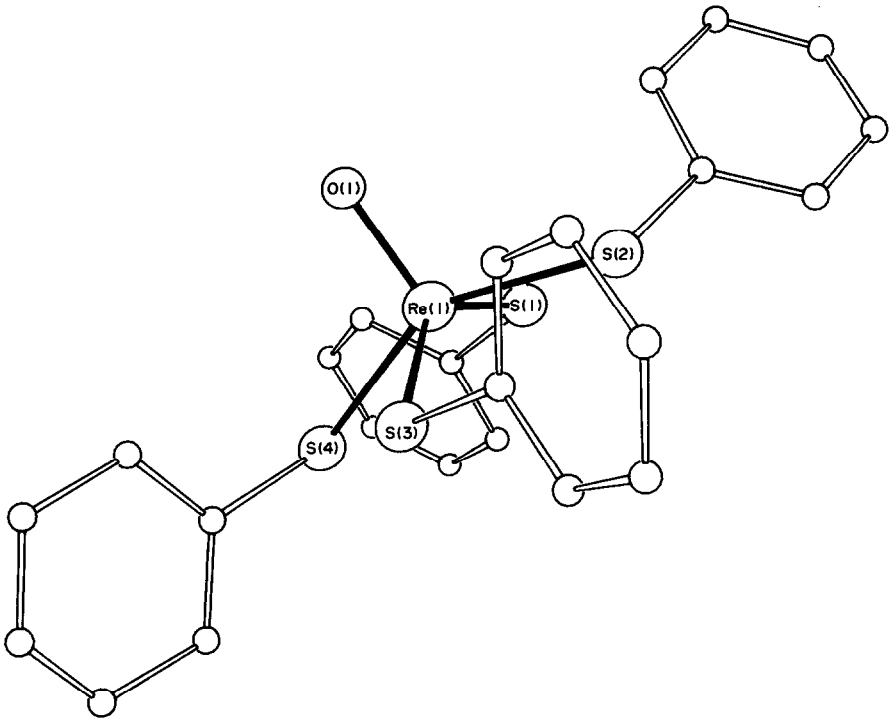

Fig. 3. ORTEP view of the structure of $[ReO(SPh)_4]^-$, crystallized as the $(PPh_4)^+$ salt.

The structure of **1** consists of discrete monomeric units. The geometry about the rhenium is best described as a trigonal bipyramidal, with the phosphine ligands axial and the equatorial plane defined by the chloro group and the α-nitrogen atoms of the diazenido ligands. The rhenium–phosphorus and rhenium–chlorine distances are unexceptional. However, an unusual feature of the structure is the inequivalence of the two rhenium–diazenido units. The Re(1)—N(1) distance of 1.80(1) Å is significantly longer than the Re(1)—N(3) distance [1.73(2) Å]. This unequivalence is reflected in the N(1)—N(2) and N(3)—N(4) distances of 1.24(2) and 1.32(3) Å, respectively, and in the Re—N(1)—N(2) and Re—N(2)—N(3) angles of 172.0(23) and 164.7(18)°. As shown in Table 3, this feature is also observed in the structures of **2** and the molybdenum(VI) cationic species $[MoCl(NNMe_2)_2(PPh_3)_2]^+$ [16] which is structurally analogous to **1** and **2**. Since there are no apparent steric interactions between the —NNR or —NNR_2 ligands and the phosphine groups, this does not appear to be simply a solid-state effect.

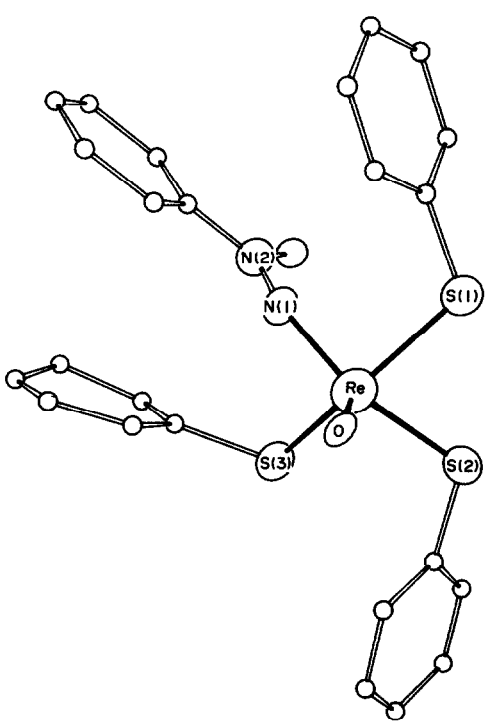

Fig. 4. ORTEP view of the structure of [ReO(NNMePh)$(SPh)_3$], showing the atom labelling.

The gross structural features of **2** are essentially identical to those of **1**, with the exception of the substitution of the thiophenolate ligand for the chloro group in the equatorial plane. The inequivalence of the diazenido ligands is pronounced, suggesting varying contributions of canonical forms **I** and **II** to the overall structure of the diazenido ligands. The Re—N(3) and N(3)—N(4) distances of 1.80(2) and 1.24(2) Å closely approximate the limiting formalism **I**, for which distances of 1.80 and 1.24 Å have been calculated.[18] On the other

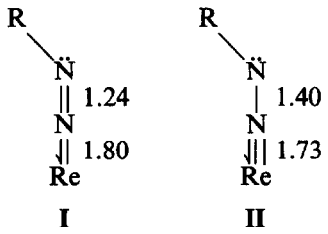
[a] tbp = trigonal bypiramidal, sq. pyr. = square pyramidal.

hand, the Re—N(1) and N(1)—N(2) distances of 1.73(1) and 1.32(2) Å suggest a significant contribution from **II** and a degree of valence isomerism for the diazenido–rhenium units of these structural types.



The structure of **3**, crystallized as the tetraphenylphosphonium salt, is identical to that of the tetraphenylarsonium salt, previously reported.[2] The geometry about the rhenium is square pyramidal with an apical oxo group. The Re—O distance of 1.66(1) Å is similar to those observed for the $(Ph_4As)^+$ salt, and for $[ReO(SCH_2CH_2S)_2]^-$[4] and $[ReO(SC_6H_2Me_3)_4]^-$.[19]

The geometry about the rhenium in **4** is best described as distorted square pyramidal with the oxo ligand occupying the apical position. The basal plane is defined by three thiolato sulfur atoms and the α-nitrogen of the hydrazido(2−) ligand. The Re atom lies *ca* 0.7 Å above the mean NS_3 basal plane.

The Re—O distance of 1.66(1) Å is identical to that observed for the parent anion (**3**), and the average Re—S distance of 2.341(6) Å is similar to that of 2.333(6) Å in **3**. The Re—S(3) distance is longer than the average of the Re—S(1) and Re—S(2) distances [2.354(4) vs 2.335(4) Å], presumably reflecting a *trans* influence of the hydrazido(2−) ligands in the pseudo-*trans* position.

The overall square pyramidal geometry adopted by **4** is similar to that observed for $[MoO(NNMe_2)(SPh)_3]^-$.[11] The presence of the oxo group in the apical position is consistent with the tendency of cylindrically symmetrical π-donors to occupy this site in order to maximize overlap with the metal d_{xz}- and d_{yz}-orbitals.[20]

The Re—N(1) and N(1)—N(2) distances of 1.858(9) and 1.26(2) Å, respectively, lie within the range found for metal hydrazido(2−) complexes,[21] and are consistent with extensive delocalization of the π-bonding throughout the Re—N(1)—N(2) unit. Although the —NNMePh ligand lies in the basal plane, the Re—N(1) distance indicates strong π-bonding to the rhenium. The hydrazido group has two orbitals available for π-bonding, the *p*-orbital on N(1) in the N(1)–N(2)–C(1)–C(7) plane and the N–N π-antibonding orbital perpendicular to this plane. The N(1)–N(2)–C(1)–C(7) plane eclipses the Re—O bond vector, ensuring that the N(1) *p*-orbital overlaps with the metal D_{z^2} orbital. The π-antibonding orbital has the correct symmetry to interact with the metal d_{xy}-orbital.

The most unusual feature of the structure is the non-linearity of the Re—N(1)—N(2) angle [145.6(10)°]. Simple electron counting suggests that $—NNR_2$ unit functions as a four-electron donor in the hydrazido(2−) formalism. Although the short N(1)—N(2) distance supports this argument, the Re—N(1)—N(2) angle suggests a contribution from a valence form with sp^2 hybridization at the α-nitrogen. This latter description of the bonding appears unlikely in view of the short Re—N(1) distance and the electronic requirements of the metal. Recent *ab initio* calculations indicate that the energies between different geometric forms of $—NNR_2$ ligand types may often be very small and that the angle at the α-nitrogen is a rather insensitive indicator of hybridization mode.[22] Consequently, extrapolating from the observed structure to an inferred charge distribution may be inappropriate.

Five-coordinate geometries appear to be quite common for rhenium complexes with strongly π-

bonding ligands, such as oxo groups and hydrazido or diazenido units. The limiting geometry, whether trigonal bipyramidal or square-based pyramidal, may be dictated in part by the steric requirements of the coligands. Thus, in the presence of bulky coligands, such as phosphines, the trigonal bipyramidal geometry is adopted with the bulky groups occupying the axial sites. Cylindrically symmetrical π-donors, such as oxo groups, appear to favor the apical position of the square-based pyramid.

EXPERIMENTAL

Materials and methods

All preparative reactions were performed in reagent grade solvents with no special precautions to eliminate atmospheric oxygen. $[ReOCl_3(PPh_3)]$ was prepared by the literature method.[23] All other reagents were obtained from standard commercial sources and used without further purification.

The following instruments were used in this work: IR, Perkin–Elmer 283B IR spectrophotometer; X-ray crystallography, Nicolet R3m diffractometer.

All compounds were isolated as crystalline solids. Microanalytical data were obtained by MicAnal, Tucson, AZ.

Preparation of compounds

$[ReCl(PPh_3)_2(NNC_6H_4Br\text{-}4)_2]$ (**1**). Oxotrichlorobis-(triphenylphosphine) rhenium (2.0 g), *p*-bromophenyl hydrazine hydrochloride (4.3 g) and triethylamine (15 cm^3) were heated under reflux with stirring in 150 cm^3 methanol for 30 min. The resulting red-brown solution is filtered, and the red precipitate washed with dry methanol, then air-dried giving 70% yield. Found: C, 51.3; H, 3.3; N, 5.0. Calc. for $[ReCl(PPh_3)_2(NNC_6H_4Br)_2]$: C, 51.7; H, 3.4; N, 5.0%.

$[Re(SC_6H_3\text{-}2,5\text{-}Me_2)(PPh_3)_2(NNC_6H_4Br\text{-}4)_2]$ (**2**). Chlorobis(triphenylphosphine) bis(*p*-bromophenyldiazenido) rhenium (0.5 g), 2,5-dimethylthiophenol (0.43 g), and diisopropylethylamine (0.5 cm^3) were warmed gently with stirring in benzene (150 cm^3) overnight. The resulting deep red solution was filtered and the benzene removed by rotary evaporation. The red oil was dissolved in dichloromethane and layered with methanol–diethyl ether. Large red crystals form within 24 h. Found: C, 55.1; H, 3.9; N, 4.5. Calc. for $[Re(SC_6H_3\text{-}2,5\text{-}Me_2)(PPh_3)_2(NNC_6H_4Br\text{-}4)_2]$: C, 55.3; H, 3.9; N, 4.6%.

$(PPh_4)[ReO(SPh)_4]$ (**3**). Was prepared by literature method with substitution of tetraphenyl phosphonium bromide for the arsonium salt.

$[ReO(NNMePh)(SPh)_3]$ (**4**). $(PPh_4)[ReO(SPh_4)]$ (1.0 g) 1,1-methylphenyl hydrazine (0.57 cm^3) and diisopropylethylamine (1.0 cm^3) were refluxed in 100 cm^3 of methanol with stirring. The color gradually changed from purple-black to red, after which the solution is filtered. The methanol was removed by rotary evaporation giving a red oil. This material is redissolved in methanol and layered with diethyl ether, giving bright red-orange crystals. Found: C, 45.9; H, 3.5; N, 4.2. Calc. for $ReO(NNMePh)(SPh)_3$: C, 46.2; H, 3.6; N, 4.3%.

X-ray crystallography

The experimental details of the data collections and structure solutions are summarized in Table 4. A complete description of crystallographic protocols may be found in Ref. 24.

Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

CHARACTERIZATION OF MAGNESIUM–ALUMINUM DOUBLE HYDROXIDE PREPARED FROM ALKOXIDES AND ITS PRODUCTS OF THERMOLYSIS

OSAMU YAMAGUCHI,* HIROYUKI TAGUCHI, YUTAKA MIYATA, MASARU YOSHINAKA and KIYOSHI SHIMIZU

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kyoto 602, Japan

(*Received* 5 *January* 1987; *accepted* 6 *February* 1987)

Abstract—A magnesium–aluminum double hydroxide was prepared by the simultaneous hydrolysis of magnesium and aluminum alkoxides. Pure double hydroxide is obtained between 0.6 and 0.8 in the $Mg^{2+}/(Mg^{2+}+Al^{3+})$ mole ratio. Infrared spectra were compared with those of $4Mg(OH)_2 \cdot Al(OH)_3$ synthesized by Feitknecht and Gerber, and the naturally occurring mineral $Mg_6Al_2(OH)_{18} \cdot 4H_2O$. The compounds MgO and $MgAl_2O_4$ crystallize slowly above $\approx$ 500°C and $\approx$ 800°C, respectively. Powders for the double hydroxide gave large aggregates of small particles. Definite signs of particle growth and a marked increase in crystallite growth were seen in powders produced above 1100°C. Specific surface areas of powders heated at low temperatures are very high and did not fall below 10 m^2/g until the heating temperature was raised above 1100°C.

A magnesium–aluminum double hydroxide is one of compounds of layer lattice structures that were shown by Feitknecht[1] to form by the combination of divalent and trivalent ions of similar atomic radii. A study dealing with the Mg–Al double hydroxide was first carried out by Feitknecht and Gerber[2] in which precipitations were prepared from magnesium and aluminum chloride solution in the presence of excess sodium hydroxide. The formula of the double hydroxide was given as $4Mg(OH)_2 \cdot Al(OH)_3$. Mortland and Gastuche[3] synthesized the double hydroxide from mixed chloride solution at pH 10 by the use of sodium carbonate. However, no data for the characterization of the double hydroxide, except for the X-ray[2,3] and infrared spectrum[2] analyses, and its heating products have been reported. Aside from the preparation of the double hydroxide, a new magnesium–aluminum hydroxide mineral $Mg_6Al_2(OH)_{18} \cdot 4H_2O$, termed as meixnerite, was recently found in cracks of a serpentine rock near Ybbs-Persenbeug (Lower Austria).[4]

In the present study, a Mg–Al double hydroxide was found to form by the simultaneous hydrolysis of magnesium and aluminum alkoxides. The present paper deals with the characterization of the double hydroxide and its products of thermolysis.

EXPERIMENTAL PROCEDURE

Magnesium methoxide $Mg(OCH_3)_2$ was prepared by the reaction of magnesium foil (> 99.99%) and analytical-grade methanol containing ethyl bromide (MeOH/EtBr = 4:1) at room temperature.[5] Aluminum isopropoxide $Al(OC_3H_7)_3$ was synthesized by heating aluminum metal (> 99.99%) in an excess of analytical-grade 2-propanol with mercury(II) chloride (10^{-4} mol/mol of metal) as a catalyst for 10 h at 82°C.[6] The mixed alkoxides in various compositions shown in Table 1 were refluxed for 10 h and then, except for the mole ratio $Mg^{2+}/(Mg^{2+}+Al^{3+}) = 0.9$, hydrolyzed by adding conductivity water containing ammonium hydroxide ($H_2O/NH_4OH = 2:1$) at room temperature. The temperature was slowly increased to 75°C while the resulting suspensions were stirred. The hydrolysis products were separated from the suspensions by filtration, washed 15 times in hot water, and dried at 80°C under reduced pressure. On the other hand, in the mole

ratio $Mg^{2+}/(Mg^{2+}+Al^{3+}) = 0.9$ an aqueous solution of sodium hydroxide was added to the mixed alkoxide at room temperature with stirring to adjust the pH to the optimum value of 11.* The resulting suspension was warmed slowly to 75°C with stirring. Subsequent operations were made by using the same technique as described above.

RESULTS AND DISCUSSION

Identification of starting powder

The starting powders were examined by X-ray diffraction (XRD) using Ni-filtered CuKα radiation (Table 1). The starting powder A contained two crystalline phases identified as boehmite AlO(OH) and a Mg–Al double hydroxide. The double hydroxide was obtained as a single phase in B through D. The starting powder E was a mixture of $Mg(OH)_2$ and the double hydroxide. According to Feitknecht and Gerber,[2] the stability of the double hydroxide is due, in part, to Cl^- ions that compensate for the induced positive charges resulting from the substitution of Al^{3+} for Mg^{2+} ions. The formation of the double hydroxide in the present study is probably due to the Br^- ions generated from ethyl bromide used in preparing the magnesium methoxide. Table 2 shows the X-ray data for B through D; the diffraction lines were shifted at higher angles with increasing Mg^{2+} content. They were indexed as a hexagonal unit cell with lattice parameters presented in Table 2. The values of the lattice parameters were generally consistent with those of $4Mg(OH)_2 \cdot Al(OH)_3$ ($a = 0.309$ nm, $c = 2.37$ nm)[2] and $Mg_6Al_2(OH)_{18} \cdot 4H_2O$ ($a = 0.30463$ nm, $c = 2.2932$ nm).[4]

Emission spectroscopic analysis showed that the impurities in starting powder B were 10 Fe, 10 Ca, 50 Pb, 50 K, 100 Si, and 100 ppm Na. All other cation impurities were present in amounts less than 10 ppm.

Experimental results obtained from starting powder B will hereinafter be described.

Thermal analysis

Thermogravimetry (TG) and differential thermal analysis (DTA) were conducted in air at a heating

* Aqueous NaOH solution was used because $Mg(OH)_2$, being one of hydrolysis products, was dissolved by NH_4OH.

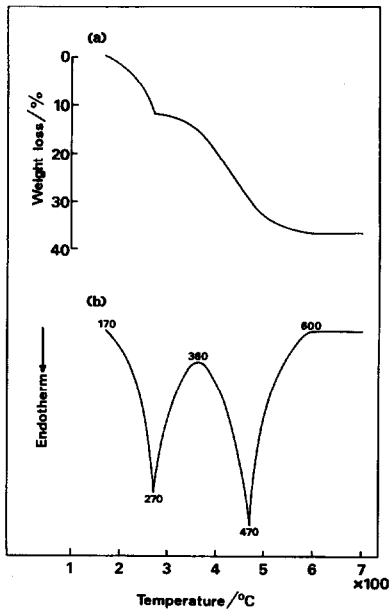

Fig. 1. (a) Thermogravimetry and (b) differential thermal analysis curves for starting powder B.

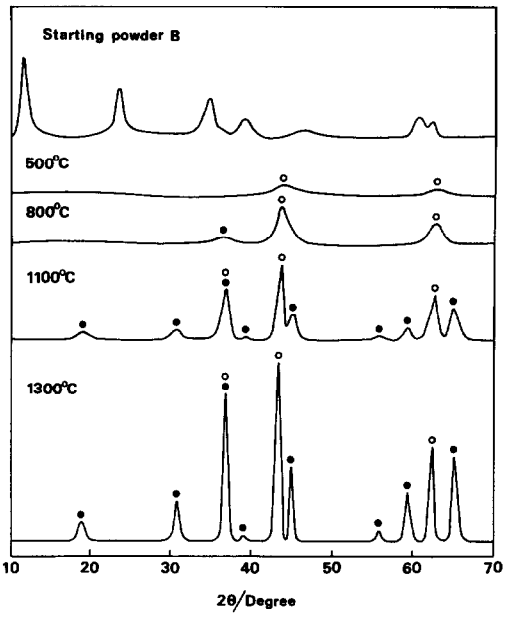

Fig. 2. X-ray diffraction patterns for starting powder B and specimens quenched after heating to various temperatures. Phases: ○, MgO; ●, $MgAl_2O_4$.

rate of 10°C/min; α-alumina was used as the reference for the DTA. Figure 1(a) shows a TG curve of starting powder. The dehydration proceeded in two steps and it was essentially completed at 600°C. The 36.7% weight loss was more than the theoretical value (32.6%) due to the release of adsorbed CO_2, as will be described in the latter section. The DTA curve reveals two endothermic peaks at 170° to 360°C and 360° to 600°C [Fig. 1(b)]; these correspond to two steps of dehydration. Although MgO and spinel $MgAl_2O_4$ crystallized slowly above $\approx$ 500°C in the latter stages of dehydration and $\approx$ 800°C, respectively, no exothermic peaks due to the crystallization were observed throughout the heating process.

Product of thermolysis

The specimens were heated at a rate of 10°C/min and then quenched and examined by XRD. Figure 2 shows the X-ray diffraction patterns for starting powder and products of thermolysis. The lines of the double hydroxide decreased in intensity with increasing temperature above 170°C and disappeared at 600°C. The lines corresponding to MgO and $MgAl_2O_4$ began to appear at $\approx$ 500°C and $\approx$ 800°C, respectively, and their intensities increased slowly up to 1100°C. The specimen heated at 1100°C gave the characteristic pattern of the mixture, although the lines were broadened. Both phases with sharp lines developed rapidly above 1100°C.

Infrared spectra

Infrared spectroscopy was performed on a dispersion in potassium bromide using the pressed-disc technique. The IR spectra of the starting powder is shown in Fig. 3 and compared with those of $4Mg(OH)_2 \cdot Al(OH)_3$[2] and $Mg_6Al_2(OH)_{18} \cdot 4H_2O$;[4] these spectra were very similar in shape. The absorption band resulting from the O–H stretching vibration based on interlayer water was observed at 3450 cm^{-1}. The bands at 3000 and 1625 cm^{-1} are due, respectively, to the O–H stretching and bending vibrations of H_2O and, on the basis of preparation history, represent adsorbed water. The mineral $Mg_6Al_2(OH)_{18} \cdot 4H_2O$ contained 2% CO_2.[4] In addition, Feitknecht and Gerber[2] reported that considerable amounts of CO_2 were adsorbed on the surface of the double hydroxide because aqueous NaOH solution was used in preparation. The absorption bands resulting from CO_3^{2-} stretching vibrations, as well as the data reported, were present at 1410, 1360, 1050, and 865 cm^{-1}; this is probably due to the NH_4OH solution containing CO_2 used in hydrolysis. These bands disappeared in the specimen heated at 600°C. Characteristic bands derived from the structure of the Mg–Al double hydroxide were observed at 780, 680, 555, and 450 cm^{-1}. The spectrum of the specimen after heating at 600°C showed the presence of the bands at 775, 690, 515, and 430 cm^{-1} and their intensities increased with increasing temperature up to 1100°C. The IR spectra for the specimen obtained by heating at 1300°C,

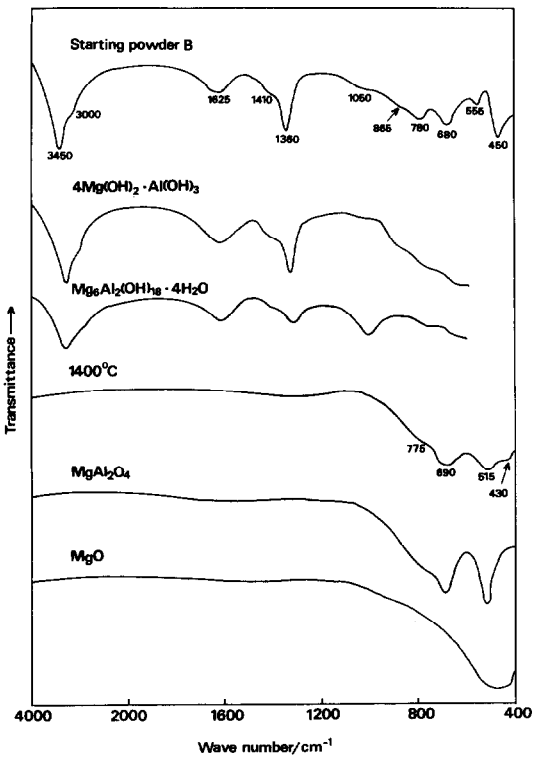

Fig. 3. Infrared absorption spectra for starting powder B, $4Mg(OH)_2 \cdot Al(OH)_3$, $Mg_6Al_2(OH)_{18} \cdot 4H_2O$, specimen quenched after heating B to 1300°C, $MgAl_2O_4$, and MgO.

$MgAl_2O_4$,* and MgO† are also shown in Fig. 3. The data for $MgAl_2O_4$ and MgO were in good agreement with those reported previously.[7-9] The spectrum pattern of the specimen, being the mixture of MgO and $MgAl_2O_4$, is similar to that of pure $MgAl_2O_4$. According to the $MgAl_2O_4$ data,[7,8] the bands in the 500–800 cm^{-1} range are assigned to the Al–O stretching vibration of AlO_6 octahedra. On the other hand, MgO is characterized by only a strong band due to the Mg–O streching vibration between 430 and 550 cm^{-1}.[9] Accordingly, the bands at 775, 690, and 515 cm^{-1} of the specimen can be assigned to Al–O stretching vibrations. The band at 430 cm^{-1} is due to Mg–O stretching vibration.

Powder characterization

Powders for electron microscopic examination were dispersed in amyl acetate by a 5 min ultrasonic treatment. Drops of the dispersion were dried on carbon film. Examination was carried out under a 100 keV beam. Electron micrographs of starting powder and specimens heated to various temperatures are shown in Fig. 4. The starting powder gave large aggregates of small particles. At 600° and 1000°C smaller aggregates (< 1 μm) were formed. Definite signs of particle growth were seen in powders produced above 1100°C.

The variation of crystallite size with increasing temperature was determined from X-ray line broadening.[11] Pure $MgAl_2O_4$ and MgO, described in the former section, were used as the samples of unbroadened line widths. The lines used were the (400) and (311) reflections for $MgAl_2O_4$ and the (200) and (220) reflections for MgO. Figure 5 shows the curves for crystallite growth of MgO and $MgAl_2O_4$ in the products with increasing temperature. A marked increase in crystallite growth of both compounds occurred above 1100°C. These results agree with observations made by the electron microscope.

Specific surface area of the specimens obtained at various temperatures was measured with a BET method using N_2 adsorption after they were dried at 200°C in vacuum. A continuous decrease in surface area with increasing temperature is shown in Fig. 6. Surface areas at low temperatures were very high and did not drop below 10 m^2/g until the heating temperature was raised above 1100°C. As described above, MgO and $MgAl_2O_4$ crystallized slowly from $\approx$ 500°C and $\approx$ 800°C, respectively, to $\approx$ 1100°C. High surface areas at low temperatures must be associated with amorphous phases.

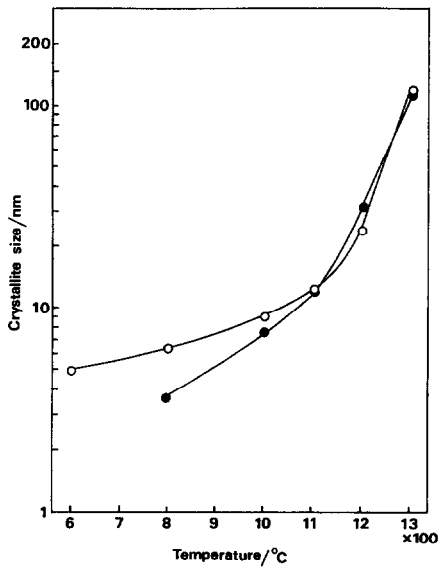

Fig. 5. Crystallite size of MgO and $MgAl_2O_4$ in products obtained from starting powder B with increasing temperature. Phases: ○, MgO; ●, $MgAl_2O_4$. Heating rate is 10°C/min.

*$MgAl_2O_4$ was prepared by solid state reaction between MgO and Al_2O_3 for 10 h at 1500°C.

†MgO was prepared by decomposition of $Mg(OH)_2$ for 3 h at 1200°C.

SYNTHESIS AND CHARACTERIZATION OF NOVEL CHALCOGEN AND PNICTOGEN COORDINATED Bi(III) COMPLEXES—THE FIRST Se,Se′ COORDINATED Bi METALLACYCLE

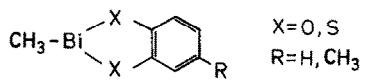
Th. KLAPÖTKE

Institute of Inorganic and Analytical Chemistry, Technical University of Berlin, Straße des 17. Juni 135, D-1000 Berlin 12, F.R.G.

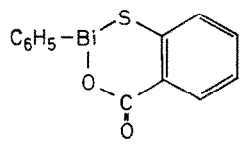
(*Received* 14 *January* 1987; *accepted* 6 *February* 1987)

Abstract—Inorganic and organometallic Bi(III) complexes with five-membered heterocycles were studied. The preparation, properties, and spectroscopic characterization (^{1}H NMR, IR, MS-fragmentation behaviour) of the new compounds are reported. The first member of Se coordinated Bi metallacycles is presented. Bi organyles with the *o*-aminobenzenethiol ligand system, at present widely investigated, are described as *o*-aminobenzenethiolate and *o*-aminobenzenethioldiate derivatives.

Several Bi(III) heterocycles with O,O′ and S,S′ coordinated five-membered chelate ring systems were prepared by a reaction of $CH_3Bi(OC_2H_5)_2$, obtained from CH_3BiBr_2 and $NaOC_2H_5$, with dioles or dithioles under C_2H_5OH elimination.[1] By means of this reaction the analogous pyrocatechol derivatives were prepared:[1]



Recently an equivalent synthesis of the corresponding (S,S′ and O,O′ coordinated) eight-membered Bi(III) ring systems was reported,[2] the ψ-tetrahedral sphere of coordination (X-ray structure determination) showing the stereochemical activity of the lone pair of electrons. Triphenylbismuth, reacting with thiosalicylic acid, lost two phenyl groups and the product was a six-membered cyclic O,S coordinated derivative:[3]



By the methods described above the synthesis of Bi containing five-membered heterocycles was possible. $Bi(C_6H_5)_3$ or $RBi(OC_2H_5)_2$ (Bi: $\delta+$; C, O: $\delta-$), reacting with the free ligand acid R–X–H (X = O, S; R: $\delta-$; H: $\delta+$) gave the desired metallacycles by benzene or ethanol elimination, respectively. Se,Se′ and Te,Te′ coordinated five-membered Bi(III) heterocycles are not yet known. The reason for this may be the difficult preparation of diselenoles or ditelluroles (e.g. hydrolysis of 1,2-$(LiX)_2C_6H_4$, X = Se, Te).

Although some organyl Bi(III)–N compounds have been produced,[4] the synthesis of five-membered metallacycles was restricted to chalcogen coordinated derivatives. In recent publications, however, Bi(III) complexes of *o*-aminothiophenol with Bi–S bondings of tris(2-aminothiobenzenethiolato)bismuth(III) were reported.[5,6] On the other hand *o*-aminothiophenol seems to be an interesting ligand in the synthesis of S,N coordinated five-membered Bi heterocycles as they exist already as members of the subgroups IV and VI.[7,8]

EXPERIMENTAL

Commercially available reagents $BiBr_3$ (Alfa), $Bi(C_6H_5)_3$ (Alfa), 1,2-$Br_2C_6H_4$ (Fluka), and 1,2-$(SH)_2C_6H_4$ (Merck) were used without further purification, *o*-aminothiophenol (Fluka) was distilled under argon and reduced pressure. CH_3BiBr_2,[9,10] $(C_6H_5)_2BiBr$,[11] *cis*-1,2-$(NaS)_2C_2(CN)_2$,[12] and 1,2-$(LiSe)_2C_6H_4$ were prepared as described in the works cited.[13]

All reactions took place in an inert gas atmos-

phere (Ar), using the Schlenk technique. The solvents were purified, dried and argon-saturated.

All melting points are uncorrected. The spectroscopic characterization was carried out with the following equipment:

Elemental analysis: Hewlett–Packard C–H–N analyser 185.

Molar mass determination: Analytische Laboratorien, Elbach.

^{1}H NMR: Bruker WP 80, samples under vacuum.

IR: Perkin–Elmer PE 457 and Perkin–Elmer 580 B, KBr technique.

MS: Varian MAT 311 A, EI, 70 eV; metastable transitions: linked scan, calculated for the following isotopes: ^{32}S, ^{79}Br, ^{80}Se, and ^{209}Bi.

Preparation of (benzene-1,2-dithiolato)bromobismuth(III) [$BiBr(S_2C_6H_4)$] (*complex* **I**)

The equivalent amount (69.32 mmol) of *n*-butyllithium in hexane at 10°C was dropped into the stirred solution of 4.93 g (34.66 mmol) 1,2-$(SH)_2C_6H_4$ in 280 cm^3 benzene. The suspension of 1,2-$(LiS)_2C_6H_4$ was stirred for 2 h and allowed to warm to 25°C and 15.55 g (34.66 mmol) $BiBr_3$ were added and stirred for 4 h. The solvent having been evaporated, the remaining residue was extracted with CH_2Cl_2 and the dark red product recrystallized from acetone.

Yield: 6.40 g (43%). Found: C, 17.0; H, 1.1. Calc. for $C_6H_4BiBrS_2$ [429.11] C, 16.8; H, 0.9%. Fp. decomposition > 200°C. ^{1}H NMR (DMSO-d_6): δ [ppm] (int.). 6.32 (2.00) m, 5.86 (2.09) m. IR: $\tilde{\nu}$ [cm^{-1}]. 3070m (ν-CH,C_6H_4), 1640s, 1435m (ν-CC,C_6H_4), 1265m, 1100w, 1030w, 750vs (γ-CH,C_6H_4). MS (210°C): *m/z* (int.). 428 (20) M^+, 349 (100) M^+-Br, 288 (8) $BiBr^+$, 241 (11) BiS^+, 209 (92) Bi^+, 140 (13) $C_6H_4S_2^+$, 108 (5) $C_6H_4S^+$.

Preparation of (cis-1,2-*dicyano-ethene*-1,2-*dithiolato*)*bromo-bismuth(III)* [$BiBr(S_2C_2(CN)_2)$] (*complex* **II**)

1.20 g (2.69 mmol) $BiBr_3$ were reacted with 0.50 g (2.69 mmol) $(NaS)_2C_2(CN)_2$ in 50 cm^3 THF at 25°C and stirred for 1 h. After filtration the resulting deep red solution was evaporated and the dark red violet residue extracted with CH_2Cl_2. Yield: 0.62 g (54%). Found: C, 11.4; N, 6.1. Calc. for $C_4BiBrN_2S_2$ [429,07] C, 11.2; N, 6.5%. Fp. decomposition under atmospheric conditions. IR: $\tilde{\nu}$ [cm^{-1}]. 2200s (ν-CN,CN). MS (140°C): *m/z* (int.). 428 (43) M^+, 352 (100) $BrBiS_2^+$, 349 (52) M^+-Br, 288 (5) $BiBr^+$, 209 (10) Bi^+.

Preparation of methyl(benzene-1,2-diselenolato) bismuth(III) [$Bi(CH_3)(Se_2C_6H_4)$] (*complex* **III**)

1.08 g (4.34 mmol) of 1,2-$(LiSe)_2C_6H_4$, dissolved in 200 cm^3 of ether, were reacted at −15°C with 1.66 g (4.33 mmol) CH_3BiBr_2 and refluxed for 30 min. The solvent was evaporated, the residue extracted with ether and the precipitated red orange solid collected by filtration, washed with ether and benzene and dried in a vacuum. Yield: 1.23 g (62%). Found: C, 18.1; H, 1.2. Calc. for $C_7H_7BiSe_2$ [458.03] C, 18.4; H, 1.5%. Fp. 142–147°C, decomposition. ^{1}H NMR (acetone-d_6): δ [ppm] (int.). 7.22 (2.00) m, 6.56 (1.98) m, 1.96 (1.52) s, 1.59 (1.59) s. IR: $\tilde{\nu}$ [cm^{-1}]. 3070m (ν-CH,C_6H_4), 2880s (ν-CH,CH_3), 1640s, 1430m (ν-CC,C_6H_4), 1265m, 1100w, 1030w, 750vs (γ-CH,C_6H_4). MS (125°C): *m/z* (int.). 460 (25) M^+, 445 (63) M^+-CH_3, 418 (1) Bi_2^+, 380 (8) M^+-Se, 369 (4) $BiSe_2^+$, 365 (5) M^+-Se-CH_3, 289 (18) $BiSe^+$, 254 (22) $Bi(CH_3)_3^+$, 239 (26) $Bi(CH_3)_2^+$, 224 (19) $BiCH_3^+$, 209 (100) Bi^+, 156 (7) $SeC_6H_4^+$.

Preparation of bis(phenyl)-o-aminothiophenolato-bismuth(III) [$Bi(C_6H_5)_2(SC_6H_4NH_2)$] (*complex* **IV**)

1.19 g (9.47 mmol) *o*-aminothiophenol and 4.17 g (9.47 mmol) triphenylbismuth were dissolved in 50 cm^3 benzene, refluxed for 2 h and stirred for 12 h at 25°C. The yellow solution was concentrated to 20 cm^3 and allowed to stand overnight yielding an orange microcrystalline solid. The product was collected by filtration and washed twice with benzene, methylenechloride, carbondisulfide, and ether. Yield. 3.00 g (65%). Found: C, 44.3; H, 3.1; N, 2.6. Calc. for $C_{18}H_{16}BiNS$ [487.38] C, 44.4; H, 3.3; N, 2.9%. Fp. 105–110°C. Molecular weight by vapor pressure osmometry (solvent N,N-DMF): 469 g/mol. Calc. for M: 487 g/mol. IR: $\tilde{\nu}$ [cm^{-1}]. 3435m (ν-NH,NH_2), 3350m (ν-NH,NH_2), 3060m (ν-CH,C_6H_4), 1598vs (δ-NH,NH_2), 1570m (δ-NH,NH_2), 1480m, 1450m, 1435s (ν-CC,C_6H_4), 1170w, 1060w, 1030w, 1010m, 765m, 745vs (γ-CH,C_6H_4), 735sh, 705s (ν-CS,CS). MS (170°C): *m/z* (int.). 487 (7) M^+, 410 (8) M^+-C_6H_5, 409 (6) M^+-C_6H_6, 363 (5) $Bi(C_6H_5)_2^+$, 333 (5) M^+-$2C_6H_5$, 332 (30) M^+-C_6H_6-C_6H_5, 286 (25) $BiC_6H_5^+$, 248 (30) $(SC_6H_4NH_2)_2^+$, 209 (100) Bi^+, 201 (46) $C_6H_4NH_2SC_6H_5^+$, 154 (8) $(C_6H_5)_2^+$, 125 (68) $H_2NC_6H_4SH^+$, 124 (92) $H_2NC_6H_4S^+$, 108 (2) $SC_6H_4^+$.

Preparation of methyl-o-aminothiophenoldiato-bismuth(III) [$BiCH_3(SC_6H_4NH)]_n$ (*complex* **V**)

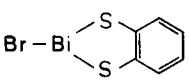
The dilithium-*o*-aminothiophenoldiate was prepared in 50 cm^3 benzene by the reaction of 0.61 g

(4.87 mmol) *o*-aminothiophenol with 9.75 mmol *n*-butyllithium in hexane. 1.87 g (4.87 mmol) CH_3BiBr_2 were added and stirred for 8 h at 25°C. The yellow solution was evaporated and the remaining residue extracted with ether. The extract was concentrated to 20 cm^3 and allowed to stand for 12 h. The slightly soluble yellow product thus prepared was collected by filtration and washed three times with ether. Yield: 1.05 g (62%). Found: C, 24.5; H, 2.5; N, 3.8. Calc. for C_7H_8BiNS [347.19] C, 24.2; H, 2.3; N, 4.0%. Fp. 165°C. Molecular weight by vapor pressure osmometry (solvent N,N-DMF): 835 g/mol. Calc. for M_n: $n = 2$, 694; $n = 3$, 1041 g/mol. IR: $\tilde{\nu}$ [cm^{-1}]. 3580m (ν-NH,NH_2), 3420m (ν-NH,NH_2), 3080w (ν-CH,C_6H_4), 2880m (ν-CH,CH_3), 1600m (δ-NH,NH_2), 1480 m, 1450m (ν-CC,C_6H_4), 760sh, 758s (γ-CH,C_6H_4). MS (150°C): *m/z* (int.). 457 (3) $CH_3Bi(SC_6H_4NH_2)(SC_6H_5)^+$, 363 (37) $(CH_3)_2Bi(SC_6H_4NH_2)^+$, 349 (23) $CH_3Bi(H)(SC_6H_4NH_2)^+$, 348 (96) $CH_3Bi(SC_6H_4NH_2)^+$, 347 (8) M^+, 333 (92) $Bi(SC_6H_4NH_2)^+$, 332 (55) M^+-CH_3, 248 (48) $(SC_6H_4NH_2)_2^+$, 239 (18) CH_3BiNH^+, 224 (24) CH_3Bi^+, 209 (96) Bi^+, 125 (98) $HSC_6H_4NH_2^+$, 124 (100) $SC_6H_4NH_2^+$.

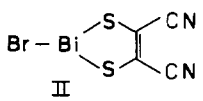
RESULTS AND DISCUSSION

Bi(III) *dithiolato derivatives*

The reaction of $BiBr_3$ with equimolar amounts of the appropriate alkali metal dithiolate ligand salts yielded for the first time by a new reaction route some five-membered Bi(III) metallacycles (complex **I** and **II**), which were only inorganically coordinated to the Bi central atom.



I



II

Generally **I** and **II** are just moderately soluble, but they are very soluble in DMF and DMSO, **II** in THF too. The ^1H NMR and IR spectra show all the expected signals in the normal ranges. The mass spectra of both complexes have as peak with the highest *m/z* value an intense signal according to the molecular ion; and under MS conditions they are more stable than the corresponding organometallic Bi(III) derivatives.[1]

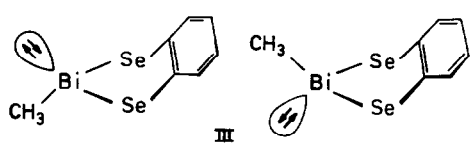
The first Bi(III) *diselenolato heterocycle*

The synthesis of Se coordinated five-membered Bi(III) metallacycles, analogous to O and S derivatives, had not been achieved on the conventional reaction route because of the difficult preparation of *cis*-1,2-diselenoles. In the present work the first Se,Se′ coordinated five-membered heterocyclic bismuth organyl (complex **III**) is reported as the product of treating CH_3BiBr_2 with an equimolar amount of the easier available dilithium ligand salt of benzene-1,2-diselenol (Fig. 1). The identity of complex **III** was proved by elemental analysis, ^1H NMR, IR, and mass spectra. The IR spectrum shows the typical absorptions of the symmetrical *o*-disubstituted benzene ring system and those of the methyl group. The aromatic range of the ^1H NMR spectrum shows two multiplets, equal in intensity, according to the AA′BB′ system of the C_6H_4 protons. In addition to the solvent quintet of CD_3COCD_2H in the methyl area two sharp singlets with a signal splitting $\Delta\nu$ of 29.6 Hz appear, similar but not equal in intensity (1.00 : 1.05) (Fig. 2). The integration relative to the C_6H_4 protons resulted in approximately a half methyl group for each singlet. This may be explained by the stereochemical activity of the lone pair of electrons and a ψ-tetrahedral geometry of **III** at the Bi central atom. Because of the anisotropy effect of the aromatic ring system (Fig. 1) two conformers with an *endo* or *exo* standing CH_3 group to the five-folded heterocyclic ring system in envelope conformation may exist with a different chemical shift of the methyl protons. In the temperature dependent ^1H NMR spectrum between +60°C and −60°C no significant effect was observable; the coalescence temperature may be higher than +60°C and by this the activation free energy of the ring inversion of the five-membered heterocycle $\Delta G^{\neq}$ can be expected to be higher than 70 kJ/mol.

The mass spectrum of **III** shows an intense peak of the molecular ion with the highest *m/z* value and the signal of the Bi^+ ion as the base peak, as is usual in the case of many Bi organyles. The transitions $(M^+) \rightarrow (M^+\text{-}CH_3)$, $(M^+\text{-Se}) \rightarrow (M^+\text{-Se-}CH_3)$, $(M^+\text{-Se}) \rightarrow (Bi^+)$, and $(CH_3Bi^+) \rightarrow (Bi^+)$ could be clarified by pursuing the metastable transitions using the linked scan technique.

o-*Aminothiophenol derivatives*

Although $Bi(C_6H_5)_3$ reacts with mercaptans with formation of Bi–S bonds and benzene elimination,



III

Fig. 1. Conformations of **III** with an exo (left) and an endo (right) standing methyl group.

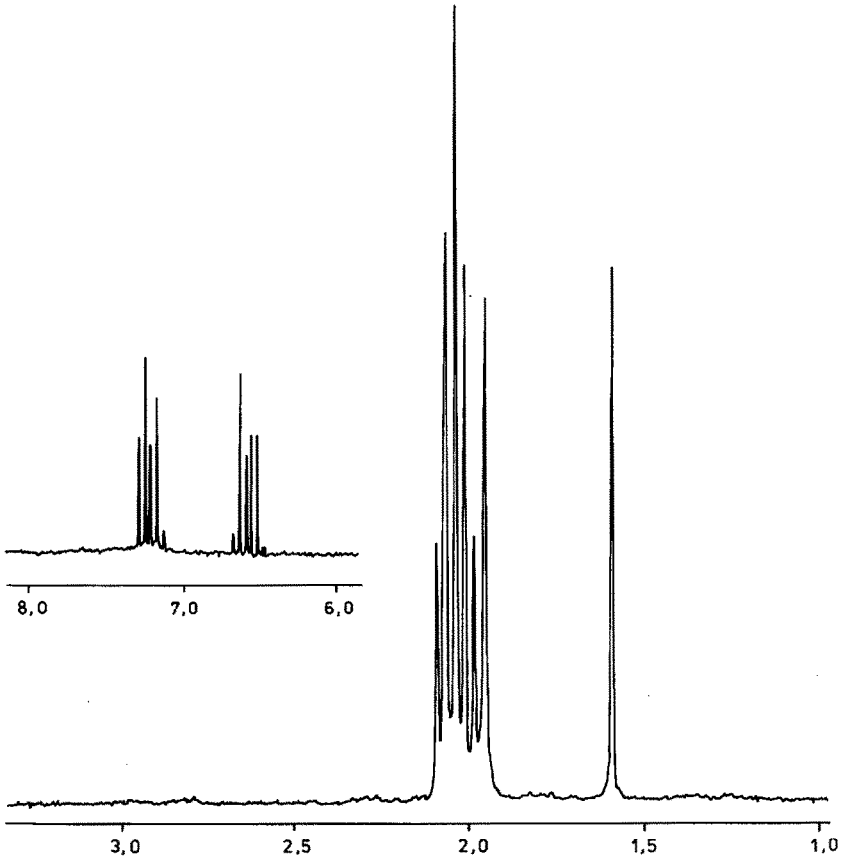


Fig. 2. ^{1}H NMR spectrum of **III**, methyl and aromatic range, −24°C, δ in ppm, solvent: acetone-d_6 (99%D).

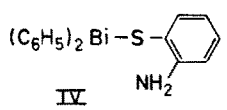
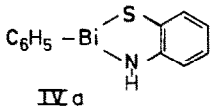
the acidity of an aromatic substituted amino group is too low for Bi–N bond formation. Treating $Bi(C_6H_5)_3$ with equimolar amounts of *o*-aminothiophenol yielded the monosubstituted complex **IV** only, and not the desired S,N coordinated derivative **IVa**. By refluxing of $Bi(C_6H_5)_3$ with 1,2-$(NH_2)_2C_6H_4$ in benzene no reaction was observed.



IV



IVa

The identity of the new complex **IV** was proved by elemental analysis, IR, ^{1}H NMR, and mass spectra, its monomeric structure in DMF solution having been determined by vapor pressure osmometry. The compound **IV** was identical with the product we isolated from the reaction of $(C_6H_5)_2BiBr$ with 1,2-$(LiS)(NH_2)C_6H_4$. The transition from **IV** to **IVa** ($m/z = 409$) by benzene elimination and a further fragmentation of a phenyl group from **IVa** to **IVa**-Ph ($m/z = 332$), proved by metastable transition, was observed under the conditions in the mass spectrometer (Fig. 3). On the other hand the non-cyclic M^+(IV)-Ph ($m/z = 410$) was identified and significantly classified because of the isotope purity of Bi (see $m/z = 209$, Bi^+; Fig. 3). With this result the synthesis of an S,N coordinated cyclic Bi derivative seemed to be possible and CH_3BiBr_2 was reacted with the dilithium *o*-aminothiophenoldiate. According to the analytical and spectroscopic data the isolated product **V** corresponds to a complex of the composition $CH_3Bi(SC_6H_4NH)$. The complex **V**, in most organic solvents barely soluble or insoluble, is moderately soluble in DMF ($\approx$ 20 mg/mL). Nevertheless it has no five-membered heterocyclic structure but is an oligomeric polynuclear compound as shown by vapor pressure osmometry and mass spectrometry. Like **IV** the derivative **V** also shows the signal of an ion ($m/z = 347$) which could be the desired monomeric five-membered metallacycle. As is usual for Bi organyles the mass spectra show many decomposition products as well as very intense signals of the Bi^+ ion.

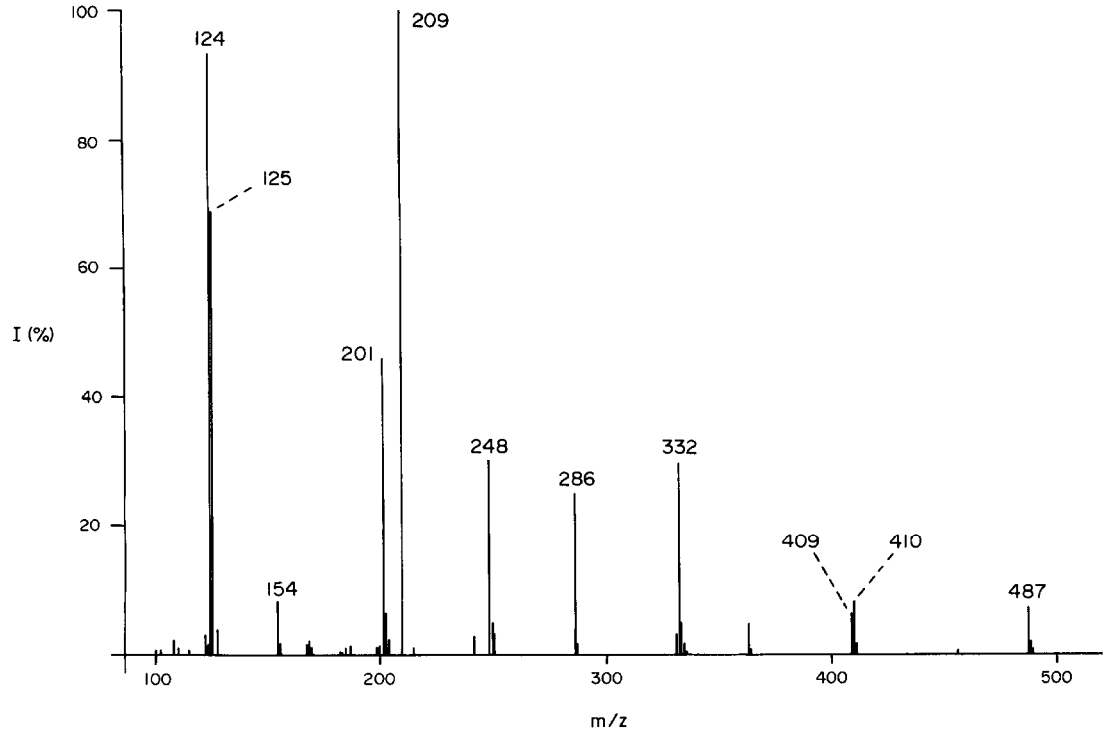


Fig. 3. Mass spectrum of **IV**, EI, 70 eV, 170°C, int. $\geqslant$ 0.2%, $m/z \geqslant 100$.

CONCLUSIONS

In the present work the preparation and spectroscopic characterization of some novel non-organometallic five-membered Bi(III) dithia heterocycles and the first diselena Bi(III) metallacycle are reported. The structure of the selenium derivative is discussed on the basis both of its metastable transition behaviour in the mass spectrum and an unexpected effect in the ^{1}H NMR spectrum; using temperature dependent measurement no dynamic effect could be observed. The synthesis of five-membered Bi(III) heterocycles by the substitution of a chalcogen atom with the isolobal NH group was not successful, although these compounds could be observed in the mass spectra. But instead of these a new interesting *o*-aminothiophenolato complex was obtained by two different reaction routes. Pnictogen coordinated five-membered Bi(III) metallacycles are still unknown under "normal" conditions, but a reference to their existence could be given and their synthesis should be carried out in the future.

Acknowledgements—Our thanks are due to A. Stöckel for mass spectra, M. Dettlaff for NMR spectra and D. Bernhard for elemental analysis.

Abstract—The complex $Re(CSiMe_3)(CH_2SiMe_3)_3Cl$ has been isolated as yellow crystals in low yield from the reaction of $ReCl_4(THF)_2$ with Me_3SiCH_2MgCl and characterised by X-ray crystallography. The molecule has a trigonal bipyramidal geometry with the alkylidyne and chlorine ligands axial.

The first monomeric alkylidyne complexes, *trans*-$X(CO)_4M{\equiv}CR$ (M = Mo and W), were prepared by treating an alkylidene complex with BX_3.[1] Higher oxidation state species of the type $M(CCMe_3)(CH_2CMe_3)_3$ have been prepared by treating $MoCl_5$ or WCl_6 with five or six equivalents of neopentyllithium.[2]

We now report the synthesis of the first monomeric rhenium(VII) trimethylsilylmethylidyne complex. The alkylation of $ReCl_4(THF)_2$ in tetrahydrofuran leads to the dinitrogen complex,[3] $[Re(CH_2SiMe_3)_4]_2N_2$, as well as low yields of bis(μ-trimethylsilylmethylidyne) tetrakis (trimethylsilylmethyl) dirhenium.[4] A third minor product from this reaction, a hexane soluble yellow air-sensitive crystalline solid $ReCl(CSiMe_3)(CH_2SiMe_3)_3$ has now been isolated.

The molecular structure as determined by X-ray crystallography is shown in Fig. 1, and confirms the structure predicted by Schrock *et al.*,[5] for the analogous neopentyl neopentylidyne complex $ReCl(CCMe_3)(CH_2CMe_3)_3$. Selected bond lengths and angles are given in Table 1. The metal has a trigonal bipyramidal configuration, with the trimethylsilylmethylidyne and chlorine ligands axial. The Re–C bonds to the equatorial trimethylsilylmethyl ligands are bent away slightly from the multiply bonded alkylidyne, as is usually found, and the Re–C–Si angles in the alkyls are somewhat greater than tetrahedral due to steric repulsions involving the $SiMe_3$ groups. Otherwise, geometry parameters are as expected.

The spectroscopic data are in agreement with the structure as determined. There are singlets in the ^1H NMR spectrum at δ 0.22 and 0.15 p.p.m. (relative intensity 27:9) indicating the trimethylsilylmethyl and trimethylsilylmethylidyne methyl protons respectively; a singlet at δ 3.22 (relative intensity 6) can be assigned to the methylene hydrogens, whose

low field value is characteristic of rhenium trimethylsilylmethyl compounds.[6] The mass spectrum shows the molecular ion m/e 568 (13%) with the correct rhenium isotope pattern, although the base mass is m/e 553 (M^+–Me). Sequential loss of the CH_2SiMe_3 groups are not well defined, due to the facile loss of CH_3 groups.

EXPERIMENTAL

Microanalysis by Pascher, Remagen. Spectrometers. I.R., Perkin–Elmer 683 (spectra in nujol mulls); NMR, Jeol FX-90Q (in C_6D_6, p.p.m. relative to $SiMe_4$); mass, Kratos MS 902 at 70 eV. Solvents were refluxed over sodium-benzophenone under nitrogen and distilled before use. All operations were carried out under vacuum or purified nitrogen.

Synthesis of $Re(CSiMe_3)(CH_2SiMe_3)_3Cl$

To a stirred suspension of $ReCl_4(THF)_2$[7] (0.51 g, 1.08 mmol) in THF (50 cm^3) at −78°C was added trimethylsilylmethylmagnesium chloride (6.0 cm^3 of a 0.73 mol dm^{-3} solution in diethylether, 4.3 mmol) under nitrogen. The solution was warmed slowly and held at room temperature for 1 h. The resulting purple solution was evaporated and the residue extracted into hexane (3×30 cm^3), concentrated to about 50 cm^3 and cooled −20°C overnight. Yield: 0.06 g, 10%; m.p. 120–122°C. Found: C, 33.3; H, 7.4; Cl, 6.1. Calc. for $ReC_{16}H_{42}Si_4Cl$: C, 33.8; H, 7.4; Cl, 6.2%. I.R. (cm^{-1}): 1410m, 1336s, 1248vs, 1179s, 1060w, 1020w, 971sh, 935sh, 906s, 845vs, 780sh, 755m, 701sh, 679m and 622m. NMR ^1H: 3.22 (6H, S, $C\underline{H}_2$–$SiMe_3$), 0.22 (27H, s, $CH_2Si\underline{Me}_3$) and 0.15 (9H, s, $Re{\equiv}C$–$Si\underline{Me}_3$). Mass spectrum: m/e, 568 (13%), $Re(\equiv CSiMe_3)$

$(CH_2SiMe_3)_3Cl^+$; 553 (100%), $Re(\equiv CSiMe_3)(CH_2SiMe_3)_3Cl{-}Me^+$; 73 (87%), $SiMe_3^+$.

X-ray crystallography. The crystal used for X-ray study was sealed under argon in a thin walled glass capillary. All X-ray measurements were made using a Nonius CAD4 diffractometer operating in the $\omega/2\theta$ scan mode and graphite monochromated Mo–Kα radiation ($\lambda = 0.71069$ Å). The structure was solved via routine application of the heavy atom method and developed and refined using Fourier and full-matrix least squares methods. Non-hydrogen atoms were refined anisotropically; hydrogens were located experimentally and included with group U_{iso} values, but with geometrical constraints applied to retain idealised geometries at the relevant carbon atoms. Crystal data and details of the data collection and refinement are as follows.

Crystal data

$C_{16}H_{42}ClSi_4Re$, $M = 568.505$, monoclinic, $P2_1/a$, $a = 17.991(2)$, $b = 12.616(2)$, $c = 12.296(2)$ Å, $\beta = 91.66(2)°$, $V = 2790.00$ Å^3, $Z = 4$, $D_c = 1.35$ g cm^{-3}, μ(Mo–K) = 46.78 cm^{-1}, $F(000) = 1144$.

Data collection

Crystal size $0.55 \times 0.45 \times 0.30$ mm, scan width $\omega = 0.8 + 0.35 \tan\theta$, scan times 1.35–6.77 deg min^{-1}, $1.5 \leqslant \theta \leqslant 25$. 4924 unique data, 2207 observed [$I > 2\sigma(I)$].

Structure refinement

No. of parameters = 202. Weights = $[\sigma^2(F) + 0.0002(F_o)^2]^{-1}$, $R = 0.0392$, $R_w = 0.0349$.*

(*Received* 14 *October* 1986; *accepted after revision* 18 *February* 1987)

Abstract—The syntheses, characterization, X-ray structure and magnetism of a number of dinuclear compounds, with general formula $M_2(\mu\text{-}OH_2)(\mu\text{-}O_2CR)_2(O_2CR)_2(tmen)_2$ are described. In this formula M = Co(II), Ni(II), R = CH_3, CH_2Cl, $CHCl_2$, and CCl_3, and tmen stands for *N,N,N′,N′*-tetramethyl-1,2-diaminoethane.

The X-ray structures of two examples, M = Co and R = CCl_3(I) and M = Co, Ni and R = CH_2Cl(II) are described in detail. Compound I crystallizes in space group $P2_1/c$, with $a = 23.610(7)$, $b = 10.439(2)$ and $c = 17.920(4)$ Å, $\beta = 110.43(4)°$ and $Z = 4$. Using 5196 measured reflections collected on a diffractometer with graphite monochromatized Mo-Kα radiation, the structure was refined to $R = 0.089$. The dimeric units $Co_2(OH_2)(O_2CCl_3)_2$ [Co . . . Co = 3.696(3) Å, angle Co–O–Co = 116.1(6)°] resemble very much those of earlier reported structures with M = Ni, Co and other bridging carboxylato anions. Apart from the two bridging carboxylato anions, two monodentate $CCl_3CO_2^-$ anions are present, in addition to the normal bidentate tmen ligands, completing the octahedral geometry for each metal ion. The dimeric structure, with the bridging water ligand, appears to be highly stabilized by intramolecular hydrogen bonding with one of the oxygens of the monodentate $CCl_3CO_2^-$ ligands (O . . . O contacts of 2.56–2.60 Å). This stabilization by hydrogen bonding appears to be very similar to the proposed hydrogen bonding in hemerythrine, in which the coordinated dioxygen seems to be hydrogen bonded with the bridging –OH group.

Compound II has essentially the same basic structure; it crystallizes also in the space group $P2_1/c$, with $a = 16.034(7)$, $b = 13.114(7)$, $c = 15.344(7)$, $\beta = 91.20(4)$ and $Z = 4$. From 4701 measured reflections the structure was refined to $R = 0.043$. The dimeric units exhibit a Co-Ni distance of 3.596(1) Å, with a Ni-O-Co angle of 116.5°. The slightly smaller distances around Ni(II) made distinction from Co(II) possible.

The metal ions in these Co and Ni compounds are antiferromagnetically coupled, just as the Fe ions in hemerythrine. This antiferromagnetic interaction has been studied by low-temperature magnetic susceptibility measurements. The magnitude of the coupling appears to vary as a function of the metal, the M . . . M distance and the M–O–M angle.

* Author to whom correspondence should be addressed.

Bridging carboxylato groups are quite common in coordination compounds, and a variety of coordination geometries and bridging modes have been described during the last three decades. The classical example, $Cu_2(OAc)_4(H_2O)_2$, a centrosymmetric structure with four bridging acetates, first described[1] in 1953, has initiated research on this type of compound and derivatives. Reviews about this topic, describing compounds with variations in the apical ligands, and with different carboxylates as the bridges are available.[2] Other classical examples of such compounds are[3,4] $Zn_4O(OAc)_6$ and $Fe_3O(OAc)_6(pyridine)_3$.

In nature, the oxygen transport protein hemerythrine has been known for some time to contain the bridging unit Fe(Glu)(Asp)(OH_x)Fe, in which the value of $x = 0$ or 1, depending upon the conditions. It is now generally accepted that in the deoxy form, the two iron ions are bridged by an OH group, whereas upon oxygenation (at one iron), the OH bridge changes into an oxo bridge,[5-7] in which the hydrogen is transferred to the coordinated peroxo ligand, thereby changing to a hydrogenperoxido, OOH^-.

Very recently, Lippard and Wieghardt independently reported synthetic coordination compounds, mimicking the active site of hemerythrin, at least for the dinuclear $Fe_2O(O_2CR)_2$ unit.[8-10] Apart from the iron(III) compounds, also the Mn(III) dimers,[11] and (very recently[12]) also the Fe(II) dimer could be isolated. This latter compound oxidizes easily and is difficult to study in detail.

It appears that the role of the hydrogen bond between the bridging OH (or O) and the coordinated dioxygen ligand (hydrogenperoxido) is very important for the stability of dinuclear unit and in particular for the binding of the dioxygen. It therefore seems useful to study the details of such dimeric units with a bridging oxygen (O, OH or H_2O) by spectroscopy and magnetism.

Unfortunately with iron, the access to a great variety of compounds seems rather small, due to oxidation and dissociation problems, although Lippard[13] has reported exchange of carboxylates by phosphates. With Co^{2+} and Ni^{2+} much more stable systems having the $M_2(OH_2)(O_2CR)_2$ bridging unit have been known for about a decade,[14-17] with $R = CH_3$, CF_3, CH_2Cl, $CHCl_2$ and CCl_3. In these compounds the bridging H_2O molecule is strongly hydrogen bonded to a non-bridging carboxylato group, see Fig. 1.

This hydrogen bonding is very similar to the pattern proposed in hemerythrin,[6,7] and in fact occurs to each of the metals. It seemed of great interest to study the details of the dimeric structure and to correlate magnetic exchange coupling with M–M, O...O and other contacts and also to study the reactivity of these compounds. The first results deal with the magnetic exchange of some Co^{2+} and Ni^{2+} dimers with *N,N,N',N'*-tetramethyl-1,2-diaminoethane(tmen) as the terminal ligand and with a variety of carboxylates, as well as with the X-ray structure of one example.

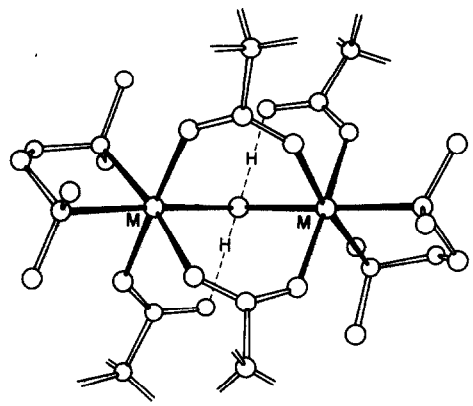

Fig. 1. Schematic structure of $M_2(OH_2)(O_2CR)_4(tmen)_2$ compounds.

EXPERIMENTAL

Starting materials and syntheses

The metal acetates and tmen were used as commercially available, without further purification. The other metal salts were prepared from the metal carbonates and the corresponding acid. Powdered microcrystalline compounds were easily obtained upon slow evaporation of aqueous ethanol solutions of the metal salts and tmen in stoichiometric ratio. The mixed-metal complex was prepared by adding 0.01 mol of green $Ni_2(C_2H_2ClO_2)_4(C_6H_{16}N_2)H_2O$ and 0.01 mol of red–brown $Co_2(C_2H_2ClO_2)_4(C_6H_{16}N_2)_2H_2O$ to 100 cm^3 ethanol. The reaction mixture was refluxed at −78°C for 5 h. After cooling of the solution to room temperature, crystallization was allowed to continue for two weeks. When the most of the solvent was evaporated large light red–brown crystals were collected by filtration. Microscopic examination suggested that crystals were homogeneous.

Characterization and analyses

The compounds were characterized by their infrared spectra and by analysis of their nickel content. The Co(II) and Ni(II) compounds were found to be isomorphous for each counter ion. Determination of nickel and cobalt contents in the mixed-

metal species revealed that the composition was $CoNi(C_2H_2ClO_2)_4(C_6H_{16}N_2)_2H_2O$. Ligand-field spectra were recorded in the diffuse reflectance mode on a Perkin–Elmer 330 instrument. Infrared spectra were taken as Nujol mulls and as KBr discs on a Perkin–Elmer 180 instrument.

Magnetic susceptibility

Powder magnetic susceptibilities were obtained in the 2–80 K region, using a PAR vibrating sample magnetometer, as described by Engelfriet[18] and calibrated with $CoHg(SCN)_4$. ESR spectra were recorded on a Varian E3 instrument at X-band frequencies.

X-ray data collection and refinement

A crystal of $Co_2(Cl_3C_2O_2)_4(C_6H_{16}N_2)_2H_2O$, **I**, used for data collection had dimensions of $0.2 \times 0.3 \times 0.4\ mm^3$. Crystal data and relevant information about the data collection and refinement have been summarized in Table 1. The data were corrected for Lorentz and polarization effects. A mixed-metal crystal of $CoNi(ClH_2C_2O_2)_4(C_6H_6N_2)_2H_2O$, **II**, used for data collection had dimensions $0.28 \times 0.35 \times 0.30\ mm^3$. Crystal data and relevant information about the data collection and refinement have been summarized in Table 2. The absorption effect was checked by empirical ϕ-scan methods, but was so insignificant that correction was excluded. The structure of **I** was solved by direct and Fourier methods using the XRAY 76 program system[19] on a UNIVAC 1100 computer. The chlorine atoms of two trichloroacetate groups appeared to be disordered and two positions were given each of these atoms. The quality of data did not allow the determination of the hydrogen atom positions. Least squares refinement with anisotropic temperature factors of Co and Cl atoms and isotropic temperature factors of the other atoms yielded final $R = 0.087$ and $R_w = 0.115$, with $w = 1/(40 + |F_o| + 0.01|F_o|^2)$. The structure determination of **II** was simplified by the observation that it is isomorphous with corresponding nickel(II) compound. The atomic parameters were taken directly from the refinement of the nickel(II) compound, and refinement with anisotropic temperature factors for non-H atoms and isotropic temperature factor for the H atoms of the water molecule gave $R = 0.042$ and $R_w = 0.038$, with $w = 1/\sigma^2(F)$. The other H atoms with $U = 0.08$ were included at idealized positions (C–H = 1.0 Å) and held fixed. During the refinement the metal ion with the shortest M–O and M–N distances was assigned as nickel. Scattering factors, including anomalous dispersion, were taken from the litera-

ture.[20] Atomic coordinates, listings of F_o and F_c values and anisotropic thermal parameters have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Description of the structure of $Co_2(OH_2)(O_2CCl_3)_4(tmen)_2$

A projection of the molecular structure is depicted in Fig. 2. A pseudo-twofold rotation axis goes through O9 and the Co–Co vector. Relevant bond distances and angles are listed in Table 3. Hydrogen-bonded intramolecular contacts are indicated by dashed lines in Fig. 2. Although the hydrogen atoms could not be located in this structure determination, the close resemblance with other, earlier reported structures,[14–17] and with the other structure described below, leads to the conclusion that a coordinated water molecule is present. The O...O contacts of 2.56–2.60 Å indicate very strong hydrogen bonding. This hydrogen bonding is confirmed by the infrared spectra (see below). The Co...Co distance of 3.696 Å is the longest contact so far observed in compounds of this type. The Co–N and Co–O distances are about the same as those found in related compounds.[14–17]

Description of the structure of $CoNi(OH_2)(O_2CCH_2Cl)_4(tmen)_2$

A projection of the molecular unit of **II** is given in Fig. 3. The structure is very similar to the structure of **I** and earlier reported ones,[14–17] as is also seen from the geometric information given in Table 4. In this structure the hydrogen atoms of the water molecule could be located. The O...O contacts of 2.54 and 2.55 Å are again indicative for a very short hydrogen bond contact, also evident from the IR spectra. The Co–O, Co-N, Ni–O and Ni–N distances are in the range normally observed.[14–17]

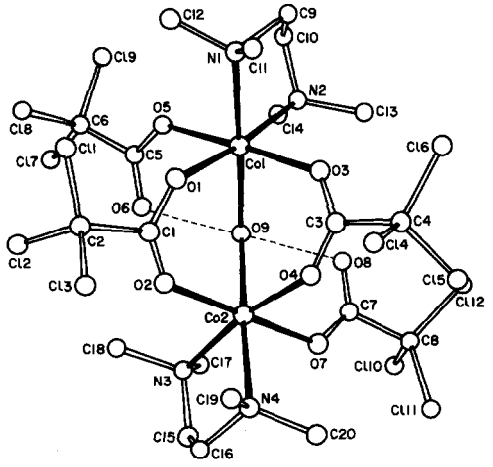

Fig. 2. Drawing of the structure and labeling of atoms of $Co_2(OH_2)(CCl_3CO_2)_4(tmen)_2$. Distances and angles are given in Table 3.

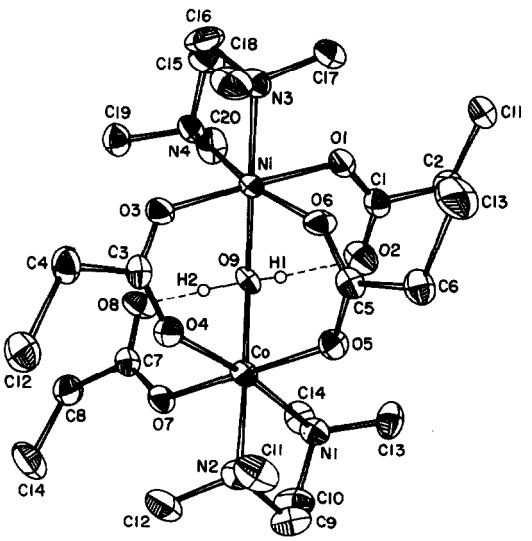

Fig. 3. ORTEP drawing and labeling of the structure of $CoNi(OH_2)(CCl_2HCO_2)_4(tmen)_2$. Geometric information is given in Table 4.

Comparison of structures

Comparing the present structures with the $Fe_2^{II}(OH)$ and the $Fe_2^{III}O$ dimers reported earlier,[8–10,12] shows that the metal–metal interactions are much shorter in the iron compounds, i.e. 3.32 Å for Fe(II) and about 3.15 Å for Fe(III). This seems to be related to the shorter Fe–O distances in Fe_2OH and Fe_2O units, compared to bridging OH_2. This also seems to influence the magnitude of the magnetic exchange (*vide infra*). Table 5 compares structural information available up to now for a variety of $M_2(OH_x)(O_2CR)_2$ dimers.

Spectroscopic measurements

The infrared spectra of all compounds show bands typical for coordinated tmen, monodentate carboxylates and bidentate bridging carboxylates.[21] In addition, however, a band for coordinated water is observed. It appears that this band, the asymmetric O–H stretch, is lowered significantly compared to normal water ligands. Depending upon the particular carboxylato ligand and metal ion, two broad bands, often accompanied by a shoulder,

are observed in the region 2000–2400 cm^{-1}. This enormous lowering compared to free water is ascribed to the very strong hydrogen-bond formation with the monodentate coordinating carboxylato group, resulting in O...O contacts of about 2.5–2.7 Å. The fact that more than one such O...O contact occurs (see Tables 3 and 4 and refs 14–17), nicely agrees with the observation of 2 or 3 IR bands.

Application of the now classical formula of Bellamy and Owen,[22] an O...O contact of 2.60 Å would predict a decrease in the O–H stretch of about 1100 cm^{-1}, just as observed. The other parts of the IR spectrum just show ligand and anion bands. The M–O stretching frequencies, observed in the far-IR are too much overlapping to allow assignments without isotopic labelling, and therefore are not discussed in this paper. The assignment as M–L bands, however, can be easily deduced from the fact that the isomorphous Co and Ni compounds have comparable bands, but with many Ni compounds having the bands some 5–15 cm^{-1} at higher wave numbers.

The ligand field spectra of all compounds are typical[23,24] for (distorted) octahedral geometry. The band maxima nicely agree with a MN_2O_4 chromophore, and are not discussed in detail. Band maxima for the Ni compounds occur at 9100, 15450 and 25900 cm^{-1}, and those for the Co compounds at 8300 and 19500 cm^{-1}. The Co–Ni mixed-metal compound has a spectrum which is the sum of both spectra.

Magnetic properties

The most interesting properties of the compounds are, apart from the fascinating H-bridge system that co-stabilizes the dimeric units, the magnetic properties. Therefore magnetic susceptibilities of a number of Co and Ni compounds have been studied, down to 2 K. The results are summarized in Table 6, together with some geometrical data. A representative curve of the susceptibility in the 2–80 K region with a clear maximum is redrawn in Fig. 4. As is seen from the results, the Co compounds generally have maxima at higher temperature than the Ni compounds, indicative for a stronger exchange coupling and originating from the fact that Co(II) has a spin of 3/2. The trend however, appears to be that when the exchange is weak in the case of the cobalt compound, also the nickel compound has a weak exchange. In some cases the Ni compounds are so weakly interacting,

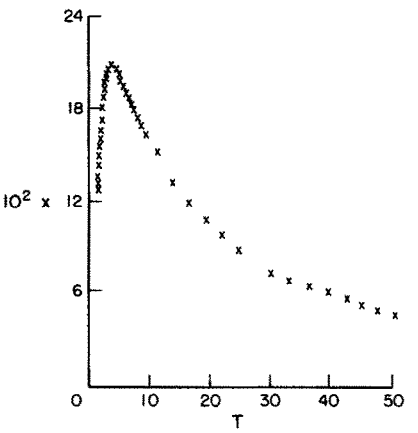

Fig. 4. Plot of the magnetic susceptibility of $Co_2(OH_2)(CCl_3CO_2)_4(tmen)_2$ as a function of temperature.

that no maximum in the susceptibility is observed above 2 K. Apparently the fine details of the exchange interaction are determined by the details

Table 6. Magnetic susceptibility results of some selected Co(II) and Ni(II) compounds with the $M_2(O_2CR)$ unit

Compound	χ_{max} (K)	θ (20–80 K)	μ (80 K) βM	M–O–M (°)
$Co_2(H_2O)(O_2CCl_3)_4(tmen)_2$	4.3	≈ 16	4.8	116.1
$Co_2(H_2O)(O_2CCH_2Cl)_4(tmen)_2$	4.8	≈ 14	4.8	113.5
$Co_2(H_2O)(O_2CCH_3)_4(tmen)_2$	3.0	8.5	4.7	115.1
$Ni_2(H_2O)(O_2CCH_3)_4(tmen)_2$	< 2	1.0	3.0	117.2
$Ni_2(H_2O)(O_2CCH_2Cl)_4(tmen)_2$	3.0	6.0	3.3	117.4
$Ni_2(H_2O)(O_2CHCl_2)_4(tmen)_2$	4.0	5.0	3.1	118.1
$NiCo(H_2O)(O_2CCH_2Cl)_4(tmen)_2$	< 2	6.0	4.0	116.5

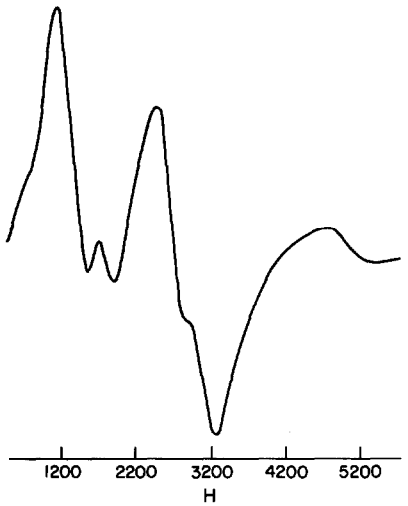

Fig. 5. ESR spectrum at 13 k for the compound $CoNi(OH_2)(CH_2ClCO_2)_4(tmen)_2$.

of the bridging geometry. Therefore, some geometric parameters, as far as available, have been included in Table 6.

In attempts to isolate compounds with two different metal ions, we have prepared several products that contain a 1 : 1 mixture of Co and Ni in the starting solution. Because of the slight asymmetry in the dimeric units, one could expect a possible preference of one site for Co and of the other site for Ni, and in fact the structure described above seems to illustrate this. Magnetic susceptibilities of the compound (see Table 6) indicate that clearly not a physical mixture of the Co_2 and the Ni_2 dimers is present, because in that case a maximum between 3.0 and 4.8 K would be expected. In fact there is no maximum at all above 2 K. Also the ESR-spectrum of the compound, recorded at 13 K and redrawn in Fig. 5, clearly shows that a new species is formed. Further work is planned to do on single-crystal magnetic measurements.

Acknowledgements—The authors are indebted to Mr F. B. Hulsbergen for the spectral measurements, and to Mr R. Prins and Mr W. Vreugdenhill for performing the magnetic susceptibilities.

(*Received* 21 *October* 1986; *accepted after revision* 23 *February* 1987)

Abstract—Praseodymium(III) macrocyclic complexes of types $[Pr(L)(H_2O)_2]Cl_3$, $[Pr(mac_1)]Cl_3$ and $[Pr(mac_2)(H_2O)_2]Cl_3$ (L = ligands derived by the condensation of diacetyl or benzil with semicarbazide or thiosemicarbazide; mac_1 = macrocyclic ligands derived by the condensation of diacetyl or benzil with carbohydrazide; mac_2 = macrocyclic ligands derived by the condensation of diacetyl or benzil with semicarbazide, thiosemicarbazide or thiocarbohydrazide) have been prepared and characterized by conductance, magnetic moment, spectral data, thermal and elemental analyses.

The coordination chemistry of polyaza macrocyclic ligands towards lanthanides has been little studied.[1–9] Recently, a number of papers have appeared on crown ether and cryptand complexes of lanthanide ions since they can be used for lanthanide separations, for stabilizing lower oxidation states and for studying high coordinated complexes of lanthanides(III).[10–12] In recent years, the bioinorganic chemistry of the lanthanides has been a research subject. In view of the similarity between the ionic radius of calcium and the trivalent rare earths and the remarkable multitude of spectroscopic and magnetic properties of lanthanides, they are considered to be useful for probing metal ion binding sites of macromolecules of biological interest including amino acids, carbohydrates, nucleotides, sugar-phosphates, porphyrins, phospholipids and membranes.[13,14]

In this paper we report the synthesis and characterization of praseodymium(III) macrocyclic complexes derived from the condensation of diacetyl or benzil with semicarbazide, thiosemicarbazide, carbohydrazide or thiocarbohydrazide.

EXPERIMENTAL

Praseodymium(III) chloride was procured from British Drug House Ltd. Praseodymium was estimated gravimetrically as its oxide, sulphur as $BaSO_4$ and nitrogen by Kjeldahl's method. Estimation of carbon and hydrogen was done by CDRI Lucknow. The details of physical measurements are the same as those described earlier.[15]

(i) *Preparation of ligands* L_1, R_4O_2 [14] *tetraene* $N_4[N_4]$

A solution of diacetyl or benzil (0.04 mol) in ethanol (25 cm^3) was added to a refluxing solution of carbohydrazide (prepared by the method of Möhr *et al.*,[16] 0.04 mol) in aqueous ethanol (30 cm^3) followed by addition of 1 cm^3 concentrated hydrochloric acid. The reaction mixture was refluxed for 4–6 h. After refluxing, the solution was kept overnight. Yellow mass was separated out which was filtered and dried. The product was recrystallized in ethanol.

(ii) *Preparation of ligands* L_2, R_4S_2 [14] *tetraene* $N_4[N_4]$

Ligands of this type were prepared by condensation of diacetyl or benzil with thiocarbohydrazide. The procedure is exactly the same as discussed for L_1. Thiocarbohydrazide was prepared by the method of Bürns.[17]

(iii) *Preparation of ligands* L_3 *and* L_4

Ligands of type L_3 were prepared by condensation of diacetyl or benzil with semicarbazide (molar ratio 1 : 2) and of type L_4 were prepared by

* Author to whom correspondence should be addressed.

condensation of diacetyl or benzil with thiosemicarbazide (molar ratio 1:2) using the same procedure as discussed for L_1

The analytical data of ligands L_1, L_2, L_3 and L_4 are given in Table 1.

(iv) *Preparation of complexes with* L_1 *and* L_2

Praseodymium(III) chloride (0.02 mol) in water (20 cm^3) was added to the refluxing solution of the appropriate ligand (0.02 mol) in ethanol (30 cm^3). The reaction mixture was refluxed for 8–10 h, when the colour of the solution turned yellowish brown. The solvent was removed *in vacuo* and brown or yellowish brown coloured product was obtained. The product was thoroughly washed with dichloromethane to remove the impurities of ligands and dried *in vacuo*. Yield ~ 50–58%.

(v) *Preparation of complexes with* L_3 *and* L_4

Praseodymium(III) chloride (0.02 mol) dissolved in water was added to the appropriate ligand (0.02 mol) dissolved in a mixture of benzene and ethanol (1:1, 30 cm^3). For the preparation of complexes with L_4, small amount of alkali solution (30%, 5 cm^3) was also added. The above solution was refluxed for 10–14 h. The solvent was removed *in vacuo* and the light brown coloured product was obtained. The complex was isolated by crystallizing the product from tetrahydrofuran. Yield ~ 60–62%.

Table 1. Analytical data of ligands

Reactants taken (molar ratio)	Product, yield (%) and colour	Analysis found (calc.) %		
		C	H	N
Diacetyl + carbohydrazide (1:1)	$L_1^{(1)}$ 80 light brown	42.7 (42.8)	5.7 (5.8)	39.5 (40.0)
Benzil + carbohydrazide (1:1)	$L_1^{(2)}$ 88 yellow	69.4 (69.5)	4.6 (4.7)	21.5 (21.6)
Diacetyl + thiocarbohydrazide (1:1)	$L_2^{(1)}$ 66 yellowish brown	38.4 (38.5)	5.1 (5.2)	35.8 (35.9)
Benzil + thiocarbohydrazide (1:1)	$L_2^{(2)}$ 82 yellow	64.3 (64.3)	4.2 (4.3)	19.9 (20.0)
Diacetyl + semicarbazide (1:2)	$L_3^{(1)}$ 76 light yellow	36.0 (36.3)	6.0 (6.2)	42.0 (42.2)
Benzil + semicarbazide (1:2)	$L_3^{(2)}$ 80 yellow	59.3 (59.4)	5.0 (5.2)	25.9 (26.1)
Diacetyl + thiosemicarbazide (1:2)	$L_4^{(1)}$ 68 yellow	31.0 (31.2)	5.2 (5.3)	36.2 (36.3)
Benzil + thiosemicarbazide (1:2)	$L_4^{(2)}$ 72 yellow	53.9 (54.0)	4.5 (4.7)	23.6 (24.0)

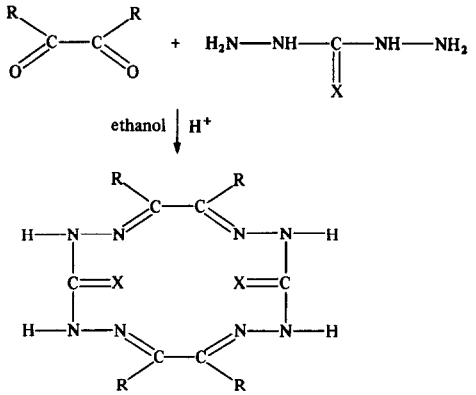
where
$L_1^{(1)}$ = 6,7,13,14 Me_4 3,10 O_2 [14] 5,7,12,14 tetraene 1,5,8,12 N_4 [2,4,9,11 N_4].
$L_1^{(2)}$ = 6,7,13,14 Ph_4 3,10 O_2 [14] 5,7,12,14 tetraene 1,5,8,12 N_4 [2,4,9,11 N_4].
$L_2^{(1)}$ = 6,7,13,14 Me_4 3,10 S_2 [14] 5,7,12,14 tetraene 1,5,8,12 N_4 [2,4,9,11 N_4].
$L_2^{(2)}$ = 6,7,13,14 Ph_4 3,10 S_2 [14] 5,7,12,14 tetraene 1,5,8,12 N_4 [2,4,9,11 N_4].
$L_3^{(1)}$ = diacetyl bis(semicarbazone).
$L_3^{(2)}$ = benzil bis(semicarbazone).
$L_4^{(1)}$ = diacetyl bis(thiosemicarbazone).
$L_4^{(2)}$ = benzil bis(thiosemicarbazone).

(vi) *Preparation of complexes with* L_5 *and* L_6

Diacetyl or benzil (0.01 mol) in ethanol (15 cm^3) was added to the complex of praseodymium with L_3 and L_4 dissolved in a mixture of benzene and ethanol (1 : 1, 30 cm^3). Glacial acetic acid (5 cm^3) was added to the above mixture and a clear solution (pH ~ 3) was obtained which was refluxed for 7–8 h, when dark brown coloured precipitate was obtained. The precipitate was filtered, thoroughly washed with benzene and ethanol and dried *in vacuo*. Yield ~ 48–56%.

RESULTS AND DISCUSSION

The condensation reactions of diacetyl or benzil with carbohydrazide, thiocarbohydrazide in ethanol in the presence of small amount of concentrated hydrochloric acid give rise to cyclic products (Table 1):



6,7,13,14 R_4 3,10 X_2 [14] 5,7,12,14 tetraene 1,5,8,12 N_4 [2,4,9,11 N_4]

R	X	
CH_3	O	$L_1^{(1)}$
C_6H_5	O	$L_1^{(2)}$
CH_3	S	$L_2^{(1)}$
C_6H_5	S	$L_2^{(2)}$

These ligands react with praseodymium(III) chloride in ethanol and the following two types of products have been isolated:

$$PrCl_3 + L_1 \xrightarrow{\text{ethanol}} [Pr(L_1)]Cl_3$$

$$PrCl_3 + L_2 \xrightarrow{\text{ethanol}} [Pr(L_2)(H_2O)_2]Cl_3$$

The elemental analyses of these complexes reveal 1 : 1 metal to ligand stoichiometry (Table 2). The purity of these complexes was checked by TLC. The complexes are found to be soluble in ethanol, dimethylformamide, dimethylsulphoxide and sparingly soluble in chloroform. The electrical conductance in dimethylformamide indicates 1 : 3 electrolytic nature. The presence of coordinated water molecules in the second type of complex was inferred from thermogravimetric analysis which indicated the loss of two water molecules at 140–180°C.

However, diacetyl or benzil reacted with semicarbazide or thiosemicarbazide in 1 : 2 molar ratio, respectively, and formed open chain ligands (Table 1).

C_6H_5	O	benzil bis(semicarbazone); $L_3^{(2)}$
CH_3	S	diacetyl bis(thiosemicarbazone); $L_4^{(1)}$
C_6H_5	S	benzil bis(thiosemicarbazone); $L_4^{(2)}$

These ligands reacted with praseodymium(III) chloride in 1 : 1 molar ratio and formed open chain complexes.

$$PrCl_3 + L_3 \longrightarrow [Pr(L_3)(H_2O)_2]Cl_3$$

$$PrCl_3 + L_4 \longrightarrow [Pr(L_4)(H_2O)_2]Cl_3$$

It appears that in the above complexes the two terminal amino groups remain uncoordinated and can take part in condensation reactions with α-diketones and, therefore, the reactions of the above complexes with diacetyl or benzil were carried out resulting in the formation of complexes with macrocyclic ligands (L_5 and L_6).

$L_6^{(2)}$ = 5,6,11,12 Ph_4 3,8 S_2 [12] 4,6,10,12 tetraene 1,4,7,10 N_4 [2,9 N_2].
DA = diacetyl.
BZ = benzil.

The metal to ligand stoichiometry of these macrocyclic products have been established on the basis of elemental analyses (Table 2). The presence of coordinated water molecules was inferred by thermogravimetric study (weight loss at 160–185°C corresponds to two water molecules). These complexes have high melting points and are soluble in dimethylformamide and dimethylsulphoxide. The complexes behave as 1:3 electrolytes in dimethylformamide. Since these cyclic products derived from semicarbazide and thiosemicarbazide could not be isolated in the absence of metal ion,

praseodymium(III) appears to act as a kinetic "template".

Magnetic moments and electronic spectra

As expected the magnetic moments of these complexes (3.50–3.62 BM) show little deviation from the Van Vleck values[18] and those of hydrated sulphate.[19]

The electronic absorption bands of Pr(III) appear due to the transitions from the ground levels $^3H_4$ to the excited J levels of the 4f configuration.[20] Praseodymium(III) complexes show bands around 1700, 20800, 22000 and 23000 cm^{-1} corresponding to the transitions from $^3H_4$ to $^4D_2$, $^2P_0$, $^3P_1$ and $^3P_2$ energy levels, respectively. It has been observed that on complexation the electronic spectral bands shift to lower energy side (nephelauxatic effect). The slight shift in the bands have been attributed by Jorgensen to the effects of crystal fields upon the interelectronic repulsions between the 4f electrons, i.e. to lowering of the interelectron repulsion parameter in the complexes.[21] Further, a marked enhancement in the intensity of the bands, upon complexation, is also observed. Values of nephelauxatic ratio (β) which is defined as ν_c/ν_f where ν_c and ν_f are energies (in cm^{-1}) of the transitions in complex and free ion, respectively, for the present derivatives lie in the range 0.9800–0.9900. From the mean β values, the covalency parameter (δ) (0.8800–1.354) and bonding parameter ($b^{1/2}$) (0.0630–0.0800) were determined using standard procedures.[22] The values of β, which are less than unity, and positive values of δ and $b^{1/2}$ support partial covalent nature of bonding between metal and ligand.

Infrared spectra

(a) *Complexes with ligands* L_1 *and* L_2. The infrared spectra of macrocyclic ligands (L_1) derived by the condensation of carbohydrazide with diacetyl or benzil show bands at ca 1675, 1500, 1260 and 660 cm^{-1} which may be assigned[15,23,24] to amide I (νC=O), amide II (νC—N+δN—H), amide III (δN—H) and amide IV (ϕC=O) vibrations, respectively. In praseodymium(III) complexes all these bands except amide I show upward shift (~ 60–40 cm^{-1}), whereas amide I shows downward shift (~ 30 cm^{-1}). These changes in amide group vibrations indicate[15] that the amide oxygens (ketonic) take part in coordination to metal atom. This has been further confirmed by the appearance of a band at ca 510–470 cm^{-1} in the complexes, assigned to ν(Pr—O). The infrared spectra of macrocyclic ligands (L_2) derived by the condensation of thiocarbohydrazide with diacetyl or benzil show bands at ca 1560, 1210, 1080 and 765 cm^{-1}, which are assigned[25,26] to thioamide I, II, III and IV vibrations, respectively. The ligands containing the HN—C=S group can undergo thione-$\rightleftharpoons$thiol tautomerism. However, the appearance of four thioamide bands in the spectra of ligands indicates[25] the existence of ligands in the thione form. The thioamide IV band has been found to have maximum νC=S contribution. However, in praseodymium(III) complexes all these bands persist at the same position indicating the non-coordination of thiocarbonyl group to the metal atom.

In addition both the ligands of type L_1 and L_2 show a weak band at ca 1640 cm^{-1} which can be assigned to the ν(C=N) vibration of azomethine linkage. The appearance of a weak ν(C=N) band is in accordance with the observations of several other workers.[27,28] In praseodymium(III) complexes the band appears at ca 1620–1610 cm^{-1} suggesting[15] the coordination of azomethine nitrogens to the metal atom. The ν(Pr—N) vibration band appears at ca 420–380 cm^{-1}, in the complexes.

The infrared spectra of praseodymium(III) complexes with ligands L_2 show broad bands at ca 3480–3420 cm^{-1} which are assigned to ν(O—H) vibrations of the coordinated water molecule.

A number of other bands also arise due to phenyl groups and methyl groups but definite assignments of these bands are not possible due to the complexity of the spectra.

(b) *Complexes with ligands* L_3 *and* L_4. The ligands of type L_3 show bands mainly due to the amide groups, amino group and azomethine groups. The infrared spectra of ligands show bands at ca 1650, 1500, 1250 and 650 cm^{-1} which may be assigned[15] to amide I, amide II, amide III and amide IV vibrations, respectively, as with ligands L_1. In the praseodymium(III) complexes amide I band shows downward shift (~ 40–20 cm^{-1}). These changes indicate[15] that amide oxygen (ketonic) takes part in coordination to the praseodymium atom. The (Pr—O) vibration band appears at ca 500–480 cm^{-1}. The ligands also show a weak band at ca 1630–1625 cm^{-1} assignable[27,28] to ν(C=N) of the azomethine linkage. In the complexes this band shifts to lower frequency (ca 30–20 cm^{-1}) suggesting that the nitrogen atoms of azomethines are coordinated to praseodymium atom. This is further supported by the appearance of weak band at ca 400–380 cm^{-1} assignable to ν(Pr—N). The ligands of type L_3 also show a broad band at 3280 cm^{-1} along with two shoulders at 3300 and 3260 cm^{-1}, which may be due to ν_{sym}(N—H) and ν_{asym}(N—H) vibrations.[29] In the complexes all these bands per-

sist indicating the non-coordination of the terminal amino group to the metal.

The ligands of type L_4 show bands mainly due to thioamide groups, amino groups and the azomethine groups. The four thioamide bands appear at ca 1570–1550, 1210, 1080–1070 and 760 cm^{-1}. The thioamide IV band having maximum contribution of $\nu_{C=S}$, undergo shifts to lower frequency ($\sim$ 35–20 cm^{-1}) in the complexes, indicating[25–30] the coordination of sulphur atom to the praseodymium(III). The new band appearing in the complexes at ca 360–325 cm^{-1} may be assigned to ν(Pr—S). A weak band in the spectra of L_4 appears at ca 1630 cm^{-1} assignable[15,25] to ν(C=N). In the complexes this band also shifts to lower frequency ($\sim$ 25 cm^{-1}) indicating the coordination of azomethine nitrogens to the praseodymium atom. The amino group vibrations appear at 3280, 3250 (shoulder) and 3220 cm^{-1} (shoulder). In the praseodymium complexes these bands appear exactly at the same position indicating the non-coordination of the terminal amino groups to the metal atom. All the complexes with L_3 and L_4 ligands show broad bands at ca 3440 cm^{-1} in the infrared spectra suggesting the presence of coordinated water molecules.

(c) *Complexes with ligands* L_5 *and* L_6. The praseodymium(III) complexes with ligands L_3 and L_4 contain terminal amino groups (as evident from above spectral discussion), which may participate in nucleophilic condensation reactions with α-diketones. Therefore the reactions of complexes of L_3 and L_4 with diacetyl or benzil have been carried out in the presence of glacial acetic acid, which causes the ring closure and formation of cyclic product with macrocyclic ligands L_5 and L_6. The infrared spectra of cyclic product show the same pattern of bands for the amide group (L_5) and thioamide group (L_6) and the azomethine group. This indicates that in the macrocyclic complexes with L_5, the ligand is bonded to the metal atom through two azomethine nitrogen atoms and two ketonic oxygen atoms. Similarly in the complexes with ligands L_6 the ligands are coordinated to the metal through two thioamide sulphur atoms and two azomethinenitrogen atoms. However, in both types of complexes, the (νNH_2) band disappears. Only one band is observed in the νN—H region at 3200 cm^{-1} which may be due to a secondary amino group, establishing the condensation of primary amino groups with the carbonyl groups of α-diketones. This is further supported by the appearance of a weak band at ca 1650–1635 cm^{-1}, due to the formation of azomethine linkages.[27] The complexes with ligands L_5 and L_6 also contain coordinated water molecules, as is evident by the presence of a broad band at ca 3480 cm^{-1} in the infrared spectra.

Proton magnetic resonance spectra

The ^1H NMR spectra (90 MHz) of the complexes with ligands L_1, L_2, L_5 and L_6, obtained in deuterated chloroform or in DMSO-d_6 solution with TMS as internal standard show the methyl protons at ca δ 2.2–2.8 ppm and phenyl protons at ca δ 6.8–7.2 ppm. These signals appear downfield compared to the corresponding signals of the ligands indicating coordination of the ligands to the praseodymium ion.

and

H.-P. ABICHT*

Department of Chemistry, Martin-Luther-University, DDR-4050 Halle (Saale), G.D.R.

(*Received* 9 *February* 1987; *accepted* 18 *February* 1987)

Abstract—Protonolysis of ortho-palladated asymmetric metallacycles [Pd(o-$C_6H_4CH_2Z_A$)(o-$C_6H_4CH_2Z_B$)] (**3**: $Z_A = NMe_2$, $Z_B = PPh_2$; **4**: $Z_A = NMe_2$, $Z_B = AsPh_2$; **5**: $Z_A = AsPh_2$, $Z_B = PPh_2$) by acetic acid leads to the departure of $PhCH_2NMe_2$ (in the case of **3** and **4**) and $PhCH_2AsPh_2$ (for **5**) and formation of corresponding dimeric acetato bridged complexes **6** and **7**, respectively. The relative stability of the palladocycles is determined by the nature of the donor atom and decreases in the order: P > As > N.

Mechanism of electrophilic cleavage of transition-metal–carbon bonds are still under intensive investigation.[1] Cyclometallated complexes of the type **1**, possessing a rather stable palladium–carbon bond, appear to be useful objects for such studies. We have previously studied the mechanism of protonolysis of complex **1**.[2] The reaction involves the formation of intermediate **2** indicating an important role of a donor group in the course of the palladocycle cleavage. To continue our study of the role of the donor centre, we investigated the protonolysis of complexes **3–5** which contain N-, P- and As-donor palladocycles, by acetic acid with a goal to compare a relative stability of those towards protonolysis.

RESULTS AND DISCUSSION

Addition of D_3CCOOD to a suspension of complexes **3–5** in $CDCl_3$ at room temperature leads to complete dissolution of the starting compounds. The reaction occurs instantaneously in the case of **3**, but it takes 5 and 120 min in the case of **4** and **5**, respectively. The reactivity decreases in the order: **3** > **4** > **5**. The ^{1}H-NMR analysis of the products formed as well as their isolation as solids in the case of **4** and **5** indicates that mixed ligand palladocycles **3–5** lose one cyclopalladated ligand affording acetato bridged dimers **6**, **7** and **6**, respectively. The leaving ligand is $PhCH_2NMe_2$ in the case of **3** and **4**, but $PhCH_2AsPh_2$ in the case of **5**. The relative lability of palladocycles is thus strongly dependent on the nature of donor atom decreases in the order: N > As > P. Note that this sequence does not correspond to that expected on the basis of relative basicity of the elements (N > P > As). A remarkable stability of phosphorus palladocycles is probably due to favourable combination of σ-donor and π-acceptor properties of this donor centre.

It should be pointed out that utilization of rather weak acetic acid allows to perform a selective cleavage of complexes **3–5**, whereas much stronger HCl cleaves both palladocycles.[3] It is also interesting to note that the pathway of decomposition of **3** could be predicted on the basis of recent results on the exchange of cyclopalladated ligands.[4] In the reaction between chloro-bridged *N,N*-dimethylbenzylamine derivative [μ-ClPd(o-$C_6H_4CH_2NMe_2$)]$_2$ and $PhCH_2PPh_2$ in the presence of acetic acid we

6 E = P
7 E = As

observed the Pd(II) transfer to give $[\mu\text{-ClPd}(o\text{-}C_6H_4CH_2PPh_2)]_2$. Both experiments show the thermodynamic preference of Pd(II) for the P-ligand.

In conclusion, a resistance of palladocycles towards protonolysis is determined by the nature of donor atom increasing in the order: N < As < P.

EXPERIMENTAL

Mixed ligand palladocycles **3–5** were prepared as previously described.[3] ^{1}H-NMR spectra were run on Tesla BS 467 and Bruker CXP 100 instruments. Chemical shifts are given in ppm with respect to TMS.

Protonolysis of complexes **3–5** *in acetic acid (exemplified by* **3**)

{[*o*-(Dimethylaminomethyl)phenyl - C^1, - N] - [*o*-(diphenylphosphinomethyl)phenyl - C^1, - P]} - palladium(II) (**3**) (30 mg) was suspended in 0.5 cm^3 $CDCl_3$. Addition of 0.25 cm^3 D_3CCOOD resulted in rapid dissolution. Hexamethyldisiloxane (0.06 cm^3) was added to the reaction mixture and its ^{1}H-NMR spectrum recorded. The latter contained signals of NCH_2 and NCH_3 protons of free $PhCH_2NMe_2$ at δ = 4.18 and 2.70, respectively, as well as a broad doublet from cyclopalladated $PhCH_2PPh_2$ at δ = 3.06 (J = 13 Hz). On addition of pyridine-d_5, which converts dimeric complexes into monomers of the type **1**, a signal from PCH_2 protons is seen as a sharp doublet at δ = 4.02. These spectral data are in agreement with those reported in the literature for ortho-palladated $PhCH_2PPh_2$ derivatives.[4,5] Similar spectral analyses were performed in the case of **4** and **5**. Compounds **6** and **7** were isolated as solids as described elsewhere.[4] RFA analyses confirmed the absence of As and the presence of P in the complex obtained from **5**. ^{1}H-NMR data of **7**, $\delta(CDCl_3$; py-$d_5)$: 6.77–7.9 m (Ar), 3.79 s ($AsCH_2$), 1.85 s ($OOCCH_3$).

ANGULAR OVERLAP PARAMETERS FOR RUTHENIUM(II) COMPLEXES

PATRICK E. HOGGARD* and PIERRE P. CLANET

Department of Chemistry, North Dakota State University, Fargo, ND 58105, U.S.A.

(*Received* 29 *May* 1986; *accepted* 6 *March* 1987)

Abstract—Approximate Angular Overlap Model e_π parameters have been obtained for a number of ligands L by comparison of the $t_{2g}(Ru) \rightarrow \pi^*(bpy)$ transition energies in $[Ru(bpy)_2L_2]$ complexes. The filled t_{2g} subshell of Ru(II) limits the effects of otherwise strongly π-donating ligands.

The Angular Overlap Model (AOM) is an additive ligand field theory that factors the ligand potential into σ and π contributions.[1,2] One of the difficulties in applying the AOM is that it is hard to obtain usable experimental values of the parameters e_σ and e_π for particular ligands. Once in hand, however, these parameters should be relatively constant from one complex to another with the same metal ion, although large changes in the electron donating and withdrawing properties of the other ligands can alter this.[3] The e_σ and e_π values may also be transferable, with a multiplicative factor,[4,5] to other metal ions with the same *d* electron configuration. AOM parameter values may, however, be quite different for metal ions with different configurations.

The most common method of determining AOM parameter values is by resolving the splittings of spin-allowed *d–d* bands in MA_5B or MA_4B_2 complexes. There are considerable experimental difficulties here, as often these splittings can only be measured using polarized absorption spectroscopy on single crystals,[6] or by performing a Gaussian curve resolution on bands that may have little or no asymmetry to the eye.[7]

We present here results from a simpler experimental technique to evaluate e_π for a series of ligands through comparison of the metal-to-ligand charge transfer (MLCT) bands in *cis*-$[Ru(bpy)_2L_2]$ complexes (bpy = 2,2′-bipyridine). The lowest-energy MLCT band can be represented as a transition from the highest Ru t_{2g}-remnant orbital, which is degenerate, or nearly so, to the lowest bipyridine π^* orbital. We assume the energy of this π^* orbital to be constant over the entire series of complexes examined, while the energy of the ruthenium orbital can be expressed, assuming all ligands coordinate linearly (which is not true, but is a useful approximation) as

$$E(t_{2g}) = 2e_{\pi bpy} + 2e_{\pi L}.$$

The orbital transition energy is then

$$\Delta E = E(\pi^*) - E(t_{2g}) = E(\pi^*) - 2e_{\pi bpy} - 2e_{\pi L}$$
$$= C - 2e_{\pi L}. \quad (1)$$

We will also assume that other components of the transition energy, including interelectronic repulsion and spin-orbit coupling, can be included in the constant C. If, as is usual in AOM problems, we take a saturated amine as a reference ligand with $e_{\pi L} = 0$, C can be calculated and $e_{\pi L}$ determined for the remaining ligands in the series.

The position of the first absorption band of $[Ru(bpy)_2X_2]$ for each ligand used is listed in Table 1. From the 531 nm value for $[Ru(bpy)_2(en)]$, the constant C in eqn (1) is 18,830 cm^{-1}. The e_π values for each ligand, as calculated from eqn (1), are also listed. Still assuming linear coordination, e_σ may be estimated from $\Delta = 3e_\sigma - 4e_\pi$, if Δ (= 10Dq) is

known for that ligand. Only a few octahedral Ru(II) complexes are known for which Δ can be determined from the absorption spectrum. Table 1 lists these, but also estimates values for others taken from the corresponding Rh(III) complexes, using 0.788 as the ratio of Δ_{Ru}/Δ_{Rh}, which is the ratio in the hexaamine complexes.[8,11]

It is instructive to compare the e_π values from this series of complexes to those for Cr(III), a d^3 ion. Table 2 lists values for some representative ligands. These should not be regarded as fixed, but as changing with the molecular environment. The relative values, however, should remain approximately as shown.[15] Examination of Table 2 leads to the conclusion that π-donation is less important with Ru(II) than π-withdrawal. This is not unexpected for low-spin d^6 complexes. The value of e_π depends on a balance between donation by ligand π orbitals

and withdrawal into ligand π^* orbitals, when accessible. The contrast is quite evident for N-bonding thiocyanate. In Cr(III) complexes the donor effects dominate, while in the bis(bipyridine)ruthenium(II) complexes donor effects are subdued and e_π is negative. Similar behavior is exhibited by many of the ligands from Table 1 with π bonds. Formate is perhaps the most unexpected case, showing net π-withdrawing characteristics, even though acetate is a relatively strong π-donor.

The list of $[Ru(bpy)_2X_2]$ complexes known is extensive. Thus many more ligands may be evaluated and their π-bonding characteristics compared with those studied here. In such comparisons, however, it should be remembered that $[Ru(bpy)_2X_2]$ absorption spectra can be quite sensitive to the solvent.

EXPERIMENTAL

Dimethylformamide was used as the solvent because of the relatively high solubilities of salts generally, and $[Ru(bpy)_3]^{2+}$ salts in particular. If a salt was found that could be dissolved in DMF to yield a 2 M concentration of the desired anion, then $[Ru(bpy)_3]Cl_2$ was added to that solution to a concentration of 0.02 M, and 3 cm^3 photolyzed with a 500-W Hg lamp until a substantial color change had taken place, usually about one hour. The photolysate was then chromatographed on Sephadex LH-20, eluting with DMF. The first band, purple, or sometimes reddish-brown, in color, was in all cases ascribed to the desired *cis*-$[Ru(bpy)_2X_2]$ complex. There were generally two trailing bands, which were *cis*-$[Ru(bpy)_2(DMF)X]^+$ (usually red) and the $[Ru(bpy)_3]^{2+}$ starting material (yellow).[18,19] When a 2 M concentration of anion could not be achieved, the $[Ru(bpy)_3]X_2$ salt was made by preparing a Dowex 1-X8 anion exchange column in the X^- form, passing an aqueous solution of $[Ru(bpy)_3]Cl_2$ through it, and evaporating the eluant. All the

$[Ru(bpy)_3]X_2$ salts prepared in this way were sufficiently soluble in DMF to carry through with the photolysis as above, but with no additional salt present. To prepare $[Ru(bpy)_2(en)]^{2+}$, the perchlorate salt was used and a hundredfold excess of ethylenediamine added. Absorption spectra of the $[Ru(bpy)_2X_2]$ species were recorded on a Cary 14 spectrophotometer.

SYNTHESIS AND MOLECULAR STRUCTURE OF THE FIRST INORGANIC QUADRUPLY-BRIDGED Ir(II) DIMER (Ir–Ir)

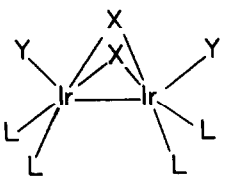
F. ALBERT COTTON* and RINALDO POLI

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

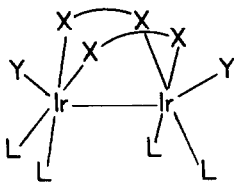
(*Received* 17 *February* 1987; *accepted* 9 *March* 1987)

Abstract—Interaction of (COD)Ir(μ-form)$_2$Ir(OCOCF$_3$)$_2$(H$_2$O) (COD = 1,5-cyclooctadiene; form = *N*,*N*′-di-*p*-tolylformamidinate ion) with two equivalents of Hform in toluene affords Ir$_2$(form)$_4$, the first inorganic Ir(II) dimer to be crystallographically characterized. The reaction involves a formal electron redistribution from a dative Ir(I) → Ir(III) to a covalent Ir(II)–Ir(II) bond. The compound crystallizes in the cubic space group Pn$\bar{3}$n with a = 21.300(9) Å. The metal–metal separation, 2.524(3) Å, is the shortest ever reported for a bonding interaction between iridium atoms.

Rh(II) dinuclear compounds containing four monoanionic bridging ligands and a single metal–metal bond of $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ electronic configuration are well known.[1] The first one, Rh$_2$(O$_2$CH)$_4$(H$_2$O)$_2$, was reported in 1960,[2a] although not initially recognized as such.[2b] Other dirhodium(II,II) tetracarboxylato compounds have been obtained, mainly by interaction of hydrated RhCl$_3$ with alkali metal carboxylates in alcoholic media.[3] Known compounds with other bridging ligands include Rh$_2$(xhp)$_4$ (xhp = 6-X-substituted hydroxypyridinato ion, X = CH$_3$,[4,5] Cl[5]), Rh$_2$(OC(R)NR′)$_4$ (R = CF$_3$, R′ = H;[6] R = Me, R′ = Ph;[7] R = Ph, R′ = H[8]), Rh$_2$(3,5-Me$_2$pz)$_4$ (pz = pyrazolate ion),[9] Rh$_2$(PhNpy)$_4$,[10] Rh$_2$(N$_2$PhCPh)$_4$[11] and Rh$_2$(form)$_4$ (form = *N*,*N*′-di-*p*-tolylformamidinate ion),[12] some of which contain axially coordinated neutral ligands. A number of Rh_2^{4+} complexes with mixed bridging ligands also exist.[13] On the other hand, Ir(II) complexes having a similar structure have never been reported, in spite of the existence of a large number of structurally different Ir(II) dinuclear complexes, these being generally of the type represented in I[14] or II.[15]



I



II

Only five diiridium(II,II) compounds that have the two metals in a square planar configuration with the two square planes parallel to each other (with or without additional axial ligands) seem to have been reported in the literature. These are $[Ir_2(TMB)_4I_2]^{2+}$ (TMB = 2,5-dimethyl-2,5-diisocyanohexane)[16] of structure III, Ir$_2$(Tcbiim)$_2$(CO)$_2$(MeCN)$_2$(P(OEt)$_3$)$_2$ (Tcbiim = dianion of tetracyanobiimidazole)[17a] of structure IV, [IrClX(CO)(dppm)]$_2$ [dppm = bis(diphenylphosphino)methane, X = Cl, CH$_3$O$_2$CC=CHCO$_2$CH$_3$][17b] of structure V, and Ir$_2$(OEP)$_2$ (OEP = dianion of octaethylporphirine)[18] of structure VI. The first four have been structurally characterized and exhibit Ir–Ir distances of 2.803[16] and 2.826(2),[17a] 2.786(1) and 3.016(1) (average) Å.[17b] Unfortunately Ir$_2$(OEP)$_2$, which is to be regarded as the only known truly inorganic Ir(II) dimer (this

VII

meaning that the coordination sphere around the metal is filled with non-carbon atoms), has not been structurally characterized.

We wish to report here for the first time the synthesis and X-ray crystal structure of an inorganic iridium(II) dimer having a structure of the type VII, i.e. of the same type as the Rh_2^{4+} compounds mentioned above. The mixed-valence Ir(I)–Ir(III) compound, $(COD)Ir(\mu\text{-form})_2Ir(OCOCF_3)_2(H_2O)$ (COD = 1,5-cyclo-octadiene),[19] reacts smoothly in warm toluene with two equivalents of Hform to produce an emerald-green solution from which dark-green crystals of $Ir_2(form)_4$ were obtained in small yields by evaporation to dryness and recrystallization from MeCN.

Such a reaction involves a proton transfer from the weaker acid, Hform, to the stronger one, CF_3COOH. The formation of two new formamidinato bridges between the two iridium centers is presumably the driving force of the reaction. A formal electron redistribution also takes place, from the compound with a dative Ir(I) → Ir(III) bond to

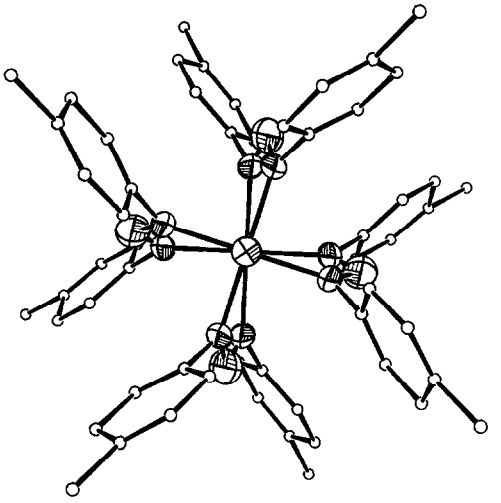

Fig. 2. View of the $Ir_2(form)_4$ molecule along the Ir–Ir′ direction.

the covalently bonded Ir(II)–Ir(II) product. Both CF_3COOH and COD that are obtained along with the iridium product were identified by their ^{1}H-NMR peaks at 13.0 (broad) and 5.55 δ, respectively.

Quite surprisingly, attempts to obtain the same product directly by oxidising $[Ir(form)(COD)]_2$ with Ag(form) failed. No reaction took place under thermal or photochemical conditions or a combination thereof.

The structure of the $Ir_2(form)_4$ molecule is shown in Fig. 1.* The molecule has D_4 imposed symmetry, the fourfold axis passing through the two iridium atoms and the twofold axes passing through and between pairs of trans-methylidyne groups. The compound is isostructural with $Rh_2(form)_4$.[12] Each iridium atom is bonded to four nitrogen atoms in a square planar arrangement. The iridium atom is displaced by 0.16(2) Å from the N_4 plane in the outward direction. The two square planes are twisted away from the eclipsed configuration by 15.6(5)° (see Fig. 2). The metal–metal distance is 2.524(3) Å and is the shortest Ir–Ir bond length ever reported. It is even shorter than the separation in $[Ir(CO)(PPh_3)(\eta\text{-}PPh_2)]_2$, 2.554 Å, for which a bond order of two has been proposed[20] and it is, expectedly, longer than the Rh–Rh separation (2.4336(4) Å) in the analogous compound $Rh_2(form)_4$.[12] The nearest neighbour separation in metallic iridium is 2.714 Å.[21]

Electrochemical, spectroscopic and theoretical studies on $Ir_2(form)_4$ are in progress. The assignment of an electron rich single bond of $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ configuration to the metal–metal interaction, however, is strongly suggested by previous work done on similar rhodium compounds.[22]

Acknowledgements—We thank the National Science Foundation for support, and Prof. Piraino for sending us a copy of his manuscript[12] prior to publication.

NEWSLETTER 1987: IUPAC COMMISSION ON NOMENCLATURE OF INORGANIC CHEMISTRY

The objective of this Newsletter is to inform all interested parties about the ongoing activities of the Commission on Nomenclature of Inorganic Chemistry (CNIC), and to draw attention to nomenclature documents that it has published recently. Readers are invited to write to the CNIC chairman about problems involving the nomenclature of inorganic chemistry: Professor Daryle H. Busch, Department of Chemistry, The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210, U.S.A., or to any of its members.*

The first CNIC Newsletter appeared in the following journals: *Transition Metal Chemistry* 1986, **11**, 35; *Polyhedron* 1986, **5**, 925; and *Chemistry International* 1986, **8**, 10.

The favourable response of the chemical community has led the Commission to continue biannual publication of Newsletters.

RECENTLY PUBLISHED DOCUMENTS

The most recent IUPAC–CNIC manual on the nomenclature of inorganic chemistry[1] was published in 1970 and the Commission has published a number of documents about topics that have evolved since that time. Documents appearing in print in 1982 or later deal with isotopically labeled and isotopically substituted compounds,[2] inorganic and coordination polymers[3] (joint with the Nomenclature Commission of the Macromolecular Division of IUPAC), and nitrogen hydrides.[4] Short summaries of these recommendations have been given in Newsletter 1985. A document on heteropolyanions[5] is in press and its synopsis is given below.

NOMENCLATURE OF POLYANIONS

The chemistry of polyanions is a rapidly growing field due particularly to the novelty and significance of some of these compounds. Some species are very large (up to 48 tungsten atoms) and extremely complicated in structure. Many examples of substituted species have been found to exist as isomers. Today the basic compounds are commonly identified among specialists by trivial names and the old rules for naming polyanions (1970 Red Book) are not adequate to treat many of the new species. New rules have been developed. The basic idea is to assign a number to each central atom, the environment of which is then described by letters associated with that number. The document describes various types of polyanions having what is called the Lindqvist structure, the Anderson structure, the Keggin structure, the Dawson structure, and some others derived from them. It is hoped that the examples given in the document will provide a procedure that can be applied to the naming of any new compound of this kind. Since these compounds are very complicated it is not surprising that their names are correspondingly intricate. Shortened names may always be used, for example to describe the composition alone; however, such names invariably will give less information about the details of the actual structure.

ONGOING ACTIVITIES

Because of the development of many new fields and the discovery of many new types of compounds since the publication of the 1970 Red Book, the Commission decided to undertake a complete revision of the rules for the nomenclature of inorganic chemistry. CNIC expects the new basic manual to be published in 1987; the project is described in detail below (1987 Red Book, Part I).

In addition to that basic manual, the Commission intends to publish a Part II that will be made up of chapters dealing with more advanced and detailed recommendations covering more specialized fields, such as those mentioned above[2–5] and organometallic compounds, clusters, inorganic rings, chains and ligand abbreviations (all in preparation).

All interested persons are encouraged to communicate their ideas or suggestions about these topics or to suggest other appropriate subjects to the Commission. Please feel free to share your feelings on topics that are or should be considered by CNIC.

OTHER DOCUMENTS OF RELEVANCE TO INORGANIC CHEMISTRY

The Commission also wants to call attention to nomenclature documents prepared under the supervision of other IUPAC commissions. Of particular note at this time are documents on zeolites,[6] graphite intercalation compounds,[7] use of numerical terms[8] and the application of the λ-convection to treat variable valence in organic nomenclature.[9]

PERIODIC TABLE

The Commission has recommended that the columns of the long form of the Periodic Table be labeled consecutively from left to right with the arabic numerals 1–

* Present titular members of the Commission are: D. H. Busch (chairman), E. Fluck (vice-chairman), P. Fodor-Csanyi, R. Laitinen, J. F. Nixon, J. Reedijk, E. Samuel (secretary) and T. E. Sloan.

18. The environment and nature of this recommendation are reviewed here.

CNIC attempts to be respectful of, and sensitive to, common usage of such basic conventions as those involving the Periodic Table. In the homelands of Mendeleev and J. Lothar Meyer, the classic eight-column short form of the table is understandably still widely used. However, most of the countries in Europe, both East and West, use an 18-column table exclusively, as do Japan and the United States. CNIC expects that, in some countries, use will always be made of the eight-column table. Those users should respect the recommendations of the 1970 Red Book. It remains true, however, the common practice throughout most of the world overwhelmingly supports the 18-column format. Therefore, recommendation of that format cannot be an issue. The labeling of the columns is the only issue.

In 1970 CNIC and IUPAC endorsed a system for column labeling that followed an early precedent for the use of the capital letters A and B to distinguish between the left- and right-side families of elements. While this practice is in common use in Great Britain and much of Europe, it has found acceptance only slowly, if at all, elsewhere. Japan has just accepted this practice while the United States has adhered rigidly to the converse use of the A and B labels. Thus, an unacceptable conflict in column labeling exists.

Exhaustive discussions have been held by CNIC on various formats and labeling schemes for the Periodic Table and representatives of CNIC have promoted public discussions on the subject through national professional organizations. At the meeting of CNIC in 1982, it was concluded that the use of the 18-column table should be encouraged and that that table would be used in the new Red Book, Part I. Further, a majority of the members of CNIC favored the labeling of the columns consecutively, from left to right, with the arabic numbers 1–18. The latter suggestion was offered as a solution to the conflicting use, on opposite sides of the Atlantic Ocean, of the column labels A and B. These conclusions were confirmed by Votes at CNIC meetings in 1983, 1984 and 1985. Now, in 1986, CNIC has reconfirmed these conclusions at its meeting in Heidelberg. While it is neither the purpose nor the intent of CNIC to arbitrarily set the format of the Periodic Table to be used in all parts of the world, it is a reasonable mission for CNIC to offer broadly useful solutions when direct conflicts in usage occur.

At the Heidelberg meeting an attempt was made to evaluate the correspondence on the Periodic Table that was available to CNIC. Least change was most often favored, with no change being most popular of all. Many would like to retain the equivalent of an A–B system. However, this was not found to be acceptable either because of problems with translation or because of the conviction that disguising the problem fails to solve it.

Critics claim that the new labeling system interfers with teaching. Those from users of the eight-column table could not be answered since CNIC expects use of that format to continue in some places. However, it is not appropriate to give credit to CNIC for the evolved dominance of the 18-column form throughout most of the world.

Otherwise, the main concern rests on perceived losses in correlations between column labels and such quantities as positive oxidation numbers and numbers of valence electrons for main-group elements. As has been pointed out by a number of correspondents, no problem of this kind actually exists. One need only show the student that for the "teen columns" the *second* digit of the column number corresponds to the number of valence electrons and to the maximum positive oxidation number. One should also recognize that the CNIC-recommended numbering scheme also displays relationships involving the numbers of electrons for the transition elements. Further, the proposed scheme eliminates the irrational (for the long form) lumping together of three families of elements under a single number (old VIII, new 8–10). In summary, one can teach all that was taught before, plus significantly more, using the proposed labels.

Several correspondents have referred to the use of the roman numerals of the familiar 18-column table in the common parlance of solid-state science; e.g. III/V semiconductors. The behaviors of these materials derive from their electronic (and crystal) structures and not from the labels on the columns of the Periodic Table. It is almost universally agreed that one should not try to reproduce electronic structure precisely in the column headings. Again, the second digit of the column heading relates to the electronic structure for *p*-block elements and the notation III/V remains perfectly rational.

A number of correspondents complained of poor or ineffective communication with regard to the proposed relabeling scheme. CNIC is deeply concerned with this matter. It has been decided that, over whatever length of time is required by appropriate and effective process, ultimate recommendations on the format and labeling of the Periodic Table must be responsive to the user constituency. That constituency ranges from school children to senior scientists and covers such disciplines, in addition to chemistry, as biology, metallurgy, ceramics, solid-state physics, and materials science. Each subgroup of this large population should have the opportunity to seek and present its local consensus. The principal goal of CNIC–IUPAC would be to offer the minimum guidance necessary to eliminate conflicting usages.

CONTENTS OF THE RED BOOK, PART I

In Newsletter 1985 we have only listed the chapter titles. Subsequently, the Commission has approved the contents of the several chapters and the documents are now subject to international public review, as required by IUPAC regulations. Accordingly, synopses of the several chapters have either already appeared or will appear in the coming year, in several journals, about the world. Copies of the chapters can be obtained from the corresponding regional distribution centers. Summaries of the 11 chapters are presented here so that interested readers can consider their contents and see the relationships between the chapters.

Chapter I-1, *general aims*

The opening chapter begins with a brief history of the nomenclature of inorganic chemistry from its birth to the present day. The general aims and functions of nomenclature are then described and the terms "trivial", "semi-systematic" and "systematic" are explained. It is then shown how and why it became necessary to establish rules. This is followed by an explanation of the methodology of name construction.

Various systems of inorganic nomenclature are presented, with examples. The discussion covers binary, additive and replacement nomenclature, and also systems used in organic chemistry and pertinent systems, such as substitutive, subtractive and index nomenclature.

The final section contains information about international collaboration on nomenclature matters, on the formation of working groups on nomenclature, and on the role which IUPAC has assumed in this endeavor. This information is not generally known to the chemical community. A survey of the accomplishments of IUPAC commissions since 1921 is presented, together with bibliographical reference to all of the inorganic nomenclature documents published by this Commission.

Chapter I-2, *grammar*

The purpose of this chapter is to guide the users of nomenclature in building the name or formula of an inorganic compound, and to help them verify that the derived name or formula fully obeys the accepted principles. Chemical nomenclature is a very special language with its own vocabulary, syntax and grammar. This chapter contains a general survey of the "grammatical" rules governing the correct use of the various devices used in the construction of a name or a formula. Sections 1–14 deal with idiomatic symbols (brackets, dots, commas, hyphens, dashes etc.), greek letters and numerals and provide many examples. The various priorities are then discussed in Section 15. The last part, Section 16, deals with suffixes commonly used in inorganic nomenclature. This chapter is an innovation in the presentation of the nomenclature of inorganic chemistry.

Chapter I-3, *elements, atoms, and groups of atoms*

This chapter defines the basic material for inorganic nomenclature, the atomic symbols and names. It also contains definitions of fundamental concepts such as element, atomic charge, and nuclide. The basic methods for indicating ionic charge, atomic number, and mass number are described, as well as a system for naming allotropes of the elements which should be of general if not universal utility.

The final section deals with the indication of groups in the Periodic Table. For the 18-column periodic table, it is recommended that the old A–B system for sub-groups be abandoned because of its inconsistent application in different parts of the world, and that a system with group numbers 1–18 (the last being the inert gases) be adopted generally. Some approved names for particular groups of elements, such as halogens and transition elements, are listed.

Chapter I-4, *formulae*

This chapter is intended to serve as a guide to the users of the nomenclature of inorganic chemistry in writing formulae correctly according to the rules recommended by IUPAC. The chapter contains the definitions of types of formulae, and shows how to indicate proportions, oxidation states, and ionic charges of constituents, and how to use structural modifiers.

The sequence of citation in formulae is based on the alphabetical order of the symbols of the electropositive and electronegative constituents, respectively. A guide to writing the formulae of isotopically modified compounds is included with cross-reference to the detailed IUPAC recommendations. Numerous examples are given to illustrate the rules. Finally, a table summarizes the method for assignment of the formulae of compounds.

The rules of formulae construction are in full agreement with the previously published rules of *Nomenclature of Inorganic chemistry* (1970) (1970 Red Book), but Chap. I-4 gathers together all of the basic information on formulae which was discussed in different chapters of the old Red Book. In addition, some rules, such as that concerning alphabetical ordering, are extended and others explicitly expressed so that it is not necessary to infer them from the examples. This latter method of presentation was used in the 1970 Red Book and has been widely criticized. The number and types of examples have now been increased.

Chapter I-5, *names based on stoichiometry*

This chapter serves as a guide in writing stoichiometric names correctly, including the derivation of names, their assembly into the correct sequence and the indication of proportions. Rules for the names of monoatomic, polyatomic and heteropolyatomic electropositive and electronegative constituents, as well as of addition compounds, are included.

The order of citation in names is based on the alphabetical order of the names of the electropositive and electronegative constituents, respectively. The proportions of the constituents can be indicated either by multiplicative prefixes (numerical prefixes and multiplicative numerals) or by indications of the oxidation numbers or the charges on the ions.

There are no changes in substance between this chapter and the 1970 Red Book; however, the discussion is more extensive and many points are explained more precisely. The chapter contains numerous examples.

Chapter I-6, *solids*

Chapter I-6 of the new Red Book, Part I, deals with the names of solid phases, chemical composition, point defect notation, phase nomenclature, non-stoichiometric phases, polymorphism, amorphous systems and glasses. The chapter is essentially a new one, differing in principle

and detail from corresponding material in 1970 Red Book.

The point defect notation is based on the Kroger–Vink system. It allows the indication of site occupation by using the element symbols as subscripts. Vacant positions are indicated with V and interstitials with the subscript i. Charges are expressed by superscripts; both real and effective charges can be indicated.

Phase nomenclature is derived from the Pearson notation. In the section on non-stoichiometric phases, descriptions are given of modulated structures, crystallographic shear structures, chemical twinning, infinitely adaptive structures and intercalates.

For the distinction between polymorphs, indication of the crystal system in combination with the name or formula is recommended. Some abbreviations are used to designate amorphous systems and glasses.

Chapter I-7, *neutral molecular compounds*

This chapter describes the essential characteristics of the nomenclature of realtively simple neutral compounds, providing guidance for name-construction: (a) for molecules regarded as substitution derivatives of parent hydrides, and (b) for coordination entities.

The principles of substituitive nomenclature are explained and the nomenclature of a chosen set of parent hydrides is described. These principles are extended to cover the nomenclature of oligonuclear hydrides, to various categories of chains of atoms, including branched, and to simple cyclic systems. The case of varying bonding numbers for the central atom, including unsaturation, is treated.

The principles of coordination nomenclature are described and extended from mononuclear coordination entities to dinuclear compounds, and to simple oligonuclear entities. Illustrative examples are provided throughout.

Chapter I-8, *names for ions, radicals and salts*

Cations, anions, radicals and salts are defined, and the two kinds of radicals are distinguished: those consisting of an atom (or groups of atoms) having one or more unpaired electrons and those consisting of a group of atoms for which the name is used as a prefix in substitutive nomenclature. Charged radicals are treated.

The sections on cations and anions deal with species obtained from organic and inorganic molecules after loss or addition of electrons, or hydrogen ions, or of hydride ions. Coordination nomenclature is used when a central atom of metal character is present, whereas substitutive nomenclature is used in other cases. Certain special names are retained (e.g. nitrosyl for NO^+ and kalide for K^-).

Formulae and names of salts are easily constructed by combination of the names of cations and anions. In double salts the cation and anion names are ordered alphabetically unless other requirements mandate an alternative arrangement. Thus, to emphasize structural similarities $AlLaO_3$ is often represented as $LaAlO_3$ (*perovskite*-type).

Chapter I-9, *inorganic oxoacids*

This chapter provides a treatment of the nomenclature of oxoacids which is intended to be comprehensive and useful. The long history of the subject and the importance and widespread use of oxoacid nomenclatures in teaching and industry warrant this extensive coverage. The approach followed involves systematization, whenever possible, based on the principles of coordination nomenclature.

The introductory sections deal with historical considerations. A definition of an oxoacid is given. Then the principles of hydrogen nomenclature and their extension to all oxoacids and their functional derivatives (halogenides, anhydrides, esters and amides) are given, with many examples. This represents a considerable expansion of the 1970 Red Book, but this systematic use was recommended, at that time, only for acids containing ligands other than oxygen and sulfur.

Acid nomenclature is then presented; it has the feature that the number of acidic hydrogens is not explicitly stated. Polynuclear acids are dealt with next. Except for special cases, this nomenclature is based exclusively on that of coordination compounds.

Chapter I-10, *coordination compounds*

The nomenclature of coordination compounds constitutes a major system of addition nomenclature that is based on structural relationships associated with the compounds of the metallic elements. Basic concepts and definitions are presented, and the discussion proceeds on to formulas and names for the simplest coordination compounds. The nomenclature of mononuclear coordination compounds with monodentate ligands is extensively developed with listings of names and abbreviations for many common ligands. Stereochemical descriptors are then presented that designate the geometric arrangements of ligands. Formulas and names for chelate mononuclear complexes follow with special attention being given to the kappa convention for identifying the ligating atoms of ambidentate and polyfunctional ligands, and to stereochemical descriptors for chelated compounds. Chirality symbols are introduced for various polyhedra structures and the skew-line helical reference is presented along with an alternative technique based on the Cahn, Ingold, Prelog priority sequence of ligands. A limited treatment is provided for the nomenclature of more intricate species including polynuclear complexes and clusters, with emphasis given to central atom numbering and bonding notation. A summary of the nomenclature for single-strand coordination polymers is given, and the final section is a brief introduction to the nomenclature of organometallic complexes.

Chapter I-11, *boron hydrides and related compounds*

Just as their structures provided novelty and a challenge to chemistry, the nomenclature of the boron

hydrides must treat distinctive relationships. The bases of boron-hydride nomenclature are discussed, and the polyhedral clusters of boron are presented and classified and the class names are given. Stoichiometric names are presented and the general aspects of structural names are discussed. Numbering schemes, steric descriptors and structural isomers are discussed. The "debor" method is given. The treatment of replacement and substitution in boron clusters is considered, including hydrogen substitution, skeletal subrogation and such species as carbaboranes and metalloboranes.

CORRESPONDENCE, SMALL MATTERS THAT MATTER ETC.

CNIC is a unit of an international public service organization, IUPAC, and we are volunteer chemists from around the world. Since nomenclature is our responsibility, we invite your inquiries and suggestions. We can serve you best if we know your needs and opinions. At worst, we should know someone who can name your cluster—or your ligand! Of course, some people already bring us their questions.

CNIC was formed to eliminate the Tower of Chemical Babel and almost every chemist has both appreciated and despised the tedium of the systematic and proper chemical nomenclature that CNIC is obliged to generate. In this second era of the computer evolution, names, formulae and the like are constrained by the inevitable superliteral reaction of the computer. With sympathy, but because precision and uniformity are increasingly important, we will point out a few conventions that deserve to be observed.

In Newsletter 1985 attention was directed to the use of aqua and the elision of vowels. Other items are: previously, bridging ligands were set out with hyphens as follows: tetrakis-(μ-acetato-)bis(pyridine)dicopper for $Cu_2(OAc)_4(py)_2$. Now, following the ongoing practices of certain journals, we have adopted the simpler convention: tetrakis(μ-acetato)bis(pyridine)dicopper.

DIOXOMOLYBDENUM(VI) COMPLEX WITH *N,N'*-ETHYLENEBIS(SALICYLIDENEIMINE)

LOUIE S. GONZALES and K. S. NAGARAJA*

Department of Chemistry, De La Salle University, Manila, Philippines

(*Received* 19 *November* 1985; *accepted after revision* 7 *May* 1986)

Abstract—The interaction of *N,N'*-ethylenebis(salicylideneimine), H_2salen, with ammonium molybdate yielded the molybdenum(VI) complex MoO_2(salen) with the *cis*-dioxo structure as inferred from IR spectral studies. The ^{1}H NMR chemical shifts of azomethine protons in the free ligand and the complex are 8.14 and 8.39 δ, respectively, suggesting the bonding of the azomethine nitrogen to MoO_2 group. The thermal decomposition behaviour of the complex is discussed.

Several complexes of salen with iron(III)[1], cobalt(II)[2], lanthanoids(III)[3] and uranyl[4] have been reported. Salen may act as a univalent-bidentate or a bivalent-tetradentate ligand. Schiff's base complexes of molybdenum have been reported by Yamanouchi and Yamada[5,6], Dilworth *et al.*[7] and Goh and Lim[8]. We now describe the ^{1}H NMR spectra, thermal decomposition and X-ray powder diffraction data on the oxomolybdenum(VI) complex with salen.

EXPERIMENTAL

Ammonium paramolybdate, salicylaldehyde, ethylenediamine and the solvents used were of laboratory grade. The ligand, H_2salen, was prepared by the condensation of salicylaldehyde with ethylenediamine by following the reported procedure.

Preparation of cis-*dioxo* N,N'-*ethyl-enebis(salicylideneiminato) molybdenum*(VI), MoO_2(*salen*)

Ammonium paramolybdate (0.50 g) was dissolved in water (15 cm^3). H_2salen (2.0 g) in ethanol (50 cm^3) was added and the solution was refluxed for 1 h. The yellow product formed was filtered when the solution was hot. The compound was recrystallized thrice from ethanol to obtain the pure complex.

Yield: 50%. The C, H, N and Mo analyses of the complex was found to be 48.8, 3.6, 7.1, 24.1% which corresponds to the calculated values 48.7, 3.6, 7.1 and 24.3%, respectively for MoO_2(salen). The "d_{hkl}" values for H_2salen and the complex are 2.76(w), 2.92(w) 3.00(m), 3.24(m), 3.86(m), 4.40(w), 4.62(m), 4.87(s), 5.02(m), 5.60(w), 5.91(vs), 6.91(vs), 7.31(s), 11.86(s) and 3.18(s); 4.84(w), 5.13(w), 5.88(s), 6.88(s), 7.21(w), 8.73(m), 10.21(s), 11.73(s), 15.36(w), respectively.

Elemental analyses of the complex were carried out using a Hewlett–Packard CHN analyzer. The IR, far-IR, UV-visible and ^{1}H NMR spectra were recorded on Shimadzu IR-435, Polytech IR 12, Pye–Unicam SP8-100 and Hitachi-R24B 60MHz spectrometers. Thermal analyses was carried out in air on a Shimadzu DTA-30 thermal analyzer using a platinum crucible with a heating rate of 10°C min^{-1}. X-ray powder photographs were taken on a Philipps X-ray diffractometer using CoK_α radiation.

RESULTS AND DISCUSSION

The complex is yellow and has poor solubility in methanol and ethanol. UV-visible spectra of the complex in CH_2Cl_2 has λ_{max} at 410 nm (ε 2870 l mol^{-1} cm^{-1}) which is attributed to a O(p_π)→Mo (d_π) charge-transfer transition. The IR absorption at 1630 cm^{-1} is attributed[7] to ν(C=N), which is characteristic of the azomethine group. The bands at 925 and 900 cm^{-1} due to ν(Mo=O) are characteristic of the *cis*-dioxo structure. The peaks observed at 500 and 305 cm^{-1} are assigned to ν(Mo—O) and ν(Mo—N), respectively.

The ^{1}H NMR is useful in determining the molecular structure of the compound. The spectra of

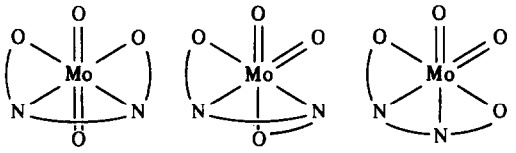
Table 1. ^{1}H NMR spectral data (δ) in ppm with reference to TMS

Compound	—CH_2—	—CH=N—	Aromatic
H_2salen	3.72, 3.29 J = 0.5 Hz	8.15, 8.19 J = 0.3 Hz	6.72, 6.75, 6.85, 6.88, 7.05, 7.16
H_2salen D_2O exchange	3.82	8.21	6.62, 6.70, 6.79, 6.88, 6.91, 7.09, 7.20
MoO_2(salen)	4.01	8.39	6.78, 6.90, 6.91, 7.06, 7.22, 7.32, 7.35, 7.48, 7.50

the ligand and the complex are recorded in $CDCl_3$. The values along with the assignments are given in Table 1. The azomethine (CH=N) and methylene (—CH_2—) protons in the H_2salen appear as a doublet at 8.19, 8.15 and 3.79, 3.72 δ, respectively. The hydrogen bonding to the azomethine N atom splits the signals of CH=N and CH_2 protons. The spectrum of H_2salen treated with D_2O exhibited resonances for CH=N and CH_2 at 8.21 and 3.82 δ as a singlet respectively. The phenolic hydrogen is involved in exchange with D_2O and no hydrogen bonding persists with the azomethine N and so no splitting is observed. The increase in δ values in deuterated H_2salen may be due to the *anti* form of the imine predominating. When hydrogen bonding exists H_2salen may be in the *syn* form.

In the spectra of the complex, MoO_2(salen), the CH=N and CH_2 signals are observed as a singlet at 8.39 and 4.01 δ, respectively, which suggests that the azomethine N is involved in coordination to molybdenum. The spectrum of the complex has more complex multiplet signals for the aromatic protons when compared to free ligand. The inference is that the aromatic protons are experiencing different chemical environments, which is possible for a *cis*-dioxo structure. Thus a *trans*-dioxo symmetrical structure **I** for the complex is ruled out. In structure **II**, the CH=N and CH_2 protons are not identical and the splitting due to coupling is expected. Thus the present ^{1}H NMR spectral studies suggest that the more appropriate structure is **III**.



I **II** **III**

Table 2. TG and DTA data

Compound	TG Thermal reaction	TG Weight loss (%) found (calc.)	DTA Temperature range (°C)	DTA Peak	DTA Reaction
H_2salen	—	—	110	Endothermic	Glass transition
	—	—	130	Endothermic	Melting
	Formation of cyclopentadienone	70.1 (70.0)	320–350	Exothermic	Decomposition
		93.0 (—)	450–560	Exothermic	Combustion
MoO_2(salen)	Loss of C_2H_4+2HCN	20.4 (20.8)	235–300	Exothermic	Decomposition
	Formation of Mo metal	75.9 (76.0)	480–550	Exothermic	Decomposition

The thermal decomposition of H_2salen and the complex are given in Table 2. The complex undergoes decomposition at a much lower temperature than the ligand. The hydrogen bonded structure with a pseudo-six-membered ring along with two double bonds may be thermodynamically more stable than a pseudo-heterocyclic ring with molybdenum atom. Further the geometry of the ligand restricts the formation of stronger bonds between molybdenum and donor atoms when compared to a O, N donor ligand such as 8-quinolinol. The end residue is gray and is recognized to be molybdenum metal as evidenced by the percentage weight loss, which was further confirmed by X-ray diffraction studies. The "d_{hkl}" values for the residue are 2.21(s), 1.59(m), 1.27(m), 1.09(w), 0.98(w), which corresponds to molybdenum metal.

The present studies suggests that H_2salen acts as a bivalent tetradentate ligand completing the six coordination around *cis*-dioxomolybdenum as in **III.**

INFRARED AND MÖSSBAUER INVESTIGATIONS ON DIMETHYLTIN(IV) COMPLEXES WITH POTENTIALLY TRIDENTATE DIANIONIC LIGANDS

L. PELLERITO,* G. DIA, A. GIANGUZZA and M. A. GIRASOLO

Istituto di Chimica Generale, Via Archirafi 26, 90123 Palermo, Italy

and

E. RIZZARELLI and R. PURRELLO

Dipartimento di Scienze Chimiche, Viale A.Doria 6, 95125 Catania, Italy

(*Received* 1 *August* 1986; *accepted after revision* 9 *February* 1987)

Abstract—Dimethyltin(IV) complexes with formulae $Me_2Sn(IMDA)\cdot H_2O$, $Me_2Sn(ODA)\cdot H_2O$ and $[Me_2Sn(OH)]_2(TDA)$ [$IMDA^{2-}$ = iminodiacetate^{2-} (NOO); ODA^{2-} = oxydiacetate^{2-} (OOO); and TDA^{2-} = thiodiacetate^{2-} (SOO donor atoms)] have been obtained and their solid state coordination investigated. Infrared and Mössbauer spectroscopic evidence would suggest tridentate behaviour of the ligands in polymeric *trans*-dimethyl structures for $Me_2Sn(IMDA)\cdot H_2O$ and $Me_2Sn(ODA)\cdot H_2O$ with bridging carboxylate groups; polymeric tetrahedral environments around the two tin(IV) atoms could be inferred with TDA acting as bidentate dianionic ligand through ester type carboxylate groups in $[Me_2Sn(OH)]_2(TDA)$, without involvement of the sulfur atom in coordination.

Organotin(IV) derivatives show biological activity which has been the subject, in recent years, of particular attention by several authors.[1–3] Structure activity correlation has been the aim of a research project for which complexes with biomolecules have been synthesized and, in some case, involved in *in vitro* or *in vivo* investigations.[4–7]

In particular, at concentrations of diorganotin(IV) complexes ranging between 0.5 and 5 nmols/mg of protein, Bu_2SnL (L = ribose and adenosine) inhibited the ATP-ase activity in rat liver mitochondria. Mössbauer measurements carried out at 10 K on rat liver mitochondria pellets, preliminary incubated with the diorganotin(IV) complexes, suggested interaction of the diorganotin(IV) moieties with the thiol groups of the membrane proteins.[6]

Inhibition of development of Ciona intestinalis, Ascidiella aspersa and Ascidia malaca eggs has been shown by R_2SnL complexes (R = Me, Bu, Oct; L = sorbitol, D(+)glucose, D(−)ribose, levulose, D(+)galactose, L(+)galactose and D(+)glyceraldehyde) at concentration of 1×10^{-4} M.[7]

The interaction of diorganotin(IV) and other biofunctional ligands such as adenosine and 5′-triphosphate has been studied in aqueous solution.[8] From the comparison of the stability constants obtained and those of complexes with oxygen and nitrogen donor atom ligands, the coordination of the nucleotide to dimethyltin(IV) through the phosphate oxygen atoms has been suggested.[8]

In order to clarify the above mentioned hypothesis it seemed opportune to investigate the nature of the interaction between the diorganotin(IV) moieties and ligands bearing O, N, S donor atoms, in the solid and in solution phase.

In this paper we report the results obtained in the solid state by infrared and Mössbauer spectroscopy.

EXPERIMENTAL

The complexes $Me_2Sn(IMDA)\cdot H_2O$ and $Me_2Sn(ODA)\cdot H_2O$ were obtained as white

* Author to whom correspondence should be addressed.

solids by mixing methanolic solutions of Me_2SnCl_2 (gift from Schering AG, Bergkamen) (2 mmols of Me_2SnCl_2 in 50 cm^3 of CH_3OH) with solutions of the disodium salts of the iminodiacetic and oxydiacetic acids, respectively (2 mmols of Na_2IMDA or Na_2ODA in 50 cm^3 of 1:1 $H_2O:CH_3OH$ solution).

Attempts to obtain, under the same experimental conditions, the complex $Me_2Sn(TDA)$ were unsuccessful and led to the precipitation of white microcrystalline compounds which analyzed as $[Me_2Sn(OH)]_2(TDA)$. The same complex was obtained in 1:1 $H_2O:CH_3OH$ solution using a ratio $[(CH_3)_2SnCl_2]/[Na_2TDA] = 2$.

The solids were recovered by filtration, recrystallized and analyzed for C, H and Sn contents.

C and H analyses were performed at the Laboratorio di Chimica Organica (Milano). Tin content was determined as SnO_2 in our laboratory as described in the literature.[9]

Analytical data are reported in Table 1.

The thermal decomposition of the complexes was carried out under N_2 atmosphere in a Mettler mod.TA 3000 System.

The samples, contained in small pyrex dishes, were heated from 25 to 600°C.

Infrared spectra were recorded as Nujol and hexachlorobutadiene mulls in the region 4000–200 cm^{-1} using a Perkin Elmer mod. 983 G infrared spectrometer and CsI windows.

^{119}Sn Mössbauer spectra were measured, with a constant acceleration and a triangular waveform, using a Laben mod.8001 multichannel analyzer, a Mössbauer closed refrigerator system mod.21 SC Cryodine Cryocooler CTI-Cryogenics (U.S.A.) and a digital temperature controller mod.DRC-80C Lake Shore Cryotronics (U.S.A.).

Suitable computer programs were used to fit the experimental line to Lorentzian line shapes, in the calculation of ΔE according to the point charge model formalism and in the estimation of the lattice dynamics parameters.

RESULTS AND DISCUSSION

Thermal decomposition

The TG/DT analysis showed a two step process for all of the complexes. The first stage occurred at 125.7, 112.3 and 269°C for $Me_2Sn(IMDA)\cdot H_2O$, $Me_2Sn(ODA)\cdot H_2O$ and $[Me_2Sn(OH)]_2(TDA)$ respectively, which could be ascribed to the loss of one water molecule (exp. 6.36, 6.79 and 4.04, theor. 6.05, 6.03 and 3.79%).

At 275.0, 319.0 and 306.3°C the complexes completely decomposed leaving residues which were analyzed as SnO for $Me_2Sn(IMDA)\cdot H_2O$ (exp. 43.81, theor. 45.22%) and Sn for both $Me_2Sn(ODA)\cdot H_2O$ and $[Me_2Sn(OH)]_2(TDA)$ (exp. 39.88 and 39.66, theor. 39.71 and 39.49%, respectively).

Infrared spectra

The interpretation of the coordination modes of the ligands towards the dimethyltin(IV) Lewis acid can be simplified by taking into account the crystal structure of the free acids and of some of their copper(II) mixed complexes.[10–16]

The iminodiacetic acid, H_2IMDA, possesses a three dimensional network of 10- and 14-membered rings of hydrogen bonded halves of the molecule, with three independent hydrogen bonds, two of the type N–H----O and one of the type O–H----O,[10] while both oxydiacetic, H_2ODA, and thiodiacetic acids, H_2TDA, are formed by infinite chains of hydrogen bonding in pairs of carboxylic groups around the symmetry centre.[11,12]

The more relevant IR bands in the free ligands (Table 2), reflected the above situations, which are

[a] Measured in Nujol and hexachlorobutadiene mulls; s = strong; m = medium; w = weak; bd = broad.

[b] H_2IMDA = iminodiacetic acid, $NH(CH_2COOH)_2$; H_2ODA = oxydiacetic acid, $O(CH_2COOH)_2$; H_2TDA = thiodiacetic acid, $S(CH_2COOH)_2$.

varied on coordination to the $Me_2Sn(IV)$ moiety.

In $Me_2Sn(IMDA)\cdot H_2O$ the band present at 3106 m cm^{-1}, slightly shifted with respect to the corresponding band in the free acid (3099 m cm^{-1}), could be attributed to coordinated NH, which did not vary appreciably its electronic surroundings on coordination by substituting one HN—H with HN→Sn bond.

More significant were the shifts which occurred in the 3000–2600 cm^{-1} and 1750–1200 cm^{-1} regions. In fact in the 3000–2600 cm^{-1} region, in the free ligand there were several strong broad bands due to contributions of both OH of hydrogen bonded carboxylic groups and CH stretching. Upon coordination a strong absorption occurred at 2929 s cm^{-1} due to CH stretching.

Only two pairs of bands at 1642 s, 1410 s cm^{-1} ($\Delta\nu = 283$ cm^{-1}) and at 1598 m cm^{-1}, 1495 s cm^{-1} ($\Delta\nu = 103$ cm^{-1}) were present in the complexes, attributable respectively to $\nu_{asym}(COO)$ and $\nu_{sym}(COO)$ of an unidentate carboxylate, the first couple, and to a bridging carboxylate, the second pair.[17] In comparison with the bands at 1709 s,bd, 1454 m and 1242 m cm^{-1} attributable to $\nu(C{=}O)$, CH_2 scissoring+OH bending and to $\delta(OH)$ of unionized carboxylic acid in a polymeric structure[18] and with the bands present at 1582 s and 1394 s,bd cm^{-1} ($\Delta\nu = 188$ cm^{-1}), characteristic of ionised carboxylate.[17]

Absorptions occurring at 610 s, 553 w and 520 w cm^{-1} might be tentatively assigned to $\nu(SnN)$,[19] $\nu_{asym}(SnC_2)$ and $\nu_{sym}(SnC_2)$,[20] with the last two bands a consequence of a distorted CSnC skeleton, while the band at 490 w cm^{-1} could be assigned to a $\nu(SnO)$.[19,20]

Differences in the free and coordinated oxydiacetic acid spectra, were in the region 3000–2600 cm^{-1}, where, according to the hydrogen bonded polymeric structure of H_2ODA,[11] OH and CH stretching absorption occurred.[19] Further variations occurred in the 1750–1200 cm^{-1} range where the two strong bands at 1726 and 1246 s cm^{-1} attributable to $\nu(C{=}O)$ and $\delta(OH)$ of unionised hydrogen bonded COOH group were substituted with bands at 1745 s and 1413 m cm^{-1} ($\Delta\nu = 332$ cm^{-1}, characteristic of unidentate ester type carboxylate) and at 1638 m and 1461 s cm^{-1} ($\Delta\nu = 177$ cm^{-1}, value for bridging carboxylate[17]); between 600 and 200 cm^{-1} bands were present due to $\nu_{asym}(SnC_2)$ at 551 s cm^{-1}, to $\nu_{sym}(SnC_2)$ at 520 m cm^{-1} and to (SnO) at 441 s cm^{-1}.[20,21]

In $[Me_2Sn(OH)]_2(TDA)$ the new band at 3419 m,bd cm^{-1} could be due to OH groups of $Me_2Sn(IV)$ moieties.[22–24]

Analogously to the first two complexes described, in the region 3000–2600 cm^{-1} the strong broad bands of the carboxylic hydrogen bonded OH and of CH are substituted by a couple of bands at 2919 s and 2900 s cm^{-1} ($\nu_{asym}(CH)$ and $\nu_{sym}(CH)$).

The $\Delta\nu$ value (= 226 cm^{-1}) between the pair of bands which occurred at 1639 s [$\nu_{asym}(COO)$] and 1413 s [$\nu_{sym}(COO)$] cm^{-1} would suggest the occurrence of an unidentate ester type carboxylate in the complex[17] [in addition the 1693 s and 1230 s cm^{-1} absorptions in the free ligand could be assigned to $\nu(C{=}O)$ and $\delta(OH)$ respectively[18]]. Coordination of the ethereal sulfur atom could be excluded on the basis of invariance of the 788 s and 658 s cm^{-1} bands, present both in the free and the coordinated ligand, which could be assigned to $\nu_{asym}(CSC)$ and $\nu_{sym}(CSC)$ vibrations.[25] Asymmetric and symmetric CSnC stretchings could be attributed to the bands at 563 m and 529 s cm^{-1} while at 510 vs cm^{-1} a $\nu(SnO)$ could be evidenced.[20,21]

Mössbauer data

The isomer shift, (δ), (Table 1), fell within the range of the values for most diorganotin(IV) compounds,[26] but the lower value for $[Me_2Sn(OH)]_2$ (TDA) would reflect a higher percentage *s*-character of the SnC bonds.[27]

All of the complexes gave a two line quadrupole split spectra, which in the case of the $[Me_2Sn(OH)]_2$(TDA) showed the equivalence of the two tin atoms.

The experimental Nuclear Quadrupole Splittings, (ΔE), (Table 1) for $Me_2Sn(IMDA)\cdot H_2O$ and $Me_2Sn(ODA)\cdot H_2O$ were characteristic of *trans*-R_2Sn octahedral complexes;[26] in principle the experimental ΔE for $[Me_2Sn(OH)]_2$(TDA) did not allow us a choice between octahedral *cis*-Me_2Sn and tetrahedral configurations, which are both $\Delta E_{exp} \approx 2$ mm s^{-1}.

The rationalization of experimental ΔE, according to the point charge model formalism,[26,28–30] was applied to the idealized structures of Fig. 1, octahedral polymeric *trans*-Me_2Sn for $Me_2Sn(IMDA)\cdot H_2O$ (Fig. 1a) and $Me_2Sn(ODA)\cdot H_2O$ (Fig. 1b).

In these configurations, in agreement with the IR data, 6-coordination would be reached by bonding three oxygen atoms, one from the unidentate carboxylate and two from bridging carboxylates and a sixth donor atom, the imino nitrogen atom for $IMDA^{2-}$ complex and the ethereal oxygen atom in ODA^{2-} derivative.

The calculations were carried out by using the partial quadrupole splittings (p.q.s., mm s^{-1}) as extracted or calculated from literature reports.[26,29,31,32]

Octahedral *cis*-Me_2 and tetrahedral were then

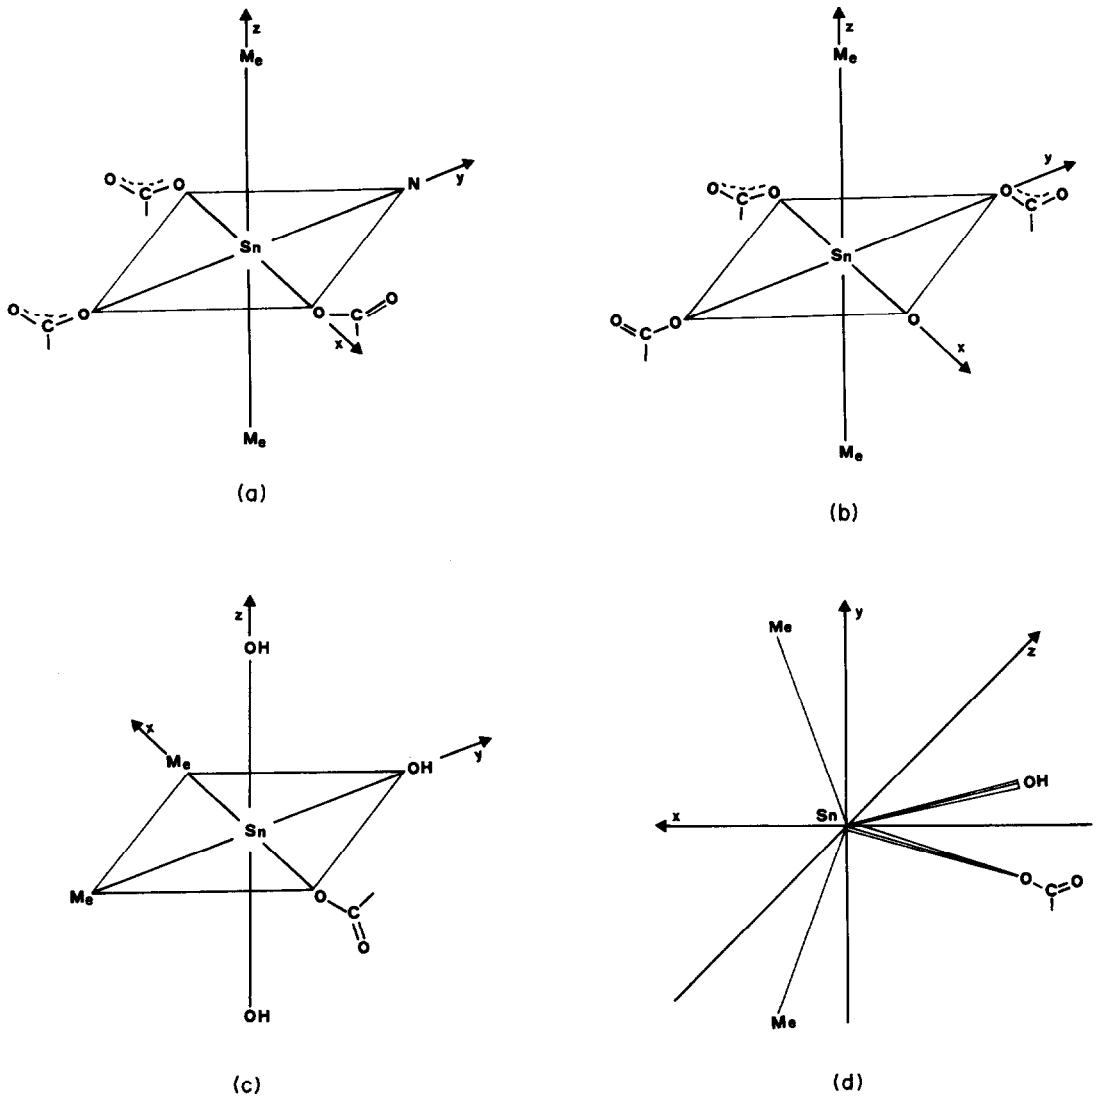

Fig. 1. The idealized structures assumed for point charge calculations of nuclear quadrupole splittings, E, and asymmetry parameter. X, Y, Z are the directions of the principal components of the electric field gradient ($|Vzz| \geq |Vyy| \geq |Vxx|$).

proposed in order to calculate ΔE for $[Me_2Sn(OH)]_2(TDA)$ (Fig. 1c,d).

The six-coordination, in the *cis*-Me_2 octahedral configuration could be obtained by polymerization through three coordinated OH groups.

Table 3 shows that ΔE_{exp} and ΔE_{calc} differed less than the tolerance limit ± 0.4 mm s^{-1} which could justify the proposed structures,[23] so that it clearly appeared that for TDA^{2-} complex both the structures of Fig. 1 (c,d) were equally probable also if there are few cases in which $Me_2Sn(IV)$ derivatives assume a *cis*-Me_2 configuration.[33,34]

Variable temperature Mössbauer studies have been carried out in order to get information on the polymeric or monomeric nature of the investigated complexes.

The more relevant lattice dynamics parameters are summarized in Table 4 together with data referring to the polymer $[-Sn(n\text{-}C_4H_9)_2\text{-}OCH(CCl_3)O-]$[36] and to the monomer Me_4Sn[37] for comparison purpose. The treatment of the data and the relative calculation of the functions were performed as described in detail in the literature[38,39] in the temperature range in which the natural logarithm of the areas under resonant peaks, $\ln A_T$, was a linear function of the temperature. The values of the slopes $d \ln A_T/dT$ obtained (Table 4) were consistent with the existence of polydimensional networks characterized by extensive crosslinking of molecular chains.[39]

These results would be confirmed by the other calculated lattice dynamics parameters (Table 4);

Table 3. Point charge parameters

Compound	ΔE_{exp}	Structure	ΔE_{calc}[a]	η_{calc}[b]
$Me_2Sn(IMDA)\cdot H_2O$	4.05	A	+3.85	0.08
$Me_2Sn(ODA)\cdot H_2O$	3.95	B	+3.71	0.03
$[Me_2Sn(OH)]_2(TDA)$	2.07	C	−2.40	0.81
		D	−1.84	0.00

[a] Point charge values of the nuclear quadrupole splitting and [b] of the asymmetry parameter (Vxx–Vyy)/Vzz. P.q.s., mm s^{-1}, values used are:

$\{(Alk)-(Hal)\}^{oct} = -1.03$; $\{(COO)-(Hal)\}^{oct}_{unid} = -0.11$.

$\{(COO)-(Hal)\}^{oct}_{bridg} = -0.075$; $\{(N)-(Hal)\}^{oct} = -0.01$;

$\{(O)-(Hal)\}^{oct} = -0.144$

$\{(Alk)-(Hal)\}^{tet} = -1.37$; $\{(OH)-(Hal)\}^{tet} = -0.55$

$\{(COO)-(Hal)\}^{tet}_{unid} = -0.15$; $\{(OH)-(Hal)^{oct}_{bridg} = -0.20\}$

[a] A_T is the total Lorentzian area under resonant peaks; f_a^{rel} the relative recoil free fraction; $\langle X^2 \rangle$ the mean square displacement; θ_D the Debye Mössbauer temperature; $\bar{\nu}_D$ the cutoff frequency and $M\theta_D^2$ the parameter of intermolecular force constant.

[b] I: $Me_2Sn(IMDA)\cdot H_2O$; II: $Me_2Sn(ODA)\cdot H_2O$; III: $[Me_2SnOH]_2(TDA)$; IV: $[\text{-}Sn(n\text{-}C_4H_3)_2\text{-}OCH(CCl_3)O\text{-}]_n$(31); V: Me_4Sn(32).

in particular by the mean square displacements $\langle X^2 \rangle$(T) and by the relative recoil free fraction, f_a^{rel}(T), for all the complexes (Table 4) were fully consistent with that reported for two and three dimensional polymers.[37,40]

Also if the results obtained studying the above systems in solution are not definitive,[41] it is possible to affirm that care must be made in hypothesizing the active species in biological systems and in suggesting structure-activity correlations.

Abstract—The anodic and cathodic behaviour of the rhenium(V) complexes nBu$_4$N[ReOCl$_3$(HOPhSal)], nBu$_4$N[ReOCl$_2$(OPhSal)], [ReOCl(OPhSal)(MeOH)] and [ReOCl(OPhSal)(PMe$_2$Ph)] in acetonitrile was studied using platinum and mercury electrodes. Cyclic voltammetry and controlled potential coulometry were the main electroanalytical techniques employed. The nature of the electrolysis products as well as the mechanisms of the electrode oxidation and reduction processes were investigated. In particular a complex of rhenium(VI) containing the group ReO^{4+} and complexes of rhenium(IV) with ReO^{2+} core were electrochemically synthesized. They were characterized by elemental analysis, IR spectroscopy, magnetic susceptibility and conductivity measurements.

A wide variety of oxidation states can be assumed by rhenium in different coordination compounds, depending on the nature of the ligands. Our first series of electrochemical studies has dealt with complexes with the metal in low oxidation states,[1–3] the ligands being typically carbon monoxide, chloride ions and different phosphines. The attention which has been recently devoted to rhenium complexes with Schiff base ligands, together with the interesting properties exhibited by the ReO^{3+} core,[4–7] has suggested the opportunity of studying the electrochemical properties of these compounds, in order to define their oxidation and reduction potentials, to identify species with the rhenium centre in +4 or +6 oxidation states, and possibly to define the nature of the electrode mechanisms.

It is worth noting that studies on the rhenium complexes, in addition to the importance they have for themselves, have often allowed us interesting comparisons with the analogous complexes of technetium.[1–3,8–10] This last aspect is of particular importance taking into account the significance that ^{99m}Tc has assumed in the field of nuclear medicine.

We have reported elsewhere on the electrochemical behaviour of rhenium complexes with the ReO^{3+} core, with bidentate–bidentate and bidentate-tridentate Schiff base ligands.[11] The complexes studied in the present paper contain a single Schiff base ligand, co-ordinated to the metal centre through two or three sites. Their formulas are reported here below.

EXPERIMENTAL

Acetonitrile (MeCN) (Fluka–Burdick & Jackson, distilled in glass) has been used without further purification; it was stored in nitrogen atmosphere over 0.3 nm molecular sieves (Union Carbide). Tetraethylammonium tetrafluoroborate (Alpha Ventron) was used in most voltammetric and coulometric experiments. It was dried for 48 h at 50°C in a vacuum oven before use.

Recovery and isolation of the electrolysis products involved some problems, mostly with respect to the separation of the supporting electrolyte. Saturated solutions of tetraethylammonium tetraphenylborate were used during exhaustive electrolyses performed with the aim of recovering the reduction products. This salt was prepared by addition of a methanol solution of sodium tetraphenylborate to a methanol solution of tetraethylammonium chloride. The white precipitate was washed repeatedly with water and then recrystallized from hot acetonitrile. The white crystals so obtained were dried for 48 h at 50°C in a vacuum oven before use.

The synthesis of the complexes studied has been described elsewhere.[6]

The solutions studied were deoxygenated by bubbling 99.99% pure nitrogen through.

A PAR 170 Electrochemistry System was used in the voltammetric tests, and the resulting voltammograms were recorded either with a Linseis LY 1800 pen recorder or with a Hewlett–Packard 1223A storage oscilloscope. An electrochemical cell with proper geometry was employed. The working microelectrode was either a platinum disc or a gold sphere freshly covered with mercury; the working electrode was surrounded by a platinum spiral counter electrode, and the reference electrode (saturated calomel electrode—S.C.E.) compartment was connected through a salt bridge ending in a Luggin capillary.

At the end of these tests bis-cyclopentadienyl iron(II) was added to the solution, in order to refer the evaluated $E^r_{1/2}$, taken as experimental approximation of the standard potential, to the corresponding electrochemical parameter of this iron(III)/iron(II) redox couple; in this way the measured quantity results are unaffected by variable liquid junction potentials at the aqueous–organic solvent interface.[12]

An AMEL Model 552 potentiostat with an associated AMEL Model 558 integrator were used in the controlled potential electrolyses, which were carried out in an H-shaped cell with anodic and cathodic compartments separated by a sintered glass disc. The working electrode was a platinum gauze, the auxiliary electrode was a mercury pool and the reference electrode still was a S.C.E.

In order to isolate the electrolysis products different procedures were followed for anodic oxidation and cathodic reduction. The oxidation products resulted scarcely soluble and could be precipitated from the electrolysis solutions, while the reduction products were soluble, so that in this case the solvent was removed under reduced pressure. The resulting solids were washed with CH_2Cl_2 to separate the supporting electrolyte. The solutions recovered by filtration were dried and the dark oils obtained were crystallized by washing with Et_2O. The solids were recrystallized from CH_2Cl_2/Et_2O. The resulting products were characterized by elemental analysis, IR spectroscopy, magnetic susceptibility and conductivity measurements.

IR spectra were recorded on a Perkin–Elmer Model 580B spectrometer. Magnetic moment measurements were performed with an Oxford Instrument at room temperature. Conductivity measurements were carried out at 25 ± 0.1°C using a Metrohm conductometer, Model E 518.

RESULTS AND DISCUSSION

nBu$_4$N[ReOCl$_3$(HOPhSal)]

Figure 1 reports anodic and cathodic behaviour of an acetonitrile solution of nBu$_4$N[ReOCl$_3$(HOPhSal)], containing 0.1 M tetraethylammonium tetrafluoroborate as supporting electrolyte, at a platinum electrode.

As regards the anodic behaviour, coulometric tests at peak A in Fig. 1(a) revealed that 2 mol of electrons are involved in the overall electrode process. The results of cyclic voltammetric tests at potential scan rates from 0.05 to 50 V s^{-1} were in agreement with an e.c.e. mechanism (one electron charge transfer–irreversible chemical reac-

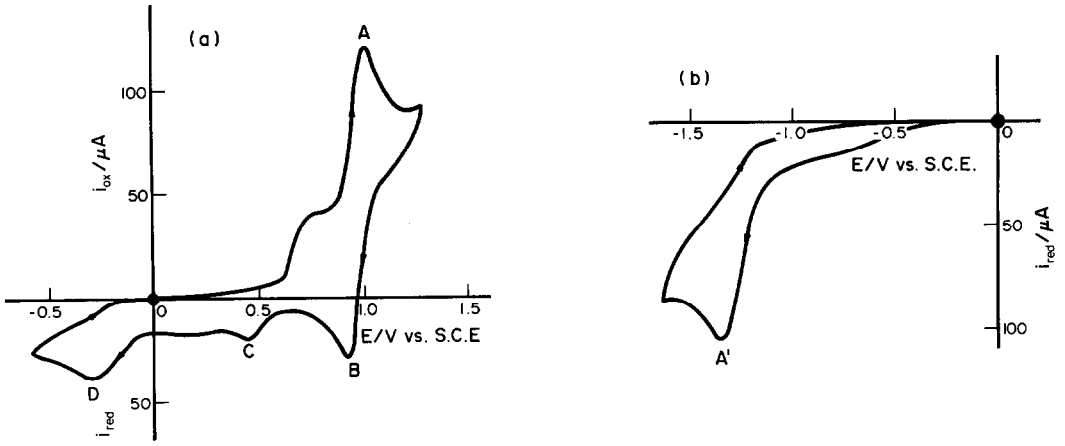

Fig. 1. Cyclic voltammetric curves recorded with a platinum working electrode on a 4.8×10^{-3} M nBu$_4$N [ReOCl$_3$(HOPhSal)], 0.1 M tetraethylammonium tetrafluoroborate, MeCN solution. Potential scan rate 0.2 V s^{-1}. ●, Starting potential; (a) anodic direct scan; (b) cathodic direct scan.

tion–one electron charge transfer). The chemical reaction is too slow to be investigated with voltammetric techniques, since the cathodic–anodic voltammetric response appeared like that of an uncomplicated one electron reversible charge transfer at potential scan rates greater than 0.2 V s^{-1}.

On the basis of the voltammetric responses it was possible to calculate, for the couple [ReOCl$_3$(HOPhSal)]/[ReOCl$_3$(HOPhSal)]$^-$ an $E^r_{1/2}$ value of 0.56 vs $E^r_{1/2}$ of the couple ferricinium ion–ferrocene.

The solutions resulting from exhaustive oxidation showed a voltammetric picture as that reported in Fig. 2. Two most significant peaks can be noted on a cathodic scan starting at the electrolysis potential. Reducing the oxidized solution in correspondence to peak C the complex [ReOCl$_2$(OPhSal)]$^-$ is apparently formed (see below) through a consumption of 1 mol of electrons per mol of starting compound; peak D could be attributed to the reduction of free hydrogen ions.

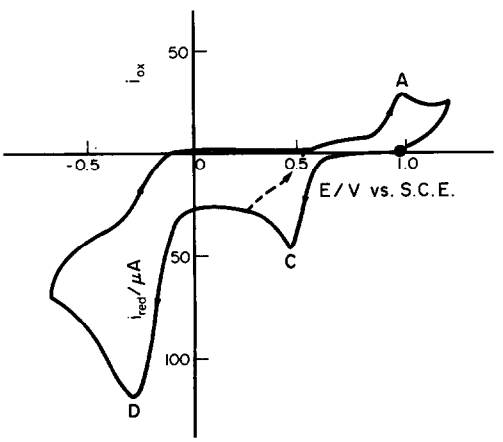

Fig. 2. Cyclic voltammetric curve recorded on the same solution of Fig. 1, after exhaustive electrolysis at +1.0 V vs S.C.E. ●, Starting potential for cathodic direct scan.

The recovery of the oxidation product has allowed us to identify the compound as [ReOCl$_2$(OPhSal)]. The elemental analysis data are as follows (Found: C, 32.5; H, 1.9; N, 3.0; Cl, 14.8. Calc. for $C_{13}H_9NO_3Cl_2Re$: C, 32.2; H, 1.9; N, 2.9; Cl, 14.6%). IR spectra show that a ν(Re=O) absorption is still present at 955 cm^{-1}, close to that noted for the starting complex [ν(Re=O) = 968 cm^{-1}]. The ν(Re—Cl) absorptions are now at 324 and 283 cm^{-1}, while for the starting complex they fall at 315 and 285 cm^{-1}. Magnetic susceptibility measurements on solid samples lead to μ_{eff} = 1.50 B.M., in agreement with a d^1 configuration in a distorted octahedral environment. The compound exhibits a non-conducting behaviour, confirming its non-ionic character. It is soluble in CH_2Cl_2, $CHCl_3$, DMF and acetone, insoluble in Et_2O, CH_3CN, alcohols and hydrocarbons.

The following stoichiometry of the overall oxidation process could account for the results found:

$$[Re(V)OCl_3(HOPhSal)]^- - 2e^- \rightarrow [Re(VI)OCl_2(OPhSal)] + H^+ + \tfrac{1}{2}Cl_2.$$

However, some results can be explained with some difficulty: in addition to the fact that chloride ions can hardly be oxidized at the working potential, as it will be reported below, 2 mol of electrons per mol of starting compound are also spent in the electrode oxidation of [ReOCl$_2$(OPhSal)]$^-$ and the same Re(VI) neutral complex is recovered from these solutions; in the following it will be also shown that the species [Re(VI)OCl$_2$(OPhSal)] is

reduced at potentials much more anodic than those of peak C in Fig. 2. It seems hence more convincing that unidentified products resulting from oxidation of $[ReOCl_3(HOPhSal)]^-$ and of $[ReOCl_2(OPhSal)]^-$ lead to the same, stable rhenium complex, [Re(VI)OCl_2(OPhSal)], as a consequence of reactions occurring during the recovery procedures.

As Fig. 1(b) reports, nBu$_4$N[$ReOCl_3$(HOPhSal)] undergoes electrode reduction [peak A′ of Fig. 1(b)]. No directly associated anodic peak can be recorded, at a potential scan rate as high as 50 V s^{-1}. In controlled potential coulometries 2 mol of electrons per mol of starting complex were spent, and since the voltammetric response is consistent with an e.c. mechanism (one electron reversible charge transfer followed by a fast irreversible chemical reaction), one must suppose the occurrence of a rather complicated overall reduction process, where a further slow chemical reaction must preceed the second, one electron reduction. Any attempt to recover stable rhenium complexes from the electrolysis solution failed, preventing the suggestion of any reliable reduction mechanism.

In order to set the potential range in which the species studied is stable, we report that the cathodic peak potential value at a scan rate of 0.2 V s^{-1} resulted equal to -1.63 V vs $E^r_{1/2}$ of the ferricinium ion-ferrocene couple. Completely similar results were obtained with platinum as well as with mercury working electrodes, indicating an outer sphere charge transfer is operative.[13]

nBu$_4$N[$ReOCl_2$(OPhSal)]

The electrochemical studies of this compound led to results comparable with those obtained with the complex reported previously. The voltammograms recorded on solutions of this compound resulted qualitatively similar to those reported in Fig. 1(a) and (b).

Also in this case the anodic oxidation implies the consumption of 2 mol of electrons per mol of starting compound and consists in two subsequent one electron charge transfers with an interposed irreversible chemical reaction. After exhaustive electrolysis a voltammogram similar to that reported in Fig. 2 could be recorded, the only significant difference being the absence of the peak we had attributed to the reduction of free hydrogen ions. Reducing the oxidized solution in correspondence to peak C of Fig. 2 the starting compound was obtained through the consumption of 1 mol of electrons per mol of starting complex.

As previously mentioned, the product recovered from the oxidized solution could be identified as [Re(VI)OCl_2(OPhSal)], suggesting the solid product separated should be different from that present in the electrolysed solution. In fact its formulation does not account for the consumption of 2 mol of electrons in the oxidation process; moreover, this compound must be reduced in correspondence to the cathodic peak directly associated to the anodic one [see, qualitatively, peak B in Fig. 1(a)], rather than in correspondence to peak C of Fig. 2. The potential difference between the location of these peaks amounts to about 0.45 V.

At high enough potential scan rate we could estimate an $E^r_{1/2}$ value equal to $+0.57$ V vs $E^r_{1/2}$ of the redox couple ferricinium ion–ferrocene, for the redox couple $[ReOCl_2(OPhSal)]/[ReOCl_2(OPhSal)]^-$.

As regards the cathodic reduction, the peak potential value at a potential sweep rate of 0.2 V s^{-1} resulted equal to -1.65 V vs the same reference redox couple.

It is noteworthy that very similar potential values are obtained for oxidation as well as for reduction of both these first compounds studied.

[ReOCl(OPhSal)(MeOH)]

Anodic oxidation of this compound takes place via two subsequent one electron charge transfers with an irreversible interposed chemical reaction; this can be affirmed on the basis of the cyclic voltammetric responses recorded at different potential scan rates and of the results of coulometric tests (2 mol of electrons are spent per mol of electrolysed compound). Although the species primarily formed at the electrode is involved in a chemical reaction faster than that of the complexes studied previously, at fast enough potential scan rate (higher than 10 V s^{-1}) it is possible to prevent the occurrence of the chemical reaction and hence to calculate an $E^r_{1/2}$ value of $+0.66$ V vs ferricinium ion–ferrocene for the couple $[ReOCl(OPhSal)(MeOH)]^+/[ReOCl(OPhSal)(MeOH)]$.

Voltammetric responses recorded on the electrolysed solution only showed ill defined peaks. Anyhow, the recovered oxidation product once more resulted to be [Re(VI)OCl_2(OPhSal)], and the formulation of a reasonable electrode mechanism is not easy.

The starting complex undergoes two subsequent reductions ($E_p = -1.22$ V and -1.61 V vs ferricinium ion–ferrocene couple, at a potential scan rate of 0.2 V s^{-1}). Both peaks do not exhibit any directly associated anodic peak, even at the highest explored scan rates. Coulometric tests at potentials of the less cathodic peak led to the consumption of 1 mol of electrons per mol of starting compound,

and the more cathodic peak is undetectable on the exhaustively reduced solution. This behaviour is consistent with several different electrode mechanisms. However, the analysis of the shape of the responses, together with the fact that after electrolysis at the first peak the second one has disappeared, suggest that chemical reactions must follow the first electrode charge transfer.

The reduction product was recovered and identified as Et_4N [Re(IV)OCl(OPhSal)]. Hence, it can be suggested that the chemical reactions involve the fast release of the MeOH ligand with a subsequent rearrangement to a five-coordinate geometry.

The elemental analysis data are as follows (Found: C, 44.5; H, 5.2; N, 4.6; Cl, 6.3. Calc. for $C_{12}H_{29}N_2O_3ClRe$: C, 43.5; H, 5.0; N, 4.8; Cl, 6.1%).

IR spectra of the recovered reduction product show a significant lowering in the wavenumber of the ν(Re=O) absorption, up to 912 cm^{-1} (976 cm^{-1} in the starting compound). This weakening of the Re=O bond could be explained by the increased negative charge of the rhenium atom. ν(Re—Cl) was observed at 320 cm^{-1}.

Magnetic susceptibility measurements on solid samples lead to $\mu_{eff} = 1.40$ B.M., in agreement with d^3 configuration in a square pyramidal environment.[14]

$\Lambda_{eq} = 1.41\ \Omega^{-1}\ cm^2\ mol^{-1}$ in acetonitrile is in agreement with a 1 : 1 electrolyte.

The product was soluble in CH_2Cl_2, $CHCl_3$, DMF and MeCN; insoluble in Et_2O, hydrocarbons, alcohols and acetone.

[ReOCl(OPhSal)(PMe_2Ph)]

On the basis of the results of cyclic voltammetric tests at different potential scan rates and of coulometric experiments (2 mol of electrons per mol of starting complex) it can be concluded that the oxidation of this compound also takes place through an electrode mechanism in which an irreversible chemical reaction is interposed between two subsequent one electron charge transfers. At high enough potential scan rate the cyclic voltammogram allowed the evaluation of the $E^r_{1/2}$ value of the couple [ReOCl(OPhSal)(PMe_2Ph)]$^+$/[ReOCl(OPhSal)(PMe_2Ph)], which resulted equal to +0.77 V vs $E^r_{1/2}$ of the ferricinium ion–ferrocene couple. Unfortunately, any attempt to recover stable electrolysis products failed.

The electrode reduction of [ReOCl(OPhSal)(PMe_2Ph)] occurs through a single cathodic peak involving, as proved by coulometric tests, a one electron charge transfer. At high enough scan rate the response appeared as that of an uncomplicated reversible charge transfer, allowing us to estimate, for the couple [ReOCl(OPhSal)(PMe_2Ph)]/[ReOCl(OPhSal)(PMe_2Ph)]$^-$, an $E^r_{1/2}$ value of −1.24 V vs ferricinium ion–ferrocene couple.

For the reduction of this complex, as well as for

Table 1. Potentials referred to $E^r_{1/2}$ of the couple ferrocinium–ion/ferrocene

Redox system	$E^r_{1/2}$
[ReOCl(OPhSal)(PMe_2Ph)]$^+$/[ReOCl(OPhSal)(PMe_2Ph)]	+0.77 V
[ReOCl(PhSal)$_2$]$^+$/[ReOCl(PhSal)$_2$]	+0.76 V[a]
[ReOCl(MeSal)$_2$]$^+$/[ReOCl(MeSal)$_2$]	+0.67 V[a]
[ReOCl(OPhSal)(MeOH)]$^+$/[ReOCl(OPhSal)(MeOH)]	+0.66 V
[ReO(OPhSal)(PhSal)]$^+$/[ReO(OPhSal)(PhSal)]	+0.57 V[a]
[ReOCl$_2$(OPhSal)]/[ReOCl$_2$(OPhSal)]$^-$	+0.57 V
[ReOCl(HOPhSal)]/[ReOCl(HOPhSal)]$^-$	+0.56 V
[ReO(OPhSal)(MeSal)]$^+$/[ReO(OPhSal)(MeSal)]	+0.53 V[a]
[ReOCl$_2$(OPhSal)]$^-$/[ReOCl$_2$(OPhSal)]$^{2-}$	−1.65 V*
[ReOCl$_3$(HOPhSal)]$^-$/[ReOCl$_3$(HOPhSal)]$^{2-}$	−1.63 V*
[ReOCl(OPhSal)(MeOH)]/[ReOCl(OPhSal)(MeOH)]$^-$	−1.62 V*

[ReO(OPhSal)(MeSal)]/[ReO(OPhSal)(MeSal)]$^-$	−1.37 V[a]
[ReO(OPhSal)(PhSal)]/[ReO(OPhSal)(PhSal)]$^-$	−1.33 V[a]
[ReOCl(OPhSal)(PMe_2Ph)]/[ReOCl(OPhSal)(PMe_2Ph)]$^-$	−1.24 V

* Peak potential value measured at a scan rate of 0.2 V s^{-1}; values without thermodynamic significance.

[a] From ref. 11.

all those previously examined, completely similar results were obtained using either platinum or mercury working electrodes.

The recovery of the electrolysis product led to the isolation and identification of the species [ReO(OPhSal)(PMe_2Ph)]. Elemental analysis data are as follows (Found: C, 46.9; H, 3.7; N, 2.2. Calc. for $C_{12}H_{20}NPO_3Re$: C, 45.7; H, 3.6; N, 2.5%). The IR spectrum showed a ν(Re=O) at 913 cm^{-1} (70 cm^{-1} lower than in the starting compound).

Magnetic susceptibility measurements on solid samples gave $\mu = 1.60$ BM, in agreement with a d^3 configuration in a square pyramidal environment. The complex has a non-conducting character confirming a non-ionic compound.

The compound is soluble in CH_2Cl_2, $CHCl_3$, DMF and MeCN; slightly soluble in MeOH, EtOH and acetone; insoluble in Et_2O and hydrocarbons.

It is hence evident that the chemical reaction following the uptake of one electron by the starting compound must consist of the release of the chloride ion. In the likely hypothesis that this reaction is of first order in respect to the rhenium complex concentration, the cyclic voltammetric responses[15] allowed us to estimate a half-life time of about 16 ms for the electrogenerated species [Re(IV) OCl(OPhSal)(PMe_2Ph)]$^-$.

The results of this study confirm our previous finding,[11] i.e. Schiff base type ligands exhibit the interesting property of allowing the Re=O moiety to be retained also with the metal in +4 and +6 oxidation states. In fact, through electrochemical methods it has been possible to prepare and characterize a number of these complexes.

By analysing the $E^r_{1/2}$ values computed in this and in our previous paper,[11] which have been collected in Table 1, we can see that by varying the ligands used the $E^r_{1/2}$ of the oxidation processes lay in quite a narrow range. As to the reduction potentials, the range of the values with thermodynamic significance is also rather narrow. In particular, the product containing phosphine ligand shows the highest $E^r_{1/2}$, and this fact is consistent with the capability of phosphine to delocalize the increased negative charge of the reduced species.

Acknowledgements—The authors thank Mr F. De Zuane for magnetic measurements and Mrs A. Moresco for technical assistance.

(*Received* 7 *October* 1986; *accepted* 9 *February* 1987)

Abstract—Two new quadridentate Schiff base ligands formed from 2,5-hexanedione and S-alkyldithiocarbazic acids and their nickel(II), zinc(II) and cadmium(II) complexes having the general formula [M(SNNS)] ($SNNS^{2-}$ is the dinegatively charged ligands) have been synthesized and characterized by elemental analysis and magnetic and spectroscopic methods. The Ni(SNNS) complexes are diamagnetic and square-planar. The Zn(SNNS) complexes are assigned with polymeric structures with mercapto sulphur-bridging. The Cd(SNNS) complexes presumably have polymeric structures.

During the past 20 years metal complexes of sulphur–nitrogen chelating agents have been studied quite extensively.[1] However, the majority of ligands studied have either the bidentate NS or tridentate NNS donor sequence. Comparatively little work has been directed to the synthesis and characterization of metal complexes of quadridentate sulphur–nitrogen ligands. The quadridentate SNNS ligand, 3-ethoxy-2-oxobutyraldehyde *bis*-(thiosemicarbazone) and its copper(II) and zinc(II) chelates have been shown to possess antineoplastic activities and their interactions with biological systems have been widely investigated.[2–7] In view of their importance as potential antineoplastic agents and as part of our general study of sulphur–nitrogen ligands, we report herein the synthesis and characterization of some new nickel(II), zinc(II) and cadmium(II) chelates of two quadridentate SNNS ligands formed from 2,5-hexanedione and S-alkyldithiocarbazic acids.

EXPERIMENTAL

Physical measurements

Conductivity measurements were carried out using a Philips conductivity bridge model PW 9501 equipped with a Philips PW 9515/10 conductivity cell. The IR spectra were recorded in the range 200–4000 cm^{-1} on a Pye Unicam Model SP3-300 IR spectrophotometer using KBr discs. Electronic spectra in Nujol mulls were measured with the help of a Shimadzu UV-120-02 spectrophotometer, PMR spectra in DMSO-d_6 were recorded on a Varian XL-200 Spectrometer using TMS as an internal standard. C, H, N and M analyses were performed as before.[8]

Preparation of the ligands and complexes

S-Methyldithiocarbazate[9] and S-benzyldithiocarbazate[10] were prepared according to literature methods.

Syntheses of the Schiff bases, H_2L_1 *and* H_2L_2. Both the ligands were synthesized by the same

general method: the appropriate S-alkyldithiocarbazate (0.03 mol) was dissolved in abs. ethylalcohol (60 cm^3) and the solution mixed with a solution of 2,5-hexanedione (0.015 mol) in the same solvent (10 cm^3). The mixture was refluxed for a period of ca. 1 h and then left standing to cool. The product which separated out was filtered off and recrystallized from abs. ethylalcohol. H_2L_1: M.p. 135°C. Found: C, 55.7; H, 5.8; N, 11.7. $C_{22}H_{26}N_4S_4$ requires: C, 55.7; H, 5.5; N, 11.8%. H_2L_2: M.p. 150°C. Found: C, 37.5; H, 5.8; N, 17.5. $C_{10}H_{18}N_4S_4$ requires: C, 37.2; H, 5.6; N, 17.4%.

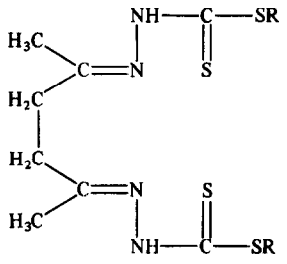
Preparation of the complexes

All the complexes were prepared by the same general method described below: a solution of the metal(II) acetate (2 mmol) in methanol (30 cm^3) was filtered into a boiling solution of the Schiff base (2 mmol) in abs. ethanol (50 cm^3). The mixture was heated on a water-bath for ca. 10–15 min and then left to stand overnight. The product which formed was then filtered off, washed thoroughly with ethanol and dried in a vacuum desiccator over P_4O_{10}.

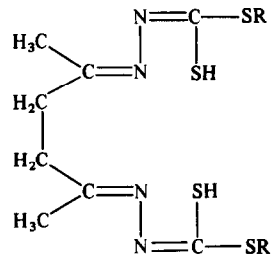
RESULTS AND DISCUSSION

The reaction of 2 mol of S-alkyldithiocarbazic acid with 1 mol of 2,5-hexanedione results in the formation of stable crystalline Schiff bases represented by the structural formula I (R = —CH_3, —$CH_2C_6H_5$).

These compounds have a proton adjacent to the thione group and consequently, they are capable of existing either as the thioketo form (IA) or as the



(IA)



(IB)

enethiol form (IB) or as a mixture of both the thioketo and thioenol forms. The IR spectra of the Schiff bases do not display the ν(S–H) band at ca. 2570 cm^{-1} but show ν(N–H) at 3140–3150 cm^{-1} indicating that in the solid state they remain as the thioketo form IA. The ^1H NMR spectra in $CDCl_3$ also do not display any peak attributable to the S–H proton. It is, therefore, assumed that the Schiff bases remain predominantly in the thioketo forms in $CDCl_3$ solution. However, enethiolization of these ligands seems to be markedly enhanced in the presence of metal ions with the concomitant formation of metal chelates containing the deprotonated ligands. The complexes isolated together with their colours, elemental analyses and molar conductivities are shown in Table 1. The molar conductance data are consistent with the non-electrolytic nature of the complexes. The ligands, therefore, must be acting as dinegatively charged species.

Comparison of the IR spectra (Table 1) of the Schiff bases with those of their metal complexes show that the ν(N–H) of the free ligands are absent in the spectra of the complexes supporting our contention that the ligands are coordinated in deprotonated forms.

The most relevant bands in the IR spectra of the

complexes and the free ligands are listed in Table 2. The strong band at 1618 cm^{-1} in the IR spectra of the ligands is attributed to ν(C=N) stretching vibration.[11] Upon complexation this band is shifted to lower frequencies by about 20 cm^{-1}, suggesting that the ligands are coordinated to the metal ion via the azomethine nitrogen donor atom. A strong band at 1050 cm^{-1} in the free ligands is tentatively assigned to the ν(C=S) of the thioketo form.[12] This band is substantially lowered in the IR spectra of the metal complexes suggesting that coordination to metal ions occurs through the sulphur atom. This is corroborated by the presence of a weak band in the far IR region (ca. 330 cm^{-1}) attributable to metal-sulphur stretching frequency.[13] All the foregoing evidences support that both the Schiff bases behave as quadridentate SNSN ligands. IR spectra of all the complexes show bands characteristic of lattice waters[14] suggesting that the solvent molecules are not coordinated.

The nickel(II) complexes were obtained as brown solids and their ready solubilities in non-polar solvents suggest that presumably they do not have polymeric structures. The diamagnetism of these complexes (Table 1) implies that they have four-coordinate square–planar configurations. Further evidence in support of a square–planar configuration comes from their electronic spectra (Table 2) which show bands at ca. 307, 355, 445 and 535 nm of which the one at 535 nm may be assigned to the *d–d* transition of square–planar nickel(II) having the NiN_2S_2 chromophore.[15] The ^1H NMR spectral data of the free ligands and their complexes are shown in Table 3. The signal at 2.60 ppm relative to TMS is assigned to the S–CH_3 protons and those at the 1.93 to the C–CH_3 protons.[16] The very small shift of the S–CH_3 proton resonances in the spectra of the complexes is consistent with our assumption that the thioether sulphur is not involved in coordination. Similarly there is also very little change in the position of the peaks due to the S–CH_2– proton resonances in the spectra of the complexes compared to those of the ligands. However, the C–CH_3 protons resonate downfield compared to those in the free ligands indicating deshielding as a result of coordination via the C=N nitrogen atom. The above magnetic, electronic and NMR spectroscopic data support a four-coordinate

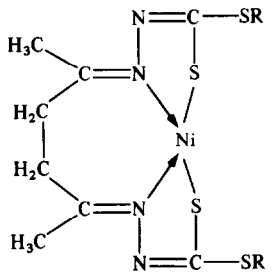
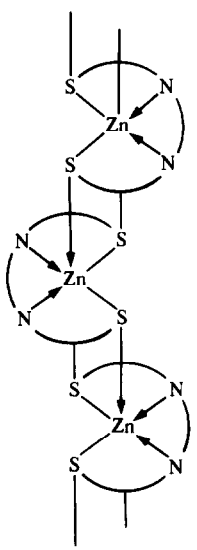
square–planar structure for the nickel(II) complexes with the ligands acting as quadridentate chelating agents bonding the metal ion via the two azomethine nitrogen atoms and the thiolo sulphur atoms as shown in Structure II.



(II)

Such a square–planar structure has, in fact, been confirmed by an X-ray crystal structure determination for the analogous nickel(II) complex of hexene-2,5-dione Schiff base of thiosemicarbazide.[17]



(III)

The zinc(II) complexes Zn(SNNS) were obtained as yellow powders. In contrast with the nickel(II) complexes these compounds were found to be virtually insoluble in all common polar and non-polar solvents suggesting that they probably have polymeric structures. A sulphur-bridged polymeric structure as shown in Structure III will be consistent with the insoluble nature of these complexes.

The cadmium(II) complexes Cd(SNNS) are slightly more soluble than the zinc(II) chelates, but the solubility is not sufficient for molecular weight measurements in solution. These compounds also presumably have polymeric structures like the zinc(II) complexes.

bis-t-BUTYLIMIDO COMPLEXES OF TUNGSTEN(VI)

ALASTAIR J. NIELSON

Department of Chemistry, University of Auckland, Private Bag, Auckland, New Zealand

(*Received* 13 *November* 1986; *accepted* 9 *February* 1987)

Abstract—WCl_6 reacts with $Me_3SiNHCMe_3$ or Me_3CNH_2 to give $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ which contains *trans* orientated chloro ligands. The reaction does not occur with Me_3SiNHR or RNH_2 (R = Me_2CH-, $MeCH_2$-). An interligand proton transfer between *cis*-orientated *t*-butylamido NH groups gives rise to the imido and amine ligands. $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ reacts with 4-picoline to give $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(4\text{-pic})]_2$ and $[W(NCMe_3)_2Cl_2(4\text{-pic})_2]$ while the bidentate ligands bipy and tmed give $[W(NCMe_3)_2Cl_2(bipy)]$ and $[W(NCMe_3)_2Cl_2(tmed)]$. All the complexes retain the *trans*-chloro orientation. With strong sigma donors, L (L = PMe_3, $PMePh_2$, Me_3CNC), $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ reacts to give the complexes $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(L)]_2$ which contain *cis*-chloro ligands. With *t*-butylamine $[W(NCMe_3)_2(NHCMe_3)_2]$ is formed but less sterically demanding amines (Me_2CHNH_2, $MeCH_2NH_2$) do not react similarly. Reaction of $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ with EtOH and Me_3CNH_2 forms $[W(NCMe_3)_2(OEt)_2]_x$. $WOCl_4$ reacts with $Me_3SiNHCMe_3$ or Me_3CNH_2 to give a complex proposed as $[WO(NCMe_3)Cl_2(NH_2CMe_3)]_x$ which reacts further with bipy to form $[W(NCMe_3)_2Cl_2(bipy)]$ and various uncharacterized oxo complexes by an oxo-imido exchange. The complexes were characterized by analytical data, IR, ^1H and ^{13}C NMR spectroscopy. The position of the *t*-butyl group quaternary carbon in the ^{13}C NMR spectra differentiates between imido, amido and amine ligands.

bis-Organoimido complexes of the group (VI) transition metals[1] are less well-known than the isoelectronic *cis* oxo complexes[2] as general preparative routes have not been established. Recent studies have shown that when the mono-organoimido complexes $[W(NR)Cl_4]_2$ (R = Ph, MePh, Me_2CH, $MeCH_2$, Me) react with the silylamines Me_3SiNHR' (R' = Ph, Me_3C, Me_2CH, $MeCH_2$) the *bis*-organoimido complexes $[W(NR)(NR')Cl_2(NH_2R')]_2$ result[3] which then react with ligands such as 2,2′-bipyridyl or PMe_3 to give the monomeric complexes $[W(NR)(NR')Cl_2(bipy)]$ and $[W(NR)(NR')Cl_2(PMe_3)_2]$.[4] *bis-t*-Butylimido complexes are not available by these methods as the reaction of $WOCl_4$ with RNCO to give the initial mono-organoimido complex, does not occur with *t*-butylisocyanate.[5] Several *bis-t*-butylimido complexes of tungsten are however known, including $[W(NCMe_3)(\mu\text{-}NCMe_3)Me_2]_2$,[6] $[W(NCMe_3)_2(OCMe_3)_2]$[7] and $[W(NCMe_3)_2(PFP)(NH_2CMe_3)]$ (PFP = perfluoropinacol)[8] which are derived from $[W(NCMe_3)_2(NHCMe_3)_2]$,[7] but a general route has so far not been reported.

Previous work in our laboratories has shown[9] that for the pentachlorides of niobium and tantalum, substitution of two chlorides by alkylamido ligands, NHR, results in formation of an alkylimido ligand and coordinated primary amine (eqn 1) by an interligand proton-transfer process which is independent of steric size. A third alkylamido ligand was able to be substituted (eqns 2 and 3) but the complex could not be induced to eliminate HCl and form a second imido function.

$$MCl_5 + 2Me_3SiNHR \rightarrow M(NR)Cl_3(NH_2R) + 2Me_3SiCl \quad (1)$$

$$M(NR)Cl_3(NH_2R) + 2RNH_2 \rightarrow M(NR)(NHR)Cl_2(NH_2R) + RNH_3Cl \quad (2)$$

$$MCl_5 + 6RNH_2 \rightarrow M(NR)(NHR)Cl_2(NH_2R) + 3RNH_3Cl. \quad (3)$$

It was thus of interest to establish whether *bis*-organoimido complexes and, in particular, *bis-t*-butylimido complexes, could be generated from WCl_6 and the silylamines Me_3SiNHR or primary amines RNH_2 (R = alkyl group).

RESULTS AND DISCUSSION

When two equivalents of $Me_3SiNHCMe_3$ were reacted with WCl_6 in benzene, a yellow–brown solution formed which gave rise to a yellow, non-crystalline product analysing as the *bis-t*-butylamido complex $[W(NHCMe_3)_2Cl_4]\cdot\frac{1}{6}C_6H_6$ (1). The ^{13}C NMR spectrum showed a quaternary carbon resonance characteristic of a *t*-butylamido ligand (63.0 ppm) but in addition there were quaternary resonances at 70 and 55 ppm which are characteristic of *t*-butylimido and *t*-butylamine ligands.[9] These features thus suggest the product to be a mixture containing (1) and the imido complex $[W(NCMe_3)Cl_4(NH_2CMe_3)]$ (2). A similar reaction between $Me_3SiNHCHMe_2$ and WCl_6 gave a purple precipitate analysing as $[W(NHCHMe_2)_2Cl_4]$ or alternatively $[W(NCHMe_2)Cl_4(NH_2CHMe_2)]$ (3), but insolubility precluded further characterization by ^{13}C NMR spectroscopy.

Reaction of four equivalents of $Me_3SiNHCMe_3$ with WCl_6, or, reaction of two equivalents of the silylamine with the mixture containing $[W(NHCMe_3)_2Cl_4]$ (1) and $[W(NCMe_3)Cl_4(NH_2CMe_3)]$ (2) gave a yellow complex which analysed as $[W(NCMe_3)_2Cl_2(NH_2CMe_3)]_x$. The ^{13}C NMR spectrum showed *t*-butylimido and *t*-butylamine quaternary carbon resonances at 69.1 and 53.5 ppm respectively and the methyl carbons at 31.3 ppm. In addition the spectrum showed a minor component (ca. 20%, resonances at 68.2, 53.2 and 30.2 ppm) indicating a second species in solution and this was also suggested by the ^1H NMR spectrum, there being three methyl proton resonances of varying intensity and two broad NH_2 proton resonances. The IR spectrum exhibited a single strong absorption at 310 cm^{-1} indicative of *trans* chloro ligands. On the basis of these data, the dimeric structure, $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4), is proposed for which some form of dissociation or isomerization in solution occurs to give rise to the NMR spectral features. Repeated crystallizations of the complex have so far given samples with similar spectra. The structure expected is similar to that found by X-ray crystallography for $[W(NCMe_3)(\mu\text{-}NPh)Cl_2(NH_2CMe_3)]_2$.[10] In this complex, however, the chloro ligands are orientated *cis* with characteristic tungsten–chlorine vibrations observed in the IR spectrum at 320 and 290 cm^{-1}.[11]

The results obtained suggest that reactions (1)–(4) occur.

$$WCl_6 + 2Me_3SiNHCMe_3 \rightarrow W(NHCMe_3)_2Cl_4 + 2Me_3SiCl \quad (1)$$

$$W(NHCMe_3)_2Cl_4 \rightarrow W(NCMe_3)Cl_4(NH_2CMe_3) \quad (2)$$

$$W(NCMe_3)Cl_4(NH_2CMe_3) + 2Me_3SiNHCMe_3 \rightarrow W(NCMe_3)(NHCMe_3)_2Cl_2(NH_2CMe_3) + 2Me_3SiCl \quad (3)$$

$$W(NCMe_3)(NHCMe_3)_2Cl_2(NH_2CMe_3) \rightarrow W(NCMe_3)_2Cl_2(NH_2CMe_3) + Me_2CNH_2. \quad (4)$$

A *cis* arrangement of the *bis-t*-butylamido ligands is preferred which can then lead to formation of *t*-butylimido and amine ligands by interligand proton transfer similar to that observed previously for mono-organoimido complexes of niobium and tantalum.[9] The unique feature of the present reaction is that the process is repeated if four chloro ligands are still available, thereby generating a second imido function. A reaction intermediate such as $[W(NHCMe_3)_4Cl_2]$ is unlikely as the strong *trans* influence of the amido ligand would prevent *trans* orientated *t*-butylamido ligands being formed.[12,13] However, a *tris*-amido intermediate, $[W(NHCMe_3)_3Cl_3]$ containing mutually *cis* amido ligands cannot be ruled out.

The silylamine reaction leads to *trans* orientated chloro ligands in (4) and this compares with reactions of the mono-organoimido complexes $[W(NR)Cl_4]_2$ and the silylamines Me_3SiNHR' which give rise to *cis* dichlorides in the resulting $[W(NR)(NR')Cl_2(NH_2R')]$ complexes,[3] the difference apparently arising from steric properties of the *t*-butyl group. Thus, while any steric strain can be relieved in a *cis* amido complex irrespective of R-group size (complex a), after proton transfer a facial arrangement of imido and amine ligands (complex b) is sterically congested if all three ligands contain *t*-butyl groups so that a meridional configuration (c) is then preferred.

The *bis-t*-butylimido complex (4) may also be prepared by reaction of seven equivalents of *t*-butylamine with WCl_6 in benzene. Four equivalents of *t*-butylamine hydrochloride are produced but the yield of complex is lower using this method, the reaction producing a significant amount of petroleum ether soluble, non-crystalline material for which the ^{13}C NMR spectrum shows various *t*-butylimido, amido and amine quaternary carbon

resonances. Other primary amines (Me_2CHNH_2, $EtNH_2$, etc.) do not give clean reactions with WCl_6, producing dark-brown solutions from which characterizable products have not yet been obtained.

With *t*-butylamine, the *t*-butylimido ligands are likely to arise via reactions (5)–(7).

$$WCl_6 + 2Me_3CNH_2 \rightarrow W(NHCMe_3)Cl_5 + Me_3CNH_3Cl \quad (5)$$

$$W(NHCMe_3)Cl_5 + 2Me_3CNH_2 \rightarrow W(NHCMe_3)_2Cl_4 + Me_3CNH_3Cl \quad (6)$$

$$W(NHCMe_3)_2Cl_4 \rightarrow W(NCMe_3)Cl_4(NH_2CMe_3). \quad (7)$$

Proton transfer between amido ligands is not the only process possible, however, as base promoted deprotonation (eqn 8) could also give rise to an imido ligand.

$$W(NHCMe_3)Cl_5 + Me_3CNH_2 \rightarrow W(NCMe_3)Cl_4 + Me_3CNH_3Cl. \quad (8)$$

$[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4) is a useful source for the preparation of a variety of complexes containing the *bis-t*-butylimido function (scheme 1). When the complex was stirred with two equivalents of 4-picoline, the *t*-butylamine ligand was replaced giving $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(4\text{-pic})]_2$ (5). Refluxing (4) with four equivalents of 4-picoline gave $[W(NCMe_3)_2Cl_2(4\text{-pic})_2]$ (6) while similar reactions with two equivalents of 2,2′-bipyridyl (bipy) or *N,N,N′,N′*-tetramethylethylenediamine (tmed) gave the complexes $[W(NCMe_3)_2Cl_2(bipy)]$ (7) and $[W(NCMe_3)_2Cl_2(tmed)]$ (8). The ^{13}C NMR spectra (Table 2), show a single *t*-butyl group quaternary carbon for each complex, in the vicinity of 71 ppm with associated ^{183}W satellites ($^2J_{W-C}$ ranging from 14.4 to 15.4 Hz) while the ^1H NMR spectra show the correct ratio of *t*-butyl methyl protons to those of the neutral donor ligand. In the IR spectra the complexes exhibit a single strong absorption near 310 cm^{-1} indicating *trans* orientated chloro ligands[10] as in the parent dimer, which necessitate the nitrogen atoms of the amine ligands to lie *trans* to the imido groups.

To maintain an 18-electron count in each of these complexes the *t*-butylimido ligands must donate a total of six electrons. A low temperature X-ray crystal structure determination of $[Mo(NPh)_2(S_2CNEt_2)_2]$[14] has shown some differentiation in W–N bond lengths [1.789(4) and 1.754(4) Å]. However, the four and two electron formalism has not otherwise been observed, structure determinations of $[W(NPh)_2Cl_2(bipy)]$[5] and $[W(NCMe_3)(NPh)Cl_2(bipy)]$[15] for example showing no difference in the W–N bond lengths. A similar situation is thus expected for the *bis-t*-butylimido complexes whereby each imido ligand would have a bond order of approximately 2.5.

When $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)_2]$ (4) is reacted with trimethylphosphine or diphenylmethyl phosphine, products analysing as $[W(NCMe_3)_2Cl_2(PMe_3)]_x$ and $[W(NCMe_3)_2Cl_2(PMePh_2)]_x$ are formed. The complexes show two bands in the IR spectra near 320 and 280 cm^{-1} characteristic of *cis* dichlorides. The absorptions are analogous to those observed in the IR spectrum of $[W(NCMe_3)(\mu\text{-}NPh)Cl_2(NH_2CMe_3)]_2$ for which the *cis*-arrangement has been confirmed by X-ray crystallography.[11] The ^1H NMR spectra confirm two *t*-butyl groups to one phosphine ligand, the phosphine methyl groups appearing as a doublet. In the ^{13}C NMR spectra, two resonances of similar intensity are observed for both the *t*-butyl group methyl and quaternary carbons. Spectra run at higher field show identical coupling constants indicating the splitting arises from long range coupling to phosphorus[16] rather than different chemical environments for the two *t*-butyl groups (see Fig. 1). The quaternaries show coupling to ^{183}W (Fig. 1), the coupling constants of 13.7 and 12.8 Hz for PMe_3 and $PMePh_2$ complexes, respectively, being slightly smaller than the previous amine complexes. On the basis of the spectral features the complexes are proposed as the dimers $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(PMe_3)]_2$ (9) and $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(PMePh_2)]_2$ (10) [see structure (d)].

As to why the phosphine complexes should adopt a dimeric *cis* chloro structure is not clear. It is apparent however, that a strong σ-donor such as a phosphine cannot be tolerated *trans* to an imido function which exerts a strong *trans* influence, and this feature appears to be general for tungsten organoimido complexes. For example, while complexes such as $[W(NPh)Cl_4 \cdot L]$ (L = amine, nitrile, t.h.f., etc.) can be formed which contain the neutral ligand *trans* to the imido function, phosphines produce gummy materials which reduce to $[W(NPh)Cl_3P_2]$ complexes.[5] For these examples, as with the tungsten IV complexes $[W(NPh)Cl_2P_3]$, X-ray crystal structure determinations[5,17] show a chloro ligand lying *trans* to the imido function. In the trimeric oxo-bridged complex $[W(NPh)(\mu\text{-}O)Me_2(PMe_3)]_3$[18] the phosphine lies *trans* to the bridging oxo group while for the *bis*-phosphine complex, $[W(NCMe_3)(NPh)Cl_2(PMe_3)_2]$, ^1H, ^{13}C and ^{31}P NMR evidence indicates *trans* phosphines which then positions the chloro ligands *trans* to the imido functions.[4] For the present complex $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4), reaction with diphenylphosphino ethane (dppe) should

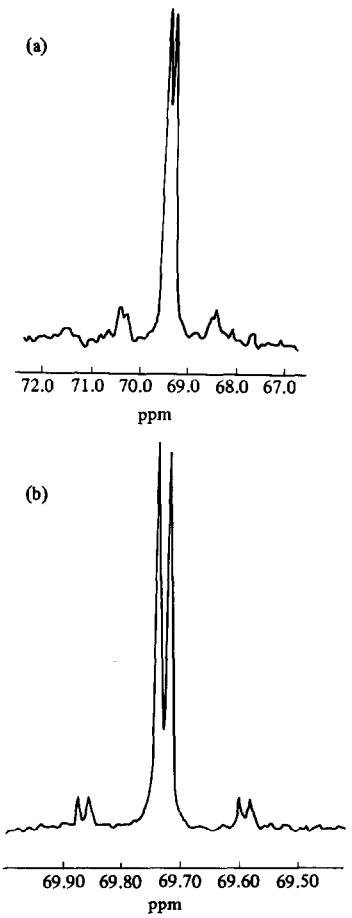

Fig. 1. The *t*-butylimido quaternary carbon resonance in the $^{13}C[^1H]$ NMR spectrum of $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(PMe_3)]_2$ showing coupling to ^{31}P and ^{183}W. (a) 15.04 MHz. (b) 100.61 MHz.

give rise to $[W(NCMe_3)_2Cl_2(dppe)]$ in which at least one phosphorus must lie *trans* to an imido function but the reaction fails to produce an isolatable product.

In a further investigation of the effect of a strong σ-donor, $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4) was reacted with four equivalents of *t*-butylisocyanide which gave the complex $[W(NCMe_3)_2Cl_2(CNCMe_3)]_2$ (11). The ^{13}C NMR spectrum showed the methyl group and quaternary carbons of the *t*-butylimido ligands each as single resonances while the IR spectrum again indicated *cis* chlorides. A structure similar to (d) (L = Me_3CNC) is thus preferred for this complex.

$[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4) does not react further with $Me_3SiNHCMe_3$ but with eight equivalents of *t*-butylamine in petroleum ether, it rapidly dissolves forming four equivalents of Me_3CNH_3Cl and the colourless *bis*-imido-*bis*-amido complex $[W(NCMe_3)_2(NHCMe_3)_2]$ (12).* The ^1H NMR spectrum shows two equal intensity singlets for the *t*-butyl methyl protons while the amido NH protons occur as a broad peak near 5 ppm.[7] In the ^{13}C NMR spectrum the methyl group carbons appear as two distinct singlets and the *t*-butylimido and amido quaternaries appear at 65.6 and 53.0 ppm which are at significantly higher field than usually found for these ligands.

In particular the amido quaternary resonance is found in the region of the *t*-butylamine quaternary of $[W(NCMe_3)(\mu\text{-}NCMe_3)_2Cl_2(NH_2CMe_3)]_2$ (4). These features are apparently a consequence of the unusual geometry that must exist in the molecule. To obtain an 18-electron count, π-bonding is necessary from three nitrogen atoms. As imido and amido ligands possess strong *trans* influencing properties, a mutually *trans* configuration of ligands will not be preferred so that a tetrahedral structure is likely, for which canonicals such as (e) and (f) are needed to maximize the electron count. The coordination geometry involved is apparently stable only for bulky *t*-butyl groups as reactions of $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4) or WCl_6 with Me_2CHNH_2 or $EtNH_2$ produce intractable gums.

Attempts to force further proton transfer within the molecule to give a *tris*-*t*-butylimido complex have so far been unsuccessful. $[W(NCMe_3)_2(NHCMe_3)_2]$ (12) remains unchanged after prolonged refluxing in benzene and ligands such as PMe_3 or 4-picoline have no effect. Addition of excess *t*-butylamine gives a dark-brown solution consisting of starting complex and some intractable material.

The chloro ligands of $[W(NCMe_3)(\mu\text{-}NCMe_3)Cl_2(NH_2CMe_3)]_2$ (4) may also be replaced by alkoxides. Reaction of the complex with four equivalents of EtOH in the presence of four equivalents of *t*-butylamine[19] produces Me_3CNH_3Cl and a colorless oil which was identified as $[W(NCMe_3)_2(OEt)_2]_x$ (13) on the basis of the correct methylene to methyl group ratio in the ^1H NMR spectrum while the ^{13}C NMR spectrum contained resonances characteristic of the *t*-butylimido group and ethoxide ligands.[20] In a similar reaction, Me_3COH and $[W(NCMe_3)_2(NHCMe_2)_2]$ have been reported[7] to give $[W(NCMe_3)_2(OCMe_3)_2]$ as a colourless oil.

It was also of interest to prepare complexes containing both oxo and *t*-butylimido ligands in view of the identification of these groups by X-ray crystallography in the trimeric complex $[W(NPh)(\mu\text{-}O)Me_2(PMe_3)]_3$.[18] When benzene solutions of

* This complex was first prepared by Nugent and Haymore by a reaction of WCl_6 with 12 equivalents of *t*-butylamine in petroleum ether.[7] A preliminary X-ray crystal structure determination showed a monomeric molecule but no further structural details have yet been reported.

$WOCl_4$ were reacted with two equivalents of $Me_3SiNHCMe_3$ or four equivalents of Me_3CNH_2, yellow non-crystalline products were obtained which have so far not been fully characterized. The ^{13}C NMR spectra show the presence of both *t*-butylimido and amine quaternary carbons while the IR spectra show vibrations in the vicinity of 800 cm^{-1} which are characteristic of W–O–W bonds.[21] The combined data suggest the presence of $[WO(NCMe_3)Cl_2(NH_2CMe_3)]_x$ but reaction of the material with bipy under reflux produced $[W(NCMe_3)_2Cl_2(bipy)]$ (7) and various as yet unidentified oxo complexes. Thus, if the $WO(NCMe_3)$ moiety is formed in the initial reaction, oxo-imido exchange must occur under the synthetic conditions to give the observed products.

EXPERIMENTAL

All preparations and manipulations were carried out under dry oxygen-free nitrogen using standard bench-top air-sensitive techniques.[22] *N*(trimethylsilyl)-*t*-butylamine was prepared by treating chlorotrimethylsilane with two equivalents of *t*-butylamine and distilling the product.[23] *t*-Butylamine, 4-picoline and *N,N,N′,N′*-tetramethylethylenediamine were dried over and distilled from calcium hydride. Absolute ethanol was distilled from magnesium ethoxide. Trimethylphosphine was prepared by a literature method[24] and tungsten hexachloride was sublimed prior to use. Petroleum ether (B.p. range 40–60°), toluene and benzene were distilled from sodium wire. Infrared spectra were recorded on a Perkin–Elmer 597 spectrometer as Nujol mulls between CsI plates, ^1H NMR spectra on a Varian T60 model spectrometer and ^{13}C NMR spectra on Jeol FX60 and Bruker AM400 spectrometers. Analytical data were obtained by Prof. A. D. Campbell and Associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under N_2 on an electrothermal melting point apparatus and are uncorrected.

bis-t-*Butylamidotetrachlorotungsten(VI)* (**1**) *and* t - *butylamine* - t - *butylimidotetrachlorotungsten(VI)* (**2**)

N(trimethylsilyl)-*t*-butylamine (1.4 cm^3, 7.2 mmol) in benzene (40 cm^3) was added to tungsten hexachloride (1.4 g, 3.5 mmol) dissolved in benzene (70 cm^3) and the mixture was stirred for 24 h. The yellow solution was filtered and the solvent removed to give a flaky yellow material which was washed with petroleum ether and ground up until a yellow powder was formed. Yield: 1.5 g (88%).

IR (Nujol) bands at 3350m, 3100s, 1585m, 1455s, 1398m, 1360s, 1290m, 1250s, 1210s, 1160m, 1050w, 1022w, 960m, 840s, 815s, 795s, 750s, 720s, 675s, 565m, 440m, 320s cm^{-1}.

Tetrachloro - iso - *propylamine* - iso - *propylimidotungsten(VI)* (**3**)

N(trimethylsilyl)-*iso*-propylamine (2.2 cm^3, 12.3 mmol) in benzene (30 cm^3) was added to tungsten hexachloride (1.2 g, 3.0 mmol) dissolved in benzene (100 cm^3) and the mixture was stirred for 14 h. The solution was filtered and the purple product washed with petroleum ether (50 cm^3) and dried *in vacuo*. Yield: 0.6 g (46%).

IR (Nujol) bands at 3350s, 3140s, 1562s, 1458s, 1390m, 1345m, 1320w, 1200s, 1155m, 1120w, 970s, 935m, 920w, 890w, 840w, 790w, 770w, 722m, 600w, 450w, 390m, 320m, 295s cm^{-1}.

bis - t - *Butylaminebis* - t - *butylimidobis*(μ - t - *butylimido*)*tetrachloroditungsten(VI)* (**4**)

(a) *N*(trimethylsilyl)-*t*-butylamine (8.9 cm^3, 46.0 mmol) in benzene (100 cm^3) was added to tungsten hexachloride (4.5 g, 11.4 mmol) dissolved in benzene (140 cm^3) and the mixture was stirred for 20–24 h. The pale green solution was filtered and the solvent volume reduced (ca. 10 cm^3) until a large mass of crystalline material formed. The product was filtered, washed with chilled benzene (5–10 cm^3 portions) until the filtrate was no longer coloured light green, and dried *in vacuo*. The filtrates and mother liquor were combined and the solvent volume again reduced. On standing for several hours, further product crystallized which was washed with chilled benzene (5 cm^3 portions) as before. Overall yield 3.74 g (71%). The complex is sufficiently pure for further use but analytically pure material is obtained by recrystallization from benzene.

IR (Nujol) bands at 3275w, 3155m, 3080m, 2690w, 2580w, 2490w, 2050w, 1600w, 1458m, 1505w, 1390m, 1350s, 1270s, 1250s, 1200s, 1175s, 1127m, 1022w, 924w, 890m, 840w, 802m, 748m, 720m, 692w, 602m, 580w, 555w, 478w, 450w, 420w, 375w, 350w, 310s, 280w cm^{-1}.

(b) *t*-Butylamine (4.8 cm^3, 45.7 mmol) in benzene (50 cm^3) was added to tungsten hexachloride (2.6 g, 6.56 mmol) in benzene (100 cm^3) and the mixture was stirred for 2 h. The light yellow solution was filtered from the precipitate of *t*-butylamine hydrochloride (approx. 3.2 g) and the solvent volume reduced to ca. 5–10 cm^3 whereupon the complex crystallized as yellow prisms. The product was filtered, washed with petroleum ether (10 cm^3) and dried *in vacuo*. Yield: 1.4 g (47%). [Found: C, 30.2;

H, 6.3; N, 9.1. $C_{24}H_{54}Cl_4N_6W_2$ requires C, 30.8; H, 5.8; N, 9.0.] The complex had identical m.p., IR, ^1H and $^{13}C[^1H]$ NMR spectrum to that prepared under (a).

bis - t - *Butylimidobis*(μ - t - *butylimido*)*tetrachlorobis*(4 - *picoline*)*ditungsten(VI)* (**5**)

4-Picoline (0.4 g, 4.2 mmol) in benzene (25 cm^3) was added to *bis-t*-butylaminebis-*t*-butylimidobis (μ-*t*-butylimido)tetrachloroditungsten(VI) (0.9 g, 0.96 mmol) in benzene (50 cm^3) and the mixture was stirred for 2 h. The solution was filtered, the volume reduced and on standing for several weeks a single large crystal of the complex formed.

IR (Nujol) bands at 1600m, 1508m, 1498m, 1398m, 1360s, 1300m, 1270m, 1220s, 1210s, 1138w, 1064m, 1035m, 945m, 880m, 818s, 720s, 585m, 552w, 518w, 498w, 450m, 350w, 322m, 299w, 280w cm^{-1}.

bis - t - *Butylimidodichlorobis*(4 - *picoline*)*tungsten(VI)* (**6**)

4-Picoline (0.5 g, 5.4 mmol) in benzene (30 cm^3) was added to *bis-t*-butylaminebis-*t*-butylimidobis (μ-*t*-butylimido)tetrachloroditungsten(VI) (1.0 g, 1.1 mmol) in benzene (50 cm^3) and the mixture was refluxed for 2 h. The solution was filtered and the solvent removed to give a yellow–green solid which was washed with petroleum ether (40 cm^3) and dried *in vacuo*. Crude yield 1.1 g (89%). The complex was dissolved in toluene (30 cm^3), the solution filtered and the volume reduced to ca. 5 cm^3. On standing at −20° the complex formed as yellow crystals. The product was always surface contaminated with small amounts of a colourless solid and was thus characterized by NMR spectroscopy (Table 2). M.p. (pure crystal) 148°C.

IR (Nujol) bands at 1600m, 1495m, 1395m, 1350s, 1290s, 1250s, 1205s, 1080s, 1015s, 950m, 850m, 800s, 722m, 660m, 590w, 492m, 480m, 445m, 383m, 242m, 200w cm^{-1}.

(2,2-*bipyridyl*)bis-t-*Butylimidodichlorotungsten(VI)* (**7**)

(a) 2,2′-bipyridyl (0.2 g, 1.3 mmol) in benzene (40 cm^3) was added to *bis-t*-butylaminebis-*t*-butylimidobis(μ-*t*-butylimido)tetrachloroditungsten(VI) (0.6 g, 0.64 mmol) in benzene (60 cm^3) and the mixture was refluxed for 30 min. The solution was filtered and the solvent removed to give a light-yellow solid which was extracted with benzene (40 cm^3). The solution was filtered and the volume reduced until the product began to crystallize. The solution was heated until all the solid dissolved and on standing large yellow prisms of the complex formed. Yield: 0.58 g (82%).

IR (Nujol) bands at 1595s, 1560w, 1490w, 1350s, 1308m, 1272s, 1235s, 1210s, 1170w, 1155w, 1135w, 1104w, 1055w, 1042w, 1020m, 970w, 902w, 890w, 800w, 764s, 730s, 650m, 626m, 590m, 564w, 470w, 412w, 355w, 305s cm^{-1}.

(b) *t*-Butylamine (2.15 cm^3, 20.5 mmol) in benzene (30 cm^3) was added to tungstenoxytetrachloride (1.75 g, 5.1 mmol) suspended in benzene (80 cm^3) and mixture was stirred for 3 h. The solution was filtered and the solvent removed to give a yellow solid.

IR (Nujol) bands at 3150m, 3050m, 2700m, 2580m, 2490w, 1604w, 1560w, 1508w, 1396m, 1340s, 1260s, 1210s, 1140w, 1024w, 905w, 835bs, 790bs, 720bs, 675s, 590m, 520m, 450w, 378w, 348w, 295bm cm^{-1}.

^1H NMR $\delta(CDCl_3)$ 1.22–1.65 (several s, CMe_3). ^{13}C NMR $\delta(CDCl_3)$ 30.2, 31.3, 32.2, 33.2 (Me_3); 52.0, 54.0 (NH_2C); broad resonance centred at 60.7 (NHC); broad resonance centred at 70.1 (NC).

The yellow solid (0.9 g) was dissolved in benzene (30 cm^3) and 2,2′-bipyridyl (0.35 g) in benzene (70 cm^3) added. The mixture was refluxed for 2 h, the solution filtered and the solvent removed to give a light-yellow crystalline solid which was washed with warm petroleum ether (50 cm^3) to remove excess 2,2′-bipyridyl. Recrystallization from benzene gave the complex as yellow crystals. [Found: C, 39.2; H, 4.7; N, 10.2. $C_{18}H_{26}Cl_2N_4W$ requires C, 39.1; H, 4.7; N, 10.1.] The complex had identical m.p., IR and NMR spectra to the sample prepared under (a).

(c) *N*(trimethylsilyl)-*t*-butylamine (1.4 cm^3, 7.2 mmol) in benzene (30 cm^3) was added to a suspension of tungsten oxytetrachloride (1.2 g, 3.5 mmol) in benzene (80 cm^3) and the mixture was stirred for 3 h. The solution was filtered and the solvent removed to give a yellow solid. The IR spectrum was similar to the product prepared under (b). ^1H NMR $\delta(CDCl_3)$ 1.20–1.60 (several s, CMe_3); 2.80 and 4.22 (b, NH). ^{13}C NMR $\delta(CDCl_3)$ 30.2, 30.9, 31.3 (Me_3); 52.7, 53.4, 54.6 (NH_2C); 68.1, 69.1, 70.5, 71.5 (NC).

The product (1.3 g) was dissolved in benzene (50 cm^3), 2,2′-bipyridyl (0.5 g) in benzene (30 cm^3) added and the mixture refluxed for 3 h. The solution was filtered, the solvent removed *in vacuo* and the resulting light-yellow solid washed with warm petroleum ether (50 cm^3) to remove excess 2,2′-bipyridyl. The solid was dissolved in hot toluene (20 cm^3), the solution filtered while hot and the volume reduced. On standing for several hours yellow crystals of the complex were formed which were filtered, washed with petroleum ether and dried *in vacuo*.

The product had identical m.p., IR and NMR spectra to the sample prepared under (a).

bis - t - *Butylimidodichloro*(N,N,N′,N′ - *tetramethylethylenediamine*)*tungsten*(*VI*) **(8)**

N,N,N′,N′-tetramethylethylenediamine (0.3 g, 2.6 mmol) in benzene (40 cm^3) was added to *bis-t*-butylaminebis - *t* - butylimidobis(μ - *t* - butylimido) tetrachloroditungsten(VI) (0.9 g, 1.0 mmol) in benzene (60 cm^3) and mixture was refluxed for 2 h. The solution was filtered and the solvent removed to give a colourless crystalline solid. Crude yield 0.7 g (92%). The product was extracted with petroleum ether (40 cm^3), the solution filtered and volume reduced to ca. 5 cm^3. On standing at $-20°$ the complex formed as colourless crystals.

IR (Nujol) bands at 2700w, 2590w, 2500w, 2075w, 1610w, 1510m, 1400m, 1350m, 1300m, 1284m, 1260m, 1244s, 1216s, 1118w, 1095w, 1065w, 1040w, 1032w, 1019m, 958s, 880s, 800s, 775m, 725s, 680m, 590w, 505w, 480w, 452s, 422w, 350s, 310s cm^{-1}.

bis - t - *Butylimidobis*(μ - t - *butylimido*)*tetrachlorobis*(*trimethylphosphine*)*ditungsten*(*VI*) **(9)**

Trimethylphosphine (0.4 cm^3, 3.6 mmol) was added to *bis-t*-butylaminebis-*t*-butylimidobis(μ-*t*-butylimido)tetrachloroditungsten(VI) (0.8 g, 0.86 mmol) in benzene (50 cm^3) and the mixture was stirred for 3 h. The solution was filtered, the solvent removed and the colourless crystalline solid washed with several portions of petroleum ether (10 cm^3) and dried *in vacuo*. Yield: 0.8 g (98%).

IR (Nujol) bands at 3010w, 2700w, 2590w, 2495w, 2060w, 1504w, 1410m, 1395w, 1350s, 1300w, 1280m, 1270s, 1230s, 1204s, 1132w, 964s, 850w, 802w, 745m, 720w, 580w, 464w, 450w, 344w, 318m, 280m, 260w cm^{-1}

bis - t - *Butylimidobis*(μ - t - *butylimido*)*tetrachlorobis*(*diphenylmethylphosphine*)*ditungsten*(*VI*) **(10)**

Diphenylmethyl phosphine (0.4 cm^3, 2.2 mmol) in benzene (50 cm^3) was added to *bis-t*-butylaminebis - *t* - butylimidobis(μ - *t* - butylimido)tetrachloroditungsten(VI) (0.9 g, 0.96 mmol) in benzene (50 cm^3) and the mixture was stirred for 3 h. The solution was filtered and the solvent removed to give the product as a colourless oil which solidified on washing with petroleum ether and drying *in vacuo*. Crude yield 1.1 g (96%). The complex was dissolved in toluene, the solution filtered and the volume reduced to ca. 5 cm^3. On standing at $-20°$ large pale green crystals of the complex were formed.

IR (Nujol) bands at 1600w, 1580w, 1508w, 1400w, 1360s, 1300w, 1268m, 1230m, 1208m, 1135w, 1100m, 1065w, 1022w, 995w, 960w, 880m, 840w, 800w, 740s, 720m, 695s, 594w, 505m, 480w, 450w, 318m, 285m cm^{-1}.

bis - t - *Butylimidobis*(μ - t - *butylimido*)bis - t - *butyl*-iso-*cyanidetetrachloroditungsten*(*VI*) **(11)**

t-Butylisocyanide (0.5 cm^3, 4.4 mmol) in benzene (30 cm^3) was added to *bis-t*-butylaminebis-*t*-butylimidobis(μ-*t*-butylimido)tetrachloroditungsten(VI) (0.8 g, 0.8 mmol) and the mixture was refluxed for 1 h. The solution was filtered, the solvent removed and the crystalline residue washed with petroleum ether (50 cm^3). Crude yield 0.7 g (91%). The solid was dissolved in toluene (30 cm^3), the volume reduced to ca. 5 cm^3 and on standing at $-20°$ yellow crystals of the complex were formed which were filtered, washed with petroleum ether (20 cm^3) and dried *in vacuo*.

IR (Nujol) bands at 2248s, 1464s, 1408w, 1364s, 1282s, 1242s, 1220s, 1200s, 1160m, 1142m, 1052w, 1034w, 980w, 945w, 890w, 852m, 812m, 740m, 728s, 604s, 560w, 538w, 478w, 460w, 400w, 385w, 340s, 300s, 272w cm^{-1}.

bis - t - *Butylamidobis* - t - *butylimidotungsten*(*VI*)[7] **(12)**

t-Butylamine (1.3 cm^3, 12.4 mmol) in petroleum ether (40 cm^3) was slowly added to *bis-t*-butylaminobis - *t* - butylimidobis(μ - *t* - butylimido)tetrachloroditungsten(VI) (1.4 g, 1.5 mmol) suspended in petroleum ether (60 cm^3) and the mixture was stirred for 3 h. The solution was filtered and the solvent removed to give the complex as a colourless solid tinged green with a small amount of impurity. Crude yield 1.2 g (85%). The complex was dissolved in petroleum ether (25 cm^3) and the volume reduced to ca. 10 cm^3. On standing at $-76°$ the complex crystallized as prisms which were washed with petroleum ether (10 cm^3) cooled to $-76°$ and dried *in vacuo*.

IR (Nujol) bands at 3150m, 3050m, 2700m, 2640m, 2500m, 1600w, 1562w, 1525w, 1392m, 1345s, 1255m, 1205m, 1020m, 930w, 835s, 805s, 725s, 595m, 450m, 275w, 250m cm^{-1}.

bis-t-*Butylimidobisethoxytungsten*(*VI*) **(13)**

Ethanol (0.15 cm^3, 2.6 mmol) and *t*-butylamine (0.26 cm^3, 2.6 mmol) in petroleum ether (40 cm^3) were added slowly to *bis-t*-butylaminebis-*t*-butyl-

imidobis(μ-*t*-butylimido)tetrachloroditungsten(VI) (0.6 g, 1.3 mmol) suspended in petroleum ether (80 cm^3) and the mixture was stirred for 4 h. The colourless solution was filtered and the solvent removed to give the product as an oil which failed to crystallize. Yield: 0.42 g (80%).

IR (smear) bands at 1435s, 1345s, 1265s, 1208m, 1140m, 1095s, 1050s, 1025s, 950m, 905s, 878s, 840m, 804m, 720m, 550s, 510s, 445w, 372w cm^{-1}.

Acknowledgement—The assistance of Dr J. M. Coddington in running the high field NMR spectra is gratefully acknowledged.

Abstract—Cu(II) complexes with salicylaldimines derived from the following aminoacids: glycine, α-alanine, β-alanine, serine, tyrosine, tryptophane, arginine, ornithine, histidine have been studied by the ESR method. On the basis of room temperature and frozen solution ESR spectra the formation of two types of the adducts have been established. The influence of additional functional groups of aminoacids on adduct formation has been found.

As follows from the literature presented by Wagner and Walker,[1] metal complexes of tridentate Schiff base ligands composed of salicylaldehyde and aminoacids (sal-aminoac), the model systems to investigate the enzymatic reaction of pyridoxal phosphate, have been extensively studied during the last few years.

X-ray analysis of the solids of Cu(sal-aminoac) complexes revealed that the compounds tend to coordinate via phenolic oxygen, one carboxylic oxygen and the imino nitrogen with a water molecule completing the near square planar coordination of Cu(II) ion.[2,3] The same equatorial position of a solvent molecule was postulated for Cu(II) salicylaldimines derived from glycine, α-alanine, phenylglycine, ε-acetyl-lysine and histidine on the basis of ESR of frozen solutions as well as room temperature spectroscopic and titration data.[1,4]

Our own studies of polymeric Cu(II) complexes with tricoordinate Schiff bases[5] indicated that the fourth coordination position taken in the solids by a bridging oxygen atom is replaced in the solutions by the solvent molecule L coordinating via an oxygen or nitrogen atom at a non-equatorial position. Only under specific conditions, when a small amount of a ligand L_1 able to coordinate via nitrogen is added to the solutions of the complexes in oxygen coordinating solvent L, the ligand L_1 binds at equatorial chelate plane. Hence, it is interesting to find out whether or not the tricoordinate character of sal-aminoac ligand would determine the formation of the adducts of Cu(sal-aminoac) in the solutions of a symmetry similar to that stated for the polymeric Cu(II) tridentate Schiff base complexes. Furthermore, the ESR studies presented here show the influence of the aminoacid residues of histidine, ornithine, tyrosine and tryptophane, their additional donor ability or bulky effects on the formation of the adducts of Cu(sal-aminoac).

EXPERIMENTAL

Cu(II) complexes with ligands derived from salicylaldehyde and aminoacids were synthesized according to a general method used by Wagner and Walker.[1] The following aminoacids were used for syntheses: glycine, L-α-alanine, β-alanine, L-serine, L-tyrosine, L-tryptophane, L-arginine, L-ornithine, L-histidine. The elemental analysis for copper, carbon, nitrogen and hydrogen confirms the formation of Cu(II) complexes with tricoordinate Schiff bases formulae: Cu(sal-glycine)·$1\frac{1}{2}H_2O$, Cu(sal-α-alanine)·$2H_2O$, Cu(sal-β-alanine)·H_2O, Cu(sal-serine)·$2H_2O$, Cu(sal-tyrosine)·H_2O, Cu(sal-ornithine)·$1\frac{1}{2}H_2O$, Cu(sal-arginine)·$2H_2O$, Cu(sal-histidine)·$1\frac{1}{2}H_2O$.

The solvents were purified according to the methods described previously.[6] The ESR spectra of liquid solutions of Cu(sal-histidine) appear to be resolved due to copper hyperfine splitting for the concentration of water in dioxan not smaller than 50%. The concentration of pyridine L_1 added as the admixture to oxygen coordinating solvents L is about 0.01 M. The ESR spectra were recorded on

JEOL JES ME X-band spectrometer using a nuclear magnetometer MJ 110R and microwave frequency meter JES-SH-30X.

RESULTS AND DISCUSSION

The complexes presented in Table 1, derived from the following aminoacids: glycine, α-alanine, β-alanine, serine, tyrosine exhibit similar behaviour in the solutions. The same, three-line pattern of syperhyperfine splitting due to one ^{14}N atom bound to copper (of the magnitude between 12–14 G) is observed in the room temperature ESR spectra when the complexes are dissolved in both oxygen or nitrogen coordinating solvents (Fig. 1). This implies, that only the imine nitrogen atom is involved in the superhyperfine interaction with the unpaired electron of the Cu(II) in the xy plane. Consequently, it becomes evident, that in the Cu(sal-aminoac)L adduct (type I), the solvent molecule L occupying the fourth coordinating position is not coplanar with the chelate ring composed of carboxylate oxygen, imine nitrogen and phenolic oxygen.

When a small amount (about 0.01 M) of pyridine is added to all five complexes in oxygen coordinating solvents L, the characteristic change of ESR parameters (decrease of g_{iso} about 0.01 and increase of $|A_{iso}|$ about 6 G) is observed (Table 1, Fig. 1).

According to our studies on tricoordinate Schiff base complexes[5] the new set of ESR parameters

Parameters A are given in 10^{-4} cm^{-1} units. A_{iso} and g_{iso} were measured at 295 K. $A_{\parallel}$ and $g_{\parallel}$ were measured at 150 K.

[a] [pyridine] = 0.01 M.

[b] No hyperfine splitting in NMF solution. diox = dioxane, NMF = N-methylformamide.

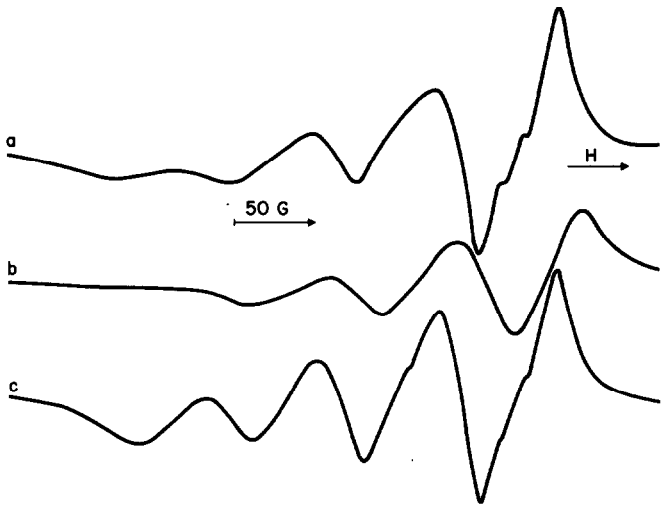

Fig. 1. ESR spectra of Cu(sal-glycine) at 295 K. (a) in 3:2 dioxane–H_2O (L), (b) after addition of L_1 = pyridine (0.01 M) to the 3:2 dioxane–H_2O (L) solution, (c) in pyridine (L).

obtained in this case is characteristic for pentacoordinate adducts. Hence, ESR results indicate the formation of the type II adducts with general formula [Cu(sal-aminoac)(L_1)L]; L_1 = pyridine coordinates probably at the fourth coordination position in the equatorial plane, whereas the oxygen coordinating solvent L transfers into the axial position. It is noteworthy, that type II adducts are formed even in the case of the complexes derived from serine and tyrosine. Thus, -OH and -C_6H_5-4-OH groups do not prevent the transition from type I to type II adducts.

Inspection of Table 1 reveals the considerable decrease of $|A_{iso}|$ and $|A_{\parallel}|$ and the increase of $g_{\parallel}$ for Cu(sal-β-alanine)L in comparison with Cu(sal-α-alanine)L. This trend is compatible with an increasing degree of tetrahedral distortion[7] and may be due to a greater deviation of the solvent molecule L from the chelate ring plane in Cu(sal-β-alanine)L. It is interesting to note other differences between α-alanine and β-alanine derivatives: e.g. contrary to the complex derived from α-alanine no transamination reaction was found in the complex derived from β-alanine which was attributed to the dissimilarities in the bond distances.[8]

The second series of complexes studied consists of Cu(II) salicylaldimines derived from aminoacids with additional functional groups: histidine, ornithine, arginine and tryptophane. The ESR properties (the superhyperfine splitting due to the ligand ^{14}N nucleus and ESR parameters) of the complexes dissolved in the O- or N-coordinating solvents are comparable with these stated for the former series of the compounds (Table 1, Fig. 2). Thus, the adducts of type I are formed for all the complexes.

The result confirms earlier studies[1] on the coordination mode of histidine in Cu(sal-histidine) indicating that the imidazole group is involved in axial interaction while the other three donor atoms are placed in the plane. Attempts to achieve the typical transition: adduct I → adduct II for these complexes results in the smaller effects in comparison with complexes of the former series and the observed changes of ESR parameters are diminished (see Table 1). One possible explanation is that the imidazole nitrogen of histidine and amine

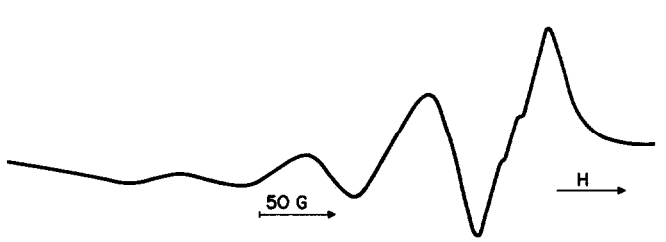

Fig. 2. ESR spectrum of Cu(sal-histidine) in pyridine (L) at 295 K.

nitrogen of ornithine or arginine coordinating at axial position block the lability of the coordination sphere of Cu(II) and hence the transition to type II adduct becomes less probable. In the case of Cu(sal-tryptophane) the indole nitrogen is not able to act as a donor and the observed effect is connected rather with steric hindrance of the bulky residue of the aminoacid.

Abstract—The synthesis, electronic absorption, infrared and ^{13}C NMR spectra, and electrochemistry of $[Cr(CO)_4]$dpp and $[W(CO)_4]$dpp (dpp = 2,3-bis(2-pyridyl)pyrazine) are reported. Electronic absorption spectra in different solvents show solvatochromic behavior and indicate the metal to ligand charge transfer (MLCT) excited state is lower in energy than the ligand field (LF) excited state. Electrochemical results show the $[Cr(CO)_4]$dpp complex undergoes semi-reversible one electron oxidation, while $[W(CO)_4]$dpp undergoes irreversible one electron oxidation. ^{13}C NMR spectra of both complexes show all carbons in the metal-bound dpp ring shift downfield. The amount of downfield shift for the series $[M(CO)_4]$dpp (M = Cr, Mo, W) is interpreted as indicating better M $d\pi \rightarrow$ dpp $p\pi^*$ back-bonding occurs for Mo and W than for Cr.

Our group has been interested in the preparation and characterization of transition metal complexes bound to nitrogen aromatic ligands, which are highly absorbing in the visible region of the spectrum and possess the ability to coordinate to remote metal centers and form polymetallic complexes.[1,2] Within these criteria, there have been several recent reports of $[M(CO)_4]L$ [M = Cr(0), Mo(0), W(0) and L = 2,2′-bipyrimidine (bpym), 2,5-bis(2-pyridyl)pyrazine (dppz), 3,6-bis(2-pyridyl) 1,2,4,5 tetrazine (dptz) and azo-2,2′-bipyridine (abpy)] type complexes.[3–6] Additionally, these metal complexes also serve as models in understanding the solvatochromic behavior of group 6 metal complexes.[6]

The dpp ligand serves as an effective bidentate ligand in either mono or bimetallic systems,[1,2,7] and the results of previous studies indicate that dpp is more effective at electronically communicating two bound metal centers than most monodentate bridges.[7–9] We report the syntheses and characterization of the highly absorbing $[Cr(CO)_4]$dpp and $[W(CO_4)]$dpp complexes. Electronic spectral, electrochemical and ^{13}C NMR comparisons within the $[M(CO)_4]$dpp (M = Cr, Mo, W) series and with other bridging ligands are presented.

EXPERIMENTAL

Materials

$Cr(CO)_6$, $W(CO)_6$, 2,3-bis(2-pyridyl)pyrazine (dpp) and deuterated solvent used for ^{13}C NMR were obtained from Aldrich Chemicals. Other solvents were obtained from Fisher, and used without redistillation. Elemental analyses were performed by Atlantic Microlab, Atlanta, GA.

Instrumentation

Electronic absorption spectra were recorded on a Beckman Model 5240 Spectrophotometer with matching quartz cells.

Cyclic voltammograms were recorded on a Bio Analytic Systems CV-1B Cyclic Voltammograph with Hewlett Packard 7044A XY recorder. All potentials are reported vs. Ag/AgCl, and are uncorrected for junction potentials.

Proton-decoupled ^{13}C NMR were obtained on a Bruker Model WM-250 Fourier Transform NMR operating at 62.9 MHz. Samples were run in a 10.0 mm probe with 30% deuterated dichloromethane as an internal lock and reference (δ = 53.8 ppm).

Infrared spectra were recorded as solid KBr

samples on a Nicolet Model 20DX FTIR with a 1 cm^{-1} resolution.

Syntheses

[$W(CO)_4$]dpp. A mixture of 0.39 g (1.66 mmol) dpp and 0.63 g (1.79 mmol) $W(CO)_6$ in 30 cm^3 toluene was heated at reflux for 30 h under Ar in the dark. After cooling to room temperature, petroleum ether was added and the product refrigerated overnight. The crude red product was collected by filtration on a sintered glass filter funnel, washed with petroleum ether and air dried. The product was then dissolved on the funnel with CH_2Cl_2, and suction filtered. The liquid was loaded on a 25 × 2 cm diameter alumina column that had been washed with CH_2Cl_2. Red [$W(CO)_4$]dpp eluted slowly with CH_2Cl_2. The liquid was collected and rotary evaporated to dryness. The solid was then re-dissolved in CH_2Cl_2, and eluted again through a freshly prepared alumina column. The product was collected and dried as described above, and stored under vacuum in the dark. Yield 0.67 g (1.27 mmol; 76%). Found: C, 40.8; H, 1.9; N, 10.5. Calc. for $C_{18}H_{10}N_4O_4W$: C, 40.8; H, 1.9; N, 10.6%.

[$Cr(CO)_4$]dpp. A mixture of 0.20 g (0.76 mmol) dpp and 0.18 g (0.81 mmol) $Cr(CO)_6$ in 25 cm^3 of toluene was heated at reflux for 9 h under Ar in the dark. The product was precipitated, collected, purified and dried as described above. Yield 0.08 g (0.20 mmol, 27%). Found: C, 53.7; H, 2.6; N, 14.0. Calc. for $C_{22}H_{10}N_4O_4Cr$: C, 54.3; H, 2.5; N, 14.1%.

RESULTS AND DISCUSSION

The [$M(CO)_4$]dpp [M = Cr(0), W(0)] complexes are soluble in a variety of organic solvents, and the electronic spectral data are reported in Table 1. The electronic spectra of both complexes are characterized by highly absorbing ($\varepsilon > 1000\ M^{-1}\ cm^{-1}$) solvent dependent transitions in the visible region of the spectrum with less intense, higher energy solvent independent transitions. The lower energy absorption is similar in position, intensity and solvent dependent behavior with previously reported α-diimine [$M(CO)_4$] metal to ligand charge transfer (MLCT) transitions,[1,3–6,10,11] and by analogy, we assign the lowest energy absorptions of [$Cr(CO)_4$]dpp and [$W(CO)_4$]dpp as being MLCT transitions. The higher energy solvent independent absorptions of [$Cr(CO)_4$]dpp and [$W(CO)_4$]dpp complexes are similar in position and behavior with previously reported [$M(CO)_4$]bpym and [$M(CO)_4$]bpy ligand field absorptions,[5,6,10] and we therefore assign the higher energy absorptions as being $^1A_1, {}^1E_1 \leftarrow {}^1A_1$ ligand field transitions. The large molar absorptivity of the ligand field transition has previously been attributed as being due to some MLCT character in the transition. We assign the highest energy transition at 300 nm to a dpp $\pi^* \rightarrow \pi$ intraligand transition. Based on the comparison of the MLCT energies of the [$M(CO)_4$]dpp vs. [$M(CO)_4$]bpym and [$M(CO)_4$]bpy complexes in a common solvent (dichloromethane), the dpp π^* LUMO appears to be approximately equivalent with the bpym π^* LUMO and lower than the bpy π^* LUMO.

The electrochemistry of [$Cr(CO)_4$]dpp and [$W(CO)_4$]dpp in dichloromethane/0.10 M tetrabutylammonium perchlorate is markedly different (Table 2). The [$Cr(CO)_4$]dpp complex exhibits a quasi-reversible ($E_{anodic} - E_{cathodic} = 160$ mV) cyclic voltammogram for a one electron oxidation, while [$W(CO)_4$]dpp exhibits a cyclic voltammogram with no return cathodic wave after one electron oxidation. The electrochemistry of [$W(CO)_4$]dpp is similar to the previously reported electrochemical irreversibility for [$Mo(CO)_4$]dpp,[1] which also exhibited no return cathodic wave following one electron oxidation. The trend of increasing oxidation potentials ([$Cr(CO)_4$]dpp < [$W(CO)_4$]dpp < [$Mo(CO)_4$]dpp) follows the order of the relative electronegativities of the metals.[12] The electrochemistry of the series of [$M(CO)_4$]dpp (M = Cr, Mo, W) parallels the series of [$M(CO)_4$]L (M = Cr, Mo, W, L = 3,3′-bipyrazine) complexes,[3] with only the [$Cr(CO)_4$]L complex showing a return cathodic wave. No comparative data are available for the [$M(CO)_4$]bpym series.

The infrared spectra of the [$Cr(CO)_4$]dpp and [$W(CO)_4$]dpp complexes were recorded as a solid in KBr and reported in Table 2. The spectra in the carbonyl region (2100–1800 cm^{-1}) reflect the four CO stretching frequencies expected for *cis* disubstituted tetracarbonyl complexes.[11,13]

^{13}C NMR spectra for dpp, [$Cr(CO)_4$]dpp and [$W(CO)_4$]dpp were recorded in deuterated dichloromethane (Table 3). The assignments of dpp ligand signals are based on those for bpy[5,6] and bpym ligands.[5,6,15] Assignment of C(6), C(5), C(6′),(6″) and C(4′),(4″) signals for [$M(CO)_4$]dpp complexes is direct, based on the dpp ligand. The comparative amount of downfield shift of C(6′) (Cr > Mo > W) from the free dpp ligand is opposed to the expected values based on inductive M–N–C through bond interaction, since Cr is the least electronegative metal.[12] The smaller amount of downfield shift in the Mo and W dpp complexes may result from more efficient M $d\pi \rightarrow$ dpp $p\pi^*$ backbonding from the larger Mo and W $d\pi$ orbitals.[14] Assignments for the group of four signals

between 120–130 ppm for the C(5′),(5″) and C(3′),(3″) of the $[M(CO)_4]$dpp complexes are less certain. If the continued larger downfield shift of the bond ring carbons (C′) vs. non-bound ring carbon (C″) remains consistent, then the two most downfield signals in the group of four are due to C(3′) and C(5′), while the two upfield signals in the same group must be due to C(3″) and C(5″). The previously reported downfield shift of all bridging ligand ring carbons in $M(CO)_4$ complexes,[5,6] has been interpreted as resulting from competitive $Md\pi \rightarrow COp\pi^*$ vs. $Md\pi \rightarrow$ bridging ligand $p\pi^*$ backbonding.

We have recently prepared the $[Cr(CO)_4]_2$dpp and $[W(CO)_4]_2$dpp complexes and are currently working on the preparation and study of the hetero bimetallic complexes.

DIAMAGNETIC ANISOTROPY OF M≡M BONDED MOLECULES FOR M = Mo OR W: HOW MUCH π IS THERE AND HOW DO WE SLICE IT?

TIMOTHY P. BLATCHFORD, MALCOLM H. CHISHOLM† and JOHN C. HUFFMAN

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, Indiana 47405, U.S.A.

(*Received* 16 *February* 1987; *accepted* 27 *February* 1987)

Abstract—The diamagnetic anisotropies of M≡M bonds for M_2X_6 molecules (M = Mo, W; X = NMe_2, $\frac{1}{2}MeNCH_2CH_2NMe$, OR, $\frac{1}{2}OCMe_2CMe_2O$) calculated by McGlinchey for X=NMe_2 (*Inorg. Chem.* 1980, **19**, 1392) are inadequate to explain the observed chemical shifts of protons located over the M≡M bond in compounds having essentially eclipsed $X_3M{\equiv}MX_3$ skeletons, namely $M_2(MeNCH_2CH_2NMe)_3$ and $M_2(OCMe_2CMe_2O)_3$ molecules. Several causes for errors in the original McGlinchey calculational approach for $\chi_{M\equiv M}$ are noted, the most important of which is the total neglect of the diamagnetic anisotropy of the M–L π bond. This is important for amides and alkoxides. A qualitative correction for this M–L π bonding is introduced and values for $\chi_{M\equiv M}$ recalculated.

Although in 1972 San Filippo[1] indicated that compounds containing metal–metal multiple bonds should have a magnetic anisotropy associated with them which ought to be manifested in their NMR spectra, it was not until recently that efforts to quantify this effect have occurred. Initially qualitative use of this concept was utilized in the interpretation of the NMR spectra of the $M_2(NR_2)_6$ molecules.[2] However, McGlinchey[3] was the first to propose actual values for both the metal–metal triple bond, using the $M_2(NR_2)_6$ molecules as a model, and quadruple bond. Cotton[4] has re-evaluated the magnetic anisotropy of Mo–Mo quadruple bonds based on newer structural and NMR data.

Calculations of values for magnetic anisotropy require three things: (1) quantitative X-ray structural data, (2) measured chemical shift difference from solution NMR spectra and (3) the general equation derived by McConnell,[5] eqn (1).

$$\Delta\sigma_d = \chi\frac{(1-3\cos^2\theta)}{3R^3} \qquad (1)$$

R = distance from M–M bond center to signal nucleus,
θ = angle between R and the M–M bond axis,
σ_d = chemical shift difference,
χ = anisotropy due to M–M bond ($\chi = \chi_\parallel - \chi_\perp$).

Our interest in this area arises from the observed discrepancy (*vide infra*) between values of $\chi_{M\equiv M}$ calculated for $M_2(NR_2)_6$ and $M_2(MeNCH_2CH_2NMe)_3$ molecules (M = Mo, W), respectively. Herein we wish to address this discrepancy in $\chi_{M\equiv M}$ and perhaps provide some insight into the necessary considerations that should enter into obtaining useful values of χ for metal–metal multiple bonded molecules.

RESULTS AND DISCUSSION

$M_2(NR_2)_6$ *and* $M_2(MeNCH_2CH_2NMe)_3$; M = Mo *or* W

McGlinchey's calculated diamagnetic anisotropies for metal–metal triple bonds of molybdenum and tungsten, as determined from the $M_2(NMe_2)_6$ molecules, have given values of $\chi_{M\equiv M}$ of -156×10^{-36} M^3/molecule and -142×10^{-36} M^3/molecule for tungsten and molybdenum, respectively.[3]‡ Analogous calculations on the

† Author to whom correspondence should be addressed.

‡ The more recent literature utilizes SI units, M^3/molecule. To convert from older literature units of cm^3/mole one must multiply by $4\pi\times10^{-6}/N = 2.086\times10^{-29}$, N = Avogadro's Number.

[b] H_1, H_2, H_3—distal; H_4, H_5—proximal.

$M_2(MeNCH_2CH_2NMe)_3$ molecules [see eqn (2), Tables 1 and 2] provide values of $\chi_{W\equiv W} = -63\times10^{-36}$ M^3/molecule and $\chi_{Mo\equiv Mo} = -92\times10^{-36}$ M^3/molecule. These results immediately pose two questions which need to be addressed. (1) Why are these values different from those obtained for the $M_2(NMe_2)_6$ compounds? (2) Why is $\chi_{M\equiv M}$ for tungsten now smaller than $\chi_{M\equiv M}$ for molybdenum? We shall address the initial question first. The answer to question 2 will become self-evident.

$$\sigma_{distal} - \sigma_{proximal} = \chi(G_{distal} - G_{proximal}) \qquad (2)$$

If one were to stop and consider: (a) the geometric differences between the two types of molecules, and (b) some convincing arguments made in the past concerning the stabilities and properties of these types of molecules, several points worthy of note lead us to a possible answer to the first question. (1) The $M_2(NMe_2)_6$ and $M_2(MeNCH_2CH_2NMe)_3$ compounds exhibit staggered and (virtually) eclipsed geometries, respectively. (2) Ligand-to-metal π-bonding is a mainstay of these molecules, and together with steric bulk, the reason for their existence as dinuclear rather than polynuclear species. This M ← L π-bonding is manifested in (i) short metal–nitrogen distances, substantially shorter than metal-nitrogen single bond distances,[7,8] (ii) the planarity of the MNC_2 moieties,[8] (iii) the alignment of the MNC_2 units along the M–M axes in the solid state to preclude competition for use of atomic orbitals used in M–M π-bonding,[8] and (iv) barriers to rotation about the M–N bonds.[9] Oxygen-to-metal π-bonding is similarly important in $M_2(OR)_6$ compounds.

Since M ← L π-bonding is unequivocally established for these compounds, it must be reasonable to consider a magnetic anisotropy attributable to the M≡N bond, $\chi_{M\equiv N}$. Therefore, if two M≡N bonds are eclipsed with respect to one another, e.g. as in $M_2(MeNCH_2CH_2NMe)_3$, then the proximal (protons) groups should be subjected to twice the effect due to any magnetic anisotropy associated with the M–N multiple bond, causing the difference in values of $\chi_{M\equiv M}$ obtained for $M_2(NMe_2)_6$ and $M_2(MeNCH_2CH_2NMe)_3$. This suggests original

[b] Ref. 10.

estimates of $\chi_{M\equiv M}$ inherently contain some component, $\chi_{M=N}$, and that the effect of magnetic anisotropy on chemical shift separations of proximal and distal groups is the sum or difference of $\chi_{M\equiv M}$ (real) and $\chi_{M=N}$, with the contribution of $\chi_{M=N}$ to the proximal chemical shifts dependent upon the positions of the metal–nitrogen bonds relative to one another on opposing metal atoms.

Let us suppose that for eclipsed M—N bonds that two $\chi_{M=N}$ interactions are the same as one $\chi_{M=N}$ for the distal groups, as they are sufficiently removed from the second M—N bond, and are therefore not abnormally shifted, *c.f.* chemical shifts of distal methyl groups in both the $M_2(NMe_2)_6$ and $M_2(MeNCH_2CH_2NMe)_3$ molecules (Table 2). This means only the proximal protons are affected by two $\chi_{M=N}$ interactions when in an eclipsed conformation. Thus, the discrepancies between values for $\chi_{M\equiv M}$ for both molybdenum and tungsten are a result of an extra $\chi_{M=N}$ contribution. Also, the effect of $\chi_{M=N}$ must be antagonistic to the true $\chi_{M\equiv M}$ since the values found for the eclipsed conformers are much smaller than those determined for their staggered counterparts.

Now, assuming the metal–metal triple bonds for both staggered and eclipsed conformations have the same magnetic anisotropy, assigning $\chi_{M\equiv M}$ and $\chi'_{M\equiv M}$ to the values of magnetic anisotropy derived from $M_2(NMe_2)_6$ and $M_2(MeNCH_2NMe)_3$, respectively, we obtain an expression for $\chi_{M=N}$, eqn (3).

$$\chi_{M\equiv M} - \chi'_{M\equiv M} = \chi_{M=N}. \quad (3)$$

Equation (3) generates $\chi_{M=N}$ of -90×10^{-36} M^3/molecule for W and -50×10^{-36} M^3/molecule for Mo. Using these numbers of $\chi_{M=N}$, McGlinchey's $\chi_{M\equiv M}$, and recalling that $\chi_{M=N}$ is antagonistic to $\chi_{M\equiv M}$ (real), we can generate the real $\chi_{M\equiv M}$, $\chi^*_{M\equiv M}$, where any magnetic anisotropy due to M–N multiple bonding has been eliminated, eqn (4).

$$\chi_{M\equiv M} + \chi_{M=N} = \chi^*_{M\equiv M}. \quad (4)$$

The values obtained from this exercise are given in Table 3. These results: (i) account for M–L π-bonding to at least a first approximation, and (ii) maintain the relative ordering of $\chi_{W\equiv W}$ and $\chi_{Mo\equiv Mo}$.

The answer to question 2 now becomes obvious. Due to the better W–N overlap (bond) relative to that found for Mo–N, the effect of $\chi_{W=N}$ is greater than that of $\chi_{Mo=N}$ to the extent that when doubled and subtracted from $\chi^*_{W\equiv W}$ the relative order of $\chi_{M\equiv M}$ for Mo and W, as calculated from $M_2(MeNCH_2CH_2NMe)_3$ is reversed.

Generating useful values of χ

Cotton's recent re-evaluation[4] of $\chi_{Mo\equiv Mo}$ gives results closer to those which might be expected (see Tables 3 and 4). Even though these values are more in line with those anticipated by extrapolation of $\chi_{Mo\equiv Mo}$, they may still be errant. Firstly, one generated value of $\chi_{Mo\equiv Mo}$ is less than $\chi_{Mo\equiv Mo}$, which is unlikely. More reliable estimates may be obtained by taking M ← L π-bonding into account during future calculations. Secondly, the reliability of comparing free ligand chemical shifts to those found in metal–metal multiple bonded systems may be suspect. Efforts to generate $\chi_{M\equiv M}$ using reported chemical shifts of the free ligands and those determined for the proximal protons of the appropriate molecule (see Tables 1, 2 and 5) gave an extremely low value of $\chi_{W\equiv W}$ for $W_2(OC(Me)_2C(Me)_2O)_3$,[10] -44×10^{-36} M^3/molecule. For the $M_2(MeNCH_2CH_2NMe)_3$ molecules values of $\chi_{M\equiv M}$ obtained using this method are -187×10^{-36} M^3/molecule for Mo and -133×10^{-36} M^3/molecule for W. Once again $\chi_{Mo\equiv Mo}$ and $\chi_{W\equiv W}$ are in reverse order, although $\chi_{Mo\equiv Mo}$ is close to our proposed $\chi^*_{Mo\equiv Mo}$. Due to the large difference in results for tungsten, however, we feel the proximity of $\chi_{Mo\equiv Mo}$ to $\chi^*_{Mo\equiv Mo}$, calculated using free ligand chemical shifts, to be fortuitous.

CONCLUDING REMARKS

(1) The use of chemical shift differences between the free and coordinated ligand to calculate $\chi_{M\equiv M}$ gives inadequate results for M = Mo or W. This suggests that this method may not be particularly reliable when applied to other metal–metal multiple bound systems.

(2) Metal–ligand π-bonding should be taken into account when attempting to evaluate $\chi_{M\equiv M}$ in M_2X_6 compounds. Methods for determining the contribution of $\chi_{M=X}$ need to be developed, especially for those molecules that do not easily

lend themselves to separation of χ_{M-M} (real) and $\chi_{M=X}$.

$\chi_{M\equiv M}$ values determined for metal–metal multiple bonded molecules must be taken *cum grano salis* due to difficulties in accounting for: (i) the magnetic anisotropy of metal–ligand π-bonds, (ii) different conformations for otherwise similar molecules, (iii) methods of determining chemical shift differences (free ligand, proximal–distal), and finally that the assumptions inherent in McConnell's derived equation hold true for these inorganic multiple bonded compounds.

Inherent in our arguments is the assumption that $\chi_{M\equiv M}$ is the same for staggered and eclipsed conformations of M_2X_6 molecules. Arguments have previously been presented to support the view that the $\sigma^2\pi^4$ triple bond is invariant to conformation based on: (i) M≡M distances, (ii) M≡M rotational barriers, (iii) U.V.–visible spectroscopy, (iv) photoelectronspectroscopy and (v) theoretical calculations.[6b]

A MECHANISTIC INVESTIGATION ON THE FORMATION OF MOLYBDOPHOSPHATE COMPLEXES IN AQUEOUS SOLUTION BY THE USE OF LASER RAMAN SPECTROSCOPY

KATSUO MURATA* and SHIGERO IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, Japan 560

(*Received* 28 *October* 1986; *accepted after revision* 6 *March* 1987)

Abstract—Two distinct reaction rates were found in the formation of 12-molybdophosphate complex. These differences in the formation processes were understood by the use of laser Raman spectroscopy. The reaction of isopolymolybdate $(MoO_4)^{2-}(MoO_3)_{11}$ with phosphate PO_4^{3-} proceeds slowly *via* formation of 11- molybdophosphate then to produce 12-molybdophosphate taken for 8 min. This reaction mechanism is considered to undergo first the replacement between MoO_4^{2-} and PO_4^{3-} then the transformation reaction from 11-molybdophosphate into 12-molybdophosphate. On the other hand, the acidification of the mixed solution of molybdate and phosphate rapidly produces 80% of 12-molybdophosphate within 30 s.

A reliable method for the analysis of elements such as P, Si, As, and Ge is based on the formation of polynuclear heteropolymolybdate complexes.[1–5] The mechanism of the formation of these complexes is complex.[6,7] Our previous Raman spectroscopic studies revealed the formation behavior of some species of isopolymolybdate[8] and heteropolymolybdate.[9] Our preliminary experiments showed the difference in the formation rate of 12-molybdophosphate by changing the addition order of phosphate, molybdate, and acid. Crouch *et al.* have studied the kinetics of the formation of heteropolymolybdate blue by spectrophotometric measurements.[10] According to their results, the rate of the formation of phosphomolybdate blue product is independent of the acidity but the spectrophotometric investigation does not clarify much about the configurational information of the chemical species in aqueous solution. The blue product was exclusively followed by measuring the absorbance at 650 nm, which gives no structural information. They lately published the spectrophotometric work in the strong acid[11] and using stopped-flow studies.[12]

We have followed the formation of the molybdophosphate complex by the use of laser Raman spectroscopy. This method has brought much information about the appearance and disappearance of several species.[13,14] It could also shed light on the formation mechanisms of molybdophosphate complexes.

EXPERIMENTAL

Reagents and apparatus

A phosphate solution was prepared of potassium dihydrogen phosphate KH_2PO_4 which was dried at 110°C. A molybdate solution was prepared of sodium molybdate $Na_2MoO_4 \cdot 2H_2O$ of analytical reagent grade and standardized by gravimetric analysis.[15] Hydrochloric acid was used to acidify solutions.

Polynuclear molybdophosphate complexes were produced by means of the mixed solutions of phosphate and molybdate. The following two mixing procedures were examined:

(1) the acidified phosphate solution was mixed with the acidified molybdate solution,

* Author to whom correspondence should be addressed.
Present address: Naruto University of Teacher Education, Naruto, Tokushima, Japan 772.

(2) the mixed solution of phosphate and molybdate was acidified with hydrochloric acid.

A conventional quartz cell was used as a reaction chamber which was kept at 25±1°C. A cell stirrer mixed the phosphate solution (2.0×10^{-2} M, pH 1) of 1 cm^3 with the molybdate solution (2.4×10^{-1} M, pH 1) of 1 cm^3.

Raman spectra were measured with JASCO R800, using 514.5 nm (Ar^+ laser) as the excitation source. The instrument was modified for the data treatment and collection equipped with the Sharp MZ-2000 personal computer. Sodium nitrate was used as an internal standard.

RESULTS AND DISCUSSION

There are two procedures to produce the yellow 12-molybdophosphate complex $[PMo_{12}O_{40}]^{3-}$; (1) acidification of the mixed solution of phosphate and molybdate, (2) mixing with the acidified molybdate solution and the acidified phosphate solution. Although both procedures form the species of 12-molybdophosphate, the rates of formation are quite different. As shown in Fig. 1, the latter procedure exhibits the slower rate in the formation of 12-molybdophosphate, which has a typical Raman band at 996 cm^{-1}.[9] The 12-molybdophosphate complex first appears in 1 min 23 s after the acidified molybdate solution of pH 1 is mixed with the acidified phosphate solution of pH 1. Some other species of polynuclear complex appear and disappear during the progress of the reaction before the 12-molybdophosphate is produced. Figure 1 reveals characteristic features that two peaks at 980 cm^{-1} and at 955 cm^{-1} decrease and correspondingly a new peak at 975 cm^{-1} appears in the initial reaction of the acidified molybdate and phosphate. The previous works[8,9] indicated that the species having the peak at 980 cm^{-1} is $Mo_6O_{19}^{2-}$, the species at 955 cm^{-1} is $(MoO_4)^{2-}(MoO_3)_{11}$, and the species at 975 cm^{-1} is $(PO_4)^{3-}(MoO_3)_{11}$. An important fact is that the first heteropolymolybdate complex formed is not the 12-molybdophosphate but 11-molybdophosphate complex of $(PO_4)^{3-}(MoO_3)_{11}$ when the acidified molybdate is mixed with the acidified phosphate solution. The species of $(PO_4)^{3-}(MoO_3)_{11}$ is produced from the species of $Mo_6O_{19}^{2-}$ and $(MoO_4)^{2-}(MoO_3)_{11}$. The species of 11-molybdophosphate subsequently transforms into 12-molybdophosphate complex: increasing the intensity at 996 cm^{-1} while decreasing the intensity at 975 cm^{-1} observed in the Raman spectra shown in Fig. 1. As shown in Fig. 2, the appearance and disappearance of three species of 11-isopolymolybdate, 11-molybdophosphate, and 12-molybdophosphate were also followed at the constant wavenumber of 955, 975 and 996 cm^{-1}, respectively. Figure 2 clearly indicates that the first heteropolymolybdate formed is not 12-molybdophosphate but 11-molybdophosphate complex. The 12-molybdophosphate complex forms gradually after an induction period of 1 min where 11-molybdophosphate complex is predominantly

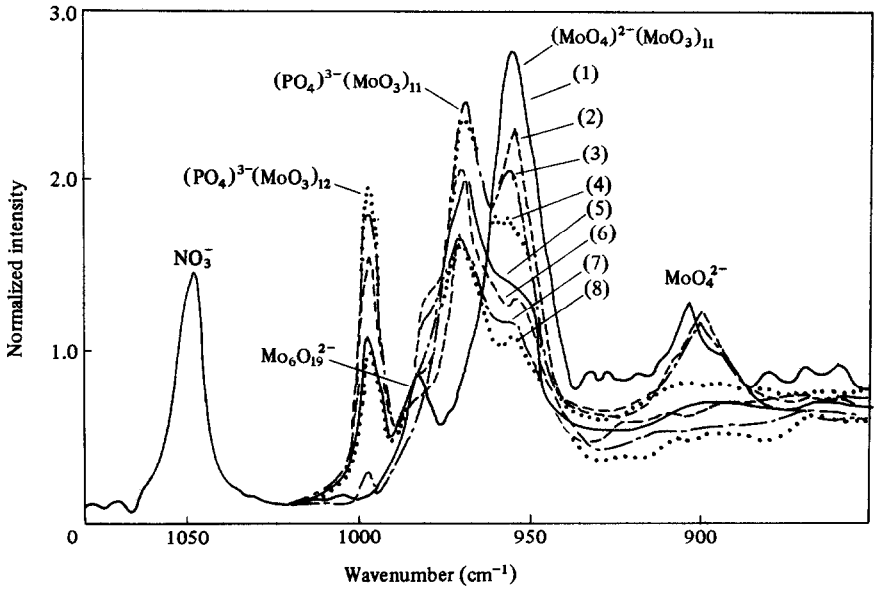

Fig. 1. The reaction of the acidified molybdate with the acidified phosphate solution on Raman spectra ([P] = 1.0×10^{-2} M, [Mo] = 1.2×10^{-1} M, pH 1). The reaction time: (1) 0 s, (2) 31 s, (3) 1 min 23 s, (4) 2 min 14 s, (5) 3 min 5 s, (6) 4 min 47 s, (7) 5 min 38 s, (8) 6 min 29 s.

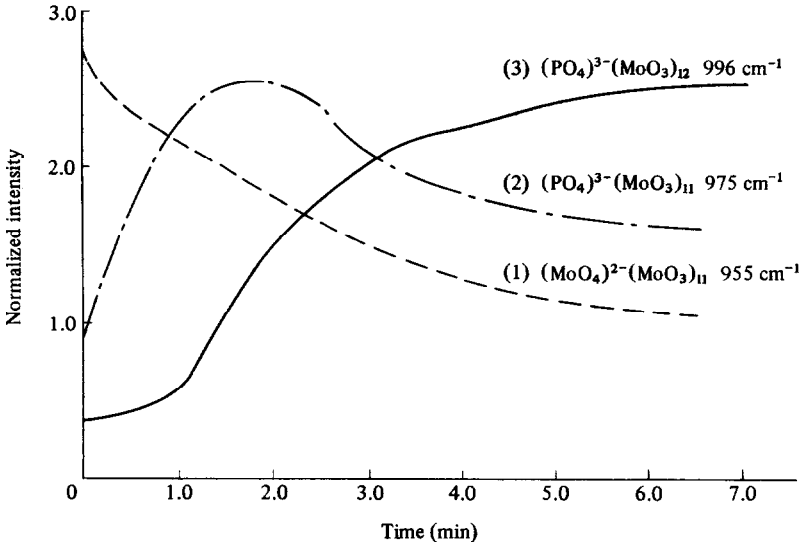

Fig. 2. Formation and decomposition curves of three species observed at each wavenumber. (1) $(MoO_4)^{2-}(MoO_3)_{11}$ at 955 cm^{-1}, (2) $(PO_4)^{3-}(MoO_3)_{11}$ at 975 cm^{-1}, (3) $[PMoO_{40}]^{3-}$ at 996 cm^{-1}.

produced. The formation of the 12-molybdophosphate was completed in 10 min.

On the other hand, the formation rate of the 12-molybdophosphate is extremely fast when the mixed solution of molybdate and phosphate ([P] = 1.0×10^{-2} M, [Mo] = 1.2×10^{-1} M) is acidified to pH 1 as shown in Fig. 3. Within only 31 s, the formation product of 12-molybdophosphate complex proceeds up to 80% of the total amount. After that, the incremental rate is slowed to 20 min 30 s. This contrast in behavior in the formation of the 12-molybdophosphate complex suggests to us the formation mechanism of the heteropoly complex. The acidified molybdate solution of pH 1 contains the predominant species of $(MoO_4)^{2-}(MoO_3)_{11}$ and the minor species of $Mo_6O_{19}^{2-}$.[8] In order to form 11-molybdophosphate from the species PO_4^{3-} and $(MoO_4)^{2-}(MoO_3)_{11}$, the unit of MoO_4^{2-} in the species of $(MoO_4)^{2-}(MoO_3)_{11}$ should be replaced by the unit of PO_4^{3-}. Then this 11-molybdophosphate of $(PO_4)^{3-}(MoO_3)_{11}$ formed should be transformed into 12-molybdophosphate of $[PMo_{12}O_{40}]^{3-}$ like

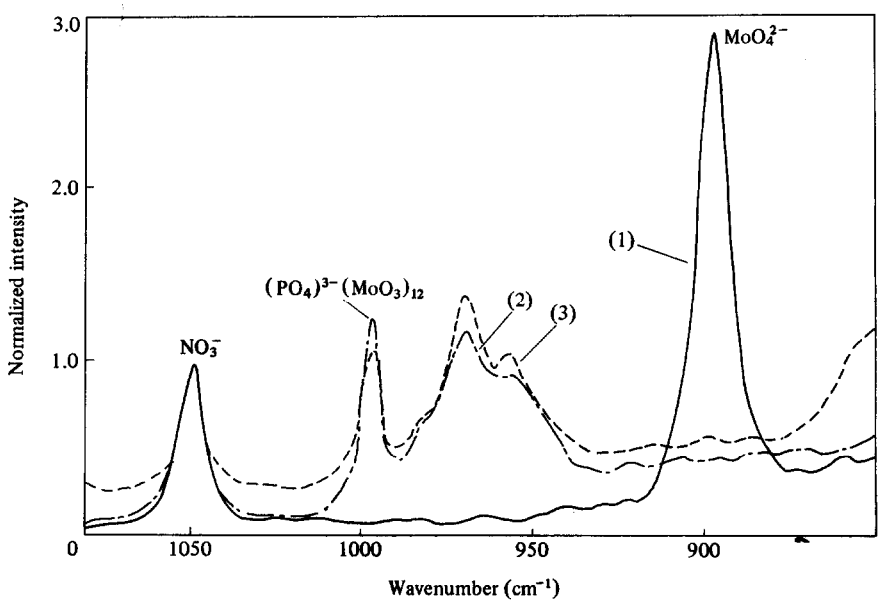

Fig. 3. The acidification of the mixed solution of molybdate and phosphate ([P] = 1.0×10^{-2} M, [Mo] = 1.2×10^{-1} M, pH 1). The reaction time: (1) 0 s, (2) 31 s, (3) 20 min 30 s.

eqns (1) and (2). This formation step takes a considerable time since it proceeds *via* the formation of the 11-molybdophosphate. The observation that the MoO_4^{2-} species appeared around 900 cm^{-1} also supports this mechanism. The MoO_4^{2-} group in the isopolymolybdate species of $(MoO_4)^{2-}(MoO_3)_{11}$ has a Raman peak at 903 cm^{-1} as shown in Fig. 1. In the reaction of isopolymolybdate with phosphate PO_4^{3-}, the free MoO_4^{2-} group is released, giving a band at 897 cm^{-1} in the Raman spectra. The free MoO_4^{2-} disappears again because it is used up to produce the 12-molybdophosphate like in eqn (2). Figure 1 shows no Raman peak of free ion MoO_4^{2-} around 900 cm^{-1} where 12-molybdophosphate is predominantly produced.

$$(MoO_4)^{2-}(MoO_3)_{11}+PO_4^{3-} \rightleftarrows (PO_4)^{3-}(MoO_3)_{11}+MoO_4^{2-} \quad (1)$$

$$(PO_4)^{3-}(MoO_3)_{11}+MoO_4^{2-}+2H^+ \rightleftarrows [PMo_{12}O_{40}]^{3-}+H_2O. \quad (2)$$

In the case of acidifying the mixed solution of molybdate and phosphate, the 12-molybdophosphate is directly formed by the process that the core phosphate shares some molybdate cluster of $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$, and $Mo_6O_{19}^{2-}$.[16,17] The formation rate of 12-molybdophosphate is extremely rapid. It is too fast to observe the initial formation behavior since the maximum scan rate of JASCO R800 is 31 s over 200 cm^{-1}. However the following features are obvious. The MoO_4^{2-} species which appeared at 897 cm^{-1} is completely consumed to construct 12-molybdophosphate by acidification as shown in Fig. 3. Around 80% yield of 12-molybdophosphate is attained within 31 s.

These findings suggest the formation mechanisms of isopoly- and heteropolymolybdate. As described in previous work,[9] the optimum acidity of 12-molybdophosphate is around pH 1. When the hetero group anion like PO_4^{3-} is not present in the acidic molybdate solution, isopolymolybdate grows to the large species[8] of $(MoO_4)^{2-}(MoO_3)_{11}$ as given in eqn (3).

$$12MoO_4^{2-}+22H^+ \rightleftarrows (MoO_4)^{2-}(MoO_3)_{11}+11H_2O. \quad (3)$$

Once this large isopolymolybdate species forms in aqueous solution, the formation rate of 12-molybdophosphate $[PMo_{12}O_{40}]^{3-}$ becomes slower because two processes should be gone through: at first the substitution of the MoO_4^{2-} group in $(MoO_4)^{2-}(MoO_3)_{11}$ by PO_4^{3-} group and then the transformation of the formed $(PO_4)^{3-}(MoO_3)_{11}$ into 12-molybdophosphate of $(PO_4)^{3-}(MoO_3)_{12}$ as given in eqns (1) and (2). However the 12-molybdophosphate forms rapidly when the molybdate solution initially contains phosphate PO_4^{3-} as shown in Fig. 3. In this case it is unnecessary to substitute MoO_4^{2-} by PO_4^{3-}. The PO_4^{3-} group directly constructs the 12-molybdophosphate of Keggin structure[18] by the surrounding molybdate clusters: $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$, and $Mo_6O_{19}^{2-}$ which are produced by acidification of the molybdate solution.[8,16,19] Despite the relative complexity of these polymolybdate ions, the steps leading to their formation are complete within a few milliseconds.[20,21] In the case of acidification of the mixed solution of phosphate and molybdate, a basic question is whether the heteropoly complex is formed from an initial reaction of phosphate with the monomer MoO_4^{2-} and subsequent polymerization as given in eqn (4) or from an initial polymerization of molybdate followed by a condensation reaction with PO_4^{3-} as given in eqns (5), (6) and (7).

$$12MoO_4^{2-}+PO_4^{3-}+24H^+ \rightleftarrows [PMo_{12}O_{40}]^{3-}+12H_2O \quad (4)$$

$$\begin{cases} 7MoO_4^{2-}+8H^+ \rightleftarrows Mo_7O_{24}^{6-}+4H_2O \\ 7PO_4^{3-}+12Mo_7O_{24}^{6-}+72H^+ \end{cases} \rightleftarrows 7[PMo_{12}O_{40}]^{3-}+36H_2O \quad (5)$$

$$\begin{cases} 8MoO_4^{2-}+12H^+ \rightleftarrows Mo_8O_{26}^{4-}+6H_2O \\ 2PO_4^{3-}+3Mo_8O_{26}^{4-}+12H^+ \end{cases} \rightleftarrows 2[PMo_{12}O_{40}]^{3-}+6H_2O \quad (6)$$

$$\begin{cases} 6MoO_4^{2-}+10H^+ \rightleftarrows Mo_6O_{19}^{2-}+5H_2O \\ PO_4^{3-}+2Mo_6O_{19}^{2-}+4H^+ \end{cases} \rightleftarrows [PMo_{12}O_{40}]^{3-}+2H_2O. \quad (7)$$

There is no evidence in the Raman spectra that the PO_4^{3-} group initially reacts with the monomer MoO_4^{2-} as given in eqn (4). But the interaction between the PO_4^{3-} and isopolymolybdate has been observed.[9,22,23] Moreover the existence of the species $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$, and $Mo_6O_{19}^{2-}$ has been investigated and established by several authors.[8,24–26] The latter cases of eqns (5), (6) and (7) seem likely because each isopolymolybdate forms easily and rapidly as above mentioned.

Acknowledgements—Dr. Katsuo Murata wishes to express his thanks to Prof. Donald E. Irish and members of University of Waterloo, Canada for their contributions and hospitality during his stay when this manuscript was finalized. The authors express their thanks to Dr. Iwao Watanabe for electronic modification of the Raman spectroscopic instrument.

METAL AND ORGANOMETAL COMPLEXES OF OXY- AND THIO-PHOSPHORUS ACIDS—I. O,O-ALKYLENE AND DIALKYL DITHIOPHOSPHATES OF TITANIUM(IV)

J. S. YADAV, R. K. MEHROTRA and G. SRIVASTAVA*

The Chemical Laboratories, University of Rajasthan, Jaipur-302 004, India

(*Received* 19 *September* 1986; *accepted after revision* 17 *March* 1987)

Abstract—O,O-Alkylene and dialkyl dithiophosphates of titanium(IV), $Cl_{4-n}Ti(dtp)_n$ [$n = 2$, 3 and 4; dtp = $S(S)\overline{POCMe_2CMe_2O}$ or $S(S)P(OEt)_2$; $n = 4$ and dtp = $S(S)\overline{POCHMeCHMeO}$, $S(S)\overline{POCH_2CMe_2CH_2O}$ and $S(S)P(OPr^i)_2$] have been synthesized by the reactions of titanium tetrachloride with ammonium or sodium salts of O,O-alkylene and dialkyl dithiophosphoric acids in appropriate stoichiometric ratios in refluxing benzene. All these complexes are hydrolysable, dark red semi-solids or viscous liquids and are soluble in common organic solvents when freshly prepared. Ionic tetrachlorodithiophosphatotitanate(IV) complexes, $[M]^+[TiCl_4(S_2\overline{POCMe_2CMe_2O})]^-$ (M = ammonium or pyridinium) have been obtained as insoluble yellow solids by mixing the reactants in equimolar ratios. All of these compounds have been characterized by elemental analyses, IR and NMR (^1H, ^{13}C and ^{31}P) spectral studies. A few codisproportionation reactions of these dithiophosphato complexes have also been studied by ^{31}P NMR spectroscopy.

The coordination chemistry of titanium(IV) with oxygen donor ligands is confined mainly to 6-coordinate octahedral complexes. Thus, the reaction of titanium tetrachloride with excess acetylacetone stops after the formation of octahedral dichlorotitanium bis(acetylacetonate), $TiCl_2(acac)_2$ as the final product.[1] Similarly 1 : 1 complexes of the type $TiCl_4 \cdot OPCl_3$[2] and $TiCl_4 \cdot CH_3COOEt$[3] dimerise through chlorine bridges to give octahedral structures.

Although titanium is a class A metal, it lies closer to the border-line of class A/class B character and forms a variety of stable complexes with sulphur donor ligands. Among these, titanium(IV) complexes of 1,1′-dithio ligands, particularly *N*,*N*-dialkyldithiocarbamic acids, have generated much interest in recent years.[4] In contrast to β-diketones, the dithiocarbamate ligands have been found to stabilise higher coordination states of titanium, probably due to their low charge and small bite. Thus derivatives of the type $Cl_2Ti(S_2CNR_2)_2$,[5] $ClTi(S_2CNR_2)_3$[6] and $Ti(S_2CNR_2)_4$[7] have been shown to contain 6-, 7- and 8-coordinated titanium atoms, respectively.

O,O-Dialkyl (and alkylene) dithiophosphoric acids behave as versatile dithio ligands[8] and form a variety of complexes with transition[9] as well as non-transition[10] elements. Surprisingly, except for some preliminary investigations[11] on reactions of titanium tetrachloride with ammonium diethyl and diisopropyl dithiophosphates, no systematic work on dithiophosphato complexes of group IV transition metals has been carried out as yet. The present communication deals with the synthesis and characterization of some acyclic and cyclic tetrakis dithiophosphates and mixed chloride dithiophosphates of titanium(IV).

EXPERIMENTAL

Owing to the extremely hydrolysable nature of the derivatives of titanium(IV), rigorous precautions were taken to exclude moisture during experimental manipulations. Solvents (benzene, chloroform, pyridine and DMF) and alcohols (ethanol and isopropanol) were dried before use by standard methods. Titanium tetrachloride (E.

* Author to whom correspondence should be addressed.

Merck) was distilled (b.p. 136.4°C) before use. O,O-Dialkyl[12] and alkylene[13] dithiophosphoric acids and their ammonium/sodium salts were prepared by methods reported in the literature. Sulphur was estimated gravimetrically as barium sulphate. Titanium was estimated as titanium oxide by the cupferon method. Phosphorus was estimated as ammonium magnesium phosphate hexahydrate and chlorine by Volhard's method.

IR spectra were recorded as neat liquids or nujol mulls using a Perkin–Elmer 577 spectrometer in the range 4000–200 cm^{-1} with CsI cell windows. ^1H NMR spectra were recorded in chloroform using a Perkin–Elmer R12B spectrometer using TMS as an external standard. ^{31}P and ^{13}C NMR spectra were recorded in chloroform/benzene using a Jeol FX 90 Q spectrometer with H_3PO_4 and TMS as external standards, respectively.

Synthetic methods

(1) *Reaction of titanium tetrachloride with ammonium O,O-tetramethylethylene dithiophosphate in 1 : 1 molar ratio.* On mixing a suspension of ammonium O,O-tetramethylethylene dithiophosphate (1.35 g, 5.89 mmol) in benzene (~ 30 cm^3) with titanium tetrachloride (1.10 g, 5.79 mmol) in the same solvent (~ 20 cm^3), the solution turned red immediately and an orange solid was precipitated out. The reaction mixture was refluxed for ~ 3 h and the product separated by filtration, washed several times with benzene and dried under reduced pressure to yield an orange powdery solid (2.44 g, 92%), m.p. 206°C. Found: Ti, 11.5; S, 15.3; P, 7.3; Cl, 29.3. Calc. for $C_6H_{16}Cl_4NO_2PS_2Ti$: Ti, 11.4; S, 15.3; P, 7.4; Cl, 29.5%.

(2) *Reaction of titanium tetrachloride with O,O-tetramethylethylene dithiophosphoric acid in presence of pyridine in 1 : 1 molar ratio.* Titanium tetrachloride (0.98 g, 5.16 mmol) in benzene (~ 20 cm^3) was added to O,O-tetramethylethylene dithiophosphoric acid (1.11 g, 5.23 mmol) in ~ 30 cm^3 benzene resulting into a red solution. An orange precipitate was formed on adding pyridine (0.41 g, 5.18 mmol) in ~ 20 cm^3 benzene drop by drop with constant stirring to the above. The contents were stirred for ~ 3 h at room temperature to ensure the completion of the reaction. The precipitate (2.15 gm, 86%) was filtered, washed with benzene and dried under reduced pressure yielding an orange powdery solid, m.p. 196°C. Found: Ti, 10.0; S, 13.3. Calc. for $C_{11}H_{18}Cl_4NO_2PS_2Ti$: Ti, 10.0; S, 13.3%.

(3) *Reactions of titanium tetrachloride with ammonium/sodium O,O-alkylene and dialkyl dithiophosphates in 1 : ⩾ 2 molar ratios.* Titanium tetrachloride in benzene was added to a suspension of ammonium/sodium alkylene or dialkyl dithiophosphate in benzene in different molar ratios (1 : 2, 1 : 3 and 1 : 4). The reaction mixture was refluxed for ~ 3 h and the precipitated ammonium/sodium chloride was removed by filtration, followed by removal of solvent under reduced pressure. The product was finally washed with *n*-hexane and dried.

The relevant data for the above reactions have been summarised in Table 1.

RESULTS AND DISCUSSION

Titanium tetrachloride reacts readily with ammonium O,O-tetramethylethylene dithiophosphate in equimolar ratio in benzene at ambient temperature with precipitation of a 1 : 1 complex, ammonium dithiophosphatotetrachlorotitanate, **I**. A similar pyridinium complex, **II** was also obtained on adding pyridine to an equimolar mixture of titanium tetrachloride and tetramethylethylene dithiophosphoric acid in benzene.

$$TiCl_4 + NH_4S_2\overline{POCMe_2CMe_2O} \rightarrow [NH_4]^+[Cl_4TiS_2\overline{POCMe_2CMe_2O}]^-$$

I

$$TiCl_4 + HS_2\overline{POCMe_2CMe_2O} + C_5H_5N \rightarrow [C_5H_5NH]^+[Cl_4TiS_2\overline{POCMe_2CMe_2O}]^-.$$

II

Both the above complexes are orange solids, insoluble in common organic solvents but soluble in dimethylformamide (DMF). The attachment of the dithiophosphate moiety to titanium is readily indicated by the presence of absorption at 350 and 390 cm^{-1} in the IR spectra of these compounds which could be assigned to ν Ti–S and ν Ti–Cl, respectively. It may be pointed out that anionic titanate complexes containing hexacoordinated titanium, e.g. $[TiX_6]^{2-}$, X = F, Cl and Br and $[TiCl_5(H_2O)]^-$, are well known.[14] The titanate complexes described here may also contain a similar hexacoordinated titanium due to the well known bidentate behaviour of the dithiophosphate moiety.

Interestingly, the ^{31}P NMR chemical shifts of these complexes (**I** and **II**) in DMF are 123.6 and 123.8 ppm respectively which are similar to the values obtained for O,O-tetramethylethylene dithiophosphate anion in the ionic salts (e.g. ammonium tetramethylethylene dithiophosphate shows a shift of 123.8 ppm in DMF). Thus, the ^{31}P NMR data indicate that in DMF solution, the titanate com-

plexes undergo solvolysis to generate dithiophosphate anions:

$$[Cl_4TiS_2\overline{POCMe_2CMe_2O}]^- + 2DMF \rightarrow Cl_4Ti \cdot 2DMF + [S_2\overline{POCMe_2CMe_2O}]^-$$

The above solvolysis is further indicated by the conductivity data of complexes **I** and **II**. The molar conductance values (73.0 and 71.2 $ohm^{-1}\ cm^{-1}\ mol^{-1}$, respectively) for 0.01 M DMF solutions of these are almost identical to the values observed for ammonium and pyridinium dithiophosphates (70.3 and 71.7 $ohm^{-1}\ cm^{-1}\ mol^{-1}$, respectively) under similar conditions and these values are consistent with their 1 : 1 electrolytic nature.[15,16] Formation of a stable nonionic 1 : 2 complex between $TiCl_4$ and DMF has already been reported[17] in the literature.

Reactions of ammonium O,O-tetramethylethylene dithiophosphate with titanium tetrachloride in higher than equimolar ratios in refluxing benzene result in replacement of the chlorines by dithiophosphate moieties and by adjusting the molar ratios of the reactants, the bis-, tris- and tetrakis-(dithiophosphates) of titanium can be prepared.

$$TiCl_4 + n NH_4S_2\overline{POCMe_2CMe_2O} \rightarrow Cl_{4-n}Ti[S_2\overline{POCMe_2CMe_2O}]_n + n NH_4Cl$$

III, $n = 2$
IV, $n = 3$
V, $n = 4$.

The products are obtained by filtering off ammonium chloride, removing the solvent and washing the residue with *n*-hexane. These replacement reactions are rather slow. The bis-derivative is obtained in poor yield and for the tetrakis-derivative, a slight excess of the ammonium dithiophosphate and longer refluxing period is required. It seems that ammonium tetrachlorodithiophosphatotitanate (formed initially) and ammonium dithiophosphate are both insoluble in benzene and would react quite sluggishly resulting in a low yield of titanium dichloride bis(dithiophosphate).

The above route was employed for the synthesis of additional examples of titanium tetrakis-(cyclic dithiophosphates):

$$TiCl_4 + 4NH_4dtp \rightarrow Ti(dtp)_4 + 4NH_4Cl$$

VI, dtp = $S_2\overline{POCHMeCHMeO}$
VII, dtp = $S_2\overline{POCH_2CMe_2CH_2O}$

For the sake of comparison, a few selected examples of acyclic dithiophosphate derivatives of titanium have also been prepared by the reaction of titanium tetrachloride with sodium dialkyldithiophosphates in refluxing benzene:

$$TiCl_4 + n Nadtp \rightarrow Cl_{4-n}Ti(dtp)_n + n NaCl$$

VIII, $n = 2$, dtp = $S_2P(OEt)_2$
IX, $n = 3$, dtp = $S_2P(OEt)_2$
X, $n = 4$, dtp = $S_2P(OEt)_2$
XI, $n = 4$, dtp = $S_2P(OPr^i)_2$.

The above reactions appear to be faster than the corresponding reactions of ammonium cyclic dithiophosphates and require less refluxing time.

All of the above dithiophosphate derivatives (**III**–**XI**) are yellowish-red semisolids or highly viscous liquids which are miscible with benzene and chloroform but immiscible with *n*-hexane and can be purified by washing with the latter solvent. These compounds are very susceptible to hydrolysis. The intense colour of the complexes is indicative of the high polarizing capacity of the small titanium atom. For comparison, it may be mentioned that similar complexes of zirconium are white solids.

The purity of these compounds was easily checked by their proton decoupled ^{31}P NMR spectra which show only a single peak. The mixed acyclic derivative **VIII**, however, appears to be prone to disproportionation. The freshly prepared compound in benzene (after filtering off the precipitated sodium chloride) shows a single ^{31}P NMR peak at 84.4 ppm. However, on removing the solvent and redissolving it in benzene after a few days, the compound shows peaks at 88.0, 87.4, 85.7 and 84.2 ppm, thus indicating the presence of all the four disproportionation products $Cl_nTi[S_2P(OEt)_2]_{4-n}$, $n = 0$, 1, 2 and 3. The corresponding cyclic derivative **III**, on the other hand, does not show any tendency to disproportionate under similar conditions.

The highly viscous and hydrolysable nature of titanium dithiophosphates precluded any attempt to determine their molecular weights. The dithiophosphate moieties were changed with the unfulfilled hope to get a crystalline sample for X-ray diffraction data. Titanium(IV) dithiophosphates also show ageing effect, on keeping for longer periods in stoppered flasks at room temperature, their colour is darkened and the solubility in benzene is reduced. The ageing effect is more pronounced in the open chain derivatives which are converted into intractable solids in about a month.

The derivatives **III**–**XI** have been subjected to IR and multinuclear NMR (^1H, ^{13}C and ^{31}P) spectral studies and data are summarised in Table 2.

Table 2. ^{1}H, ^{31}P and ^{13}C NMR spectral data for titanium(IV) O,O-alkylene and dialkyl dithiophosphates

Compound number	^{1}H chemical shift[a] in δ ppm (in chloroform)	^{31}P chemical shift in δ ppm (in benzene)	^{13}C chemical shift[b] in δ ppm
III	1.50, s	94.4	90.63, s (O<u>C</u>—) 23.64, d, (<u>C</u>H$_3$) J = 6.10 Hz
IV	1.40, s	93.7	90.50, s, (O<u>C</u>—) 23.86, d (CH$_3$) J = 6.10 Hz
V	1.45, s	92.4	90.53, s, (O<u>C</u>—) 23.67, d (<u>C</u>H$_3$) J = 4.88 Hz
VI	—	96.4, 95.0	
VII	1.05, S, 24H(-CH$_3$) 3.95, d (J = 15 Hz), 16H (-CH$_2$O)	76.5	
VIII	1.25, t (J = 7 Hz), 12H(–CH$_3$) 3.80–4.50, dq (J = 10 and 6 Hz), 8H(-CH$_2$O)	84.4	
IX	1.20, t (J = 7 Hz), 18H (-CH$_3$) 3.70–4.40, dq (J = 10 and 6 Hz), 12H (-CH$_2$O)	87.3	
X	1.25, t (J = 7 Hz), 24H (-CH$_3$) 3.80–4.50, dq (J = 11 and 6.5 Hz), 16H (-CH$_2$O)	85.6	
XI	1.25, d (J = 6 Hz), 48H (-CH$_3$) 4.40–5.00, m, 8H (-CHO)	82.3	

[a] s = singlet, d = doublet, t = triplet, dq = double quartet and m = multiplet.
[b] III and IV in chloroform, V in benzene.

Infra-red spectral studies

Due to their immiscibility with nujol, suitable mulls for IR spectral study could be made with difficulty. The assignment of relevant peaks have been made on the basis of published literature[9,10,18] on other metal dithiophosphates and on titanium-sulphur bonded compounds.[5,19] A comparison of the spectra of parent ligands (O,O-alkylene and dialkyl dithiophosphoric acids) and the corresponding titanium derivatives reveal the following observations:

(i) The bands due to ν (P)–O–C and ν P–O–(C) present in the region 1150–980 cm^{-1} and 835–770 cm^{-1}, respectively in the parent acids do not show any change in the titanium complexes. In the cyclic derivatives the strong intensity band present at $\sim$ 950 cm^{-1} and attributed to ring vibrations (probably coupled with C–C-stretching vibrations[20,21]) similarly remains unchanged on complexation.

(ii) The band due to ν P=S present at 670–630 cm^{-1} in the acyclic[9] and at 690–670 cm^{-1} in the cyclic[13] derivatives shows a small but notable shift ($\Delta\nu$ = 20–10 cm^{-1}) to lower frequencies in the titanium complexes indicating the involvement of the thiophosphoryl sulphur in bonding to the metal atom.

(iii) All of the titanium complexes have a new band of weak intensity in the region 360–340 cm^{-1} which may be assigned to ν Ti–S vibrations.[5,19] In the complexes **VIII–X**, a regular lowering of this band (**VIII**, 335 cm^{-1}, **IX**, 325 cm^{-1}, **X**, 320 cm^{-1}) may be associated with an increase in the coordination number of titanium atom.

(iv) In the spectra of all the mixed chloride dithiophosphate derivatives, a low intensity band is present in the ν Ti–Cl region of 400–380 cm^{-1}. The position of this band in the monochloride derivative is lower than in the dichloride derivative (e.g. **IX**, 380 cm^{-1}, **VIII**, 400 cm^{-1}) and this may again be attributed to the higher coordination number of titanium in the former.[22]

NMR spectral studies

The ^{1}H and ^{13}C NMR spectra of titanium complexes are remarkably similar to those of the ligand dithiophosphoric acids, probably due to the large distance between the metal atom and these nuclei.

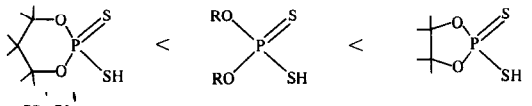
The spectra, however, indicate the presence of single species in each case.

In the ^1H NMR spectra, the signal due to S–H proton is as expected absent. The tetramethylethylene dithiophosphate derivatives show only a singlet, thus indicating negligible ^4J P–H coupling. All other derivatives, however, have hydrogens attached to the α-carbon atoms of the alkoxy or glycoxy groups and these show coupling with phosphorus (^3J P–H being in the range 10–15 Hz).

The ^{13}C NMR spectra of only the tetramethylethylene derivatives (**III** and **IV** in chloroform and **V** in benzene) were measured. In these, the tertiary carbons appears as singlet at ~ 90.5 ppm and the methyl carbons give a doublet around 23.7 ppm, thus showing that whereas there is no observable two-bond C–P coupling, the corresponding three-bond coupling is present in the range of 4–6 Hz. It may be mentioned that in the parent acid (tetramethylethylene dithiophosphoric acid in CCl_4), the coupling of both the types of carbons with phosphorus is observed ($^2J = 2.44$; $^3J = 4.88$ Hz). Interestingly, the ^3J C–P value remains the same in tetrakis-derivative **V**, but increases to 6.66 Hz in the mixed chloride dithiophosphate derivatives (**III** and **IV**).

^{31}P NMR studies of titanium dithiophosphates (Table 2) lead to the following observations:

(i) The chemical shifts of O,O-alkylene and dialkyl dithiophosphoric acids increase in the following order:



Phosphorus in 6-membered 1,3,2-dioxaphosphorinanes is more shielded where as the same in 5-membered 1,3,2-dioxaphospholanes is less shielded than phosphorus in the corresponding acyclic compounds. Such observations have been made before also with different phosphorinanes and phospholanes.[23]

(ii) The ^{31}P shifts for titanium dithiophosphate complexes are surprisingly almost in the same range as those for the parent acids.

(iii) In tetramethylethylene dithiophosphate complexes (**III–V**), the chemical shift increases, although only slightly, with increasing number of chlorine at the metal. In open chain comlexes also, the same pattern is obtained with the exception of the dichloro derivative.

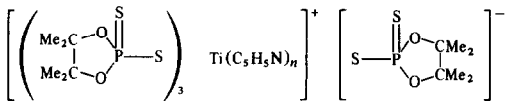
(iv) All compounds give a single peak when freshly prepared except **IX** (which appears to be contaminated with the tetrakis derivative) and **VI** which may be present as a mixture of diasterioisomers.

(v) Titanium tetrakis (tetramethylethylene dithiophoshate) (**V**) shows ^{31}P signal at 92.4 ppm in benzene. However, in pyridine, it shows two peaks, one of lower intensity at 123.9 ppm and another of higher intensity at 71.3 ppm.

Phosphorus chemical shifts of various metal dithiohosphate complexes have been reported in recent years and an attempt has also been made by Glidewell[24] to correlate the shifts in metal diisopropyl dithiophosphates with the bonding behaviour (monodentate, bidentate or ionic) of the ligand. It was suggested that phosphorus deshielding increases in the order monodentate attachment < bidentate attachment < $[(Pr^iO)_2PS_2]^-$ anion.

Phosphorus chemical shifts in general depend on many factors (e.g. bond angle, steric effect, size of the ring and electronegativity of attached groups)[23,25] and our attempts to correlate the same in metal alkylene dithiophosphates on the lines of Glidewell have not been successful. For example, trimethyltin tetramethylethylene dithiophosphate and dimethyltin bis(tetramethylethylene dithiophosphate) have been shown to contain 4- and 6-coordinated tin respectively on the basis of ^{119}Sn NMR shifts and also by $^1J^{13}C^{-119}Sn$ values.[26] However, the ^{31}P chemical shifts of these two compounds are almost the same (104.5 and 102.1 ppm, respectively).[26]

We, therefore, believe that in titanium dialkyl dithiophosphates also, the ^{31}P chemical shifts are helpful in identification and determination of the purity of compounds, but one should be very cautious in correlating these with the structural features of the compounds. However, the observations that ^{31}P signal of the derivative **V** in pyridine splits into two peaks (one upfield at 71.3 and other down field at 123.9 ppm) can be correlated with the formation of an ionic species of the type **XII** in which there are three monodentate and one ionic dithiophosphate moieties. It is thus an indirect proof of the bidentate



XII

behaviour of all the ligand moieties towards titanium in non polar solvents or in neat compounds. It may be pointed out that a change from bidentate to monodentate behaviour of dithiophosphate moieties in transition metal complexes in the presence of a stronger coordinating ligand has been recorded before. Thus, tetra coordinate $Ni[S_2P(OMe)_2]_2$ forms a 5-coordinate 1 : 1 complex with the bidentate ligand 2,9-dimethyl-1,10-phenanthroline, the crystal structure of which shows one

of the dtp ligands being monodentate.[27] Similarly, palladium and platinum complexes, $M[S_2P(OEt)_2]_2$ react with tertiary phosphines by stepwise cleavage of metal–sulphur bonds to form 4-coordinate 1 : 1 and 1 : 2 adducts having unidentate-bidentate and bidentate-ionic dtp ligands, respectively.[28]

The known titanium-sulphur bonded compounds are very limited in number and in all these cases, titanium shows an enhanced tendency to increase its coordination number. Titanium tetrathiolates are oligomeric in nature (with suggested coordination number eight);[29] the dithiocarbamates, on the other hand, are monomeric with the ligand always acting as bidentate. In case of titanium dithiophosphates also, the IR and ^{31}P NMR spectroscopic data, as discussed earlier, point towards bidentate attachment of the ligand moieties.

Further, due to the similarity between dithiocarbamate and dithiophosphate moieties, the titanium dithiophosphate complexes are expected to be structurally similar to the corresponding dithiocarbamate complexes. On the basis of this comparison the dichloride bis-(dithiophosphate) complexes should be six coordinated octahedral, the monochloride tris-(dithiophosphates) should be 7-coordinated pentagonal bipyramidal and the tetrakis-(dithiophosphates) should be 8-coordinated dodecahedral. The octahedral dichloro bis-(chelate) complexes of titanium (e.g. $Ti(acac)_2Cl_2$,[30] $Ti(dtc)_2Cl_2$[6a] etc.) have invariably *cis* geometry and the same may be expected for the $Ti(dtp)_2Cl_2$ complexes also.

As described earlier, the NMR (^{31}P, ^{13}C and ^1H) data for all the dithiophosphate derivatives of titanium show the presence of only one type of ligand moiety in the molecule at ambient temperature and, thus, indicate the stereochemical non-rigidity of the complexes. Unfortunately variable temperature NMR studies could not be carried out due to lack of facilities. However, it may be worthwhile to mention here that the corresponding dithiocarbamate complexes $Ti(S_2CNR_2)_nCl_{4-n}$ are also stereochemically non-rigid and their variable temperature NMR spectra show that R groups remain equivalent over the temperature range +40 to −90°C.[6a]

(*Received* 17 *November* 1986; *accepted after revision* 17 *March* 1987)

Abstract—The molecular structure of a new osmium–silver complex is reported. The compound crystallizes in space group $P\bar{1}$ with $a = 14.486(3)$ Å, $b = 14.711(3)$ Å, $c = 10.233(2)$ Å, $\alpha = 95.55(2)°$, $\beta = 98.75(2)°$, $\gamma = 126.88(1)°$, $V = 1675(2)$ Å^3, and $Z = 1$. Full-matrix least-squares refinement with 3548 independent reflections led to final residual indices of $R = 0.041$ and $R_w = 0.047$. The compound, $OsCl_6Ag_2[P(C_6H_5)_3]_4$, is prepared by precipitation from an acetonitrile solution containing $(n\text{-}Bu_4N)_2OsCl_6$, triphenylphosphine and silver nitrate. The synthesis of $(n\text{-}Bu_4N)_2OsCl_6$ makes use of anhydrous conditions. The molecule is made up of two $Ag(PPh_3)_2$ units which are symmetrically bound to a central $OsCl_6$ group.

The title compound was prepared as part of a study investigating methods of chlorine substitution in $OsCl_6^{2-}$. Osmium–chlorine bonds in the ion are relatively inert, and chlorine substitution represents a synthetic challenge. Legzdins and Nurse[1] made use of silver salts to affect substitutions of iodide in some molybdenum complexes. They obtained silver adducts as isolable intermediates. In the experiment leading to the title compound, a solution of $OsCl_6^{2-}$ with triphenylphosphine was treated with silver nitrate. The result was the formation of excellent dark red crystals in essentially quantitative yield. No reaction of this kind had been reported, and a new silver complex was suspected. An osmium–silver complex was prepared by Clark, and co-workers,[2] who structurally characterized their material and found that it contained an Os–Ag bond. The objective of the work reported in this paper was to structurally characterize the new compound and identify the nature of the silver binding.

EXPERIMENTAL

Syntheses

Preparation of $(n\text{-}Bu_4N)_2OsCl_6$. The compound was prepared in a 100 cm^3 round bottom flask equipped with a mantle for warming, a magnetic stirrer, and a reflux condensor. The flask was charged with one ampoule of osmium tetroxide (0.8694 g, 3.42 mmoles) and 10 cm^3 of freshly distilled benzoyl chloride, C_6H_5COCl. In addition to serving as the initial solvent in the preparation, benzoyl chloride insures that solution conditions remain anhydrous throughout the reduction of OsO_4. The reaction mixture was stirred and warmed (50°C) until the OsO_4 dissolved. At this point, 25 cm^3 of 100% ethyl alcohol saturated with gaseous HCl was added through the top of the reflux condensor. The reaction mixture was refluxed for 0.5 h. During the reflux, the color of the reaction mixture changed from pale yellow to deep red and then to orange-yellow. The reaction mixture was allowed to cool, and then evaporated on a rotary evaporator until the solution volume was about 10 cm^3. A

solution of tetra-*n*-butyl ammonium bromide, (*n*-Bu_4N)Br (3.8 g, 11.8 mmoles), in 10 cm^3 of 100% ethyl alcohol was added to the cold (RT) reaction mixture, followed by 100 cm^3 of diethyl ether. The flask was capped and stored overnight in a freezer (−22°C). The precipitate was filtered, washed with diethyl ether and vacuum dried. The yield was 2.107 g (83%) of orange-yellow solid. Found: C, 43.2; H, 8.3; N, 3.1; Cl, 23.9. Calc.: C, 43.3; H, 8.1; N, 3.2; Cl, 24.0%.

Preparation of $OsCl_6Ag_2[P(C_6H_5)_3]_4$. In a typical preparation, 0.2 g (0.2 mmoles) of $(n\text{-}Bu_4N)_2OsCl_6$ was dissolved in 20 cm^3 of acetonitrile together with an excess of triphenylphosphine (0.3 g, 1 mmoles). An excess of silver nitrate (0.1 g, 0.6 mmoles) dissolved in 20 cm^3 of acetonitrile was then added to the solution. The color of the solution became red and small, red crystals precipitated leaving a colorless solution. The solid was filtered, washed first with acetonitrile until tests of the filtrate with Cl^- revealed no remaining Ag^+, and then it was washed with ethyl ether and dried (yield 0.3 g, > 90%). In order to obtain crystals of the size and quality needed for crystal structure analysis, the compound was again prepared (as described above), this time from very dilute solutions (one-fifth the quantities of materials in twice the solvent). An IR spectrum of the compound in the range 400–4000 cm^{-1} exhibited only peaks attributable to triphenylphosphine bound in the complex. Found: C, 52.0; H, 3.6; Cl, 12.9. Calc.: C, 51.8; H, 3.6; Cl, 12.8%.

Crystal data

$OsCl_6Ag_2[P(C_6H_5)_3]_4$; $M = 1667.82$, space group = $P\bar{1}$, $Z = 1$, $a = 14.486(3)$ Å, $b = 14.711(3)$ Å, $c = 10.233(2)$ Å, $\alpha = 95.55(2)°$, $\beta = 98.75(2)°$, $\gamma = 126.88(1)°$, $V = 1675(2)$ $Å^3$, $D_c = 1.65$ g cm^{-3}, $\mu(MoK\alpha)(cm^{-1}) = 29.44$, $F(000) = 824$.

Data collection

Data were collected from a dark red, columnar crystal with dimensions $0.07 \times 0.06 \times 0.12$ mm using a Rigaku AFC-5S diffractometer and graphite monochromatized MoKα radiation ($\lambda = 0.71069$ Å). A total of 25 reflections, in the 2θ range of 9–24° were used for orientation, lattice parameter determination/refinement, and Laue group differentiation. The intensities of 5891 unique reflections were measured (2θ range: 2.5–50°, temperature: 23°C) using θ–2θ scans and a maximum of 3 scan repetitions/reflection in order to obtain $\sigma F/F < 0.10$; 3548 reflections were considered observed with $I > 3\sigma(I)$. Three standard reflections varied −0.20, −0.04 and −1.14% during data collection. All data were corrected for background, Lorentz, polarization, and absorption (numerical method, transmission range: 0.840–0.866).

Structure solution and refinement

Direct methods were used to locate the Os, Ag, Cl, P, and approximately one-half the C atomic sites; the remaining carbons were located by difference Fourier syntheses.

Full matrix least-squares refinement of the non-H atoms proceeded to convergence uneventfully, with all atoms anisotropic. The ring-hydrogens were then placed in geometrically correct positions (C–H = 0.95 Å) and fixed, while all other variables were again refined. The hydrogen generation/refinement procedure was repeated until no significant parameter shifts occured (maximum shift/esd, final cycle: 0.0007). Convergence, with 385 variables, occurred at $R = 0.041$ and $R_w = 0.047$ where $R = \Sigma ||F_o| - |F_c||/\Sigma |F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ and $w = 1/\sigma^2(|F_o|)$. The final difference synthesis showed $(\Delta\rho)_{max} = 0.57$ e/$Å^3$ and $(\Delta\rho)_{min} = -0.55$ e/$Å^3$. All calculations were performed with Molecular Structure Corporation's TEXSAN structure analysis package.[3]

The atomic positional and thermal vibration parameters, plus complete distance, angle, and structure factor tables have been deposited with the Editor as supplementary material.

DISCUSSION

The structure of the osmium-silver complex can be described most simply as having a central $OsCl_6$ moiety to which two $Ag(PPh_3)_2$ groups are symmetrically attached (Fig. 1). The osmium atom is located on a center of symmetry within a distorted octahedral array of chloride ions. Each of the silver ions are four-coordinate in distorted tetrahedra formed by two chlorides bridging to the osmium atom and two triphenylphosphine ligands. Selected bond distances and angles are reported in Table 1.

While this compound is unique for osmium, there are several complexes of silver reported in which the silver binding is similar.[4–10] That is, the silver ions are four-coordinate, bridged through two or more atoms to other metal ions, and have two phosphine ligands in their coordination spheres. Of these, the dimer, $\{[(C_6H_5)_3P]_2AgCl\}_2$, may be most directly compared to the osmium-silver complex.[10] In the dimer, the silver ions are bridged by two chloride ions in which the Ag–Cl bond distances are 2.741(2) and 2.596(2) Å. This bond distance asymmetry is typical of halogen bridged silver ions. Bond angles for the dimer are 122.91(7)° for the P–Ag–P angle

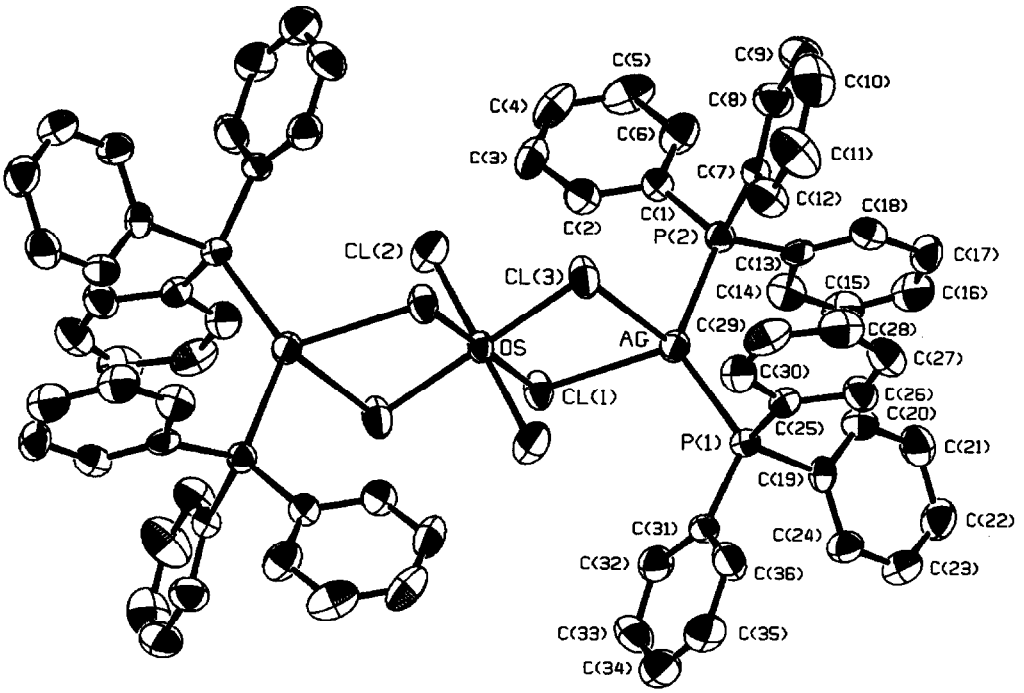

Fig. 1. General view of $OsCl_6Ag_2[P(C_6H_5)_3]_4$ showing labelling scheme. Atoms are represented by their thermal ellipsoids at the 50% probability level. Hydrogen atoms have been omitted for clarity.

and 88.03(6) ° for the Cl–Ag–Cl angle in the bridge.

Silver–chlorine distances in the osmium–silver complex are longer than those in the silver dimer, 2.678(2) and 2.807(3) Å, and the Cl–Ag–Cl bond angle is only 74.05(7)°, a more than 10° reduction from the angle observed in the silver dimer. Silver phosphine distances in the osmium–silver complex are only slightly shorter than those for the dimer, but the P–Ag–P bond angle is significantly larger at 128.49(9)°.

Table 1. Selected bond distances and angles for $OsCl_6Ag_2[P(C_6H_5)_3]_4$

Osmium–chlorine distances in uncomplexed $OsCl_6^{2-}$ average 2.337 Å.[11] When bound to silver in the osmium–silver complex, the Os–Cl distances are 2.356(2) and 2.334(2) Å for the bridging chlorines, and 2.315(3) Å for the chlorine bound only to osmium. Metal–chlorine distances in the bridging structure suggest that each silver ion is relatively strongly bound to one of the bridging chlorines and weakly associated with the other. Cl–Os–Cl angles are essentially 90°, so the asymmetry in the central octahedron is primarily a result of Os–Cl bond distance variation.

METAL COMPLEXES OF HYBRID OXYGEN–ARSENIC LIGANDS—VI. STABILIZATION OF MANGANESE(II)–ARSINE COMPLEXES USING LIGANDS FROM *o*-$R_2AsC_6H_4CO_2Na$

SWARN S. PARMAR,* HARKEERAT K. BHARAJ and MANOHAR L. SAIGHAL

Chemistry Department, Guru Nanak Dev University, Amritsar-143005, India

(*Received* 20 *January* 1987; *accepted after revision* 1 *April* 1987)

Abstract—A reaction of $MnCl_2 \cdot 4H_2O$ with *o*-$R_2AsC_6H_4CO_2$ Na in 1:2 molar ratio in 95% EtOH yields four manganese(II)–monotertiaryarsine complexes [Mn(*o*-$Me_2AsC_6H_4CO_2$)Cl]·$0.5H_2O$, [Mn(*o*-$R_2AsC_6H_4CO_2)_2(H_2O)_2] \cdot nH_2O$ ($n = 0$ and R = Ph or *p*-tolyl; $n = 1$ and R = Et). The stabilization of these four complexes is significant in view of the only two already known.

Manganese(II) has little tendency to form complexes with arsines since these are extremely susceptible to oxidation even by the traces of moisture in the presence of this metal ion.[1] Manganese(II) halides are known to react with $AsPh_3$ to yield manganese(II)–arsine oxide complexes $Mn(OAsPh_3)_2X_2$.[2] Manganese(II)–arsine complexes [Mn(L–L′)$_2X_2$] (X = Cl or Br; L–L′ = $AsMe_2$(*o*-$C_6H_4EMe_2$) with E = As or Sb) have been obtained only in the absence of oxygen and moisture.[3] However, a nitrogen–arsenic hybrid ligand has been reported to stabilize two manganese(II)–monotertiary arsine complexes [Mn($AsMe_2$(*o*-$C_6H_4NH_2$))X_2] (X = Br or ClO_4) even in the presence of both; water being removed azeotropically.[4] We now report the characterization of the products from reactions of $MnCl_2 \cdot 4H_2O$ with (1) (Fig. 1) in 95% EtOH to know if the oxygen–arsenic ligands derived from (1) also stabilize the manganese(II)–arsine complexes in the presence of both oxygen and water.

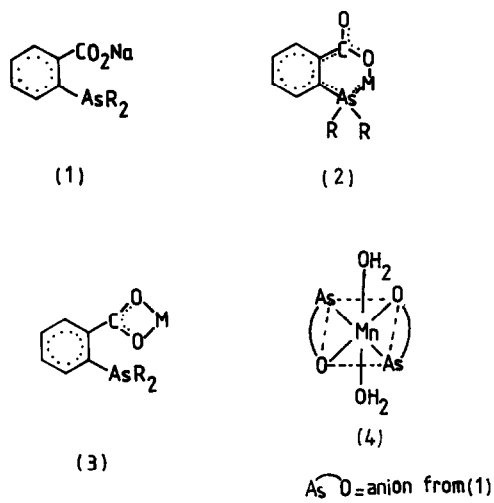

Fig. 1.

EXPERIMENTAL

Mn(*o*-$Me_2AsC_6H_4CO_2$)Cl·$0.5H_2O$, [Mn(*o*-$R_2AsC_6H_4CO_2)_2(H_2O)_2] \cdot nH_2O$ ($n = 0$ *and* R = Ph *or p*-tolyl; $n = 1$ *and* R = Et)

A white solid first formed on the addition of [(1), 6 mmol] in 95% EtOH (20–25 cm^3) to a 95% ethanolic solution (10 cm^3) of $MnCl_2 \cdot 4H_2O$ (0.6 g, 3 mmol) dissolved on shaking. However, these contents on refluxing (30 min for R = Me or Et and 1 h for R = Ph or *p*-tolyl) gave a white† compound which was filtered washed with 95% EtOH (to remove NaCl), EtOH and Et_2O and finally dried in vacuo. Yield: 60%.

Physical methods

Details of spectral and other measurements, preparation of (1) and estimation of arsenic(III) have been published elsewhere.[5,6]

* Author to whom correspondence should be addressed.

† The colour changes to dirty-white or light-pink on drying.

Table 1. Analytical and IR (cm^{-1}) data of manganese(II) complexes

Complex (colour, m.p. ° C)	Found (calc.) (%) C	H	As^{III}	Mn	ν(OH) (δ(HOH))	$\nu_{as}(CO_2)$ ($\nu_s(CO_2)$)

(dirty white, 198)	(33.3)	(3.4)	(23.1)	(17.0)	(1615sh)	(1388)
$[Mn(o\text{-}Et_2AsC_6H_4CO_2)_2(H_2O)_2]H_2O$	41.3	5.0	—[a]	9.3	3500m	1587
(light pink, 300)	(42.3)	(5.6)		(8.8)	3410br (1610sh)	(1385)
$[Mn(o\text{-}Ph_2AsC_6H_4CO_2)_2(H_2O)_2]$	58.4	4.8	19.6	6.8	3410brm	1590
(light pink, 144)	(57.4)	(4.1)	(19.1)	(7.0)		(1375)
$[Mn(o\text{-}(p\text{-tolyl})_2AsC_6H_4CO_2)_2(H_2O)_2]$	59.9	4.5	17.6	6.6	3410brm	1595
(dirty white, 175)	(59.6)	(4.7)	(17.8)	(6.5)	(1620sh)	(1395)

[a] As^{III} could not be estimated because of its spontaneous oxidation to As^{V} as evidenced by the presence of As=O band in the IR spectrum of the resulting compound.

RESULTS AND DISCUSSION

The analytical (C, H, N, As) TGA and IR data of the reaction products suggests that $MnCl_2\cdot 4H_2O$ reacts with (1) in 1 : 2 molar ratio in 95% EtOH to yield four manganese(II)–arsine complexes $[Mn(o\text{-}Me_2AsC_6H_4CO_2)Cl]\cdot 0.5H_2O$ and $[Mn(o\text{-}R_2AsC_6H_4CO_2)_2(H_2O)_2]\cdot nH_2O$ ($n = 0$ for R = Ph or *p*-tolyl; $n = 1$ for R = Et). The presence of water in these complexes has been indicated by the appearance of broad ν(OH) and shoulder δ(OH) bands.[7,8] The $\rho(H_2O)$ band expected[9] at 800–900 cm^{-1} seems to be obscured by the ligand δ(OCO) band.[10]

Application of the reported criterion for the assignment of the bonding mode of these ligands to the $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ values (Table 1) of these four complexes suggests the coordination of carboxylate oxygen and arsenic(III) as given in structure (2)[11] and rules out the structure (3).[6,12]

The observed room temperature μ_{eff} values of 5.37–5.98 B.M of these complexes suggest the presence of high-spin manganese(II); the subnormal μ_{eff} value of 5.40 B.M for the chloro complex being attributed to Mn–Cl–Mn bridging indicated by the appearance of a ν(Mn–Cl) band[13] at 280 cm^{-1}. However, the subnormal μ_{eff} value of 5.37 B.M for the complex with R = Et is not understood while the values for the complexes with R = Ph (5.98 B.M) and *p*-tolyl (5.82 B.M) are normal as expected. An octahedral stereochemistry is also favoured by the appearance of doubly forbidden very weak bands in their electronic absorption spectra. Only the complexes with R = Ph and *p*-tolyl give an X-band EPR signal at room temperature as a broad single line with $g \approx 2$ which indicates their nearly-axial symmetry having small distortions from octahedral stereochemistry.[13] Only the complex with R = *p*-tolyl is soluble in $PhNO_2$ and behaves as a nonelectrolyte. These observations favour structure (4) for all the complexes except the chloro complex for which the octahedral stereochemistry may only be achieved if the chloride ion acts as triply bridging and the ligand is tridentate.

The net result of the present work is the stabilization of four new stable manganese(II)–monotertiary arsine complexes which is significant in view of the only two already known.[4] Further McAuliffe's emphasis[1-3,14] on the use of strictly deoxygenated and anhydrous reaction medium does hold good for the soft ligands but the results of the present investigation and those of Chiswell *et al.*[4] clearly suggest that the presence of water and oxygen in a reaction of a manganese(II) salt with an As–O/As–N hybrid ligand does not inhibit the formation of a manganese(II)–arsine complex.

(*Received* 23 *February* 1987; *accepted* 1 *April* 1987)

Abstract—The acetone complex $[Fe(CO)_2(Me_2CO)(\eta^5\text{-}C_5H_5)][PF_6]$ reacts with L ($L = H_2NNHCSNH_2$, cy-$C_5H_{10}CNNHCSNH_2$, or $R'R''CNNHCSNH_2$ where $R' = R'' = Me$; $R' = H$, $R'' = Ph$; $R' = H$, $R'' = p\text{-}NO_2Ph$; $R' = p\text{-}MePh$) in refluxing trichloromethane to give the new complexes $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$. The complexes are clearly coordinated through the sulphur atom since the thiosemicarbazide complex reacts with benzaldehyde to afford the corresponding thiosemicarbazone compound.

Thiosemicarbazones have been shown to be active against protozoa,[1] influenza,[2] smallpox[3] and certain kinds of tumour,[4] and their activity has often been thought to be due to their ability to chelate trace metals. For example, Liebermeister[5] showed that copper ions enhance the anti-tubercular activity of p-acetamidobenzaldehydethiosemicarbazone.

Many "classical" complexes containing thiosemicarbazide and thiosemicarbazones as coordinated ligands with bidentate coordination through the sulphur and hydrazinic nitrogen atoms have been reported.[6,7] However, there are very few papers describing complexes with monodentate(S) coordination. The only examples of thiosemicarbazide or thiosemicarbazones acting as monodentate ligands reported so far are those of Ag(I),[8] Hg(II)[9,10] and Co(II).[11] Also, very few organo-transition-metal complexes containing attached thiosemicarbazide or thiosemicarbazones have been reported.[12–15] In this communication we wish to describe the synthesis of the new monodentate(S) bonded complexes $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$ ($L = H_2NNHCSNH_2$, cy-$C_5H_{10}CNNHCSNH_2$, or $R'R''CNNHCSNH_2$, $R' = R'' = Me$; $R' = H$, $R'' = Ph$; $R' = H$, $R'' = p\text{-}NO_2Ph$; $R' = Me$, $R'' = p\text{-}MePh$) and preliminary studies of their reactivity.

Equimolar quantities of $[Fe(CO)_2(Me_2CO)(\eta^5\text{-}C_5H_5)][PF_6]$[16] and L ($L = H_2NNHCSNH_2$, cy-$C_5H_{10}CNNHCSNH_2$ or $R'R''CNNHCSNH_2$, $R' = R'' = Me$; $R' = H$, $R'' = Ph$; $R' = H$,

(6)	p-$MeC_6H_4CMeNNHCSNH_2$	41	38.8 (38.7)	3.4 (3.5)	7.9 (7.9)	2057s 2009s

[a] Calculated values in parentheses.
[b] Spectra recorded as KBr discs, s, strong.

R″ = p-NO_2Ph; R′ = Me, R″ = p-MePh) react in refluxing $CHCl_3$ to give good yields of the new complexes $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$ via displacement of acetone. The complexes have been fully characterized by elemental analysis (C, H and N), IR spectroscopy (Table 1) and ^1H NMR spectroscopy.* All of the complexes are stable in the solid state in air and decompose very slowly in solution when exposed to air. The compounds are insoluble in hydrocarbon solvents, sparingly soluble in dichloromethane and trichloromethane and very soluble in dimethyl sulphoxide.

It is revealing that the thiosemicarbazide complex $[Fe(CO)_2(H_2NNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ (**1**) reacts smoothly with benzaldehyde to give the benzaldehydethiosemicarbazone complex which can also be prepared by reacting $[Fe(CO)_2(Me_2CO)(\eta^5\text{-}C_5H_5)][PF_6]$ with benzaldehyde thiosemicarbazone in refluxing chloroform. This indicates that the ligands must be bound through the sulphur atom since as expected the complexes $[MoX(CO)_2(H_2NNHCSNH_2)(\eta^3\text{-}C_3H_4R)]$(R = H or 2-Me, X = Cl or Br)[14] with bidentate (SN) coordination do not appear to react with ketones to afford thiosemicarbazone complexes.

The infrared spectrum of the acetone complex $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][BF_4]$ shows two metal-carbonyl bands at 2070 and 2028 cm^{-1} which are slightly higher than for the new complexes with a sulphur atom coordinated to the metal which is to be expected. The X-ray crystal structure of free thiosemicarbazide shows the molecule to be in a *trans*-configuration[17] and it is likely that the iron complexes (**2**), (**4**) and (**6**) have the thiosemicarbazone ligand in this configuration [Fig. 1(a)] whereas complexes (**1**), (**3**) and (**5**) show either two cyclopentadienyl or 3 carbonyl bands which are probably due to the *trans*- and *cis*-isomers [Fig. 1(a) and (b)]. Further studies are in progress.

SYNTHESIS AND CHARACTERIZATION OF A Tc(V) GLYCOLATO COMPLEX

G. HUBER, G. ANDEREGG* and K. MAY

Laboratorium für Anorganische Chemie, ETH Zürich, CH-8092 Zürich, Switzerland

(*Received* 20 *March* 1987; *accepted* 6 *April* 1987)

Abstract—The preparation of the Tc(V) glycolato complex $(C_4H_9)_4N[^{99}TcO(OCH_2CH_2O)_2]$ is described. On the basis of IR, ^{1}H-NMR and ^{13}C-NMR spectra, a structure for the complex is postulated.

As the Tc(IV) alcoholato complexes can be obtained from $TcBr_6^{2-}$ by ligand substitution,[1] an attempt was made to synthesize an oxo-Tc(V) glycolato complex, starting with $Bu_4N[TcOCl_4]$. The substitution of chloride by the chelating glycolate ($OCH_2CH_2O^{2-}$) was carried out in non-aqueous organic solvents because $TcOCl_4^-$ is prone to hydrolysis.

$$TcOCl_4^- + 2HOCH_2CH_2OH + 4Bu_4NOH \xrightarrow{\text{i-propanol}} [TcO(OCH_2CH_2O)_2]^- + 4Bu_4NCl + 4H_2O.$$

It seems that the oxo-Tc(V) unit prefers oxygen as a donor atom as does Tc(IV).

EXPERIMENTAL

$Bu_4N[TcOCl_4]$ was recrystallized from dichloromethane/hexane. Bu_4NOH in dry isopropanol was commercially available.

Synthesis of $Bu_4N[TcO(OCH_2CH_2O)_2]$ **(I)**

15 cm^3 of a solution of 0.1 M Bu_4NOH (1.5 mmol) in isopropanol were added to 160 mg $Bu_4N[TcOCl_4]$ (0.32 mmol) and 0.2 cm^3 ethyleneglycol (3.5 mmol) in an argon atmosphere, and the mixture treated in an ultrasonic vibrator. The colour of the solution changed to deep-violet within 2 min. After all of the $Bu_4N[TcOCl_4]$ had dissolved, the solvent was removed first by a stream of dry argon and then *in vacuo*. The excess ethyleneglycol was removed by distillation under high vacuum. The dark-violet residue was dissolved in 5 cm^3 of dry acetone and mixed with 10 cm^3 dry diethylether. The clear solution was left to stand overnight at −20°C, and virtually all of the chloride precipitated as white Bu_4NCl crystals. The filtered solution was reduced to a total volume of 1 cm^3 by purging with dry argon. Dried ether was added, yielding an opaque violet solution, which was then left to stand for 3 days at −20°C. 105 mg of violet crystals were obtained, which were washed twice with hexane and dried *in vacuo*. Even after recrystallization from deoxygenated chloroform/ether the NMR spectrum showed one ethyleneglycol-unit per three molecules of Tc-complex.

Elemental analysis. Found: C, 49.8; H, 9.4; Tc, 19.8. Calc. for $Bu_4N[TcO(OCH_2CH_2O)_2] \cdot \frac{1}{3}(HOCH_2CH_2OH)$: C, 49.8; H, 9.3; Tc, 19.9%.

The complex is very soluble in water, alcohols, acetone, acetonitrile, dimethylformamide, dimethylsulfoxide, tetrahydrofuran, chloroform, methylenechloride, benzene; slightly soluble in toluene; insoluble in ether and hexane. It decomposes in aqueous solution at pH < 10. The complex is sensitive to oxygen and slowly decomposes particularly in solution into pertechnetate. In paper chromatography the R_f-value of the title complex is 0.5 (CH_3CN/H_2O = 5:2 v/v). The dry crystals can be stored under argon at least for several months.

Spectroscopic properties of the complex. The IR band at 964 cm^{-1} can be assigned to a Tc=O

* Author to whom correspondence should be addressed.

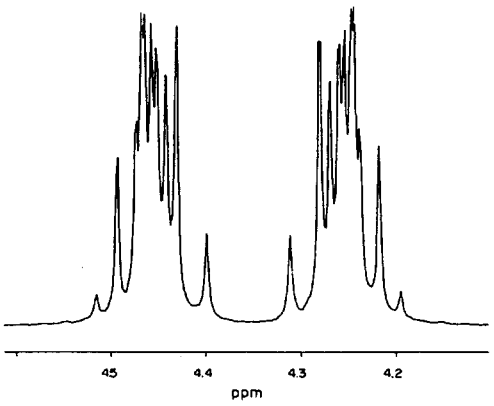

Fig. 1. H-NMR spectrum of coordinated glycolates in $Bu_4N[TcO(OCH_2CH_2O)_2]$.

stretching frequency. This is similar to other five-coordinate oxo-Tc(V) complexes.[2] Moreover, the IR spectrum shows bands characteristic of Bu_4N^+ and ethyleneglycol.

UV–VIS spectrum in dry CH_3OH:

$\lambda_{max} = 249\,nm, \varepsilon = 3000 : sh = 350\,nm, \varepsilon = 50$

$\lambda_{max} = 524\,nm, \varepsilon = 90.$

250 MHz-H-NMR *spectroscopy in* $CDCl_3$. This shows a multiplet centred at $\delta = 4.36$ ppm due to coordinated glycolate. The symmetric structure of the 20 signals points to an aa'bb'-spin-system, while the CH_2-group of ethyleneglycol resonates at $\delta = 3.62$ ppm. The other signals are identical to those of salts containing Bu_4N^+.

63 MHz-^{13}C-NMR *spectroscopy in* $CDCl_3$. The signal of coordinated glycolate is a singlet at 77.5 ppm. The small signal of ethyleneglycol is at 64.4 ppm. The other four signals of Bu_4N^+ are, as expected, at 58.8/24.3/19.9/13.9 ppm.

DISCUSSION

It has long been known that most metal centres with significant A-character form complexes with alcoholates.[3,4,5] Such complexes can also be synthesized with Tc(V), which suggests that Tc(V) also has A-character. The +V oxidation state of Tc can be deduced from chemical measurements and elemental analysis. Known Tc(V) complexes, e.g. the tetraza-dioxo-Tc(V) complex[6] $TcO_2(2,3,2\text{-tet})^+$ using the title compound as starting material, can be obtained in good yields (2,3,2-tet = $NH_2(CH_2)_2NH(CH_2)_3NH(CH_2)_2NH_2$):

$$TcO(OCH_2CH_2O)_2^- \xrightarrow[\text{in MeOH/H}_2O]{\text{2,3,2-tet}} TcO_2(2,3,2\text{-tet})^+.$$

As already mentioned, the glycolato complex is soluble in water and stable at pH > 10 in deoxygenated water. Below pH = 8 the solution darkens quickly (due to formation of TcO_2), and needles of Bu_4NTcO_4 precipitate. Hydrolysis can be prevented by adding a strong ligand. This provides a useful method of synthesizing new Tc(V) complexes directly from aqueous solutions.

A fivefold coordination of Tc(V) in the glycolato complex can be derived from IR- as well as from NMR-spectra. The H-NMR-signals of coordinated glycolates show a pattern typical of an aa'bb'-spin-system, which is consistent either with a square-pyramidal or a trigonal-bipyramidal structure (Fig. 1).

The ^{13}C-NMR spectrum shows only one signal for the coordinated glycolates favoring the square-pyramidal configuration. Analogous results have been obtained elsewhere ($TcO(SCH_2CH_2O)_2^-$,[8] $TcO(SCH_2CH_2S)_2^-$[9]). Since the chemical shift of the glycolate signals is similar to that of related cyclic glycolate esters (4–4.5 ppm), a diamagnetic behaviour of the compound may be tentatively assumed as in some paramagnetic complexes shifts of approximately 20 ppm are observed.[10]

(*Received* 24 *March* 1987; *accepted* 6 *April* 1987)

Abstract—Reaction of {Ru(styrene)(dppe)$_2$}, (dppe = 1,2-bis(diphenyl-phosphino)ethane), with trimethylphosphine affords [Ru(dppe)$_2$(PMe$_3$)], which has been characterized spectroscopically, and which is in equilibrium with [RuH(C$_6$H$_4$P(Ph)CH$_2$CH$_2$PPh$_2$)(dppe)] and free PMe$_3$in solution at room temperature.

The preparation of highly electron rich metal centres is a goal of considerable importance since such centres may be useful in the activation of saturated hydrocarbons. To this end, attempts have been made to stabilize ruthenium in oxidation state zero with ligands which are poor π-acceptors, such as tertiary phosphines. This has not proved straight forward, since, although [Ru(P(OMe)$_3$)$_5$] can be isolated,[1] attempts to synthesize the analogous [Ru(PMe$_3$)$_5$] have been unsuccessful and have led[2] to [RuH(CH$_2$PMe$_2$)(PMe$_3$)$_3$], presumably because PMe$_3$ is an insufficiently good π-acceptor to stabilize the ruthenium(0) centre.

Indeed, only two examples of complexes in which ruthenium(0) is coordinated only to phosphine ligands have been reported. Chatt postulated[3] [Ru(dmpe)$_2$(PEt$_3$)], dmpe = 1,2-bis(dimethylphosphino)ethane, from the reaction of [RuH(naphthyl)(dmpe)$_2$] with PEt$_3$, whilst the analogously prepared [Ru(dmpe)$_2$(PMe$_3$)] has recently been structurally characterized.[4]

We have reported[5] upon the chemistry of [Ru(dppe)$_2$styrene], dppe = 1,2-bis(diphenylphosphino)ethane, available from the reaction of [Ru(PPh$_3$)$_2$(styrene)$_2$] with dppe, including the replacement of styrene by CO or P(OMe)$_3$ (L) to give [Ru(dppe)$_2$L]. We now report that an analogous reaction using PMe$_3$ gives [Ru(dppe)$_2$(PMe$_3$)], another example of an all phosphine stabilized ruthenium(0) centre.

Addition of excess PMe$_3$ to [Ru(dppe)$_2$styrene] in tetrahydrofuran (thf) results in an orange solution from which orange-red crystals analysing for [Ru(dppe)$_2$(PMe$_3$)] can be isolated in high yield. Although these crystals are well formed, they do not diffract X-rays so that their characterization relies on spectroscopic investigations. There is no IR or ^{1}H NMR evidence for the presence of a hydride ligand, and combined IR and ^{31}P NMR studies confirm that the dppe ligand has not undergone an internal metallation reaction. Thus, there are no IR absorptions[6] at 1550 or 1410 cm^{-1} and the ^{31}P NMR spectrum consists of a doublet from the four equivalent phosphorus atoms and a quintet from the PMe$_3$ phosphorus atom. There is evidence

* Author to whom correspondence should be addressed.

that PMe_3 dissociates in solution since resonances for free PMe_3 and for [RuH($C_6H_4P(Ph)CH_2CH_2PPh_2$)(dppe)] (III in ref. 5) are observed in the ^{31}P NMR spectrum. These correspond to *ca.* 35% dissociation and do not vary with time, suggesting that equilibrium 1 is established but that exchange of free and bound PMe_3 is slow on the NMR time-scale. The existence of equilibrium 1 is confirmed since addition of excess PMe_3 removes the peaks from [RuH($C_6H_4P(Ph)CH_2CH_2PPh_2$)(dppe)] and only peaks from [Ru(dppe)$_2$(PMe_3)] and PMe_3 are observed in the ^{31}P NMR spectrum.

$$[Ru(dppe)_2(PMe_3)] \rightleftharpoons [RuH(C_6H_4P(Ph)CH_2CH_2PPh_2)(dppe)] + PMe_3. \quad (1)$$

Doublets from both free and bound PMe_3 are also observed in the ^1H NMR spectrum. Observation of this equilibrium lends support in the suggestion,[4] made as a result of kinetic measurements, that exchange of PMe_3 in the related [Ru(dmpe)$_2$(PMe_3)] with $P(CD_3)_3$ or with [$CNCH_2CMe_3$] involves preliminary phosphine dissociation. Metallated species,[3,4] although undetected, may also be present in the dmpe system.

The simple nature of the ^{31}P NMR spectrum suggests that [Ru(dppe)$_2$(PMe_3)] adopts a square pyramidal configuration with apical PMe_3, as has been observed for [Ru(dmpe)$_2$(PMe_3)][4] and [Ru(dppe)$_2$($P(OMe)_3$)][5] rather than the more usual trigonal bipyramidal structure adopted by [Ru(dppe)$_2$(CO)][4] and related molecules.

EXPERIMENTAL

Microanalyses were by the University of Oviedo and NMR spectra were obtained on Perkin–Elmer R12 (60 MHz, ^1H) or Brüker Associates WM250 (^{31}P) spectrometers, the latter operating in the Fourier Transform mode with noise proton decoupling. The melting point was measured on an electrothermal melting point apparatus in a sealed capillary under argon and is uncorrected.

Bis - (1,2 - bis(diphenylphosphino)ethane)(trimethylphosphine)ruthenium(0)

Thf (5 cm^3) was added to a mixture of [Ru(dppe)$_2$(styrene)][5] (0.3 g) and PMe_3 (0.3 cm^3) under argon. The dark-orange solution was stirred for 30 min at room temperature. Petroleum (10 cm^3, 40–60°C bpt) was added before the solution was filtered and cooled to −20°C for 3 days. The solution was filtered again and allowed to stand at −20°C for 3 weeks. The dark-orange crystals, which are indefinitely stable at room temperature under argon and are stable for a few minutes in air, were collected, washed with petroleum and dried *in vacuo*. Yield *ca.* 60%. M.p. 94–96°C.

(*Received* 3 *April* 1987; *accepted* 27 *April* 1987)

Abstract—The cation in the ruthenium blue $[Ru_2(NH_3)_6Cl_3](BPh_4)_2$ is a trichloro-bridged bioctahedral dimer, with a Ru—Ru distance of 2.753 Å.

The intense blue solutions formed either by adding hydrochloric acid to solutions of ruthenium(II) complexes containing *N*-donor ligands or by reducing solutions of ruthenium(III) in hydrochloric acid have been the subject of much controversy. It is now generally accepted that these "ruthenium blues" are mixed-valence dimeric species,[1] although to date no definitive structural work has been carried out due to the difficulties in preparing suitable crystals.

We have studied the biological and chemical properties of the blue Ru(II,III) compound formed by reaction between $[Ru(NH_3)_6]Cl_2$ and hydrochloric acid. Compounds of this type have remarkable biological activity, for example as potent inhibitors of accumulation of calcium by everted membrane vesicles of *Escherichia coli*,[2] and in the elicitation of filamentation in *E. coli*.[3] This activity is not found for the oxidised Ru(III,III) dimer. It should be noted that the mixed-valence dimer is mutagenic.

The mixed-valence dimer has been formulated[4] as a di-chloro-bridged complex, $[Ru_2(NH_3)_6Cl_4(H_2O)]Cl$, partly on the basis of conductivity data, which was judged appropriate for a 1 : 1 electrolyte. However, other evidence is indicative of a doubly charged complex with three bridging chloride groups, $[Ru_2(NH_3)_6Cl_3]Cl_2 \cdot H_2O$. This evidence includes ion-exchange studies, which indicate a doubly-charged complex,[5] and vibrational spectroscopy.[6] Furthermore, it is possible to isolate salts of the type $[Ru_2(NH_3)_6Cl_3]I_2 \cdot H_2O$ and $[Ru_2(NH_3)_6Cl_3]ZnX_4$, where X = Cl, Br.[6] We have prepared the tetraphenylborate salts $[Ru_2(NH_3)_6Cl_3](BPh_4)_2$, which have identical electronic spectra and magnetic properties to the chloride, and now report full details of the crystal structure.[3]

EXPERIMENTAL

Preparation of hexaammine-μ-trichlorodiruthenium(II,III) tetraphenylborate

The complex chloride was prepared by the method of Bottomley and Tong[4] and recrystallized from methanol. It was precipitated as the tetraphenylborate from an aqueous deoxygenated solution by addition of a concentrated solution of sodium tetraphenylborate. The product was separated by centrifugation and recrystallized twice from methanol to give dark blue, rod-like crystals of maximum length about 1 mm. The formulation $[Ru_2(NH_3)_6Cl_3](BPh_4)_2$ was confirmed by analysis for Ru, Cl, C, H, N. Attempts to prepare crystal-

* Authors to whom correspondence should be addressed.

line products with other anionic species were all unsuccessful.

X-ray crystallography

The crystal used for the X-ray work was a rod of maximum dimension 0.6 mm. It was sealed in a thin-walled capillary under argon. All measurements were made using a CAD4 diffractometer operating in the $W/2\theta$ scan mode and graphite-monochromatized Mo–K_α radiation ($\lambda = 0.71069$ Å), following previously detailed procedures.[7] In spite of the size of the crystal used, the scattering was rather weak, and the specimen showed considerable mosaic spread.

The structure was solved by use of the heavy atom method and refined by full-matrix least squares. All non-hydrogen atoms were refined with anisotropic displacement factor coefficients; hydrogen atoms were included in idealised positions and assigned group isotropic coefficients. Experimental data were as follows:

Crystal data. $[Ru_2Cl_3N_6H_{18}]^{2+}[C_{24}H_{20}B]_2^-$, Mr = 1048.56, monoclinic, $P2_1/a$, $a = 18.257(4)$, $b = 18.151(3)$, $c = 18.319(6)$ Å, $\beta = 115.80(2)°$, $U = 5465.6$ Å^3, $Z = 4$, $Dc = 1.27$ g cm^{-3}, μ(Mo–K_α) = 6.56 cm^{-1}.

Data collection. Scan width $\omega = 0.8 + 0.35 \tan\theta$, scan time 1.35–6.77° min^{-1}, $1.5 \leqslant \theta \leqslant 25.0°$. 9012 data recorded, 8437 unique, 4387 observed [$I > 1.5\sigma(I)$]. Data corrected for absorption empirically.

Structural refinement. 470 parameters, weights $= 1/[\sigma^2(Fo) + 0.00045(Fo)^2]$, $R = 0.066$, $R_w = 0.078$. Final atomic parameters, full lists of bond lengths and angles and lists of *Fo/Fc* values have been deposited as supplementary material with the Editor, from whom copies are available on

request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The cation has a confacial bioctahedral structure, as shown in Fig. 1. Bond lengths and angles are given in Table 1. The octahedra are very similar in geometry. The presence of the triple chloride bridge is confirmed, while the short Ru—Ru distance of 2.753 Å is consistent with metal–metal interaction. The mean Ru—Cl—Ru bridging angle is 70.2°, close to the value of 70.5° expected for two regular octahedra sharing one face.[8]

The electronic absorption spectra and electronic configuration of the trichloro-bridged species have recently been discussed[9] in terms of a delocalized mixed valence electronic ground state in which both ruthenium atoms are equivalent and the unpaired electron is occupying a σ^* molecular orbital. The structure as found, and especially the Ru—Ru distance, which probably indicates a bond order slightly less than one,[10] is consistent with this picture.

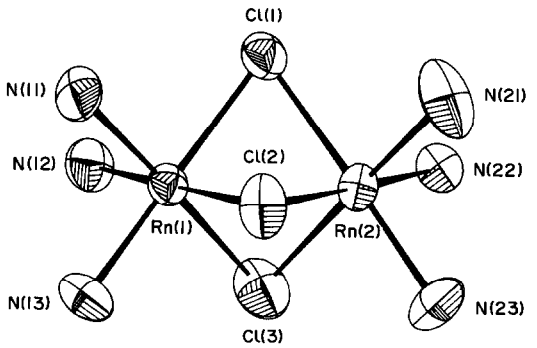

Fig. 1.

BOOK REVIEWS

Structural Methods in Inorganic Chemistry. E. A. V. Ebsworth, David W. H. Rankin and Stephen Cradock, Blackwell Scientific, Oxford, 1987, ISBN 0-632-01592-6 (price unknown)

This is the most enjoyable chemistry book I have read for years. We all have systematic textbooks in inorganic chemistry and I am glad this is not another of those. We all have books as well on the physical methods we specialise in, but not many people are able to take on writing a book which covers the application of nearly all the spectroscopic, diffraction and other techniques we need to solve structural problems. This is what these three authors from Edinburgh have done, and their success shows that the intellectual tradition of the Athens of the North lives on.

Each chapter describes a single, or two similar, techniques. Short theoretical and practical introductions precede penetrating accounts of applications. There is emphasis on the strengths and weaknesses of each method and all the chapters end with a set of testing problems and plenty of references to books, reviews and papers.

When you turn to the end of the book to see if you've got the problems solved you will be surprised to find only half the problems have been given answers. This is because the authors are trying to stimulate us to do some open-ended thinking and discussion. They rightly maintain that a researcher's work is never done and that an interesting piece of chemistry always throws up fresh ideas for more experiments.

After you have recovered from that shock you get another when you find there are no answers at all to the problems in chapter 10. This last chapter is worth the money alone. It consists of 18 case studies, intriguing problems which have fascinated chemists for years. There is the XeF_6 story, the N_2O_3 story, the problem of eclipsed or staggered ferrocene, agostic hydrogens, where the electrons go in reduced or excited dipyridyl complexes, and more. Most of these illustrate the principles that we need to use a combination of techniques to solve structural problems in inorganic chemistry, and that for worthwhile chemistry there are no easy answers.

I particularly enjoyed the crystallography and NMR chapters. The former is the best account I have yet seen for people who may not do it themselves but want to know what it is about, and you will not need to know what a reciprocal lattice is. You can also read how alleged $[ClF_6]^+[CuF_4]^-$ might really be $[Cu(H_2O)_4]^{2+}[SiF_6]^{2-}$.

In the NMR chapter there is a clear critical survey of modern developments, including multiple resonance, multi-pulse methods, applications to the solid state and use of liquid crystals, as well as all those delights like INEPT and INADEQUATE which make the layman think he is. If you want to know what these and other acronyms like MIKES and RIKES stand for there's a good glossary in the first chapter. This is an excellent innovation which all books should have in the space often wasted with accounts of nomenclature rules.

Another good chapter contains a sensible combination of "ordinary" electronic spectra with photoelectron spectra, but the balance favours the second of these unduly. There is still plenty of good work being done on ligand field transitions in electronic spectra. A more extended treatment of these would have allowed a case study in the last chapter on how electronic and ESR spectra can be combined to reveal structure in copper(II) compounds. I was also sorry not to see a chapter about magnetochemistry, which is so closely linked to structure. If this had been covered we could have had a case study on haemocyanin or some other biological system. Some of the necessary space could be generated by omitting the well written but unnecessary sections on quantitative analysis by IR or UV spectra.

Mentioning haemocyanin brings me to my other adverse criticism, that the authors take a slightly restricted view of inorganic chemistry. Nearly all the main text and all the case studies describe work on discrete molecules or ions, but the subject of inorganic chemistry is much wider than this and students in particular would benefit from reading about how ideas developed by the study of molecules can be applied, with adjustment, to proteins, say, or intercalation compounds or electronic materials.

The greatest use of this book ought to be to train Ph.D. students. There is plenty of material here for postgraduate courses and exercises. If your students do get hold of this book, make them read it all, not just use it as a reference book for odd topics or even a few chapters. The writing is fluent and conversational, and even funny, as when $[PtMe_3OH]$ "was reported to explode on combustion, and explosion can lead to inaccurate results", or when the WAHUHA technique in NMR is described as "not an easy experiment to perform successfully, and it is even harder to understand".

I detected no serious errors in any section in which I thought myself knowledgeable and strongly recommend this book to all readers of this journal.

Gmelin Handbook of Inorganic Chemistry. Gmelin Institute for Inorganic Chemistry of the Max-Planck-Society for the Advancement of Science, 8th edn. Cu-Organocopper Compounds, Part 3. Springer, Berlin, 1986, xii+249 pp. ISBN 3-540-93537-1, DM 1152.

Parts 1 and 2 covered organocopper compounds with alkyl, alkenyl and aryl ligands. The present volume completes the coverage of mononuclear organocopper compounds with ligands bonded through one carbon atom, and contains all derivatives with alkynyl, carbonyl and isocyanide groups.

The copper acetylides, which are extensively used in organic synthesis, occupy the greater part of the volume (187 pages). The literature on the acetylides is first indexed, and their general preparations, structures, properties and reactions are reviewed. The remainder of the chapter (some 50 pages) is then taken up with a tabulation, with extensive footnotes and references, of the compounds RC≡CCu. Their reactions, particularly their conversions to the products RC≡CR′ and RC≡C—C≡CR are listed, and the more complex reactions are described in more detail in subsequent sections.

Acetylides containing copper(I) and a second metal are then dealt with in a similar way, and the volume concludes with sections on copper carbonyls (27 pp.) and isocyanide compounds (24 pp.).

The literature is covered through 1985. The presentation of the material, now wholly in English, is exemplary, as it is in all of these volumes. Organometallic chemists, and organic chemists who need to use organocopper intermediates, are indebted to the authors Helmut Bauer, Jürgen Faust, Rolf Froböse, and Johannes Füssel, and to the Max-Planck Institute and Springer-Verlag, for completing this valuable series.

An Introduction to Organometallic Chemistry. A. W. Parkins and R. C. Poller, Macmillan, Basingstoke, 1986, xii+252 pp. ISBN 0-333-3642-5, ISBN 0-333-36433-3 Pbk, £25.00 (hard back), £9.95 (paper back).

Conventional organic chemistry is concerned with the organic chemistry of some half-dozen electronegative elements. It constitutes a major fraction of any degree course in chemistry and is served by many excellent text books of 1000 pages or more.

Organometallic chemistry on the other hand covers the organic chemistry of some 90 elements (some of them admittedly not very common), and it is necessarily more diverse and varied (and some would say more interesting) then organononmetallic chemistry. Yet organometallic chemistry provides a relatively small fraction of any first degree course, and its text books have to be correspondingly smaller.

Few authors have yet undertaken the difficult task of the drastic compression that is required for a general text book in this field, and the appearance of a new one is very welcome.

Parkins and Poller have chosen an approach which integrates main group and transition metal compounds. They do not discuss particular metals or particular ligands separately at any length, but build up a picture of the preparations, structures and reactions involved in organometallic chemistry as a whole.

The first third of the book deals with the preparation of organometallic compounds and with their structures and the bonding principles which are involved. The approach here is one which most teachers of the subject would approve.

The remaining two-thirds of the book cover the reactions of organometallic compounds, with chapters devoted to carbanion chemistry, carbene chemistry, coordination chemistry, reactions of the bonded organic ligands, stoichiometric applications and catalytic applications. Leading references are given throughout.

Most of the topics which you expect to find are mentioned, if only very briefly. You can quibble about the short shrift with which some of your favourite topics are treated, but on the whole the authors have made a very good job of presenting the salient features of organometallic chemistry. The balanced approach will appeal to teachers of the subject, and renders the book suitable as recommended reading for many university courses in organometallic chemistry.

(*Received* 3 *February* 1987; *accepted* 18 *February* 1987)

Abstract—Determination of the stability constants for the system Co(II)/SO_3^{2-}, was made potentiometrically using SO_3^{2-}/HSO_3^- as buffers. Computation and matrix methods lead to the following overall stepwise constants: $\beta_1 = 4.3 \times 10^2$ M^{-1}, $\beta_2 = 2.2 \times 10^4$ M^{-2} and $\beta_3 = 3.0 \times 10^6$ M^{-3}. The partial constants (M^{-i}) obtained were: $K_1 = 4.3 \times 10^2$, $K_2 = 51$ and $K_3 = 1.4 \times 10^2$. The HSO_3^- competition was eliminated by using the extrapolation procedure.

Although a few studies have been reported on the complexation of amines of Co(III) and sulfite in aqueous solutions,[1,2] the literature is very lacking in data reporting the complexation reaction between cobalt(II) and sulfite. In the present work a potentiometric study[3,4] of the system SO_3^{2-}/HSO_3^-/Co(II), in ionic strength 2.0 M maintained with $NaClO_4$ and temperature of 25°C, is reported.

EXPERIMENTAL

Reagents and solutions

The reagents used in this work were of analytical grade (Merck). $NaClO_4$ was recrystallized and stock solutions 4.0 M were made and standardized gravimetrically by drying at 110°C to constant weight. Sulfite and bisulfite were prepared with boiled and de-aerated water, by passing through N_2 and standardized gravimetrically.[5] Cobalt(II) perchlorate was synthesized by reaction of the pure metal with $HClO_4$, the excess of the acid being evaporated in a sand bath. The pH of the resulting solution was measured from 0.100 M solution in Co(II), at the ionic strength 2.0 M ($NaClO_4$).

Apparatus and procedure

A glass electrode (Metrohm E-6.0203.00), saturated with NaCl and a titroprocessor (Metrohm E-636), with an adequate program for following the pH variations of the system were used in all measurements.

The experiments were taken at 25.0 ± 0.1°C. The conditional pH was measured in relation to solutions of [H^+] concentration of 1.0×10^{-2} M and 1.0×10^{-4} M, with the ionic strength adjusted to 2.0 M with $NaClO_4$, and used in the electrode calibration.

The experimental procedure was based on the titration of 20.00 cm^3 of a mixture of [HSO_3^-]/[SO_3^{2-}] in different relations, whose pH_1, free of metal, was measured with a metallic solution. After each injection of the metallic solution, with conditional hydrogen ion concentration well known, a new pH_2 of equilibria was measured.

The mass balance and volume corrections lead to curves of $\bar{n}$ (the average ligand number) vs [SO_3^{2-}]

* Author to whom correspondence should be addressed.

(concentration of free sulfite). Influence of the bisulfite ions was detected in the measurements and curves of $\bar{n}$ vs $[SO_3^{2-}]$ were taken in various HSO_3^-. Extrapolation of these curves allowed the values of $\bar{n}$ free of $[HSO_3^-]$ to be obtained using a programmable calculator HP-97.

All the measurements were made under N_2 atmosphere maintained in order to prevent the ligand oxidation.

RESULTS AND DISCUSSION

Method utilized

The competitive method,[6] is used based on the variation of the conditional pH (referred to the hydrogen ion concentration instead of its activity) of a sulfite/bisulfite buffer, by the presence of Co(II).

The mass balance applied to the system, based on the pH changes, leads to the final concentration of free sulfite and the average ligand number ($\bar{n}$), as previously discussed.[3]

The conditional pK_a calculated for the weak acid in each solution, instead of the average value, eliminates several sources of errors such as drift in junction potential, reference electrode potential, etc.

The conditional pK_a values obtained, varied in relation to the various buffers, which could be explained by the formation of the $S_2O_5^{2-}$ ion, studied by Golding,[7] according to the equilibria:

$$2HSO_3^- \rightleftharpoons S_2O_5^{2-} + H_2O. \quad (1)$$

Table 1 shows the buffer relations used and the pK_a value obtained. The existence of polynuclear species were not evidenced by the independence of the $\bar{n}$ in relation to the metal concentration.

Four buffer relations were measured each one giving one curve $\bar{n}$ vs $[SO_3^{2-}]$, with the total concentration of sulfite being maintained constant and varying the total concentration of bisulfite. At many points of this curve were taken values of $\bar{n}$ and $C_{HSO_3^-}$, these being values extrapolated to $C_{HSO_3^-}$ equal to zero. Figure 1 shows the set of curves while Fig. 2 presents the final formation curve obtained.

Table 1. Relationship between $C_{SO_3^{2-}}/C_{HSO_3^-}$ used, and their respective pK_a values

Sample	Relationship $C_{SO_3^{2-}}/C_{HSO_3^-}$		pK_a
100:1	10/0.10	20/0.20	6.37
40:1	10/0.25	20/0.50	6.44
20:1	10/0.25	20/1.0	6.48
10:1	10/1	20/2.0	6.52

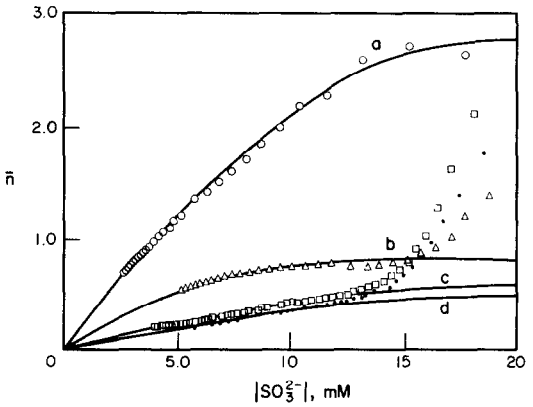

Fig. 1. Formation curves for the solutions measured. The relationship between $C_{SO_3^{2-}}/C_{HSO_3^-}$ were: a = 100:1, b = 40:1, c = 20:1, d = 10:1.

The extrapolation of $\log \bar{n}$ vs $C_{HSO_3^-}$ leads to straight lines, facilitating the extrapolation. After this extrapolations the $\bar{n}$ values obtained (Fig. 2), free of the influence of $C_{HSO_3^-}$, were treated giving the Leden functions,[8] which were treated according to DeFord and Hume[9] giving three complex species.

The overall stepwise constants formation

The curve $\bar{n}$ vs SO_3^{2-}, was integrated,[10] in order to obtain the Leden function, $F_0(x)$, which permits by graphic extrapolation calculation of the value of the overall constants n of equilibria:

$$F_0(x) = 1 + \beta_1[L] + \beta_2[L]^2 + \cdots + \beta_n[L]^n. \quad (2)$$

The graphic treatment leads us to three species, according to the general reaction:

$$Co^{2+} + nSO_3^{2-} \rightleftharpoons Co(SO)_3)_n^{(2-2n)+} \quad (3)$$

with

$$\beta_n = \frac{[Co(SO_3)_n^{(2-2n)+}]}{[Co^{2+}] \cdot [SO_3^{2-}]^n}. \quad (4)$$

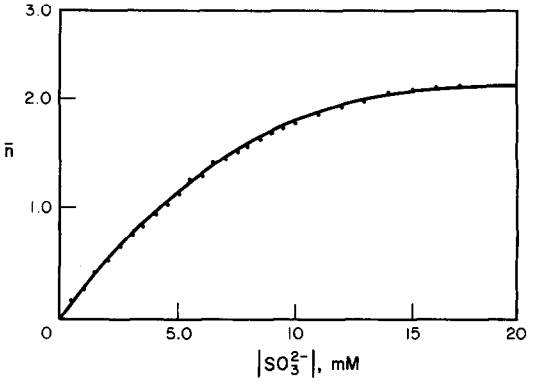

Fig. 2. Definitive formation curve obtained by extrapolation of $\log \bar{n}$ vs $C_{HSO_3^-}$. These data were integrated in order to give the $F_0(x)$ function.

In spite of being an incontestable reference for the calculation of the constants, we must take into account the possibility of subjective errors caused by the extrapolations. Because of this, many methods have been developed for the refinement of data obtained graphically; in this study the matrix method has been chosen, proposed initially by Milcken and Neves.[11] This method is based on a "normalization factor", fi, given by:

$$fi = F_0(x)_{max}/F_0(x) \quad (5)$$

which is introduced in the function $F_0(x)$, by:

$$F_0(x)_{max} = F_0(x)_i fi = fi + fi\beta_1[L] + fi\beta_2[L]^2 + \cdots + fi\beta_n[L]^n. \quad (6)$$

The resolution of the system by matrix method is given by the following constants:

$$\beta_1 = \frac{[CoSO_3]}{[Co^{2+}]\cdot[SO_3^{2-}]} = 4.3\times10^2\,M^{-1}$$

$$\beta_2 = \frac{[Co(SO_3)_2^{2-}]}{[Co^{2+}]\cdot[SO_3^{2-}]^2} = 2.2\times10^4\,M^{-2}$$

$$\beta_3 = \frac{[Co(SO_3)_3^{4-}]}{[Co^{2+}]\cdot[SO_3^{2-}]^3} = 3.0\times10^6\,M^{-3}$$

$$K_1 = \frac{[CoSO_3]}{[Co^{2+}]\cdot[SO_3^{2-}]} = 4.3\times10^2\,M^{-1}$$

$$K_2 = \frac{[Co(SO_3)_2]}{[Co(SO_3)]\cdot[SO_3^{2-}]} = 51\,M^{-1}$$

$$K_3 = \frac{[Co(SO_3)_3]}{[Co(SO_3)_2]\cdot[SO_3^{2-}]} = 1.4\times10^2\,M^{-1}.$$

This set of constants gives an $F_0(x)$ calculated by eqn (1), which differ in $\pm0.91\%$ from the integrated value. This gives a good support for the calculation procedure.

It is important to note that in higher concentrations of the ligand precipitation occurs. In order to help this work, a preliminary study of the K_{ps} of system was conducted.[12] The value obtained was $K_{ps} = 7.3\times10^{-3}$ M^2, in the presence of bisulfite.

Considering the partial constants (K_n), we can see that K_2 is the smaller one, probably because it represents the formation of a charged species from a neutral one. The formation of this neutral species gives to K_1 the biggest numerical value of the set.

Figure 3 shows the distribution curves for the system.

Considering that the coordination number for the cobalt(II) ion is generally 6 and that SO_3^{2-} is doubly charged, it is possible to suppose that the ligand acts like a bidentate ligand in this case, because of the formation of three species.

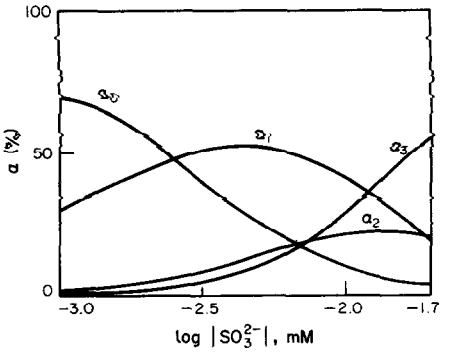

Fig. 3. Distribution curves for the various species of the system Co(II)/SO_3^{2-}.

The possibility must also be considered of the second species to be square planar, because there are known Co(II)(d^7)[13] complexes, having this behavior.

The HSO_3^- anion can influence this system in two ways, the first one like the proper HSO_3^-, or in the form of $S_2O_5^{2-}$ ion, as has been discussed, it coexists with the sulfites in aqueous solution and has variable concentration with the pH and the concentration of HSO_3^- in the media.

CHROMIUM(VI) OXIDATION OF THALLIUM(I)

G. S. GOKAVI and J. R. RAJU*

Department of Chemistry, Karnatak University, Dharwad-580 003, India

(*Received* 13 *November* 1986; *accepted after revision* 6 *March* 1987)

Abstract—The chromium(VI) oxidation of thallium(I) in 3 M hydrochloric acid at ionic strength 4 M and 25°C is studied spectrophotometrically and is found to follow a second-order rate law. The reaction is understood to occur between the species $ClCrO_3^-$ and TlCl and the possible mechanisms are discussed.

The reported standard potentials of the couples, Cr(VI)/Cr(III) and Tl(III)/Tl(I) of 1.33 and 1.25 V in acid solutions[1] do not preclude the possibility of the chromium(VI) oxidation of thallium(I) from occurring yet the reaction does not take place even in concentrated solutions of perchloric and sulphuric acids. In dilute hydrochloric acid solutions, the two potentials are nearly the same but diverge as the acid concentration is increased. The values in 5 M hydrochloric acid at 25°C are 1.17 and 0.606 V for the Cr(VI)/Cr(III) and the Tl(III)/Tl(I) couples respectively and the chromium(VI) oxidation of thallium(I) in such a solution occurs with great facility.[2] Indeed, solutions of 6 M hydrochloric acid have been used in the titrimetric analysis of thallium(I) by chromium(VI).[2,3] The reaction is of considerable interest because of its non-complementary nature and the possibility of a variety of mechanisms involving reactive intermediates such as Cr(V), Cr(IV) and Tl(II) all of which have been encountered in chemical reactions.[4] Moreover, the crucial role of hydrochloric acid, without which the reaction does not occur, needs to be understood.

EXPERIMENTAL

Chemicals

Reagent grade chemicals were used. Doubly distilled water was used for solutions. The Cr(VI) solution was obtained by dissolution of potassium dichromate (BDH,AR) in distilled water and appropriate dilution. The Cr(VI) concentration was ascertained by measuring the absorbance of the Cr(VI) solution at 360 nm in a Bausch and Lomb Spectronic 2000 instrument. The application of Beer's law was tested in the case of the 3 M hydrochloric acid solutions containing 2×10^{-4} to 6×10^{-4} M Cr(VI) using 1 cm cells with $\varepsilon = 1153$. Higher concentrations of Cr(VI) than 6×10^{-4} M were not required in any of the kinetic runs as the solubility of TlCl in 3 M hydrochloric acid was slight (1.6×10^{-3} M). The Tl(I) solution was obtained by dissolving TlCl (BDH) in distilled water and standardization with potassium bromate.[5] Most of this work employed hydrochloric acid, Acid Chem AR, although, at the later stages, Glaxo AR sample was also used. As different samples of hydrochloric acid tended to lead to discrepencies in results, one batch was usually collected and used for related studies to enable comparison of results. Acetic acid was purified by refluxing with chromium(VI) oxide for 5–6 h and distilling.[6] A further distillation gave the product to be used.

Kinetic runs

The ionic strength was maintained at 4 M in most runs with lithium perchlorate. Runs were usually carried out in 3 M hydrochloric acid solutions. In a typical run, the concentrations of Cr(VI) and Tl(I) were 3×10^{-4} and 5×10^{-4} M respectively in 3 M hydrochloric acid at an ionic strength of 4 M. The kinetics were followed by mixing the equilibrated reactant solutions. The resulting reaction mixture was transferred to a 1 cm cell and the absorbance at 360 nm was followed with a Bausch and Lomb Spectronic 2000 Spectrophotometer. The temperature was maintained at 25 ± 0.05°C. Kinetic

* Author to whom correspondence should be addressed.

runs could be reproduced to ±3% or better and runs were usually followed to about four half-lives.

RESULTS

Oxidation of hydrochloric acid by Cr(VI)

The oxidant, Cr(VI), exists mainly in the form of acid chromate ion, $HCrO_4^-$, in dilute acid solutions and, in concentrated hydrochloric acid, the predominant form of the oxidant is the chlorochromate ion,[7] $ClCrO_3^-$. Hence it may be expected that this is the species responsible for oxidation of Tl(I) in concentrated hydrochloric acid solutions. In addition to the main Cr(VI)–Tl(I) redox reaction, there is also a marginal oxidation of hydrochloric acid in the medium. At 25°C, with Cr(VI) and hydrochloric acid concentrations of 3×10^{-4} M and 3 M respectively, the extent of the latter oxidation is very small, only about 0.3% and less than 1% of oxidant being consumed in 30 and 60 min respectively. Under similar conditions, with the Tl(I) concentration at 5×10^{-4} M, 95% of the oxidant is consumed in 30 min. Hence no correction for the Cr(VI) oxidation of hydrochloric acid has been made at this temperature. The reduction of Cr(VI) by hydrochloric acid is accelerated at higher temperatures (0.5% in 15 min) as shown by the data at 32.5°C. However, the rate of the Cr(VI)–Tl(I) redox reaction is also enhanced with temperature, 95% of the reaction taking place in about 15 min at 32.5°C.

Air oxidation

Air oxidation does not occur to any significant extent under the conditions of the present study at 25°C and time durations of the Cr(VI)–Tl(I) reaction as found from runs in the presence and absence of air. At a higher hydrochloric acid concentration of 6 M and 29°C, marginal air oxidation has been reported as occurring in one study[2] while no such air oxidation interfered under similar conditions in another study.[3]

Stoichiometry

Several reaction mixtures were prepared in 3 M hydrochloric acid at ionic strength of 4 M and analysed after keeping for 2 h at 25°C. Cr(VI) was found by measuring the absorption at 360 nm. Tl(I) was determined by titrating 40 ml of the reaction mixture with 2×10^{-3} M potassium bromate and Cr(III) does not interfere. Tl(III) was found as difference of total oxidant titrated by iodometry with 2×10^{-3} M thiosulfate and Cr(VI) found by spectrophotometry. The results are shown in Table 1 and indicate a 2:3 stoichiometry for the Cr(VI) oxidation of $Tl(I) : 2Cr(VI) + 3Tl(I) = 2Cr(III) + 3Tl(III)$.

Effect of added products

The effect of added products, Cr(III) and Tl(III), was studied at an ionic strength of 4 M and hydrochloric acid concentration of 3 M and at constant Cr(VI) and Tl(I) concentrations. The products did not have any significant effect on the reaction.

Rate law

The order of the reaction with respect to Cr(VI) and Tl(I) was found by log (rate) vs log (conc.) plots in the case of the 3 M hydrochloric acid solutions at ionic strength 4 M. The order in Cr(VI) in the concentration range of 2×10^{-4} to 6×10^{-4} M at a constant Tl(I) concentration of 5×10^{-4} M was 0.9; whereas, in the concentration range of 1×10^{-4} to 6×10^{-4} M of Tl(I) at a constant Cr(VI) concentration of 3×10^{-4} M, the order in Tl(I) was 0.64. The fractional orders in Tl(I) and Cr(VI) were taken to be due to the main active species being TlCl and CrO_3Cl^- with the formation equilibrium constants of 3.9 (this work) and 14[7] respectively at 25°C. The formation constant, K_2, of TlCl at 25°C was determined at an ionic strength of 4 M from solubilities in presence of varying concentrations of hydrochloric acid. In view of the slowness of the Cr(VI)–Tl(I) reaction in solutions containing

Table 1. Stoichiometry of chromium(VI)–thallium(I) reaction [HCl] = 3.0; I = 4.0 M; temp. 25°C

$[Tl(I)] \times 10^4$ taken	$[Cr(VI)] \times 10^4$ taken	$[Tl(I)] \times 10^4$ remaining	$[Cr(VI)] \times 10^4$ remaining	$[Tl(III)] \times 10^4$ found
3.0	1.0	1.5	—	1.5
4.0	2.0	1.0	—	3.0
5.0	3.0	0.50	—	4.48
3.0	3.0	Zero	1.0	3.00
5.0	3.0	0.50	—	4.44

hydrochloric acid less than 3 M, the effect of H^+ and Cl^- concentrations on the reaction were studied at an ionic strength of 5 M in solutions containing H^+/Cl^- (4 M) and varying the concentration of the other ion from 1.0 to 4.0 M (data of Table 2); the order in H^+ and Cl^- thus found was 0.97 in either case. The rate law is given by (1) where K_1 and K_2 are the formation equilibrium constants of CrO_3Cl^- and TlCl respectively. Rates of reaction at around 30 different sets of concentrations of Tl(I) and Cr(VI) were found to bear an approximately linear relationship with the product of the two reactant concentrations as shown in Fig. 1(a). Second order plots according to (2) with a and b representing Tl(I) and Cr(VI) concentrations respectively were found to be linear in most cases to about 90% reaction [Fig. 1(b)], k_s giving the second order rate constant.

$$-\frac{d[Cr(VI)]}{dt} = k_o \frac{K_1K_2[H^+][Cl^-]^2}{(1+K_1[H^+][Cl^-])(1+K_2[Cl^-])} \times [Tl(I)][Cr(VI)] \quad (1)$$

$$k_s = \frac{2.303}{t(a-3b/2)} \log \frac{b(a-3x/2)}{a(b-x)} \quad (2)$$

Effect of solvent polarity

The effect of dielectric constant (D) on the reaction was studied by changing the solvent polarity by use of different quantities of acetic acid in the solvent keeping the ionic strength constant at 3 M. The plot of $\log k_s$ vs $1/D$ was linear with positive slope. The dielectric constants used were computed from the values of pure liquids as in earlier work.[8]

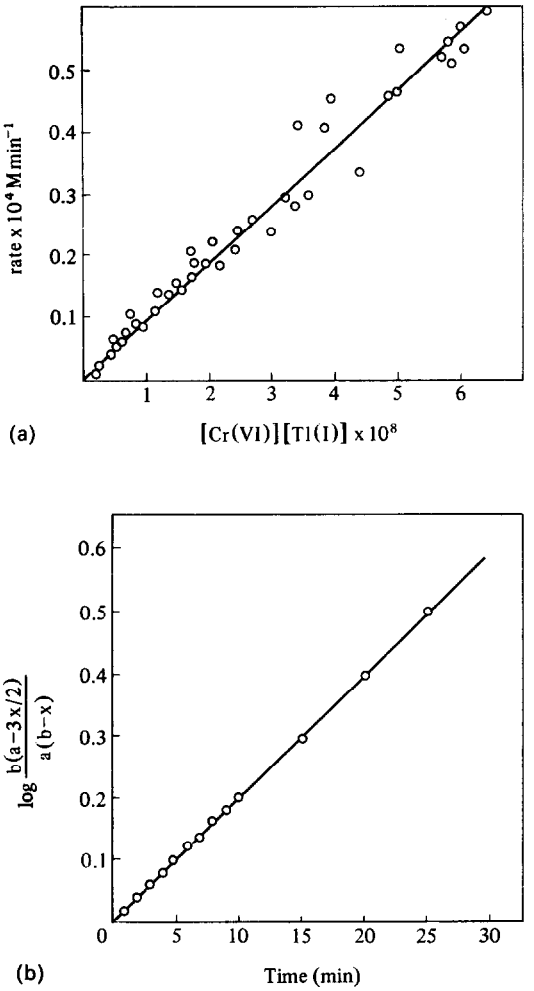

Fig. 1. (a) Graph of rate of Cr(VI)–Tl(I) reaction vs product of reactant concentrations. I = 4.0 M; [HCl] = 3.0; T = 25°C. (b) Second order plot of Cr(VI)–Tl(I) reaction at 25°C. I = 4.0 M; [Cr(VI)] = 3.0×10^{-4}; [Tl(I)] = 5.0×10^{-4}; [HCl] = 3.0.

DISCUSSION

The stoichiometry of the Cr(VI)–Tl(I) redox reaction is found to be 2:3. The marginal reduction of Cr(VI) by the hydrochloric acid present in high concentrations in the reaction medium occurs only to the extent of about 0.3% in 30 min at 25° and that too in the absence of Tl(I). During this time, 95% of the main reaction, i.e. of Cr(VI) oxidation of Tl(I), is complete. There was also no need of excluding air from the reaction under the present conditions although an earlier study found that, at a concentration of 6 M hydrochloric acid, an inert atmosphere was needed[2] while another study[3] under similar conditions did not find it necessary to exclude air from the reaction.

Table 2. Effect of chloride and hydrogen ions on second order rate constant. I = 5.0 M; [Cr(VI)] = 3.0×10^{-4}; [Tl(I)] = 5.0×10^{-4}; temp. 25°C

(a) $[H^+] = 4.0$		(b) $[Cl^+] = 4.0$	
$[Cl^-]$	k_s M^{-1} s^{-1}	$[H^+]$	k_s M^{-1} s^{-1}
1.0	6.6	1.0	7.0
2.0	17	2.0	9.4
3.0	25	3.0	22
4.0	44	4.0	44

The rate law (1) and other results may be accommodated by Scheme I or Scheme II. In both schemes, Cr(VI) and Tl(I) are converted into the species $ClCrO_3^-$ and TlCl respectively in prior equilibria. In Scheme I, these species are involved in a first reversible step giving the reactive intermediates Cr(V) and Tl(II) and the latter species are involved

in further steps. A steady state treatment of Cr(V) and Tl(II) results in the rate law (3). With constant factors on the right hand side identifiable with k_s as 15.6 $M^{-1} s^{-1}$ [Fig. 1(a)] and using an approximate value of k_1 as 19.9 $M^{-1} s^{-1}$, a value of 6.5 is obtained for the ratio k_3k_4/k_2.

$$-\frac{d[Cr(VI)]}{dt} = \left(\frac{k_3k_4}{k_2}\right)\left\{\left(1+\frac{4k_1k_2}{k_3k_4}\right)^{1/2}-1\right\} \times \left\{\frac{K_1K_2[H^+][Cl^-]^2}{(1+K_1[H^+][Cl^-])(1+K_2[Cl^-])}\right\} \times [Tl(I)][Cr(VI)]. \quad (3)$$

Scheme II is essentially the same as Scheme I except that the prior equilibria are succeeded by the rate determining and irreversible step of formation of Cr(V) and Tl(II) followed by other steps as in Scheme I. While this mechanism is in agreement with the results, more often than not in non-complementary reactions involving Cr(VI) or Tl(III), the formation of Cr(V) or Tl(II) involves a reversible step. However, in view of the fact that both Cr(V) and Tl(II) are reactive and are likely to be present in very low concentrations, it is difficult to distinguish between Schemes I and II.

The Cr(VI)–Tl(I) reaction is facile only in the presence of large concentrations of hydrochloric acid and, as mentioned already, the reduction potentials of the couples Cr(VI)/Cr(III) and Tl(III)/Tl(I) become more and more favourable as the hydrochloric acid concentration increases.[2] From the difference in reduction potentials, the equilibrium constant for the reaction in dilute acids and in 6 M hydrochloric acid at 25°C may be calculated to be around 10^5 and 10^{28} respectively showing the facility of the reaction in the latter solution as compared to the dilute sulphuric/perchloric acid medium. In Cr(VI) solutions containing hydrochloric acid concentrations greater than 1 M, the Cr(VI) which is present mainly in the form of the acid chromate ion, $HCrO_4^-$, in dilute acid solutions, is almost entirely transformed into chlorochromate,[9] $ClCrO_3^-$. Hence, it is the latter species that is responsible for the oxidation of Tl(I) in concentrated hydrochloric acid solutions. The Tl(I) in chloride solutions forms chloride species, $(TlCl_n)^{1-n}$, with $n = 1$ and $n = 2$ and higher chloride species may also be expected in concentrated chloride solutions.[10] The major species is TlCl with an equilibrium constant of formation of 3.9 in 3 M hydrochloric acid at an ionic strength of 4 M at 25°C. Thus, the active species is likely to be TlCl which is also supported by the fact that the second order rate constant, k_s, of the Cr(VI)–Tl(I) reaction in such media increases with the decrease of the dielectric constant of the solvent medium. Unfortunately, as the solubility of Tl(I) in hydrochloric acid is severely limited and since analysis of Tl(I) at such low concentrations is difficult, this cannot be further studied under pseudo first order conditions. If the reactants are in the form of $ClCrO_3^-$ and TlCl, they may be expected to form in prior equilibria.

In Scheme I, no Cr(IV) is involved but Cr(V) is. Induction experiments with iodide could not be performed in the present case as one of the products, Tl(III), also oxidises iodide along with Cr(VI) and any Cr(V) that forms. Furthermore, the Cr(V)–Tl(I) reaction, being a complementary one, is expected to be fast and Cr(V), as well as Tl(II), is likely to be present in very low concentrations.

It was observed in the case of the γ-radiation induced reduction of Cr(VI) by Tl(I) in 0.4 M air saturated sulphuric acid, that the OH radicals produced oxidised Tl(I) to Tl(II) and the latter produced Cr(V) by reduction of Cr(VI).[11] The Cr(VI), Cr(V) and any Cr(IV) did not oxidise Tl(I) to Tl(II) nor did Tl(II) oxidise Cr(III). The products, Cr(III) and Tl(III), also did not have any effect on the reaction. In the present case also, the products Cr(III) and Tl(III) do not affect the reaction but Cr(VI) and Cr(V) attack Tl(I) and Tl(II) in Scheme I unlike the γ-ray induced reduction of Cr(VI) in dilute sulphuric acid solution. In the latter solution, the oxidant is mainly present as the acid chromate, $HCrO_4^-$, while in the hydrochloric acid solution, the species, $ClCrO_3^-$, is involved. Moreover, high chloride concentrations favour Tl(I) oxidations[12] and, as in the present case, hydrogen and chloride ions have been found to together facilitate the reduction of Cr(VI) by Tl(I) (Table 2). Chloride ions accelerate the reaction to a greater extent at constant hydrogen ion concentration (Table 2).

$$HCrO_4^- + H^+ + Cl^- \rightleftharpoons ClCrO_3^- + H_2O \quad (K_1)$$
$$Tl^+ + Cl^- \rightleftharpoons TlCl \quad (K_2)$$
$$ClCrO_3^- + TlCl \rightleftharpoons CrO_3^- + TlCl_2 \quad (k_1, k_2)$$
$$ClCrO_3^- + TlCl_2 \rightarrow CrO_3^- + TlCl_2^+ + Cl^- \quad (k_3)$$
$$2(CrO_3^- + TlCl + 6H^+ \rightarrow Cr^{3+} + TlCl^{2+} + 3H_2O) \quad (k_4)$$

Scheme I.

SYNTHESIS AND CHARACTERIZATION OF NOVEL PLATINUM GROUP METAL COMPLEXES OF BIS[2-(DIPHENYLPHOSPHINO)ETHYL]AMINE

M. M. TAQUI KHAN* and E. RAMA RAO

Discipline of Co-ordination Chemistry and Homogeneous Catalysis, Central Salt & Marine Chemicals Research Institute, Bhavnagar 364002, India

(*Received* 9 *December* 1986; *accepted* 6 *March* 1987)

Abstract—A mixed donor tridentate ligand bis [2-(diphenylphosphino)ethyl]amine (DPEA) was synthesized in its hydrochloride form by a modified procedure and characterized by ^{1}H, ^{13}C and ^{31}P NMR spectral data. Reaction of $RhCl(CO)(PPh_3)_2$ with DPEA · HCl and $NaBPh_4$ in methanol gave the cationic Rh(I) complex $[Rh(DPEA)PPh_3]BPh_4$ but the reaction of $IrCl(CO)(PPh_3)_2$ with DPEA · HCl in boiling benzene gave a unique complex, [Ir(H)(Cl)(CO)(DPEA)]Cl, in which five different donor atoms are coordinated to the single Ir(III) ion. A neutral, Rh(III) complex of the composition $[RhCl_3(DPEA)]$ was prepared by the reaction of $RhCl_3 \cdot xH_2O$ with DPEA · HCl in methanol. Reaction of $PdCl_2(COD)$ with DPEA · HCl in benzene or methanol gave the cationic complex [PdCl(DPEA)]Cl the above reaction conducted in benzene-acetone-methanol mixture gave the 1:2 complex $[Pd(DPEA)_2]Cl_2$. A novel trinuclear Pt(II) complex of the composition $[Pt_3Cl_3(DPEA)_3]Cl_3$ was prepared by the reaction of K_2PtCl_4 and DPEA · HCl in water-acetone mixture. Reaction of K_2PtCl_4, DPEA · HCl and NH_4PF_6 in water ethanol mixture gave the binuclear, cationic complex, $[Pt_2(DPEA)_3](PF_6)_4$. All the complexes were characterized by elemental analysis, conductivity, ^{1}H and ^{31}P NMR spectral data.

Recently we have been interested in the synthesis and chemistry of transition metal complexes of polydentate ligands containing mixed donor atoms like N, P, As.[1–5] Though considerable research interest has been concentrated on mononuclear complexes of polydentate mixed donor ligands, only recently active interest has been evinced in the use of these polydentate ligands in the synthesis of bi- and polynuclear metal complexes,[6–8] mostly due to their catalytic importance.[9–11]

In this paper we report the synthesis of mononuclear platinum group metal complexes of bis[2-(diphenylphosphino)ethyl]amine (DPEA) which has been synthesized by a modified procedure. Binuclear and trinuclear Pt(II) metal complexes of DPEA in which the two metal ions are held apart at a sufficient distance and incapable of forming metal–metal bonds, have also been synthesized. All the complexes and the ligand DPEA are characterized on the basis of their analytical and spectral data.

RESULTS AND DISCUSSION

The ligand DPEA · HCl is soluble in most of the organic solvents and was characterized by analytical and spectral measurements. The ^{1}H NMR spectrum of the ligand DPEA · HCl, exhibits a complex asymetric phenyl proton resonance at 7.3 δ. The resonance of the protons of the CH_2CH_2 bridge are also observed as multiplets centered at 2.9 δ ($-CH_2$ protons attached to diphenylphosphino group) and 2.5 δ ($-CH_2$ protons attached to amine center). The spectrum also exhibits the NH resonance at 1.9 δ, in concurrence with earlier reported values.[12,13] The $^{31}P\{^{1}H\}$ NMR spectrum of the ligand in $CHCl_3$ gave an intense singlet at -20.3 δ. The $^{13}C\{^{1}H\}$ NMR spectrum of DPEA · HCl in $CDCl_3$ gave two well defined doublets centred at 44.4 δ and 24.0 δ in the aliphatic region. The more downfield doublet is assigned to the methylene car-

* Author to whom correspondence should be addressed.

bon of the CH_2CH_2 bridge attached to phosphorus, with larger $^1J(C-P) = 26.4$ Hz and the other high field doublet with $^2J(C-P) = 17.6$ Hz, can be assigned to the methylene carbon attached to nitrogen. The aromatic carbons of the diphenylphosphino moieties gave doublets centred at 136.3, 132.7 and 128.8 δ with J(C–P) values of 13.2, 19.1 and 5.8 Hz assigned to C-2(6), C-1, C-3(5), respectively, whereas C-4 carbon gave a singlet at 129.7 δ.

Platinum group metal complexes

The ligand DPEA · HCl was utilized for the synthesis of various platinum group metal complexes.

The reaction of DPEA · HCl with $RhCl(CO)(PPh_3)_2$ in 1 : 1 molar ratio gave the cationic complex, $[Rh(DPEA)(PPh_3)]BPh_4$ **1** best isolated as its BPh_4^- salt. Complex **1** gave a conductance value indicative of a 1 : 1 electrolyte[14] (Table 1). The $^{31}P\{^1H\}$ NMR spectrum of complex **1** (Fig. 1, Table 2) exhibits an A_2MX pattern of spectrum with a pair of triplets and doublets. The doublets are centred at 41.5 and 38.2 δ with $J(Rh-P_a) = 134.3$ Hz and are assigned to the two equivalent *trans* phosphorus atoms (P_a) of the ligand (structure I). The triplets are centred at 32.0 and 29.3 δ with $J(Rh-P_b) = 117.2$ Hz, $J(P_a-P_b) = 24.4$ Hz, and assigned to triphenyl phosphine (P_b), which is coordinated to rhodium *trans* to the nitrogen of

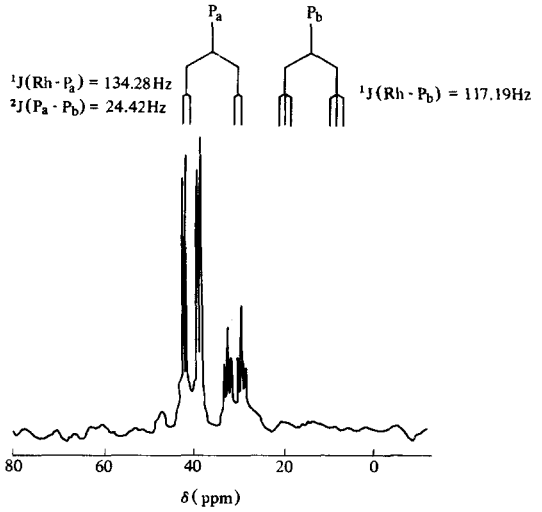

Fig. 1. $^{31}P\{^1H\}$ NMR spectrum of [Rh(DPEA)(PPh$_3$)]BPh$_4$.

DPEA. There is a considerable downfield shift of ^{31}P resonance of the phosphorus atoms of the ligand DPEA upon chelation to form a five-membered ring[15] and also the $^1J(Rh-P_a)$ coupling is larger than that of $^1J(Rh-P_b)$, due to the strong bond of the chelated phosphorus atoms rather than the monodentate phosphorus atom. Complex **1** can be assigned a square-planar structure as shown in Structure I.

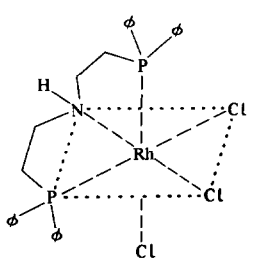
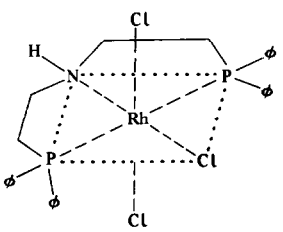
I

Interaction of hydrated rhodium trichloride with DPEA · HCl in 1 : 1 mole ratio gives a neutral, octahedral complex of the composition [$RhCl_3$(DPEA)] **2** which can exist in two isomeric forms: *facial* and *meridional*. The far-infrared spectrum exhibits a broad band at 335 cm^{-1} and also two more bands at 350 and 386 cm^{-1} indicative of ν(Rh–Cl) and cannot be unambiguously assigned to either isomer. However, $^{31}P\{^{1}H\}$ NMR spectrum (Table 2) corroborates the presence of both *facial* and *meridional* isomers. The spectrum displays two doublets centred at 44.5 δ (J(Rh–P) = 122.2 Hz) and 28.4 δ (J(Rh–P) = 84.2 Hz) that can be assigned to the *fac* and *mer* isomers (Structure II, IIa), respectively. The above spectral assignment was based on the following considerations in the *fac* isomer (**II**) the two phosphorus atoms *trans* to a more electronegative and a weak ligand would exhibit a more downfield resonance with a large J(Rh–P) in comparison to the *mer* isomer, in accordance with the earlier observed data.[16,17]



II



IIa

Interaction of DPEA · HCl with $IrCl(CO)(PPh_3)_2$ in boiling benzene, however gave a unique and interesting complex of the composition [Ir(H)(Cl)(CO)(DPEA)]Cl **3** wherein the metal ion is coordinated to five different donor atoms. Analytical and conductivity data (Table 1) support the above formulation for complex **3**. Complex **3** is obtained by an oxidative-addition of the HCl, derived from the ligand DPEA · HCl, to the Ir(I) complex $IrCl(CO)(PPh_3)_2$ followed by the coordination of Ir(III) to DPEA. The infrared spectrum of complex **3** (Fig. 2) displays an intense peak at 2020 cm^{-1} indicative of the coordinated carbonyl absorption band. This band is red shifted about 50 cm^{-1} compared to that of the starting material (Vaska's complex) and is in support[18] of the oxidation of Ir(I) to Ir(III). The IR spectrum of the complex also exhibits an intense metal-hydride stretching frequency at 2095 cm^{-1} (Fig. 2). The far-infrared spectrum of **3** shows a ν(Ir–Cl) band at 333 cm^{-1}.

The ^{1}H and ^{31}P NMR are of great help in corroborating the above formulation for complex **3**. The ^{1}H NMR spectrum (Fig. 3) exhibits the proton resonance centred at 7.5 δ and two types of the methylene protons at 3.4 and 3.3 δ as broad intense peaks. The proton of the secondary amine gave the resonance at 10.1 δ (Fig. 3) indicating the coor-

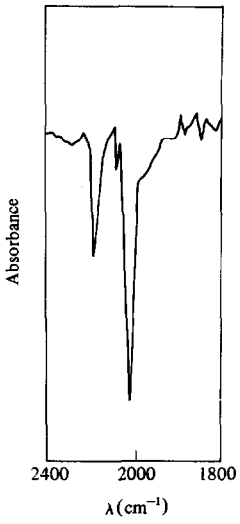


Fig. 2. IR spectrum of [Ir(H)(Cl)(CO)(DPEA)]Cl.

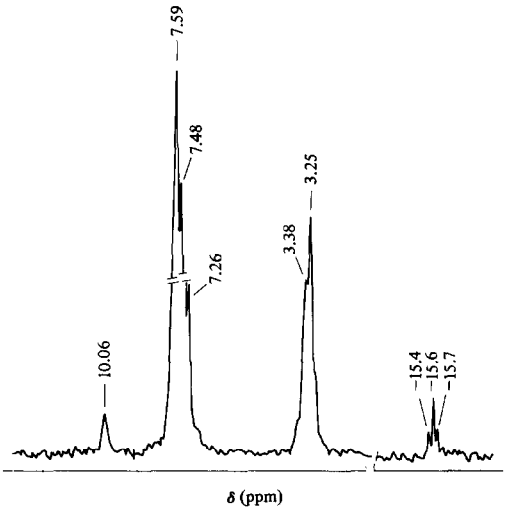

Fig. 3. ^{1}H NMR spectrum of [Ir(H)(Cl)(CO)(DPEA)]Cl.

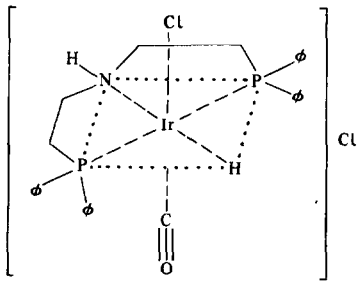
dination of nitrogen of the secondary amine to the metal ion.[19] The ^{1}H NMR spectrum in the high field region displays a well defined triplet (Fig. 3) centred at -15.6 δ indicating the presence of hydride species in the coordination sphere of the metal ion. The triplet is due to coupling of the hydride with two equivalent *trans* disposed phosphorus atoms of the ligand DPEA (Structure III).

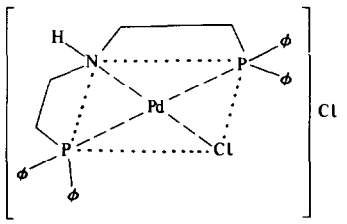


III

The J(P–H) of 12.8 Hz is also in agreement with the *cis* disposition of the hydride to the two phosphorus atoms of the ligand.[20]

The ^{31}P{^{1}H} NMR spectrum exhibits an intense singlet at 27.7 δ in support of structure III for complex **3**.

The reaction of $PdCl_2$(COD) with DPEA·HCl in refluxing methanol or benzene, resulted in the formation of the square planar complex [PdCl(DPEA)]Cl **4**, by the complete displacement of 1,5-COD. The conductance value is consistent with a 1:1 electrolyte[14] (Table 1). The far-infrared spectrum of the complex displays a ν(Pd–Cl) absorption band at 337 cm^{-1}. The ^{31}P{^{1}H} NMR spectrum of complex **4** exhibits a singlet at 37.2 δ indicating the magnetic equivalence of the two *trans* disposed phosphorus atoms of the ligand DPEA, as shown in Structure IV.



IV

When the reaction of $PdCl_2$ with DPEA·HCl was conducted in a methanol/acetone/benzene mixture a five-coordinated 1:2 complex of the composition $[Pd(DPEA)_2]Cl_2$ **5** resulted. The formulation of complex **5** is corroborated by the elemental analysis, conductance values (Table 1) and the ^{31}P{^{1}H} NMR. The ^{31}P{^{1}H} NMR spectrum of complex **5** displays an interesting spectrum (Fig. 4). The spectrum has a downfield doublet centred at 45.4 δ, a triplet centred at 15.5 δ and a higher field singlet at -22.4 δ. The spectrum suggests that one of the two coordinated DPEA ligands which is potentially terdentate is coordinated to the metal ion through only one of two phosphorus atoms and the other phosphorus donor end (P_c) is free as

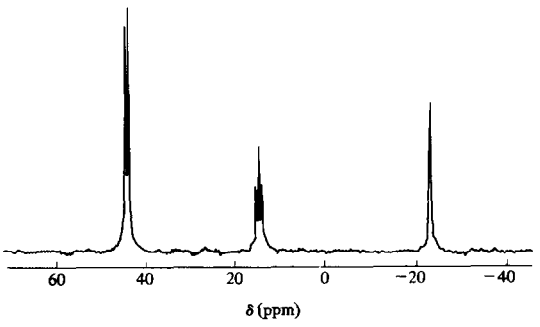


Fig. 4. ^{31}P{^{1}H} NMR spectrum of $[Pd(DPEA)_2]Cl_2$.

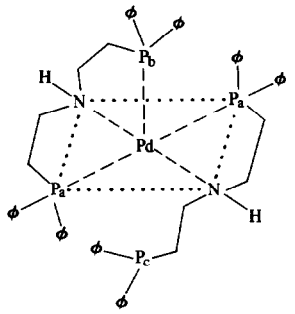
evidenced by the high field singlet. Thus the ligand DPEA acts as a bidentate ligand in the complex (Structure V). The doublet is assigned to the two



V

equivalent phosphorus donor atoms (P_a) and the triplet to the phosphorus (P_b). The $J(P_a–P_b)$ value of ~ 24 Hz also confirms the *cis* coordination of the phosphorus atoms P_a and P_b as shown in Structure V. The complex is shown with a five coordinated square pyramidal Pd(II) ion. Such a five coordination of Pd(II) was also suggested in other complexes.[21] Five coordination is more common in Pd(II) complexes as compared to those of Pt(II) complexes.

The reaction of $PdCl_2$ with DPEA · HCl in methanol however gave a mixture of complexes **4** and **5** as evidenced by the $^{31}P\{^1H\}$ NMR spectrum in $CHCl_3$ with complex **4** being the predominant species.

The reaction of K_2PtCl_4 with DPEA · HCl in 1 : 1 molar ratio in water–acetone medium gave a trinuclear ligand bridged complex of the composition $[Pt_2DPEA)(\mu^3\text{-}DPEA)(PtCl_3)]Cl_3$ **6**. The above reaction when conducted in water–methanol medium in the presence of NH_4PF_6 resulted in the formation of a binuclear, ligand bridged complex of the composition, $[Pt_2(DPEA)_2(\mu\text{-}DPEA)](PF_6)_4$ **7**. The elemental analysis and conductance data obtained is in confirmation of the above formulations for the complexes **6** and **7**. The far-infrared spectrum of complex **6** displays a broad band at 325 cm^{-1} due to ν(Pt–Cl).

The infrared spectrum of **7** exhibits a strong absorption at 840 cm^{-1} characteristic of ν(P–F) stretching frequency.[22]

The $^{31}P\{^1H\}$ NMR spectrum of complex **6** supports its formulation as a trinuclear ligand bridged species. The $^{31}P\{^1H\}$ NMR spectrum of **6** (Fig. 5) exhibits a doublet centred at 42.0 δ and a triplet centred at -5.3 δ with ^{195}Pt satellites in 2 : 1 ratio, respectively. This also indicates the presence of two different types of phosphorus atoms in accordance with the geometry shown in Structure VI. The doublet is assigned to the two equivalent *trans* disposed phosphorus atoms (P_a) of the ligand DPEA and the triplet to the phosphorus atom (P_b) which is *trans* to a nitrogen donor and *cis* to the two equivalent P_a nuclei. The platinum–phosphorus coupling constants $J(Pt–P_a)$ and $J(Pt–P_b)$ calculated from the platinum satellites are found to be 2578 Hz and 3123 Hz, respectively, in accordance with the earlier observed values.[17,19,23] The $J(Pt–P_b)$ value is larger as compared to that of $J(Pt–P_a)$ due to the fact that the phosphorus atom (P_b) *trans* to a σ-donor nitrogen group is bound strongly to the metal ion with a greater *s* character of the Pt–P

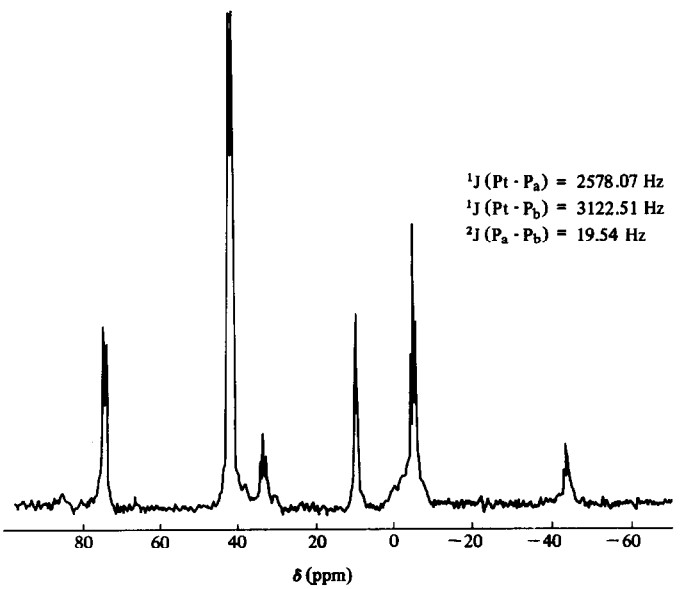


Fig. 5. $^{31}P\{^1H\}$ NMR spectrum of $[Pt_2(DPEA)(\mu^3\text{-}DPEA)(PtCl_3)]Cl_3$.

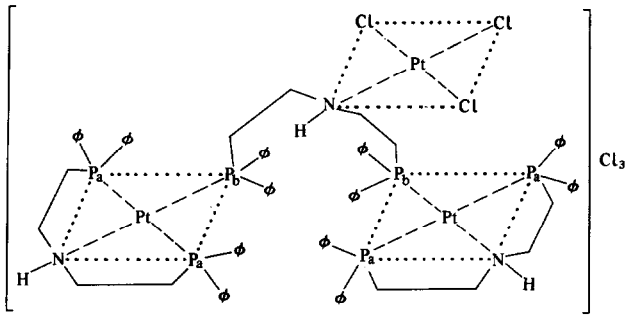
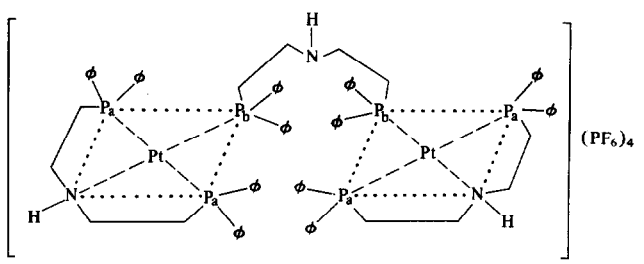


VI

bond as compared to the mutually *trans* phosphorus atom (P_a).[17,23]

The $^{31}P\{^1H\}$ NMR spectrum of complex **7** (Fig. 5) shows a doublet centred at 42.0 δ and a triplet centred at -7.0 δ with ^{195}Pt satellites. The doublet is assigned to *trans* disposed phosphorus aroms (P_a) and the triplet is assigned to the phosphorus atom (P_b) which is *trans* disposed to a σ-donor nitrogen group and *cis* to two P_a atoms as shown in Structure VII. The $^1J(Pt–P_a)$ = 2537 Hz, $^1J(Pt–P_b)$ = 3147 Hz and $^2J(P_a–P_b)$ = 19.5 Hz, values are in accordance with earlier observed data.[17,19,23] The $^{31}P\{^1H\}$ spectrum of complex **7** also displays seven sharp lines (J = 713 Hz) in the high-field region centred at -143.3 δ due to the PF_6^- ion.[24,25] The geometry of complex **7** is shown in Structure VII.



VII

The far-infrared spectra of complexes **1–7** gave bands around 520 cm^{-1} due to ν(M–P).

The electronic spectral data of all the complexes **1–7** agree with the proposed geometries of the complexes. All the square-planar complexes in this work have nd^8 whereas octahedral complexes have nd^6 valence orbital electronic configurations, respectively. Complex **1** gave bands at 340 nm (4160) and 335 nm (3200) assignable to *d–d* transitions and the bands at 272 nm (25120) and 268 nm (25440) are attributed to π–π^* transitions. Similarly, complex **4** displays a band at 353 nm (31840) assigned to *d–d* transition with LMCT character and bands at 288 nm (35360) and 262 nm (24000) are due to LMCT transitions between the metal ion and the ligand. The polynuclear Pt(II) complexes **6** and **7** gave bands at 274 nm (12900) with LMCT character and 360 nm (3360), respectively, assigned to *d–d* transitions. The bands observed at 256 nm (17000), 226 nm (25000) and 266 nm (25600), 250 nm (24000) for **6** and **7**, respectively, are assigned to charge-transfer transitions between metal ion and the ligand. The results obtained are in agreement with the earlier reported work with nd^8 metal ions.[26,27]

The octahedral Rh(III) complex **2** gave bands at 425 nm (11207), 353 nm (64000), 330 nm (11360) and 257 nm (29046) whereas Ir(III) complex **3** gave bands at 355 nm (2160), 290 nm (11360), 272 nm (15040) and 265 nm (16640). The bands around 425 and 350 nm are assigned to the transitions from $^1A_{1g}$ ground state to the $^1T_{1g}$ excited state. Whereas the other high energy bands are assigned to charge-transfer transitions between metal ion and the ligand.

EXPERIMENTAL

The hydrated trichlorides of rhodium and iridium, $PdCl_2$ and K_2PtCl_4 were purchased from Alfa Inorganics (USA) and Johnson Matthey (England). Triphenyl phosphine was purchased from Strem Chemicals Inc. (U.S.A.). $NaBPh_4$ and NH_4PF_6 were obtained from SISCO (India). 1,5-cyclooctadiene obtained from Fluka was used as such. The complexes $RhCl(CO)(PPh_3)_2$,[28]

$IrCl(CO)(PPh_3)_2$,[28] were prepared by published procedures. Diethanolamine, thionyl chloride were of Analar grade and were used without further purification. Bis(2-chloroethyl)amine hydrochloride was prepared by published procedure.[29] All the preparations were carried out in a dry nitrogen atmosphere.

Microanalysis, melting points, infrared spectra, conductivity measurements were done as reported.[30] Proton NMR spectra were recorded on a Jeol FX100 spectrometer operating at 100 MHz using TMS as an internal standard. The carbon-13 NMR spectrum of the ligand was also recorded on the same instrument operating at 24.9 MHz in $CDCl_3$ using TMS as an internal standard. The proton noise decoupled phosphorus-31 NMR spectra of the ligand and complexes were taken in the indicated solvents (Table 2) using the same instrument operating at 40.3 MHz in the FT mode with a deuterium lock. 85% H_3PO_4 was used as an external reference. The electronic spectra of complexes were measured on a Shimadzu UV 240 spectrophotometer.

Synthesis of the ligand

The terdentate mixed donor (N and P) ligand bis[2-(diphenylphosphino)ethyl]amine hydrochloride (DPEA · HCl) was synthesized by modified published procedures,[31,32] as shown in scheme.

$$HN(CH_2CH_2OH)_2 + 2SOCl_2 \xrightarrow{CHCl_3} Cl^-H_2N^+(CH_2CH_2Cl)_2 + 2SO_2 + 2HCl$$

a

$$\mathbf{a} + 10\%NaOH \longrightarrow HN(CH_2CH_2Cl)_2 + 2NaCl + 2H_2O$$

b

$$PPh_3 + 2K \xrightarrow{1,4,dioxan} KPPh_2 + KPh$$

$$\mathbf{b} + 2KPPh_2 \xrightarrow[THF]{1,4,dioxan} HN(CH_2CH_2PPh_2)_2 + 2KCl$$

c

$$\mathbf{c} + 2NHCl \xrightarrow{n\text{-hexane}} Cl^-H_2N^+(CH_2CH_2PPh_2)_2$$

Bis(2-chloroethyl)amine hydrochloride **a** was prepared by the published procedure[28] and its free amine **b** was liberated by the treatment of a stoichiometric amount of 10% NaOH. The free amine was liberated as an insoluble oil and was dried over sodium sulfate prior to its use. Free amine **b** (6.42 g, 0.045 mol) was dissolved in 40 cm^3 of THF and added dropwise with stirring to an orange-red solution of $KPPh_2$, which was obtained previously through the reaction of metallic potassium (7.04 g, 0.18 mol) with PPh_3 (25.66 g, 0.09 mol) in dioxane. Prior to the addition of the organic halide **b**, KPh was destroyed carefully by the addition of NH_4Cl to the reaction mixture containing both KPh and $KPPh_2$. This *in situ* method of reaction is found to be more convenient to us. After the addition of **b** the reaction mixture was refluxed for an hour and poured into a beaker containing ice-cold water before which the unreacted potassium was destroyed by methanol. The ligand DPEA was separated as an insoluble oil **c**, which on treatment with 2N HCl, in *n*-hexane with vigorous stirring gave a solid white crystalline ligand **d** in its hydrochloride form. The ligand DPEA · HCl was purified by recrystallizing from hot acetonitrile. Yield: 90%. M.p. 175°C; mol wt. 477.5 (calculated), 470 (experimental, osmometric in chloroform). Found: C, 70.1; H, 6.3; N, 2.9. Calc. for $C_{28}H_{30}NClP_2$: C, 70.4; H, 6.3; N, 2.9%.

Preparation of metal complexes

(1) *Triphenylphosphinebis*[2 - (*diphenylphosphino*)*ethyl*]*aminerhodium*(I)*tetraphenylborate*, [Rh(DPEA)(PPh_3)]BPh_4. To a refluxing methanolic solution of DPEA · HCl (0.11 g, 0.22 mmol) was added $RhCl(CO)(PPh_3)_2$ (0.15 g, 0.22 mmol) and further refluxed for 3 h to get a dark yellowish orange solution. An excess of $NaBPh_4$ was then added to the above solution, which on concentration gave a crystalline yellow compound. The compound was filtered, washed with benzene, methanol and recrystallized from dichloromethane-*n*-hexane mixture. Yield: 0.2 g (82%).

(2) *Trichlorobis*[2 - (*diphenylphosphino*)*ethyl*]-*aminerhodium*(III), $RhCl_3$(DPEA). $RhCl_3 \cdot 3H_2O$ (0.11 g, 0.42 mmol) in methanol was reacted with the ligand DPEA · HCl (0.2 g, 0.42 mmol) to give a yellow solution. After refluxing the solution for 6–7 h, the solution was concentrated to a small volume by a vacuum rotary evaporator and diethyl-ether added to get a yellow precipitate. The complex was filtered, washed with benzene, diethyl ether and recrystallized from dichloromethane-*n*-hexane mixture. Yield: 0.17 g (63%).

(3) *Chlorohydridocarbonylbis* [2 - (*diphenylphosphino*)*ethyl*]*amineiridium*(III) *chloride*, [Ir(Cl)(H)(CO)(DPEA)]Cl. The ligand DPEA · HCl (0.1 g, 0.21 mmol) and $IrCl(CO)(PPh_3)_2$ (0.11 g, 0.21 mmol) in benzene were refluxed for 6 h, to get a pale yellow crystalline complex. The complex was filtered, washed with benzene and dried *in vacuo*. Yield: 0.11 g (73%).

(4) *Chlorobis*[2-(*diphenylphosphino*)*ethyl*]*aminepalladium* (II) *chloride*, [PdCl(DPEA)]Cl. To the refluxing benzene solution of DPEA·HCl (0.2 g, 0.42 mmol) was added $PdCl_2$(COD) (0.12 g, 0.42 mmol), when a clear solution was obtained. The refluxing was continued till a yellowish green crystalline compound separated. The complex was filtered, washed with benzene and recrystallized from dichloromethane-*n*-hexane mixture. Yield: 0.21 g (72%).

The above reaction when conducted in refluxing methanol also gave the same product.

(5) *Bis* (*bis* [2 - (*diphenylphosphino*) *ethyl*] *aminepalladium* (II) *chloride*, $[Pd(DPEA)_2]Cl_2$. The reaction of $PdCl_2$ (0.10 g, 0.56 mmol) with DPEA·HCl (0.27 g, 0.56 mmol) was conducted in a mixture of 25 cm^3 of benzene, 5 cm^3 of acetone and 5 cm^3 of methanol. The above reaction mixture was refluxed for 2 h, and the solution concentrated to a small volume by a vacuum rotary evaporator. The addition of diethyl ether gave a yellow complex which was filtered, washed with diethyl ether and recrystallized from dichloromethane-*n*-hexane mixture. Yield: 0.48 g (80%).

(6) *Bis*(*bis*[2 - (*diphenylphosphino*)*ethyl*] *amine* - μ^3 - *bis*[2 - (*diphenylphosphino*)*ethyl*]*aminediplatinum* (II)*trichloroplatinum*(II)*trichloride*, [(DPEA) $\overline{Pt(Ph_2PCH_2CH_2}$ $\overline{N(H)CH_2CH_2PPh_2}](PtCl_3)$ Pt (DPEA)] Cl_3. To a 1:1 water acetone mixture of K_2PtCl_4 (0.13 g, 0.42 mmol) was added DPEA·HCl (0.2 g, 0.42 mmol) in hot acetone. On addition of the ligand the solution is decolourized and the reaction mixture was refluxed for 6 h. After removing the acetone by rotary vacuum evaporator, the compound was extracted by dichloromethane. The extracted solution was dried over Na_2SO_4, concentrated to a small volume and the complex precipitated by the addition of *n*-hexane. The complex was filtered, washed with benzene and *n*-hexane and recrystallized from dichloromethane-*n*-hexane mixture. Yield 0.23 (76%).

(7) *Bis*(*bis*[2-(*diphenylphosphino*)*ethyl*]*amine*-μ-*bis*[2-(*diphenylphosphino*)*ethyl*]*aminediplatinum*(II) *hexafluorophosphate*, $[Pt_2(DPEA)_2(\mu\text{-DPEA})](PF_6)_4$. To an aqueous solution of K_2PtCl_4 (0.13 g, 0.42 mmol) was added an ethanolic solution of the ligand DPEA·HCl (0.2 g, 0.42 mmol) to get a colourless solution. The reaction mixture was stirred for about 2 h at room temperature and then refluxed for 5 h. To the refluxing solution NH_4PF_6 (0.1 g, 0.62 mmol) was added and the refluxing continued for a further period of 2 h. Ethanol was completely removed by a vacuum rotary evaporator and an addition quantity of 10 cm^3 of water was added to the solution. On keeping the solution overnight crystalline flakes were obtained. The complex was filtered, washed with water, benzene and recrystallized from dichloromethane-*n*-hexane mixture. Yield: 0.29 g (78%).

HALOGENATION OF 4,5-DICARBA-ARACHNO-NONABORANE(13),4,5-$C_2B_7H_{13}$

TOMÁŠ JELINEK, BOHUMIL ŠTIBR,* FRANTIŠEK MAREŠ, JAROMIR PLEŠEK and STANISLAV HEŘMÁNEK

Institute of Inorganic Chemistry, Czechoslovak Academy of Sciences, 250 68 Řež near Prague, Czechoslovakia

(*Received* 10 *February* 1987; *accepted* 6 *March* 1987)

Abstract—The AlX_3-catalyzed (X = Cl, Br, and I) halogenation of *arachno*-4,5-$C_2B_7H_{13}$ with anhydrous hydrogen halides produces a series of 6-substituted derivatives, 6-X-4,5-$C_2B_7H_{12}$. The same compounds along with 6,8-I_2-4,5-$C_2B_7H_{11}$ are obtained in non-catalyzed reactions with elemental halogens. The electrophile-induced nucleophilic substitution concept (EINS) of the substitution with hydrogen halides is suggested. The constitution of all compounds isolated was unambiguously determined via ^1H, ^{13}C, ^{11}B, and two-dimensional (2-D) ^{11}B-^{11}B NMR spectra.

The *arachno*-4,5-$C_2B_7H_{13}$ carborane (**1**) (Fig. 1) was first reported by Rietz and Schaeffer[1] in 1973; however, it has been only recently that a high-yield synthesis of this compound has been developed in our laboratory.[2,3] Nevertheless, carborane (**1**) has been for almost 15 years taken as "*nido*-4,5-$C_2B_7H_{11}$" or, alternatively, as "*nido*-2,6-$C_2B_7H_{11}$" according to the latest trend in nomenclature.[4] Just recently, its structure has been unambiguously reinterpreted in our laboratory[5] on the basis of multinuclear NMR measurements. This paper reports on halogenation reactions of (**1**) with hydrogen halides and elemental halogens.

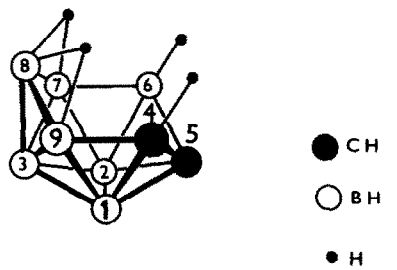

Fig. 1. Simplified structure and numbering system of *arachno*-4,5-$C_2B_7H_{13}$ (**1**).

EXPERIMENTAL

^1H (200 MHz), ^{13}C (50.31 MHz), and ^{11}B (64.18 MHz) pulse Fourier transform NMR spectra were recorded in deuteriochloroform on a Varian XL-200 spectrometer, and data manipulation utilized standard Varian software. Chemical shifts are given in δ [ppm, referenced to TMS (^1H and ^{13}C) and $BF_3 \cdot OEt_2$ (^{11}B); positive shifts downfield]. Two-dimensional (2-D) ^{11}B-^{11}B NMR spectra were produced on all samples via procedures described elsewhere.[6] Unit resolution mass spectra in the NI mode (chemical ionization of negative ions) were obtained on a GC/MS MAT 44S spectrometer. TLC was performed on Silufol sheets (silica gel on aluminium foil; detection by iodine vapours followed by $AgNO_3$ spray) in 1 : 2 benzene–hexane.

Chemicals and syntheses

Carborane (**1**) was prepared by the previously reported method.[3] Hydrogen bromide was prepared in the reaction of bromine with refluxing tetraline and hydrogen iodide by adding dropwise concentrated hydroiodic acid to excess P_4O_{10}; both products were condensed at −78°C and then generated by slow evaporation. Benzene and hexane were distilled with sodium metal prior to use and other commercially available chemicals were reagent grade and were used as purchased. Except where otherwise indicated, all syntheses and standard isolation procedures were conducted in an inert atmosphere or *in vacuo*.

	C(5)H	exo-C(4)H	endo-C(4)H	μH	C(5)	C(4)
6-Cl (**2a**)	2.83	1.86	1.72	−1.28	—	—
6-Br (**2b**)	2.94	1.85	1.68	−1.26	29.34(184)	8.94(165)
6-I (**2c**)	3.02	1.81	1.44	−1.24	—	—
6,8-I_2 (**2d**)	3.29	1.98	1.65	−1.27	29.01(163)	9.32(161)

[a] Singlets of relative intensities 1 : 1 : 1 : 2.
[b] Doublets and triplets of equal intensities, J(CH) in parentheses(in Hz).

Arachno-6-Cl-4,5-$C_2B_7H_{12}$ (**2a**). (a) Dry HCl was slowly introduced for 2 h at ambient temperature to a stirred solution of (**1**) (1.1 g; 0.01 mol) in benzene (60 cm^3) in the presence of $AlCl_3$ (0.13 g; 1 mmol). After the hydrogen evolution had ceased (*ca.* 3 h), the mixture was filtered, the filtrate was reduced in volume to *ca.* 20 cm^3, and hexane (40 cm^3) was carefully added onto the surface of the solution. The two-layer mixture was left standing overnight to separate white crystals which were isolated by filtration, washed with cold hexane and vacuum-dried to give 1.4 g (95%) of IIb; mass spectrum, high mass m/z 149, corresponding to $[^{12}C_2{}^{11}B_7{}^1H_{11}{}^{37}Cl]^-$ (P-1, C_2B_7Cl pattern). For NMR spectra see Tables 1–4.

(b) Gaseous chlorine was slowly passed through a solution of (**1**) (1.1 g; 0.01 mol) in hexane (60 cm^3) under stirring at −30°C until carborane (1) had disappeared from the solution (checked by TLC, R_F 0.4). The separated white crystals were isolated by filtration, washed with cold hexane and vacuum-dried to afford 0.7 g (47%) of (**2a**).

Arachno-6-Br-4,5-$C_2B_7H_{12}$ (**2b**). (a) Dry HBr was slowly passed through a stirred mixture of $AlBr_3$ (0.27 g; 1 mmol) and a solution of (**1**) (1.1 g; 0.01 mol) in benzene (60 cm^3) at ambient temperature until carborane (**1**) had disappeared from the mixture (*ca.* 3 h). Analogous work-up as in the preceding experiment (a) led to the isolation of 1.6 g (83%) of (**2b**); high mass m/z 193, corresponding to $[^{12}C_2{}^{11}B_7{}^1H_{11}{}^{81}Br]^-$ (P-1, C_2B_7Br pattern). For NMR data see Tables 1–4.

When the $AlBr_3$ catalyst was replaced by $AlCl_3$ (1 : 1 molar ratio of the latter and carborane (**1**)) and the reaction was conducted exactly in the way described above, 1.4 g of *ca.* 4 : 1 mixture of (**2a**) and (**2b**) was obtained, as assessed by ^{11}B NMR by comparing the signal intensities of the B(6) resonances of both compounds at δ_B −16.47 and −22.87, respectively.

(b) A solution of (**1**) (1.1 g; 0.01 mol) in benzene (30 cm^3) was treated with a solution of bromine (0.6 cm^3; 0.02 mol) in benzene (20 cm^3) under stirring at 5°C. After the colour of bromine disappeared, the solution was reduced in volume to *ca.* 20 cm^3 and filtered. Further work-up as in the preceding experiment with Cl_2 (b) produced 0.7 g (36%) of (**2b**).

Arachno-6-I-4,5-$C_2B_7H_{12}$ (**2c**). (a) Dry HI was slowly introduced into a stirred mixture of AlI_3 (0.41 g; 1 mmol) and a solution of (**1**) (1.1 g; 0.01 mol) in benzene (60 cm^3) at ambient temperature until the hydrogen evolution had ceased (*ca.* 3 h). Further work-up as in the preceding experiment (a)

[a] Atoms giving cross peaks with the observed atom (on diagonal) are listed in brackets with right superscipts indicating relative intensities of the off-diagonal interactions (s-strong, m-medium, w-weak, 0-zero interaction). Observed atoms (off brackets) are listed upfield.

[b] The cross peaks cannot be unambiguously defined due to a high degree of overlap.

resulted in the isolation of 1.1 g (80%) of (**2c**); mass spectrum, high mass m/z 239, corresponding to $[^{12}C_2{}^{11}B_7{}^1H_{11}{}^{127}I]^-$ (P-1, C_2B_7I pattern). For NMR data see Tables 1–4.

(b) A solution of (**1**) (1.1 g; 0.01 mol) in benzene (30 cm^3) was refluxed with iodine (2.5 g; 0.02 mol) for 48 h. The mixture was then shortly evacuated, shaken with solid Na_2SO_3 to remove excess iodine, filtered and reduced in volume to *ca.* 20 cm^3. Analogous work-up as in the experiment with Cl_2 (b) led to the isolation of 1.1 g (60%) of (**2c**).

Arachno-6,8-I_2-4,5-$C_2B_7H_{11}$ (**2d**). Carborane (**1**) (0.6 g; 5 mmol) was added to solid iodine (1.3 g; 0.01 mol). After the initial exothermic reaction had ceased, the reaction was finished by heating at 90°C for 1 h. The decolourized melt was dissolved in benzene (20 cm^3), the solution was filtered and the filtrate was reduced in volume to *ca.* 10 cm^3. Hexane (30 cm^3) was added onto the surface and the two-layer mixture was left standing overnight to separate pale yellow crystals which were washed with cold hexane and vacuum-dried to give 1.1 g (60%) of (**2d**); mass spectrum, high mass m/z 238, corresponding to $[^{12}C_2{}^{11}B_7{}^1H_{10}{}^{127}I]^-$ (P-1-HI, C_2B_7I pattern). For NMR data see Tables 1–4.

RESULTS AND DISCUSSION

The AlX_3-catalyzed reactions (X = Cl, Br, and I) of (**1**) with anhydrous hydrogen halides in benzene at ambient temperature give rise to a series of monohalogenated compounds of the general formula 6-X-4,5-$C_2B_7H_{13}$ [(**2a**), X = Cl; (**2b**), X = Br, and (**2c**), X = I, for numbering see Fig. 1] with the evolution of one mole of hydrogen. It is to be noted that these reactions do not proceed without catalysis at any measurable rate. In contrast, there is evidence for direct involvement of AlX_3 in the halogenation process. When the reaction of (**1**) with hydrogen

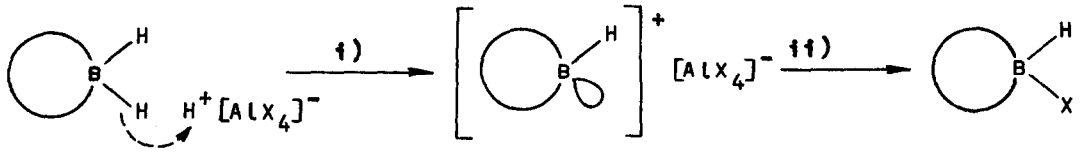

Scheme 1. Electrophile-induced nucleophilic substitution of the cage BH_2 group of (1) by hydrogen halides; (i) H^+ attack, $-H_2$: (ii) X^- attack, $-AlX_3$.

bromide is carried out in the presence of an equimolar amount of $AlCl_3$, *ca.* 4:1 mixture of 6-Cl and 6-Br derivatives of (**1**) is obtained, as assessed from ^{11}B NMR. The observed parallel substitution on the cage $B(6)H_2$ group by Cl and Br is consistent with a proton attack by $H^+[AlX_4]^-$ at the B(6) exo-hydrogen to remove the H^- anion and evolve dihydrogen. The vacant exohedral molecular orbital thus formed is subsequently filled with X^- (from AlX_4^-) to recover AlX_3 and form exohedral B(6)H-X bond as in Scheme 1.

In view of this approach, the substitution process outlined above can be regarded as an electrophile-induced nucleophilic substitution reaction (EINS). This EINS concept, characteristic by hydride removal on the attack by the electrophilic particle with a subsequent attack by the nucleophilic particle, can be applied more generally to other "electrophilic" reactions of boron hydrides. The difference between these reactions and electrophilic Friedel–Crafts substitutions on organic aromatic substrates[7] obviously consists both in the hydridic character of the BH bond and in the electron deficient nature of the boron atom under attack.

The same series of compounds (**2a–c**) is also obtained in noncatalyzed reactions of (**1**) with elemental halogens (Cl_2, $-30°C$; Br_2, 5°C, and I_2, reflux) in hexane or benzene. Spontaneous solid-phase reaction of (**1**) with iodine, finished by heating at 90°C, results in the formation of 6,8-I_2-4,5-$C_2B_7H_{11}$ (**2d**). The observed relative ease of the noncatalyzed halogenation seems to consist of a strong hydridic character of the cage $B(6)H_2$ group.

NMR spectra of compounds (**2a–d**) (Tables 1 and 2) exhibit general features of those published for parent 4,5-$C_2B_7H_{13}$.[5] ^1H NMR spectra show 1:1:1:2 patterns of singlets due to three CH resonances [C(5)H, $C(4)H_{exo}$, and $C(4)H_{endo}$] and two coincidentally overlapping bridge proton signals. ^{13}C NMR spectra of (**2b**) and (**2d**), exhibiting one doublet and one triplet of equal intensities, clearly evidence the presence of one CH and one CH_2 groups. The relevant ^{11}B NMR data of (**2a–d**) unambiguously indicate the presence of seven non-equivalent boron environments with three borons coupled to hydrogen bridges. The most interesting feature is the presence of the doublet of the monohalogenated $B(6)H_2$ group.

Additional insight was given by 2-D ^{11}B–^{11}B measurements on (**2a–d**). In the scheme presented in Table 3, all adjacent borons give rise to observed cross peaks expected in 2-D spectra for the geometry depicted in Fig. 1 except for those between the B(1)-B(9), B(7)-B(8) and B(2)-B(3) nuclei which are not observable in a few cases.

Table 4 reflects the influence of the B(6) halogen substitution on the ^{11}B NMR shifts in terms of $\Delta\delta$, $\Delta\tilde{\delta}$, and k_2 values. The trends seen in this table for substituted borons are similar to those observed with other substituted borane systems, e.g. $B_{10}H_{14}$,[8] 2,4-$C_2B_5H_7$,[9] and 6,9-$C_2B_8H_{14}$.[10] Taking unsubstituted boron atoms of (**2a–d**) into account, a regular trend of increase in $\Delta\tilde{\delta}$ and a decrease in k_2 values is seen on going through the 6-Cl, 6-Br, and 6-I series; similar trends were observed with all monohalogenated derivatives of $B_{10}H_{14}$,[8] but not with 1-haloderivatives of 6,9-$C_2B_8H_{14}$.[10] To draw more general conclusions, more derivatives substituted on other cage atoms should be isolated and characterized.

Acknowledgements—The authors wish to thank Drs I. Koruna and M. Ryska of the Research Institute for Pharmacy and Biochemistry, Prague, for mass spectral measurements.

DIRECT SYNTHESIS FROM $MoCl_3(THF)_3$ OF A COMPLEX CONTAINING THE $[Mo_3S_4]^{4+}$ CORE

F. ALBERT COTTON* and ROSA LLUSAR

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 12 *January* 1987; *accepted* 9 *March* 1987)

Abstract—By reaction of $MoCl_3(THF)_3$ with NaSH in tetrahydrofuran, followed by addition of $Me_2PCH_2CH_2PMe_2$(dmpe), then chromatography on silica-gel, and finally addition of NH_4PF_6, the compound $[Mo_3S_4Cl_3(dmpe)_3]PF_6 \cdot CH_3OH$ was prepared in moderate yield. X-ray crystallography showed the presence of a chiral cation based on a Mo_3S_4 core with chelating dmpe units arranged like the blades of a ship's screw. The three Cl atoms fill the remaining octahedral sites on each metal atom. The compound crystallizes in space group R3c with (hexagonal) cell dimensions of $a = 15.310(7)$ Å, $c = 30.640(3)$ Å and $Z = 6$. The $[Mo_3S_4Cl_3(dmpe)_3]^+$ ion and the PF_6^- ion each have crystallographic C_3 symmetry. The principal distances and theirs esds are: Mo–Mo, 2.766(4) Å; Mo–(μ_3-S), 2.360(9) Å; Mo–(μ_2-S), 2.290(7) Å, 2.336(7) Å; Mo–P, 2.534(8) Å, 2.605(8) Å; Mo–Cl, 2.473(7) Å; P–F, 1.56(2) Å, 1.64(3) Å. The correct enantiomer was obtained by refining both to convergence, which give $R = 0.059$ and $R = 0.064$.

The synthetic chemistry leading to compounds containing the $Mo_3S_4^{4+}$ core has recently been developing very rapidly. The following types of synthetic entry to this field have been reported:

(1) Those in which the Müller complex,[1] $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3(S_2)_3]^{2-}$ (1) is treated with desulfurizing reagents. Examples are:

$$1 + 12CN^- \rightarrow [Mo_3S_4(CN)_9]^{5-} + 3SCN^- + 3S_2^{2-} \quad (1)^2$$

$$1 + 3[SCH_2CH_2S]^{2-} \rightarrow Mo_3S_4(SCH_2CH_2S)_3]^{2-} + \text{polysulfur species.} \quad (2)^3$$

(2) Desulfurization of 1 without the use of any exogenous S-atom acceptor:[4]

$$1 + 3H_3NTA \rightarrow [Mo_3S_4(NTA)(HNTA)_2]^{2-} + S_n^{2-} \text{ species}$$

$$1 + 3H_2C_2O_4 \rightarrow [Mo_3S_4(C_2O_4)(HC_2O_4)_2(H_2O)_3] + S_n^{2-} \text{ species.}$$

(3) Degradation of an $[Mo_4S_4]^{n+}$ unit, which proceeds in 60% yield[5] under appropriate conditions:

$$[Mo_4S_4(NCS)_{12}]^{6-} + 3[9]aneN_3 \rightarrow [Mo_3S_4([9]aneN_3)_3]^{4+}.$$

(4) Coalescence of $[Mo_2(\mu\text{-}S)_2O_2(cys)_2]^{2-}$ dimers to give an Mo_4S_4 intermediate that degrades *in situ* to $Mo_3S_4^{4+}$.[6]

We now report a new, convenient, non-aqueous method for making $[Mo_3S_4]^{4+}$ derivatives. Because the method is non-aqueous it allows access to types of compounds not heretofore obtained. We describe and illustrate the method by providing full preparative and crystallographic details for the compound $[Mo_3S_4Cl_3(dmpe)_3]PF_6 \cdot CH_3OH$.

EXPERIMENTAL

Materials

NaSH[7] and $MoCl_3(THF)_3$[8] were prepared as described elsewhere. 1,2-bis(dimethylphosphino) ethane (dmpe) was obtained from Strem Chemicals and used as received.

* Author to whom correspondence should be addressed.

Synthesis of $[Mo_3S_4Cl_3(dmpe)_3]PF_6 \cdot CH_3OH$

NaSH (40 mg, 0.072 mmol) was added to a solution of $MoCl_3(THF)_3$ (300 mg, 0.072 mmol) in 15 cm^3 of THF under argon. This mixture was cooled to −78°C and the dmpe (120 μL, ca. 0.72 mmol) was introduced. Addition of 3 cm^3 of MeOH (to dissolve the NaSH) followed by slow warming to room temperature produced a mixture consisting of a dark precipitate and a green solution.

This green solution was filtered under argon and it seemed to be air stable, at least for several days. It was taken to dryness in vacuum, the residue redissolved in CH_2Cl_2 and the solute adsorbed on a silica-gel column. After washing the column with acetone, the green band that remained on the top was eluted with methanol. The UV–visible spectrum of this green solution showed a band at 625 nm. Addition of NH_4PF_6 to the above solution followed by slow evaporation in air afforded green crystals suitable for X-ray diffraction studies. Yield: ca. 40%. These crystals were characterized as $[Mo_3S_4Cl_3(dmpe)_3]PF_6 \cdot CH_3OH$.

X-ray diffraction studies

A green crystal of dimensions $0.1 \times 0.15 \times 0.15$ mm was mounted on the top of a glass fiber with epoxy cement. Data were collected on a CAD-4 four-circle diffractometer using monochromated Mo Kα radiation. Preliminary cell parameters were determined from 25 reflections and confirmed by axial photographs. Data pertaining to the crystallographic procedures are given in Table 1. During data collection three intensity standards were collected every hour. No decay was observed during the 47.5 h of exposure to X-rays.

Corrections for polarization and Lorentz factors were applied to the measured intensities. An absorption correction was based on the variation in the intensities of reflections at Eulerian angle χ

[c] Quality-of-fit = $[\Sigma x(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

close to 90° during azimuthal scans (ψ-scans). Five sets of reflections were averaged to produce an absorption profile for the crystal with maximum, minimum and average experimental transmission factors of 1.27, 0.84 and 0.99, respectively.

The crystal belongs to the Laue class $\bar{3}m$. Systematic absences limited the possible space groups to R3c and R$\bar{3}$c. The unit cell volume suggested $Z = 6$, which would require the trinuclear unit to be located on a special position such that a three-fold axis of crystallographic symmetry would be in accord with the molecular symmetry. The trinuclear unit could be accommodated in an ordered model only in the non-centrosymmetric space group R3c because in R$\bar{3}$c the location of the molecule around the three fold axis requires the presence of an inversion center. Since the amount of data was limited by the small size of the crystal, Friedel pairs (which are independent observations in a noncentrosymmetric space group) were collected to improve the data to parameter ratio.

The position of the unique Mo atom was obtained from direct methods, MULTAN, and the remainder of the molecule was located and refined by alternating difference Fourier maps and least squares cycles, employing the Enraf-Nonius Structure Determination Package. All the atoms in the cluster and the anion, except three of the carbon atoms in the phosphine were refined anisotropically. C(2), C(5) and C(6) had to be refined isotropically. After location and refinement of the cluster and the anion, two peaks, one in a special position (3-fold axis) and one in a general position, remained in the difference Fourier map. The distance between them was suggestive of a methanol molecule and they were refined with isotropic thermal parameters as C and O atoms. The C–O distance calculated after the last cycle of refinement was slightly short (1.22 ± 0.12 Å), but acceptable under the circumstances.

RESULTS AND DISCUSSION

The preparative procedure described here differs from all others previously used in that it provides access to the $Mo_3S_4^{4+}$ moiety by a non-aqueous route, thus making it possible to prepare derivatives that are, or contain ligands which are not amenable to handling in aqueous media. At some stage the Mo(III) present in the starting material is oxidized to Mo(IV) but this, as well as other aspects of the procedure, remains to be elucidated.

The identity and structure of the green product were conclusively established by X-ray crystallography. The trinuclear cation is shown in Fig. 1. It has a crystallographically imposed three-fold axis of symmetry. The bond distances and angles within it are listed in Tables 2 and 3.

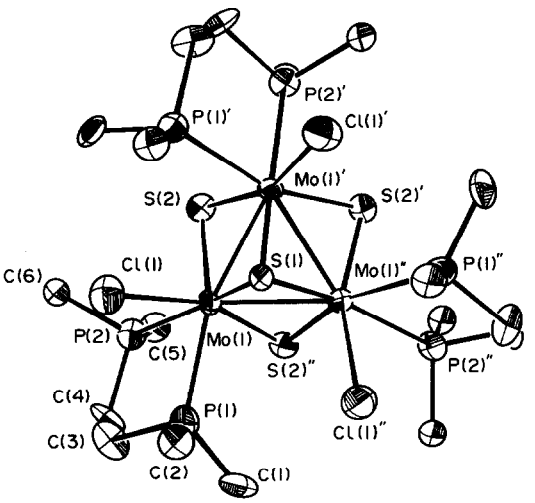

Fig. 1. The $[Mo_3S_4Cl_3(dmpe)_3]^+$ ion viewed approximately along the three-fold axis. The labeling scheme employs primes and double primes to identify symmetry equivalent atoms.

There are some small but real deviations from C_{3v} symmetry in the Mo_3S_4 core, attributable to the arrangement of the two P and one Cl atom in the external sites on each Mo atom. The Mo–Mo and Mo–(μ_3-S) distances are, of course all equal, but there are two kinds of Mo–(μ_2-S) distances and some attendant slight differences in the two sorts of Mo–Mo–(μ_2-S) angles. The Mo–(μ_2-S) distance that is roughly *trans* to an Mo–P bond is significantly longer, by 0.046(10) Å, than the one that is roughly *trans* to an Mo–Cl bond. The two types

of Mo–P distance also differ, by 0.071(11) Å, with the one *trans* to the capping sulfur atom being shorter. We may also note that in this electron-poor type of cluster the Mo–Cl distance is appreciably shorter than the Mo–P distances, a quite common situation in early transition metal phosphine complexes.

Finally, in Table 4, we compare the dimensions of the Mo_3S_4 unit in the present compound with those previously reported for other compounds. It is clear that despite differences in the sets of external ligands, the three principal types of distances that characterize this unit are substantially the same in all cases.

In further exploratory work spectroscopic measurements (UV–visible) have shown that this compound can also be prepared by reaction of $MoCl_3$ and NaSH with dmpe in MeOH at −78°C followed by a workup of the solution similar to the one described previously.

Similar reactions have been observed with other halides (MoI_3) or other phosphines (dmpm). The compounds obtained in those cases appear to be less stable. Reactions with monodentate phosphines seem to follow quite different pathways. Efforts to establish the nature of these products are in progress.

(*Received* 9 *March* 1987; *accepted* 17 *March* 1987)

Abstract—The reactions between $W_2(OBu^t)_6$ and each of pinacol (3 equiv) and cyclohexanol (> 6 equiv) yield the title compounds $W_2(OCMe_2CMe_2O)_3$, **I**, and $W_2(OCy)_6$, **II** (Cy = cyclohexyl) as yellow needles, which are sparingly soluble in hydrocarbon solvents. In the solid-state both compounds form infinite chains. Compound **I** has three pinacolate ligands which span the W≡W bond: W–W = 2.2738(8) Å, W–O = 1.90 Å (av) and W–W–O = 99° (av). The three bridging ligands lead to a near eclipsed W_2O_6 skeleton having O–W–W–O torsion angles = 10° (av). The infinite chain is caused by weak intermolecular oxygen-to-tungsten bonding, W...O = 2.9 Å. The $W_2(OCy)_6$ molecule has crystallographically imposed C_{2h} symmetry and the central W_2O_6 moiety is staggered (virtual D_{3d}) with W–W = 2.340(1) Å, W–O = 1.87 Å (av) and W–W–O = 107° (av). The infinite chain in the solid-state results from the stacking of the cyclohexyl ligands. The intermolecular contacts are essentially identical to the intramolecular ones. In solution $W_2(OCMe_2CMe_2O)_3$ undergoes rapid enantiomerization such that a time-averaged eclipsed W_2O_6 moiety is seen on the NMR time-scale. The cyclohexyl rings in $W_2(OCy)_6$ are not inverting (chair ⇌ boat ⇌ chair) on the NMR time-scale.

Albright and Hoffmann's[1] provocative claim that M_2X_6(M≡M) dimers[2,3] "should prefer the eclipsed conformation" stimulated several theoretical appraisals of these molecules (M = Mo and W, and X = a uninegative ligand).[4–7] While the other calculations generally supported the view that there should be no electronic preference for either geometry, it is easy to see why the original suggestion was made. If the M_2X_6 dimers are constructed from two MX_3 fragments then the M–M bonding will reflect the geometry of the MX_3 fragments. If MX_3 fragments derived from an octahedron[8] are brought together, the eclipsed geometry will be preferred. However, if two trigonal planar ML_3 fragments are used to form the M_2X_6 unit then no electronic preference is predicted. Calculations employing EHMO and other methods naturally prefer to employ ligands such as H, Cl or CH_3 for which there are no known M_2X_6 (M≡M) compounds.[2,3] These compounds are not likely to be isolable either, so it was a challenge for the synthetic chemist to address the points raised by the theoreticians.

We recently described in full our comparative studies of staggered and eclipsed M_2N_6 moieties in $M_2(NMe_2)_6$ and $M_2(MeNCH_2CH_2NMe)_3$ compounds.[9] We describe here our preparation and characterization of two new compounds $W_2(OCMe_2CMe_2O)_3$ and $W_2(OCy)_6$. These provide the appropriate comparison of staggered and eclipsed $O_3W{\equiv}WO_3$ units and provide the first examples of structurally characterized unligated $W_2(OR)_6$ compounds.[10]

RESULTS AND DISCUSSION

Syntheses

Both new compounds were prepared by the addition of the alcohol to a hydrocarbon solution of $W_2(OBu^t)_6$. This obviates problems associated

* Author to whom correspondence should be addressed.

with oxidative addition reactions and the formation of dimethylamine adducts.[11]

In reactions involving cyclohexanol, the $W_2(OCy)_6$ compound, **II**, is precipitated as a pale yellow microcrystalline powder. It is only sparingly soluble in toluene and benzene and even less soluble in aliphatic hydrocarbons. It is more soluble in THF and was recrystallized from warm THF/toluene solvent mixtures. **II** does not undergo the reversible dimerization that we have recently observed for $W_2(O\text{-}i\text{-}Pr)_6$ under identical conditions.[10]

In reactions involving pinacol an initial dark-purple crystalline compound is formed which is formulated as a pinacol adduct $W_2(OCMe_2CMe_2O)_3$(pinacol). Even when only 3 equivalents of pinacol are used this is formed leaving some unreacted $W_2(OBu^t)_6$. The ^1H NMR spectrum reveals six inequivalent pinacolate Me resonances of equal intensity and a downfield signal *ca.* δ 10 ppm indicative of the hydroxyl group, together with a singlet of three times the intensity of the other methyl signals. Regrettably it is not possible to formulate a unique structure based on these data. However, the initially formed pinacol adduct slowly loses pinacol in THF or hydrocarbon solutions containing pyridine to give $W_2(OCMe_2CMe_2O)_3$, **I**, as fine yellow needles. [It seems that the donor molecules assist in the disruption of the hydrogen-bonded pinacolate adduct.] The crystals obtained for the X-ray study were obtained by recrystallization from warm THF. **I** is only sparingly soluble in aromatic hydrocarbon solvents and essentially insoluble in alkanes.

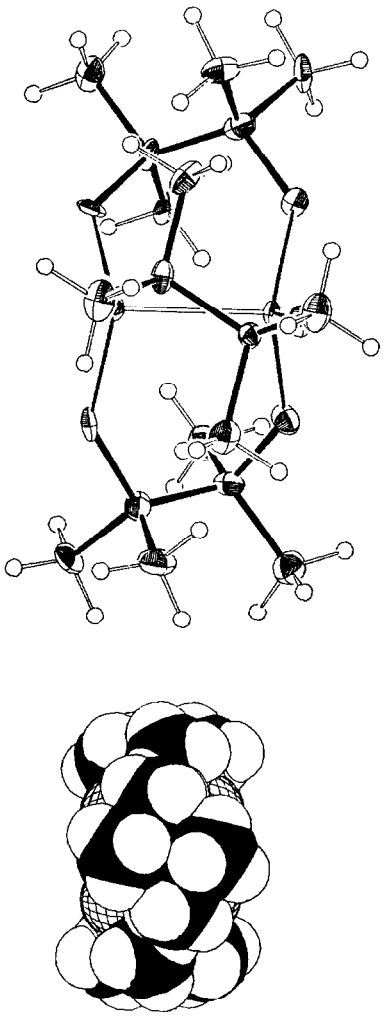

Fig. 1. An ORTEP view of the $W_2(OCMe_2CMe_2O)_3$ molecule looking down one of the virtual C_2 axes. A space filling drawing of the same view is shown below.

Solid-state and molecular structures

$W_2(OCMe_2CMe_2O)_3$. Crystallizes from THF as a 1 : 1 solvent complex, though the THF molecule is not coordinated to any tungsten atom. An ORTEP view of the $W_2(OCMe_2CMe_2O)_3$ molecule is shown in Fig. 1 and a view looking down the W–W bond with the atom number scheme is given in Fig. 2. The molecule has virtual D_3 symmetry as a result of the tris-bridging pinacolate ligands which form $M_2O_2C_2$ six membered rings in the skew-boat conformation. The average syn-O–W–W–O torsion angle is 10°. Selected bond distances and angles are given in Table 1.

$W_2(OCy)_6$. Has a crystallographically imposed mirror plane containing the M–M bond and a C_2 axis perpendicular to this, i.e. C_{2h} molecular symmetry. An ORTEP plot giving the atom number scheme is shown in Fig. 3 and a view looking down the M–M bond is given in Fig. 4. Pertinent bond distances and bond angles are given in Table 2. The most striking feature of this structure is the orientation of the cyclohexyl ligands which are all essentially perpendicular to the M–M axis.

The infinite chains. Compounds containing multiple bonds between metal atoms provide interesting building blocks for molecular design of new solid-state materials and metalloorganic liquid crystal phases. (1) The architectural signature of the M–M quadruple bond, for example, in $M_2(O_2CR)_4$ compounds is the four bladed paddle wheel while that of the $(M{\equiv}M)^{6+}$ moiety (M = Mo or W) is the staggered or ethane-like $X_3M{\equiv}MX_3$ moiety. (2) The subunits tend to stack due to weak intermolecular interactions involving either the metal atoms or the ligands. In the two compounds reported here we see an example of each phenomenon.

The pinacolate compound **I** consists of infinite chains of $W_2(OCMe_2CMe_2O)_3$ units which are

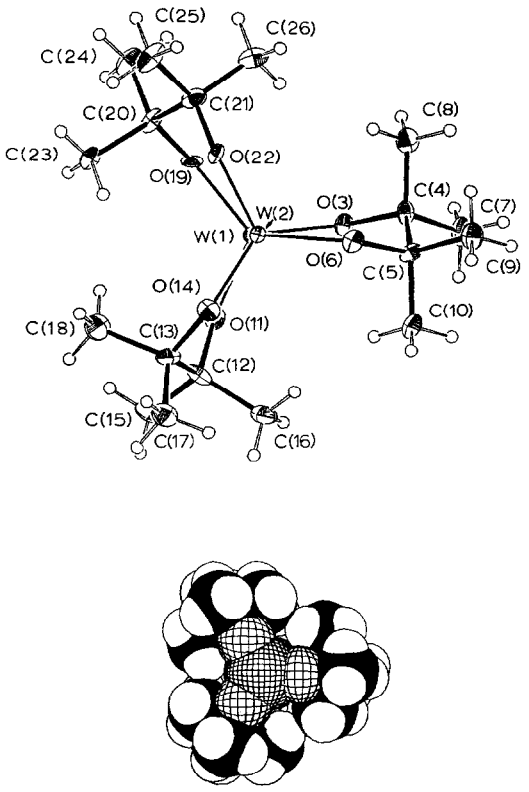

Fig. 2. A view of the $W_2(OCMe_2CMe_2O)_3$ molecule, with the atom number scheme used in the tables, looking down the W–W bond emphasizing the near eclipsed O_3WWO_3 moiety. A space filling drawing of the same view is shown below.

propagated along the *a* axis. The intermolecular O...to...W distances are *ca.* 2.9 Å. See Fig. 5. In the cyclohexoxide, the stacking is caused entirely by the hydrocarbon interactions. See Fig. 6. Again the infinite chains grow along the *a* axis but now the O...to...W distances along the chain are *ca.* 4.5 Å. Note also the intermolecular and intramolecular cyclohexyl ring distances are essentially identical.

We mention here these interesting fundamental stacking properties of M–M multiple bonded compounds because they have drawn little attention this far but are clearly of potential interest with respect to the molecular design of linear polymers. Note also the cavities within the chain may readily accommodate guest molecules as is seen for THF in the solid-state structure of $W_2(OCMe_2CMe_2O)_3 \cdot THF$.

Comparisons of molecular parameters for M_2X_6 *moieties.* The orientation of the cyclohexyl ligands in **II** and the pinacolate ligands in **I** are such that the $W_2(OC)_6$ skeletons of the two molecules differ only significantly with respect to the staggered and eclipsed W_2O_6 moieties. The W–O–C angles in I span a range 133° to 139° while in **II** the W–O–C angles are 141 and 145°. In both molecules the W–O–C units are aligned along the M–M axis in the proximal manner.

Table 1. Selected bond distances (Å) and bond angles (°) for the $W_2(O_2CMe_2CMe_2O)_3$ molecule

W(1)	O(3)	C(4)	136.0(6)
W(2)	O(6)	C(5)	136.4(6)
W(1)	O(11)	C(12)	139.0(6)
W(2)	O(14)	C(13)	139.1(7)
W(1)	O(19)	C(20)	133.3(6)
W(2)	O(22)	C(21)	135.0(6)

The oxygen lone-pairs which may be termed[12] σ and π are thus orientated in the same way in **I** and **II**. The π-lone pairs will principally interact with the metal d_{xy} and $d_{x^2-y^2}$ orbitals and the σ lone-pairs will be largely non-bonding.

In the pinacolate two oxygen σ-lone pairs, one at each tungsten atom, are in fact weakly bonded to neighbouring W_2 units, W(1)...O(19) = 2.83(1) Å and W(2)...O(6) = 2.91(1) Å. This is the range of M–to–O distances that we have previously termed semi-bridging. It is worth noting that the oxygen atoms involved in this "intermolecular" interaction

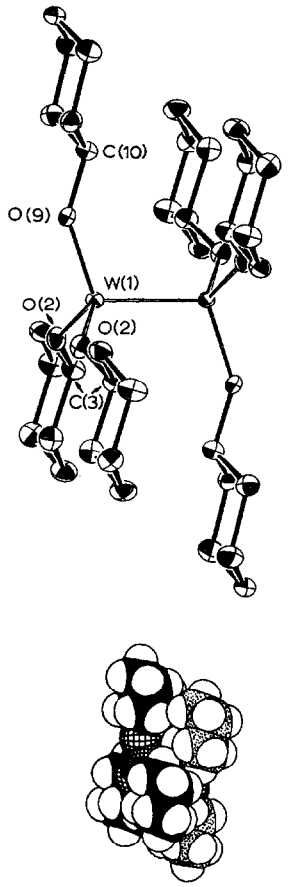

Fig. 3. An ORTEP view of the $W_2(OCy)_6$ molecule giving the atom number scheme used in the tables. A space filling drawing of the same view is shown below.

Table 2. Selected bond distances (Å) and angles (°) for the $W_2(OCy)_6$ molecule

A	B	Distance
W(1)	W(1)′	2.340(1)
W(1)	O(2)	1.880(4)
W(1)	O(9)	1.856(6)

O(9)	C(10)	1.437(10)
C	C	1.52(1) (av) cyclohexyl

A	B	C	Angle
W(1)′	W(1)	O(2)	107.22(13)
W(1)′	W(1)	O(9)	107.62(18)
O(2)	W(1)	O(9)	111.39(15)
O(2)	W(1)	O(2)′	111.74(27)
W(1)	O(2)	C(3)	141.0(4)
W(1)	O(9)	C(10)	144.9(5)

form somewhat longer intramolecular W–O distances, W(1)–O(6) = 1.915(7) Å and W(2)–O(19) = 1.971(7) Å. There is little doubt that this weak intermolecular W . . . O bonding is responsible for the formation of the infinite chain structure and for the low solubility in hydrocarbon solvents.

In Table 3 we compare W–W, W-X and proximal W–X–C angles for the compounds $W_2(NMe_2)_6$, $W_2(MeNCH_2CH_2NMe)_3$, **I** and **II**. Three points are worthy of note. (1) The M–M distances are shorter in the eclipsed $X_3M{\equiv}MX_3$ compounds. (2) The M–M distances decrease as the M–M–X angles decrease for X = O and N. (3) The M–X–C proximal angles of the bridged molecules are smaller than those in the staggered molecules.

Regrettably it is impossible to separate the steric from the electronic factors in this series and the effective constraints imposed by the bridging chelates. For example, for alkoxides, the bulkier the alkyl group the greater the steric repulsion across the M–M bond. This will lead to larger M–M–O and M–O–C angles both of which will tend to lead to a lengthening of the M–M bond as a competition for M–M and M–O π-bonding sets in. For M–M–O angles equal 90° and M–O–C angles of *ca.* 120° with the M–O–C planes aligned along the M–M axis, the oxygen *p*-to-metal-*d* π-donation will not be mixed with M–M π-bonding. The two e sets, (d_{xz}, d_{yz}) and (d_{xy}, $d_{x^2-y^2}$), will be involved in M–M π and M–O π-bonding, respectively. As the M–M–O angle increases the e sets mix and O–to–M π-bonding competes with M–M π-bonding. The same is

true as the M–O–C angle goes from 120° to 180°, even though the M–M–O angle remains 90°. A specific bridging chelate will have a geometrically preferred M–M–O and M–O–C angle which, whether eclipsed or staggered, will influence the M–M distance. In the present case the pinacolate ligand favors the factors which favor short M≡M distances.

NMR studies

The ^{1}H NMR spectrum of **I** shows only one methyl signal at room temperature at 360 MHz. This implies that the enantiomerization must be rapid on the NMR time-scale; i.e. the time averaged syn-O–W–W–O torsion angles are zero. A similar result was found for $M_2(MeNCH_2CH_2NMe)_3$ compounds.[9]

$W_2(OCy)_6$ shows a single downfield multiplet at *ca.* δ 5.4 assignable to its methyne proton. This is similar to that of the isopropoxy methyne resonances in $M_2(O\text{-}i\text{-}Pr)_6$ compounds (M = Mo, W) and presumably reflects the proximity of the methyne hydrogen to the M≡M bond as indeed is seen in the molecular structures in the solid-state. The remaining cyclohexyl proton resonances appear in the region 2.5 to 1.2 ppm as partially overlapping multiplets. It is, however, apparent that ring inversion is slow on the NMR time-scale at 360 MHz, and 25°C. This is not surprising since ring inversion in cyclohexanol is also virtually frozen-out under these conditions (360 MHz, 25°C).

Concluding remarks

The present work shows that little shortening of the W≡W bond occurs in going from a staggered to an eclipsed $O_3W{\equiv}WO_3$ moiety, the difference being 0.07 Å in compounds **I** and **II**. The origin in the lengthening could be ascribed to either electronic or steric factors (or a combination of both) but is unlikely to be associated with the W_2O_6 conformation. The reactivity of **I** is currently under investigation. It is noticeably different from other $W_2(OR)_6$ compounds in having a hydrocarbon girth around the W≡W bond and uniquely exposed tungsten atoms along the metal–metal axis.

EXPERIMENTAL

Dry and oxygen-free solvents were used in all experiments. All manipulations were carried out under inert atmospheres using standard Schlenk techniques. $W_2(OBu^t)_6$ was prepared by the addition of Bu^tOH to $W_2(NMe_2)_6$ according to literature procedures.[13]

^{1}H NMR spectra were recorded on a Nicolet NT-360 spectrometer at 360 MHz using toluene-d_8 or benzene-d_6 as solvents. The cyclohexyl resonances of **II** were assigned by a combination of homonuclear decoupling and 2D ^{1}H NMR experiments.

Single frequency decoupling of the multiplet at 2.39 ppm collapsed the resonance of H_α to a triplet with vicinal $J_{H-H} = 9$ Hz. The resonance at 2.39 ppm was therefore assigned to the two H^e_β proton (where the superscript represents axial (a) or equatorial (e), and the subscript the position on the ring). Decoupling the multiplet at 1.65 ppm collapsed H_α to a triplet $^3J_{H-H} = 4$ Hz. The resonance at 1.65 ppm was therefore assigned to H^a_β. The remaining resonances could be assigned from a 2D ^{1}H NMR chemical shift correlated contour plot assuming $J^{ae}_{gem} \simeq J^{aa}_{vic} > J^{ee}_{vic} > J^{ae}_{vic}$. 2D Matrix: 128×512, 8 scans, total acquisition time 27 min. Elemental analyses were obtained by Bernhard Analytical Laboratories, West Germany. Cyclohexanol was dried over, and distilled from finely divided magnesium.

$W_2(OCMe_2CMe_2O)_3$. $W_2(OBu^t)_6$ (500 mg, 0.62 mmol) was dissolved in hexane (20 cm^3) and 0.45 M pinacol in toluene (5.6 cm^3, 2.5 mmol) was added. The resulting red solution was cooled immediately to 0°C. After 24 h, the solution had become deep purple. On reducing the volume, deep purple-black crystals were obtained. The compound which is formulated as $W_2(OCMe_2CMe_2O)_3(HOCMe_2CMe_2OH)$ is formed nearly quantitively in this reaction. ^{1}H NMR data at 22°, toluene-d_8: δ(Me) 0.86(3H, s), 1.22(3H, s), 1.26(3H, s), 1.61(3H, s), 1.75(3H, s), 1.94(3H, s), 1.36(9H, s), δ(OH) 10.2(1H, no coupling to ^{183}W). $W_2(OCMe_2CMe_2O)_3(HOCMe_2CMe_2OH)$ (180 mg, 0.22 mmol) was dissolved in THF (10 cm^3). After stirring at ambient temperature for *ca.* 18 h, the solution had become pale yellow. The solvent was removed *in vacuo* and the resultant pale yellow solid was washed with toluene (5 cm^3) to remove any residual traces of pinacol. $W_2(OCMe_2CMe_2O)_3$ was recrystallized from THF solution in *ca.* 80% yield.

^{1}H NMR data, 22°C in $CDCl_3$: δ(Me) = 1.46(s); in toluene-d_8: δ(Me) = 1.43(s).

Found: C, 30.1; H, 5.0. Calc. for $W_2O_6C_{18}H_{36}$: C, 30.2; H, 5.1%.

$W_2(OCy)_6$. To W_2(O-t-Bu)$_6$ (700 mg, 0.87 mmol), dissolved in 20 cm^3 of hexane, 2 cm^3 (20.7 mmol) of dry cyclohexanol was added dropwise. The solution darkened as the alcohol was added and after about 5 min a yellow precipitate had formed. The mixture was stirred for 1 h at 25°C, filtered, the yellow solid washed with 2×6 cm^3 portions of hexane and 575 mg (0.60 mmol) of $W_2(OCy)_6$ (**II**) was recovered in 70.0% yield. Crystallization of **II** from toluene resulted in formation of long, pale yellow needles unsuitable for X-ray diffraction, however, larger crystals were grown from an 80% toluene/20% THF mixture at 40°C.

^{1}H NMR data, 22°C in toluene-d_8: $\delta(H\alpha) = 5.38$ ppm, (t of t) $^3H_{H_\alpha-H^a_\beta} = 9$ Hz, $^3J_{H_\alpha-H^e_\beta} = 4$ Hz; $\delta H^e_\beta = 2.39$ (m); $\delta H^e_\gamma = 1.86$ (m); $\delta H^a_\beta = 1.65$ (m); $\delta H^e_\delta = 1.50$ (m); $\delta H^a_\gamma = 1.40$ (m); $\delta H^a_\delta = 1.22$ (m). ^{13}C NMR data, 22°C, toluene-d_8: $\delta(C\alpha) = 87.7$ ppm; $\delta(C\beta) = 37.2$ ppm; $\delta(C\gamma) = 24.6$ ppm; $\delta(C\delta)$ = not obs. UV–visible spectrum, 22°C in THF: $\lambda = 347$ nm ($\varepsilon = 2317$ mol^{-1} cm^{-1}), $\lambda = 420$ nm. (sh.)

Crystallographic studies

General operating procedures and listings of programs have been described previously.[14] A summary of crystal data is given in Table 4.

$W_2(OCMe_2CMe_2O)_3 \cdot$THF. A suitable sample was cleaved from a larger crystal using standard inert atmosphere handling techniques and transferred to the goniostat where it was cooled to −158°C for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space revealed a set of diffraction maxima which could be indexed as monoclinic, space group $P2_1/c$. Subsequent solution and refinement confirmed the choice.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques, and refined by full-matrix least squares. Although hydrogen atoms were visible in a difference Fourier phased on the non-hydrogen atoms, no attempt was made to refine them. They were included as fixed idealized contributors in the final cycles. No attempt was made to include hydrogen atoms for the THF solvent molecule in the structure.

A final difference Fourier was featureless, the largest peak being 1.21 e/Å^3, located at one of the metal sites.

$W_2(OCy)_6$. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the Indiana University Molecular Structure Center and cooled to −158°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to a C centered monoclinic space group. Initial solution was in the noncentrosymmetric space group C2, but examination of the structure revealed additional symmetry and the space group C2/m was selected. Subsequent refinement of the structure confirmed this choice.

Data were collected in the usual manner using a continuous θ-2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and

Abstract—$[M_mFe(CN)_5L \cdot xH_2O]$ (M = Mn, Fe, Co, Ni, Cu; L = pyridine or pyrazine derivative) have been synthesized, and their UV–vis and IR spectral characteristics are reported. Thermolysis of the solids leads to water release, ligand release and/or decomposition, redox interaction between Fe^{3+} (or Cu^{2+}) with CN^- or L, and redox interaction between M^{2+} (or Cu^+) and CN^-, yielding elemental metal and metal carbides.

Mixed metal cyanides have been studied extensively from the point of view of the intervalence bands appearing in their visible or near infrared spectra.[1–6] Structural characterizations have been also carried out, showing that in $M_m[M(CN)_6]_n \cdot xH_2O$ two types of M′ ions may be found, i.e. hydrated interstitial cations,[7–12] and cations coordinated to nitrile nitrogen. The thermal behaviour of simple and complex cyanides has also been the subject of much work. The decomposition has been shown to involve cyanogen release, usually with nitrogen evolution, and formation of metal carbides.[13–18] The characteristics of the resulting solids however have not been studied, partly because of their "intractable nature".[13]

In the present paper we report the preparation, characterization and thermal behaviour of several complexes of the type $[M_mFe(II)(CN)_5L \cdot xH_2O]$, where M is a divalent or trivalent transition metal cation and L is an aromatic amine derived from pyridine or pyrazine. The main questions addressed in this paper are: (1) the nature of the water molecules of hydration and their corresponding thermal dehydration behaviour; (2) spectroscopic evidence on the interaction between anions and cations, including the possibility of Fe–CN–M and/or Fe–L–M bridges; (3) the unambiguous characterization of a $Fe(CN)_5$ derivative as the

original decomposition product. In the case of ferrocyanides, $Fe(CN)_5^{3-}$ may be formed at relatively low temperatures (ca. 200°C, for Prussian Blues);[13] (4) the influence of the nature of M on the thermal behaviour of these compounds; (5) the composition and morphology of the solids formed at high temperature (ca. 900°C).

EXPERIMENTAL

Preparation of the complexes

$Na_n[Fe(CN)_5L]\cdot xH_2O$ complexes for L = nicotinamide (nide), isonicotinamide (isonide), pyrazinamide (pzide), nicotinate (nic) and isonicotinate (isonic) were prepared from $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ by literature methods.[19,20] The complexes $M_m[Fe(CN)_5L]\cdot xH_2O$ [M = Mn(II), Fe(II), Fe(III), Co(II), Ni(II) and Cu(II)] were precipitated by adding a threefold excess of aqueous metal sulphate or nitrate solution to an aqueous solution of $Na_m[Fe(CN)_5L]\cdot xH_2O$]. After stirring for 15 min the solid thus obtained was collected, washed with distilled water, ethanol and diethylether and then dried over $CaCl_2$ in a desiccator for several days. In some instances, oily products were formed; in these cases, precipitation was achieved by adding NaI and working with cooled materials and solvents.

Elemental analysis

C, H and N microanalyses were performed by UMYMFOR, UBA using standard techniques. The results, although only of semiquantitative value because of carbide formation (see below), confirmed the presence of $Fe(CN)_5L^{n-}$ moieties. Metal contents were determined in a Varian Techtron A-A5R atomic absorption spectrometer. About 30–40 mg of each complex were treated in concentrated sulphuric and/or nitric/or hydrochloric acid and diluted with distilled water. The ratio Fe : L was in all cases (except for M = Fe) unity, and the ratio Fe : M was in agreement with a simple precipitation process [i.e. the ratio was two for anionic L^- and M(II), etc.].

Thermogravimetric analysis

Thermograms were obtained in a Mettler Recording Thermoanalyser 1 with samples of about 15 mg in N_2 atmosphere in the temperature range 25–900°C.

Spectral characterization

IR measurements were made using a Perkin–Elmer 580 B spectrophotometer in KBr disks. Reflectance and transmittance UV-visible spectra were recorded for solid samples or 10^{-4} M solutions using a Shimadzu 110 A spectrophotometer.

RESULTS AND DISCUSSION

Characterization of the starting solids

Amorphous materials were obtained in all cases showing no X-ray diffraction peaks. The $[Fe(CN)_5L]^{n-}$ moiety remained intact as apparent from chemical analysis and spectral data. For all cations other than Fe(III) and Cu(II) the electronic spectra in the visible range is dominated by the metal to ligand charge transfer (MLCT) band typical of the anion. These bands are located in the range 374–401 nm for nide, 415–460 nm for isonide, 479–543 nm for pzide, 338–385 nm for nic and 391–440 nm for isonic. The nature of the counter cation does not alter the energy sequence of the MLCT bands as the ligand L is charged; the wavelength increases in the order nic < nide < isonic < isonide < pzide. This is a well known effect of the electron-accepting properties of the heterocycles.[21,22] For Fe(III) and Cu(II), an intervalence band is also observed, in the ranges 650–670 and 480–540 nm respectively. Co(II) complexes also exhibit a second maximum in addition to the MLCT at ca. 600–620 nm characterized by a rather low absorptivity ($\varepsilon = 116\ M^{-1}\ cm^{-1}$) that is assigned to a *d–d* transition of Co(II) in a quasi-tetrahedral environment.[23,24]

In the IR spectra, cyanide stretching values for M(II) salts are very similar to those for hexacyanoferrate(II) complexes.[25] In several cases the absorption profiles exhibit faint shoulders or humps in the range 2130–2170 cm^{-1}, but the lack of resolution prevents any further elaboration (symmetry splitting, or distinct cis- and trans-CN). The frequency increases from ca. 2045–2050 cm^{-1} (sodium salts) following the sequence Mn < Fe < Co < Ni < Cu, the highest values for divalent M being in the range 2093–2100 cm^{-1}. This trend follows the Irwing–Williams series and reflects the formation increasingly stronger of Fe(II)–CN–M(II) bridges.[26–28] For Fe(III) complexes cyanide stretching frequencies are in the same range (2065–2075) cm^{-1}, as found earlier by Fluck[27] for L = H_2O, NH_3 and CO. Hydration water does not influence appreciably the value of ν_{CN}; upon dehydration at ca. 100°C, the observed frequency remains unchanged.

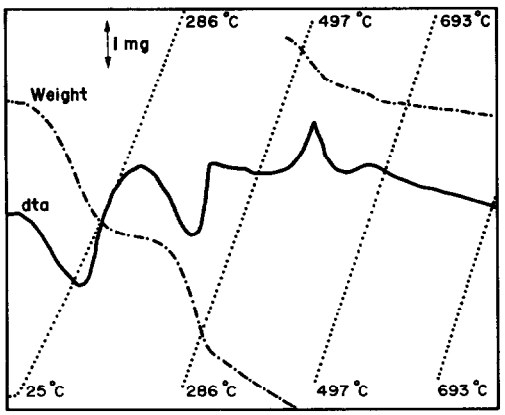

Fig. 1. TGA (-·-·-) and DTA (——) curves for $Ni_3[Fe(CN)_5(isonida]_2 \cdot 13.5H_2O$.

The possibility of chelation of M by carboxylate or amide groups is ruled out by the values of the symmetric and antisymmetric CO_2 stretching, the C=O stretching and NH_2 deformation, that are similar to those of the sodium salt. Similar results have been reported for sodium and copper nicotinate and isonicotinate, and for copper isonicotinamide and nicotinamide complexes.[29,30]

Thermal behaviour

A typical thermogram, obtained in N_2 atmosphere is shown in Fig. 1. Thermograms for other compounds are similar in general, except as noted below. Dehydration, ligand L release and cyanogen plus dinitrogen evolution occur at stages reasonably well delimited. A summary of the observed peaks is given in Tables 1 and 2.

Table 2. Ligand release or decomposition temperature data (°C)[a]

Compound	nide	isonide	pzide	nic	isonic
Na	277	252	320	401	436
Mn	309	331	400	428	415
Fe(II)	290	305	300	400	390
Co	358	362	392	391	390
Ni	291	316	388	397	370
Cu	210 325	235 315	[b]	180 335	230 320
Fe(III)	295	275	[b]	270 360	250 340

[a] Those values within the rectangular field correspond to reasonably neat ligand evolution without decomposition; other values indicate release of gases arising from decomposition of ligand that can be resolved from peaks corresponding to cyanide decomposition.

[b] Not measured.

Dehydration

The differentiation between physisorbed and constituent water molecules is difficult to establish. Different hydration numbers are obtained by thermal analysis, depending on the previous drying procedure of the sample. Samples dried in a desiccator over $CaCl_2$ for 24 h or more yield solids that usually show H_2O : M ratios between 3 and 5. Samples previously dried for 24 h or more in vacuum at 40°C

Table 1. DTG/DTA water release peak maxima (°C) and H_2O : M ratio (in parentheses)

	Ligand				
M	nide	isonide	pzide	nic	isonic
Mn	120 (1.8)	120 (1.9)	116 (2.3)	106 (2.7)	133 (1.6)

Cu	90* (3.5)	105* (3.7)	—	80* 105* (3.5)	120* (3.8)
Fe(III)	100* (5.0)	100* (5.0)	—	100* (4.1)	100* (4.1)

Solids previously dried in vacuum at 40°C for 24 h, except those noted by *, corresponding to samples dried over $CaCl_2$ in vacuum at room temperature. Selected cases showing the result of applying both procedures on the same sample are included.

lose water upon heating that corresond typically to H_2O : M ratios between one and three (see Table 1). The difference is probably related to the initial formation of solids containing partially hydrated cations, and the existence of cation hydration and crystallization water molecules. Thermograms run at 5°C min^{-1} do not resolve both types of water molecules, although humps are usually apparent in the DTA and DTG peaks. The usual release temperature for all the water molecules, in samples dried by either procedure, is 90–120°C. Experiments under static air atmosphere give indication of sequential (although not completely resolved) water loss.

Ligand release

IR spectra of samples heated up to 150°C demonstrate that the complex anion suffers no change during dehydration. Ligand L release takes place in the temperature range 280–400°C, except for Cu(II); it is a simple process in the case of neutral L species in salts of all cations other than Fe(III) and Cu(II). In favourable cases weight loss and peak profiles are in good agreement with the stoichiometry (1), but usually separation from following peaks is not complete.

$$M_3[Fe(CN)_5L]_2(s) \rightarrow M_3[Fe(CN)_5]_2(s) + 2L(g). \quad (1)$$

Operation of process (1) is demonstrated also by IR characterization of the condensed evolved gaseous products: neutral L ligands remain undercomposed during release. The behaviour is similar to that of sodium salts[31] although ligand release from Fe(III) complexes is characterized by a rather broad peak that may reflect a more complex process (or the overlap with ensuing cyanide release).

Table 2 shows a summary of the temperatures of the DTA–DTG peaks, under the constant condition of our measurements; both neutral and anionic ligands are included. For neutral L, the temperature generally increases in the sequence: nide < isonide < pzide. This indicates that the thermolysis is governed by the breaking of the Fe(II)–L bond in the anion, as the bond strength increases in the same order.[22,31] The reverse order nide > isonide found in the sodium salts,[31] in disagreement with the general trends, was related earlier to an exothermic peak that produced local heating in the isonide complex. Our present observations reinforce the idea that the order of release of isonide and nide in the sodium salts is anomalous. In all the thermograms of isonide complexes an exothermic peak is observed, but in the present cases this unexplained feature takes place only after ligand L release (see Fig. 1 for a typical example).

M–L interactions are secondary in determining thermal stability. There is however also an ordering for the decomposition temperatures of the various M salts of a given $Fe(CN)_5L^{n-}$ anion, that is generally valid for the studied neutral ligands; the decomposition temperature increases in the order: Na < Fe < Ni < Mn < Co.

As can be seen from Table 2, anionic L ligands are decomposed and released at higher temperatures: carbon dioxide is one of the evolved products, as shown by the formation of $BaCO_3$ upon bubbling in $Ba(OH)_2$ solution; the other decomposition products of the organic ligand were not characterized. This process overlaps with cyanogen release (see below).

For Cu(II), neutral L are released at substantially lower temperatures, in a complex process that shows typical "ripples" in the DTA curve prior to the main weight loss. This suggests a redox process, with possible generation of Cu(I). In iron(III) complexes neutral ligands loss may also overlap with redox processes (see above), but this is not clearly demonstrated by the thermograms. In fact, for Cu(II) and Fe(III) solids the thermal behaviour in this temperature range is governed by the redox chemistry of the metal centre, and there are no substantial differences between neutral and anionic L ligands. Depending on the nature of L and M electron transfer may take place either solely from cyanide or both from cyanide and L. Thus, either $(CN)_2$ or mixtures $(CN)_2 + CO_2 +$ other decomposition products are expected in the evolved gas. The presence of $(CN)_2$ and CO_2 was detected through the formation of AgCN upon bubbling in $AgNO_3$ solution, and the formation of $BaCO_3$ upon bubbling in $Ba(OH)_2$ solutions. For Cu(II) the decomposition takes place at lower temperatures and involves essentially cyanogen release, e.g.

$$Cu_3[Fe(CN)_5L]_2 \rightarrow Cu_3Fe_2(CN)_7L_2 + (3/2)(CN)_2(g). \quad (2)$$

The milder oxidizing power of Fe(III) is reflected in higher decomposition temperatures. In this range, ligand L decomposition overlaps with CO_2 release. Oxidation of carboxylates by Cu(II) and Fe(III) are known to proceed with a rather low activation energy and in the temperature range 220–400°C.[33]

The nature of the decomposition products of L in our Fe(III) and Cu(II) complexes is not known; ligand loss takes place over a wide temperature range, with some indications of more than one step and this is probably related to fragmentation of the

ligand. For example, for L = isonicotinate, M = Fe(III), weight loss analysis and chemical characterization of the evolved gas suggest that CO_2 is the main (if not only) released product at ca. 250°C. Also, carbonization is suggested by the chemical analysis of the solid residues obtained upon calcination at 900°C: the carbon percentage is too high to be compatible with complete release of the ligand. The same situation is found for L = nide and M = Fe(III).

The nature of the solid phases formed upon ligand release was investigated in more detail in experiments carried out with controlled heating up to previously selected temperatures and subsequent isothermal decomposition until nearly constant weight was achieved. The behaviour of the solids in these experiments was sensitive to the nature of M but was very similar for different L complexes of a given M. In the case of M = Cu, as explained above ν_{CN} decreased alongside with L bands; ν_{CN} shifts at first to lower wavenumbers (i.e. from 2070 to 2040 cm^{-1} for L = nide) and its intensity decreases relative to the intensity of ligand L bands in agreement with (2). The shift to lower wavenumbers may be attributed to the replacement of Cu(II) by Cu(I) in the solid. At longer heating times, ν_{CN} shifts to higher wavenumbers (for instance, to 2100 cm^{-1} in the noted L = nide case); this effect may be related to an increasing Cu(I)–NC interaction[26] (for polymeric CuCN, featuring Cu–CN–Cu bridges, ν_{CN} = 2172 cm^{-1} has been reported[26]).

For M = Ni, after nearly complete removal of L, in the ν_{CN} region two bands were apparent, the more intense one being centred at 2168 cm^{-1}, and the weaker one at 2036 cm^{-1}; cobalt complexes behave similarly. For M = Mn, the most intense band in the ligand-free residue is located at 2036 cm^{-1} and a much weaker band is seen at 2150–2180 cm^{-1}. The high frequency band is attributable to bridged Fe–CN–M groups[32] but may also be explained through other processes involving the rupture of the $Fe(CN)_5$ moiety (note that 2176 cm^{-1} is the ν_{CN} frequency in $Ni(CN)_2$[26]). Thus, there is no conclusive evidence regarding the nature of the thermolysis product in Ni complexes. On the other hand, the low frequency value of 2036 cm^{-1} can be reasonably attributed to $Fe(CN)_5$ moieties where Fe interacts most weakly with a sixth ligand; no evidence of ligand scrambling is apparent, and thus the solid is best formulated as $Mn_3[Fe(CN)_5]_2$.

Cyanide release

Cyanide ions start to break down at temperatures that in some cases overlap with ligand L release temperatures. These temperatures, for Cu(II) are as low as 200°C. In the usual case, cyanide decomposes in a wide temperature range starting around 400°C or higher. In agreement with previous work,[13–16] weight loss is indicative of metal carbide and elemental carbon formation in varying degrees. X-

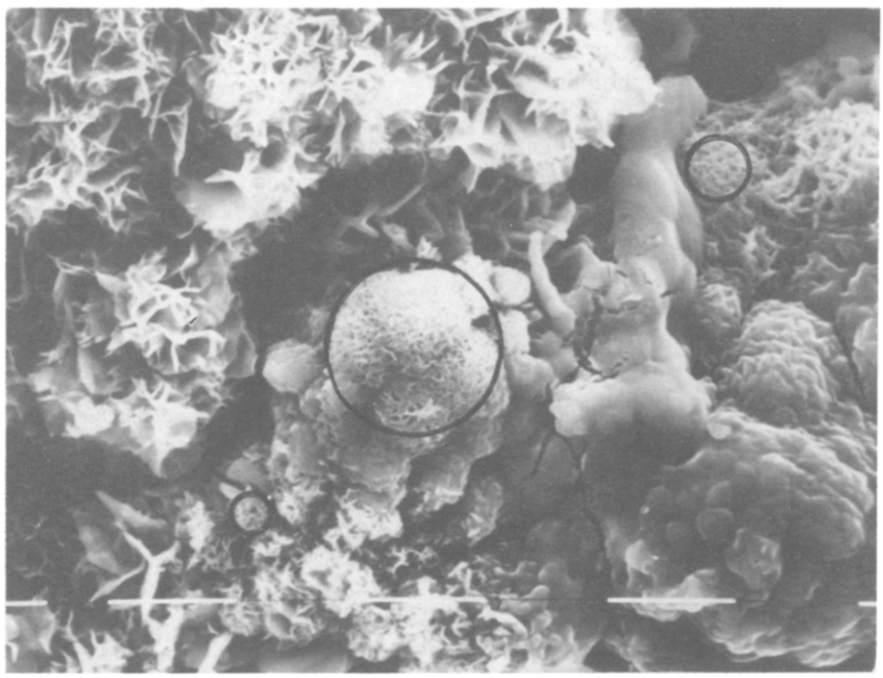

Fig. 2. SEM picture (1700×) of the pyrolysis (700°C) product of $Co_3[Fe(CN)_5nide]_2 \cdot 9H_2O$. Circles indicate Co-rich regions according to EDAX; other regions are Fe-rich.

ray diffraction of the solid residues indicates the presence of mixtures of both metals and cementite. For neutral L the overall stoichiometry arises from the overlap of (3) and (4):

$$M_3Fe_2(CN)_{10} \rightarrow 3M + 2Fe + 2xC + xN_2 + (5-x)(CN)_2 \quad (3)$$

$$M_3Fe_2(CN)_{10} \rightarrow 3M + (2/3)Fe_3C + (2x-2/3)C + xN_2 + (5-x)(CN)_2. \quad (4)$$

Eventually metal M carbides may also form. Cyanogen is detected in the evolved gas by reaction with $AgNO_3$. Carbide formation in general and cementite formation in particular is well documented in the literature.[16,18,33]

The prevalence of (3) or (4) may reflect the influence of M on the stability of the carbide. In the case of Fe(III) solids, X-ray diffraction and iron analysis of the residues indicates that cementite Fe_3C is the main reaction product. On the other hand, in Cu solids, the residue is made up essentially of pure copper and iron in the expected ratio, with little carbon in it; again, weight losses are compatible with X-ray diffraction and chemical analysis. In the case of other M(II) cations, intermediate situations are found, corresponding to the formation of both carbides and elemental metals. Weight loss data in all cases indicates substantial carbon contents in the residual solid.

In some cases (M = Co) the nature of the solid residue was characterized by SEM and EDAX, see Fig. 2. It is apparent that both metals are segregated in the process, and complex morphologies arise. Thus, the thermolysis of mixed metal cyanides, although potentially suited to produce high area intermetallics, in fact yield the individual metals in an intimate mixture. Segregation is possible because the absolute temperature of the process is as high as 0.5–0.6 times the melting point of the metals.

The following competing events may therefore be visualized: (a) cyanide oxidation by Fe(II) and M(II) (or Cu(I)) to yield Fe(0) + M(0) + cyanogen; (b) cyanide decomposition to yield cementite, M(0) and N_2. Depending on the nature of M, either (a) or (b) may be favoured. In general, only M = Fe favours strongly carbide formation. The initial solid product of pathway (a) should be an intermetallic FeM_m that then evolves to yield Fe + mM.

Abstract—$TaCl_5$ reacts with two equivalents of lithium 2,6-di-t-butylphenoxide in benzene to give [$TaCl_3$(2,6-di-t-butylphenoxide)$_2$] (**1**) in 70% yield and with three equivalents of the lithium phenoxide in diethyl ether to give [$TaCl_2$(2,6-di-t-butylphenoxide)$_3$] (**2**) which can also be prepared by reaction of (**1**) with one equivalent of the lithium phenoxide. Three equivalents of lithium 2,6-di-isopropylphenoxide react with $TaCl_5$ to give [$TaCl_2$(diethyl-ether)(2,6-di-isopropylphenoxide)$_3$] (**4**) which, on attempted recrystallization in the presence of air, gave [$Ta_2Cl(\mu\text{-}Cl)_2$(2,6-di-isopropylphenoxide)$_5(\mu\text{-}O)$] (**5**). Complexes (**1**), (**2**), and (**4**) were characterized by elemental analysis, IR, and ^1H and ^{13}C NMR spectra. Coordination of the phenoxide ligand in (**2**) is accompanied by downfield shifts of the phenyl ring *ipso*, *ortho* and *para* carbon resonances of 9.6, 3.6 and 3.1 ppm respectively, compared with the free ligand. For complex (**4**) the relative shifts are 5.9, 6.1 and 2.9 ppm. The structures of (**2**) and (**5**) have been determined by single-crystal X-ray diffraction methods. Crystals of (**2**) are monoclinic, space group $P2_1/c$ with $a = 18.902(6)$ Å, $b = 10.815(8)$ Å, $c = 20.259(4)$ Å and $\beta = 92.62(2)°$; crystals of (**5**) are monoclinic, space group $P2_1/c$ with $a = 11.174(1)$ Å, $b = 20.402(4)$ Å, $c = 27.143(3)$ Å and $\beta = 94.58(1)°$. Both structures were solved by Patterson and Fourier methods and refined to R values of 0.063 for the 1690 observed data for (**2**) and 0.062 for the 3693 observed data for (**5**). Complex (**2**) is monomeric with a square pyramidal coordination geometry about Ta. Observed distances are: $Ta\text{–}O_{axial}$ 1.83(2) Å; $Ta\text{–}O_{basal}$ each 1.90(2) Å; $Ta\text{–}Cl_{basal}$ each 1.37(1) Å. Complex (**5**) is binuclear with a distorted octahedral geometry about each tantalum atom. The structure consists essentially of $TaCl_2$(2,6-di-isopropylphenoxide)$_3$ and $TaCl_2$(O)(2,6-di-isopropylphenoxide)$_2$ units bridged through the oxygen and Cl atoms. Observed distances are $Ta\text{–}O_{bridge}$ 1.69(1) and 2.10(1) Å; $Ta\text{–}Cl_{bridge}$ 2.498(7), 2.396(8), 2.634(7) and 2.781(7) Å; $Ta\text{–}Cl_{terminal}$ 2.309(8) Å. The $Ta\text{–}O_{phenoxide}$ distances range from 1.77(2) to 2.19(2) Å. In both (**2**) and (**5**) the phenyl rings are orientated such as to minimise interactions between the 2- and 6-substituents. In both molecules electron counts are maximized using π-electron density from the terminal ligands.

There are now many examples of early transition metal complexes which contain the phenoxide ligand (-OPh).[1,2] Recent interest has centred on complexes containing alkyl substituents at the 2,6 positions of the phenoxide phenyl ring, as unusual coordination geometries and coordinatively unsaturated molecules can result.[3–10] In general, the structures of complexes containing bulky ligands cannot be rationalised on steric grounds alone, as there is always a subtle interplay of both steric and electronic factors.[11,12] However, where a series of related complexes can be prepared in which the steric size of a particular ligand is able to be varied structural changes may be related more specifically to steric effects.

For tantalum(V), a variety of phenoxide complexes have been synthesised. The pentaphenoxide

* Author to whom correspondence should be addressed.

$[Ta(OPh)_5]$, and the mixed chloro-phenoxides $[TaCl_{5-x}(OPh)_x]$ have been prepared from $TaCl_5$ and phenol.[13,14] Reactions between a series of lithium 2,6-disubstituted phenoxides and $TaCl_5$ have given the *penta* phenoxide complex using lithium 2,6-dimethylphenoxide, the *tris* phenoxide complex using lithium 2-t-butyl-6-methylphenoxide and *bis*-phenoxide complexes using lithium 2,6-di-isopropylphenoxide and lithium 2,6-di-t-butylphenoxides.[15] Of the complexes prepared, only $[TaCl_3(2,6\text{-di-t-butylphenoxide})_2]$ has been characterised by X-ray crystallography.[15]

As part of our studies of the chemistry of group V transition metals we have prepared complexes containing three sterically demanding phenoxide ligands. We report here the preparation and characterisation of *tris* 2,6-di-isopropylphenoxide and *tris* 2,6-di-t-butylphenoxide complexes of tantalum(V) and the X-ray crystal structures of $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ and $[Ta_2Cl(\mu\text{-Cl})_2(2,6\text{-di-isopropylphenoxide})_5(\mu\text{-O})]$.

RESULTS AND DISCUSSION

2,6-*Di-t-butylphenoxide complexes*

It has previously been reported that tantalum pentachloride reacts with an excess of lithium 2,6-di-t-butylphenoxide in benzene to give the *bis* phenoxy complex $[TaCl_3(2,6\text{-di-t-butylphenoxide})_2]$ (**1**) in 30–40% yield.[15] We have found however that the complex can be obtained in an improved yield of up to 71% if two equivalents of the lithium phenoxide are employed.

The ^{13}C NMR spectrum of (**1**) shows that on coordination of the phenoxide the *ipso* carbon signal shifts downfield by 9.9 ppm compared with the free ligand, the *ortho* and *para* carbon resonances each shift by 5.5 ppm, while the *meta* carbon resonance shifts by 1.1 ppm.

Deshielding of these carbons indicates electron withdrawal from the aromatic ring.[16] The methyl carbons of the t-butyl group show a single resonance, shifted 2 ppm downfield from the free ligand, while the quaternary carbon resonance position is unchanged.

When tantalum pentachloride was reacted with slightly more than three equivalents of lithium 2,6-di-t-butylphenoxide in diethyl ether for up to 24 h, an orange coloured solution formed from which the *bis* phenoxy complex (**1**) could again be obtained. However, when the reaction was carried out for longer periods, the solution colour paled to yellow. After a total reaction period of 3 days, isolation of the product gave a gummy material containing the *tris* phenoxy complex $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ (**2**). This complex could also be obtained by reacting the *bis* phenoxy complex (**1**) with slightly more than one equivalent of the lithium phenoxide reagent.

The gummy *tris* phenoxide product obtained from these reactions failed to solidify and we have been unable to crystallise the product directly from hydrocarbon solvents in which it is very soluble. However it is only slightly soluble in acetonitrile, addition of which causes the complex to precipitate out analytically pure, in a yield of approximately 40%. Further complex can be obtained from the washings, bringing the total yield to *ca.* 50%. The success of this procedure results from the complex being suitably non-polar whereas the lithium phenoxide reagent, the phenol and the *bis* phenoxy complex (**1**) are all sufficiently polar to dissolve in acetonitrile.

Pure $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ (**2**) decomposes slowly in air but more rapidly in solution. It is soluble in hydrocarbon solvents and is best crystallised from benzene solution from which large yellow crystals are obtained. In the infrared spectrum the OH absorption of the free ligand is absent, and in the 1300–1000 cm^{-1} region where ν(C–O)Ta is characteristically observed[17] there are two strong absorptions at 1160 and 1088 cm^{-1}. In addition, the spectrum contains absorbances at 880, 875, 690, 463 and 320 cm^{-1} which are not present in the free ligand. The bands at 463 and 320 cm^{-1} are assigned to Ta–O and Ta–Cl vibrations respectively on the basis of tentative assignments made for similar bands in the *bis*-phenoxy complex (**1**).[15]

The ^1H NMR spectrum of (**2**) (Table 1) shows only one resonance for the methyl protons of the t-butyl group, no phenol OH proton resonance and an aromatic multiplet similar to that found for the free ligand. In the ^{13}C NMR spectrum only one set of resonances for the three phenoxide ligands is observed. The *ipso* carbon resonance is shifted downfield 9.6 ppm compared with the free ligand while the *ortho*, *para* and *meta* carbon resonances show downfield shifts of 3.6, 3.1 and 1.3 ppm respectively. The *ortho* and *para* carbon shifts are smaller than those observed for the *bis* phenoxide complex (**1**) which suggests slightly less electron withdrawal from the aromatic rings when three phenoxide ligands are present. This feature may be related to the overall π-bonding properties of the ligands (see later).

Crystal structure of $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ (**2**)

A crystal structure determination of $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ (**2**) was carried out to com-

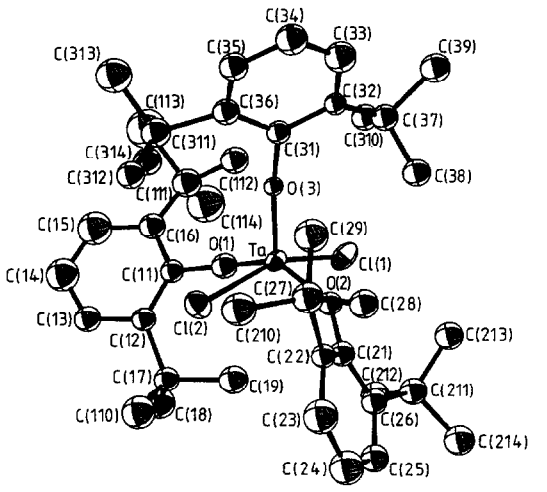

Fig. 1. Molecular geometry and atomic numbering for [$TaCl_2$(2,6-di-t-butylphenoxide)$_3$] (**2**).

pare its geometry with those of the *bis* phenoxy complexes [$TaCl_3$(2,6-di-t-butylphenoxide)$_2$] (**1**)[15] and [$Ta(Me)_3$(2,6-di-t-butylphenoxide)$_2$] (**3**).[18] The molecular structure of (**2**) is shown in Fig. 1 and bond lengths and angles are contained in Table 2. The molecule adopts a square pyramidal geometry about the tantalum atom with one 2,6-di-t-butylphenoxide ligand occupying the axial position and the other two occupying opposite sites of the square pyramid base. The two chloro ligands fill the remaining basal positions. The geometry is thus similar to that observed for the *bis* phenoxy complex (**1**) but it differs from the trigonal bipyramidal geometry of [$Ta(Me)_3$(2,6-di-t-butylphenoxide)$_2$] (**3**).[18]

The axial Ta–O bond length (1.83(2) Å) is considerably shorter than the two basal Ta–O bond lengths (each 1.90(2) Å), as was found in the *bis* phenoxy complex (**2**) (Table 3 compares data for complexes (**1**) and (**2**).) The axial Ta–O–C bond angle 162(2)° is larger than the two basal Ta–O–C bond angles (153(2)° and 148(2)°). All these angles are significantly smaller than those observed for the *bis* phenoxy complex (**1**). The two Ta–Cl bond lengths are slightly longer than the equivalent bond lengths in [$TaCl_3$(2,6-di-t-butylphenoxide)$_2$] (**1**) but lie within the range found for other tantalum(V) complexes.

Several features relating to π-bonding arise from the molecular dimensions observed. The Ta–O and Ta–Cl bond distances are all shorter than expected for single bonds and this is apparently a consequence of the low formal electron count for the molecule. If the chloro and phenoxide ligands are regarded formally as one-electron donors for purposes of the 18-electron rule then the molecule has an electron count of 10. Adoption of the square-pyramidal geometry increases the ability for ligand to metal π-bonding,[18] thus increasing the formal electron count. In general, -OR ligands are better π-donors than are chloro ligands.[19] In complex (**2**), where three phenoxides are capable of donating π-electron density to the metal, the Ta–Cl bonds are slightly longer than those in the *bis* phenoxy complex (**1**) (see Table 3). An 18-electron count can theoretically be attained if three phenoxides and just one of the chloro ligands act as 3-electron donors, with the remaining chloride acting as a 1-electron donor. However, the structure shows that all of the Ta–O and Ta–Cl bonds are relatively short, indicating that all are involved in π-bonding to the metal. The Ta–O(3) bond (1.83(2) Å) is sufficiently short to suggest that the axial phenoxide acts as a full 3-electron donor with the basal ligands sharing the remaining contribution

[a] Data taken from Reference 15.

[b] Data from present work.

[c] Values in square parentheses show change in bond angles (**2**) compared with those of (**1**). Positive values indicate angle opens, negative values angle closes relative to $[TaCl_3(2,6\text{-di-t-butylphenoxide})_2]$ (**1**).

to the π-bonding through a series of PhO⇄Ta and Cl⇄Ta canonicals. The basal Ta–O–C bond angles are smaller in complex (**2**) compared with (**1**) but the bond lengths are not sufficiently different to confirm less π-donation from the phenoxide oxygens in (**2**).

While the overall geometries of the *bis* and *tris* phenoxy complexes are similar, it is of interest to examine the effect of adding the third bulky phenoxide ligand. Bond angles for the two complexes are compared in Table 3. The O(1)–Ta–O(3) bond angle in (**2**) is similar to the equivalent bond angle in (**1**). In both molecules the t-butyl groups of the axial phenoxide are positioned over the basal chlorine ligands while the plane of the two phenyl rings is approximately perpendicular (for (**2**) the angle made by the two planes is 115(1)°). Addition of the third phenoxide ligand opens up the Cl–Ta–Cl bond angle by 12.6° and decreases the equivalent Cl(2)–Ta–O(3) bond angle by 9.6° while the O(2)–Ta–O(3) bond angle (equivalent to the Cl(3)–Ta–O(20) bond angle in (**1**)) opens up by 8.4° resulting in a decrease of the equivalent O(1)–Ta–O(2) bond angle by 10.5°. Changes in the other bond angles are comparatively small.

The phenyl rings in complex (**2**) are positioned to minimise steric interactions between t-butyl substituents. The aromatic ring of the third phenoxide lies somewhat below the basal plane at an angle of 57° to the plane made by the axial phenoxide phenyl ring. As observed in the *bis* phenoxy complex the t-butyl group attached to C(12) in (**2**) occupies the "open" site *trans* to the axial Ta–O bond. We have been unable to refine the positions of the hydrogens on the methyl groups but a non-bonded metal–proton interaction similar to that found in (**1**)[15]

is likely to be present. However the ^1H NMR spectrum indicates that in solution all protons are equivalent.

2,6-*Di-isopropylphenoxide complexes*

Tantalum pentachloride reacts with three equivalents of lithium 2,6-di-isopropylphenoxide in diethyl ether to give a yellow-orange coloured solution which pales considerably when the reaction period is extended to 20–36 h. The product isolated persisted as a yellow gum and we have so far been unable to obtain reliable analytical data. However, on the basis of the chlorine analysis and spectroscopic data, the product was characterised as $[TaCl_2(diethylether)(2,6\text{-}di\text{-}isopropylphenoxide)_3]$ (**4**). The complex is very soluble in hydrocarbons and in polar solvents such as MeCN or $MeNO_2$, but resisted crystallisation from these media.

The infrared spectrum does not contain OH absorptions and there are bands at 1262 and 1200 cm^{-1} characteristic of ν(C–O)M.[1] In the far infrared the Ta–Cl stretch occurs at 295 cm^{-1}. In the ^1H NMR spectrum the methyl protons of the isopropyl group appear as a slightly broadened doublet, the methine proton as a broadened septet shifted 0.6 ppm downfield compared with the free ligand and the spectrum does not contain an OH proton resonance. In addition, the spectrum contains a quartet and a triplet which integrate as one diethyl ether molecule for every three phenoxide ligands. In the ^{13}C NMR spectrum there is only one set of phenoxide resonances. The *ipso* carbon resonance shows a downfield shift of 5.9 ppm compared with the free ligand, while the *ortho*, *para* and *meta* carbon resonances show downfield shifts of 6.1, 2.9 and 0.1 ppm respectively. The methyl and methine carbons of the isopropyl groups show small downfield shifts of 1.7 and 1.1 ppm.

During attempts to crystallise $[TaCl_2(diethylether)(2,6\text{-}di\text{-}isopropylphenoxide)_3]$ (**4**) from petroleum ether, air was inadvertently admitted into the crystallisation flask. After several weeks a small quantity of yellow crystals was obtained, which are identified as $[Ta_2Cl(\mu\text{-}Cl)_2(2,6\text{-}di\text{-}isopropylphenoxide)_5(\mu\text{-}O)]$ (**5**) by X-ray crystallography.

Crystal structure of $[Ta_2Cl(\mu\text{-}Cl)_2(2,6\text{-}di\text{-}isopropylphenoxide)_5(\mu\text{-}O)]$ (**5**)

The crystal structure determination shows the complex to be binuclear (Figs 2 and 3) in which the two tantalum atoms are in distorted octahedral geometries and are bridged by oxo and two chloro ligands. The oxo ligand lies *trans* to a chloro ligand

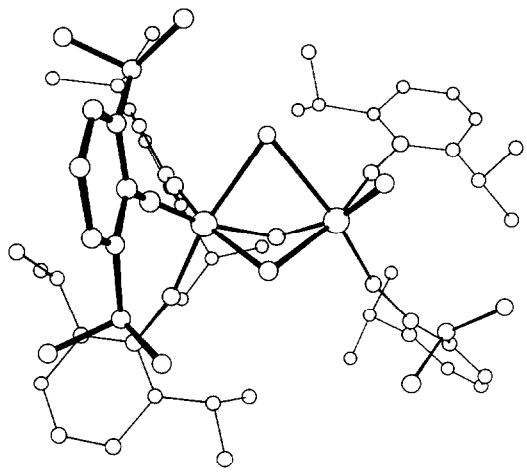

Fig. 2. Molecular geometry for $[Ta_2Cl(\mu\text{-}Cl)_2(2,6\text{-}di\text{-}isopropylphenoxide)_5(\mu\text{-}O)]$ (**5**).

on one tantalum atom and *trans* to a 2,6-di-isopropylphenoxide ligand on the other. Both bridging chlorides lie *trans* to phenoxide ligands. Bond distances and angles for the molecule are contained in Table 4.

The short Ta(1)–O(1) bond distance (1.69(1) Å) and long Ta(2)–O(1) bond distance (2.10(1) Å) indicate an asymmetric bridge in which oxygen forms a double bond to Ta(1) and a 2-electron sigma bond to Ta(2). The two Ta–Cl–Ta bridges are also asymmetric, the Ta–Cl bond lengths indicating that both Cl(1) and Cl(3) form essentially single bonds to Ta(1). The Ta(1)–Cl(3) bond length at 2.781(7) Å is extremely long and probably represents the limit of lone pair donation from chlorine to a tantalum(V) centre. By comparison, in $[TaCl_2(\mu\text{-}Cl)(NPh)(SMe_2)]_2$ the Ta–Cl bond length *trans* to the phenylimido ligand (which exerts a strong *trans*

influence) is shorter at 2.751(3) Å.[20] The two Ta–Cl–Ta bond angles in the phenoxide dimer are 70.4(2) and 71.5(2)° which are considerably smaller than those observed in $[TaCl_2(\mu\text{-}Cl)(NPh)(SMe_2)]_2$ (103.6°).[20] The Cl–Ta–O(1) bond angles are similar on both sides of the dimer, while the Cl(1)–Ta(1)–Cl(3) bond angle is 11° smaller than the Cl(1)–Ta(2)–Cl(3) bond angle.

For the 2,6-di-isopropylphenoxide ligands, the Ta-O bond lengths range from 1.77(2) to 2.19(2) Å, a wider range than that found in the *tris* 2,6-di-t-butylphenoxide complex (**2**) (1.83(2) to 1.90(2) Å). The ligands about each tantalum atom are considerably distorted from ideal octahedral geometry (see Table 4) as a result of the two halves of the molecule being chemically distinct. For example, the O(2)–Ta(1)–O(3) angle is 94.0(6)° whereas the three O–Ta(2)–O bond angles average 103.5°; Cl(1)–Ta–Cl(3) is 73.1(2)° whereas Cl(1)–Ta(2)–Cl(3) is 82.5(2)°.

The Ta–O–C bond angles range from 161(1)° to 174(2)° and on average are larger than the Ta–O–C bond angles observed for the *tris* 2,6-di-t-butylphenoxide ligands in complex (**2**). At Ta(1) the angles are such as to push the phenyl rings away from the bridge structure. At Ta(2) the Ta–O–C angles are such that the equatorial phenoxides bend away from each other while the axial phenoxide ligand bends into the space between them. In this way the isopropyl substituents at the 2,6-positions of the phenyl rings are able to minimise steric repulsions.

All the phenyl rings orientate on either side of the molecule so as to minimise interactions between the isopropyl groups (see Fig. 3). The isopropyl groups themselves are rotated so that all the methyl groups project away from the metal centres. A corollary is the methine hydrogens in each case project towards the metal centres. However none of these hydrogens make particularly close approaches to Ta, Cl or O atoms.

The structural features thus show that the molecule is able to maintain a +5 oxidation state for

each tantalum atom as it consists essentially of $TaCl(phenoxide)_2(O)$ and $TaCl_2(phenoxide)_3$ fragments which form a binuclear structure using lone pairs from the oxo and chloro ligands. As such, the Ta(1) fragment is formally a 14-electron species and the Ta(2) fragment is a 12-electron species, but the ligands about each metal centre contribute additional electron density through π-bonds. The Ta(1)–Cl(2) bond length of 2.310(7) Å is significantly shorter than the two Ta(2)–Cl bonds in which the chloro ligands can only act as one-electron donors to Ta(2). Thus Ta(1) uses π-electron density from Cl(2) (as well as that from the two phenoxide ligands) to increase its electron count. It is interesting to note that the terminal chlorine can π-bond to the metal when lying *trans* to the 2-electron donor bridging oxo group. In high-valent monomeric complexes containing the terminal oxo ligand or the isoelectronic organoimido ligand, both of which act as 4-electron donors to the central atom, only lone pair donation from a ligand in the *trans* position has been observed.[20–23] However, in lower-valent complexes, chlorides are found *trans* to such ligands but in these cases the M–Cl bonds are considerably lengthened.[24,25]

A formal electron count for Ta(2) gives 12 electrons but this also is increased by π-electron density from the phenoxide ligands. The Ta(2)–O(6) bond distance (2.19(2) Å) is however significantly longer than the Ta(2)–O(4) and Ta(2)–O(5) distances (1.83(1) and 1.77(2) Å) so that the π-electron contribution comes mainly from O(4) and O(5).

The effect of phenoxide π-bonding on the *trans* ligand is also apparent in the molecule. About each tantalum centre the phenoxides are placed *trans* to ligands co-ordinating by σ-electron density only. The phenoxides orientate *cis* to one another which allows the metal atoms maximum use of oxygen π-electron density. *trans*-Orientated phenoxides would result in a competitive π-bonding situation leading to less effective use of the electron density available. This feature is similarly found in dialkylamido complex of tantalum(V). Crystal structure determinations of $[Ta(NMe_2)_3Cl_3(NHMe_2)]$, $[\{Ta(NMe_2)Cl_2(NHMe_2)\}O]$ and $[Ta(NMe_2)_3Cl_2]_2$ show the dimethylamido ligands are orientated *cis*.[26]

CONCLUSION

The studies show that when three of the chloro ligands in $TaCl_5$ are replaced by 2,6-di-alkylphenoxide ligands, octahedral geometry is possible when the alkyl substituents are isopropyl groups. However, when three or even two of the chloro ligands are replaced by 2,6-di-t-butylphenoxide ligands the steric size of the t-butyl substituents is sufficient to force a square-pyramidal geometry on the molecule. The results thus suggest that electronic effects are less important, the change in geometry apparently arising from steric factors alone.

EXPERIMENTAL

Lithium phenoxides were prepared by adding one equivalent of *n*-butyllithium to the phenol in petroleum ether and stirring for 2 h. Tantalum pentachloride was sublimed prior to use. Acetonitrile was dried over and distilled from calcium hydride. Petroleum ether (bpt range 40–60°), benzene and diethyl ether were distilled over sodium. All distillations were carried out under N_2 treated to remove oxygen and water, as were manipulations, using bench-top air sensitive techniques.[27] Infrared spectra were recorded on a Perkin–Elmer 597 spectrometer, ^1H NMR on a Varian T60 Model spectrometer and ^{13}C NMR spectra on a Jeol FX60 spectrometer. Analytical data were obtained by Prof. A. D. Campbell and Associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under N_2 on an Electrothermal melting point apparatus and are uncorrected.

Trichlorobis(2,6 - *di* - *t* - *butylphenoxo*)*tantalum*(*V*) (1)

Lithium 2,6-di-t-butylphenoxide (3.2 g, 15.1 mmol) in benzene (50 cm^3) was added to a suspension of tantalum pentachloride (2.6 g, 7.3 mmol) in benzene (80 cm^3) and the mixture was stirred for 20 h. The orange solution was separated from the precipitate by centrifuging and the solvent removed to give an orange-red gum which was washed several times with petroleum ether. On drying *in vacuo* the complex was obtained as an orange powder. Yield: 3.6 g (71%). (Found: C, 48.6; H, 5.7%. $C_{28}H_{42}Cl_3O_2Ta$ requires C, 48.2; H, 6.1%.)

IR(Nujol) bands at 1570w, 1370s, 1358s, 1252s, 1192s, 1175s, 1150s, 1104s, 1080s, 1020w, 915s, 895s, 864m, 819m, 790s, 780m, 732s, 688m, 670w, 630w, 568w, 538w, 519w, 460w, 440w, 354s, 345s and 300m cm^{-1}.

Dichlorotris(2,6 - *di* - *t* - *butylphenoxo*)*tantalum*(*V*) (2)

(a) A suspension of lithium 2,6-di-t-butylphenoxide (4.2 g, 19.8 mmol) in diethyl ether (100 cm^3) was added slowly to a suspension of tantalum pentachloride (2 g, 5.6 mmol) in diethyl ether (200

cm^3) and the reaction mixture was stirred for 3 days. The yellow solution was filtered and the solvent removed giving a yellow crystalline solid which was contaminated with an orange gummy substance. The product was extracted several times with petroleum ether (200 cm^3 in all) until the residue was no longer coloured yellow, the extracts were combined and the solvent removed. The resulting yellow orange gum was washed with acetonitrile (3 cm^3) leaving the complex as a yellow solid which was dissolved in petroleum ether (150 cm^3). The complex was obtained as yellow micro-crystals on reducing the solution volume and standing at −20°C. Yield: 2.3 g (48%). [M.p. 120–122°C] (Found: C, 57.8; H, 7.3; Cl, 7.8%. $C_{42}H_{63}Cl_2O_3Ta$ requires C, 58.1; H, 7.3; Cl, 8.2%.)

IR(Nujol) bands at 1570w, 1465m, 1420m, 1380s, 1358s, 1310w, 1258m, 1225m, 1194m, 1160s, 1088s, 1020w, 880s, 875s, 820m, 804w, 785m, 740s, 720w, 690m, 635w, 565w, 522w, 464w, 442w, 418w, 378w, and 320m cm^{-1}.

(b) A suspension of lithium 2,6-di-t-butylphenoxide (1 g, 1.43 mmol) in diethyl ether (50 cm^3) was added to trichloro*bis*(2,6-di-t-butylphenoxy) tantalum(V) (0.35 g, 1.64 mmol) in diethyl ether (100 cm^3) and the mixture was stirred for 2 days. The yellow solution was filtered, the solvent removed, and the residue extracted with petroleum ether (120 cm^3). The solution was filtered, the solvent removed, and the residue washed with acetonitrile (5 cm^3) leaving the complex as a yellow solid. Yield: 0.54 g (43%). The complex had identical m.p., IR, ^{13}C NMR spectra to the sample prepared under (a). Recrystallisation from benzene gave the complex as large yellow crystals.

Dichlorodiethylethertris(2,6 - *di* - *isopropylphenoxo*) *tantalum*(*V*) (**4**)

Lithium 2,6-di-isopropylphenoxide (4.0 g, 21.6 mmol) in diethyl ether (100 cm^3) was added to tantalum pentachloride (2.5 g, 7.0 mmol) suspended in diethyl ether (150 cm^3) and the mixture was stirred for 36 h. The solution was filtered and the solvent removed to give a gum which failed to solidify. The product was dissolved in petroleum ether, the solution filtered, and the solvent removed to give the complex as a gummy material which failed to completely solidify even when held under vacuum for extended periods. Yield: 5.2 g (87%). (Found: Cl, 8.0%. $C_{40}H_{61}Cl_2O_4Ta$ requires: Cl, 8.3%.) The complex was further characterised by spectral properties.

IR (Nujol) bands at 1600w, 1490s, 1335s, 1262s, 1200s, 1152m, 1110m, 1065w, 1050m, 1020w, 930s, 902m, 985w, 830m, 800s, 755s, 720s, 660w, 610w, 550w, 510w, 440w, 320m and 295m cm^{-1}.

Chloro(*μ* - *dichloro*)*penta*(2,6 - *di* - *isopropylphenoxo*) (*μ* - *oxo*)*ditantalum*(*V*) (**6**)

Air was admitted to a solution of dichlorodiethylethertris(2,6 - di - isopropylphenoxy)tantalum(V) in petroleum ether. The flask was stoppered and allowed to stand at −20°C whereupon a small quantity of yellow crystals was formed. The complex was filtered, washed with petroleum ether, chilled to ice temperature and dried *in vacuo*. Characterisation was made by X-ray crystallography.

Crystallographic studies

Single crystals of $[TaCl_2(2,6\text{-di-t-butylphenoxide})_3]$ (**2**) and $[Ta_2Cl(\mu\text{-}Cl)_2)(2,6\text{-di-isopropylphenoxide})_5(\mu\text{-}O)]$ (**5**) were grown from benzene and toluene solutions respectively and sealed under nitrogen in glass capillaries. They were mounted on an Enraf-Nonius CAD-4 diffractometer.

Crystal data: *Complex* (**2**). $C_{42}H_{63}Cl_2O_3Ta$, $M = 866.8$, monoclinic, $a = 18.902(6)$ Å, $b = 10.815(8)$ Å, $c = 20.259(4)$ Å, $\beta = 92.62(2)°$, $U = 4137.1$; space group $P2_1/c$, $Z = 4$, $D_c = 1.392$ g cm^{-1}, $F(000) = 1784$, $\mu(\text{Mo-}K_\alpha) = 29.6$ cm^{-1}.

Crystal data: *Complex* (**5**). $C_{60}H_{85}Cl_5O_6Ta_2$, $M = 1440.2$, monoclinic, $a = 11.174(1)$ Å, $b = 20.402(3)$ Å, $c = 27.143(3)$ Å, $\beta = 94.57(1)°$, $U = 6168.2$; space group $P2_1/c$, $Z = 4$, $D_c = 1.551$ g cm^{-1}, $F(000) = 2896$, $\mu(\text{Mo-}K_\alpha) = 40.0$ cm^{-1}.

Data collection. Accurate unit cell parameters were determined by least-squares fits to the setting angles of 25 reflections measured using Mo-K_α ($\lambda = 0.71069$ Å) radiation. Data collection was by $2\theta/\omega$ scans with a background/peak count-time ratio of 1/2. For complex (**2**) reflections were counted for 60 s or until $\sigma(I)/I$ was 0.02, a total of 6258 reflections being measured to θ_{max} of 22°. The intensity of three reflections monitored throughout the collection showed an isotropic decline with time. For complex (**5**) decomposition in the X-ray beam was more severe and the maximum count time was reduced to 40 s. Even so, it was necessary to use four crystals to measure 2567 reflections to θ_{max} of 19°.

The data were corrected for Lorentz, polarisation, crystal decay and absorption.[28] Each crystal for (**5**) was treated separately and the data placed on a common scale by comparison of common reflections. Subsequently separate scale factors were refined for each crystal.

Structural solutions and refinements. Both structures were solved by Patterson and Fourier methods and refined by the full-matrix least-squares technique. Computing was carried out using the SDP suite of programs on a PDP-11 computer and SHELX-76 in an IBM 4341 computer. The function minimised was $\Sigma w(|F_o|-|F_c|)^2$. Atomic scattering factors and dispersion corrections were for neutral atoms. After initial isotropic refinement, anisotropic thermal parameters were refined for the heavier atoms. Final residuals R and R_w were 0.063 and 0.061 for the 1690 observed data of complex (**2**) and 0.062 and 0.068 for the 3693 observed data of complex (**5**).

Final atomic coordinates for both complexes, tables of thermal parameters, and listings of observed and calculated structure factors have been deposited with the Editor as supplementary material.*

(*Received* 5 *January* 1987; *accepted* 25 *March* 1987)

Abstract—The crystal structure of the racemic dihydrated ammonium salt of the *tris*-pentasulfidorhodate(III) anion is compared with those of salts of the *tris*-pentasulfidoplatinate(IV) ion.

Notwithstanding growing interest in transition metal polysulfides,[1] the homoleptic polysulfides of rhodium have hardly been examined, despite an early report[2] by Hofmann of the iridium system $(NH_4)_3[IrS_{15}]$. Two reports by Krause remain the only studies of such homoleptic systems,[3,4] although Malatesta and Turner characterized[5] the mixed complex of rhodium(III) formed from "dimethylglyoxime" H_2DMG and yellow ammonium sulfide as $H[Rh(HDMG)_2S_6]_n$. We have repeated Krause's preparation of $(Nh_4)_3RhS_{15}$ and obtain only the dihydrate $(NH_4)_3RhS_{15}\cdot 2H_2O$. We have also been able to prepare unsolvated $[N(C_2H_5)_3H]_3RhS_{15}$ by using CH_3CN–THF solutions. We report here these preparations, and the crystal structure of $(NH_4)_3Rh(S_5)_3\cdot 2H_2O$.

EXPERIMENTAL

Ammonium *tris*-pentasulfidorhodate(III) dihydrate, $(NH_4)_3Rh(S_5)_3\cdot 2H_2O$, was prepared by bubbling H_2S through 50 cm^3 of concentrated ("880") ammonia solution, which contained sulfur (20 g) until all dissolved. $Na_3RhCl_6\cdot 12H_2O$ (2.35 g) in water (10 cm^3) was added, causing a darkening of the solution. The system was well stirred and then filtered through celite. The dark brown red prismatic crystals formed from the filtrate during a few days at room temperature. Yield (1.5 g) was about 57%. Found: H, 2.2; N, 5.9; H_2O, 5.5. Calc. for $(NH_4)_3RhS_{15}\cdot 2H_2O$: H, 2.4; N, 6.2; H_2O, 5.3%. (Thermogravimetric analysis gave 15.0% residue at 1000°C, calculated for metal 15.3%.) However, sulfur analyses for this compound gave consistently low values *ca.* 64% versus the calculated value 71%. The analyses were done by oxidizing S to SO_4^{2-} by OH^-/H_2O_2, a method which had given good results[6] in ammonium and other salts of $[PtS_x]^{2-}$ anions.

The crystals of this compound are very soluble in water, DMF and DMSO, but sparingly soluble in methanol, ethanol, acetonitrile, THF and NH_3 solution, and insoluble in hydrocarbons. The compound was unstable in water and DMF. After dissolving it in water, a yellow precipitate rapidly appeared. In fresh DMF solution, the salt had λ_{max} at 320 nm ($\varepsilon = 14670$ 1 mol^{-1} cm^{-1}, this molar extinction coefficient calculated from the mass of $(NH_4)_3[RhS_{15}]2H_2O$ used) and 24 h later λ_{max} was still at 320 nm, but the apparent value of ε was 9660 1 mol^{-1} cm^{-1}.

* Author to whom correspondence should be addressed.

As the above properties might suggest some kind of polymer structure for $(NH_4)_3RhS_{15}\cdot 2H_2O$, a single crystal X-ray study was undertaken, as a precursor to our work on optical resolution.

Preparation of tri-ethylammonium tris(pentasulfido)rhodate(III), $[NEt_3H]_3RhS_{15}$

The preparation of the above salt was undertaken making two important solvent changes. The polysulfide (S_5^{2-}) solution was prepared by weighing 2.55 g sulfur into a 3 necked flask, adding 6 cm^3 NEt_3, 35 ml dry MeCN, 35 cm^3 dry THF (dried by reflux over Na benzophenone). H_2S was bubbled slowly through until all sulfur dissolved. (Prior degassing of solutions was performed.)

The Rh(III) complex used was prepared by stirring 660 mg $RhCl_3\cdot 3H_2O$ in 50 cm^3 ethanol for 45 min, filtering off any undissolved material and evaporating the filtrate to dryness, taking up the residue in the minimum amount of ethanol (20 cm^3). Three 5 cm^3 portions were taken and (1) 6.7 cm^3, (2) 11.2 cm^3, (3) 22.4 cm^3 S_5^{2-} solution (i.e. a 3-fold, 5-fold, 10-fold excess respectively of polysulfide solution) was added.

From (1) a very dark crystalline material formed after 15 min which was filtered off and washed with ether. After 2 h (2) had some small red needle-like crystals, and the flask was left in the refrigerator overnight. Unfortunately, the red crystals had become a dark crystalline material after 18 hours, (400 mg) which was filtered off and washed with toluene and ether. Flask (3) after 3 days yielded 100 mg of very nice acicular red crystals which were collected by filtration and washed with toluene and then ether.

Another similar S_5^{2-} solution and Rh(III) solution in 18 cm^3 ethanol were prepared. To two batches of 9 cm^3 of the Rh(III) solution were added (1) 22.6 cm^3 S_5^{2-} (5-fold excess), (2) 45.2 cm^3 S_5^{2-} (10-fold excess). After 90 min 470 mg of red microcrystals were filtered from (1), washed with toluene and ether. After 48 h nice acicular red crystals (150 mg) were collected from flask (2), and washed first with toluene, then with ether.

The materials are very soluble in DMF, DMSO, quite soluble in MeCN, CH_3NO_2, slightly soluble in MeOH, $CHCl_3$, H_2O and insoluble in EtOH, acetone, THF. The red crystals seem to be light sensitive decomposing to a blackish substance over a few weeks in "lab. light".

The TG of the products are similar, as are the infrared spectra and indicate no solvent of crystallization.

Crystal data

Dark brown red prismatic crystals of $(NH_4)_3Rh(S_5)_3\cdot 2H_2O$ ($M_r = 673.95$) are monoclinic, space group $C_{2/c}$, $a = 2597.8(6)$, $b = 1182.7(3)$, $c = 1591.6(2)$ pm, $\beta = 109.69(2)$; $Z = 8$, $D_c = 1.94$ g cm^{-3}. Single crystal, X-ray diffraction data were collected on an Enraf-Nonius CAD4 diffractometer using Mo–K_α radiation. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and refined by least-squares techniques to an R value of 0.047 ($R_w = 0.056$) for 1228 independent reflections having $I > 3\sigma(I)$.* Hydrogen atoms were not included in refinements and two oxygen atoms were refined with lower population parameters giving the calculated number of water molecules as 1.25 though thermogravimetric analyses of bulk samples had clearly indicated that the salt is a dihydrate.

DISCUSSION

The structure is made of water molecules, ammonium and *tris*-pentasulfidorhodate(III) $[Rh(S_5)_3]^{3-}$ ions. The crystal is held together by ionic interaction and by hydrogen bonds from N–H and O–H hydrogens to S and O atoms. Water molecules are in the large holes between the ions. This water of crystallization is easily lost from the crystals.

The anion is illustrated in Fig. 1. Each rhodium atom is surrounded by six sulfur atoms and these form a distorted octahedron around rhodium. Rh–S bond distances are from 234.7(4) to 240.5(5) pm, the mean being 237.4. In rhodium(III)-thiolate and -thioether structures Rh–S bond lengths are[7,8] in the range from 231.4 to 236.9 pm. The present S–S bond distances are from 202.1(9) to 207.9(8) pm. All RhS_5 rings have a chair conformation.

There is a three-fold axis through the rhodium ion, relating the three chelate rings, so that the complex ion has the symmetry C_3. There is, of course, another possible conformer, with C_1 symmetry. Both conformers were indeed detected, in the case of $[Pt(S_5)_3]^{2-}$, by the temperature variation[9] of the ^{195}Pt magnetic resonance spectrum. The C_1-isomer, judging on a statistical basis alone, would be the more probable. Nevertheless, in the present

*Final atomic coordinates, tables of thermal parameters and observed and calculated structure factors have been deposited with the Editor as supplementary data; atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

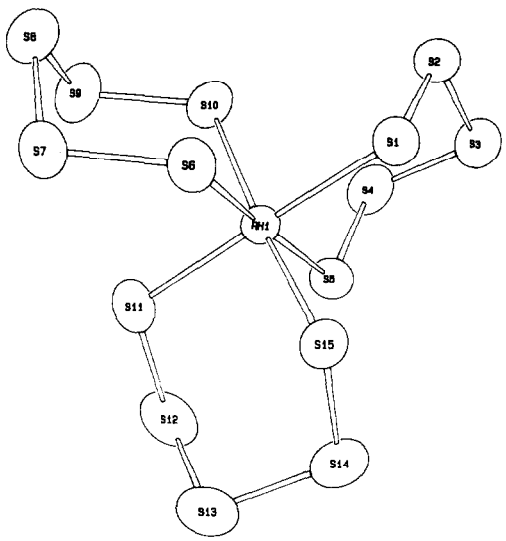

Fig. 1. Ortep drawing of $Rh(S_5)_3^{3-}$ anion showing the labelling scheme.

case for the $[Rh(S_5)_3]^{3-}$ ion and in the 3 known structures[10-12] of solid salts of the $[Pt(S_5)_3]^{2-}$ anion, the more symmetrical C_3 conformer is found. It may well be that efficient packing is easier to achieve with the more compact C_3-isomer.

There is, by virtue of the relative sizes of the sulfide atoms and of the rhodium(III) ion, one unusual feature in the *tris*-chelated anions, which is that the angles within the chelate rings (we use the general symbol α) are all greater than 90°. As shown in Table 3, the angles S_1RhS_5, S_6RhS_{10} and $S_{11}RhS_{15}$ are 92.7(2), 92.4(2) and 93.1(2) respectively. For the recently discovered[12] and analyzed dimorph of the platinum(IV) analogue, $(NH_4)_2[Pt(S_5)_3]2H_2O$, also crystallizing in the $C_{2/c}$ space group, the three intra-chelate ring angles α are S_1PtS_5, S_6PtS_{10}, $S_{11}PtS_{15}$ 90.9(2), 92.6(2), and 92.8(2) respectively.

Most of the examples of homoleptic compounds whose structures are known in detail have angles α within their chelate rings less than 90°. Currently, the nature of the electronic transition giving rise to the observed Cotton effects for *tris*-chelated octahedral ions is uncertain. Several theories[13] utilize the "trigonal splitting parameters" (or an equivalent quantity) which describes the effect on octahedral (O_h) levels (for example, $^1T_{1g}$ of spin-paired cobalt(III) in $[Co(NH_3)_6]^{3+}$) of imposing a trigonal field, as in $[Co(en)_3]^{3+}$, where en = 1,2-diaminoethane. Where the intra-chelate angles α at the metal ion are $< 90°$, the trigonal splitting for example, between A and E components of $^1T_{1g}$ in Co(III) is of one sign, and where these angles α are $> 90°$, it is of the opposite sign. That is, the circular dichroism of 2 *tris*-chelated molecules of the same absolute stereochemistry—say D or $S(C_3)$—will appear enantiomeric if the intra-chelate angle α is $< 90°$ in one case and $> 90°$ in the other.

The test cannot yet be made for the present molecule $[Rh(S_5)_3]^{3-}$ (with $\alpha > 90°$) as against say $(-)[Rh(en)_3]^{3+}$ or $[Rh(C_2O_4)_3]^{3-}$ (with $\alpha < 90°$) because we have not yet succeeded in resolving the racemic-*tris*-pentasulfidorhodate(III) into its enantiomers (although attempts continue). For the platinum(IV) analogue, where we do have the enantiomers,[6] the lowest energy absorptions are not *d–d* in character.

As a final point, whereas most racemic solid *tris*-chelated species crystallize in space groups such that neighbouring three-bladed propellers are of opposite hands (stacking —DLDLDL—), the present case $(NH_4)_3[Rh(S_5)_3]2H_2O$, with its $C_{2/c}$ space

S6	Rh1	S10	92.4(2)	Rh1	S5	S4	112.0(3)	Rh1	S15	S14	114.6(4)

Numbers is parentheses are estimated standard deviations in the least significant digits.

group is exactly similar to the second dimorph[12] of $(NH_4)_2[Pt(S_5)_3]2H_2O$ (space group $C_{2/c}$) where the 8 molecules of the unit cell are made up of 4 in one half cell of one hand of propeller (say D) and the other 4 in the other reflection related half cell of the other hand (L), so that the stacking is —DDLLD-DLLDDLL—. These are the only known cases of such stacking.

The structural parameters of the present anion have nearly the same values as found in the $Pt(S_5)_3^{2-}$ anion.[10] For example, the average Rh–S distance is 237.4 pm as the average Pt–S distance is 239.0 pm. The average S–S bond distance in the rhodium compound is 204.1 pm and in the platinum compound 204.9 pm.

In general, the $Pt(S_5)_3^{2-}$ anion seems to be more stable (or at least easier to handle) than the $Rh(S_5)_3^{3-}$ anion. In the light of the similar structural results, the differences are due to kinetics. Anionic Rh(III) complexes are often labile, but anionic Pt(IV) complexes are inert. The redox couples Rh(I)/Rh(III) and Pt(II)/Pt(IV) may play an important role in the stabilities of the above anions: we hope to evaluate this possibility through optical activity studies.

Abstract—New heterotrimetallic complexes were isolated by reaction of M(CO)$_3$(NN)L (M = Mo, W; NN = bipy, phen; L = thioureas) either with HgX_2 (X = Cl, Br, I) giving complexes of the formula [M(CO)$_3$(NN)(X)]$_2$Hg or with M′(CO)$_3$(NN′)(Cl)(HgCl) (M′ = Mo, W; NN′ = bipy, phen) producing compounds of the type (Cl)(NN)(CO)$_3$M–Hg–M′(CO)$_3$(NN′)(Cl). These new photosensitive substances were characterized through IR spectroscopy and conductivity measurements. Structures involving X–M–Hg–M′–X bonding are proposed and the reactions are discussed in terms of an insertion of the fragment M(CO)$_3$(NN) into the Hg–X bonds.

Mixed derivatives of the formula *fac*-M(CO)$_3$(NN)L (M = Mo, W; NN = 2,2′-bipyridine (bipy), 1,10-phenantroline (phen) L being a wide range of unidentate Lewis bases are well known,[1–6] but their reaction with mercuric halides, $HgCl_2$, has been reported when L is triphenylphosphine or derivative,[7,8] pyridine[9] and thiourea,[10] giving tricarbonyl complexes containing either M–Hg or M–Hg–M bonds.

The formation of the metal–mercury compounds above has been considered to be a Lewis acid-base reaction, the metal complex being the nucleophilic centre, yielding HgCl or $HgCl_2$ complexes. The reaction would occur without elimination of the ligands in the complexes M(CO)$_3$(NN)PPh_3,[7] due to the soft character of the phosphorus atom in PPh_3 and the chelate nature of the bipy or phen,[11] but when L is a p-substituted triphenylphosphine it would be displaced,[8] the same would pass with the thiourea[10] while the pyridine complexes would show both types of behavior.[9]

The aim of this work is to clarify the way of the reaction of *fac*-M(CO)$_3$(NN)L complexes with mercuric halides, HgX_2 (X = Cl, Br, I). In this regard we chose L to be several N-substituted thioureas. The results of this investigation show that the active species towards the Hg–X bonds are the M(CO)$_3$(NN) fragments.

RESULTS AND DISCUSSION

The only known complex of the type M(CO)$_3$(NN)L (M = Mo, W; NN = bipy, phen) in which L is thiourea is the Mo(CO)$_3$(NN)(thiourea)[6,10] procedure prepared by Houk and Dobson.[6] In this work the above synthesis route was modified, using less drastic conditions, introducing the thioureas through a substitution reaction in the complex M(CO)$_3$(NN)(CH_3CN),[6] by refluxing in methanol.

The reaction of the complexes M(CO)$_3$(NN)(thioureas) with mercury halides, HgX_2 (X = Cl, Br, I), in the molar ratio 1/1 or more in acetone gave, in all cases, complexes of the formula [M(CO)$_3$(NN)]$_2$$HgX_2$. Nevertheless, in some cases the quoted reaction products were obtained contaminated with the mercury thiourea compounds, HgX_2(thiourea)$_2$.

The new compounds are air stable, orange or red colored microcrystalline solids, but they undergo rapid decomposition on exposure to sunlight or on heating, as manifested by mercury deposition. They are insoluble in non-polar organic solvents and very

* Authors to whom correspondence should be addressed.

slightly soluble in methanol or acetone. In DMFA no conductivity was detected, but an increase with the time was observed probably due to the displacement of the halide by the solvent.[12]

When the reaction was carried out in the presence of a large excess of the mercury halide, the seven-coordinate metal complexes $M(CO)_3(NN)(X)(HgX)$ were precipitated. These have been prepared by other authors[13,14] through the reaction of HgX_2 with the tetracarbonyls $M(CO)_4(NN)$. The crystal structure of one of them, $Mo(CO)_3(bipy)(Cl)(HgCl)$, shows the presence of the Mo-HgCl and Mo–Cl bonds.[15]

The IR spectra of the compounds $[M(CO)_3(NN)]_2HgX_2$ reveals the absence of the thioureas but the presence of the bipy and phen. The position of these latter bands show no significant differences compared to those of the parent complex $M(CO)_3(NN)$(thioureas).

The CO stretching region (Table 1, compounds 1–12) shows two strong absorptions; that of lower frequency is broad and in some cases split into two. Furthermore, no significant displacements of their positions occur by changing the halide. On the other hand, in the $[M(CO)_3(NN)(X)(HgX)]$ complexes these bands are shifted to higher frequencies.[13,14] A similar behaviour was observed in comparing the complexes $[(\eta\text{-}C_5H_5)M(CO)_3]_2Hg$ and $(\eta\text{-}C_5H_5)M(CO)_3(HgX)$, which are connected by an exchange process with HgX_2.[16]

Accordingly, these antecedents permit us to suggest the existence of a new tricarbonyl complex system related by the reaction:

$$[M(CO)_3(NN)]_2HgX_2 + HgX_2 = 2M(CO)_3(NN)(X)(HgX). \quad (1)$$

There are two possible structures for the halides $[M(CO)_3(NN)]_2HgX_2$: $[M(CO)_3(NN)]_2HgX_2$ or $[M(CO)_3(NN)(X)]_2Hg$. In both situations M–Hg–M bonding would be present and the mercury atom would have a coordination number of four in the first case and of two in the second one. Nevertheless, in related compounds co-ordination numbers higher than two for the mercury atom were not observed.[16] Hence, the second possibility seems to be more plausible. Moreover, in this way the seven-coordinate metal atom would reach the inert gas configuration.

With the above discussion, the structure for the complexes $[M(CO)_3(NN)(X)]_2Hg$ implies the existence of the X–M–Hg–M–X system. Hence, it seems reasonable to interpret the mechanism of formation of these compounds as the insertion of the fragment

$M(CO)_3(NN)$ between the atoms of the Hg-X bond:

$$M(CO)_3(NN)L + X-Hg-X = M(CO)_3(NN)(X)(Hg-X) + L \quad (2)$$

$$M(CO)_3(NN)L + M(CO)_3(NN)(X)(Hg-X) = [M(CO)_3(NN)(X)]_2Hg + L. \quad (3)$$

The concept of the insertion behavior of the groups $M(CO)_3(NN)$ enabled us to isolate a series of new asymmetric trimetallic M–Hg–M′ complexes just based in the eqn (3) (M′ = Mo, W; NN′ = bipy, phen):

$$M(CO)_3(NN)L + M'(CO)_3(NN')(Cl)(Hg-Cl) = (Cl)(NN)(CO)_3M-Hg-M'-(CO)_3(NN')(Cl) + L. \quad (4)$$

The IR spectra of these asymmetric trimetallic complexes (Table 1, compounds 13–18) do not show any noticeable difference with those of the symmetric ones, except in the fact of the simultaneous appearance of the bands of the bipy and phen ligands.

In addition, the insertion fragment $M(CO)_3NN$ was made to react with the complex $Fe(CO)_4(HgCl)_2$,[17] yielding $[M(CO)_3(NN)(Cl)]_2Hg$ and the polymeric $[HgFe(CO)_4]_n$. This result may be explained by the insertion between the Hg–Cl bonds, giving an unstable complex in which Hg(I) disproportionates.

The behavior of the system under study showed that the thioureas are good leaving ligands, but they can cause contamination of the reaction products. This prompted us to find a clean source of $M(CO)_3(NN)$ fragments, and so the $M(CO)_3(NN)(CH_3CN)$ complexes achieved successfully all the requirements.

EXPERIMENTAL

All the reactions were carried out under nitrogen and with de-aerated solvents. The compounds $M(CO)_3(NN)(CH_3CN)$ (M = Mo, W; NN = bipy, phen)[6] and $M(CO)_3(NN)(X)(HgX)$[13,14] were prepared by similar methods to those described in the literature. Mercury salts and substituted thioureas (e.g. thiourea, *N*-methylthiourea, *N*,*N*-dimethylthiourea, *N*-phenylthiourea, *N*,*N*-dimethyl *N*′-phenylthiourea, tetramethylthiourea) were of commercial origin and used without further purification. The $M(CO)_3(NN)$(thioureas) compounds were characterized by their elemental analysis and their IR spectra. The shapes and positions of these latter bands are in agreement with literature data for sulphur bonded ligands.[6] The IR spectra were obtained using a Perkin–Elmer 577 spectrophotometer. The conductivity was measured at room temperature in DMFA with a direct lecture L. Pusl instrument.

Synthesis of $[M(CO)_3(NN)(X)]_2Hg$ (X = Cl, Br, I)

These compounds were synthesised by reaction of the complexes $M(CO)_3(NN)L$ (L = thioureas or acetonitrile) and HgX_2 in acetone. All these substances were either orange or red colored microcrystalline solids. The following synthesis is described as a typical one.

$[Mo(CO)_3(bipy)(Cl)]_2Hg$: A solution of $Mo(CO)_3$(bipy)(tetramethylthiourea) (0.241 g; 0.51 mmol) and $HgCl_2$ (0.70 g; 0.25 mmol) in 10 cm^3 acetone was vigorously stirred in the dark for 30 min. The solution became yellowish and an orange precipitate was formed. It was then filtered and washed 3–4 times with 5 cm^3 portions of acetone. 0.14 g of an orange colored microcrystalline solid were obtained. The results of the elemental analysis are presented in Table 1.

Synthesis of $[(Cl)(NN)(CO)_3M-Hg-M'(CO)_3(NN')(Cl)]$ (M′ = Mo, W; NN′ = bipy, phen)

The general procedure was the addition of half of the stoichiometric quantity of solid $M'(CO)_3(NN')(Cl)(HgCl)$ to a solution of $M(CO)_3(NN)(CH_3CN)$ in acetonitrile. All these reaction products were orange-red colored microcrystalline solids. The following reaction is given as an example.

$[(Cl)(bipy)(CO)_3Mo-Hg-W(CO)_3(bipy)(Cl)]$: $W(CO)_3$(bipy)(Cl)(HgCl) (0.14 g; 0.2 mmol) was added to a freshly prepared solution of $Mo(CO)_3$(bipy)(CH_3CN) (0.15 g; 0.4 mmol) in acetonitrile and was vigorously stirred for 2 h. The orange-red precipitate was filtered and washed 3–4 times with 5 cm^3 portions of acetonitrile and finally with acetone. 0.15 g of the microcrystalline compound was obtained. The elemental analysis of these compounds are given in Table 1.

Abstract—The mononuclear complexes $[M(CO)_5(CH_3E)_nCH_{4-n}]$ ($n = 2$, M = Cr and W, E = S and Se; $n = 3$, M = Cr and W, E = S; $n = 4$, M = Cr, E = S) have been synthesized and characterized. In addition to the facile atomic inversions of the metal co-ordinated sulphur and selenium atoms, there are intramolecular 1,3-metallotropic shifts among all the available co-ordination sites on each ligand. From dynamic NMR studies activation energies have been determined for these metal commutations.

The metal complexes of organosulphur and selenium ligands have been shown to possess a striking array of fluxional phenomena.[1] Cyclic sulphide ligand complexes of pentacarbonyl-chromium, -molybdenum and -tungsten have been observed to undergo 1,3-metallotropic shifts,[2–5] as also have the complexes of the acyclic 2-selena-4-thiapentane.[6] We have now sought to extend the complexity of these motions by presenting to metal pentacarbonyl moieties the opportunity to commute over either two, three or four isosteric sulphur atoms in the ligands bis(methylthio)methane, $(CH_3S)_2CH_2$, tris-(methylthio)methane, $(CH_3S)_3CH$, and tetrakis (methylthio)methane, $(CH_3S)_4C$, and between two selenium atoms in bis(methylseleno)methane $(CH_3Se)_2CH_2$. We report herein the synthesis and characterization of pentacarbonylmetal derivatives of these ligands. These complexes all display 1,3-metal chalcogen shifts, and we have determined accurate energy barriers for all of these processes utilizing well developed spectral line-shape analysis techniques.[7]

EXPERIMENTAL

Materials and preparations

Metal hexacarbonyls were used directly as obtained commercially. $(CH_3S)_2CH_2$,[8] $(CH_3S)_3CH$,[9] $(CH_3S)_4C$,[9] $(CH_3Se)_2CH_2$,[10] $[(C_2H_5)_3O]^+BF_4^-$[11] and $[WBr(CO)_5]^-N(C_2H_5)_4^+$[12] were prepared as previously reported. All reactions and purification procedures were carried out under nitrogen.

Pentacarbonylbis(methylthio)methanetungsten(O) $[(CO)_5WS(CH_3)CH_2SCH_3]$. Tetraethylammonium bromopentacarbonyltungstate (1.32 g, 2.91 mmol) and bis(methylthio)methane (0.36 g, 3.3 mmol) were dissolved in dichloromethane (5 cm^3). A solution of triethyloxonium tetrafluoroborate, $(C_2H_5)_3OBF_4$ (0.57 g, 3.00 mmol) in dichloromethane (2 cm^3) was added with stirring causing an immediate clearing of the cloudy solution, and a change of colour to light orange. Solvent was removed under reduced pressure to leave a yellow residue which was extracted with hexane (2×30 cm^3). The combined hexane extracts were filtered through a medium glass frit, reduced in volume (low pressure) at 20°C, and then left at −20°C for

three days to produce yellow crystals of $[(CO)_5WS(CH_3)CH_2SCH_3]$ (0.84 g, 1.9 mmol) (67% yield).

Pentacarbonyltungsten and pentacarbonylchromium complexes of $(CH_3S)_2CH_2$, $(CH_3Se)_2CH_2$, $(CH_3S)_3CH$ and $(CH_3S)_4C$ were all prepared in analogous ways and are characterized in Table 1.

NMR spectra. All of the compounds studied were sensitive to decomposition by air in solution, hence solutions were made up in standard 5 mm bore tubes with Taperlock joints (Wilmad Glass Co. Inc.). Reference material and solvent were distilled under vacuum onto the sample, and tube and contents were subsequently flushed with nitrogen. Variable temperature ^1H NMR spectra were recorded using a JEOL PS/PFT–100 spectrometer operating at 100 MHz. Sample temperatures were controlled by a standard JES-VT-3 accessory and measured with a digital thermometer (Comark Ltd). Temperatures recorded are accurate to at least $\pm 1°C$ over the reported range. NMR bandshape analyses were carried out as described[13] previously.

RESULTS

^1H NMR studies

$[M(CO)_5(CH_3E)_2CH_2]$ *complexes,* M = Cr *and* W, E = S *and* Se. The NMR spectra of all four of these complexes (Table 2) consist of three separate signals with integrated peak intensities of 2 : 3 : 3. This would be the anticipated spectrum for such compounds with a methylene group along with one metal co-ordinated methylthio/seleno group and one pendant methylthio/seleno group as in Fig. 1. As illustrated, however, the two protons of the methylene group should be anisochronous due to the chiral nature of the co-ordinated sulphur/selenium atom. In view of the extensive data already reported on inversion barriers in sulphur/selenium co-ordinated metal pentacarbonyls it is reasonable to assume that rapid inversion about the co-ordinated pyramidal sulphur/selenium atom is causing equilibration of the protons in the prochiral methylene group. On cooling the solutions

of the complexes $[M(CO)_5(CH_3Se)_2CH_2]$, M = Cr and W to −60°C the room temperature methylene singlet resolves to the expected AB quartet with the slowing/cessation of inversion about the co-ordinated selenium atom. We were, however, unable to bring about the geminal proton chemical shift distinction at reduced temperature for the complexes $[M(CO)_5(CH_3S)_2CH_2]$. This may be attributable to either (or both) of the following reasons: (i) accidental chemical shift degeneracy, or (ii) still rapid equilibration of proton environments by sulphur atom inversion. Despite our best efforts, we have been unable to resolve these protons, but we still believe co-ordinated chalcogen atom inversion to be one of the fluxional characteristics of each of these complexes.

On recording NMR spectra at above room temperature, lineshape changes become evident at about 70°C whence the two methylthio/seleno signals in each complex are observed to broaden and proceed towards coalescence at *ca* 120°C. The absence of inter-broadening of complexed ligand and free ligand signals, or any concentration effects on the bandshape indicate that an intramolecular process is responsible for the observed methyl equilibrations. This we interpret as a shuttling of the metal between two chalcogen atoms as depicted in Fig. 2. The exchange broadened SMe/SeMe bandshapes due to this 1,3-shift process may be simulated as a simple 2-site exchange problem with no scalar coupling.

Due to the high temperatures required for observation of the phenomenon, some complexes underwent partial decomposition, and consequently the recorded spectra were not always ideal for computer simulation. Only cases where the spectral fittings produced reliable values of $\Delta G^{\ddagger}$ for the 1,3-commutation process are reported in Table 3.

The graph diagram in Fig. 3 illustrates interchange pathways by atomic inversion and by 1,3-shift for the four co-ordination topomers of the complexes $[M(CO)_5(CH_3E)_2CH_2]$.

$[M(CO)_5(CH_3S)_3CH]$ *complexes*, M = Cr *and* W. The NMR spectra of these two complexes (Table 2) consist of three separate signals with integrated peak intensities 1 : 3 : 6 corresponding to methine, ligand co-ordinated methylthio and two unco-ordinated methylthio groups respectively. It can be assumed, at room temperature, that metal co-ordinated sulphur atom inversion is rapid, thus rendering the potentially anisochronous unco-ordinated methylthio groups equivalent. Between 60 and 110°C the signals of the co-ordinated and unco-ordinated methylthio groups coalesce with an absence of any exchange with the signal of the free ligand present in solution. This observation is the result of intramolecular commutation of the metal pentacarbonyl moiety among all three methylthio

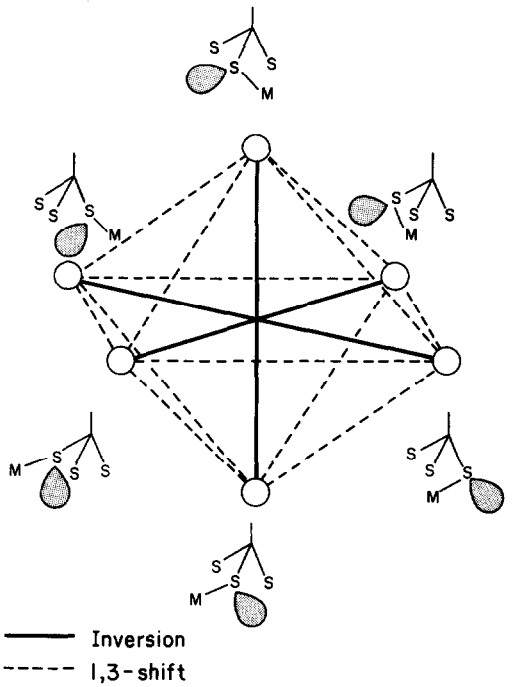

Fig. 4. Graph diagram illustrating the six topomers of $[M(CO)_5(CH_3S)_3CH]$ and their exchange pathways.

groups of the ligand. This results in a total of six possible topomers, and Fig. 4 illustrates how each topomer may access four others by the 1,3-metallotropic shift and the other by sulphur atom inversion. Simulation of the spectra was straightforward as the rapid sulphur inversion rendered the spin problem for the exchanging methylthio groups as $A \rightleftharpoons B_2$, and the energy barriers so obtained are recorded in Table 3.

$[Cr(CO)_5(CH_3S)_4C]$. Pure samples of $[W(CO)_5(CH_3S)_4C]$ could not be obtained, but we were able to prepare, characterize and investigate the chromium analogue fully. The NMR spectrum shows a 1 : 3 signal ratio in its methylthio region, resulting from one only of the four methylthio groups being co-ordinated to the chromium pentacarbonyl moiety. The temperature collapse of the methylthio signals indicates the onset of the intramolecular 1,3-metallotropic shift which moves the chromium pentacarbonyl group over the surface of the ligand. The eight sites of attachment yield the eight topomers of this species. The graph diagram of Fig. 5 illustrates their interconversion pathways either by sulphur atom inversion or by 1,3-metal commutation.

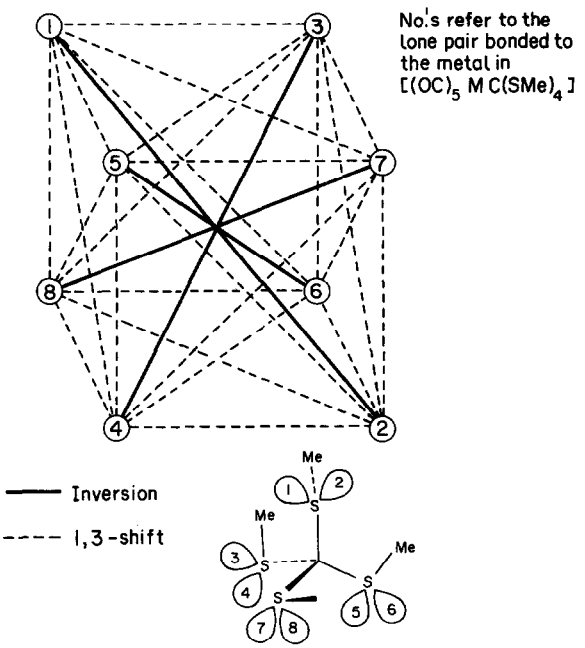

Fig. 5. Graph diagram illustrating the eight topomers of $[M(CO)_5(CH_3S)_4C]$. Numbers at the cube corners identify the topomer corresponding to the metal pentacarbonyl moiety co-ordinated at the corresponding numbered position on the ligand illustration. It is not possible in such a graph digram to give identical processes the same geometrical values. Thus all edges and face-diagonals represent 1,3-commutations and the remaining trans-cube diagonals represent interchange of topomers by ligand atom inversion.

DISCUSSION

1,3-Metallotropic shifts have been extensively reported[2-5] for cyclic ligands, and the cor-

responding process in the acyclic 2-selena-4-thiapentane has been studied.[6] Now, the complexes reported herein have either two, three or four completely identical ligand sulphur/selenium atoms for co-ordination to a metal pentacarbonyl moiety in an acyclic ligand.

In all cases we observe temperature variable ^1H NMR spectra which we associate with 1,3 metal commutation between all available co-ordination sites on the molecule. In all species we find the rates to be independent of concentration. This fact coupled with an absence of any exchange between the signals of complexed ligand and free ligand, suggest a completely intramolecular process. In the transition state we envisage the $M(CO)_5$ moiety as being equally bonded to the two methylthio/seleno groups between which it commutes. In such an intermediate, the metal may be thought of as pseudo seven co-ordinate and as such be stereochemically non-rigid, with a resultant possibility for scrambling of the carbonyl groups. A recent report[14] on the 1,2-metallotropic shifts of metal pentacarbonyls on organic disulphides, however, indicates that in these commutations the $M(CO)_5$ group remains rigid, with non-exchanging axial and equatorial carbonyl groups. The stereochemistry of the $M(CO)_5$ moiety in a wide range of 1,3-commutations in both cyclic and acyclic ligands is now under investigation, and will be reported later.

In Table 3 the considerable decrease in free energy of activation for the 1,3-metal commutation is notable as the number of methylthio groups on the ligand increases. In each case the transition state involves simultaneous co-ordination of two methylthio groups to the metal, and changes in other groups on the central carbon atom appear unlikely to effect the steric requirements of the transition state. In the ground state, however, the steric congestion increases significantly as the number of methylthio groups on the ligand increases from two to three to four. This would therefore suggest that the decreasing activation energy for the 1,3 shifts with increasing methylthio groups is due to steadily increasing ground state energies in $[M(CO)_5(MeS)_2CH_2]$, $[M(CO)_5(MeS)_3CH]$ and $[M(CO)_5(MeS)_4C]$ rather than changes in the transition state energy.

FORMATION OF SPINEL FROM METAL ORGANIC COMPOUNDS

OSAMU YAMAGUCHI,* HIROYUKI TAGUCHI and KIYOSHI SHIMIZU

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kyoto 602, Japan

(*Received* 24 *March* 1987; *accepted* 6 *April* 1987)

Abstract—A magnesium–aluminum product, which can be used to form spinel, is prepared by the simultaneous hydrolysis of magnesium acetylacetonate and aluminum isopropoxide. Infrared spectrum and X-ray diffraction analyses show that the product is a magnesium substituted γ-alumina-like amorphous material. Spinel is formed slowly at $\approx$ 700–1250°C at a heating rate of 10°C min^{-1}. A marked increase in crystallite size occurs between 1100 and 1200°C. Spinel powders consist of aggregates of plate-like particles. The kinetics of crystallization of spinel have been studied by X-ray measurements. The initial stage at each temperature proceeds rapidly in a short time. The final stage can be described in terms of the contracting square equation $1-(1-f)^{1/2} = kt$, the activation energy being 164 kJ mol^{-1}.

Magnesium aluminate spinel $MgAl_2O_4$ is usually prepared by solid state reaction between MgO and Al_2O_3. Preparation conditions require heating for 100 h at 1302°C even when submicron reactants are used.[1] In contrast, chemical methods[2–7] permit the preparation of spinel at lower temperatures. Bratton[2,3] showed that the coprecipitate prepared from aqueous solutions of $MgCl_2 \cdot 6H_2O$ and $AlCl_3 \cdot 6H_2O$ by ammonium hydroxide was an intimate mixture of $2Mg(OH)_2 \cdot Al(OH)_3$ and gibbsite $Al(OH)_3$. Sugiura and Kamigaito[7] reported that the hydrolysis products of magnesium aluminum double alkoxide $MgAl_2(OC_3H_8)_8$ depended on the atmosphere; thus, under inert gas, an AlO(OH) boehmite-like compound was formed, but in air, a variety of compounds were formed because of the influence of carbon dioxide. However, no kinetic study of the formation of spinel has been carried out using the specimens prepared by chemical methods.

In the present study, the simultaneous hydrolysis product of magnesium acetylacetonate and aluminum isopropoxide was amorphous. The present paper deals with the formation of spinel from metal organic compounds.

EXPERIMENTAL

Magnesium acetylacetonate $Mg(C_5H_7O_2)_2$ (> 99% pure) as-received was dissolved in 2-propanol. Aluminum isopropoxide $Al(OC_3H_7)_3$ was synthesized by heating 99.9% aluminum metal in an excess of analytical-grade 2-propanol with mercury (II) chloride (10^{-4} mol/mol of metal) as a catalyst for 10 h at 82°C.[8] The mixed solution prepared in the mole ratio $Mg^{2+}:2Al^{3+}$ was refluxed for 10 h and then hydrolyzed at room temperature in air by adding drops of ammonia water (28%) with stirring. After the termination of dropping, the resulting suspension was further stirred for 30 min at room temperature. The hydrolysis product was separated from the suspension by filtration, washed 10 times in conductivity water, and dried at 80°C under reduced pressure. The powder obtained is termed "starting powder".

Thermal analyses (TG, DTA) were conducted in air at a heating rate of 10°C min^{-1}; α-alumina was used as the reference for the DTA. The starting powder and specimens heated at a rate of 10°C min^{-1} and then quenched were examined by X-ray diffraction using Ni-filtered CuKα radiation. The kinetics of crystallization of spinel were followed by X-ray measurements. The starting powder was preheated as will be described. The specimens were

* Author to whom correspondence should be addressed.

placed in an electric furnace equipped with a temperature regulator, heated for the desired time, and then quenched rapidly to room temperature. The fraction of crystallization was determined from the intensity ratio of the spinel line (311) to the spinel $+CaF_2$ line (220) as an internal standard, using a calibration curve prepared with known compositions. Powders for electron microscopic observation were dispersed in amyl acetate by an ultrasonic treatment for 5 min. The dispersed drops were dried on carbon film, and observed under a 35 keV beam. Infrared spectroscopy was performed on a dispersion in potassium bromide using the pressed-disk technique.

RESULTS AND DISCUSSION

Characterization of starting powder

X-Ray diffraction analysis showed that the starting powder was amorphous. The average particle size, determined by electron microscopy, was ≈ 60 nm (Fig. 1). Figure 2(A) shows the IR spectrum of starting powder. The absorption bands at 3450 and 1630 cm^{-1} are due, respectively, to the O–H stretching and bending vibrations of H_2O[9] and, on the preparation history, represent adsorbed water and water of hydration. The bands resulting from CO_3^{2-} stretching vibrations were present at 1545, 1415 and 1055 cm^{-1};[10] this is probably due to CO_2 absorbed in the aqueous ammonia. Two main spectral bands for ammonia (gas, solid) are located in the vicinity of 3380 and 1640 cm^{-1}.[11,12] They may be overlapped with the bands due to water described above. No bands due to NH_4^+ were observed. According to the Deo *et al.*[13] data for 2-propanol adsorbed on γ-alumina, six bands are located at 2960, 2930, 2870, 1465, 1170 and 650 cm^{-1}. Therefore, the bands at 2925, 2850, 1465 and 1160 cm^{-1} must be assigned, as shown in Fig. 2(A), by reference to their data. The spectrum pattern below 1000 cm^{-1} is similar to that of γ-alumina* (spinel-type structure) shown in Fig. 2(B). On the basis of the γ-alumina[14] data, a broad band at 530 to 845 cm^{-1} in starting powder is assigned to the Al–O stretching vibration. From the results of X-ray diffraction, no species other than spinel were observed throughout the heating process. Thus, it

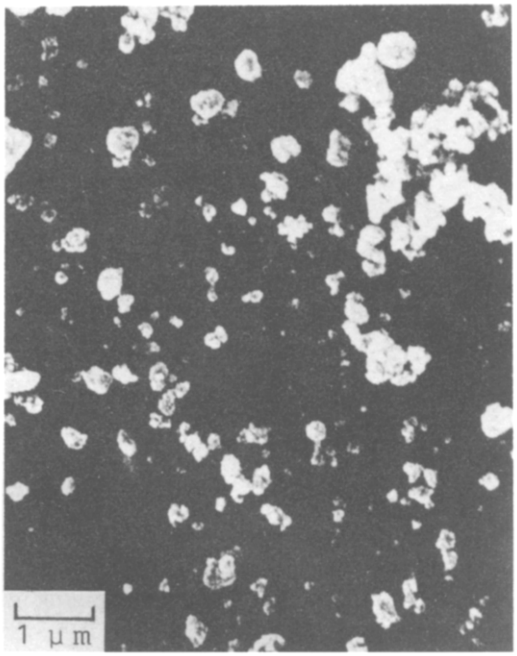

Fig. 1. Scanning electron micrograph for starting powder.

can be considered that the starting powder is Mg^{2+}-substituted γ-alumina-like amorphous containing water, ammonia, 2-propanol, and carbon dioxide.

Thermal analysis

Thermogravimetric examination of starting powder showed that the weight decrease was essentially completed at 540°C [Fig. 3(A)]. This can be attributed to the release of ammonia, water and organic residues from the parent alcohol. In addition, the weight decrease of 2.5% was recognized at 540–900°C; IR spectrum data suggested the release of water and carbon dioxide. A DTA curve is shown in Fig. 3(B). Except for an endothermic peak due to the release of ammonia and water, and an exothermic peak to the combustion of organic residues, no peak due to the crystallization of spinel was clearly detected in the DTA, although it was observed above $\approx$ 700°C as will be described.

Formation of spinel

Figure 4 shows the X-ray diffraction patterns of specimens with increasing temperature. The starting powder did not change up to 650°C. The (311) and (400) lines for spinel began to appear after heating at 700°C. Other lines were recognized when heated at 800°C. The intensity of the lines increased gradually with increasing temperature. Well-crystallized spinel was obtained by heating at 1250°C.

* Boehmite gel, prepared by the hydrolysis at room temperature of aluminum isopropoxide using conductivity water, was heated to 900°C at a heating rate of 10°C/min.

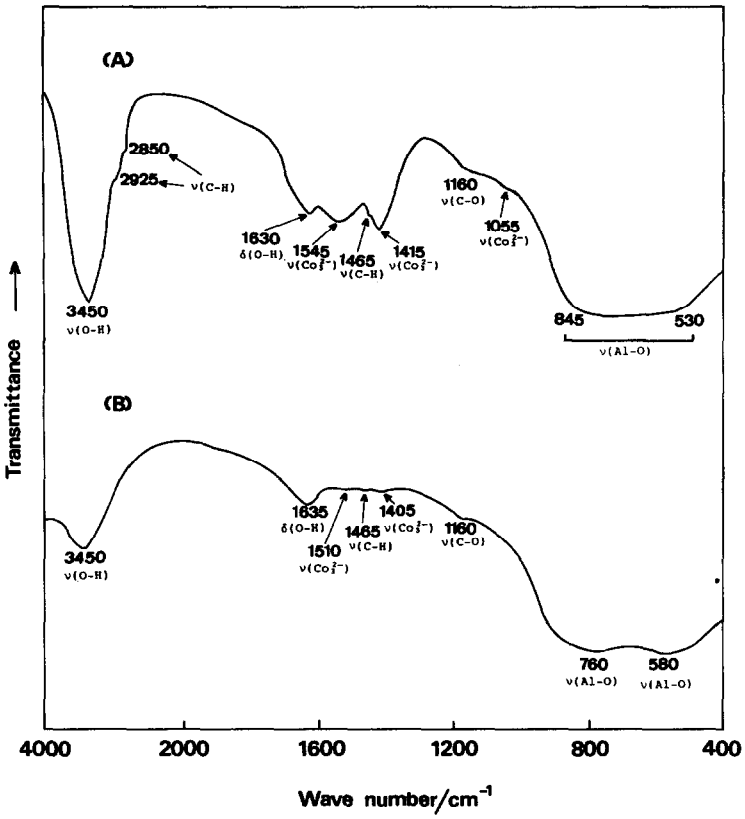

Fig. 2. Infrared spectra for (A) starting powder and (B) γ-Al_2O_3.

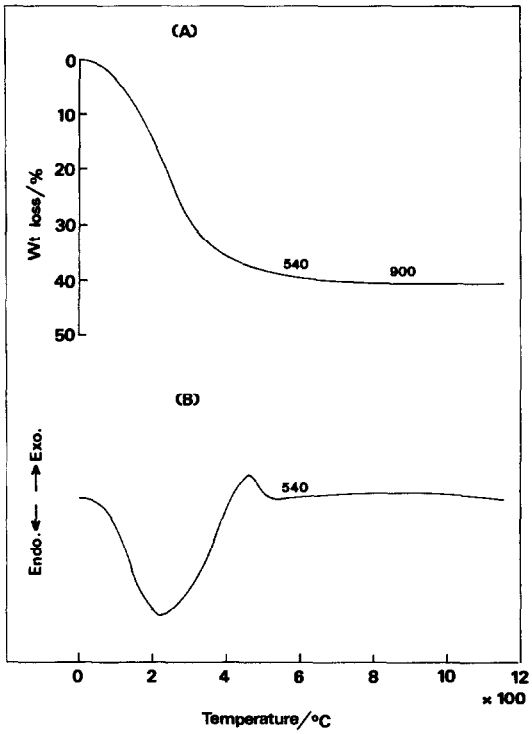

Fig. 3. (A) TG and (B) DTA curves for starting powder.

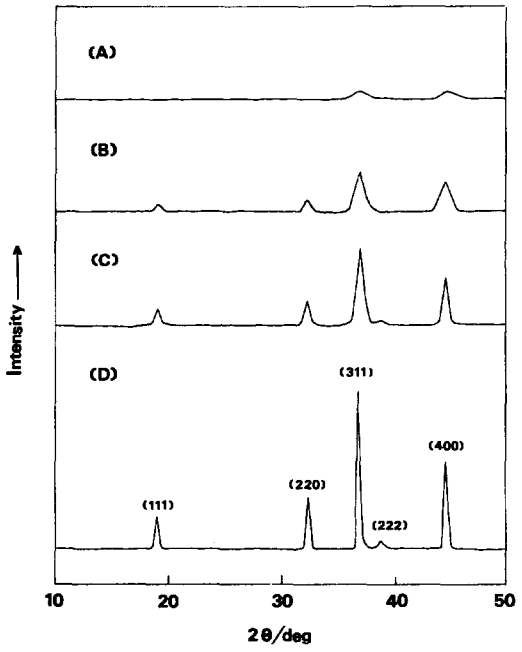

Fig. 4. X-ray diffraction patterns for specimens heated at (A) 700, (B) 1000, (C) 1100 and (D) 1250°C.

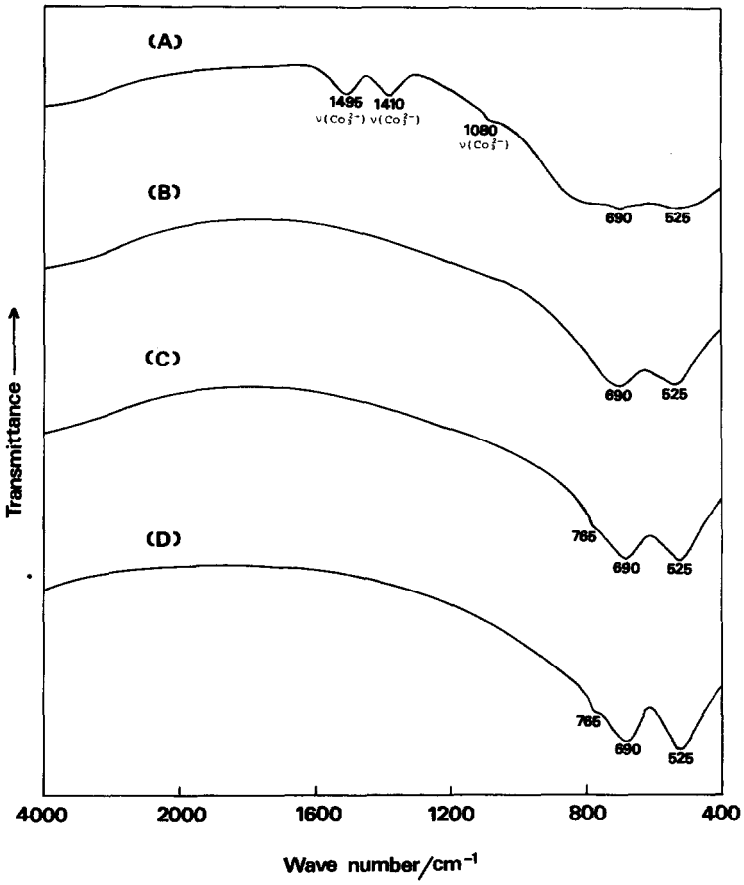

Fig. 5. Infrared spectral patterns for specimens heated at (A) 700, (B) 1000, (C) 1100 and (D) 1250°C.

The infrared spectral patterns of specimens heated to various temperatures are shown in Fig. 5. In accordance with the results of X-ray diffraction, IR spectrum data indicated that the characteristic bands of spinel at 690 and 525 cm^{-1} come to appear at 700°C;[15] however, the specimen contained carbon dioxide. The intensity of both bands increased with further increase in the heating temperature. The characteristic pattern of spinel with a shoulder at 765 cm^{-1} was observed above 1100°C.

From the above mentioned results, the crystallization of spinel was found to proceed slowly at $\approx$ 700–1250°C. The variation of crystallite size with increasing temperature was determined from X-ray line-broadening measurements.[16] The formula $D = K\lambda/\beta\cos\theta$ was used, where D is the mean crystallite dimension, K the crystalline-shape constant, λ the X-ray wavelength, β the corrected line breadth, and θ the Bragg angle. A spinel standard, which was prepared by solid state reaction between MgO and Al_2O_3 for 12 h at 1500°C, was used to obtain unbroadened line widths of the (311) and (400) reflections. A mean crystallite size was calculated by using an averaged broadening $\bar{\beta}_{12}$ defined as $\sqrt{\beta_1\beta_2}$ where $\beta_1 = B-b$ and $\beta_2^2 = B^2-b^2$; B is the width of a broadened line and b is the width of a standard line. Figure 6 shows the curve for crystallite growth of the spinel powders. A marked increase in crystallite size occurred between 1100 and 1200°C. Spinel powders consisting of aggregates of plate-like particles are shown in Fig. 7; the morphology is in agreement with that of particles reported.[3,7] The lattice constant of spinel obtained by heating for 3 h at 1250°C was estimated as a = 0.8084 nm, comparing with the value of a standard (a = 0.8083 nm)[2] prepared by solid state reaction between MgO and Al_2O_3.

Kinetics of crystallization of spinel

The fraction of crystallization of spinel was determined as a function of time at different temperatures. The starting powder had been heated previously up to 540°C at a rate of 10°C min^{-1}. A well-crystallized specimen was obtained by heating the starting powder for 3 h at 1250°C. As shown in

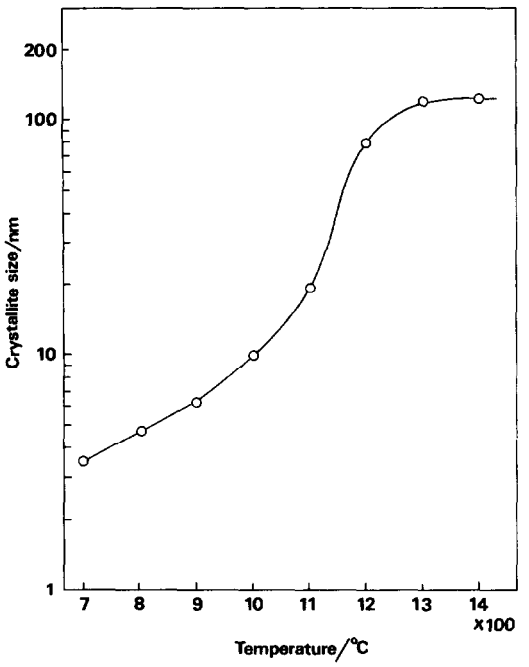

Fig. 6. Crystallite size of spinel with increasing temperature.

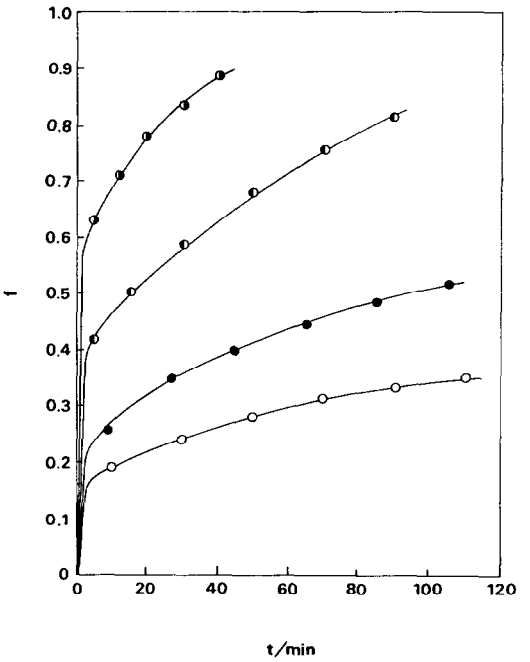

Fig. 8. Isotherms for crystallization of spinel at (○) 960, (●) 1020, (◐) 1100 and (◑) 1160°C.

Fig. 8, the initial stage of crystallization at each temperature proceeded rapidly in a short time; this may represent the process of nucleation. The data in the final stage can be described in terms of the contracting square equation (1)[17] (Fig. 9):

$$1-(1-f)^{1/2} = kt \qquad (1)$$

where f, t and k are the fractional crystallization, time, and rate constant, respectively. Equation (1), which has been employed to explain the kinetics of thermal decomposition of solids, is equivalent to one of the limiting forms of the Mampel equation.[18] In the present case, it indicates that crystallization is controlled by the rate of advance of interfacial

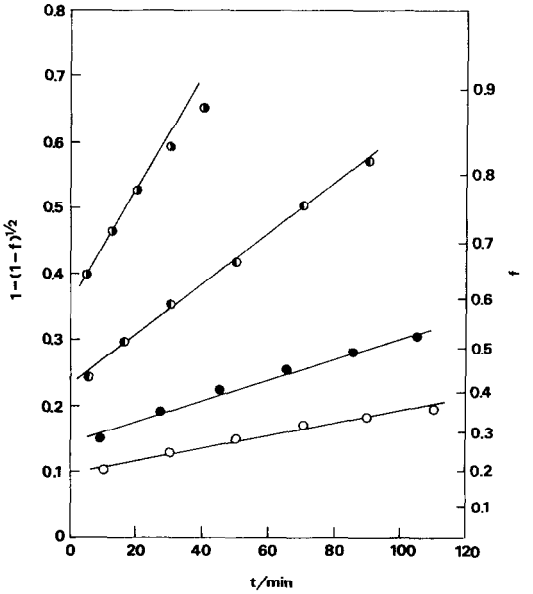

Fig. 9. Plots of $1-(1-f)^{1/2}$ vs time t of the data shown in Fig. 8. f is the fraction of spinel crystallized in time t. See Fig. 8 for key.

growth. An Arrhenius plot of the rate constants gave an activation energy of 164 kJ mol^{-1}.

THE DIMERIZATION OF DIPHENYL(CYCLOPENTADIENYL)PHOSPHINE LIGANDS BY DIELS–ALDER ADDITION

GREGORY G. GARVIN, TIMOTHY J. SLOAN and RICHARD J. PUDDEPHATT*

Department of Chemistry, University of Western Ontario, London, Canada N6A 5B7

(*Received* 5 *March* 1987; *accepted* 10 *April* 1987)

Abstract—Reaction of diphenyl(cyclopentadienyl)phosphine, **1**, with $[PdCl_2(PhCN)_2]$, $[PtCl_2(SMe_2)_2]$ or $[M(CO)_4(norbornadiene)]$, where M = Mo or W, gave the complexes $[PdCl_2\{(Ph_2P)_2C_{10}H_{10}\}]$, $[PtCl_2\{(Ph_2P)_2C_{10}H_{10}\}]$ or $[M(CO)_4\{(Ph_2P)_2C_{10}H_{10}\}]$ respectively, in which the ligand underwent dimerization by Diels–Alder addition. The reaction occurs in a very selective way and this is rationalized in terms of a template effect, in which two ligands **1** in mutually *cis* positions undergo the Diels–Alder reaction. In contrast, the complex $[Fe(CO)_4(Ph_2PC_5H_5)]$ is stable to Diels–Alder addition. The structures of the complexes were deduced by ^1H, ^{13}C and ^{31}P NMR spectroscopy. The major product contains a six-membered chelate ring while a minor product, formed in the palladium and platinum systems only, contains a five-membered chelate ring.

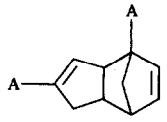
Cyclopentadienyldiphenylphosphine, **1**, has been shown to exist as a mixture of isomers **1a** (85%) and **1b** (15%), with none of the third possible isomer **1c**. Exchange between **1a** and **1b** was shown to be slow on the NMR time scale at room temperature.[1]

1a

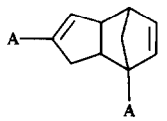
1b

1c

The phosphine **1** did not undergo dimerization by Diels–Alder addition of cyclopentadienyl groups but, on oxidation to the phosphine oxide or sulfide or the methylphosphonium ion, dimerization did occur to give the Diels–Alder adduct identified as **2a** or **2b** (A = Ph_2PO, Ph_2PS or Ph_2PMe^+).[1] Both **2a** and **2b** would be formed from the major isomeric form of the oxidized phosphine **1a**.



2a



2b

The ligand **1**, in its deprotonated form $[Ph_2PC_5H_4]^-$, has proved to be very useful for bridging between two different metal atoms. The preferred synthetic method has been to coordinate the C_5H_4 unit first to give an η^5-$C_5H_4PPh_2$ complex and then to coordinate a second metal through the phosphine group.[2] In ferrocene, the phosphino groups can be added later and $[Fe(\eta^5\text{-}C_5H_4PPh_2)_2]$ and its derivatives have been used to great effect as bidentate diphosphine ligands.[3] An alternative approach would be to coordinate the phosphine of **1** first, followed by deprotonation and coordination to a second metal via the cyclopentadienyl group. This article shows that this approach is likely to be limited to a single bridging ligand, since rapid Diels–Alder addition occurs when two of the ligands **1** are coordinated in mutually *cis* positions. The nature of this reaction is of considerable interest and gives two new bidentate diphosphine ligands $(Ph_2P)_2C_{10}H_{10}$.

RESULTS

Reaction of two equivalents of cyclopentadienyldiphenylphosphine, **1**, with $[PdCl_2(PhCN)_2]$ or $[PtCl_2(SMe_2)_2]$ gave the corresponding complexes $[PdCl_2\{(Ph_2P)_2C_{10}H_{10}\}]$, **3**, and $[PtCl_2\{(Ph_2P)_2C_{10}H_{10}\}]$, **4**, respectively. Simi-

* Author to whom correspondence should be addressed.

larly, reaction of $[M(CO)_4(NBD)]$, NBD = norbornadiene, with two equivalents of **1** gave $[Mo(CO)_4\{(Ph_2P)_2C_{10}H_{10}\}]$, **5**, or $[W(CO_4)\{(Ph_2P)_2C_{10}H_{10}\}]$, **6**, respectively. It was immediately apparent that the ligands had undergone Diels–Alder addition. Thus a complex $M(Ph_2PC_5H_5)_2$, with the ligand in either isomeric form **1a** or **1b**, should give a ^1H NMR spectrum with integration of olefinic : aliphatic protons = 3 : 2, whereas either **5** or **6** gave this integration = 3 : 7 as previously found for the Diels–Alder adduct **2**.[1] The situation was more complex for **3** and **4** as discussed below, but it was still clear that Diels–Alder addition had occurred. The structures were studied by ^1H, ^{13}C and ^{31}P NMR spectroscopy and the data are given in Tables 1–3.

If a template effect is assumed in the Diels–Alder coupling then, because of the constraints imposed by the dicyclopentadiene bridge, only five- or six-membered chelate rings are possible, and the coupling must be different from that observed in forming **2**.[1] The size of a diphosphine chelate ring can be determined from the ^{31}P chemical shifts and from the magnitudes of the coupling $^2J(PMP)$, using established empirical correlations.

The ^{31}P NMR spectra of the complexes **5** and **6** showed them to be single isomers, each giving an "AX" spectrum containing two doublet resonances. The chemical shifts were characteristic of a six-membered ring (Table 3). In addition, the magnitudes of $^2J(PP)$ of $\geqslant 20$ Hz are characteristic of a six-membered chelate ring (Table 3) but much too large for a five-membered ring.[4]

The nature of the dicyclopentadiene bridge was studied by ^{13}C and ^1H NMR spectroscopy (Tables 1 and 2), by comparison with the known spectra of endo- and exo-dicyclopentadiene, **7a** and **7b**.[5] The spectra are complex and assignments for the molybdenum complex **5** were confirmed by recording the 2D ^{13}C–^1H chemical shift correlated spectrum and the 2D ^1H–^1H correlated spectrum. The ^1H–^1H correlation identified H^2 and H^3 as a coupled pair and hence H^8 was identified as the remaining olefinic hydrogen. The corresponding carbon atoms were identified from the ^{13}C–^1H correlation and the signal for C^9 identified as the only remaining olefinic carbon. The aliphatic carbon and hydrogen signals could be assigned similarly and hence the overall connectivity determined. The NMR data thus determine the skeleton as **I** or **II**, formed by endo- or exo-addition respectively. The positions of the phosphorus atoms are confirmed by the magnitudes of the couplings $^1J(PC^1)$ and $^1J(PC^9)$. Consideration of molecular models indicates that both **I** and **II** are possible structures, with neither having significant ring strain. The spectra of the tungsten

and molybdenum complexes are almost identical and clearly indicate the same structure for both compounds; this chelate ligand is labelled LL in the tables and has structure **I** as shown below.

The situation was more complex for the palladium and platinum complexes **3** and **4**. The ^{31}P NMR spectra showed the presence of two isomers in each case, each giving an "AX" spectrum. The ^{31}P chemical shifts of each (with chelate ligands labelled LL′ and LL) showed that both five-membered (LL′) and six-membered (LL) chelate rings were formed,[4] with the ratio of LL:LL′ being approximately 70:30 in each case. For the palladium complex **3**, the major isomer $[PdCl_2(LL)]$ could be separated by fractional crystallization but the minor isomer was not isolated pure. However, multiple partial separations using thin layer chromatography followed by recrystallization gave a sample containing ~ 75% $[PdCl_2(LL')]$/25% $[PdCl_2(LL)]$ and the ^1H NMR spectrum of $[PdCl_2(LL')]$ (Table 1) was obtained from this impure sample. Separation was also difficult for the platinum complexes, but in one case a small amount of $[PtCl_2(LL')]$ was isolated in pure form. The spectrum of $[PtCl_2(LL)]$ was obtained on a sample containing ~ 15% $[PtCl_2(LL')]$, as determined by ^{31}P NMR. The coupling constants $^1J(PtP)$ for these compounds are also characteristic of chelate ring size[4] and confirm the conclusion based on the ^{31}P chemical shifts.

The ^1H and ^{13}C NMR spectra of the major palladium complex, containing the six-membered chelate ring $[PdCl_2(LL)]$ (Tables 1 and 2), were assigned using 2D NMR as described for the molybdenum

III *endo* **IV** *exo*

V *endo* **VI** *exo*

complex. The close similarity in spectra strongly suggest the same structure **I** or **II** for the diphosphine ligand LL in all cases, and the endo structure **I** was established by X-ray crystallography for the palladium complex (Fig. 1).[6]

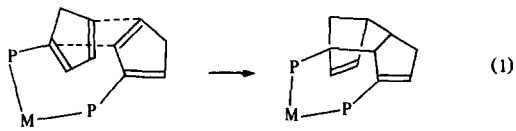
Satisfactory ^{13}C NMR spectra of the minor complexes $[PdCl_2(LL')]$ and $[PtCl_2(LL')]$ shown by ^{31}P NMR to contain a five-membered chelate ring, could not be obtained and the structure of the dicyclopentadiene bridge is deduced only from the ^1H NMR spectra. In these complexes four olefinic protons were identified, consistent with the structures **III**–**VI**. The exo structures **IV** and **VI** are more strained than the endo structures **III** and **V** and are therefore considered unlikely. In the ^1H NMR spectra of both $[PdCl_2(LL')]$ and $[PtCl_2(LL')]$, the signal for H^7 appears as a broad doublet of doublets with $^2J(H^7H^{7'}) = 18$–19 Hz and a second coupling of 8 Hz, as expected for isomer **III** due to the vicinal coupling $^3J(H^6H^7)$ (Table 1) but not for structure **V**. The signal due to H^6 is partially obscured but also appears as a doublet with J(HH) ~ 8 Hz. It is therefore tentatively concluded that the structure is **III** for the ligand LL′.

Reaction of $PPh_2(C_5H_5)$ with $[Fe(CO)_5]$ gave $[Fe(CO)_4\{PPh_2(C_5H_5)\}]$, which did not readily dimerize by intermolecular Diels–Alder addition. The complex existed as a single isomer (^{31}P NMR evidence) with the ligand present in form **1a** or **1b** (^1H NMR evidence) and the cyclopentadienyl group could be deprotonated reversibly.

DISCUSSION

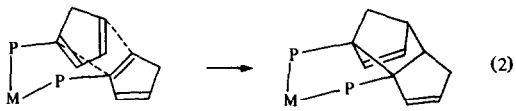
There are a number of interesting features of the above reactions. The increased rate of Diels–Alder addition on complexation of the ligand **1** could be due simply to an electronic effect, just as oxidation of the phosphorus atom of **1** to the oxide, sulfide or methylphosphonium derivative leads to increased reactivity to dimerization.[1] However, the complex $[Fe(CO)_4\{PPh_2(C_5H_5)\}]$ does not readily dimerize, whereas all of the complexes containing two phosphine ligands underwent rapid dimerization of the cyclopentadienyl substituents. This indicates clearly that a template effect is primarily responsible for the increased reaction rate of the Diels–Alder addition. Such an effect is expected since the entropy term is usually a major component of the activation energy for Diels–Alder additions, which have a highly ordered transition state.[7]

The selectivity of the observed Diels–Alder reactions is impressive. The free phosphine ligand exists as a mixture of 85% **1a** and 15% **1b**, and the probabilities of pairs of phosphines **1a**·**1a**, **1a**·**1b** and **1b**·**1b** are therefore 72%, 26% and 2% respectively.[1] The complexes formed contained the coupled ligands, LL, in structure **I** which is formed by coupling of **1a**·**1b** pairs as either the major or only product (eqn 1). The diene is **1a** and the dienophile is **1b**. The minor products with ligands LL′ are thought to have structure **III** which is also formed by coupling of **1a**·**1b** pairs (eqn 2). These observations can only be understood if hydrogen migration, which is necessary to interconvert **1a** ⇌ **1b** (in either free or complexed form), is faster than the Diels–Alder addition reaction. Otherwise the major products should be formed by coupling of **1a**·**1a** pairs.



(1)

I



(2)

III

Why are the isomeric forms **I** and **III** formed? We note that both are formed by *endo*-addition, which is the favored mode of Diels–Alder addition of cyclopentadiene itself.[7] There is still some debate in the organic literature about the reasons for *endo* rather than *exo* addition.[7] In the present case, it is clear that the template effect is primarily responsible for the selectivity of the addition. Molecular models clearly show that the diene in the Diels–Alder addition must be in form **1a**, as is observed experimentally. In form **1b** the diphenylphosphino group would be at C^2 in the product and chelation would not be possible. Now, the six-membered chelate ring can only be formed if the dienophile is in form **1b** (eqn 1) rather than **1a**. Form **1c** would be allowed, but this appears to be of too high energy to be formed. The formation of **I** thus follows naturally from the template effect.

The five-membered ring could be formed with the dienophile in either form **1a** or **1b**, but it seems that the product is formed selectively from the form **1b**. Since the ligand structure **III** is tentative in this case, no further comment is justified. The preference for formation of the six-membered ring **I**, rather than the five-membered ring **III**, is probably due to a slightly less strained transition state. In the absence of such effects, the five-membered ring **III** would be expected to be thermodynamically more stable than **I**.

EXPERIMENTAL

^1H NMR spectra were recorded using Varian XL100 or XL200 spectrometers. Chemical shifts are given with respect to Me_4Si (^1H, ^{13}C) or 85% H_3PO_4 (^{31}P).

The ligand $PPh_2(C_5H_5)$ was prepared by the literature method.[1]

$[PtCl_2(Ph_2PC_{10}H_{10}PPh_2]$, 4

A solution of $[PtCl_2(SMe_2)_2]$ (0.83 g) in CH_2Cl_2 (25 cm^3) was added dropwise to a solution of $PPh_2(C_5H_5)$ (1.08 g) in tetrahydrofuran (40 cm^3). The mixture was allowed to stir for 2 h, the solvents were evaporated under vacuum and the residue was crystallized from CH_2Cl_2/MeOH to give colorless crystals of the product (1.26 g) m.p. 220°C (decomp.). Found: C, 53.1; H, 4.0; Cl, 9.1. Calc. for $C_{34}H_{30}Cl_2P_2Pt$: C, 53.3; H, 3.9; Cl, 9.3%. The pure isomer **4–III** was obtained by repeated recrystallization.

$[PdCl_2(Ph_2PC_{10}H_{10}PPh_2)]$, 3

This was prepared similarly from $[PdCl_2(PhCN)_2]$ (1.00 g) and $PPh_2(C_5H_5)$ (1.30 g) and purified by crystallization from $CHCl_3$/MeOH. M.p. 210°C (decomp.). Found: C, 59.8; H, 4.3; Cl, 10.7. Calc. for $C_{34}H_{30}Cl_2P_2Pd$: C, 60.3; H, 4.4; Cl, 10.5%.

The pure isomer **3-I** was obtained by repeated recrystallization from CH_2Cl_2/MeOH. Found: C, 55.2; H, 4.0. Calc. for $C_{34}H_{30}Cl_2P_2Pd \cdot CH_2Cl_2$: C, 55.4; H, 4.2%.

$[Mo(CO)_4(Ph_2PC_{10}H_{10}PPh_2)]$, 5

A solution of $[Mo(CO)_4(NBD)]$, NBD = norbornadiene (0.72 g) in CH_2Cl_2 (10 cm^3) was added to a solution of $PPh_2(C_5H_5)$ (1.68 g) in $CHCl_2$ (10 cm^3). The mixture was stirred for 2 h, the solvent was evaporated and the product was purified by recrystallization from $CHCl_3$/pentane at 0°C. Yield 0.96 g. Found: C, 64.2; H, 4.2; P, 8.4. Calc. for $C_{38}H_{30}O_4P_2Mo$: C, 64.4; H, 4.2; P, 8.8%.

$[W(CO)_4(Ph_2PC_{10}H_{10}PPh_2)]$, 6

A solution of $[W(CO)_4(NBD)]$ (0.20 g) and $PPh_2(C_5H_5)$ (0.33 g) in CH_2Cl_2(10 cm^3) was stirred at room temperature for 20 h. The solvent was evaporated and the product was purified by recrystallization from $CHCl_3$/pentane (0.35 g). Found: C, 57.3; H, 3.6; P, 7.2. Calc. for $C_{38}H_{30}O_4P_2W$: C, 57.3; H, 3.8; P, 7.8%.

$[Fe(CO)_4(Ph_2PC_5H_5)]$

$Fe(CO)_5$ (3.92 g) was added to a refluxing solution of $PPh_2(C_5H_5)$ (2.50 g) in toluene (50 cm^3) containing $CoBr_2 \cdot 3H_2O$ (0.08 g) as catalyst. After 1 h the volume was reduced and the product was purified by chromatography on 5 g/20 g/20 g $CoBr_2 \cdot 6H_2O$/alumina/silica column with benzene eluent. Recrystallization from CH_2Cl_2/hexane gave the product as a red solid. Yield 91%. ^1H NMR: δ = 6.90, 6.75, 6.60 (*m*, 3H, =CH); 3.20 (m, CH_2). ^{31}P NMR: δ = 55.8 (s, ^{31}P). IR: 2040, 1980, 1940

[ν(CO)]. Found: C, 60.3; H, 3.7. Calc. for $C_{21}H_{15}FeO_4P$: C, 60.3; H, 3.6%.

Reaction of the above complex with TlOEt in toluene gave a precipitate of [$Fe(CO)_4(Ph_2PC_5H_4Tl)$] as a brown powder. The complex was too insoluble for characterization by NMR, but addition of CF_3CO_2H to a suspension of the complex in C_6D_6 gave [$Fe(CO)_4(Ph_2PC_5H_5)$], characterized by its NMR spectrum.

COMMUNICATION

A PARTIALLY CLOSED-MODE PLATINUM DIMER BASED ON A BINUCLEATING HEXAPHOSPHINE LIGAND SYSTEM: CRYSTAL STRUCTURE OF $[Pt_2Cl_2(eHTP)^{2+}][PF_6^-]_2$ (eHTP = $(Et_2PCH_2CH_2)_2PCH_2P(CH_2CH_2PEt_2)_2$

SUZANNE E. SAUM and GEORGE G. STANLEY*

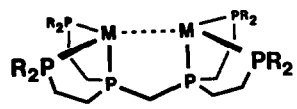
Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803-1804, U.S.A.

(*Received* 9 *December* 1986; *accepted after revision* 29 *April* 1987)

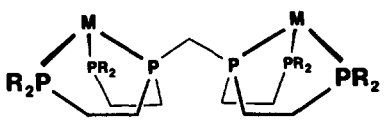
Abstract—The reaction of two equivalents of K_2PtCl_4 with the hexaphosphine ligand system $(Et_2PCH_2CH_2)_2PCH_2P(CH_2CH_2PEt_2)_2$, eHTP, quantitatively yields the diamagnetic dimer species, $Pt_2Cl_2(eHTP)^{2+}$, **3**. The single-crystal X-ray structure of the PF_6^- salt of **3** reveals a distorted square-planar environment about the metal atoms with the eHTP ligand adopting a symmetrical *bis*chelating/bridging, partially closed-mode coordination geometry with a Pt—Pt distance of 4.6707(9) Å.

Our studies of the coordination chemistry of the powerful binucleating hexatertiaryphosphine ligand, $(Et_2PCH_2CH_2)_2PCH_2P(CH_2CH_2PEt_2)_2$, eHTP, have revealed that the ligand's ability to both bridge and *bis*-chelate two metal centers has so far produced only open-mode complexes of the general type **1b**[1] or **1c**,[2] while the closed-mode conformer **1a** has not yet been crystallographically characterized. Van der Waal energy calculations on the nickel complex $Ni_2Cl_2(eHTP)^{2+}$, **2**, have revealed that the closed-mode configuration should be inaccessible for an eHTP arrangement in which two terminal phosphine groups are *trans* to one another, i.e. for square-planar coordination geometries.[2] In light of these results, we would like to report the synthesis and structural characterization of the platinum(II) complex, $[Pt_2Cl_2(eHTP)^{2+}][PF_6^-]_2$, **3**, in which the eHTP ligand has adopted a square-planar coordination and a partially closed-mode conformation.

The reaction of two equivalents of K_2PtCl_4 with eHTP[1] in ethanol under inert atmosphere conditions, followed by addition of $NaPF_6$, produces the air-stable, colorless, diamagnetic binuclear complex $[Pt_2Cl_2(eHTP)^{2+}][PF_6^-]_2$, **3**, in very high yields. A single-crystal X-ray structure (Fig. 1, selected bond distances and angles are listed in Table 1) on **3** shows that the eHTP ligand adopts a tridentate, distorted square-planar geometry about each



1a



1b

* Author to whom correspondence should be addressed.

of the two platinum centers.† The distortion from square-planar coordination about each platinum atom is considerable, as indicated by the *trans* P—Pt—P angle of 163.6(2)°. This distortion is undoubtably related to the strain induced by the placement of two fused 5-member chelate rings in a transoidal geometry. The presence of ethylene bridges in eHTP favors *confacial* rather than *meridional* type coordination for each tridentate half of the ligand.[3] Although other mononuclear Pt(II) halide complexes with two-carbon bridged tridentate phosphine ligands have been reported, this represents the first structurally characterized complex.[4–7]

What is immediately evident from the structure is that the eHTP ligand adopts a rather different rotomeric conformation about the central P—CH_2—P linkage from anything we have previously seen. The related nickel complex, $[Ni_2Cl_2(eHTP)^{2+}][BF_4^-]_2$, for example, has a structure that corresponds to **1c**, while the chloride salt has a structure midway between **1b** and **1c**.[2] The platinum structure, however, is approaching that of a closed-mode configuration, **1a**, with a Pt—Pt distance of 4.6707(9) Å. The rotational orientation of the eHTP ligand can be clearly seen in Fig. 1 which also shows an orthogonal view of the molecule looking down the P1···P4 vector. The Pt1—P1···P4—Pt2 torsional (dihedral) angle is 62°, where 0°, represents the closed-mode form **1a**.

A remarkable feature of the structure of **3** is that the central P—CH_2—P angle has a value of

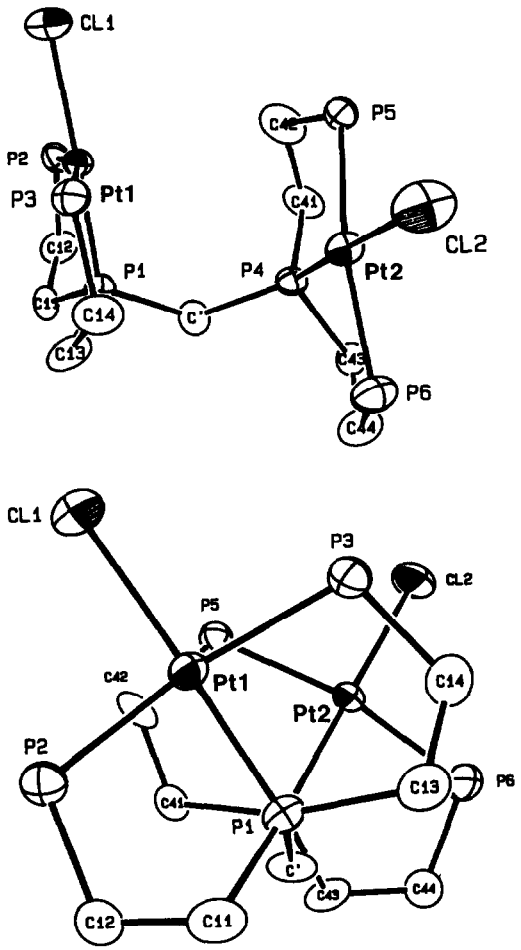

Fig. 1. ORTEP plots of $Pt_2Cl_2(eHTP)^{2+}$ showing views parallel and perpendicular to the central P1···P4 vector. Ethyl groups on the external phosphorus atoms have been omitted for clarity. Probability ellipsoids are shown at a 33% level.

129.7(9)°. This can be contrasted to typical P—CH_2—P angles seen in other *bis*(phosphino)methane bridged structures which are in the range of 109–118°.[8] This angle is also 8° greater than that seen in the analogous isoelectronic nickel complex, **2**,[2] and even surpasses the P—CH_2—P angle of 127.7(3)° seen in $Co_2(CO)_4(eHTP)^{2+}$.[1] Indeed, this is one of the largest angles observed about a methylene bridge, on par with that observed for *bis*(9-triptycyl)methane which has a C—CH_2—C angle of 129.3°.[9] The M—M bond distances in eHTP complexes are, of course, related to the rotational orientation of the ligand with the cobalt complex having the maximum M—M separation of 6.697(1) Å, while the nickel systems show M—M bond distances of 5.9333(8) Å and 5.7505(6) Å. **3**, with its partially closed-mode structure, has the shortest M—M distance observed in an eHTP

†X-ray analysis: Compound **3** crystallizes in the orthorhombic space group $P2_12_12_1$ with $a = 13.418(3)$ Å; $b = 17.795(6)$ Å; $c = 18.906(4)$ Å; $V = 4514(4)$ Å^3; $Z = 4$. 5930 Friedel pair reflections were collected at 25°C on a Nicolet P3 diffractometer using Mo Kα radiation and the ω scan data collection technique with a maximum 2θ angle of 45°. The structure was solved using the MULTAN direct methods programs and refined using 2529 reflections with $F_o^2 > 3\sigma(F_o^2)$ to give discrepancy indices of $R = 0.035$ and $R_w = 0.047$ for 352 variables representing 37 anisotropic non-hydrogen atoms (the flourine atoms on the PF_6^- groups were refined isotropically). An empirical absorption correction using Friedel pair reflections and program DIFABS was performed.

Supplementary Materials Available. Tables of fractional coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre. Tables of data collection and structure solving details, full listings of bond distances and angles, and observed and calculated structure factor tables have been deposited with the Editor at Indiana University and are also available from the author.

complex so far with a Pt—Pt distance of 4.6707(9) Å.

An important question one must ask is why **3** adopts such a large P—CH_2—P angle allowing access to the partially closed-mode eHTP orientation. One possible answer is that crystal packing forces are responsible, just as they cause rotational differences in the nickel structures.[2] Although it is rather difficult to predict the effects or magnitudes of crystal packing forces, it would appear unlikely that they represent the sole factor in determining the extremely large P—CH_2—P angle and unusual (for a square-planar complex) eHTP conformation observed. It is very difficult at this point to determine whether it is the flexibility of the P—CH_2—P bond angle that allows access to the partially closed-mode conformation or whether there is some driving force favoring this conformation that is forcing the methylene bridge angle open to its remarkable value. As with most physical explanations it is most probably a subtle mixture of several features. We feel that some of the important factors that work together to influence the molecular conformation are: considerable low-energy flexibility of the P—CH_2—P linkage; increased *intra*molecular steric contacts due to chelate ring puckering differences caused by the larger terminal Pt—P bond distances (approx. 0.1 Å greater than the nickel or cobalt systems); and the possible presence of a *weak* Pt—Pt bonding interaction which could help overcome the steric and electrostatic factors favoring the open-mode conformations. We plan to further explore these points through van der Waal energy calculations and solution NMR experiments to study the conformational preferences of **3**.

(*Received* 10 *September* 1986; *accepted* 6 *March* 1987)

Abstract—$VOCl_3$ formed six-coordinated complexes with *N*-aryl-*N'*-2(4,5,6-monosubstituted pyridyl)thioureas of the general formula $[VOCl_3(RNHC{=}SNHR')]$, where R = pyridyl, 5-nitropyridyl, 4-methylpyridyl, 6-methylpyridyl groups and R' = $-C_6H_5$, *o*-$C_6H_5(CH_3)$ and *p*-$C_6H_4(CH_3)$. The complexes have been characterized by means of elemental analysis, molar conductance, magnetic susceptibility, IR, UV–VIS, and ^1H NMR spectral data. The thermally stimulated depolarization effect was studied in samples polarized under different conditions. The results indicate two distinct transitions in the temperature range 92–100°C and 120–125°C for the ligands, whereas the $VOCl_3$-complexes show no breaks. The polarization–depolarization phenomena were correlated with the physicochemical changes occurring in the matrix. Depolarization kinetic data such as activation energy (E_a) and relaxation time (τ) of the electrets are reported.

Vanadium halides and oxyhalides are reported to form a number of complexes with mono, bi and polydentate ligands, but very little is known about the vanadyl(V)chloride complexes. Metal complexes of the substituted thioureas having heterocyclic group as one of the substituents have been studied by many workers.[1–3] Electrical properties of several metal Cu(II), Co(II), Ni(II) and Pt(II)-phthalocynin complexes have been reported.[4–5] Earlier communications[6–14] have described the metal chelates of C=S, C=O and C=NH donor ligands. However, less work is available on the synthesis and physiochemical properties of $VOCl_3$ complexes with *N*-aryl-*N'*-2(4,5,6-monosubstituted pyridyl)thioureas. A literature survey reveals that a number of phase transitions have been reported in ferroelectric materials like substituted thioureas.[15–19] Thus it was of interest to see what the electrical behaviour of such a ferroelectric substance will be, when incorporated in a complex matrix. The present study on $VOCl_3$-complexes with the title ligands was undertaken with the view to study the electrical changes.

EXPERIMENTAL

All the solvents and reagents used were guaranteed reagents. 2-aminopyridine, 2-amino-4-methyl, 2-amino-6-methyl and 2-amino-5-nitro pyridines were of Aldrich chemicals. The mustard oils like phenyl, orthotolyl, paratolyl-isothiocyanates were prepared by reported methods.[20] Vanadyl(V) chloride was prepared by refluxing equimolar quantities of V_2O_5 and $SOCl_2$ for 6–8 h and the product was distilled and the $VOCl_3$ fraction obtained at 125–127°C. The ligand *N*-aryl-*N'*-2(4,5,6-monosubstituted pyridyl)thioureas were prepared by the method reported earlier.[13]

GENERAL METHOD OF THE PREPARATION OF $VOCl_3$-COMPLEXES

All the operations in the preparation of metal complexes were carried out in a dry box. To a requisite amount of ligand (0.02 M) in $CHCl_3/CCl_4$ mixture was added 0.03 M CCl_4 solution of $VOCl_3$ drop by drop with constant stirring and was ice-cooled maintaining in each case a slight excess of the ligand. The mixture was shaken and allowed to stand for 8 h to attain equilibrium. The intensely coloured complexes were separated out, filtered washed with CCl_4 and $CHCl_3$. The complexes were analysed for V, S and Cl after fusion with alkali.

Magnetic measurements were carried out on a Gouy balance using a field strength of 5×10^3 Gauss

and mercury tetrathiocyanato cobaltate (II) as standard. Molar conductances were determined in *N,N*-dimethylformamide with conductivity meter type LBR of Wissenschaftlich technisch Werkenstatten, Germany using a dip-type cell. The IR spectra of the ligands and their metal-complexes were determined using KBr pellets on an infrared spectrophotometer of the type Beckman-20. Absorption spectra of $VOCl_3$ complexes were measured by standard methods using Perki–Elmer UV–VIS spectrophotometer model 139. Transition energy (E_T) was calculated by the relation

$$E_T = \frac{2.859 \times 10^5}{\lambda_{max}(\text{in Å})}$$

and the oscillatory strength "f" was calculated from the equation

$$f = 4.32 \times 10^{-9} \int E_{dv}.$$

Utilizing

$$E_{max}\Delta\bar{v} = \int E_{dv}$$

where $\Delta\bar{v}$ is the wave number of the half band width.

All the electrical measurements were made on pellets pressed at a load of 9 tons at room temperature. The pellets were sandwiched between two aluminium electrodes. The capacitance was measured with a standard LCR bridge (Systronics 921) at 1 and 10 kHz as a function of temperature. The area A of the pellet was measured geometrically and graphically and the thickness d of the pellet was measured by a micrometer screw reading up to 0.001 cm. The dielectric constant ε was calculated from the equation

$$\varepsilon = C_0 d/(\varepsilon_0 A)$$

where $\varepsilon_0 = 8.85 \times 10^{-14}$ F cm^{-1}.

The sample was polarized at conditions $T_p = 90°C$, $E_p = 2.50 \times 10^3$ V cm^{-1}, $t_p = 2$ h. The heating rate was maintained at 6°C min^{-1}.

TSD spectra was recorded in the temperature range of 20 to 200°C. Activation energy, E_a was calculated by the initial rise method of Garlick and Gibson,[21] from the slope of the straight line curve of log current (i) vs $1/T$ for the first lower half of the TSD peak.

$$\log i(T) = \text{constant} - \frac{E_a}{T}$$

where E_a = activation energy, T = absolute temperature and K = Boltzmann's constant.

Relaxation time of polarization created by ionic motion or by dipoles orientation is given by the Arrhenius equation

$$\tau(T) = \tau_o \exp(-E_a/KT)$$

where $\tau(T)$ is the temperature dependent relaxation time of the dipoles in a dielectric, τ_o is the time constant and can be written as

$$\tau_o = \frac{kT_{max}}{\beta E_a \exp(E_a/k\bar{T}_{max})}$$

where β = heating rate and T_{max} = peak temperature.

RESULTS AND DISCUSSIONS

All the $VOCl_3$ complexes are dark yellow–green coloured and soluble in chloroform, DMF, THF and nitrobenzene. All of them decompose above 225°C. The analytical results (Table 1) correspond to the general empirical formula $VOCl_3 \cdot L$ where L is a bidentate ligand molecule. Since there is no loss of chlorine (wt%) in the complexes, reduction of V(V) to V(IV) may not be taking place. The electrolytic conductance measurements of these complexes (29–60 Ohm^{-1} cm^2 mole^{-1} in freshly distilled DMF solution indicate non-electrolytic nature of these complexes. The molar conductance of uni-univalent electrolytes are 80–90 mhos.[22] It seems that partial replacement of chloride by solvent may be taken place as follows

$$[VOCl_3(L)] + S \rightleftharpoons [VOCl_2(L)S]^+ + Cl^-$$

where S is solvent. The magnetic susceptibility of the complexes were found in the range -0.043 to -0.71×10^{-6} G. The negative values of susceptibility indicate the diamagnetic nature of $VOCl_3$ complexes.

The electronic spectral bands of the complexes are listed in Table 2. All these bands are due to M ← S charge-transfer absorption. Moor and Larsen[23] have earlier observed that S → M charge-transfer in xanthate complexes appears at 6000 cm^{-1} below that of the corresponding dithiocarbamate complexes, and have suggested that xanthates are much greater reducing agents than dithiocarbamates. From the spectral data in our case, it is observed that the present ligands are not reducing agents.

The IR spectra of substituted thioureas and their $VOCl_3$ complexes are quite complicated, and therefore the effect of substitution could not be studied with a degree of certainty. The bands appearing at 3000–3400 cm^{-1} have been assigned to ν_s(NH) and ν_{as}(NH), the latter being the higher frequency band. A medium broad band appearing at 3000–

3100 cm^{-1} has been assigned to 2-aminopyridine vibrations. Bands appearing at 1600 and 1640 cm^{-1} are assignable to ν(C=C+C=N) modes of aryl groups. In the case of metal complexes there is a little change in this band. The bands appearing at 1132–1010 cm^{-1} due to ν(NCS+C=S) modes in the case of ligands are either reduced in intensity or shifted to the higher frequency side in most of the complexes. The ν(C=S) mode occurring at 750–775 cm^{-1} in ligands is also shifted to the lower frequency side (20–25 cm^{-1}) in $VOCl_3$ complexes. The behaviour of the bands assigned to ν(C=C+V=N) is of considerable importance in deciding whether or not the heterocyclic nitrogen is

involved in the coordination with the metal ion. This band has been reported to be shifted to higher frequency in the case of coordinated pyridyl nitrogen.[1] In the present vanadyl(V)chloride complexes the band is increased by 10–30 cm^{-1}, which indicates that the ring nitrogen is also involved in the bond formation.

The frequency of the band assignable to V=O stretching mode in $VOCl_3$ is in agreement with the reported values.[23] (V=O stretch at 1035 cm^{-1} and νV–Cl at 408 cm^{-1}), which in the present case have been shifted to lower frequencies 950 cm^{-1} (V=O) and 315–400 cm^{-1} (V–Cl).

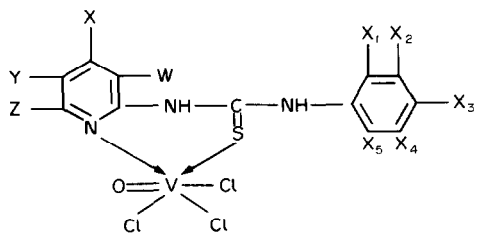
The ^{1}H NMR spectra of PyPTU, Py·*o*TTU, Py·*p*TTU and 4MePyPTU indicate four distinct resonances: (i) a sharp singlet (δ 7.4–7.8 ppm) due to $-C_6H_5$ ring protons, (ii) a broad multiplet (δ 3.2–3.4 ppm) due to *o,p*-$CH_3C_5H_4$ ring protons, (iii) a sharp signal (δ 2.3–2.4 ppm) due to the protons of CH_3 groups and (iv) a doublet at (δ 4.35–4.42 ppm) due to NH protons of S=C—NH group. Finally a singlet at δ 8.4–8.6 ppm is possibly due to protons of the pyridyl ring. On account of poor solubility, the NMR spectra of $VOCl_3$ complexes with the above ligands were taken in deuterated DMSO. The spectra of V(V) complexes show the signal due to —CNH group without any shift. The positions of the C_6H_5 and *o,p*-$CH_3C_5H_4$ ring protons remain unperturbed ruling out the possibility of coordination of —NH group of NHC_6H_5. The lone pair of electrons on the nitrogen of the pyridyl ring causes a paramagnetic shielding of the 2- and 6-protons.[24] Formation of the dative bonds using this electron pair greatly reduces the paramagnetic shielding giving a significant upfield shift for the adjacent protons. In other words we can say that there is a decrease in the electron density of the pyridine ring upon complex formation. This decrease causes a reduction of the paramagnetic anisotropic effect. This will result in the almost uniform upfield shift for all the ring protons. In the $VO(V)Cl_3$ complexes of PyPTU, Py·*o*TTU, Py·*p*TTU and 4MePyPTU, an upfield shift of heterocyclic ring protons by 3.0 to 4.8 ppm is observed confirming the coordination through pyridyl nitrogen.

All these observations show that ligands are coordinated to the vanadium metal though thio-keto sulphur and pyridyl ring nitrogen atoms.

$VOCl_3$ has been reported to have a distorted tetrahedral structure[25] which possibly has the d^2sp hybridization. It seems possible that the distorted tetrahedral symmetry of $VOCl_3$ has been changed to six coordinated irregular octahedral configuration with d^2sp^3 hybridization. On the basis of the information, the complexes of $VOCl_3$ with the title ligands may be represented by Structure I.

ELECTRICAL PROPERTIES

Eley[26,27] first observed the semiconducting properties of organic ligands and proposed that conductivity arose through thermal or optical excitation of electrons from the highest filled to the lowest empty orbital. The mechanism of conductivity is associated with the mobile electrons of the ligand rings. Earlier Day *et al.*[28] reported the resistivity of Fe-*p*H-thalocyanin as 4×10^9 Ω cm by a single crystal method. The present data on $VOCl_3$



Structure I.

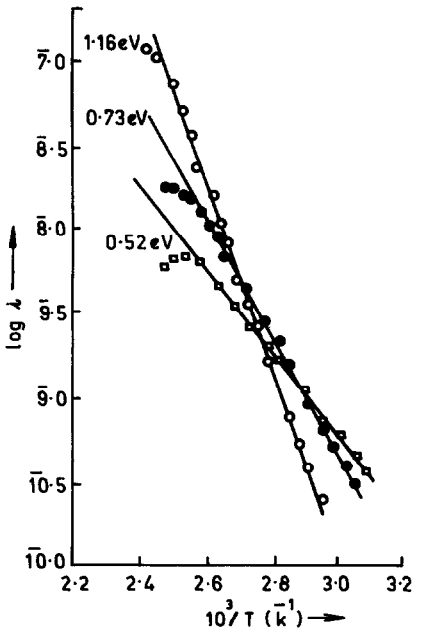

Fig. 1. Current (i) vs $1/T$ for determination of activation energy (E_a) at T_{max}: ○, 138°C; ●, 130°C, □. 122°C; for o-TP$_y$TU.

complexes is plotted as log × current as a function of temperature in Fig. 1. At room temperature ρ is of the order of 4.7×10^{11} Ω cm and decreases with increasing temperature (3.1×10^{11} Ω cm at 98°C). The log i vs $1/T$ plot is linear showing breaks at 92–100°C and 120–125°C for ligands. Activation energies, E_a have been calculated from the semi-logarithmic plots of current (i) in the initial rise of the depolarization peak vs $1/T$. The corresponding values of relaxation times were also calculated using Arrhenius equation from E_a values obtained in the initial rise method and are listed in Table 3.

As T_p increases, the t.s.d. peak shifts to higher temperatures. It is well known that, in homogeneous systems, polarization and depolarization phenomena are associated with dipoles and space charge effect, while the Maxwell–Wagner effect (interfacial polarization) becomes operative in a heterogeneous system. For example, in the presence of an air gap, heterogeneity is created giving rise to t.s.d. peaks. In the present study t.s.d. peaks were obtained from samples coated with aluminium as well as sandwiching them between aluminium electrodes. In both the cases similar types of t.s.d. peaks are obtained indicating the presence of no air gap in the samples, avoiding the possibility of interfacial polarization due to an air gap. Since the charging voltages are low (10^3 V cm^{-1}), the homocharges by injection may not be present. Hence only polarization by dipole orientation and space charge effect are considered. Thus though the data taken together cannot conclusively establish the mechanism of depolarization, the trends are indicative of space-charge polarization. Beside physical effects, Stupp and Carr have shown that chemical changes can be associated with the t.s.d. peaks. In the present case heating will lead to further condensations, which would effect the t.s.d. peaks. Both the ligands and their $VOCl_3$ complexes show high dielectric constants. The dielectric constant of the ligands and complex are plotted as a function of temperature (Fig. 2). A broad shoulder is observed in the region 90–150°C in the PyPTU. On heating the dielectric constant of the complexes increases rapidly above 150°C, thus exhibiting the pyroelectric effect.

Thus, the electrical measurements along with the variations in IR spectral data, indicate the presence of two distinct transition temperature ranges 92–100°C and 120–125°C. It is proposed that up to 92–100°C trapped water as well is present in the matrix. This is reflected in a decrease in resistivity.[30] On continuous heating chain mobility is increased. Thus it is proposed that the t.s.d. peaks at 92–100°C

^{51}V AND ^{17}O NMR STUDIES OF THE MIXED METAL POLYANIONS IN AQUEOUS V–Mo SOLUTIONS

R. I. MAKSIMOVSKAYA* and N. N. CHUMACHENKO

Institute of Catalysis, Novosibirsk 630090, U.S.S.R.

(*Received* 1 *December* 1986; *accepted* 25 *March* 1987)

Abstract—$NaVO_3$–Na_2MoO_4 solutions acidified with HCl were studied at the atomic V/Mo ratios equal to 3 : 1, 1 : 1, 1 : 3, 1 : 6 and vanadium concentration [V] = 0.1, 0.04, 0.004 and 0.0004 M in the range pH 7–2. Their ^{51}V NMR spectra (measured at $H_o = 7$ T) were compared with those of V–W solutions containing mixed metal complexes of known composition. The $VMo_5O_{19}^{3-}$ (^{51}V NMR chemical shift relative to $VOCl_3$, δ, −502 ppm), $V_2Mo_4O_{19}^{4-}$ (δ −494), $HV_2Mo_4O_{19}^{3-}$ (δ −507), $V_9MoO_{28}^{5-}$ (δ −422, −492, −501, −512, −521.5) and $HV_9MoO_{28}^{4-}$ polyanions (p.a.) have been found to be dominant mixed species in Na–V–Mo solutions. Along with them the $V_xMo_{13-x}O_{40}^{-x-3}$ p.a. ($x \sim 2$–3) of the Keggin type (δ −496, −498, −516, −522) are supposed to be formed at pH < 4 in concentrated solutions ([V] > 0.01 M). The $V_2Mo_6O_{26}^{6-}$ p.a., isolated at pH ~ 5 as the sodium salt (solid state δ −482), seem to be present in concentrated Na–V–Mo solutions only as minor species. On dissolving the salt the $V_2Mo_6O_{26}^{6-}$ p.a. mainly disproportionates into the complexes mentioned. From solutions containing mainly the $V_9MoO_{28}^{5-}$ p.a. the sodium salt of $V_{10}O_{28}^{6-}$ is crystallized. The $V_9WO_{28}^{5-}$ p.a. are detected in V–W solutions at V/W > 1. ^{17}O and ^{95}Mo NMR spectra of some mixed complexes are described. The distribution diagrams for V–Mo and V-W solutions at [V] = 0.004 M and V/Mo(W) = 1 : 3, derived from their ^{51}V NMR spectra, are given.

In acid aqueous V–Mo solutions several mixed metal complexes are formed, the exact number and composition of which have not been established yet.[1] From potentiometric and spectrophotometric studies of dilute solutions[2–4] complexes with the atomic V/Mo ratios equal to 1 : 1, 1 : 2, 1 : 5 and 9 : 1 were supposed to form, but they were not isolated. Only one mixed complex of the composition $Na_6[V_2Mo_6O_{26}]\cdot 16H_2O$ was isolated from weak acid Na–V–Mo solutions at different V/Mo ratios.[5] Its discrete polyanions have the same structure as α-$Mo_8O_{26}^{4-}$.[6] The $VMo_5O_{19}^{3-}$, is isostructural with the hexaniobate, and was isolated only from nonaqueous solutions as the tetrabutylammonium(TBA) salt.[7]

From weak acid K–V–Mo solutions the $K_7[Mo_8V_5O_{40}]\cdot 8H_2O$ and $K_8[Mo_4V_8O_{36}]\cdot 12H_2O$ crystals, containing discrete polyanions, were also obtained and their structures were determined.[6]

The preparation of a red-orange compound with V/Mo = 1 : 6 at high acidity (pH < 3) was described in [8]. That complex was extracted from solutions with ether. From chemical analysis the composition of the complex was supposed to be $H_6V_2Mo_{12}O_{44}$ but it was not supported by any structural data.

We hoped to obtain some new data on the composition of the V–Mo complexes in solutions by means of ^{51}V NMR, which was shown to be a very informative method in studying V–W and some other solutions containing vanadium.[9–12] It allows one to observe directly different complexes of V(V), which are simultaneously present in a solution, and to find their concentration. On the basis of chemical similarity of Mo and W(VI) it is reasonable to expect an analogy in the compositions of some of their complexes with V(V) and in the way they manifest themselves in the NMR spectra as well. The high concentration sensitivity of ^{51}V NMR allows measurements to be made in a wide concentration range including dilute solutions, which were studied earlier by potentio and spec-

trophotometric techniques. In this paper the ^{51}V and ^{17}O NMR data on the V–Mo solutions are reported and assignments of several resonances are given, mostly for the first time. A comparison is made with the V-W system containing several mixed metal polyanions of known composition.

EXPERIMENTAL

^{51}V NMR spectra of V–M (M = Mo, W) solutions were studied at the atomic V/M ratios equal to 3 : 1, 1 : 1, 1 : 3, 1 : 6 and vanadium concentrations, [V], equal to 0.1, 0.04, 0.004 and 0.0004 M in the case of Mo–V and to 0.004 M in the case of W–V solutions. The 0.1 and 0.04 M solutions were prepared from $NaVO_3 \cdot 2H_2O$ and $Na_2MO_4 \cdot 2H_2O$ of reagent grade and acidified with dilute HCl. The degree of acidification P = [HCl]/[V+M] was changed in the range 0.1 to 1.8–2.5. The 0.004 and 0.0004 M solutions were prepared by diluting the 0.04 series. After storing the solutions at 20° for several days their pH values and NMR spectra were measured. $Na_6[V_2Mo_6O_{26}] \cdot 16H_2O$ was prepared as described in Fig. 5.

The pH values were measured on a pH-meter "pH-262" with the silver chloride electrode. NMR spectra were measured on a BRUKER CXP-300 spectrometer using a high power probe head and cylindrical 8 mm o.d. (1.5 ml solution volume) horizontal sample tubes without sample spinning. The ^{17}O spectra were obtained at 40.7 MHz with a spectral width of 50 kHz and a pulse duration of 10 μs. The number of transients was about 50,000, the pulse delay was 0.02 s. All spectra were obtained at natural abundance of ^{17}O. For obtaining the $Na_6[V_2Mo_6O_{26}]$ solution, water enriched with ^{17}O ($\sim$ 1%) was used as well. Because of the baseline roll the ^{17}O peak intensities were measured from peak areas and not from integrals and were checked by recording under various conditions (delay, spectral and pulse width). An average uncertainty in measuring ^{17}O peak intensities was about 20%. The chemical shifts (δ) are given in ppm relative to solvent H_2O.

^{51}V spectra were obtained at 78.88 MHz with a spectral width of 25 kHz, a pulse duration of 7 μs and a pulse delay of 0.1 s. For dilute solutions the number of transients was about 2000. The concentrations of different vanadium forms were found from peak intensities which were measured from integrals and peak areas. The overlapped peaks were resolved graphically. An average uncertainty was about 15%. The chemical shifts are given relative to $VOCl_3$ as an external standard.

^{95}Mo spectra were obtained at 19.56 MHz. The spectrum width was 20 kHz, the pulse width was 10 μs and the pulse delay was 0.3 s. The number of transients was 1000–5000. The 1 M Na_2MoO_4 solution was used as an external standard. For all nuclei the downfield shifts are taken as positive.

^{51}V NMR spectra of solid samples were measured using the magic angle spinning (MAS) technique.

RESULTS

The ^{51}V NMR spectra of the isopolyvanadates are rather well known.[9–11] The 0.004 M solution of $NaVO_3$ (pH $\sim$ 7.1) contains vanadium in the meta- (mainly with $\delta = -573$ ppm) and diprotonated ortho- and pyrovanadate forms (-556 and -568). On mixing with Na_2MoO_4 new complexes are not formed. The titration curve of one of the V–Mo solutions is shown in Fig. 1. On acidifying up to P = 0.1–0.3 a yellow colour appears and a modified spectrum of dacavanadate, containing five peaks instead of the usual three (noted as I, Table 1, Figs 2 and 3), arises. At P = 0.1–0.4 (depending upon the V/Mo ratio) a peak at -494 appears, which is displaced upfield with the increase in acidity (Fig. 4). In more acid solutions (P = 0.6–1.0) a peak at -502 is observed and another modified spectrum of the decavanadate type (II, Table 1, Fig. 3) appears. There is also a weak peak at -533 in the spectra of the 1 : 3 and 1 : 6 solutions at pH 5.5–4. This peak is more intense in the 1 : 6 series. At pH < 3 the VO_2^+ oxycations are formed in the solutions.

At [V] = 0.0004 M the -494 and -502 peaks and weak spectrum I are again observed. The total amount of vanadium in the V–Mo complexes decreases relative to free vanadium, which is present at that concentration only as $H_2VO_4^-$, transforming into VO_2^+ at pH < 4.

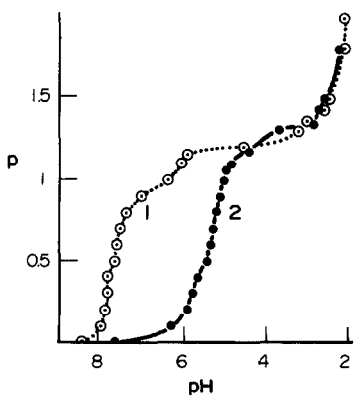

Fig. 1. The curves of titration of the $NaVO_3$–Na_2MO_4 solutions with HCl solution; V/M = 1 : 3, [V] = 0.004 M, M = W(1) and Mo(2).

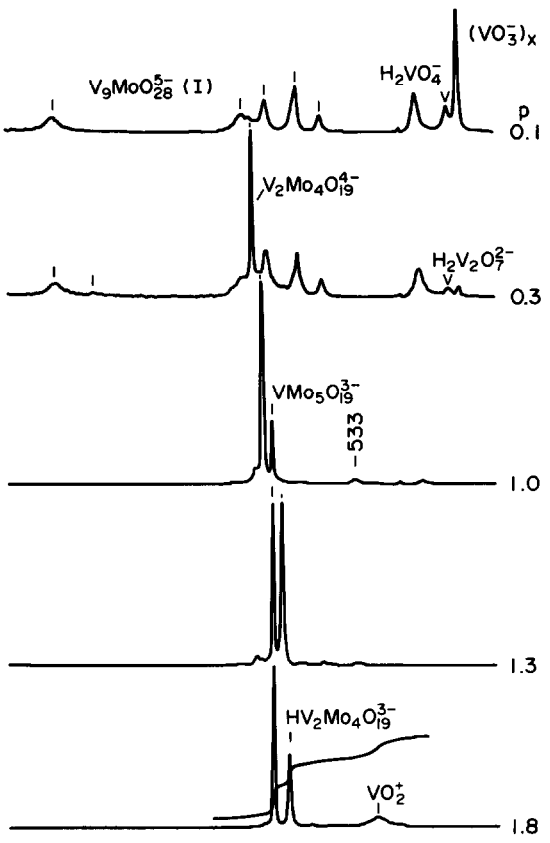

Fig. 2. ^{51}V NMR spectra of the $NaVO_3$–Na_2MoO_4 solutions (V/Mo = 1:3, [V] = 0.004 M) at different acidifications.

Thus, only four different mixed metal complexes are formed in dilute V–Mo solutions.

The same signals are observed in the spectra at [V] = 0.04 and 0.1 M and at pH > 4, but the relative intensities of spectra I and II increase and there appears one more modified decavanadate spectrum, (III Table 1, Fig. 3). The relative intensity of the −533 peak also increases and in some spectra a new peak is observed at −536 ppm.

On storing the orange 1:3 and 1:6 solutions (pH ~ 5.5) at 20° colourless or slightly yellow prismatic crystals were gradually formed, which were shown to be $Na_6[V_2Mo_6O_{26}]\cdot nH_2O$.

At pH < 4 the composition of the concentrated solutions is markedly different from that of the dilute solutions. Besides the above mentioned signals there is a new group of relatively broad peaks at −522, −516, −498 and −496 ppm. At pH < 3 the VO_2^+ peak (δ −541) and broad peaks at −600 and −628 ppm also appear. The same spectra are observed for solutions prepared as described in ref. 8. On heating, the solutions become darker red-orange, the intensity of the −522 signal increases and the signal is split into several components due to their narrowing. On storing the solutions at 20° the precipitates of hydrated oxides are formed in several days, with the intensity of the −541, −600 and −628 peaks decreasing considerably.

In the case of V–W solutions ([V] = 0.004 M) a yellow colour appears on mixing $NaVO_3$ and Na_2WO_4 without additional acidification, with pH value increasing as compared with that of the initial solutions. In the ^{51}V NMR spectra of these solutions a weak peak of $V_2W_4O_{19}^{4-}$ (noted as V_2W_4) is visible at −507 ppm[10,12] (Fig. 5). On acidifying the solutions the peak intensity increases. At V/W > 1 the modified decavanadate spectrum of type (I) is also observed. In more acid solutions the $VW_5O_{19}^{3-}$ species (VW_5) are formed (δ −522) and the V_2W_4 peak is shifted upfield (Fig. 4). At pH < 3 the VO_2^+ oxycations are produced.

DISCUSSION

The V–W polyanions are known to have either $M_6O_{19}^{n-}$ or Keggin structures.[1] As it can be seen (Fig. 5), only two of them, VW_5 and V_2W_4, are produced at [V] = 0.004 M. The $V_3W_3O_{19}^{5-}$ (V_3W_3) and $V_xW_{13-x}O_{40}^{x-3}$ ($x = 3$ and 4) polycomplexes are formed in more concentrated solutions.[10,12]

From the data available on the V–Mo complexes[1-4] and by the anology with the V–W system one can expect first of all the $V_xMo_{6-x}O_{19}^{2-x}$ polyanions to be present in the V–Mo dilute solutions. The peculiarities of the ^{51}V NMR spectra of the corresponding V–W species were discussed elsewhere.[12] They contain single relative narrow signals, which are shifted downfield and broadened in the order $VW_5 \rightarrow V_2W_4 \rightarrow V_3W_3$. As the vanadium content in the polyanions increases the pH range of their stability shifts to a less acid region, the V_3W_3 species existing in solutions only at pH > 7. The more highly charged V_3W_3 and V_2W_4 species are protonated at pH < 8.7 and < 4, respectively, which can be concluded from the upfield shift of their signals.

From careful analysis of all data obtained we can conclude that the VMo_5 and V_2Mo_4 species are formed in V–Mo solutions and that their signals are those at −502 and −494 ppm. Actually the −502 peak is the only one in the ^{51}V spectrum at [V] = 0.0002, [Mo] = 0.01 M and at pH 3, when according to the data[3] there is only the 1:5 mixed complex in the solution. The assignment of the −494 peak to the V_2MO_4 species is also confirmed by the ^{17}O NMR spectrum, and will be discussed below.

The shift of the V_2Mo_4 peak with acidity (Fig. 4) indicates the presence of the increasing amount of the HV_2Mo_4 species and the fast exchange between

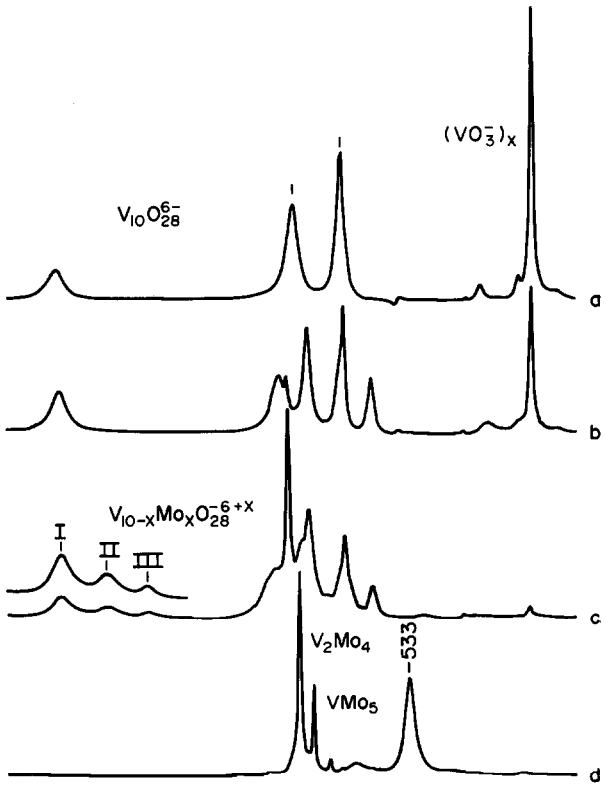

Fig. 3. ^{51}V NMR spectra of solutions: $V_{10}O_{28}^{6-}$ and $(VO_3^-)_x$, [V] = 0.05 M, pH 6.45 (a); $NaVO_3$–Na_2MoO_4, 1 : 1, [V] = 0.04 M, pH 6.25 (b); [V] = 0.1 M, pH 5.8 (c); [V] = 0.04 M, pH 4.9 (d).

Table 1. ^{51}V and ^{95}Mo NMR chemical shifts of polyanions

Polyanion	^{51}V NMR δ ±0.5 ppm	^{95}Mo NMR δ ±2 ppm
$V_{10}O_{28}^{6-}$, pH 5.4	−420(2), −495(4), −511(4)

( ) is the relative intensity.
[a] Is the supposed composition.

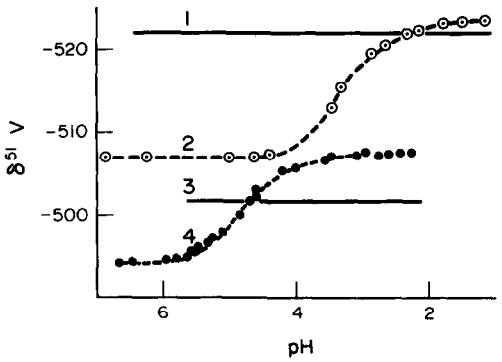

Fig. 4. The plot of the ^{51}V NMR δ value against pH for $VW_5O_{19}^{3-}$, $V_2W_4O_{19}^{4-}$ (1,2) and $VMo_5O_{19}^{3-}$, $V_2Mo_4O_{19}^{4-}$ (3,4).

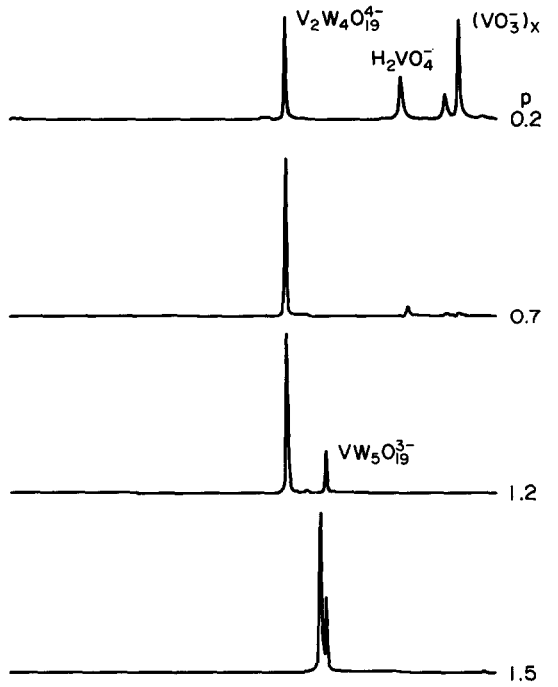

Fig. 5. ^{51}V NMR spectra of the $NaVO_3$–Na_2WO_4 solutions (V/W = 1:3, [V] = 0.004 M) at different acidifications.

the two forms. The observable δ value depends on their proportion, which allows us to evaluate the amount of each form. At pH < 4.5 the V_2Mo_4 signal is shifted upfield relative to the VMo_5 signal. The horizontal part of curve 4 (Fig. 4) corresponds to the complete $V_2Mo_4 \rightarrow HV_2Mo_4$ conversion. The V_2W_4 anions are protonated in more acid solutions (curve 2, Fig. 4) and the VW_5 and V_2W_4 signals are interchanged at pH < 2, where the HV_2W_4 polyanions are not stable and can only be observed at V/W > 1 immediately after acidification of the solution.

Unlike the V–W system in the V–Mo system a mixed complex, based on the decavanadate structure, predominates in the 1:3 and 1:6 series at low acidity and in the 1:1 and 3:1 series in the whole pH range studied. The $V_{10}O_{28}^{6-}$ species contains V atoms of the three types (Fig. 6).[14] There are three peaks with the intensity ratio 2:4:4 in their ^{51}V NMR solution spectrum. The weaker signal at −420 ppm arises from the two V_{III} atoms. The assignment of the two other signals has been recently made with the use of ^{17}O $\{^{51}V\}$ decoupling experiments.[16] In the modified decavanadate spectrum (I) these two signals are split into four in the intensity ratio 2:2:2:1 showing that one of either V_I or V_{II} atoms is replaced by the Mo atom, i.e. that the $V_9MoO_{28}^{5-}$ species is formed.

Further support for this composition comes from the ^{17}O NMR spectra (Fig. 6, Table 2). In case of $V_9MoO_{28}^{5-}$ the number of the terminal O=V peaks increases as compared with $V_{10}O_{28}^{6-}$ and a new peak arises from an O=Mo oxygen atom. The peak of the two sixfold bridging O_A atoms is split into two peaks, one of them being shifted upfield. Two peaks of equal intensities appear instead of the peak of four threefold bridging O_B atoms. A new peak arises from oxygen in the V–O–Mo bridge, its intensity corresponding approximately to two atoms. The peak of four quasi-terminal O_E atoms is split into two peaks of equal intensities. The δ values and the number of the V–O–V peaks also change. A spectrum like that seems to correspond better to the substitution of one of the V_I than the V_{II} atoms.

It is very imortant that there is a possibility of comparing the spectra of the isostructural $V_9MoO_{28}^{5-}$ and $V_9WO_{28}^{5-}$ complexes as the O atoms of the same type bound to the Mo and W atoms should have different chemical shifts. In the ^{17}O NMR spectrum of $V_9WO_{28}^{5-}$ the A, B and C peaks are displaced slightly further upfield than in the $V_9MoO_{28}^{5-}$ spectrum, the other peaks having very similar splittings and δ values (Table 2). This shows that exactly the O_B atoms as well as the O_C and O_A atoms have a direct contact with the alien atom, which is only possible for the V_I position.

Two other mixed complexes (II and III, Table 1), based on the decavanadate structure, which were only observed in V–Mo solutions, may be supposed to be either the two other positional isomers of $V_9MoO_{28}^{5-}$ or $V_{10-x}Mo_xO_{28}^{6+x}$ complexes with $x > 1$. Due to overlapping ^{51}V NMR spectra of several complexes we were unable to determine the exact number and the intensity ratio of the peaks in each spectrum and to distinguish between these alternative possibilities.

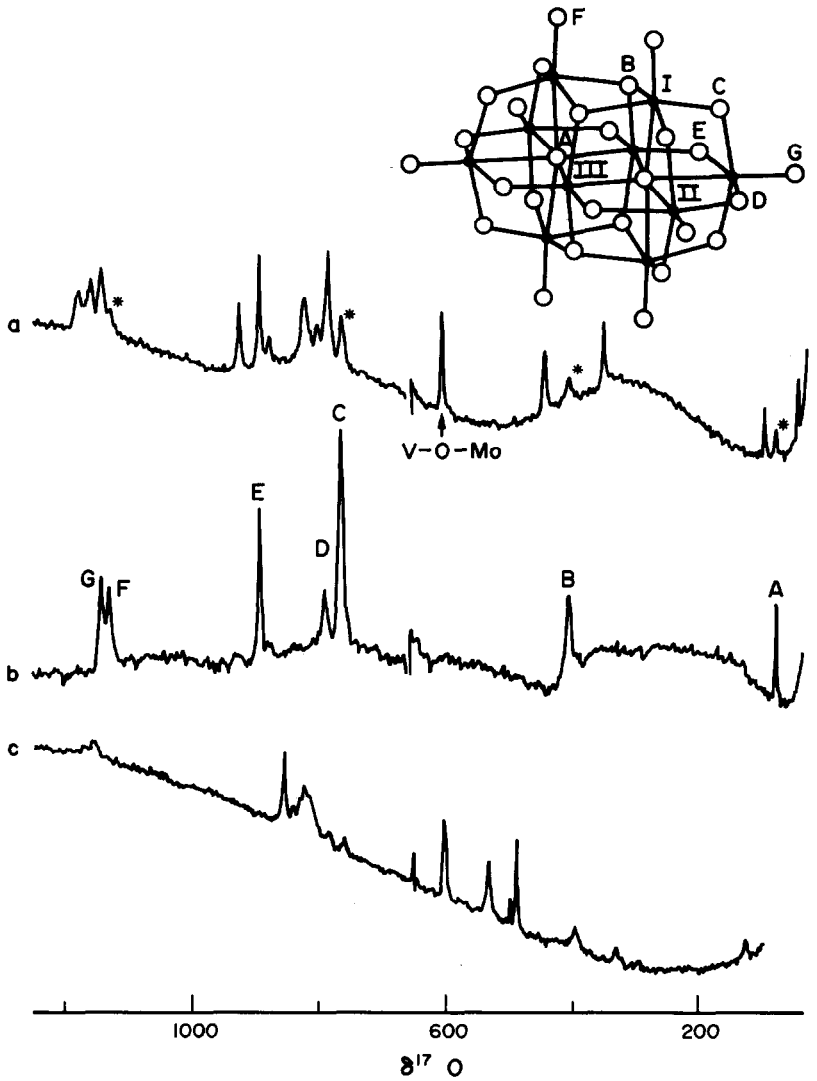

Fig. 6. ^{17}O NMR spectra of solutions of $V_9MoO_{28}^{5-}$ (* are the decavanadate peaks) (a) and $V_{10}O_{28}^{6-}$ (at natural ^{17}O content) (b) and of the $Na_6[V_2Mo_6O_{26}]$ solution (in enriched water) (c); idealized bond structure of $V_{10}O_{28}^{6-}$.

It is to be noted that on mixing the $Na_6V_{10}O_{28}$ and $Na_6Mo_7O_{24}$ solutions (V/Mo ~ 9:1) the $V_9MoO_{28}^{5-}$ polyanions were formed during several days. That shows that the V_1 position is more preferable for the exchange with cations from a solution.

The ^{51}V NMR spectrum of $V_9Mo(W)O_{28}^{5-}$ is usually overlapped with that of $V_{10}O_{28}^{6-}$, but the admixture of the latter is not large and can be evaluated from the intensities of the −512 and −521.5 signals (at pH 5.5). The V–Mo solution contains about 85% of vanadium as $V_9MoO_{28}^{5-}$ at V/Mo = 9:1.5 and [V] = 1 M. However, we have failed in isolating $V_9MoO_{28}^{5-}$ from such a solution. The less soluble sodium salt of $V_{10}O_{28}^{6-}$ is crystallized instead and equilibrium in the solution is gradually shifted to V_2Mo_4.

The ^{51}V NMR peaks of $V_{10}O_{28}^{6-}$ begin to be displaced upfield at pH < 5.5 and those of $V_9MoO_{28}^{5-}$ at pH < 4 due to protonation and the mutual position of their spectra is changed with acidity.

The $Na_6[V_2Mo_6O_{26}]\cdot nH_2O$ salt is crystallized from solutions at V/Mo < 1 and pH 5.5. The crystals give an isotropic ^{51}V NMR signal 5.5 kHz in width at δ −482 ppm. Rotating the sample at a magic angle narrows the signal up to 0.9 kHz. Such a signal shows a rather high symmetry of the nearest oxygen environment of the V atoms and corresponds to the VO_4 tetrahedra with nearly equal V–O bonds,[15] which is consistent with the

( ) is the relative intensity.
[a] Corresponds to Fig. 6.

structural data.[6] The downfield shift of this signal relative to that of the orthovanadate VO_4^{3-} anion (δ −535) may result from the decrease in the electron density transferred from oxygen to vanadium in the O–V bonds due to their lengthening.

On dissolving the slightly yellow crystals of $Na_6V_2Mo_6O_{26}$ give a bright orange solution with pH 5.5. The ^{51}V NMR spectrum of this solution is closely similar to that of the mother liquor having V/Mo = 1 : 3. There is a strong signal at −494, the −533 signal, modified decavanadate spectrum (II) and a weak peak at −485 ppm in this spectrum. ^{17}O and ^{95}Mo NMR show MoO_4^{2-} and $Mo_7O_{24}^{6-}$ to be present in the solution as well. The question arises, which of the ^{51}V peaks may be ascribed to $V_2Mo_6O_{26}^{6-}$. The chemical shift of −485 is almost equal to the δ value of the complex in solid state, but the −485 peak is too weak. We may then suppose the −494 signal, which is dominant in the spectrum, to arise from $V_2Mo_6O_{26}^{6-}$ when in solution, although the signal with the same δ value has been concluded from the ^{51}V NMR data to arise from V_2Mo_4. In order to elucidate this point it is necessary to examine the ^{17}O NMR spectrum of this solution.

The $V_2Mo_6O_{26}^{6-}$ species is known to be isotypic with α-$Mo_8O_{26}^{4-}$,[6] the ^{17}O NMR spectrum of which is also described.[7] We could expect the $V_2Mo_6O_{26}^{6-}$ spectrum to be of the similar type with some modification caused by introducing two V atoms into the structure. However, in the ^{17}O NMR spectrum of the $Na_6[V_2Mo_6O_{26}]$ solution (Fig. 6c) we did not find a set of peaks that could be attributed to $V_2Mo_6O_{26}^{6-}$. On the contrary, all the peaks observed besides those of MoO_4^{2-} and $Mo_7O_{24}^{6-}$ can be assigned to a V–Mo complex of a hexaniobate type. All these peaks are displaced upfield relative to the VMo_5 peaks.[7] Although we were unable to evaluate all the peak intensities with high accuracy, we could conclude the spectrum to arise from $V_2Mo_4O_{19}^{4-}$. On the whole this spectrum is like that of $V_2W_4O_{19}^{4-}$,[12] especially the narrow resonances of the Mo–O–Mo bridges, which are split in the intensity ratio 1 : 4 exactly as the corresponding resonances of the W–O–W bridges. We were unable to detect only the weakest two peaks arising from a sixfold bridging O atom and from one atom in the V–O–V bridge probably due to their overlap with other more intense signals (H_2O, $Mo_7O_{24}^{6-}$).

Thus, the ^{51}V and ^{17}O NMR spectra together show that on dissolving in water $V_2Mo_6O_{26}^{6-}$ mainly disproportionates into V_2Mo_4, $Mo_7O_{24}^{6-}$ and some other complexes. Only the weak peak at −485 seems to arise from $V_2Mo_6O_{26}^{6-}$ in solution.

We tried to obtain the TBA salt of $V_2Mo_6O_{26}^{6-}$ in order to dissolve it then in nonaqueous solvent

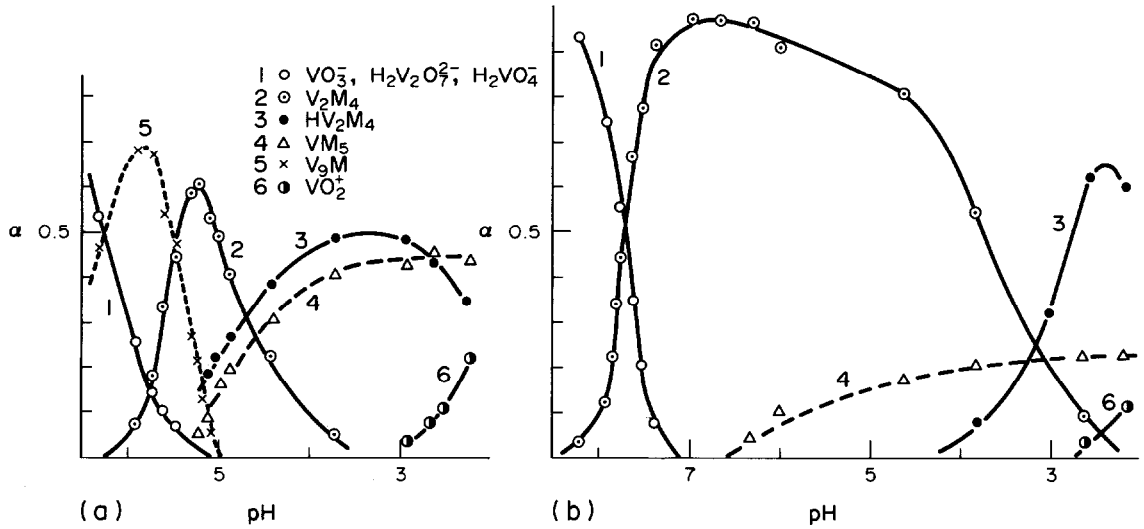

Fig. 7. Distribution diagrams of V(V) for the $NaVO_3$–Na_2MO_4 solutions (1:3, [V] = 0.004 M), M = Mo (a) and W (b).

therefore preventing hydrolysis. On dissolving $Na_6[V_2Mo_6O_{26}]$ in the aqueous solution of TBA · Br a yellow precipitate was gradually formed. However, the ^{17}O NMR spectrum of the CH_3CN solution of this precipitate shows that the TBA salt of VMo_5 has really been obtained.

We have not identified a mixed complex observed at δ_V −533. From relative intensity variations of this peak for the different V–Mo series we may only conclude the V/Mo ratio in it to be < 1/5. The pH interval of the formation of this complex coincides with that of $Mo_7O_{24}^{6-}$. If $NaVO_3$ and $Na_6Mo_7O_{24}$ are mixed in the ratio V/Mo = 1/20, nearly all vanadium is observed by this peak. Probably the complex in question is obtained by replacing a Mo atom with a V atom in the $Mo_7O_{24}^{6-}$ species. However, further studies of the true composition of this complex are needed.

At high concentration and acidity (pH < 4) VW_5 and V_2W_4 are known to convert to the darker coloured complexes having the Keggin structure.[1,10] The similarity of the V–Mo and V–W systems in forming the V_xM_{6-x} species allows us to suppose the V–Mo red-orange complexes (δ_V −496 to −522 ppm), which are formed under similar conditions, to be of the Keggin type too. The pH range of their formation and the ability to form etherate complexes are typical for polyanions having the Keggin structure. Besides, their ^{51}V NMR spectra consisting of several rather broad peaks showing a number of different positions of the V atoms and the larger dimensions than in the case of the V_xM_{6-x} species, these spectra are similar to those of the 1:12 PMoV, PWV and WV complexes. But the corresponding $V_xMo_{13-x}O_{40}^{n-}$ species ($x \sim 2$ and 3) seem to be less stable. They can exist in equilibrium with VMo_5, HV_2Mo_4 and cationic V and Mo forms. At the given pH value equilibrium strongly depends on concentration and temperature. However, further studies of these complexes are necessary.

^{95}Mo was used mainly for studying rather concentrated solutions ([Mo] > 0.1 M). The MoO_4^{2-} and $Mo_7O_{24}^{6-}$ anions as well as mixed V_2Mo_4 and V_9Mo species were detected in the solutions studied (Table 1).

Thus, most of the mixed polyanions observed by ^{51}V NMR in dilute Na–V–Mo solutions ([V] < 0.01) have been identified in this work. That makes it possible to compose the distribution diagrams for dilute V–Mo as well as V-W solutions, which show the ratio between vanadium in a V or V–M complex to total vanadium as evaluated from the ^{51}V NMR peak intensities. The diagrams for [V] = 0.004 M and V/M = 1:3 are shown in Fig. 7. MoO_4^{2-} and $Mo_7O_{24}^{6-}$ are not included as their content has not been examined in the 0.004 M solutions due to the low concentration sensitivity of the ^{95}Mo and ^{17}O NMR.

It can be seen that the mixed species prevailing in Na–V–Mo solutions are not crystallized and some minor species are crystallized instead probably due to the lower solubility of their Na salts. This can partly explain the contradiction of the data available on the composition of the V–Mo complexes, which were obtained from studies of solutions and crystal phases. Besides, we have also found that the

cations (Na, K, NH_4) influence the composition of the concentrated V–Mo solutions. As a result some other complexes can be isolated from K(NH_4)–V–Mo solutions.

Abstract—Reaction of phenyldichlorophosphine, **2b**, with *N,N'*-dimethyl-*N,N'*-bis(trimethylsilyl)urea, **1**, leads to a symmetrical diphosphorylation product, **3b**. A mechanism for the formation of **3b**, on the basis of ^{31}P NMR-data, is proposed. **3b** reacts with oxalic acid bis(trimethylsilyl)ester, **5**, with intramolecular P–P-coupling and formation of the λ^3P–λ^4P-mixed-valence diphosphorus compound, 1,4-dimethyl-2,3-diphenyl-1,4,3,2-diazadiphospholidin-5-one-2-oxide, **6**, which has been oxidized by means of tetrachloroorthobenzoquinone (TOB), **7**, to the λ^4P–λ^5P-compound, **8**. The structures of **3b**, **6** and **8** have been elucidated by ^{1}H- and ^{31}P-NMR-spectroscopy; single crystal X-ray diffraction studies of **3b** and of **6** have been conducted. The identity of both compounds has been confirmed. In the acyclic diphosphorus compound, **3b**, a remarkably short non-bonding P–P distance of 280.6 pm has been found while the P–P bond length in the cyclic compound **6** is of the usual order of magnitude (221.1 and 221.8 pm, respectively).

Recently, the reaction of *N,N'*-dimethyl-bis(trimethylsilyl)-urea, **1**, with methyldichlorophosphine, **2a**, has been shown to yield a symmetrical diphosphorylation product, **3a**, which has been found to undergo various further transformations.[1,2] We have now prepared the related compound, **3b**, as a crystalline solid from **1** and phenyldichlorophosphine, **2b**:

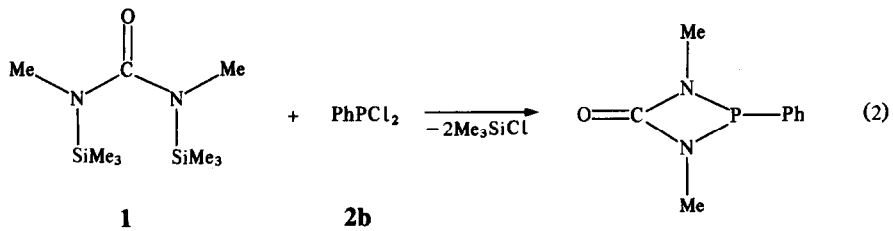
2b R = Ph **3b** R = Ph

The reaction of **1** with **2b**, in a molar ratio 1 : 1, has already been described by Roesky and his co-workers, with formation of different products.[3] In a subsequent publication a possible pathway has been suggested,[4] and it would seem reasonable to assume the reactions to proceed via a common intermediate. In a ^{31}P NMR investigation of the reaction of **2b** with $(Me_3Si)(Me)NC(:O)N(Me)(SiMe_3)$, **1**, only the signals for $PhPCl_2$, **2b** (δ_P +160) and for the product, Ph(Cl)P(Me)NC(:O)N(Me)P(Cl)Ph, **3b**, (δ_P +120) were observed at room temperature. No evidence for an intermediate product was found. In an experiment, conducted in an NMR tube at −45°C between $PhPCl_2$, **2b** and **1** in a molar ratio 2 : 1 evidence for a two-step reaction was obtained, however. Upon warming the sample in the NMR tube two strong signals, one at δ_P 160 ($PhPCl_2$), and one for an intermediate product (δ_P 124.8), and a weak signal for **3b** (δ_P 120) were noted. In the following spectrum, recorded within about 1 min of the first one, a reversal of the signal intensities was already noted. Finally, in a spectrum recorded at room temperature 5 min later only the product **3b** (δ_P +120) was observed.

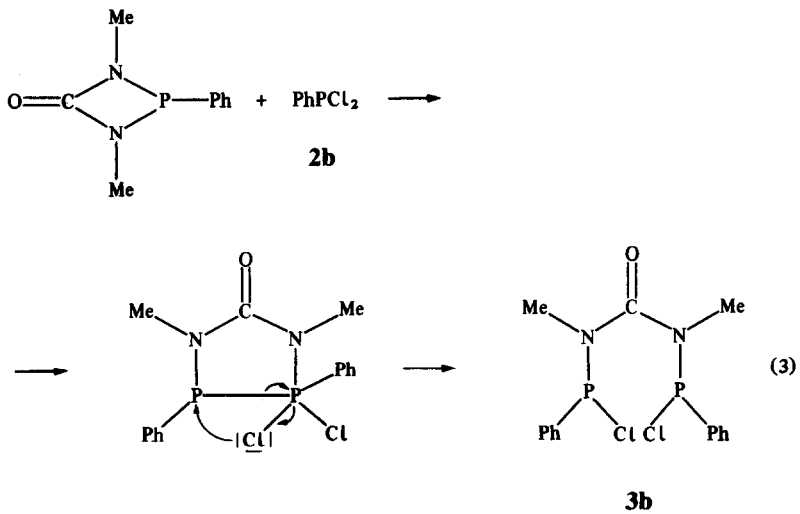
On the basis of the above evidence the following pathway is suggested for the reaction:



(2)

1 **2b**

In a second step, insertion of $PhPCl_2$ into the P–N bond is suggested to occur:



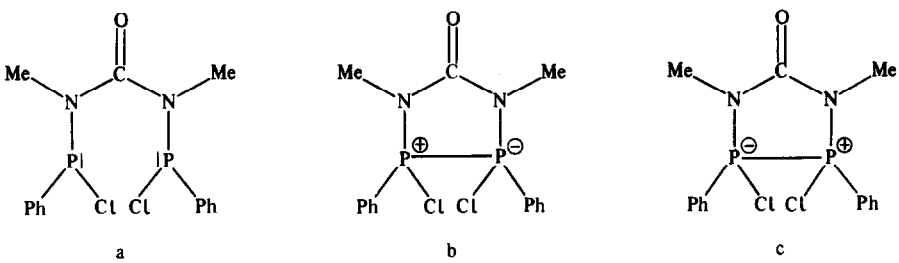
(3)

3b

The reaction is accompanied, presumably, by simultaneous migration of chlorine and cleavage of the P–P bond, with formation of **3b**.

As both compounds, **3a** and **3b**, show a triplet in the ^{1}H NMR spectrum for the N–Me-protons, indicating coupling between the phosphorus atoms,[5] a single crystal X-ray structure determination of **3b** was carried out, in order to support the evidence for this interaction.

The most remarkable finding originating from the structure determination of **3b** is the unusually low P–P-distance of 280.6 pm in the solid state which may, perhaps, be represented in terms of contributions by the mesomeric structures depicted below:



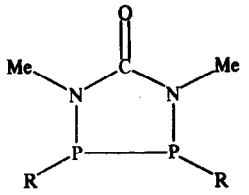
3b

In b and c the urea grouping may function as a kind of "electron sink" which serves to compensate or alleviate the consequences of a shift of electron density. It cannot be ascertained to which extent the remarkable proximity of the two phosphorus atoms in **3b** persists in the solution state.

It may well be of some relevance to the ease of P–P bond formation when the transformation of **3b** into **6** is effected [eqn (4)].

Since bonds involving the negatively charged hypervalent phosphorus atom are probably weakened to the same extent to which those to the positively charged phosphorus are strengthened, the P–Cl, P–N and P–C bonds, as a consequence of these effects, would appear to be normal single bonds. The coordination of both phosphorus atoms is rather similar. While it cannot be described in terms of a regular polyhedron it may, perhaps be referred to as strongly distorted ψ-trigonal bipyramidal. The five-membered ring invoked in structures b and c is non-planar (see also Fig. 2). The phosphorus atoms are situated *ca* 60 pm above and below the plane, respectively, in which the atoms, N1, N2 and C1 are situated (see Fig. 1).

An attempt was undertaken at the intramolecular coupling of the two phosphorus atoms in **3b**, with formation of the cyclic diphosphorus compound, **4b**, the P,P′-dimethyl analogue of which, **4a**, is known.[2]



4a R = Me
4b R = Ph

As a new reagent which, it was hoped, would bring about this intramolecular dehalogenating condensation, oxalic acid bis(trimethylsilyl)ester,[6] **5**, was employed. A smooth reaction, involving P–P coupling, was indeed observed but, instead of **4b**,

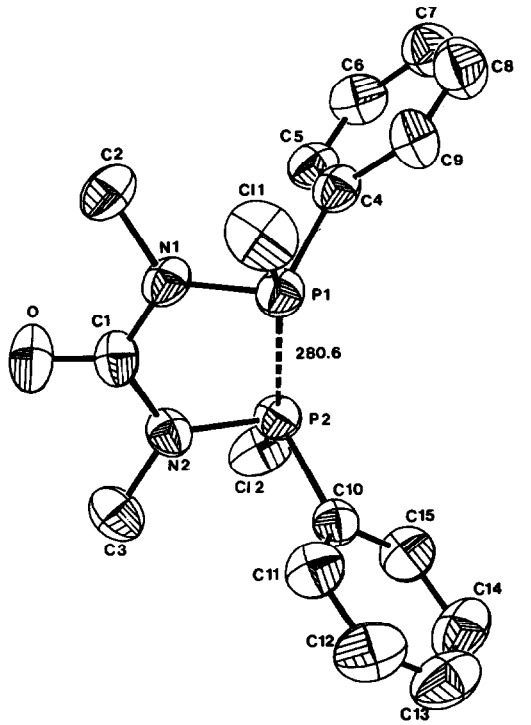


Fig. 1. Molecule of **3b** showing the atom number; r(P–P) in pm; vibrational ellipsoids with 50% probability (excluding hydrogen atoms).

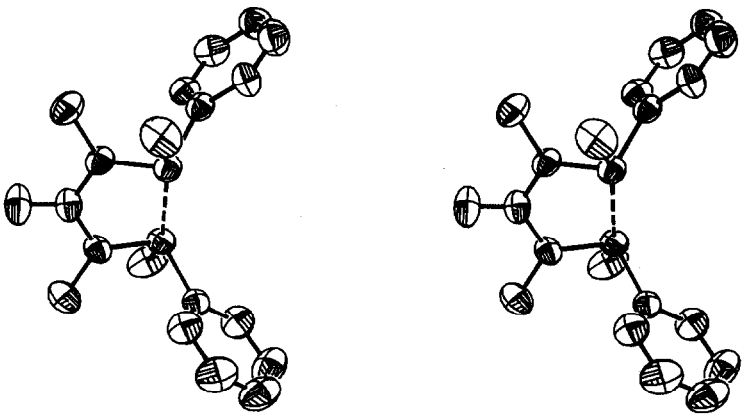

Fig. 2. Stereoview of a molecule of **3b**.

the mixed valence diphosphorus compound, **6**, was formed, in accord with eqn (4).

It may be envisaged that, in subsequent steps, from one molecule each of **3b** and **5** an initial cyclic product is formed which undergoes loss of CO and CO_2, as indicated, to give the λ^3P–λ^4P diphosphorus compound, **6** [eqn (4)]. The NMR spectra of **6** (Table 1) suggest the existence of the compound in two stereoisomeric forms, **6a** and **6b**, which are believed to differ with regard to the positions, relative to each other, of the phenyl groups at the phosphorus–phosphorus bond. According to the X-ray

crystal structure determination of **6**, however, only one species is present in the solid state (*vide infra*).

The mass spectrum of **6** reveals its thermal stability, in that the base peak of the spectrum corresponds to the molecular ion. Based on the observation of two metastable ions, the loss of one methyl group (m* 288.71; 318 → 303; Δm = 15) and of methyl isocyanate (m* 214.22; 318 → 261; Δm = 57) is indicated.

The NMR spectra of **6** both for ^{1}H and ^{31}P (Table 1) are different for each isomer. Isomer **6a** is present in excess over **6b** which is thought to be a consequence of less steric hindrance (*trans* arrangement of phenyl groups), compared to **6b** (*cis*).

The preparation of **6** by a thermolytic reaction, apparently in a lower state of purity (reported m.p. 118°; our m.p. 150°) has been reported.[7] An attempted X-ray crystal structure determination of **6** confirmed its identity, but a structure refinement has been reported as being impossible, due to the unsatisfactory quality of the crystals.[7] We have, therefore, undertaken a new single crystal X-ray determination of **6**.

The present X-ray investigation confirms the preliminary results of Sheldrick *et al.*[7] There are two crystallographically independent molecules of **6** per asymmetric unit. As Fig. 3 shows, the two molecules (labeled A and B) have the same configuration (with the phenyl groups *cis* relative to the heterocyclic ring, as opposed to **3b** where the phenyl groups are trans). Furthermore A and B have an almost identical conformation.* The molecular packing is illustrated in Fig. 4. The heterocyclic rings are slightly puckered. The deviations (in pm) of atoms from the respective least squares planes defined by the ring atoms are for A: P(1a) 2; P(2a) −5; N(2a) 8; C(1a) −6; N(1a) 1; for B: P(1b) 3; P(2b) −4; N(2b) 6; C(1b) −3; N(1b) −2. The phosphorus–phosphorus bond lengths in **6** of 221.1(2) (A) and 221.8(2) pm (B) fall in the range typical of phosphorus–phosphorus single bonds (c.f. e.g.[8]).

Since there are only very few examples of P–P compounds involving the λ^4P–λ^5P-structural unit,[8] and as only one example of a product of direct oxidation of TOB to a λ^4P–λ^5P compound is known,[8c] we were interested in the oxidation of **6** by TOB. In many cases investigated previously, the P–P bond was broken upon oxidation.[9]

The reaction proceeded as shown below, eqn (5); the P–P bond remained intact; P–P coupling,

* Bond distances and angles are listed in Table 3.

Crystal structure determination of **3b**

Colourless prisms of **3b** were employed for the X-ray determination conducted on a Syntex $P2_1$ diffractometer, (Mo-K_α radiation; graphite monochromator; λ (K$\bar{\alpha}$) 71.069 pm); the crystal dimensions were $0.3 \times 0.3 \times 0.4$ mm, triclinic; space group $P\bar{1}$. Cell parameters: $a = 808.2(3)$; $b = 948.9(3)$; $c = 1201.2(4)$ pm; $\alpha = 80.12(3)$; $\beta = 90.58(3)$; $\gamma = 75.67(3)$. Cell volume 877.96×10^6 pm^3 ($Z = 2$). Intensity data were collected to a θ_{max} of 24°, yielding a total of 2760 independent reflexions of which 2108 ($I > 2\sigma(I)$) were used in the subsequent calculations, using direct methods (programme SHELXTL; computer CM S 140). Final values for R and R_w, 0.048 and 0.054, respectively (hydrogens in fixed positions, remaining atoms refined with anisotropic temperature factors); weighting scheme: $w = (\sigma^2(F_o) + 0.01F_o^2)^{-1}$.

Crystal structure determination of **6**

Crystals of **6** were colourless and transparent, and of isometric habitus. A crystal of 0.24 mm average diameter was used for the X-ray measurements on a Philips PW 1100 diffractometer (graphite monochromator; (Mo-K$\bar{\alpha}$) = 71.069 pm). Cell parameters: $a = 1948.0(6)$, $b = 875.9(3)$, $c = 1973.9(4)$ pm; $\beta = 112.32(3)°$.

The space group (from systematic absences) is $P2_1/n$. $D_{calc} = 1.357$ g/cm^3 for $Z = 8$. Intensity data were collected to a θ_{max} of 22°, yielding a total of 3828 independent data. The 3143 reflexions with $F_o > 2.5\sigma(F_o)$ were used in the subsequent calculations. The structure was solved by Patterson techniques. All hydrogen atoms could be located in difference Fourier maps. The final values for R and R_w were 0.063 and 0.069, respectively (hydrogens in fixed positions, remaining atoms refined with anisotropic temperature factors). The weighting scheme was given by $w = 1.18(\sigma^2(F_o) + 0.003F_o^2)^{-1}$.* The calculations were carried out using the SHELX system.[10]

Abstract—The complex Na(Pic)(PHEN)$_2$ (Pic = picrate, Phen = 1,10-phenanthroline) is unique in being a cluster with two independent Na ions in the asymmetric unit. Na(1) is seven-coordinated involving two N atoms of two Phen molecules (Na—N, 2.492–2.622 Å), phenoxide O (Na—O$^-$, 2.381 Å) and an *o*-nitro-oxygen (Na—ONO, 2.584 Å) of Pic(1) and also to the phenoxide O (Na—O$^-$, 2.656 Å) of Pic(2). Na(2) is six-coordinated through four N atoms of the two other Phen molecules (Na—N, 2.510–2.570 Å), phenoxide O (Na—O$^-$, 2.317 Å) and *o*-nitro-oxygen (Na—ONO, 2.592 Å) of Pic(2). Thus Pic(2) serves as a linkage residue between two clusters. The Phen molecules are planar and nearly perpendicular to each other in either cluster.

With the aim of understanding the vital bioinorganic functions of Na, K, Mg and Ca,[1] we have been interested in unravelling the fundamental coordination chemistry of alkali (M^+) and alkaline earth (M^{2+}) cations (general abbr. M^{z+}). In order to understand the individual Lewis acid behaviour of each M^{z+}, a wide range of chemical and crystallographic investigations[2] have been undertaken on the systems of the type $M^{z+}(X)_z^-$(ligand)$_x$ and $M^{z+}(L)_z^-$(ligand)$_x$ where X and L are inorganic and organic charge neutralizers, respectively. The ligand may be a macrocycle such as benzo-15-crown-5,[3] a protic acyclic multidentate such as tetraethyleneglycol (Teg)[4] or triethanolamine (Tea),[5] or an aprotic conventional bidentate such as 2,2-bipyridine (Bipy)[6] or 1,10-phenanthroline (Phen).[7–9] The macrocycles have the advantage of the macrocyclic effect,[10] the protic Teg and Tea type of ligands enjoy the advantage of being double action[2] in that they coordinate the M^{z+} while also stabilizing (bridging) the counteranion. Bipy and Phen carry fairly anionic N-sites[11] and bind efficiently the hard M^{z+} in the capacity of being "anionic ligands".

During our extensive chemical[7–9] work on the ML_z-Phen systems under the solvating effect of the diverse protic and aprotic media, we realized that Na^+ and Ca^{2+}, for Pic (picrate) as L, display outstanding ability to yield solid Phen-complexes. Their complexes insolubilize easily irrespective of the solvating medium, in particular from water. To know about the chemical principles related to this conspicuous feature we have undertaken X-ray structural analysis of selected ML_z-Phen complexes with the hope that it would add to the understanding of the chemical differentiation of Na and Ca from their biologically important analogues K and Mg. In this paper we report on the structural results of Na(Pic)(Phen)$_2$.

EXPERIMENTAL

Synthesis of $Na(Pic)(Phen)_2$

A 1 : 2 reaction mixture of Na(Pic) (0.002 mmol) and Phen-monohydrate was dissolved by warming in 5 cm^3 ethanol and set aside in a closed beaker at room temperature to allow a slow crystallization of the title complex. Bright yellow crystals (m.p. 280°C), recovered by filtration, were subjected to structural analysis.

X-ray structural analysis

From a yellow, transparent rod shaped crystal of dimensions $0.4 \times 0.2 \times 0.1$ mm, mounted on an Enraf–Nonius CAD-4 Diffractometer, 5057 reflections were measured for one half of the reflection sphere with Zr-filtered MoKα radiation up to $2\theta = 44°$ using ω-2θ scan technique. Lattice constants were determined by least squares refinement of the setting angles of 24 reflexions.

Crystal data

$Na^+(C_6H_2N_3O_7)^-(C_{12}H_8N_2)_2$, $M_r = 611.55$, triclinic with $a = 12.535(11)$, $b = 13.364(8)$, $c = 17.664(6)$ Å, $\alpha = 93.20(4)$, $\beta = 94.36(5)$, $\nu = 110.97(6)°$, $V = 2744$ Å^3, space group $P\bar{1}$ with $Z = 4$, $d_c = 1.436$ g cm^{-3}, (MoKα) = 0.71069 Å, μ(MoKα) = 1.1 cm^{-1}, $F(000) = 1256$, $T = 298$ K. Final R for 4614 observed reflections was 0.043.

The structure was determined by direct methods. MULTAN 80[12] yielded Fourier maps that could not be interpreted; however, SHELX 84[13] gave all but two non-hydrogen atoms. Subsequent Fourier methods revealed the remaining two atoms.

Isotropic refinement of the 90 non-hydrogen atoms was carried out with the SHELX 76[14] program on the Cyber 855 computer of the University of Utrecht and converged at $R = 0.14$. Subsequent refinement was performed on an in-house DG-Eclipse s/230 mini-computer, using a locally modified SHELX 76[14] implementation. Anisotropic non-hydrogen refinement converged at $R = 0.07$. All 36 H-atoms were placed at idealized aromatic C(sp^2)-H positions with a C—H distance of 1.08 Å and were kept fixed during refinement. The H-atoms were assigned an overall isotropic temperature parameter, which refined to a final value of 0.13. Scattering factors were taken from the *International Tables for X-ray Crystallography*.[15] The molecular geometry was calculated and the illustrations were prepared with the EUCLID-package.[16]

RESULTS AND DISCUSSION

The atom numbering of the phenanthroline and picrate molecules are shown in Fig. 1. There are two types of Na^+ ion, the coordination of which are shown in Figs 2 and 3. The numbering of atoms in Figs 2–4 is derived from the number of the corresponding moiety, i.e. O(201) denotes O(1) of picrate (2). Coordination geometry around Na(1) and Na(2) is detailed in Table 1. Other bond distances, angles, torsion angles and positional and thermal parameters have been deposited in the supplementary material.

There are only a few M^{z+}-Phen complexes the structural analysis of which have been reported. The $Sr(ClO_4)_2(Phen)_4 \cdot 4H_2O$ and $Ba(ClO_4)_2(Phen)_4 \cdot 4H_2O$ systems[17] are isomorphous wherein the cation is within the environment of only two bidentate Phen molecules and the four water molecules. More details for the Ba-system are available in our recent publication.[18] Bonding modes of Ba in $Ba(Pic)_2(Phen)_2$ acetone[19] and $Ba(Dnp)_2(Phen)_3$[20] (Dnp = 2,4-dinitrophenolate) have also been examined. In the $M(Onp)(Phen)_2$ (M = K or Rb; Onp = *o*-nitro-phenolate) complexes[21] the cation is within the environment of the two bidentate Phen molecules, the chelating Onp, and the unused nitro-oxygen belong to the Onp of the adjoining molecule in the lattice. The analogous $Na(Onp)(Phen)_2$ is not dimerized in this way but exists in discrete molecules[21] containing a 6-coor-

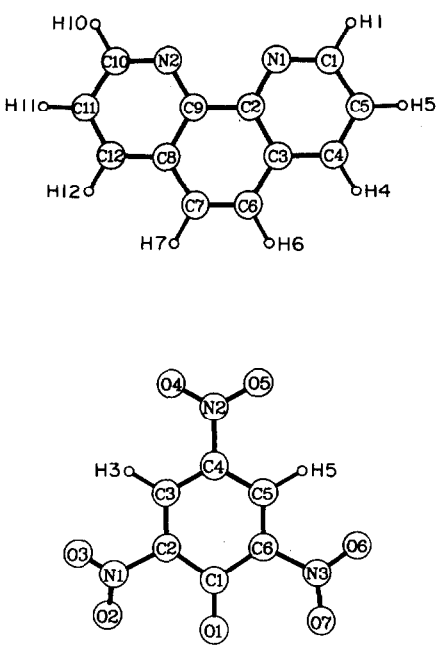

Fig. 1. Atom numbering of phenanthroline and picrate residues.

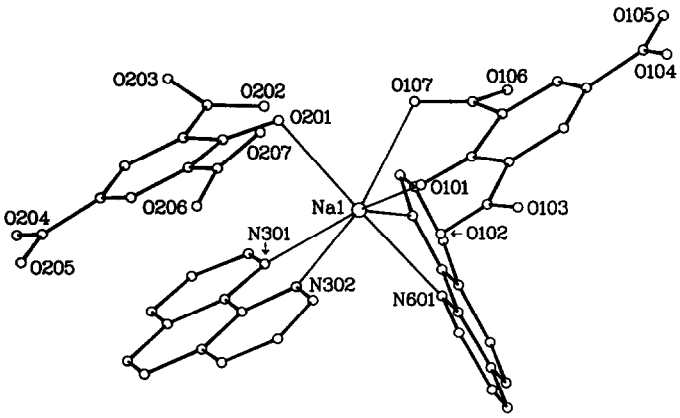

Fig. 2. Coordination of Na(1). [The residue number precedes the atom number, e.g. O(201) is atom O(1) of picrate(2), and N(301) is atom N(1) of phen(3) etc.]

dinated cation (Na—N, 2.444–2.557 Å; Na—O^-, 2.281 Å; and Na—ONO, 2.421 Å).

The present complex represents a unique example of being a cluster (Fig. 4) wherein there are two crystallographically different Na ions for each asymmetric unit. One cation, Na(1), is seven coordinated through the two bidentate Phen molecules (Na—N, 2.492–2.622 Å), the Pic(1) phenoxide (Na—O^-, 2.381 Å), an ortho-nitro-oxygen of the same Pic (Na—O, 2.584 Å) and also the Pic(2) phenoxide through a rather long contact (Na—O^-, 2.656 Å). The other cation, Na(2), is six coordinated through the two bidentate Phen molecules (Na—N, 2.510–2.570 Å), the Pic(2) phenoxide (Na—O^-, 2.317 Å) and an ortho-oxygen of this Pic (Na—O, 2.592 Å).

The two Phen molecules in each cluster are planar (ave. σ plane, 0.025 Å), nearly perpendicular to each other (88.2 and 84.0°) with the uniqueness that one C—N bond of each is consistently short (ave. 1.323 Å) while the other is distinctly longer (ave. 1.354 Å). As seen in Table 1, the two Na—N bond lengths for each Phen with a given cation, Na(1) or Na(2), are different, especially for the Phen molecule roughly in plane with Pic (and approaching the cation from the direction opposite to it); in fact it forms the shortest and the longest Na—N bonds and the effect is more pronounced for Na(1) which is in contact with two anionic oxygens. Similar differences are traceable for the $Na(Onp)(Phen)_2$ complex although, both Phen molecules in this compound are equally inclined to the Onp moiety.[21] Recently, the compound $NaMoO(CN)_3(Phen)_3 \cdot MeOH \cdot H_2O$ has been examined crystallographically[22] and has been found to contain Na within the cationic moiety of the complex $[Na(Phen)_2 \cdot MeOH,H_2O]^+[MoO(NC)_3(Phen)]^-$ wherein it is six-coordinated through two bidentate Phen

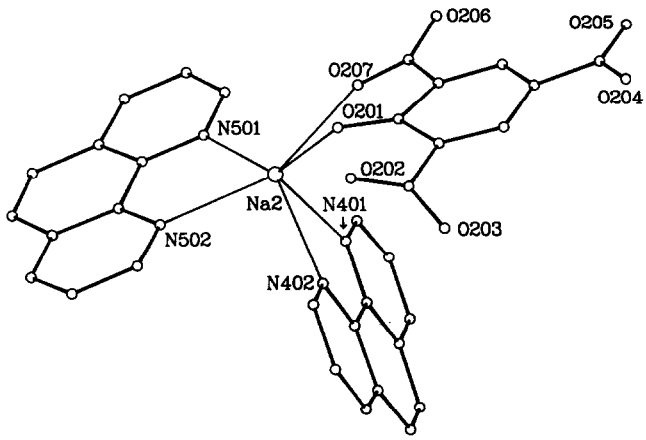

Fig. 3. Coordination of Na(2).

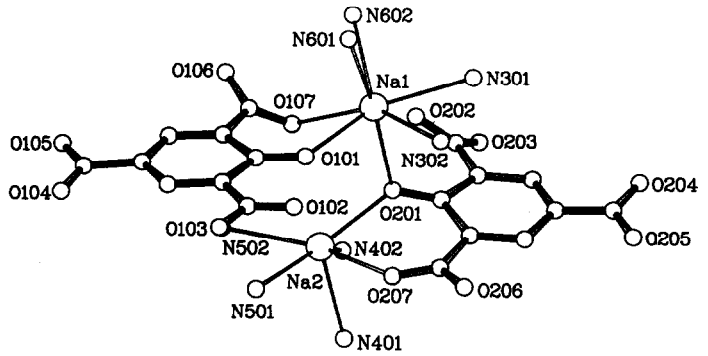

Fig. 4. The asymmetric unit consisting of two interlinked Na clusters.

molecules (Na—N, 2.500–2.521 Å), the water molecule (Na—OH_2, 2.380 Å), and methanol (Na—O, 2.413 Å). Na^+ is not under formal pairing with any charge neutralizer but the intriguing deformation of one Phen molecule still takes place which yields the shortest (2.500 Å) and the longest (2.521 Å) distance. The phenomenon is, therefore, an inherent feature of the Phen molecule.

The aromatic rings of Pic(1) and Pic(2) are also planar (σ plane, 0.055 and 0.020 Å) but nitro groups of both are rotated to different degrees (0.0, 4.5 and 33.3°, and 35.9, 6.5 and 16.4°, respectively). It

N(301)—Na(1)—O(101)	88.5(0)		

indicates a different conformation for the two Pic moieties. Rotation of nitro groups of the nitrophenolates is a common feature of Onp[21,23,24] and Dnp[20] and in particular Pic.[25,26] Yet other chemically significant features of Pic in the present complex are the shortening of the C—O^- bond, elongation of the two C—C bonds next to C—O compared to the rest and decrease of the C—C—C angle at the C—O^-. This effect is practically the same as noted for Onp in K(Onp)·H_2O,[23] Rb(Onp)(Phen)$_2$[21] and K(Onp. isonitrosoacetophenone)[24] and to a decreased extent for Pic in K(Pic)[25] and Ba(Pic)$_2$(benzo-15-crown-5)·H_2O.[26] The origin of these deformities is the electron donating nature of the phenoxide and electron withdrawing nature of the nitro group, and the consequent hybridization change of the connected carbons.[27,28]

The Na—O^- and Na—ONO distances in the present complex are distinctly longer (Na—O^-, 2.381, 2.317 and 2.656 Å (bridging); Na—ONO, 2.584 and 2.592 Å) compared to the analogous distances in Na(Onp)(Phen)$_2$ (Na—O^-, 2.281; Na—ONO, 2.421 Å) suggesting a diminished anionic state of oxygens in Pic and an enhanced ionicity in the present complex. This feature, apparently relates itself to its inert (insoluble) characteristics in water medium; the Ca(Pic)$_2$(Teg)·H_2O,[29] which is highly inert in protic media and is rather quantitatively insoluble in isoproponal, is found through structural analysis to be practically charge separated. A vital clarification at this juncture is in order in that chemical inertness (insolubility) of ionic compounds in protic media, including water, increases with the ionicity of the compound.[2] The cross linkage of Na(1) with phenoxide of Pic(2) may add to the chemical inertness of the complex; Ba(Onp)$_2$, which we have found through X-ray analysis[30] to be an intricately Ba—O cross-linked, displays typical chemical inertness.

X-RAY CRYSTAL STRUCTURE OF $W(OAlBr_3)(CH_2t\text{-}Bu)_3Br$, A MODEL FOR CATALYST–COCATALYST INTERACTION

J. FISCHER, J. KRESS, J. A. OSBORN,* L. RICARD and M. WESOLEK

Laboratoire de Chimie des Métaux de Transition et de Catalyse (UA au CNRS 424), Université Louis Pasteur, Institut Le Bel, 4 rue Blaise Pascal, 67000 Strasbourg, France

(*Received* 9 *January* 1987; *accepted* 23 *April* 1987)

Abstract—The crystal structure of the acid-base adduct obtained from $WO(CH_2t\text{-}Bu)_3Br$ and $AlBr_3$ is described. The interaction between the Lewis acid and the oxo ligand of the tungsten compound is discussed on the basis of bond distances and bond angles in the Br—W—O—Al linkage. The role of the W—O—Al linkage in homogeneous catalysis and of such interactions modelling the catalyst-support interactions in heterogeneous catalysis are briefly considered.

In recent years the organometallic chemistry of transition metals in formally high oxidation states has been greatly developed. The wide expansion of this field has emphasized the need for the use of π-donor ligands such as alkoxo, amido, oxo, imido or nitrido groups, which were shown to stabilize the generally electron deficient high oxidation state compounds. The oxo ligand has elicited interest for at least two further reasons: it has been suggested that it can serve as a "spectator" group in certain catalytic reactions[1] or as a reactive entity in both chemical and biochemical[2] oxidation processes. In this report, we describe an additional possible role for the oxo group, that of a bridge between catalyst and cocatalyst in certain catalytic reactions.

Previously[3] we have reported that tungsten(VI)–oxo-alkyl complexes of the type $WO(CH_2t\text{-}Bu)_3X$ (X = halide, alkoxide, ...) become catalytically active for the metathesis of olefins after addition of suitable Lewis acids such as boron, aluminum, gallium or tin halides. Acid-base interaction between the Lewis acid and the oxo function, both in the initial trialkyl precursors and in the propagating tungsten carbene derivatives, was suggested to be at the origin of this catalytic activity. We now report the X-ray structure of one of the initiating addition products, i.e. that formed from $WO(CH_2t\text{-}Bu)_3Br$ and $AlBr_3$.

EXPERIMENTAL

Suitable single crystals of the title compound **1** were obtained from a saturated toluene solution at low temperature under argon in the absence of light. A systematic search in reciprocal space using a Philips PW1100/16 automatic diffractometer showed that crystals of **1** belong to the orthorhombic system. The unit-cell dimensions and their standard deviations were obtained and refined at room temperature with CuKα radiation (λ = 1.5405 Å) by using 25 carefully selected reflections and the standard Philips software. Crystal data: $C_{15}H_{33}OAlBr_4W$, M = 759.9, a = 18.643(6) Å, b = 15.996(5) Å, c = 17.092(6) Å, V = 5097 Å^3, Z = 8, d_{calc} = 1.98 g cm^{-3}, μ = 162.94 cm^{-1}, F_{000} = 2864, space group Pbca.

A crystal of 0.14 × 0.18 × 0.22 mm was sealed in a Lindemann glass capillary and mounted on a rotation free goniometer head. All quantitative data were obtained from a Philips PW1100/16 four circle automatic diffractometer, controlled by a P 852 computer, using graphite monochromated radiation and standard software. The vertical and horizontal apertures in front of the scintillation counter were adjusted so as to minimize the background counts without loss of net peak intensity at 2σ level. The total scan width in $\theta/2\theta$ flying step-scan used was $\Delta\theta = 1.0+0.143tg(\theta)$ deg. a step width of 0.05 deg. and a scan speed of 0.024 deg s^{-1}. 3785 hkl reflections were recorded ($4° < \theta < 57°$). The

resulting data-set was transferred to a PDP 11/60 computer, and for all subsequent computations, the Enraf-Nonius SDP/PDP package was used,[4] with the exception of a local data-reduction program. Three standard reflections measured every hour during entire data-collection period has a mean loss of 16% in intensity which was corrected using a time-dependent linear interpolation function.

The raw step-scan data were converted to intensities using the Lehmann–Larson method[5] and then corrected for Lorentz, polarisation and absorption factors, the latter computed by the numerical integration method of Busing and Levy[6] (transmission factors between 0.08 and 0.31). A unique data set of 1333 reflections having $I > 3\sigma(I)$ was used for determining and refining the structure.

The structure was solved using the heavy atom method. After refinement of heavy atoms, a difference-Fourier map revealed maxima of residual electronic density close to the positions expected for hydrogen atoms; they were introduced in structure factor calculations by their computed coordinates (C—H = 0.95 Å) and isotropic temperature factors of the form B(H) = 1 + *Beqv*(*C*) Å^2 but not refined. Full least-squares refinement minimizing $\Sigma\omega(|Fo|-|Fc|)^2$ converged to $R(F) = 0.060$ and $R_w(F) = 0.073$, $w = (\sigma^2_{\text{counts}}+(pI)^2)^{-1}$. The unit weight observation was 1.38 for $p = 0.08$. A final difference map revealed no significant maxima. The scattering factors coefficients and anomalous dispersion coefficients come respectively from Refs 7 and 8.

Tables of atomic positional parameters [Table 2 (1 page), Tables 3_1 (1 p.), and 3_2 (1 p.)] and thermal parameters [Table 4 (1 p.)] and lists of *Fo*/*Fc* values (*10, Table 5 (6 pp.)), have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS

The crystal consists of discrete molecular units separated by normal Van der Waals distances. There are no unusual intermolecular contacts. An ORTEP view of the molecular unit is displayed in Fig. 1 along with the atom labelling scheme. Selected bond distances and bond angles are given in Table 1.

The molecule consists of a central tungsten(VI) atom which has a slightly distorted trigonal bipyramidal coordination geometry. The equatorial positions are occupied by the three neopentyl groups,

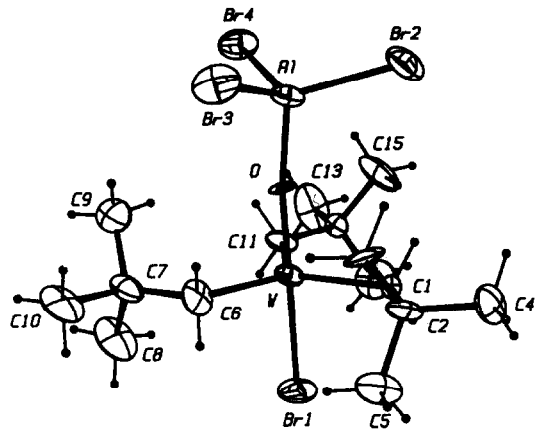

Fig. 1. ORTEP view of complex 1 (50% probability thermal ellipsoids).

and the axial positions by the oxo and bromo ligands. The oxo oxygen is linked to the aluminum of the $AlBr_3$ moiety resulting in a distorted tetrahedral arrangement about Al.

The three neopentyl groups adopt a helical arrangement about the tungsten centre, the β carbon atoms C(2), C(7) and C(12) being located almost within the plane defined by the α carbons C(1), C(6), C(11). The tungsten atom lies out of this plane by only 0.01 Å, being displaced towards the Br(1) axial ligand. The three W—C bonds, as well as the three C—W—C and W—C—C angles are not significantly different from each other with normal mean values of 2.11 Å, 120° and 121° respectively (Table 1) similar to those observed in $[WO(CH_2t\text{-}Bu)_3]_2(\mu\text{-}O)$.[9]

The oxo bridge between tungsten and aluminum is characterized by an almost linear alignment of the three atoms (W—O—Al = 172°). The short Al—O distance (1.79 Å)[10,11] is indicative of a strong coordination bond. The tungsten–oxygen bond distance (1.77 Å), although *ca* 0.1 Å longer than in other W(VI) oxo compounds,[9,12–15] is consistent with the presence of a double bond. The W—Br(1) bond distance, on the other hand, is particularly short (2.428 Å),[16–18] despite the location of the bromine in position *trans* to the oxo ligand. Both axial O and Br(1) are slightly tipped with respect to normal of the plane defined by the equatorial atoms C(1), C(6), C(11) (3.1 and 2.7° respectively), with a Br(1)–W–O angle of 177°.

The $AlBr_3$ moiety is linked to the oxygen so that the three bromine atoms are staggered with respect to the three neopentyl ligands in a gear-type arrangement. The three Al—Br bond distances as well as the O—Al—Br bond angles are very similar and show no unexpected feature.

DISCUSSION

The overall geometry observed for the complex is clearly consistent with the minimization of steric interactions within the molecule.

As predicted from spectroscopic[3] and theoretical[19] studies, the Lewis acid $AlBr_3$ is shown to interact with the oxo function of $WO(CH_2t\text{-}Bu)_3Br$ (**2**) which thereby acts as a Lewis base. The W—O—Al bond angle near to 180° is not surprising according to both steric and electronic[19] considerations. The Al—O bond length, but also the two other bond lengths of the quasi linear Br(1)—W—O—Al linkage, allow us an insight into the nature of the acid-base interaction and its effects on the electronic structure in the molecule.

The most surprising result would seem to be the very short W—Br(1) bond length (2.428 Å) when compared to tungsten–bromine distances observed in other W(VI) complexes such as $W[C(CH_2)_3CH_2](OCH_2t\text{-}Bu)_2Br_2$ (2.566 Å)[18] and even the highly electron deficient $WOBr_4$ (2.444 Å).[17] This indicates the presence of a substantial Br to W π-donating interaction, compensating undoubtedly for the loss of O to W π-donation when the Lewis acid binds to the oxo group.

The strong donor–acceptor nature of the oxygen–aluminum bond results in the very short Al—O bond distance (1.79 Å) compared to those observed in the relatively strong THF adducts Al(Ph)C=C(Ph)Al(Ph)C=C(Ph)·2THF (1.907 Å)[10] and $AlCl_3$·2THF (1.99 Å).[11] These differences can only partly be accounted for by the change in oxygen hybridisation[20] (*sp* and sp^3 respectively), and we propose result from π-donation of oxygen lone pairs in vacant *d* orbitals on Al. The essentially double bond character of the tungsten–oxygen bond is indicated by a distance of 1.77 Å which although similar to that observed in the unsymmetrically oxo-bridged $WOBr_4$ (1.78 Å),[17] is *ca* 0.1 Å longer than for the terminal oxo atoms in $[WO(CH_2t\text{-}Bu)_3]_2(\mu\text{-}O)$ (1.71 Å),[9] $WOBr_4$ (gaseous phase) (1.70 Å),[12] $WO(CHt\text{-}Bu)(PEt_3)Cl_2$ (1.66 Å),[13] $WO(CHt\text{-}Bu)(PMe_3)_2Cl_2$ (1.69 Å)[14] and $WOCp(CH_2SiMe_3)_3$ (1.66 Å).[15] In these latter compounds significant O to W π-donation and bond orders superior to two are present. We note further that coordination of the oxo grouping to aluminum also causes ^1H NMR resonance of $WO(CH_2t\text{-}Bu)_3Br$ (**2**) to be shifted *ca* 1 ppm downfield after coordination to $AlBr_3$.[3]

As discussed earlier,[3] the adduct $W(OAlBr_3)(CH_2t\text{-}Bu)_3Br$ when dissolved in chlorobenzene under ambient light is a moderately effective catalyst for the metathesis of olefins,[21] whereas compound $WO(CH_2t\text{-}Bu)_3Br$ by itself is inactive. The interest of the present structural characterisation of the W–O–Al interaction between the transition metal "catalyst" and the Lewis acid "cocatalyst" is thus evident. More generally, this interaction can

also be considered as a model for catalysts supported on alumina or silica surfaces. Similar Al-O-M,[22] Si–O–M[23] or Ti–O–M[24] interactions have thus been shown to occur in such supported metal catalysts for the hydrogenation or the polymerisation of olefins. They might also be involved in olefin metathesis reactions catalysed by molybdenum or tungsten alkyls supported on SiO_2 or Al_2O_3.[25]

Abstract—The synthesis and characterization by spectroscopic techniques of compounds with general formulae MX_2(bbdh) and MX_2(bbdhp) is described. In these formulae M = Co(II), Ni(II); X = Cl, Br bbdh = 1,6-bis(benzimidazol-2-yl)-2,5-dithiahexane and bbdhp = 1,7-bis(benzimidazol-2-yl)-2,6-dithiaheptane. The compounds have been characterized by chemical analysis, infrared spectra, ligand field spectra, X-ray powder diagrams and in one case by a single crystal structure analysis. The metal ions are octahedrally (all Ni compounds and the Co compound of bbdh) or tetrahedrally (Co compounds of bbdhp) coordinated by the ligands and the anions. The detailed structure of $NiBr_2$(bbdh) was determined by X-ray methods at 290 K. Crystals of $C_{18}H_{18}Br_2N_4NiS_2$, M_r = 572.995, crystallized in the orthorhombic space group Pnc2, with a = 8.502(3), b = 13.748(2), c = 8.794(3) Å, V = 1027.96(57) Å^3, Z = 2, D_x = 1.851 Mg/m^3, were studied with CuKα radiation (using monochromator, λ = 1.54178 Å), μ(CuKα) = 7.931 mm^{-1}, F(000) = 568. The final conventional R-factor = 0.064, (R_w = 0.083) for 1600 "observed" reflections and 122 variables. The structure was solved using Patterson and DIRDIF techniques and refined by SHELX. The coordination around Ni(II) is octahedral with a *cis*-geometry of the two bromide anions (Ni—Br = 2.543(2) Å), a *trans*-arrangement of the benzimidazole ligands (Ni—N = 2.132(8) Å) and a *cis*-geometry of the thioether groups (Ni—S = 2.441(3) Å). The packing in the crystal results in hydrogen bond interactions between the N–H groups of the imidazoles and bromine atoms of nearby units. The structures of the nickel compounds and the isomorphous Co(II) bbdh compound are believed to be essentially the same, as deduced from spectroscopic analysis. The Co(II) compounds of bbdhp, however, appear to be tetrahedrally coordinated, as deduced from ligand field spectra. It seems that in this case the thioether groups are not coordinated to the Co(II) ion.

Chelating ligands containing imidazole-type ligands have been the subject of many investigations during the last decade.[1–4] A major aim to study such compounds originates from the fact that a very large number of metalloproteins contain at least one imidazole group from a histidine side chain as a ligand for the metal in the protein. Knowledge of this type of coordination, especially when more than one imidazole ligand is present, will lead to a better understanding of the structure and reactivity

* Author to whom correspondence should be addressed.

of metalloproteins that contain histidine ligands. Most of the work with this type of ligand has dealt with Cu(I) and Cu(II) compounds, since all copper proteins that play a role in redox reactions, have at least two histidine ligands.

However, this type of ligand is also of interest for other metal ions, such as cobalt(II), zinc(II) and nickel(II), because these metal ions are easily studied by spectroscopic methods such as ligand–field spectra. Moreover, Cu(II) is known to have very flexible coordination requirements, whereas the other metal ions, and especially nickel(II), have stronger preferences for more regular structures, such as octahedral and tetrahedral.

Therefore we have decided to study the coordination chemistry of two ligands, i.e. 1,6-bis (benzimidazol-2-yl)-2,5-dithiahexane (abbreviated bbdh), and bis(benzimidazol-2-yl)-2,6-dithiaheptane (abbreviated bbdhp), with known[2,3] coordination properties towards Cu(II) and having different steric constraints. The results described in this paper deal with Co, Ni and Zn metal ions, with Cl and Br as counterions. To prove the coordination geometry, the crystal structure has been determined in the case of $NiBr_2$(bbdh).

EXPERIMENTAL

Starting materials

The ligands bbdh and bbdhp were synthesized as described in earlier work.[2,3] Metal salts were used as the commercially available hydrates. Reagent grade solvents were used.

Synthesis

The solid coordination compounds were obtained by mixing 1 : 1 solutions of the metal salt and the ligand in ethanol. The desired compounds were obtained upon standing while slowly cooling. In a few cases addition of a small amount of diethyl ether facilitated the precipitation. The products were isolated as finely divided crystalline powders and isolated by filtration. In the case of $NiBr_2$(bbdh) crystals were grown by slow evaporation of the ethanol solution.

Characterization

The compounds were characterized by elemental analysis, infrared spectra, ligand–field spectra, X-ray powder diagrams and NMR spectra, using standard techniques and equipment, previously described.[2,3] Analysis showed the compounds to be MX_2(L).

X-RAY DATA COLLECTION AND STRUCTURE DETERMINATION OF $NiBr_2$(bbdh)

An irregularly shaped crystal of approximately $0.30 \times 0.26 \times 0.19$ mm, mounted in a capillary tube, was used during the measurements. Throughout the experiment CuKα radiation was used with a graphite crystal monochromator on a Nonius CAD4 single crystal diffractometer ($\lambda = 1.54178$ Å). The unit cell dimensions, $a = 8.502(3)$, $b = 13.748(2)$, $c = 8.794(3)$ Å, $V = 1027.96(57)$ Å^3, were determined from the angular settings of 25 reflections with $10° < \theta < 44°$. The space group was determined to be Pnc2 from the systematic absences: $0kl$, $k+l = 2n+1$, $h0l$, $l = 2n+1$, $0k0$, $k = 2n+1$ and $00l$, $l = 2n+1$ and from the structure determination. The intensity data of 7817 reflections (the full sphere up to $\theta = 70°$), were measured, using the ω–2θ scan technique, with a scan angle of 1.80° and a variable scan rate with a maximum scan time of 15 s per reflection. The intensity of the primary beam was checked throughout the data collection by monitoring three reference reflections every 30 min. The final drift correction factors were between 1.00 and 1.15. A decline in the intensities of approximately 11% occurred over the course of the data collection. A smooth curve based on the reference reflections was used to correct for this drift. On all reflections profile analysis was performed,[5,6] the crystal shape and the capillary tube used, prevented a description of the crystal for an analytical absorption correction, but an empirical absorption correction was applied, using psi-scans,[7] μ(CuKα) = 7.931 mm^{-1} (correction factors were in the range 0.88 to 1.00). Symmetry equivalent reflections were averaged, $R_{int} = \Sigma(I - \langle I \rangle)/\Sigma I = 0.053$, resulting in 1960 unique reflections of which 1600 were observed with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied and the data were reduced to $|Fo|$ values.

The nickel and bromine atoms were found using Patterson techniques. All non-hydrogen atoms were found with DIRDIF[8] (direct methods applied to difference structure factors). The structure was refined by full-matrix least-squares on $|F|$ values, using SHELX.[9] The origin was fixed in the c direction by keeping the z-parameter of bromine fixed during the refinement. Scattering factors were taken from International Tables (1974).[10] Hydrogen atoms were included in fixed idealized positions 1.08 Å from the carbon c.q. nitrogen atom to which they were bonded. Isotropic refinement converged to $R = 0.079$. At this stage an additional empirical absorption correction was applied,[11] resulting in a

further decrease of R to 0.077 (correction factors were in the range 0.719–1.632).

After completion of the isotropic refinement the Bijvoet coefficient was calculated,[12] resulting in a value of −0.97(3), based on 118 Friedel pairs. The structure was therefore inverted before continuing the refinement. During the final stages of the refinement the positional parameters of all atoms and the anisotropic thermal parameters of the non-hydrogen atoms were refined. The hydrogen atoms had fixed isotropic temperature factors of 0.07 Å.^{2} The final conventional agreement factors were $R = 0.064$ and $R_w = 0.083$ for the 1600 "observed" reflections and 122 variables. The function minimized was $\Sigma w(Fo-Fc)^2$ with $w = 1/(\sigma^2(Fo) + 0.00400Fo^2)$ with $\sigma(Fo)$ from counting statistics. The maximum shift over error ratio in the last full matrix least-squares cycle was less than 0.05. The final difference Fourier map showed a number of peaks around Br up to 3 e/Å^3, around Ni up to 2 e/Å^3 and around S up to 1 e/Å^3 in the remaining space no peaks higher than 0.5 e/Å^3 were found. The quality of the intensity data would not allow a better parameterization because an accurate absorption correction was impossible.

Plots were made with PLUTO.[3] Final atomic coordinates and thermal parameters for the non-hydrogen atoms, hydrogen atom parameters and anisotropic thermal parameters are given as supplementary material, together with a table of observed and calculated structure factors. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

General aspects and spectroscopy

All compounds have been listed in Table 1, with some relevant spectroscopic data. From the similarities in the infrared spectra and the X-ray powder diffraction diagrams, it is easily seen that all four bbdh compounds must have similar structures. The ligand field maxima for the cobalt and the nickel compounds with bbdh agree with octahedrally based coordination geometry.[14,15]

The ligand field maxima listed in Table 1 for these compounds agree nicely with an $MN_2S_2X_2$ (X = Cl, Br) geometry. Apparently the splittings in the bands due to the low symmetry are not large enough to be resolved. This is not uncommon in *cis*-distorted octahedral compounds.[16] In case of the ligand bbdhp the spectral data of the Ni(II) compounds agree with octahedrally based coordination, whereas the data of the cobalt compounds indicate clearly a tetrahedrally based coordination geometry.

To determine the precise coordination geometry of the ligand, when coordinated to the metal, it was decided to perform a single-crystal X-ray analysis. The compound $NiBr_2$(bbdh) appeared to yield crystals suitable for X-ray diffraction, and the results of the structure determination are described below.

Crystal structure of $NiBr_2$(bbdh)

The most important geometrical data have been given in Table 2, whereas a stereoview of the molecule is depicted in Fig. 1. The molecular unit with the numbering system used is given in Fig. 2.

Detailed inspection of Table 2 and the Figs, shows that no unusual geometrical features are present. The observed Ni—Br, Ni—S and Ni—N distances all fall in the range normally observed for octahedral Ni(II).[17] The *cis*-orientation of the bromide ligands is like one would expect from geometrical consideration of the bbdh ligand. A *trans*-orientation would require a tetradentate square planar geometry for the Ni(bbdh) unit, which would

result in serious steric hindrance of the benzimidazole groups.

The benzimidazole ligands are planar within experimental error, and the intraligand distances and angles are also normal for benzimidazole ligands.[2,3] The packing of the molecules in the solid state is determined by van der Waals interactions and N(1)–H(1)...Br(1′) hydrogen bonds (N(1)...Br(1′) = 3.35(1) Å, H(1)...Br(1′) = 2.35(5) Å for Br(1′) at x, $0.5-y$, $-0.5+z$).

CONCLUSIONS

The compounds described in the present paper indicate clearly that the bis(benzimidazole) thioether ligands bbdh and bbdhp are good tetradentate chelating ligands for Co(II) and Ni(II). A comparison with the previously studied copper coordination compounds with these ligands is appropriate. In case of Cu(II) the bbdh ligand yields a five-coordinated $[Cu(bbdh)Cl]^+$ species, although a six-coordinate species $Cu(bbdh)Cl_2$ could be detected spectroscopically.[2] With the ligand bbdhp, rapid reduction occurs to the Cu(I) state, yielding a coordination entity consisting of $[Cu(bbdhp)]^+$ with very long—and hardly coordinating—Cu–S distances.[3] When we look at our Cobalt(II) compounds, the ligand bbdh yields octahedral species $Co(bbdh)X_2$, whereas bbdhp yields tetrahedrally coordinated $Co(bbdhp)X_2$. In this

case one could ask whether the thioethers are coordinated to the halides. Study of the details of the ligand-field spectra immediately shows that the chromophore is an N_2X_2 chromophore,[16,18] so that the thioether groups of bbdhp do not coordinate to Co(II). A study of molecular models immediately makes clear that in a tetrahedral geometry the Co...S contacts can indeed be very large so that one cannot speak of coordination anymore.

Finally, when considering the nickel compounds, the spectral data indicate an octahedrally based coordination for all species. Knowing the preference of Ni(II) for octahedral coordination, it can be understood that the extra CH_2-group of bbdhp is unable to distort the octahedral coordination significantly, contrary to the case of Co(II), where a relatively large preference for tetrahedral geometry is imposed by the cation.

In other words, the ligand bbdhp is a ligand that imposes all kinds of geometries, depending upon the nature of the metal ion actually present.

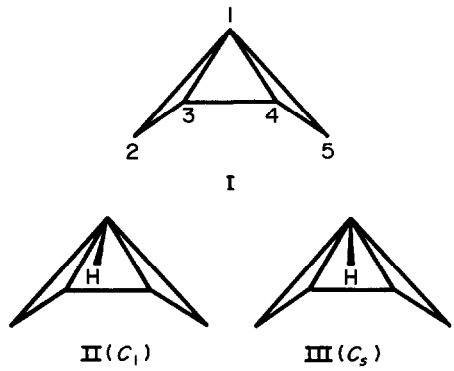
(*Received* 25 *March* 1987; *accepted* 23 *April* 1987)

Abstract—The structure of gaseous *arachno*-B_5H_{11} has been redetermined by electron diffraction and shown to be similar to that found in the solid state at low temperature (93 K) except that the inner basal interatomic distance B(3)—B(4) appears to be somewhat shorter in the gas phase. The data are consistent with the presence of asymmetric B(2)—H(2,3)—B(3) and B(5)—H(4,5)—B(4) bridges with the two halves of each bridge differing in length by *ca.* 12 pm. The unique *endo*/face-capping H atom attached to the apical B(1) atom has not been located with high precision, but the best fit to the data is obtained for an asymmetric structure with the distances B(2)...$H(1)_{endo}$ and B(5)...$H(1)_{endo}$ differing by 31 pm. For comparison, the structure of *nido*-B_5H_9 has also been redetermined by electron diffraction. The interatomic distances are in excellent agreement with those previously obtained from microwave data. The directly-bonded B–H(bridge) distances reveal an unusually large amplitude of vibration of the bridging H atoms but it was not possible to establish whether this was a real effect or whether the structure has a lower symmetry than that expected.

There is an unresolved problem in the structure of *arachno*-B_5H_{11}. The boron framework has long been established as that of an open-sided tetragonal pyramid (structure **I**) but there is some uncertainty about the precise location of the unique *endo*/face-capping H atom attached to the apical B(1) atom. Early X-ray diffraction work[1] suggested that the H atom was asymmetrically disposed above the open triangular face (structure **II**), but subsequent refinement of the data favoured C_s symmetry (structure **III**) rather than C_1 (structure **II**).[2]

Later, a more precise low-temperature study clearly established that the molecule has C_1 point symmetry in the crystalline state.[3] The most recent theoretical study, involving complete optimization at the 3-21G level, whilst favouring C_1 symmetry, points to a very low barrier (7 kJ mol^{-1}) for the C_1–C_s–C_1 fluxional process.[4] It is therefore not surprising that the proton and boron NMR spectra on



Structures I–III.

* Author to whom correspondence should be addressed.

the neat liquid revealed no evidence for the asymmetry.[5] The question therefore remains as to whether the asymmetry observed in the X-ray diffraction study is the result of crystal-packing forces, or whether it arises from some more deep-seated electronic-bonding effect. There has been no accurate determination of the structure of the gaseous molecule, the interpretation of early electron diffraction data being either palpably incorrect[6] or yielding no direct information about the hydrogen atom positions.[7]

In order to define as accurately as possible the positions of the atoms, including the so-called "anomalous" *endo*/face-capping hydrogen atom, we have now re-investigated the structure of the gaseous *arachno*-B_5H_{11} molecule by electron diffraction. Because it was readily available in the laboratory, we have also taken the opportunity of redetermining the molecular parameters of *nido*-B_5H_9 by the same technique for comparison with the results obtained by previous electron diffraction[8] and X-ray diffraction[3,9] studies and in particular with the more recent microwave data.[10]

EXPERIMENTAL

Preparation and purification of materials

The boranes were handled in a conventional high-vacuum system equipped with greaseless O-ring taps and spherical joints [J. Young (Scientific Glassware) Ltd]. *Nido*-B_5H_9 was supplied by Dr R. E. Williams (Chemical Systems, Inc. California). *Arachno*-B_5H_{11} was prepared from B_4H_{10} by the general method of Shore and coworkers.[11] Specifically, deprotonation was achieved using KH in dimethyl ether, and BCl_3 was used as the hydride-abstracting agent. The B_4H_{10} intermediate was prepared by the action of BF_3 on $[NMe_4][B_3H_8]$.[11] The B_5H_{11} was purified by repeated fractionation on a low-temperature fractional distillation column,[12] the effluent from which was sampled continuously by mass spectrometry. Traces of B_5H_9 are difficult to remove from B_5H_{11} and are also difficult to detect by mass spectrometry because of the similarity of the spectra of the two compounds. The sample of B_5H_{11} used in the electron diffraction study was shown by ^{11}B NMR to contain $< 0.5\%$ B_5H_9 as the only detectable impurity; its vapour pressure at 0°C was 52.5 mmHg, in excellent agreement with the published value.[13]

Electron diffraction

Electron diffraction scattering intensities were recorded on Kodak electron image plates, using the Edinburgh apparatus,[14] with nozzle-to-plate distances of 128 and 285 mm, and an accelerating voltage of *ca.* 44 kV. The nozzle was maintained at room temperature, 285 K, during the experiments and the samples were kept at room temperature (B_5H_9) or 250 K (B_5H_{11}). We have noticed that plates for boranes and related compounds have often shown dark patches, suggesting that there is some reaction between sample and emulsion, and this problem was particularly severe with B_5H_{11}. To minimize these effects, the plates were pumped for 24 h before being removed from the diffraction apparatus, and they were then washed thoroughly with water before development.

Data were obtained in digital form using a computer-controlled Joyce-Loebl MDM6 microdensitometer at the S.E.R.C. Laboratory, Daresbury, using the scanning program described previously.[15] Electron wavelengths were determined from the scattering patterns of gaseous benzene, recorded on the same occasions as the sample data. Calculations were carried out using standard data-reduction[16] and least-squares refinement programs. Weighting points used in setting up the off-diagonal weight matrices are given in Table 1, with other pertinent data. In all calculations the complex scattering factors of Schäfer *et al.*[17] were used.

RESULTS AND DISCUSSION

Refinement of the structure of B_5H_9

For almost all refinements it was assumed that B_5H_9 had C_{4v} symmetry, with one terminal hydro-

gen atom associated with each boron atom, and with four bridging hydrogen atoms, each one bonding equally to two boron atoms. The atom numbering scheme used in this work is shown in Fig. 1(a). The structure was then defined by the two different B—B interatomic distances (base–base and base–apex), the mean B—H distance, the difference between bridging and mean terminal B—H distances, the difference between the lengths of the basal and apical terminal B—H bonds, and two angles defining the positions of the terminal and bridging hydrogens associated with the base of the pyramid. These angles were chosen to be B(1)B(2)H(2), and the angle between the base plane and the plane BH(bridge)B, which is labelled "H(2,3)dip" in Table 2.

Table 2. Molecular parameters for B_5H_9 (distances in pm, angles in degrees)

p_1	r(B—B) (base–base)	181.1(4)
p_2	r(B—B) (base–apex)	169.4(4)
p_3	r(B—H) (mean)	127.1(8)
p_4	Δr(B—H) (bridge–terminal)	16.7(18)
p_5	$\angle$B(1)B(2)H(2)	125.4(73)
p_6	H(2,3)dip	68.8(29)
p_7	Δr(B—H) (terminal, base–apex)	0.5(fixed)

All geometrical and vibrational parameters relating to the B_5 pyramid refined easily, as did the mean B–H distance and the difference between terminal and bridging B—H bond lengths, and the amplitudes of vibration for both terminal and bridging bonds. The small difference in lengths of the two types of terminal bonds could not be refined, and was fixed at the value found by microwave spectroscopy.[10c]

The two remaining parameters, defining the positions of hydrogen atoms, were much more difficult to determine, because there are five different non-bonding B...H distances between 240 and 280 pm, and the non-bonding B...B distance also falls in this region. In the end it was possible to refine three vibrational parameters for the B...H atom pairs, as well as the two angles, but strong correlations between these parameters [Table 3(a)] make their estimated standard deviations relatively large. The refined parameters are listed in Table 2, and interatomic distances and vibrational amplitudes are given in Table 4. In both these tables the quoted errors are estimated standard deviations obtained in the least-squares analysis, increased to allow for systematic errors.

In this refinement the amplitudes of vibration for the atom pairs B(2)...H(5) and B(2)...H(1) were assumed to be equal, and that for B(1)...H(2) was fixed at a value close to that obtained for the other two, as all of these relate to a boron atom and a terminal hydrogen on an adjacent boron atom. However, the values obtained for these atom pairs are *smaller* than that for the directly-bonded B—H(bridge) pairs. This unusually large value suggests that either the bridging hydrogen atoms are involved in a large-amplitude vibration in which they move tangentially to the C_4 axis (an a_2 mode) or they are displaced from the positions equidistant from the neighbouring boron atoms, so that the molecular symmetry is reduced to C_4. Tests using a model with C_4 symmetry showed that substantial displacements of these atoms could be accommodated with little effect on the quality of the fit. For this purpose an additional parameter was introduced, representing the difference between the lengths of the two parts of the B—H—B bridges. The possibility of simultaneous displacement of the other basal hydrogen atoms was not investigated. With the difference between the lengths of the two parts of the bridge set to 20 pm, the R factor (R_G) rose only from 0.0874 to 0.0875, and the amplitude of vibration for the two bridge distances reduced from 13.9 to 11.5 pm. The results are therefore inconclusive on this point.

The results quoted in Tables 2–4 are for the C_{4v} model. Atomic coordinates are given in Table 5(a),

so that angles of interest may be calculated. The observed and final weighted difference molecular scattering intensities are shown in Fig. 2, and the radial distribution curve in Fig. 3.

Refinement of the structure of B_5H_{11}

The numbering of atoms is shown in Fig. 1(b).

The boron framework. This structure was defined by five parameters—the mean nearest neighbour B—B interatomic distance, the difference of the average interatomic distance between neighbouring basal boron atoms from the average of those between base and apex, the difference between distances B(1)—B(2) and B(1)—B(3), the difference between B(3)—B(4) and B(2)—B(3), and the angle at the apex of the open face, ∠B(2)B(1)B(5). In all refinements the mean B—B distance was close to

Table 5. Atomic coordinates (pm)

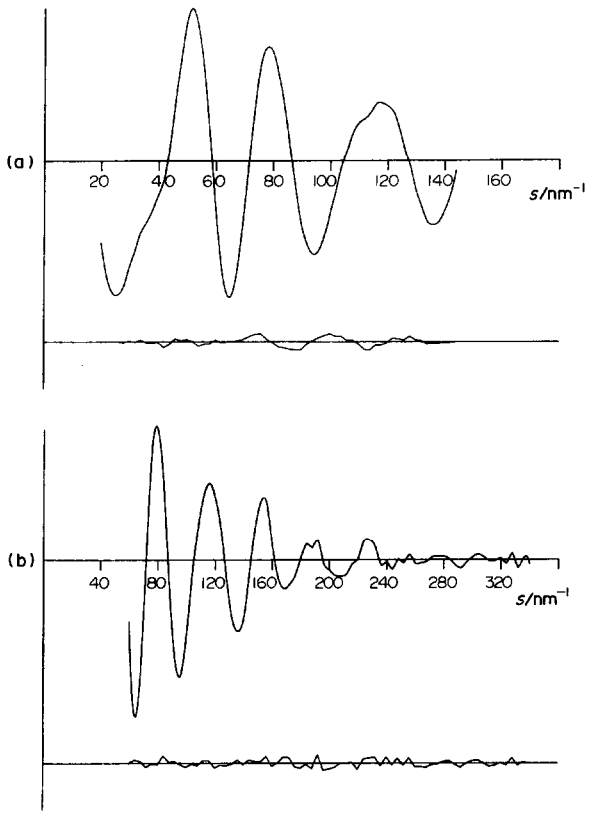

Fig. 2. Observed and final weighted difference molecular scattering intensities for B_5H_9 at nozzle-to-plate distances of (a) 285 and (b) 128 mm.

179 pm, and the angle B(2)B(1)B(5) was around 109°. The interatomic distances B(1)—B(2) were always substantially longer than for B(1)—B(3) so the apical boron atom is displaced away from the open edge of the base. The interatomic distances around the base were consistently shorter than those to the apex, but the difference varied, depending on the refinement conditions. In all the best refinements the difference was around −4 or −5 pm. Similarly, the basal distance B(3)—B(4) was always less than B(2)—B(3), but here the difference varied from −2 to −9 pm, being close to −5 pm in the best refinements.

Hydrogen atoms [*not including the face-capping hydrogen*, $H(1)_{endo}$]. It was assumed that all terminal B—H distances were equal. The B(3)H(3,4)B(4) bridge was assumed to be symmetrical, with bonds equal in length to the mean of all the bridge bond lengths. The other bridges, B(2)H(2,3)B(3) and B(5)H(4,5)B(4) were asymmetric, with the bonds B(2)—H(2,3) and B(5)—H(4,5) longer than the mean, and the other bonds shorter than the mean by an equal amount. The positions of hydrogen atoms were then defined by the following angle parameters:

$H(1)_{exo}$ "tilt"-angle between B(1)—$H(1)_{exo}$ bond and z axis (defined as perpendicular to plane of basal boron atoms). A positive tilt is towards the open face of the cluster.

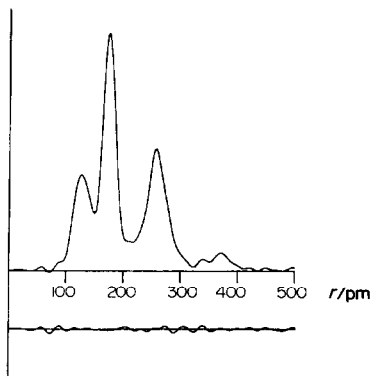

Fig. 3. Observed and final difference radial distribution curves, $P(r)/r$, for B_5H_9. Before Fourier inversion the data were multiplied by $s\exp[-0.00002s^2/(Z_B-f_B)(Z_H-f_H)]$.

$H(2)_{exo}$"dip"-angle of B(2)—$H(2)_{exo}$ bond below base plane.
$H(2)_{exo}$"wag"-angle between projection of B(2)—$H(2)_{exo}$ bond in base plane and x axis [defined as parallel to B(2)...B(5)].
$H(2)_{endo}$"dip" and "wag"—defined as for $H(2)_{exo}$.
H(3)"dip"-angle defined as for $H(2)_{exo}$. The projection of the bond B(3)—H(3) was assumed to bisect the angle B(2)B(3)B(4).
H(2,3)"dip"-angle of B(2)H(2,3)B(3) below base plane.
H(3,4)"dip"—defined as for H(2,3).

The two B—H interatomic distances both refined consistently, and their values did not change significantly during the whole series of refinements. All the other angles were refined at some time, but only four of the eight could be included in the final refinement. Quoted errors are therefore probably under-estimates. The difference between the lengths of the bridging B—H bonds and the mean was not refined, but was fixed at various values between 0 and 6 pm. The best fit to the data was found with it set at 6 pm, which corresponds to the value reported for the solid phase structure.[2(a),3]

The face-capping hydrogen $H(1)_{endo}$. Tests on the position of the anomalous hydrogen atom $H(1)_{endo}$ bound to B(1) were carried out with all positional parameters for terminal hydrogens $H(1)_{exo}$, $H(2/5)_{exo}$, $H(2/5)_{endo}$ and H(3/4) fixed, except for the mean B—H(terminal) bond length. The position of $H(1)_{endo}$ was defined by three parameters, B(1)—$H(1)_{endo}$, the angle between this bond and the z axis, which is perpendicular to the plane of the basal boron atoms, and a wag angle, which represented displacement of this bond from the mirror plane. With B(1)—$H(1)_{endo}$ fixed at 126 pm and the wag set at 5°, the remaining angle [called $H(1)_{endo}$ tilt] was refined to 116.7(26)° indicating that the hydrogen atom did indeed lie over the open face of the boron cluster. The distances B(2)...$H(1)_{endo}$ and B(5)...$H(1)_{endo}$ were 161 and 179 pm. Refinements with the wag angle fixed at various values between 0 and 20° showed a minimum R factor at about 8°, and this angle was then allowed to refine to 8.7(31)°. The tilt angle decreased systematically as the wag increased, and when both angles were refined the tilt went to 111.3(44)°. With this structure the distances B(2)...$H(1)_{endo}$ and B(5)...$H(1)_{endo}$ were 159 and 190 pm. Finally, the B(1)—$H(1)_{endo}$ distance was also allowed to refine, to 132(10) pm, and under these conditions the tilt and wag angles were 113.0(67) and 8.1(36)° respectively, and the B(2)...$H(1)_{endo}$ and B(5)...$H(1)_{endo}$ distances were 159(4) and 190(10) pm.

The parameters, interatomic distances and amplitudes of vibration obtained in the final refinement, for which R_G was 0.063, are given in Tables 6 and 7, and the least-squares correlation matrix is listed in Table 3(b). This last table shows substantial correlations between refining parameters, and it must be realized that correlations with fixed parameters

would increase these values further. Atomic coordinates listed in Table 5(b) enable bond angles to be calculated. Molecular scattering intensities are shown in Fig. 4 and the radial distribution curve in Fig. 5.

GENERAL CONCLUSIONS

The main results of the present structural determinations of gaseous pentaborane(9) and pentaborane(11), based on electron-diffraction data, are compared in Tables 8 and 9 with those derived from various other methods. The interatomic distances for B_5H_9 are seen to correspond well with the earlier electron diffraction results, but are now defined with considerably improved precision and agree to within 1% with the microwave data. The unusually large value observed for the amplitude of vibration of the directly-bonded B—H(bridge) pairs is worthy of comment, but unfortunately we are unable to say whether this is a real effect or whether the structure is of lower symmetry than expected. The rotational spectrum[10c] indicated that the molecule must have some low-frequency mode, but the rotation constants themselves are insensitive to a distortion of a_2 symmetry.

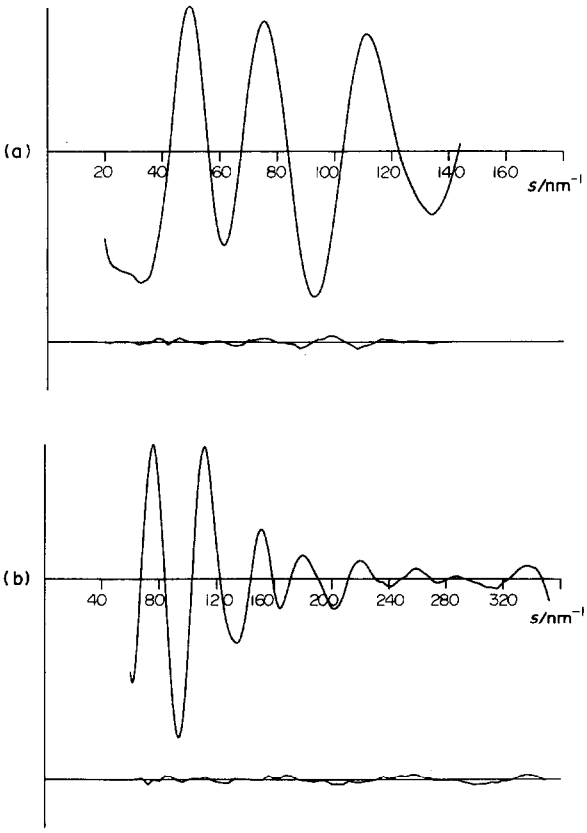

Fig. 4. Observed and final weighted difference molecular scattering intensity curves for B_5H_{11} at nozzle-to-plate distances of (a) 286 and (b) 128 mm.

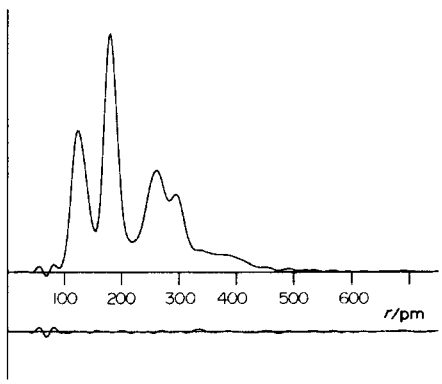

Fig. 5. Observed and final difference radial distribution curves, $P(r)/r$, for B_5H_{11}. Before Fourier transformation the data were multiplied by $s\exp[-0.00002s^2/(Z_B-f_B)(Z_H-f_H)]$.

In the case of B_5H_{11} the structure of the boron framework is marked by the length of the interatomic distances to the boron atoms at the open edge. For all reasonable positions of hydrogen atoms the parameters relating to the cluster vary little, and its structure is well determined. The interatomic distances are close to those reported for the compound in the crystalline phase,[2a,3] except that B(3)—B(4) is apparently shorter in the gas phase. Admittedly the interatomic distances B(2)—B(3) and B(4)—B(5) have been held equal in the present

[a] Distances in pm. Estimated standard deviations are given in parentheses where values are available. [b] Ref. 3. [c] Ref. 4. Complete optimization at 3-21G level assuming C_1 symmetry. [d] Boron framework fixed to experimental dimensions in Ref. 3. [e] This work; the interatomic distances were constrained to be equal as indicated. [f] Refined to 132(10) pm, but fixed in final refinement, see text. [g] B(3)—H(3,4)—B(4) bridge assumed to be symmetrical.

study, but it is unlikely that this alone is responsible for the observed effect on B(3)—B(4).

The asymmetrical nature of the B(2)—H(2,3)—B(3) and B(5)—H(4,5)—B(4) bridges in gaseous B_5H_{11} has been confirmed. In the present study the best fit to the data was found when the difference between the two halves of the bridge was set at the value reported for the solid phase structure,[2a,3] i.e. 12 pm, leading to values of 139.4(7) and 127.4(7) pm. The average B—H bridge distance is of course substantially longer than is found by X-ray diffraction, as we are looking at nuclear positions and not at centres of electron density. Unsymmetrical B—H—B bridges are a common feature of many polyhedral boranes, including for example B_3H_7CO,[18] B_4H_{10},[19] B_6H_{10},[3] $B_6H_{10}(PPh_3)_2$,[20] and $B_{10}H_{14}$.[21]

As regards the position of the face-capping hydrogen atom H(1)$_{endo}$, the results are to some extent inconclusive. There is no doubt that the best fit to the data has been obtained with an asymmetric structure, but the improvements observed on relaxing the symmetry requirement were not so great that the symmetric structure can be entirely ruled out. The evidence that H(1)$_{endo}$ lies over the open face B(2)B(1)B(5) is fairly strong—the angle of tilt has at no time had an uncertainty of more than 9°. The effect of fixing the parameters relating to other hydrogen atoms and many amplitudes of vibration on the quoted errors cannot be determined but must be substantial. All we can say therefore is that the hydrogen atom may well be asymmetrically located above the B(2)B(1)B(5) face, the best fit being obtained when the distances B(2)...H(1)$_{endo}$ and

B(5)...H(1)$_{endo}$ are 159(4) and 190(10) respectively, the difference of 31 pm being 2.2 times the sum of the estimated errors.

Abstract—The title complex $[RuCl(CO)(PPh_3)_2(S_2CH)](thf)$ has been prepared by the insertion of carbon disulphide into the Ru—H bond of $[RuHClCO(PPh_3)_2(4\text{-Vp})]$ followed by crystallization from a mixture of benzene and thf (4-Vp = 4-vinyl pyridine). Its structure has been determined by single crystal X-ray diffraction methods. The crystals are triclinic, space group $P\bar{1}$, $z = 2$, $a = 10.042(1)$, $b = 11.216(1)$, $c = 17.772(2)$ Å, $\alpha = 99.80(1)$, $\beta = 93.26(1)$ and $\gamma = 90.86(1)°$. The structure, which has been refined to $R = 0.078$ for 4949 reflections, is a distorted octahedron.

Phosphine substitution in the complex $RuHCl(CO)(PPh_3)_3$ (I) has been reported to be carried out using phosphites, phosphonites and phosphinites.[1] Recently we reported the synthesis of monosubstitution products of the complex (I) using nitrogen heterocyclics.[2] The 4-vinylpyridine ruthenium(II) complex $RuHCl(CO)(PPh_3)_2(4\text{-Vp})$ (II) reacts with a variety of bidentate chelating ligands containing potential hydroxyl groups in the presence of a base to give chelated ruthenium complexes having O—O coordination with the elimination of chlorine and 4-vinyl pyridine.[3] Activated olefins can readily be inserted into the Ru—H bond in the complex (II) to yield insertion products.[4] We have extended this reaction by the synthesis of a dithioformate complex of Ru(II) using carbon disulphide.

EXPERIMENTAL

Reactions were carried out in a dry, oxygen-free nitrogen atmosphere, using dried, freshly distilled and degassed solvents.

(a) *Carbonylchlorohydridobis (triphenylphosphine) (4-vinylpyridine)ruthenium(II)*

Freshly distilled 4-vinyl pyridine (0.84 g; 8 mmol) was added to a suspension of $RuHCl(CO)(PPh_3)_3$ (0.95 g; 1 mmol) in thf (50 cm^3) in a Schlenk tube. The solution was stirred at 25° for 20 h to yield a white solid. This was filtered through a sintered disc, washed with thf and dried at 60° at 1 mm pressure, m.p. 199°C. Yield 0.62 g (78%). Found: C, 66.3; H, 4.9; P, 8.0. Calc. for $C_{44}H_{38}ClNOP_2Ru$: C, 66.4; H, 4.8; P, 7.8.

(b) *Carbonylchlorobis (triphenylphosphine) dithioformatoruthenium(II)*

To a suspension of $RuHCl(CO)(PPh_3)_2(4\text{-Vp})$ (0.20 g; 0.25 mmol) in benzene (25 cm^3) was added carbon disulphide (5 cm^3). The contents turned brown in 2 h and were kept at room temperature for 24 h. The yellow crystals separated were filtered and dried at 60°C at 1 mm pressure for 2 h. M.p. 223°C. Found: C, 59.5; H, 4.1; P, 8.0. Calc. for $C_{38}H_{31}ClOP_2S_2Ru$: C, 59.5; H, 4.1; P, 8.1. A portion of the product was crystallized from a benzene–

* NCL Communication No. 4028.

† Author to whom correspondence should be addressed.

thf mixture (90 : 10, vol./vol.) to get crystals for X-ray studies.

(c) *X-ray studies*

A crystal of dimension $0.7 \times 0.35 \times 0.17$ mm was used for data collection. Formula weight 838.37, triclinic, $P\bar{1}$; $a = 10.042(1)$, $b = 11.216(1)$, $c = 17.772(2)$ Å, $\alpha = 99.80(1)$, $\beta = 93.26(1)$, $\gamma = 90.96(1)°$ and $V = 1968.6$ Å^3; $z = 2$, density (by flotation) 1.412 g/cm^3 (calc. 1.414 g/cm^3), μ(Mo–K$_\alpha$) = 6.76 cm^{-1}, $F(000) = 860$.

Intensity data were collected on an Enraf Nonius CAD 4F-11M diffractometer using the $\omega/2\theta$ scan technique with Mo–K$_\alpha$ ($\lambda = 0.7107$ Å, graphite monochromated) radiation. Cell dimensions were taken from 20 reflections ($32 \leqslant 2\theta \leqslant 39°$). A total of 6438 reflections ($\theta < 23.5°$) were collected with three standard reflections measured every 1000 s. The variations in these standard reflections were within 3%. A total of 4949 reflections with $|F_o| \leqslant 3\sigma|F_o|$ were used in the final refinement of structural parameters. The structure was solved using a modified[5] MULTAN 78[6] package. The crystallographic numbering of the atoms is shown in Fig. 1.

Full-matrix least squares refinement[7] of scale, positional, anisotropic thermal parameters for Ru, S, P and Cl atoms, and isotropic thermal parameters for the rest of the non-hydrogen atoms (hydrogen atoms were geometrically fixed and were not refined) gave an R value of 0.078. A final difference Fourier map was featureless. Atomic scattering factors used were from the International Tables for X-ray Crystallography.[8] Lists of observed and calculated structure factors, final positional and equivalent temperature factors for all non-hydrogen atoms, atomic coordinates for hydrogen atoms and anisotropic thermal parameters have been deposited with the Editor. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The complex [RuHCl(CO)(PPh$_3$)$_2$(4-Vp)] reacts with carbon disulphide in benzene at an ambient temperature to yield the insertion product as an air-stable yellow crystalline solid with the elimination of 4-vinyl pyridine. Upon crystallization from benzene–thf mixture, one molecule of tetrahydrofuran is retained in the crystal as seen by X-ray diffraction studies but it can be removed by heating the crystals at 60°C at 1 mm pressure. The thf-free sample was used for spectral studies. This yellow product shows IR absorption bands in the carbonyl region at 1945 cm^{-1} characteristic of a terminal carbonyl group. The bands at 1235 and 930 cm^{-1} are attributable to δ(HCS) and ν_{as}(CS$_2$) respectively, which suggest the presence of a chelated dithio ligand.[9,10]

^{1}H NMR spectrum comprises of a triplet at δ 11.88, ^{4}J(PH) ~ 8 Hz due to the coupling of dithioformate proton (S$_2$CH) with *trans* phosphorus nuclei.

Crystal structure of [C$_{42}$H$_{39}$ClO$_2$P$_2$S$_2$Ru]

A perspective view of the molecule is given in Fig. 2. Table 1 gives interatomic bond distances and bond angles along with e.s.d.'s in parentheses. The molecule has a distorted octahedral coordination around the ruthenium atom. The two sulphur atoms are *cis* with respect to each other which enables chelation with the metal atom, thereby closing a four membered ring. The two triphenylphosphine groups are also *cis* to each other while the carbonyl group is *trans* to the chlorine atom. The bite angle of the dithioformate group is 70.5° and is nearly equal to that in bis(dithioformato)-bis(triphenylphosphine)ruthenium(II) (71°).[11] There is a delocalization in the HCS$_2$ ligand [C(1)—S(1) = C(1)—S(2) = 1.67(1) Å]. Similar delocalization is found in the rhenium complex[12] Re(CO)$_2$(HCS$_2$)$_2$(PPh$_3$)$_2$, in Pd(S$_2$CPh)$_2$ and its nickel analogue.[13]

P(1)—Ru—P(2)	105.9(1)
P(1)—Ru—C(2)	87.8(5)
P(2)—Ru—C(2)	96.7(5)
Ru—S(1)—C(1)	86.9(5)
Ru—S(2)—C(1)	87.6(5)
S(1)—C(1)—S(2)	115.0(10)

The distances of all coordinating atoms are normal. However, the C(2)—O(1) is too short (0.76 Å). A strikingly similar value is seen in the structure of *trans*-carbonylbis(triphenylphosphine)rhodium(I) chloride.[14] The difference Fourier map does not indicate any disorder in this region and also the temperature factor associated with this oxygen atom is normal. The crystal structure has a molecule of tetrahydrofuran (thf) of crystallization and there are no significant interactions of this moiety with the structure. The thermal vibrations associated with the thf molecule are large; however the bond lengths and the bond angles are about normal. The crystal structure is stabilized by van der Waal's interactions.

STUDY OF CATION EFFECTS ON INORGANIC CYCLOPHOSPHATES HYDROLYSIS IN AQUEOUS SOLUTIONS

GENICHIRO KURA

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41, Japan

(*Received* 26 *January* 1987; *accepted* 27 *April* 1987)

Abstract—The ionic strength dependence of cyclophosphates hydrolysis rates was investigated at constant acid concentration. The rates decreased with the increase in the ionic strength, and hence the degree of association of cyclophosphate anions with hydrogen ions strongly affects the hydrolysis rates. In alkaline solutions, the hydrolysis rates for each phosphate decrease in the order: LiOH > NaOH > KOH > $N(CH_3)_4OH$. When copper(II) ion of concentration 5×10^{-3} M was added, the hydrolysis rates of the phosphates were accelarated. The "metaphosphate abstraction" was briefly discussed.

Of the inorganic condensed phosphates, the cyclic phosphates containing P—O—P bonds are very interesting and useful electrolytes, having multivalent anionic charge on their comparatively compact molecules, (e.g. $P_3O_9^{3-}$, $P_4O_{12}^{4-}$, $P_6O_{18}^{6-}$ and $P_8O_{24}^{8-}$).[1] We have extensively studied various chemical properties of these phosphates.[2–14] The present study was undertaken to understand the cation effects on the hydrolysis of the cyclophosphates in acidic, neutral and alkaline conditions. These cyclophosphates are very stable in neutral aqueous solution even if they are boiled for up to one hour provided a large amount of cation is not present. However, it has been elucidated by our previous study that in acidic solutions the hydrolysis rates of cyclophosphates increase rapidly.[11,13] The cyclophosphate ions are not so strong as a Brønsted base, however, the interactions between the phosphate ions and hydrogen ions were observed at higher H^+ concentrations.[5] This is considered to be the main reason to accelerate the hydrolysis reaction. In this study, the ionic strength dependence of the hydrolysis rate at a constant hydrogen ion concentration was determined and it is verified that the bond formation between the phosphate ions and H^+ is the major factor to catalyze the hydrolysis rates. As a supporting electrolyte to keep the ionic strength at a constant, tetramethylammonium chloride was used.

In alkaline solutions, the hydrolysis rates are affected not only by the hydroxide concentration but by the presence of other cations. Great discrepancies in the rates were observed when NaOH or $N(CH_3)_4OH$ was used as an alkali.[14] In $N(CH_3)_4OH$ solution, the hydrolysis rates of cyclophosphates decrease with the increase in the polymerization degree. The reverse tendency was found for the hydrolysis of linear phosphates.[15] In the present study, LiOH and KOH were used as the alkali to investigate the effect of Li^+ and K^+ on the cyclophosphate hydrolysis. By comparing the results in $N(CH_3)_4OH$ and NaOH with those in LiOH and KOH, the hydrolysis rates in the LiOH solution were shown to be fastest for each cyclophosphate. This explains the strongest interactions of Li^+ ion with cyclophosphate anions and the interactions might facilitate the nucleophilic attack of the OH^- ion on the P atom.

Cyclophosphate anions have such high negative charges on their compact molecules that they form complexes (or ion-pairs) with various cations and the stability constants of some complexes have been determined.[3–5,7,12] The effect of copper(II) ion on the cyclophosphate hydrolysis at pH 5 was investigated. At this pH, the hydrolysis of copper(II) and cyclophosphate ions are negligible. The hydrolysis rates were accelerated by the addition of copper(II) ion. This might be due to the complex formation of the copper(II) ion with the cyclophosphate ions.

The hydrolysis rates of the cyclophosphate ions

thus have been affected not only by the H^+, OH^- ions but by the ionic strength and cations present.

In this paper, cyclophosphates and linear phosphates are abbreviated as P_{nm} and P_n, respectively, where n is the degree of the polymerization.

EXPERIMENTAL

Materials

Sodium salts of cyclo-tri-, cyclo-tetra-, cyclohexa- and cyclo-octaphosphates were prepared by the methods described previously.[2] As the copper(II) salt, the perchlorate was used. The other chemicals used were reagent grade and commercially available.

Analysis

Hydrolysis products were analyzed by anion-exchange chromatography. The chromatographic system consisted of a Hitachi 655 A-11 pump, a Hitachi 655-0300 reaction pump and a Hitachi 228A spectrophotometer as a detector. As an anion-exchanger, TSK gel SAX, particle sice 10 μm, was used and the column dimension was 250×4 mm I.D. The flow system is similar to that schematically represented in our previous paper[11] and the elution condition is also the same as that used previously.[11]

Details of the hydrolysis procedure have been described in a previous paper.[11]

RESULTS AND DISCUSSION

The analysis of the hydrolysis products was achieved by liquid chromatography using an anion-exchange column. As an example, the chromatograms of the hydrolysis samples were shown in Fig. 1(a) and (b). In the chromatograms, the first peaks were characterized as a mixture of linear polymers as the hydrolysis products of cyclo-octaphosphate.[11] The concentration of the parent species can be calculated from the area of its chromatogram.

Hydrolysis reactions of cyclophosphates have been known as first-order for the phosphates under various experimental conditions.[8-11] If the total concentration of the phosphates to be degraded is designated as c, the rate can be presented as

$$-\frac{dc}{dt} = k_{obs}c. \quad (1)$$

The apparent rate constant, k_{obs} was determined in each case. The hydrolysis rates of cyclophosphates are most strongly affected by the hydrogen ions and depend on its concentration.[13] The effect might be

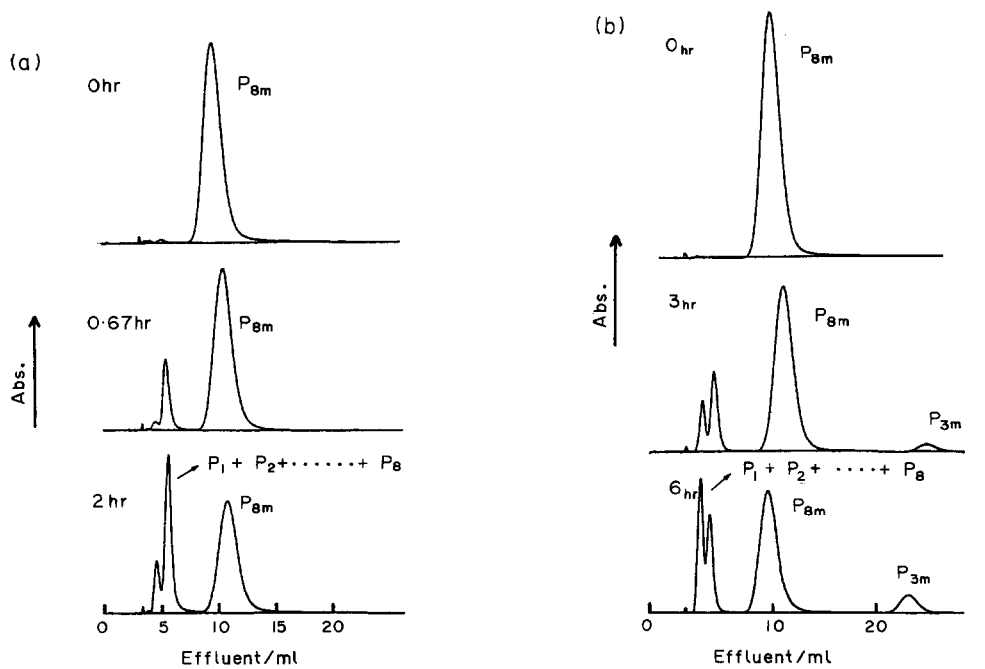

Fig. 1. Chromatograms of the hydrolysis samples of $P_8O_{24}^{8-}$ in (a) 0.75 M LiOH at 50°C and (b) 0.005 M HCl at 40°C.

due to the bonding of the hydrogen ions with PO^- on the PO_4 tetrahedra. In this study, the ionic strength dependence of the hydrolysis rates of the phosphates at a constant acid concentration was investigated to verify the above assumption. The variation of the rate constants, k_{obs}, at a hydrogen concentration of 0.05 M at 40°C, in the ionic strength range 0.05–1 were determined. The ionic strength was controlled by adding tetramethylammonium chloride as an inert electrolyte. The results obtained are shown in Table 1 and Fig. 2. The significant decrease in the k_{obs} was observed with increase in the ionic strength. For each cyclophosphate, the k_{obs} is reduced to one-half or a quarter of the initial value by changing the ionic strength from 0.05 to 1. The results correspond to the decrease in the degree of bonding of H^+ with $P_nO_{3n}^{n-}$, with the increase in the ionic strength.

As summarized above, in the acidic solution, hydrogen ions play an important role to catalyze the hydrolysis rates. In the alkaline solutions, it has been elucidated that the hydrolysis rates depend not only on the concentration of OH^- which attacks the P atoms but on the kinds and concentration of the cations present.[14] In this study, the hydrolysis rates using KOH and LiOH as an alkali were further determined. In the tetramethylammonium hydroxide solution, the hydrolysis reaction is first-order for OH^- since the rate determining step is the nucleophilic attack of OH^- on the P atom.[14] Accordingly, the rate equation can be written as

$$-\frac{dc}{dt} = k[OH^-]c \qquad (2)$$

where if

$$k[OH^-] = k_{obs} \qquad (3)$$

we can obtain the same equation as eqn (1). The $\log k_{obs}$ obtained for the hydrolysis of the cyclophosphates in 0.5 M LiOH and KOH at 50°C are shown in Fig. 3 and Table 2 with data for 0.5 M NaOH and $N(CH_3)_4OH$. This result suggests that Li^+ interacts most strongly with the cyclophosphate anions and the intensity of the interaction decreases from Na^+ to K^+. This decrease is in accord with the increase in the crystal radii of the cation. In the tetramethylammonium hydroxide solution, the cyclophosphate with the larger ring is rather stable, however, in other alkaline solutions, the hydrolysis rate of cyclo-octaphosphate begins to increase again. This tendency was observed in the case of the hydrolysis in the acidic solution.[13] The higher-membered cyclo-octaphosphate has a much larger ring structure with higher flexibility, and conse-

quently the interaction of the anions with H^+, Li^+, Na^+ or K^+ ions increases.[5,12]

When the effect of multi-valent cations on the cyclophosphates hydrolysis is investigated, the concentration of the cations is limited within the lower value to prevent the formation of a precipitate. Thus, the hydrolysis rates at the same concentration of mono- and multi-valent cations for each cyclophosphate could not be compared with each other. In this study, copper(II) ion of concentration 5×10^{-3} M was added to each cyclophosphate solution and the rates were determined. The concentration of each cyclophosphate was 2.5×10^{-3} M for cyclo-tri and cyclo-tetraphosphate, and 1.25×10^{-3} M for cyclo-hexa- and cyclo-octaphosphate. The pH of the mixed solution to be hydrolyzed was adjusted to 5.0 to prevent the formation of OH^- complexes of the copper(II) ion. At this pH, the hydrolysis rates of the four above cyclophosphates were negligibly slow[13] and the effects of hydrogen ions on the hydrolysis rates can be ignored. The rate acceleration observed is due to the copper(II) ion effect. The hydrolysis reaction under this condition were first-order for the phosphates and half-lives at 50°C for cyclo-tri-, cyclo-tetra-, cyclo-hexa- and cyclo-octaphosphates were 5.8, 68, 70 and 72 hr, respectively. The hydrolysis reaction of the phosphates is accelerated by the copper(II) ion. At higher copper(II) ion concentrations, the enhanced promotion of the hydrolysis rates might be expected.

From the chromatograms shown in Fig. 1, the following speculation is deduced. At a similar stage during the hydrolysis of cyclo-octaphosphate in acidic or alkaline solutions, cyclo-triphosphate as a side product could not be observed after the alkaline hydrolysis. On the other hand, in the case of acidic hydrolysis, an appreciable amount of cyclo-triphosphate was observed. The neutralization of the charges on the linear phosphates produced by the cyclo-octaphosphate hydrolysis with hydrogen ions might permit coiling of the linear polymers and cyclo-triphosphate is also formed by the mechanism called "metaphosphate abstraction".[15] While, at much higher pH, the coiled structure becomes difficult due to the repulsion between charges of PO^- ion on the linear phosphate chain. At even higher concentrations of LiOH, Li^+ did not catalyze the "metaphosphate abstraction". This suggests that Li^+ form looser bonds with the linear phosphate anions than the H^+ ions do. For the hydrolysis reactions studied in all the alkaline solutions "metaphosphate abstraction" was not observed.

(*Received* 27 *January* 1987; *accepted* 27 *April* 1987)

Abstract—Cu(II) complexes of 2-methoxybenzoic acid (MBH), 2,*x*-dimethoxybenzoic acids (2,*x*-DMBH; $x = 3$, 4, 5 and 6) and 3,*y*-dimethoxybenzoic acids (3,*y*-DMBH; $y = 4$ and 5) have been prepared and characterized by spectroscopic methods. They involve tetracarboxylate bridged dimeric arrangements of the copper(II) acetate monohydrate-type. The thermal decomposition of such complexes has been studied by thermogravimetric measurements and spectroscopic as well as mass spectrometric analysis of the evolved products and the intermediate residues. A mechanism which involves the shift of a CH_3 group from a ligand molecule to the carboxylic group of a second ligand, to give the methyl ester of the parent methoxy- or dimethoxy-benzoic acid, has been substantiated. Simultaneously, monomeric copper(II) complexes involving a 1 : 1 metal to ligand ratio and metal coordination by a carboxylate and a phenolate group are formed in the residues.

In the course of a study on the metal complexes formed by simple humic-like molecules, namely dihydroxy- and dimethoxy-substituted benzoic acids, we have recently reported the structure of the complexes of 2,6-dimethoxybenzoic acid with some divalent metal ions.[1–9] Dimeric arrangements of the copper(II) acetate monohydrate-type were observed for the Cu(II) compounds,[4] while polymeric aqua-bridged structures were found in the case of Mn, Co, Ni and Zn.[9]

For the latter compounds the thermal decomposition was also investigated and a mechanism leading to the formation of complexes of 2-hydroxy-*o*-anisic acid, in the 1 : 1 metal to ligand molar ratio, plus methyl 2,6-dimethoxybenzoate was substantiated.[3]

We report here the synthesis and the spectroscopic characterization of the Cu(II) complexes formed by 2-methoxybenzoic, 2,*x*- and 3,*y*-dimethoxybenzoic acids ($x = 3$, 4 or 5; $y = 4$ or 5), together with a thermal study on these complexes and on the previously described Cu(II)–dimethoxybenzoates.

EXPERIMENTAL

Materials

The acids, purchased from Fluka, were twice recrystallized from water or aqueous ethanol and dried *in vacuo*. Copper(II) acetate monohydrate (Carlo Erba) was the metal source.

Preparation of complexes

The preparation methods were similar for all the complexes. Typically, a solution or a suspension of

[a] Calculated values in parentheses.
[b] Thermogravimetric determination.

3.2 mmol of acid in 50 cm^3 of warm water was stirred while slowly adding 50 cm^3 of an aqueous solution containing 1.6 mmol of copper(II) acetate. Microcrystalline precipitates formed rapidly or after a few hours. They were filtered, washed with warm water and air-dried. Analytical data are listed in Table 1. The $[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$ and $[Cu_2(2,6\text{-DMB})_4(H_2O)_2]$ complexes, were those described previously.[4]

Instruments

Thermogravimetric data were obtained by using a Perkin–Elmer TGS-2 apparatus in nitrogen or air atmosphere. A scanning rate of 5°C min^{-1} was employed. Chemical analyses for C and H were performed on a Perkin–Elmer 240 B elemental analyser. IR spectra were recorded on a Perkin–Elmer 683 B spectrophotometer. Electronic diffuse reflectance spectra were obtained on a Beckman Acta M IV spectrophotometer using $BaSO_4$ as the reference sample. ^1H NMR spectra were recorded on a Varian XL-200 spectrometer. ESR spectra were obtained on a Varian E 9 spectrometer at the X-band frequency. Mass spectra data were obtained on a VG Analytical 7070 EQ instrument. Acetic acid was identified by GLC analysis (Perkin–Elmer F 30 gas chromatograph; 2.3 m × 2.5 mm column packed with SP 2100 10% on Chromosorb WAW at 300°C).

Dissociation constants of ligands

The dissociation constants of the acids (except 3,5-DMBH which has a too low solubility in water) were determined by potentiometric titration in aqueous solution with 0.1 M $NaClO_4$ as the supporting electrolyte. The following pK_a values were obtained: 3.97 (MBH), 3.47 (2,3-DMBH), 4.24 (2,4-DMBH), 3.85 (2,5-DMBH), 3.40 (2,6-DMBH) and 4.26 (3,4-DMBH).

RESULTS

Spectral data

All the complexes exhibit spectral properties (Fig. 1 and Table 2) consistent with dimeric structures of the copper(II) acetate monohydrate-type, just as in the case of the structurally known 2,6-DMB derivative $[Cu_2(2,6\text{-DMB})_4(H_2O)_2]$.[4] Thus, their description needs no further comment. As is usual for such a type of complex, the slight differences between the observed solid-state spectral parameters may be attributed to minor differences in the copper(II) coordination geometry, e.g. the metal–water distances.

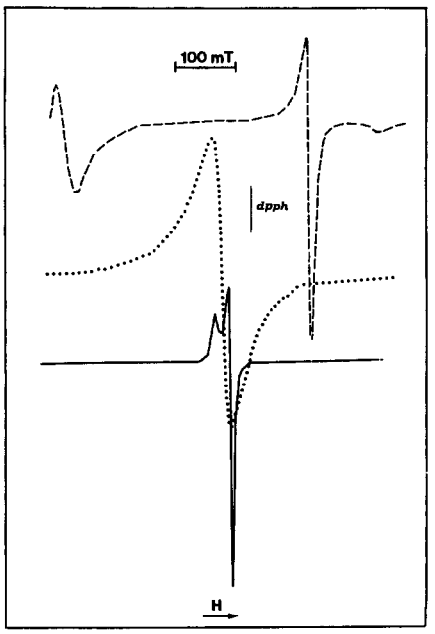

Fig. 1. X-band ESR spectra recorded at room-temperature on $[Cu_2(2,4\text{-DMB})_4(H_2O)_2]$ (– – –), $[Cu_2(2,4\text{-DMB})_4]$ (· · ·) and its intermediate residue after evolution of methyl 2,4-dimethoxybenzoate (——).

$[Cu_2(2,5\text{-DMB})_4(H_2O)_2]\cdot H_2O$	13.8	2.35	2.07	0.34	2.26		2.06
$[Cu_2(2,6\text{-DMB})_4(H_2O)_2]$	13.5	2.36	2.08	0.35	2.28	166	2.07
$[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$	14.8	2.36	2.06	0.34	2.28	166	2.07
$[Cu_2(3,4\text{-DMB})_4(H_2O)_2]\cdot 4H_2O$	13.7	2.34	2.08	0.34	2.29	167	2.07
$[Cu_2(3,5\text{-DMB})_4(H_2O)_2]\cdot 2H_2O$	14.1	2.35	2.06	0.34	2.29	167	2.07

Also the IR absorptions are typical for tetracarboxylate-bridged copper(II) complexes, the carboxylate bands falling within the expected ranges (ν_{as}: 1580–1620 cm^{-1}; ν_s: 1385–1420 cm^{-1}; $\Delta\nu$: 190–230 cm^{-1}).

Thermal data

The thermogravimetric curves of the complexes (Figs 2 and 3) show distinct steps due to the release of water and decomposition of the anhydrous compounds. The onset of the decomposition step appears to be dependent on the ring substitutions of the ligands. Namely, 2-methoxy-substituted ligands yield complexes which are substantially less stable than the other ones, thus suggesting that a methoxyl group in an *ortho*-position to the carboxylate function activates the thermal decomposition process. At first glance, however, no immediate information concerning the decomposition mechanism may be drawn from the thermogravimetric curves, which,

in most cases, apparently involve overlapping weight-losses.

Evolved products

To obviate the above lack of information, 0.5–1.0 g samples of the complexes were decomposed under static air in a round-bottomed flask kept at constant temperature (*ca.* 200°C) and fitted with a reflux condenser. Volatile products evolved during decomposition were collected along the condenser and analyzed by IR, ^{1}H NMR and mass spectrometry. In all cases (Table 3) these products were identified as the methyl esters of the ligands. For $[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$, methyl 2,6-dimethoxybenzoate and acetic acid (the latter analysed also by GLC) were the evolved products.

By examination of the thermogravimetric curves it may be observed that in some cases (2,4- and 2,5-DMB complexes) the weight-loss subsequent to dehydration corresponds well to the release of a molecule of ester. In other cases, e.g. for $[Cu_2(MB)_4(H_2O)_2]$, the change of the operative conditions (Fig. 4) allowed an almost theoretical weight-loss for a molecule of ester. This may suggest that the first decomposition step of all the complexes involves the formation of a molecule of ester, but TG weight-losses of rather complex shape can result because (i) the ester, with increasing temperature, may decompose instead of being evolved as such, or (ii) its release can overlap with subsequent decomposition steps.

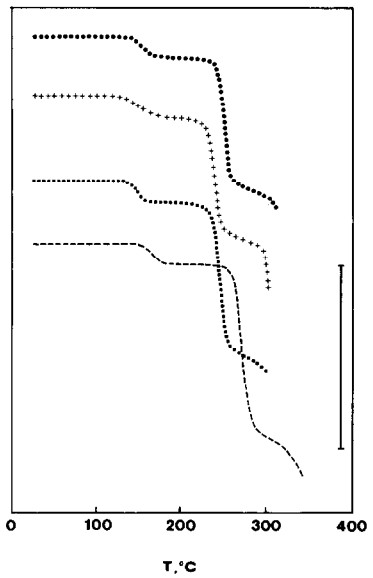

Fig. 4. Thermogravimetric curves of $[Cu_2(MB)_4(H_2O)_2]$: (● ● ●) nitrogen atmosphere, 5°C min^{-1}; (+ + +) static air, 5°C min^{-1}; (■ ■ ■) static air plus nitrogen purge, 5°C min^{-1}; (– – –) static air plus nitrogen purge, 10°C min^{-1}. The vertical bar represents the loss-weight corresponding to a molecule of methyl 2-methoxybenzoate (43.3 wt.%).

Residues

After evolution of volatile products, the residues were washed with $CHCl_3$ and dissolved in dilute aqueous HCl to separate the copper from ligands. By concentrating the solutions, the ligands were isolated and analysed by IR, ^{1}H NMR and mass spectrometry. In some cases, they were identified as pure compounds differing from the parent acid by having a phenolic function in the place of a methoxyl group (2-hydroxy-4 (or 5)-methoxybenzoic acid from 2,4- and 2,5-DMB complexes, respectively). In other cases, the precipitates were a mixture, easily distinguishable, containing the phenolic derivative and the undecomposed parent acid. In particular, the residue of $[Cu_2(MB)_4(H_2O)_2]$ gave salicylic acid, while those of $[Cu_2(2,6\text{-DMB})_4(H_2O)_2]$ and $[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$ gave 2-hydroxy-6-methoxy-benzoic acid. Finally, it was impossible to isolate the intermediate residues of 2,3-, 3,4- and 3,5-DMB complexes, due to their thermal instability, in agreement with the thermogravimetric results.

Spectral study of residues

The decomposition of the complexes was also followed by spectroscopic (reflectance absorption and ESR) methods. After evolution of esters, the residues exhibited ESR signals attributable to magnetically dilute species (Table 2 and Fig. 1). On the other hand, a band around 450 nm, which could be assigned as a phenolate oxygen to Cu(II) transition,[10] was observed in the reflectance spectra.

DISCUSSION

The result of this study are in full agreement with those found previously for the $[M(2,6\text{-DMB})_2(H_2O)_3]\cdot H_2O$ complexes (M = Mn, Co, Ni and Zn). They support the view that the thermal decomposition of complexes formed by methoxy-substituted benzoic acids proceeds through a general pathway. This involves the intermolecular shift of an ethereal methyl group from a ligand molecule to the carboxylate moiety of a second ligand. As a consequence, the former ligand is demethylated and forms a phenolate bond with the metal ion, while the latter is transformed into the corresponding methyl ester.

Support for the proposed mechanisms is given by all the experimental data:

(i) all the released esters and most of phenolic ligands, which are the primary decomposition products, have been isolated and fully characterized;

(ii) ESR and electronic spectra of all the intermediate residues after evolution of ester indicate the presence of magnetically dilute Cu(II) complexes, where the metal ion is bound to a carboxylate and a phenolate group.

The temperature over which such a process occurs is clearly dependent on the position of the substituents within the aromatic ring of the ligands. Particularly, it appears that the decomposition of complexes formed by *ortho*-substituted ligands occurs at temperatures which are substantially lower than those for the 3,4- and 3,5-DMB analogues. Therefore the formation of intermediates with a 1 : 1 metal to ligand ratio, involving chelation by phenolate and carboxylate groups in *ortho*-positions, is a factor favouring the first decomposition step.

With increasing temperature, the 1 : 1 intermediates decompose but, if this process is too near to the first decomposition step, low yields are expected when attempting to isolate the 1 : 1 intermediates. Accordingly, the maximum yield of phenolic ligands is obtained for 2,4- and 2,5-DMB complexes whose thermogravimetric curves are consistent with almost theoretical weight-losses for a decomposition occurring in two steps distinct enough to allow the isolation of 1 : 1 intermediates.

Turning to the first decomposition stage, the detection of acetic acid as a volatile product evolved by $[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$ in static air is clear evidence that the acetate is, at least in part, hydrolysed by water vapour, analogously to the findings, e.g. for nitrate.[11] Acetic acid is also evolved by heating copper(II) acetate under the same conditions (static air), also the mechanisms under nitrogen flow could be different. Therefore, the thermal behaviour of the complex $[Cu_2(2,6\text{-DMB})_2(O_2CCH_3)_2(H_2O)_2]$ may be reasonably interpreted as that of a mixture of copper(II) acetate and copper(II) 2,6-dimethoxybenzoate.

Finally, a further comment is needed on the absence of complexes involving mixed bridges (acetate and methoxy- or dimethoxy-benzoate) for all ligands except 2,6-DMB, in spite of the similar synthetic procedures used. 2,6-DMBH differs from the other ligands by having the most acidic carboxylic group and two methoxyl substituents in *ortho* positions to the carboxylic function. The pK_a value is, however, comparable to that of 2,3-DMBH. Thus, the most likely reason for the isolation of the "mixed" complex is the steric hindrance produced by the bulky *o*-methoxy substituents, which, in the presence of acetate, disfavours the formation of a binary 2,6-DMB complex.

Acknowledgement—The authors wish to thank Mr S. Cossu for GLC analyses.

TRIFLUOROMETHANESULFONATO COMPLEXES OF (1,4,8,11-TETRAAZACYCLOTETRADECANE)COBALT(III) AND RUTHENIUM(III) WITH *TRANS* GEOMETRY

PAUL V. BERNHARDT and GEOFFREY A. LAWRANCE*

Department of Chemistry, The University of Newcastle, New South Wales 2308, Australia

(*Received* 28 *January* 1987; *accepted* 27 *April* 1987)

Abstract—Reaction of *trans*-[M(cyclam)Cl_2]Cl (M = Co, Ru; cyclam = 1,4,8,11-tetraazacyclotetradecane) with anhydrous CF_3SO_3H at elevated temperatures formed initially *trans*-[M(cyclam)Cl(OSO_2CF_3)](CF_3SO_3), with *trans*-[M(cyclam)(OSO_2CF_3)$_2$](CF_3SO_3) formed after extended reaction time. The complexes were characterized by spectroscopy, and rate constants for the rapid aquation of the bound $CF_3SO_3^-$ determined. In the case of the cobalt(III) complexes, derivatives were prepared by substitution of the $CF_3SO_3^-$ ligand by the neutral ligands acetonitrile and dimethylformamide.

The coordination chemistry of the weakly nucleophilic trifluoromethanesulfonate (triflate) anion has been well documented in recent years, since it has proved to be an excellent leaving group from a range of inert metal ions.[1,2] The lability of bound triflate is comparable to that of the perchlorate ligand; however, complexes of the former are inherently safer to handle as the triflate anion is non-oxidizing. The use of triflato complexes as precursors in inorganic chemistry has been demonstrated by the development of facile and high yielding routes to a range of previously inaccessible complexes.[2] For inert metal complexes, introduction of the triflato ligand to the coordination sphere is usually and conveniently achieved by reaction of the chloro complex with anhydrous acid (CF_3SO_3H). The elimination of hydrogen chloride drives the reaction, and yields of the triflato complexes are essentially quantitative.

Although there are a range of examples of *mono*, *bis* and even *tris* triflato complexes of octahedral metal amines, there are very few examples of stable complexes in which the triflato ligand is *trans* to any ligand other than an ammine or amine.[1,2] For cobalt(III), the only known complex is the ion *trans*-[Co(en)$_2$Cl(OSO_2CF_3)]$^+$ reported during the course of this work, and prepared by reaction of *trans*-[Co(en)$_2$Cl$_2$]$^+$ with CF_3SO_3H at −5°C for several hours.[3] Replacement of the second chloro ligand was not possible without isomerization to the *cis* isomer during reaction. Previously, reaction at elevated temperature showed *cis*-[Co(en)$_2$(OSO_2CF_3)$_2$]$^+$ to be the sole product of reaction from either *cis*- or *trans*-[Co(en)$_2$Cl$_2$]$^+$,[4] consistent with *cis* isomers being more stable in polar solvents than *trans* isomers. For *bis*(1,2-ethanediamine) complexes, it is only with the more stereoretentive Rh(III) and Ir(III) that *trans*-[M(en)$_2$Cl(OSO_2CF_3)]$^+$ complexes can be prepared at elevated temperatures.[5]

Greater structural rigidity of metal complexes can be imposed by replacing *bis*(1,2-ethanediamine) ligands by a cyclic tetraamine such as 1,4,8,11-tetraazacyclotetradecane (cyclam). There exist cyclam complexes of most transition metals, especially those in higher oxidation states stabilized by the strong ligand field of the macrocycle.[6,7] Geometric isomers of cyclam complexes exist with the preferred configuration (*cis* or *trans*) dependent on the ionic radius of the metal and the absolute configuration of the asymmetric nitrogen donor atoms. The cyclam complexes of cobalt(III) show a preference for the *trans* geometry compared with *bis*(1,2-diaminoethane) analogues, although *cis* isomers are known with both unidentate and particularly chelating ligands in the other two coordination sites.[8] This preference suggests that *trans*-dichloro(cyclam)cobalt(III) may provide a route to the first stable *trans*-chloro(triflato) and *trans*-

bis(triflato) complexes of cobalt(III). Further, although both *cis*- and *trans*-$[Ru(cyclam)Cl_2]^+$ complexes are known, the *trans* isomer is thought to be more stable,[9] and it may also yield *trans*-triflato complexes. Reaction of both of these *trans*-dichloro ions with CF_3SO_3H has been probed in this work.

EXPERIMENTAL

trans-$[Co(cyclam)Cl(OSO_2CF_3)](CF_3SO_3)$

To *trans*-$[Co(cyclam)Cl_2]Cl$[8] (3 g) in a three-necked round bottomed flask (100 cm^3) fitted with a gas bubbler was carefully added anhydrous CF_3SO_3H (8 cm^3). A stream of nitrogen was bubbled through the solution as it was warmed in an oil bath at 100°C for 90 min. The flask was then allowed to cool with the gas supply maintained. Dropwise addition of diethyl ether (70 cm^3) to the rapidly stirring solution precipitated a green solid, which was collected on a fine porosity sintered glass frit. The green powder was washed several times with diethyl ether (30 cm^3), and dried *in vacuo* (4.7 g, 96%). The product is stable indefinitely if stored in a desiccator. Found: C, 22.7; H, 3.8; N, 7.8. $C_{12}H_{24}ClCoF_6N_4O_6S_2 \cdot \frac{1}{2}CF_3SO_3H$ requires: C, 22.5; H, 3.7; N, 8.35%. Vis. spectrum (CF_3SO_3H): 630 nm (ε 22 dm^3 mol^{-1} cm^{-1}), 410 (ε 35).

trans-$[Co(cyclam)(OSO_2CF_3)_2](CF_3SO_3)$

Anhydrous CF_3SO_3H (8 cm^3) was added cautiously to *trans*-$[Co(cyclam)Cl_2]Cl$ (2 g) in a three-necked flask fitted with a gas bubbler. A gentle stream of nitrogen was passed through the solution, which was heated in an oil bath at 100°C for 50 h. The green product was precipitated with diethyl ether (70 cm^3) and isolated as above (3.5 g, 90%). Found: C, 20.1; H, 3.4; N, 6.6. $C_{13}H_{24}CoF_9N_4O_9S_3 \cdot CF_3SO_3H$ requires: C, 19.7; H, 3.0; N, 6.5%. Vis. spectrum (CF_3SO_3H): 635 nm (ε 83 dm^3 mol^{-1} cm^{-1}), 410 (ε 151).

trans-$[Co(cyclam)(NCCH_3)Cl](CF_3SO_3)_2$

A solution of *trans*-$[Co(cyclam)Cl(OSO_2CF_3)](CF_3SO_3)$ (0.5 g) in dry acetonitrile (20 cm^3) was stirred at room temperature for 2 h, then added to rapidly stirring diethyl ether (100 cm^3). The resulting oil was separated from the supernatant by decantation, the oil was dissolved in ethanol (20 cm^3) and the product precipitated as a red powder by addition of diethyl ether (100 cm^3) with stirring. The product was collected, washed with ether, and dried *in vacuo* (0.27 g, 50%). Found: C, 25.9; H, 4.1; N, 10.3. $C_{14}H_{27}ClCoF_6N_5O_6S_2 \cdot H_2O$ requires: C, 25.8; H, 4.15; N, 10.7%. ^1H NMR (D_2O): δ 2.57 ($C\underline{H}_3CN$; 2.06, free CH_3CN), 2.0–3.0 ($-C\underline{H}_2-$, multiplets). Vis. spectrum (water): 535 nm (ε 33 dm^3 mol^{-1} cm^{-1}), 420 nm (ε 48). IR spectrum (KBr disc): 2340, 2380 cm^{-1} (nitrile stretch).

trans-$[Co(cyclam)(OCH \cdot N(CH_3)_2)Cl](CF_3SO_3)_2$

A solution of *trans*-$[Co(cyclam)Cl(OSO_2CF_3)](CF_3SO_3)$ (0.5 g) in dry dimethylformamide (20 cm^3) was stirred at room temperature for 2 h, then isolated as described for the nitrile analogue. The green product (0.34 g, 60%) was dried *in vacuo*. Found: C, 25.5; H, 4.6; N, 9.5. $C_{15}H_{31}ClCoF_6N_5O_7S_2 \cdot 2H_2O$ requires; C, 25.65; H, 5.0; N, 9.9%. ^1H NMR (D_2O): δ 7.95 ($-C\underline{H}O$), 3.02, 2.87 ($-C\underline{H}_3$), 2.0–3.0 ($-C\underline{H}_2-$, multiplets). Vis. spectrum (water): 580 nm (ε 21 dm^3 mol^{-1} cm^{-1}), 410 (ε 35). IR spectrum (KBr): 1670 cm^{-1} (amide).

trans-$[Co(cyclam)(NCCH_3)_2](CF_3SO_3)_3$

A solution of *trans*-$[Co(cyclam)(OSO_2CF_3)_2](CF_3SO_3) \cdot CF_3SO_3H$ (0.5 g) was dissolved in dry acetonitrile (20 cm^3) and stirred for 4 h at room temperature. The product was isolated by addition of diethyl ether (100 cm^3), as an oil. After decanting the ether solution, the oil was dissolved in ethanol (10 cm^3) and added with vigorous stirring to diethyl ether (100 cm^3). The orange powder precipitated was collected, washed with ether, and dried *in vacuo* (0.31 g, 60%). Found: C, 23.6; H, 3.9; N, 8.8. $C_{17}H_{30}CoF_9N_6O_9S_3 \cdot C_2H_5OH \cdot HOSO_2CF_3$ requires: C, 23.2; H, 3.8; N, 8.55%. The product may be recrystallized as a perchlorate, but was (apart from detected ethanol) pure by NMR measurement. ^1H NMR (D_2O): δ 2.57 ($C\underline{H}_3CN$), 2.0–3.0 ($-C\underline{H}_2-$, multiplets). Vis. spectrum (water): 495 nm (ε 86 dm^3 mol^{-1} cm^{-1}), 405 (ε 125). IR spectrum (KBr): 2320 cm^{-1} (nitrile stretch).

trans-$[Co(cyclam)(OCH \cdot N(CH_3)_2)_2](CF_3SO_3)_3$

A solution of *trans*-$[Co(cyclam)(OSO_2CF_3)_2](CF_3SO_3)$ (0.5 g) was dissolved in dimethylformamide (20 cm^3) and stirred at room temperature for 4 h. The green product was isolated as described for the acetonitrile analogue, and dried *in vacuo* (0.39 g, 65%). Found: C, 26.9; H, 4.5; N, 9.8. $C_{19}H_{38}CoF_9N_6O_{11}S_3$ requires: C, 26.75; H, 4.5; N, 9.85%. ^1H NMR (D_2O): δ 7.95 ($-C\underline{H}O$), 3.01, 2.85 ($C\underline{H}_3-$), 2.0–3.0 ($-C\underline{H}_2-$, multiplets). Vis.

spectrum (water): 535 nm (ε 53 $dm^3\ mol^{-1}\ cm^{-1}$), 410 (ε 87). IR spectrum (KBr): 1670 cm^{-1} (amide).

trans-[Ru(cyclam)Cl(OSO_2CF_3)](CF_3SO_3)

To *trans*-[Ru(cyclam)Cl_2]Cl[9] (2.0 g) in a three-necked round bottomed flask fitted with a gas bubbler was added anhydrous CF_3SO_3H (6 cm^3). A stream of nitrogen was passed through the solution, which was heated in an oil bath at 100°C for 2 h. After the mixture had been allowed to cool, the nitrogen flow was disconnected and precipitation of the product was achieved by careful addition of diethyl ether (50 cm^3) with vigorous stirring. The brown solid was collected, washed several times with diethyl ether, and dried in a vacuum desiccator (2.95 g, 95%). The product was stable if stored in a desiccator in the dark. Found: C, 21.1; H, 3.5; N, 7.9. $C_{12}H_{24}ClF_6N_4O_6S_2Ru$ requires: C, 21.6; H, 3.6; N, 8.4%. Vis. spectrum (CF_3SO_3H): 370 nm (ε 1520 $dm^3\ mol^{-1}\ cm^{-1}$).

trans-[Ru(cyclam)(OSO_2CF_3)$_2$](CF_3SO_3)

A solution of *trans*-[Ru(cyclam)Cl_2]Cl (2.0 g) in CF_3SO_3H (6 cm^3) was reacted at 100°C for 24 h under nitrogen. It was isolated as described above for the other ruthenium complex (3.3 g, 90%). Found: C, 19.9; H, 3.5; N, 7.1. $C_{13}H_{24}F_9N_4O_9S_3Ru \cdot 2H_2O$ requires: C, 20.0; H, 3.6; N, 7.1%. To permit accurate analysis of this moisture-sensitive compound, it was hydrated and analyzed as the aqua complex; all other triflato compounds were analyzed as isolated.

Physical methods

Electronic spectra were recorded using a Hitachi 220A spectrophotometer, while infrared spectra were recorded with the complexes dispersed in KBr discs on a Nicolet MX-1 fourier-transform infrared spectrometer. Proton magnetic resonance spectra of complexes dissolved in D_2O were recorded using a Jeol FX-90Q spectrometer. Rates of hydrolysis of triflato complexes were determined from absorbance–time responses determined spectrophotometrically, using standard computational methods.

RESULTS AND DISCUSSION

The facile and high yielding synthesis of triflato complexes from chloro precursors developed earlier[1–5] has been applied successfully to the synthesis of *trans*-chloro(triflato) and *trans-bis*(triflato) complexes of (cyclam)cobalt(III) and ruthenium(III). The *trans-bis*(triflato) complexes are the first reported for any complex, *cis* stereochemistry being common.[1] Spectroscopic evidence detailed later defines the *trans* geometry. Since synthesis and isolation is performed in strongly acidic conditions, preservation of the geometry is expected since many isomerization reactions of polyamine complexes involve deprotonation of secondary amine groups, which cannot occur under the experimental conditions employed. Although the lability of triflate forbids recrystallization, the compounds as isolated were of acceptable purity, and derivatives of microanalytical and spectroscopic purity were prepared directly from the triflato precursors. The lability of the triflato ligand was demonstrated by the ready substitution by acetonitrile (AN), *N*,*N*-dimethylformamide (DMF) and even acetone at room temperature.

It was apparent from the electronic spectra of both triflatocobalt(III) precursors and their derivatives that *trans* geometry was maintained. A striking feature of the spectra was the large splitting of the octahedral $^1T_1$ state under the tetragonal field to give a ^1E and a $^1A_2$ state with the former of lower energy. Transitions (from a $^1A_1$ ground state) to these states occurred in the visible region; the ultraviolet region was dominated by intense bands due to charge transfer or intra-ligand transitions which masked the other *d–d* transition to the $^1T_2$ state. The two bands in the visible region (see Experimental) converged with increasing strength of the *trans* ligand. Spectra of triflato complexes were recorded in anhydrous CF_3SO_3H, since variation in the spectra in dry acetone indicates that even that weak ligand may displace triflate, as previously observed.[4] Observed spectra are consistent with the earlier location of $CF_3SO_3^-$ near Cl^- in the spectrochemical series,[5] since maxima for *trans*-dichloro (625, 420 nm), *trans*-chloro(triflato) (630, 410 nm) and *trans-bis*(triflato) (635, 410 nm) are similar. Substitution of $CF_3SO_3^-$ by DMF or AN causes significant shifts of the low energy maxima to higher energy, as expected.

The low frequency infrared spectra of the triflato complexes displayed evidence for coordinated as well as ionic triflate. The spectrum of ionic triflate has been studied in detail[1,10] and by comparison with the spectrum of the cobalt triflate complexes assignments to coordinated triflate were possible. One obvious difference was the appearance of a peak at 655 cm^{-1}, adjacent to the resonance of ionic triflate at 640 cm^{-1}. This higher energy peak, which was more intense in the *bis*(triflato) complex, disappeared on substitution of the triflato ligands by both DMF and AN. Earlier, it has been noted that the band at 1280 cm^{-1} for ionic triflate is shifted

approximately 100 cm^{-1} higher in energy on coordination.[4]

The IR absorption frequencies associated with the cyclam ligand are essentially invariant for all complexes of cobalt(III), consistent with retention of geometry. For derivatives, characteristic vibrations of carbonyl or nitrile groups were observed also. For the ruthenium(III) complexes, the region from 800 to 1000 cm^{-1} is useful for identifying *cis* and *trans* cyclam complexes.[11] The bands in this region, assigned to methylene group rocking, differ significantly, with a doublet near 890 cm^{-1} and a singlet at 805 cm^{-1} being indicative of *trans* geometry. The *cis* dichloro isomer shows a more complicated series of bands which are mutually exclusive with those in the *trans* complex. The spectra of the triflato complexes showed bands common with those of the *trans* dichloro complex, consistent with retention of geometry throughout.

The lability of the triflato ligand was quantified by measurement of rates of aquation for complexes. The chloro(triflato)cobalt(III) complex hydrolyzes rapidly under acidic conditions ($k_{obs} = 0.048$ s^{-1}, 25°C, 0.1 mol dm^{-3} H^+) to the *trans*-aqua chloro complex; further reactions are slow, and were not pursued. This rate constant is similar to that reported for the simple $[Co(NH_3)_5(OSO_2CF_3)]^{2+}$ ion (0.024 s^{-1}, 25°C). The chloro(triflato)ruthenium(III) also aquates rapidly ($k_{obs} = 0.060$ s^{-1}, 25°C, 0.1 mol dm^{-3} H^+), again with a rate constant similar to that reported for $[Ru(NH_3)_5(OSO_2CF_3)]^{2+}$ (0.093 s^{-1}, 25°C). The *bis*(triflato) cobalt(III) complex displayed two successive relatively fast aquation processes ($k_1 = 0.038$ s^{-1}, $k_2 = 0.0017$ s^{-1}, 25°C, 0.1 mol dm^{-3} H^+) assigned to successive hydrolyses of triflato ligands. Notably, the aquation rate constant for $[Co(cyclam)Cl(OSO_2CF_3)]^+$ is very close to that for $[Co(cyclam)(OSO_2CF_3)_2]^+$ (0.048 s^{-1} vs 0.019 s^{-1}, dividing the latter by two for statistical correction), indicating that the *trans* labilizing influence of $CF_3SO_3^-$ is not a lot less than that of Cl^-. Further, aquation of the *trans*-aqua(triflato) intermediate is approximately twenty times slower than aquation of the *trans*-chloro(triflato) complex, which may be related to the greater *trans* labilizing effect of chloro compared with aqua ligand. The lability of coordinated triflate observed in these complexes is consistent with general observations.[1]

The lability of coordinated triflate permitted ready substitution by coordinating solvents, with the O-donor DMF and the N-donor AN introduced into the coordination sphere of the cobalt(III) systems to illustrate the process. Products isolated in high yield were microanalytically pure, and exhibited characteristic electronic and infrared spectra. Further, proton NMR spectra in D_2O defined coordination clearly. For all derivatives a series of multiplets associated with the cyclam ligand were seen in the region 2.0–3.0 p.p.m., comparable with known *trans*-cyclam complexes. Coordinated AN was apparent from the appearance of a singlet from the methyl of AN in both chloro(acetonitrile) and *bis*(acetonitrile) complexes at 2.57 p.p.m., shifted substantially from the resonance for free AN in the same solvent at 2.06 p.p.m. Both *mono* and *bis* DMF complexes exhibited signals at 3.02 and 2.87 p.p.m., from the two non-equivalent methyl groups on the DMF ligand, as well as a singlet at 7.95 p.p.m. from the amide proton, again shifted as a result of coordination.

Syntheses of labile *trans*-$[M(cyclam)(OSO_2CF_3)_2]^+$ complexes (M = Co, Ru) from dichloro precursors have been developed, and facile syntheses of derivatives demonstrated for cobalt(III) complexes. The cobalt(III) complexes are the first geometrically stable cobalt triflato complexes with *trans* geometry, and their synthesis may provide a route to previously inaccessible complexes, including polymetallic chains with bridging ligands replacing the labile triflates.

CATIONIC CARBONYL COMPLEXES OF MANGANESE(I) WITH DIPHENYLPHOSPHINE

G. A. CARRIEDO, V. RIERA,* M. L. RODRÍGUEZ and J. J. SAINZ-VELICIA

Departamento de Química Organometálica, Universidad de Oviedo, 33071 Oviedo, Spain

(*Received* 12 *March* 1987; *accepted* 27 *April* 1987)

Abstract—The cationic complexes $[Mn(CO)_{6-n}(PHPh_2)_n]ClO_4$, for $n = 1$ to 4 and $[Mn(CO)_{4-n}(L\frown L)(PHPh_2)_n]A$ ($L\frown L$ = dppm or dppe, $n = 1$, $A = ClO_4$; $L\frown L$ = bipy or phen, $n = 1$ or 2, $A = ClO_4$ or PF_6) have been prepared from $PHPh_2$ and $Mn(OClO_3)(CO)_5$ or *fac*-$MnX(CO)_3(L\frown L)$ respectively (X = Br or $OClO_3$). The *fac*-tricarbonyls *fac*-$[Mn(CO)_3(PHPh_2)_3]ClO_4$ and *fac*-$[Mn(CO)_3(L\frown L)(PHPh_2)]ClO_4$ for $L\frown L$ = dppm or dppe, isomerize upon heating to the corresponding *mer*-tricarbonyls, and the dicarbonyl *cis*-$[Mn(CO)_2(PHPh_2)_4]ClO_4$ gives the *trans* isomer under UV irradiation.

It is known that the reaction of the neutral perchlorate complex $Mn(OClO_3)(CO)_5$ with monodentate ligands (L) gives $[Mn(CO)_5L]ClO_4$ or *fac*-$[Mn(CO)_3L_3]ClO_4$, and that, in the case of the phosphites $[P(OR)_3]$, the more substituted products $[Mn(CO)_2L_4]ClO_4$ can be obtained.[1] The tetracarbonyls $[Mn(CO)_4L_2]ClO_4$ were not made from $Mn(OClO_3)(CO)_5$, but the BF_4 salts can be prepared by other routes.[2] We have found that the reaction of the secondary phosphine $PHPh_2$ with $Mn(OClO_3)(CO)_5$ leads to the cationic carbonyl complexes $[Mn(CO)_{6-n}(PHPh_2)_n]ClO_4$ for $n = 1$ to 4 by varying the reaction conditions. Herein we describe the preparation of those complexes and of the related species $[Mn(CO)_{4-n}(L\frown L)(PHPh_2)_n]A$, where for $L\frown L$ = dppm† or dppe, $n = 1$ and for $L\frown L$ = bipy or phen $n = 1$ or 2 and $A = ClO_4$ or PF_6.

EXPERIMENTAL

All reactions were carried out under dry, oxygen-free argon. The NMR spectra were recorded with a JEOL FX 90Q instrument and the IR with a Perkin–Elmer 298 spectrometer. The compounds $Mn(OClO_3)(CO)_5$,[1] *fac*-$[Mn(OClO_3)(CO)_3(L\frown L)]$ ($L\frown L$ = dppm or dppe,[9] $L\frown L$ = bipy or phen[10] were prepared by published methods.

$[Mn(CO)_5(PHPh_2)]ClO_4$ (I)

A mixture of the complex $Mn(OClO_3)(CO)_5$ (0.32 g, 1 mmol) and the phosphine $PHPh_2$ (0.19 cm^3, 1 mmol) in dichloromethane (40 cm^3), was stirred for 17 h at room temperature and evaporated almost to dryness. The residue was washed repeatedly with diethyl ether and crystallized from CH_2Cl_2: Et_2O as a pale yellow microcrystalline solid (0.45 g, 86%). The compound was stored cooled and under dry argon

cis-$[Mn(CO)_4(PHPh_2)_2]ClO_4$ (II)

A mixture of $Mn(OClO_3)(CO)_5$ (0.22 g, 0.75 mmol) and $PHPh_2$ (0.39 cm^3, 2.24 mmol) in ethanol (8 cm^3) was refluxed for 75 min and cooled to room temperature. The white crystalline precipitate was separated from the mother liquor and recrystallized from CH_2Cl_2: Et_2O (0.32 g, 67.5%). From the mother liquor a mixture of **II** and **III** was obtained by concentrating and precipitating with ether.

fac-$[Mn(CO)_3(PHPh_2)_3]ClO_4$ (III)

A solution of $Mn(OClO_3)(CO)_5$ (0.4 g, 1.36 mmol) in acetone (15 cm^3) was refluxed for 90 min and allowed to cool to room temperature. To the resulting solution of *fac*-$[Mn(CO)_3(Me_2CO)_3]ClO_4$, the phosphine $PHPh_2$ (0.85 cm^3, 4.9 mmol) was added and the mixture was stirred for 2 h at room temperature. Part of the product precipitated as a

† Throughout this paper dppm = $Ph_2PCH_2PPh_2$, dppe = $Ph_2PCH_2CH_2PPh_2$, bipy = 2,2′-bipyridine and phen = 1,10-orthophenanthroline.

white solid. Excess of diethyl ether was added and the precipitate was separated and washed with ether. Recrystallization from CH_2Cl_2: Et_2O gave white microcrystalline **III** (0.78 g, 72%).

Isomerization of **III**

The salt **III** (0.1 g, 0.125 mmol) was heated in refluxing *n*-butanol (10 cm^3) for 1 h and the resulting solution was allowed to cool to room temperature. Addition of a small amount of diethylether gave a first precipitate that was mainly the *mer* isomer (**V**), and from the mother liquor the remaining *fac*-tracarbonyl mixed with some **V** was precipitated with hexane.

cis-$[Mn(CO)_2(PHPh_2)_4]ClO_4$ (**IV**)

To a solution of **III** (0.10 g, 0.13 mmol) and $PHPh_2$ (0.1 cm^3, 0.57 mmol) in acetone (12 cm^3), freshly sublimed $ONMe_3$ (0.01 g, 0.13 mmol) was added and the mixture was stirred at room temperature for 5 h. The volatiles were removed *in vacuo* and the residue was washed with diethylether. The resulting solid was recrystallized from CH_2Cl_2: Et_2O as pale yellow microcrystals (0.06 g, 49%).

trans-$[Mn(CO)_2(PHPh_2)_4]ClO_4$ (**VI**)

A mixture of **III** (0.16 g, 0.2 mmol) and $PHPh_2$ (0.8 cm^3, 4.6 mmol) in CH_2Cl_2 (10 cm^3) was irradiated at $-15°C$ until the IR of the solution no longer showed the $\nu(CO)$ absorptions of the starting material. The solution was concentrated to *ca.* 3 cm^3 and diethylether was added to give a pale yellow microcrystalline precipitate (0.1 g, 52%) that was recrystallized from CH_2Cl_2: Et_2O.

fac-$[Mn(CO)_3(\widehat{L\ L})(PHPh_2)]ClO_4$ (**VII**)

A solution of *fac*-$Mn(OClO_3)(CO)_3(dppe)$ (0.74 g, 1.16 mmol) and $PHPh_2$ (0.36 cm^3, 2.1 mmol) in CH_2Cl_2 (40 cm^3) was stirred for 7 h. The solvent was removed *in vacuo* and the residue was washed with ether. Recrystallization from CH_2Cl_2: Et_2O gave pale yellow microcrystalline **VIIb** (0.88 g, 92.5%).

The other *fac*-tricarbonyls **VII** were similarly prepared from the corresponding *fac*-$[Mn(OClO_3)(CO)_3(\widehat{L\ L})]$ with the following reaction times and yields: $\widehat{L\ L}$ = dppm, 48 h, 61%; $\widehat{L\ L}$ = bipy, 17 h, 60% (made in acetone); $\widehat{L\ L}$ = phen, 16 h, 64% (made in acetone).

fac-$[Mn(CO)_3(bipy)(PHPh_2)]PF_6$ (**VIIe**)

A mixture of *fac*-$[MnBr(CO)_3(bipy)]$ (0.3 g, 0.8 mmol), $PHPh_2$ (0.24 cm^3, 1.38 mmol) and $TlPF_6$ (0.4 g, 1.14 mmol) in CH_2Cl_2 (15 cm^3) was stirred for 5 h at room temperature and filtered through celite. Evaporation of the solvent *in vacuo* gave an oil that was washed several times with hexane. Recrystallization from CH_2Cl_2: Et_2O gave yellow–brown microcrystalline **VIIe** (0.49 g, 98%).

Isomerization of fac-$[Mn(CO)_3(\widehat{L\ L})(PHPh_2)]ClO_4$ ($\widehat{L\ L}$ = dppm *or* dppe)

The compound *fac*-$[Mn(CO)_3(dppm)(PHPh_2)]ClO_4$ (0.5 g, 0.62 mmol) was heated in refluxing *n*-butanol (25 cm^3) for 4.5 h and the mixture was cooled to room temperature. After concentrating (*in vacuo*) to half the volume, hexane was added and the yellow precipitate was washed with hexane to give 0.42 g of *mer*-$[Mn(CO)_3(dppm)(PHPh_2)]ClO_4$ mixed with some *cis*-$[Mn(CO)_2(dppm)_2]ClO_4$.

Similarly, the dppe compound gave a mixture of the corresponding *mer*-tricarbonyl and *trans*-$[Mn(CO)_2(dppe)_2]ClO_4$.

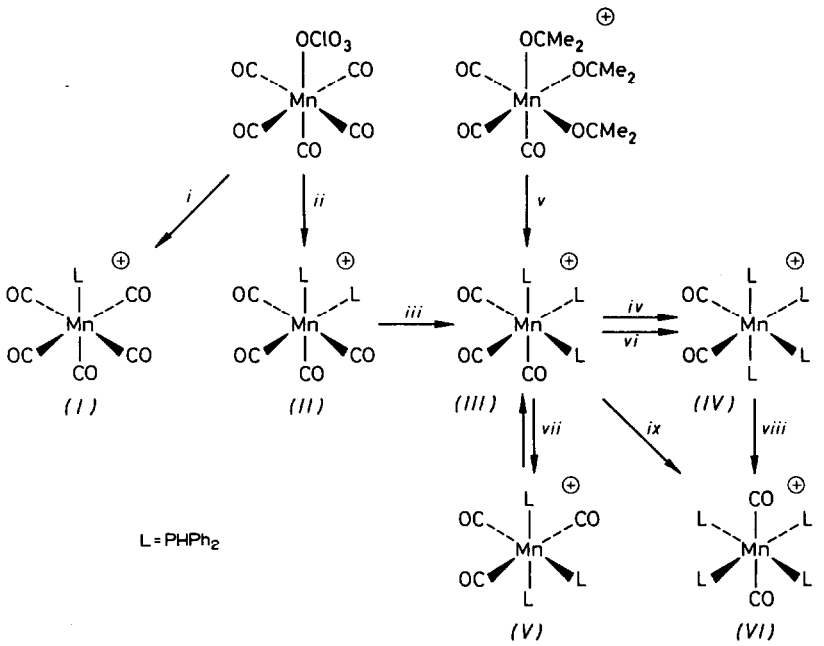
cis-trans-$[Mn(CO)_2(bipy)(PHPh_2)_2]PF_6$ (**VIII**)

A mixture of **VIIe** (0.10 g, 0.16 mmol) and $PHPh_2$ (0.05 cm^3, 0.29 mmol) in toluene (10 cm^3) was refluxed for 1 h and allowed to cool to room temperature. On standing an orange precipitate was formed that was recrystallized from CH_2Cl_2: Et_2O (0.10 g, 78%).

RESULTS AND DISCUSSION

Stirring a 1:1 molar mixture of $Mn(OClO_3)(CO)_5$ and $PHPh_2$ in CH_2Cl_2 at room temperature (i in Scheme 1) gave the cationic pentacarbonyl $[Mn(CO)_5(PHPh_2)]ClO_4$ (**I**), characterized by the data in Tables 1 and 2. This compound could be purified by precipitation with Et_2O from CH_2Cl_2 solutions under argon, but when a solution in CH_2Cl_2: EtOH (free or $PHPh_2$) was concentrated by heating at reduced pressure, it was almost quantitatively transformed into the previously known dimer $[Mn_2(CO)_8(\mu\text{-}PPh_2)_2]$[3] with concomitant formation of CO and $HClO_4$, as evidenced by the strong acidity of the mother liquor. This decomposition also occurred by heating the pure cationic pentacarbonyl **I** in ethanol and also in CH_2Cl_2 solutions in the presence of H_2O* or

* The IR spectrum of **I** in CH_2Cl_2 solution was better obtained using CaF_2 windows. On some occasions when NaCl windows were used, particularly in the presence of water vapour, the formation of the dimer was observed, probably favoured by the heat of the IR source.



Scheme 1. Key to reagents and conditions. (i) $PHPh_2$ (1 : 1) in CH_2Cl_2 at room temperature, (ii), (iii) and (iv) $PHPh_2$ (excess) in refluxing ethanol, (v) $PHPh_2$ (3 : 1) in Me_2CO at room temperature, (vi) $PHPh_2$ (excess) and $ONMe_3$ in CH_2Cl_2 at room temperature, (vii) refluxing *n*-butanol, (viii) and (ix) in CH_2Cl_2 at $-15°C$ with U.V. irradiation.

Na_2CO_3, although in the latter case the dimer was formed along with another red unidentified product. These transformations are clearly favoured by the stability of the diphenylphosphido bridged species, and by the enhanced acidity of the $PHPh_2$ ligand coordinated to the $Mn(CO)_5^+$ fragment. On the other hand, **I** reacted very quickly with Bu^n_4NBr in refluxing CH_2Cl_2 to give the known tetracarbonyl *cis*-$[MnBr(CO)_4(PHPh_2)]$,[3] indicating that one CO is labilized in the cationic pentacarbonyl.

The reaction of the perchlorate complex $Mn(OClO_3)(CO)_5$ with a two- or three-fold excess of $PHPh_2$ in refluxing ethanol (ii in the scheme) gave the tetracarbonyl *cis*-$[Mn(CO)_4(PHPh_2)_2]ClO_4$ (**II**) as a crystalline precipitate. The ^1H NMR of this compound in $CDCl_3$ solution showed a pattern consistent with an AA′XX′ system similar to that described for the analogous neutral molybdenum complex $Mo(CO)_4(PHPh_2)_2$.[4] In Table 2 only the centre of the multiplet and the separation (in Hz) between the two more intense signals (the external ones) are given. The preparation of the tetracarbonyl **II** by reaction of $PHPh_2$ with $Mn(OClO)_3(CO)_5$ is similar to the result obtained with the ligand tetramethylthiourea (TMTU),[5] but contrasts with the observation that the reaction of the perchlorate complex with other monodentate ligands gives the tricabonyls *fac*-$[Mn(CO)_3L_3]ClO_4$, probably passing through the tetracarbonyls, although the latter are not detected by monitoring the reaction by IR.[1] In the reaction (ii in scheme) the *fac*-tricarbonyl *fac*-$[Mn(CO)_3(PHPh_2)_3]ClO_4$ (**III**) was also observed, but its formation from **II** (iii in Scheme) was slow in refluxing ethanol and on prolonged heating it was obtained together with some remaining **II** and the *cis*-dicarbonyl *cis*-$[Mn(CO)_2(PHPh_2)_4]ClO_4$ (**IV**). The latter compound could be prepared from the tricarbonyl **III** and excess of $PHPh_2$ in refluxing ethanol (iv in scheme) but only in poor yield because it had to be carefully crystallized out from the mixture before the reaction is completed otherwise some decomposition to an unidentified dicarbonyl begins.

The cationic tricarbonyl **III** could be conveniently obtained pure in good yield from $PHPh_2$ and *fac*-$[Mn(CO)_3(Me_2CO)_3]ClO_4$[1] in acetone (reaction v in the scheme). The dicarbonyl **IV** was easily prepared, also in good yield, by reacting **III** with $PHPh_2$ in CH_2Cl_2 in the presence of $ONMe_3$, (vi in scheme) a method often employed to promote CO substitution,[6] that in some cases has led to unexpected isomers.[7] Heating the *fac*-tricarbonyl **III** in refluxing *n*-butanol (viii in scheme) resulted in the formation of *mer*-$[Mn(CO)_3(PHPh_2)_3]ClO_4$ (**V**), as evidenced by the changes in the $\nu(CO)$ IR spectrum

[h] For the *mer* isomer ν(CO): 2040w, 1960s.br.
[i] Before melting the colour changed from yellow to red.

[from two equally strong bands to one weaker than the other (Table 1)]. This process is similar to that observed in the case of many other cationic tricarbonyls with phosphorus ligands;[1] however, the isomerization could not be completed after prolonged heating and a mixture of the two isomers **III** and **V** was obtained. This suggests that at high temperatures, the equilibrium vii shown in the Scheme is established. The $^{31}P(^1H)$NMR spectrum of **III** featured a very broad signal even at −90°C centred at *ca.* 33 ppm with $\Delta\nu_{1/2} = 750$ Hz. (920 Hz at −60°C) while the spectrum of the mixture having more of the *mer*-isomer taken at −60°C, showed also a doublet centred at 43.6 ppm and a triplet centred at 26.1 ppm with intensity ratio 2:1 and with $^2J(P,P) = 39$ Hz. In the non-decoupled ^{31}P NMR spectrum the doublet centred at 43.7 ppm was split into two broad multiplets separated by *ca.* 360 Hz and the triplet was split into two broad multiplets separated by *ca.* 390 Hz. The ^1H NMR spectrum of **III** showed a complex multiplet centred at 6.43 ppm with a separation of 396 Hz between the two extreme and more intense peaks. In the ^1H NMR spectrum of the isomer mixture, two complex multiplets assignable to the *mer*-tricarbonyl were observed, one was centred at 6.35 ppm with a separation between the more intense peaks of 369 Hz but only half of the other multiplet (at 3.46 ppm) could be observed, the other half probably being hidden by the strong signal of the PPh_2 groups. All these features are consistent with the structures proposed for **III** and **V**.

The *cis*-dicarbonyl **IV** could be converted into the isomer *trans*-$[Mn(CO)_2(PHPh_2)_4]ClO_4$ (**VI**) by

[f] The spectrum is in fact a AA'BB' system, that has been measured directly from the spectrum as a first-order approximation.

[g] Estimated.

[h] Not observed because of the Ph protons.

[i] In d_6-acetone.

irradiating a CH_2Cl_2 solution with UV light at −15°C (viii in scheme), a reaction that resembles the UV promoted isomerization of the cationic dicarbonyl *cis*-$[Mn(CO)_2(dppm)_2]ClO_4$.[8] The spectroscopic data obtained for both isomeric dicarbonyls (Tables 1 and 2) were in accord with the structures proposed. The salt **VI** could be conveniently prepared directly from **III** and $PHPh_2$ under UV irradiation (ix in scheme).

Replacement of the coordinated $OClO_3$ ligand by $PHPh_2$ from the neutral complexes *fac*-$[Mn(OClO_3)(CO)_3(L\frown L)]$, gave the cationic carbonyls *fac*-$[Mn(CO)_3(L\frown L)(PHPh_2)]ClO_4$ [$L\frown L$ = dppm (**VIIa**), dppe (**VIIb**), phen (**VIIc**) or bipy (**VIId**)]. The analogous salt *fac*-$[Mn(CO)_3(bipy)(PHPh_2)]PF_6$ (**VIIe**) could be prepared directly from *fac*-$[MnBr(CO)_3(bipy)]$ and $PHPh_2$ in the presence of $TlPF_6$. Heating the *fac*-tricarbonyls containing the diphosphines resulted in the isomerization to the *mer*-tricarbonyls [ν(CO) IR: 2050 w, 1965 s.br (dppm) and 2040 w, 1960 s.br (dppe)]. This behaviour is similar to that observed for other cationic tricarbonyls with diphosphines,[9] however the *mer*-tricarbonyls with $PHPh_2$ were accompanied by the dicarbonyls *cis*-$[Mn(CO)_2(dppm)_2]ClO_4$ (in the case of the dppm complex) and *trans*-$[Mn(CO)_2(dppe)_2]ClO_4$ (in the dppe compound) and were not obtained pure.

By contrast, heating the *fac*-tricarbonyls with bipy or phen, resulted in decomposition giving the red dicarbonyls *cis-trans*-$[Mn(CO)_2(N\frown N)(PHPh_2)_2]ClO_4$ ($N\frown N$ = bipy or phen). This was confirmed by reacting the PF_6 salt **VIIe** with $PHPh_2$ in refluxing toluene that gave the complex *cis-trans*-$[Mn(CO)_2(bipy)(PHPh_2)_2]PF_6$ (**VIII**), characterized by the data in Tables 1 and 2 and that is analogous to other cationic *cis-trans* dicarbonyls with bipyridine or phenenthroline and two monodentate phosphorus ligands already known.[10]

ADDUCTS OF COORDINATION COMPOUNDS—XIII.* NITRATES, HYDROGEN AND SILVER DINITRATES, AND POLYSILVER NITRATES OF *TRANS*-DIHALOTETRAKISPYRIDINERHODIUM(III) AND IRIDIUM(III) IONS

R. D. GILLARD† and S. H. MITCHELL‡

Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL, U.K.

(*Received* 14 *July* 1986; *accepted after revision* 5 *May* 1987)

Abstract—The synthesis and characterization, chiefly as salts of the anions $[X(ONO_2)_2]^-$ ($X = H^+$ or Ag^+) (by analysis, X-ray powder photography, vibrational spectra and thermogravimetry) of adducts of the nitrates *trans*-$[M(L)_4X_2](NO_3)$ (M = Rh or Ir; L = pyridine, perdeuteriopyridine or 4-methylpyridine; X = Cl or Br) with hydrogen nitrate and silver nitrate are described.

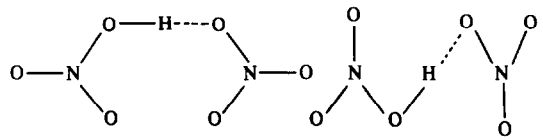
Salts (usually nitrates) with incorporated "extra" nitric acid or silver nitrate have been known for over a century. $CsNO_3 \cdot HNO_3$, described by Schultz[2] in 1862, was the first example of a hydrogen dinitrate salt,§ although unrecognized as such at the time.

Double salts containing silver nitrate have also been known for a long time. Silver halide–silver nitrate combinations, $nAgX \cdot AgNO_3$ (X = Cl or Br, n = 1; X = I, n = 1–4) are among the earliest described.[3] The double salts $CNO_3 \cdot AgNO_3$ ($C = K^+$ or NH_4^+) were first made[4] in 1877, but their structures have been determined[5] only recently.

In 1935, Poulenc reported[6] the synthesis of salts of the complex cation *trans*-$[Rhpy_4Br_2]^+$ containing "extra" nitric acid, silver nitrate and silver bromide; he formulated them as $[Rhpy_4Br_2]NO_3 \cdot HNO_3$, $[Rhpy_4Br_2Ag](NO_3)_2$ and $[Rhpy_4Br_2Ag]Br_2$. The nitric acid adduct and some analogues have received much attention. The existence of the hydrogen dinitrate anion was first recognized by Gillard and Ugo[7] in this compound. Our IR spectra indicated that the structure involved pairs of nitrate ions linked through oxygen atoms by symmetrical hydrogen bonds thus giving the hydrogen dinitrate anion.

trans-$[Rhpy_4Cl_2]^+$ has proved useful for isolating unusual species as stable adducts; besides its salts with $[H(ONO_2)_2]^-$, $(X_3)^-$ [X = Cl, Br or I], or Br_2Cl^- as gegen-ions, double salts with $(H_5O_2)^+$ have been described.[8] In contrast to the fairly well understood adducts of Brønsted acids, there are no published studies on the two argentous adducts of Poulenc since his original report, though Miss Davies confirmed[9] their existence.

The compounds known (from diffraction work) to contain hydrogen dinitrate anions are listed in Table 1. Two distinct conformations are known for the anion (**1** and **2**). The initial confusion



(1) **(2)**

for $CsH(ONO_2)_2$ and *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$, where the two nitrate groups were said to form a distorted tetrahedron[14,15] around the proton, arose because, although the individual hydrogen dinitrate

§ We name these compounds of $[H(\underline{O}NO_2)_2]^-$ as hydrogen dinitrates [on the pattern of "hydrogen difluoride" for $(HF_2)^-$]. By analogy, we call the ion $[Ag(\underline{O}NO_2)_2]^-$ silver dinitrate, though dinitratoargentate(I) would be more fully descriptive.

Table 1. Structures of hydrogen dinitrate salts

	Conformation	X-ray/neutron	Ref.
$CsH(NO_3)_2$	**1**	n	10
trans-$[Rhpy_4Cl_2]H(NO_3)_2$	**1**	n	11
trans-$[Rupy_4Cl_2]H(NO_3)_2$	**1**	X	12
$Ph_4AsH(NO_3)_2$	**2**	X	13

anions in those salts have the structure **1**, they occur disordered throughout the lattice.[10,11]

Oligonitric acid adducts have also been isolated and studied by infrared and Raman spectroscopy,[16–18] and one crystal structure has been determined,[19] that of $NH_4NO_3 \cdot 2HNO_3$.

Hydrogen dinitrate and oligonitric acid adducts are not confined to the solid or solution phases. A large number of such anions have been proposed[20–23] as components of the troposphere and stratosphere. Families of nitrate- and/or sulphate-containing species form the bulk of the ions "identified" (by mass spectrometry): $NO_3^-(HNO_3)_n$; $HSO_4^-(HNO_3)_n$; $HSO_4^-(H_2SO_4)_n$ ions (n = 1 and 2) are dominant[22] below about 27 km. The enthalpy, ΔH^0, of the dissociation, in the vapour phase,

$$NO_3^- \cdot HNO_3 \rightarrow NO_3^- + HNO_3 \qquad (1)$$

is given[23a] by Kebarle as > 26.4 kcal mol^{-1} (i.e. > 110.4 kJ mol^{-1}), an estimate relying on a value for

$$NO_3^- \cdot H_2O + HNO_3 \rightleftharpoons NO_3^- \cdot HNO_3 + H_2O \qquad (2)$$

in the vapour phase, of $\Delta G_{300} \geqslant -7.3$ kcal mol^{-1} (i.e. 30.5 kJ mol^{-1}).

EXPERIMENTAL

Source complex cations were prepared first as chloride salts of chloro-complexes using published methods,[24] with minor variations. Bromo-analogues were then prepared[24] from these:

$$trans\text{-}[RhL_4Cl_2]^+ \xrightarrow[\Delta,NaBr]{EtOH/H_2O} trans\text{-}[RhL_4Br_2]^+. \qquad (3)$$

Subsequently, all halide salts were converted into nitrate salts by metathesis. The following complexes were prepared: *trans*-$[Rhpy_4Cl_2]NO_3 \cdot 5H_2O$, *trans*-$[Rh(py\text{-}d5)_4Cl_2]NO_3 \cdot 5H_2O$, *trans*-$[Irpy_4Cl_2]NO_3 \cdot 5H_2O$, *trans*-$[Rh(4\text{-}pic)_4Cl_2]NO_3 \cdot 2H_2O$, *trans*-$[Ir(4\text{-}pic)_4Cl_2]NO_3 \cdot 2H_2O$, *trans*-$[Rh(4\text{-}pic)_4Br_2]NO_3 \cdot 2H_2O$. (4-pic = 4-methylpyridine).

Nitric acid adducts were prepared by heating the parent complex in concentrated nitric acid. Crystals, usually flakes, were produced on cooling: these were filtered off, washed with 8 M HNO_3, and air dried.

The silver nitrate salts were made by dissolving the parent nitrate salt in ethanol, and adding silver nitrate dissolved in a drop or two of water. Most solutions were then cooled to 0°C, and kept at that temperature for crystallization. The concentrations and ratios of reactants used are shown in Table 2. Usually from 0.5–2 cm^3 of solution were prepared for each experiment. The conditions were chosen with the following requirements in mind: (i) that the parent nitrate does not precipitate on addition of silver nitrate through the "common ion" effect, (ii) silver nitrate itself does not form and (iii) product formation occurs sufficiently rapidly that the

silver ion does not abstract the halide from the complex. The same requirements, especially (iii), have so far prevented growth of single crystals large enough for X-ray work, though powder pictures for $[Mpy_4Cl_2][Ag(NO_3)_2]$ are good.

The pyridine complexes readily crystallize from solution as their silver dinitrate salts. For the 4-picoline complexes the usual procedure for formation of silver nitrate salts gave several products, depending on the concentration and ratio of factors.

Thermogravimetric and chemical analysis

Chemical analyses for carbon, hydrogen and nitrogen are consistent with compounds containing pyridine (or picoline) and nitrate. With metal analyses from the thermogravimetric runs, they enable the compositions to be calculated (Table 3).

The residue found from thermogravimetric runs could not always be relied on as an analytical result. There are several sources of error; (i) the residue was not entirely metallic: silver and rhodium oxides sometimes formed that could not be decomposed on prolonged heating at 900°C and (ii) sublimation of silver halide sometimes occurred before a metallic phase was reached. When these effects were gross they were readily observed, and the analysis rejected. There were only two instances of extensive sublimation, involving AgCl and AgBr. However, sublimation of trace amounts might have gone unnoticed, leading to under-estimation of silver content. The loss of silver from the residue is not unexpected because silver halides and nitrates melt at low temperatures[25] (Cl^-, 455; Br^-, 432; NO_3^-, 212°C). Silver analysis by atomic absorption gave unsatisfactory results. For all compounds, the silver contents found were much too low (when compared with the content deduced from the thermogram and CHN analysis) probably due to the formation in solution of AgX (X = Cl or Br).

Tables 3 and 4 give analytical details.

X-ray powder diffraction

X-ray powder diffraction patterns were recorded using a Guinier camera and CuK_α radiation (unfiltered). Exposure was from 2 to 5 h; α-Al_2O_3 was included as a reference. The data have been deposited as supplementary material.*

* The tabulated data on X-ray powder diffraction are available from the Editor on request.

[a] Decomposition temperature of $[H(NO_3)_2]^-$.

Infrared spectra

Mulls were prepared using Nujol, fluorolube, hexachlorobutadiene, acetone or carbon tetrachloride on caesium iodide plates. Attempts to prepare potassium bromide discs usually resulted in decomposition of the compounds, shown as a reversion to a pattern containing bands of free nitrate ion. Compounds containing an excess of nitric acid were dried by heating on a thermobalance to constant weight. An excess of nitric acid results in rapid decomposition and deterioration of the spectrum, extra bands appear and iodine forms. Similarly, with acetone mulls, there is fairly rapid decomposition, nitrate is liberated and extra unidentified bands appear.

Infrared spectra are illustrated in Figs 1–3, and tables of data have been deposited as supplementary data.* The figures are composites of spectra recorded in Nujol, acetone and CCl_4. No bands due to the mulling agent are present, except where indicated. Nujol-free spectra (estimated from acetone mulls) are shown in Figs 1 and 3.

RESULTS

IR spectra of the parent nitrate and halide salts were used as a basis for identifying bands of the nitric acid and silver nitrate adducts. The changes in the spectrum of pyridine on its coordination to metal ions are well documented, and most bands may be readily assigned.[26] Differences between compounds are chiefly confined to changes in the splitting pattern of the B_2 modes (ν23–ν27), which are particularly sensitive to the crystal environment. There are of course also differences in the region (below about 400 cm^{-1}) where the M—X/L bands occur (Table 5).

Nitrate hydrates

All the parent hydrated nitrate salts readily lose water to a drying atmosphere, either as the normal laboratory atmosphere or in a stream of nitrogen as used in the thermobalance. Consequently, samples were kept in a humidity chamber ($Na_2SO_4 \cdot 10H_2O$, RH 93% at 20°C) for at least 12 h prior to analysis. Also, when available, large crystals were used in preference to powders or small crystals. On heating, water loss is complete by 80°C, and if heating is stopped water will be reabsorbed, giving back the original hydrate. The pyridine complexes were all found to be pentahydrates, and the 4-picoline complexes dihydrates.

The main weight loss from the anhydrous material begins with a rapid loss of pyridine or 4-picoline from 226–280°C. This loss corresponds to between 2 and 3 mol of base per mol of metal. In general, loss of pyridine and 4-picoline occurs at a similar temperature for a given metal. Iridium complexes are more stable to heat than their rhodium analogues. The rate of subsequent losses (halide and remaining organic material) begins slowly, gradually increasing until a metal residue remains.

[a] Raman band frequencies for some related compounds (e.g. *trans*-$[Rhpy_4Cl_2][H(\underline{O}NO_2)_2]$) are in Ref. 12.

* The tables of IR data are available from the Editor on request.

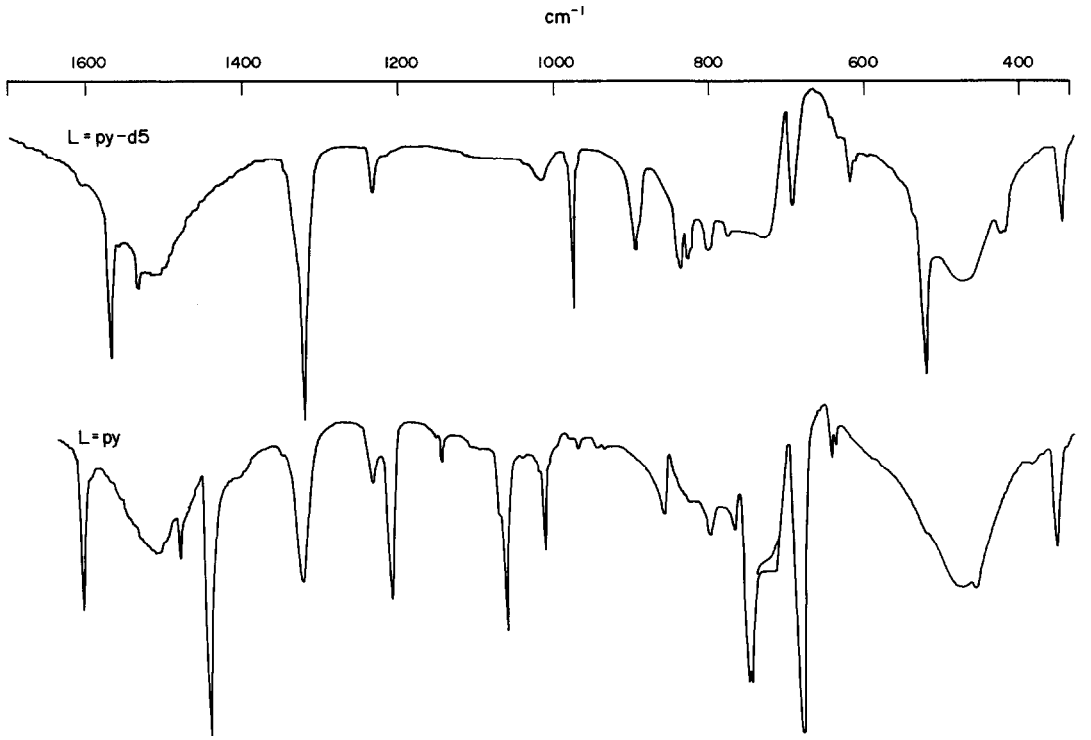

Fig. 1. Infrared spectra of *trans*-$[RhL_4Cl_2][H(ONO_2)_2]$; upper spectrum, $L = C_5D_5N$: lower spectrum, $L = C_5H_5N$. In this, and in both spectra of Fig. 3, in the region of 720 cm^{-1}, the lower curve of lesser absorption represents the Nujol-free spectrum.

Two phases of pyridine complex were identified by X-ray powder diffraction. *trans*-$[Rhpy_4Cl_2]NO_3 \cdot 5H_2O$ and *trans*-$[Irpy_4Cl_2]NO_3 \cdot 5H_2O$ crystallize as different phases, while both these phases were found for *trans*-$[Rh(py\text{-}d5)_4Cl_2]NO_3 \cdot 5H_2O$. The governing factors were not studied. However, in related work, we found that the chlorides *trans*-$[Mpy_4Cl_2]Cl \cdot 6H_2O$ (M = Ir or Rh) each crystallized from water in two forms. The crystal structure of the "low temperature form" for iridium is known.[27]

Nitric acid adducts

When prepared in concentrated nitric acid, most salts incorporated nitric acid in excess over that required for $H(NO_3)_2^-$. Apparently dry samples showed an initial loss of weight on heating from

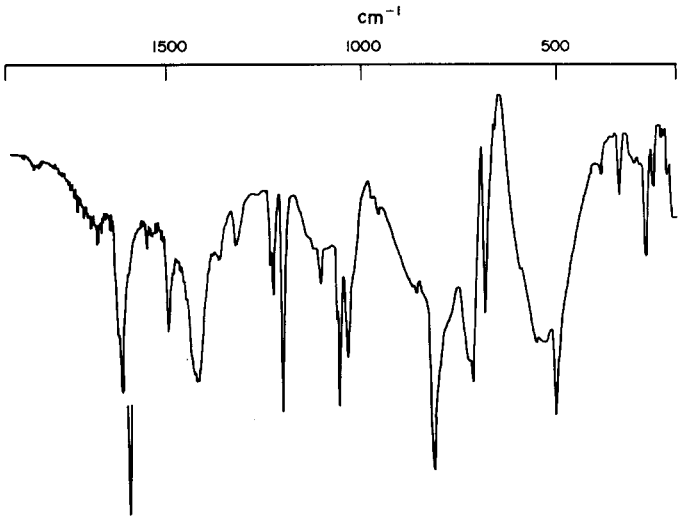

Fig. 2. Infrared spectrum (1900–200 cm^{-1}) of *trans*-$[Rh(4\text{-methylpyridine})_4Cl_2][H(ONO_2)_2]$.

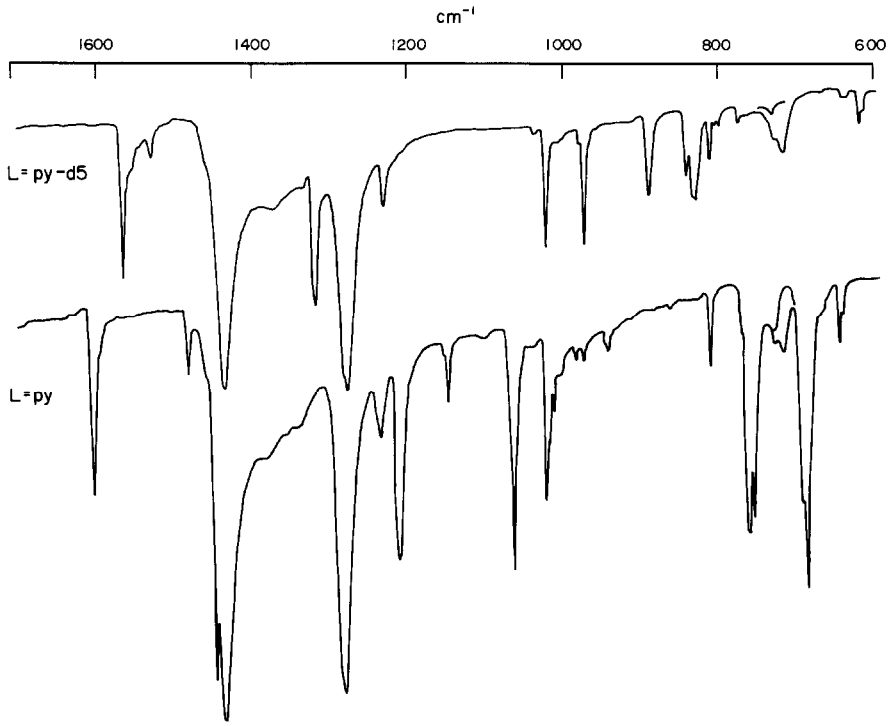

Fig. 3. Infrared spectrum (1700–600 cm^{-1}) of *trans*-$[RhL_4Cl_2][Ag(ONO_2)_2]$: upper spectrum, L = C_5D_5N; lower spectrum, L = C_5H_5N. (See note in caption of Fig. 1.)

room temperature. A stable stage is reached, the $H(NO_3)_2^-$ salt, which loses no more nitric acid until about 145°C. This loss may merge with decomposition of the complex unit, 250°C for Rhpy and 240°C for Rh(4-pic) (heating rate 5°C/min).

Diffraction lines of *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ are assigned to 2.913 Å (reflection 063). Assignments were made by comparison with line positions calculated from the known[11] orthorhombic cell of *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$. There was good agreement between the observed and calculated patterns. The iridium analogue gives an almost indistinguishable pattern, indicative of a similar structure, and the pattern was similarly assigned (available from the Editor).

The three compounds *trans*-$[M(4\text{-pic})_4Cl_2]H(NO_3)_2$ (M = Rh, Ir) and *trans*-$[Rh(4\text{-pic})_4Br_2]H(NO_3)_2$ give almost identical powder diffraction patterns (available from the Editor), but since no crystallographic details are yet known, lines cannot be assigned. With non-dried samples, a few new lines are observed, which are probably due to the presence of oligonitric acid adducts.

Silver nitrate adducts

Pyridine complexes: as already noted, the complex cations *trans*-$[Mpy_4X_2]^+$ readily form silver dinitrate salts. In contrast to the picoline cases, no compounds with silver nitrate contents higher than one per complex unit were found.

The X-ray powder diffraction patterns of the hydrogen and silver dinitrate salts of *trans*-$[Mpy_4Cl_2]^+$ (M = Rh or Ir) are sufficiently similar in terms of line position and intensity that their structures may be considered isomorphous. Thus lines in the pattern of the silver dinitrate salts were assigned by analogy with the known line assignments of the hydrogen dinitrate salt. Using these lines, the unit cell dimensions were calculated by solving simultaneous equations for all possible combinations of these lines. This gave for *trans*-$[Mpy_4Cl_2]Ag(NO_3)_2$;

Rh $a = 7.71(5)$, $b = 21.55(12)$, $c = 14.97(24)$ Å

Ir $a = 7.72(3)$, $b = 21.57(23)$, $c = 15.05(10)$ Å

from which a powder pattern was calculated (Rh only) and the remaining lines assigned.

Thermograms of the silver nitrate adducts follow a pattern of decomposition similar to those of the anhydrous nitrates. The initial loss of pyridine occurs at a slightly lower temperature (190 vs 240°C). Decomposition of the silver nitrate merges with decomposition of the complex. A stage is

reached where the residue comprises of rhodium or iridium and silver metals: limited oxidation of the silver may occur soon after and on prolonged heating this returns to silver metal.

Silver dinitrate infrared bands were located in the same manner as hydrogen dinitrate bands. The spectrum is shown in Fig. 3 and a table of these bands has been deposited with the Editor.

Picoline complexes: There was considerable difficulty with the analysis of these compounds, because—in part—of their intractable nature, and (for some) rapid decomposition. The formulae given may not completely describe each compound: they are used chiefly to indicate separate compounds, and their probable composition. A compound is recognized by its X-ray powder diffraction pattern (tables deposited with Editor). No assignment of the diffraction lines was made because there are no data available for single crystals of these compounds.

Thermograms begin with an unexpected low temperature loss. The temperature of this loss is much lower than that of coordinated 4-picoline as found in the nitrate salts, and although ethanol or water is implicated in some compounds, this loss is probably premature loss of 4-picoline.

The formulations were arrived at by using %mol ratios in the following way. The only source of carbon is from 4-picoline and that provides the rhodium content, %Rh, all of which is found in the residue. The percentage of silver is derived from the difference total %M (residue) minus %Rh. The nitrogen content arises from 4-picoline and nitrate: the amount due to 4-picoline has been fixed by the carbon analysis and thus the difference, the nitrate content, may be apportioned first to that part neutralizing the single positive charge of the complex, and the remainder to silver. As a final check on the validity of the above scheme the figures for silver and nitrate(silver) should be the same.

The infrared bands arising from "nitrate" for all the complexes examined are collected in Table 6.

[a] From solvent.
[b] The region 1400–1300 cm^{-1} was not studied.

Preparations based on trans-[Rh(4-pic)$_4$Cl$_2$]NO$_3$

At low mol ratio (1 complex : 3 $AgNO_3$) yellow crystals slowly form. These are the silver dinitrate salt. Raising the mol ratio to 1 : 11 gave fine golden yellow crystals of *trans*-[Rh(4-pic)$_4$Cl$_2$]NO$_3$·3AgNO$_3$.

trans-[Rh(4-pic)$_4$Cl$_2$]Ag(NO$_3$)$_2$. This preparation was done thrice. Crystals (a) were grown overnight at room temperature. A thermogram of the product begins with a steady (0.15%/C° heating rate 10°/min) weight loss from 133°C, that becomes very rapid at 215°C and culminates in a steady decomposition leaving metal residue (27.1%), the figure expected for *trans*-[Rh(4-pic)$_4$Cl$_2$]Ag(NO$_3$)$_2$. Its X-ray powder pattern and IR spectrum (which showed no bands of solvent) have been deposited with the Editor.

When crystals (b) from a second preparation (mol ratio 1 : 3.1, [Rh] = 2.62×10^{-2} M, grown at 0°C) were removed from solution they immediately went opaque. Their thermogram is the same as that of (a) above 145°C, but there is an early loss below 145°C: it begins at 55°C, and there are two distinct loss steps, of 2.9 and 3.5%. Crushing (b) released ethanol (smell) which may account for the loss of weight at low temperature. The IR spectrum has a weak band at 3375 cm^{-1} which might indicate ethanol or water. If ethanol is indeed present, then the thermogram indicates about 1 mol per formula unit. A diffraction pattern (of a sample which had been aged and crushed) shows a mixture of compounds; the pattern of (a), that of silver chloride, and lines not identified with any other salt. The strongest new lines occur at 10.28, 7.00, 4.91 and 4.13 Å.

Crystals (c) from the third preparation (mol ratio 1 : 4.5, [Rh] = 3.93×10^{-2} M) were like (b) in going opaque, but if quickly returned to the mother liquor, transparency returned. The diffraction pattern is extremely similar to that recorded from (a), and the infrared spectrum has a band at 3415 cm^{-1}, indicating that the compound contains a solvent.

The nitrate bands from this compound are recorded in Table 6. Unfortunately, decomposition occurs on the plates (CsI) and the bands at 1400–1300 cm^{-1} increase in intensity at the expense of the pair at 1300–1260 cm^{-1}.

trans-[Rh(4-pic)$_4$Cl$_2$]NO$_3$·3AgNO$_3$. This com-

pound was also prepared three times, and gave thermograms substantially identical in form. There is a minor loss (1.5–2.0%) as a distinct step, beginning at 90°C and accompanied by the formation of a brown tar and AgCl. The major loss begins at 175°C with no distinct stages, and a metal residue is produced (% obs: 32.1, 34.0 and 36.5). There was a considerable amount of sublimed AgCl in the furnace from the first of these. A table of IR spectra has been deposited with the Editor.

Preparations based on trans-$[Ir(4\text{-pic})_4Cl_2]NO_3$. The mol ratio 1 : 15.2 gave a product of *trans*-$[Ir(4\text{-pic})_4Cl_2]NO_3 \cdot 3AgNO_3$; the thermogram is similar to that of the analogous rhodium complex, with the initial minor loss beginning at 150°C. Infrared spectra and X-ray powder patterns are identical with those of the rhodium analogue.

Preparations based on trans-$[Rh(4\text{-pic})_4Br_2]NO_3$. The silver dinitrate salt was produced at low mol ratio (1 : 3) of factors. At high mol ratio (1 : 9) the product that forms first is a $4AgNO_3$ salt as orange–brown flakes; the $3AgNO_3$ salt crystallizes later.

trans-$[Rh(4\text{-pic})_4Br_2]Ag(NO_3)_2$. This formed during several hours as orange crystals, which behave like their chloro-analogue in that when removed from solution they go opaque. There is a weak band at 3430 cm^{-1} in the IR spectrum.

The thermogram begins with a low temperature (33°C) loss of variable duration, magnitude (5.8–11%), and form. It may be due in part to loss of ethanol but during this loss AgBr (X-ray powder picture) is formed. The subsequent losses follow the pattern already established for *trans*-$[Rh(4\text{-pic})_4Cl_2][Ag(NO_3)_2]$.

trans-$[Rh(4\text{-pic})_4Br_2]NO_3 \cdot 3AgNO_3$. This compound has the same X-ray powder diffraction pattern as that found for its rhodium and iridium chloro-analogues. While recording a thermogram, silver bromide sublimed into the furnace.

trans-$[Rh(4\text{-pic})_4Br_2]NO_3 \cdot 4AgNO_3$. This has a thermogravimetric pattern similar to that of the corresponding silver dinitrate salt, except that a much higher residue is finally obtained. The first slow loss begins at 38°C. There is a weak band at 3390 cm^{-1} which may indicate solvent (ethanol) in the lattice.

In each instance (except *trans*-$[Rh(4\text{-pic})_4X_2][Ag(NO_3)_2]$) where ethanol is thought to be present in the structure, its calculated content is small (less than 2%) and cannot itself account for all the low temperature loss seen in the thermograms. Its loss may however initiate decomposition. The easy decomposition of *trans*-$[Rh(4\text{-pic})_4X_2][Ag(NO_3)_2]$ (X = Cl or Br) shows that this first loss is related to changes in the coordination sphere.

DISCUSSION

Hydrogen dinitrate

The crystal structures of $CsH(NO_3)_2$ and of *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ contain hydrogen dinitrate anions with C_2 symmetry on C_2 sites: this corresponds to Speakman's class A hydrogen bonding.[28] In both structures, two hydrogen dinitrate anions occur disordered throughout the lattice.[10,11]

The anions have similar geometry. The O—H—O bonds are, as far as can be determined, symmetrical, the O...O distances are the same, and thus the strengths of the O—H bonds must be similar. The only major difference is in the dihedral angle between the places of the nitrate groups. With $CsH(NO_3)_2$ this angle is 75.4(4)°, and in *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ 96(3) and 91(4)°.

The O—H—O bonds between the nitrate groups are considerably bent: 167.5(14)° (Rh) and 172.6(7)° (Cs). This bending does not destroy the point group symmetry but may contribute to determining the band positions in the IR spectrum.

The X-ray study of *trans*-$[Rupy_4Cl_2][H(NO_3)_2]$ gives[12] the O...O distance for the hydrogen bond as 2.88 Å, much larger than expected for a strong hydrogen bond, or as indicated by the position given for the O—H stretch. Our present recalculation of this distance from the coordinates given indeed leads to the reported result. In the isomorphous rhodium complex, this distance is[10] 2.461(18) and 2.480(18) Å.

However, a large O...O distance was also found for the other hydrogen dinitrates before allowance is made for disorder of hydrogen dinitrate in their lattices.

The "C_{2h}" form of hydrogen dinitrate (**2**) found[13] in $Ph_4AsH(NO_3)_2$ may be considered as one extreme of the C_2 structure with a nitrate–nitrate dihedral angle of 180°. This gives it higher symmetry than C_2, and changes symmetry-related properties. However it occupies a site in the lattice with site symmetry ($\bar{1}$), which lowers its point group from C_{2h} (E, C_2, i, σ) to C_i (E, i): even so, the nitrate groups are coplanar.[13]

Infrared spectra. The symmetry of the hydrogen dinitrate anion is so different from that of nitrate that designations of molecular motion are not readily transferred. Treating it as a perturbed nitrate allows only the qualitative estimation of a few band positions and gives no indication where the many new modes will occur. In summary, the isolated hydrogen dinitrate anion has 21 vibrational degrees of freedom, which occur as the following species for the geometries of symmetry C_2, C_{2h} and C_i:

C_2: 11A, 10B—all IR and Raman active

C_{2h}: $7A_g$, $2B_g$—Raman active; $4A_u$, $8B_u$—IR active

C_i: $9A_g$—Raman active; $12A_u$—IR active.

Normal coordinate calculations have been done[29] for the geometries of hydrogen dinitrate found in $CsH(NO_3)_2$ and $Ph_4AsH(NO_3)_2$, assuming C_{2h} symmetry in the latter. The same set of derived force constants was used to calculate frequencies, but torsion modes, of which there are five, were not included in the analysis. Comparison between observed and calculated (fitted) spectra show good agreement for the Cs salt, but less so for Ph_4As as the gegen ion because just over half the bands were not located. One important result of the calculation is the indication of considerable mixing of hydrogen bond modes with nitrate modes.

Other authors have assigned bands using as a model a perturbed nitrate group with D_{3h}, C_{2v} or C_s symmetry.[7,12,30,31] Although the spectra appear simple, this simplified approach to assignment leaves problematic the location of modes involving the hydrogen bonds. In broad terms, the descriptions of some bands agree with those found from the normal coordinate analyses.

Nitrate and hydrogen dinitrate bands were located in our present work by comparison between spectra of the chloride, nitrate (hydrate and dehydrated), and hydrogen dinitrate salts of the pyridine, perdeuteropyridine, and 4-picoline complexes. Spectra are shown in Figs 1 and 2 and the data have been deposited with the Editor. In particular, the bands identified as arising from hydrogen dinitrate or from its influence are given in Tables 7 and 8.

The nitric acid adducts examined here divide into two groups according to their IR spectra; these are typified by *trans*-$[Mpy_4Cl_2]H(NO_3)_2$ and *trans*-$[M(4\text{-pic})_4X_2]H(NO_3)_2$.

trans-$[Mpy_4Cl_2]H(NO_3)_2$ (M = Rh *or* Ir; py = py *or* py-d5)

The spectrum of hydrogen dinitrate in *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ is[30] the same as in the dichlorocobalt(III) analogue (which is isomorphous[30] with

[b] Of dubious validity as hydrogen dinitrate bands.

the *bromo*-complex *trans*[Rhpy$_4$Br$_2$][H(ONO$_2$)$_2$]) but simpler than in CsH(NO$_3$)$_2$: it is however complicated by ligand modes. The pattern calculated for CsH(NO$_3$)$_2$ may serve as a model for assigning the modes of *trans*-[Rhpy$_4$Cl$_2$]H(NO$_3$)$_2$, although the differences in structure must modify the pattern especially in respect of torsion modes. Hydrogen dinitrate bands from *trans*-[RhL$_4$Cl$_2$]H(NO$_3$)$_2$ (L = py, py-d5) are given in Table 7.

The spectrum (*Fig. 1*). 1800–900 cm^{-1}: In this region there are three bands. Modes ν_1 and ν_2, and ν_3 and ν_4 (see Table 7 for descriptions, following Ref. (29) are well separated ($\Delta \sim 180$ cm^{-1}), but neither shows the further splitting found for CsH(NO$_3$)$_2$, the extent of which was said[30] to be dependent on the nitrate–nitrate torsion angle. The third band (1018 cm^{-1}) might be ν_6, ν_7 or both; whichever is the case, it is of symmetric components $\nu_{N=O}$ and ν_{N-O}. This region contains a group of bands reported[7,12,31] as belonging to the hydrogen dinitrate anion (1000–945 cm^{-1}). They are here identified as pyridine bands, since they also crop up in the spectra of *trans*-[Mpy$_4$Cl$_2$]Cl and[26] *mer*-[Mpy$_3$Cl$_3$] (M = Rh or Ir).

900–600 cm^{-1}: This region is difficult to interpret because Evans windows and ligand bands are superimposed on anion band(s). There are hydrogen dinitrate bands at 806, 728 and 696 cm^{-1}. The broad structure between $\sim$ 850 and 710 cm^{-1} may contain several broad bands (e.g. ν_9 and ν_{10}) or be the high frequency wing of a very asymmetric band peaking at 730 cm^{-1}.

The ν_{OHO} band has been placed here but calculations indicate a lower frequency. Discussion of its location follows.

600–300 cm^{-1}: There are two bands in this region. One at $\sim$ 482 cm^{-1} is strong and roughly symmetrical while the other is a weak shoulder at higher energy ($\sim$ 600 cm^{-1}).

trans-[M(4-pic)$_4$X$_2$]H(NO$_3$)$_2$ (M = Rh, X = Cl *or* Br; M = Ir, X = Cl)

The spectra from the three compounds in this second isomorphous group are essentially identical, except for the expected differences in the M—X/M—L stretching region, which are the same as found in the parent nitrate salts. Thus comments and descriptions are made only on the spectrum of *trans*-[Rh(4-pic)$_4$Cl$_2$]H(NO$_3$)$_2$ (Fig. 2). They apply, *mutatis mutandis*, to the others.

This spectrum is not complicated by Evans windows, but unfortunately a number of 4-picoline and hydrogen dinitrate bands coincide: probable values for the latter are given in Table 8 (with caveats).

The spectrum (*Fig. 2*). 1800–1000 cm^{-1}: There are two broad bands in this region, and another two that are possibly hydrogen dinitrate bands. The moderately strong picoline band at $\sim$ 1430 cm^{-1}, of irregular shape in the chloride and nitrate salts, is broader and more regular in the hydrogen dinitrate salt. This may indicate the presence of an underlying hydrogen dinitrate band. The 1334 cm^{-1} picoline band (identified from Cl$^-$ salt) changes slightly, becoming broader and in some mulls appearing as a doublet: its structure may be due either to genuine splitting or to superposition of a weak hydrogen dinitrate mode on a picoline band.

1000–200 cm^{-1}: This region is in many respects similar to that of the pyridine analogue, but without the complicating Evans windows. There are six bands. The only band of dubious nature is at $\sim$ 315 cm^{-1} (weak and broad). It is not present in chloride or nitrate salts or the dibromo-rhodium hydrogen dinitrate analogue.

Acetone mulls of the complex deteriorate rapidly (minutes). Only the limited range 900–400 cm^{-1} was examined. The bands at $\sim$ 810 and 535 cm^{-1} rapidly disappear to reveal weak bands at 860 and 618 cm^{-1}, while the medium bands at 730 and 691 cm^{-1} are weakened.

The hydrogen bond

If a hydrogen bond is considered to be the interaction of a base and a proton donor as in —O—H...O then as the hydrogen bond strength increases the O—H bond is weakened, and becomes longer. Thus the O—H stretching mode shifts to lower wavenumber, becomes asymmetric and broadens considerably.[28,32] Eventually, with the proton midway between the oxygen atoms, there is no distinction between O—H and H...O stretching modes.

Recently there has been detailed discussion[33–35] of infrared band shaping mechanisms, applied to

hydrogen stretching modes in particular. Although, strictly speaking this is restricted to non-crystalline phases, we adopt it here. The main band-shaping mechanism is anharmonic coupling with external modes, responsible[35] for the asymmetry and large band width. The broadened band can have a smooth profile or have many sub-bands. The sub-bands arise from Fermi coupling with low frequency fundamentals or combination bands, shown as regions of enhanced transmission, with "ABC" type structures[36] or Evans windows.[37] Recent theory suggests that rather than continuing to broaden as the hydrogen bond gets stronger (i.e. very strong) the band becomes narrower and symmetrical.[35]

Evans windows are regions of enhanced transmission observed on broad bands. Evans showed[38] that they may be accounted for by Fermi coupling of a vibration capable of adopting many energy states with a sharply peaked transition of similar energy. The result of the interaction is to produce the broad-band regions of enhanced and decreased transmission connected by a sharp change of intensity, or, if the band maxima coincide—a symmetrical window. The effect is seen at 856–865 and 775–770 cm^{-1} in the spectrum of the pyridine complex and at about 836 cm^{-1} in the deuteropyridine complex.

In the particular cases of *trans*-$[Rhpy_4Cl_2][H(NO_3)_2]$, $Cs[H(NO_3)_2]$ and $[Ph_4As][H(NO_3)_2]$, the hydrogen bonds are very short ($O\ldots O < 2.5$ Å) and must be considered as being very strong. In each of these compounds, one nitrate half of the anion is related to the other by lattice symmetry. This would indicate possible class A hydrogen bonding in Speakman's classification.

Strictly, such class A hydrogen bonding would require[28] that the proton lie on a centre or along a two-fold proper or improper rotation axis. This would seem likely in the present compounds and would give equivalent O—H bonds. However, this may represent only the average situation, because it is not possible[39] even by neutron diffraction to distinguish between a proton occupying a single minimum potential well, or a symmetric double minimum well where the minima are less than 0.1 Å apart.

There is a third possibility, unlikely in the present case because the nitrate groups are symmetry related, that the proton occupies an asymmetric double minimum potential well, which is disordered throughout the lattice giving apparently a symmetric double minimum well.

The $\nu_{O—H}$ mode in *trans*-$[Rhpy_4Cl_2][H(NO_3)_2]$ might be expected at similar energy to that in $CsH(NO_3)_2$ (observed[30] at ~ 600 cm^{-1}) in view of the similarity of structure. The differences, in particular the nitrate–nitrate torsion angle and O—H—O bend, are unlikely of themselves to determine to any great extent the position of the $\nu_{O—H}$ mode.

The accepted position for the O—H stretching mode of *trans*-$[Rhpy_4Cl_2][H(NO_3)_2]$ and analogous compounds is[12] the broad feature between 850–700 cm^{-1}, peaking at 785–750 cm^{-1}. Its position may be estimated from the figure of Novak,[32] in which the O—H stretching frequencies for a number of compounds are plotted against $r_{O—H}$. Given $r_{O—H} = 1.23$ Å, a frequency of 690 cm^{-1} is indicated for $\nu_{O—H}$. This is lower than the accepted position. Calculation of its position in $CsH(NO_3)_2$ and $Ph_4AsH(NO_3)_2$ indicates still lower stretching frequencies, 619 and 621 cm^{-1} respectively, while inelastic neutron scattering experiments on $CsH(NO_3)_2$ point[40] to an even lower frequency (450(30) cm^{-1}). This latter technique is particularly sensitive to proton motion and so should give a reasonable indication of the stretching frequency.

Thus one of the two bands found below 700 cm^{-1} might not be a torsion mode but instead the O—H stretching mode, while the broad feature above 700 cm^{-1} is—at least in part—the nitrate bending mode γNO_3 which is expected in this region.

There is a good deal of similarity between the IR spectra of *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ and $CsH(NO_3)_2$. It may be a little unreasonable to expect exact correspondence between bands of the two series in view of the differences in structure of the anion and lattice. The crystal environment must be important in determining the exact geometry of the anion.

The analogous 4-picoline hydrogen dinitrate salts are new. Their IR spectra indicate that they have a different structure for the hydrogen dinitrate moiety from that in *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$. However the pattern does have features similar to those of $Ph_4AsH(NO_3)_2$, $CsH(NO_3)_2$ and *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$.

All these nitric acid adducts give similar spectra over the region 1000–400 cm^{-1}, indicating some similarity of structure. Since this region contains the O—H stretching mode, *trans*-$[Rh(4\text{-pic})_4X_2]H(NO_3)_2$ must be like the others in having a short and probably symmetrical hydrogen bond.

Between 1800 and 1000 cm^{-1}, its pattern is most closely similar to that of $Ph_4AsH(NO_3)_2$. The modes $\nu^a_{(N=O)}$ and $\nu^s_{(N=O)}$ should aid assignment of its stereochemistry. If $\nu^a_{(NO)}$ is at ~ 1430 cm^{-1} and $\nu^s_{(NO)}$ is absent, then the hydrogen dinitrate species contains a centre of symmetry. The band at 1683 cm^{-1} has an analogue in $[Ph_4As][H(NO_3)_2]$; this was first assigned[31] as ν^a_{NO} at 1670 cm^{-1}, later as[30]

$\nu^{s}_{NO_2}$ at 1705 cm^{-1} and finally re-assigned[29] as bending modes δ_{OHO} and ε_{NOH}, these last calculated to be at least 1688 cm^{-1}. However, the vibrational assignments are still insecure because over half the 27 fundamental modes of the anion in $[Ph_4As][H(ONO_2)_2]$ have not been observed.

Silver nitrate adducts

There are quite a few reports of double compounds or adducts containing silver nitrate. Table 9 lists some of them.

The silver halide–silver nitrate double salts all have structures[41-45] in which silver is coordinated irregularly by halide, and mono and bidentate nitrate ions. Some nitrate is also present as a counter ion. These compounds include some "inverse complexes".

$HgI_2 \cdot 2AgNO_3 \cdot H_2O$ has a polymeric structure, the silver ions alternating with mercury in a chain linked by iodide ions; nitrate acts only as a counter ion. The structures of $[Ag(bipy)_2](NO_3)_2 \cdot AgNO_3 \cdot HNO_3$ and $Ag[Ni(acac)_3] \cdot AgNO_3$ are not known, but the latter compound probably has a structure similar to that of $Ag[Ni(acac)_3] \cdot 2AgNO_3 \cdot H_2O$. There, the silver ions are bonded to the "active methylene" carbons and oxygen atoms of the acetylacetonate (2,4-pentanedionate) ligands. Of the three unique silver ions, one binds intermolecularly, while the others bind intramolecularly and are also coordinated to nitrate. The coordination geometry is approximately tetrahedral about each silver.

$CAg(NO_3)_2$ ($C = K^+$, NH_4^+ or Rb^+) are the only compounds of those in Table 9 where the sole ligand available is nitrate. Its structure is composed of $_{\infty}^{1}[Ag_2(NO_3)_4]^{2-}$ chains. Bridging monodentate nitrate and silver ions form a spiral parallel to *b*, and bridging bidentate nitrates link together every other silver. We made $KAg(NO_3)_2$ to examine nitrate bands in its IR spectrum. The data on its preparation, X-ray powder pattern and IR spectrum have been deposited.

Table 9. Adducts of silver nitrate

$AgCl \cdot AgNO_3$	Ag_2ClNO_3	41, 42
$AgBr \cdot AgNO_3$	Ag_2BrNO_3	43
$AgI \cdot AgNO_3$	Ag_2INO_3	44
$AgI \cdot 2AgNO_3$	$Ag_3I(NO_3)_2$	45
$CNO_3 \cdot AgNO_3$	$CAg(NO_3)_2$ ($C = K^+$, NH_4^+ or Rb^+)	5
$HgI_2 \cdot 2AgNO_3 \cdot H_2O$	$HgAgI_2(NO_3)_2 \cdot H_2O$	46
$[Ag(bipy)_2](NO_3)_2 \cdot AgNO_3 \cdot HNO_3$		47
$Ag[Ni(acac)_3] \cdot 2AgNO_3 \cdot H_2O$		48, 49
$Ag[Ni(acac)_3] \cdot AgNO_3$		49

The only other compound that might have a structure with discrete silver-containing anions analogous to silver dinitrate (itself, of course, like other $[AgX_2]^-$, where $X^- = Cl^-$ or Br^-) is[50] $[Ag(NH_3)_2][Ag(NO_2)_2]$. However, that structure contains linear diamminosilver ions, and an $Ag—NO_2$ framework in which one silver ion is coordinated by four nitrite ions to give a distorted tetrahedron.

Given that the monomeric anion silver dinitrate does exist in the solid state, then it follows that it must also exist at some concentration in solution. Its known salts are "insoluble" and so its concentration need not be large.

There have been many studies on the species present in solutions or melts containing silver nitrate. Chief and most useful among these are the Raman spectroscopic studies. In aqueous solution a number of species have been established.[51-53] They have been resolved from each other by fitting curves to the observed bands arising from nitrate. The species proposed and their relationship are described by eqn 4:

$$Ag^{+}_{(aq)} + NO^{-}_{3(aq)} = (Ag \cdot H_2O \cdot NO_3)^{0}_{(aq)} = (Ag \cdot NO_3)^{0}_{(aq)} = (Ag \cdot nNO_3)^{(n-1)-}_{(aq)} \quad (4)$$

No bands due to vibration of Ag—O were identified in the Raman spectrum, and at high concentration (> 6 M), the last species has been described[53] as a "second inner-sphere complex".

Silver dinitrate has not been thought to be a participant species in concentrated solutions of silver nitrate, but might actually be one of the inner sphere complexes described. Its symmetry might well be such that there is only one Raman active Ag—O stretching mode, and this at a frequency as yet unidentified.

The situation is much the same in melts of $AgNO_3$ or $AgNO_3$–alkali metal nitrates. There is[54] preferential association of silver and nitrate ions, more along the lines of a salt-like structure in which Ag^+ ions occupy holes in a lattice of nitrate ions, rather than specific coordination of silver by nitrate.

There have been no studies on the species present in solutions of silver nitrate in ethanol or ethanol–water mixtures. But it must be that as the concentration of silver and nitrate ions increase, they associate to a greater extent. Because ethanol's dielectric constant is lower than that of water, an ethanol–water mixture would be expected to favour a higher concentration of associated species including silver dinitrate.

The isomorphism of the silver and hydrogen dini-

trate salts of *trans*-$[Rhpy_4Cl_2]^+$ indicates that they may have similar structures in respect of the anion, namely monomeric C_2 (**1**). One factor controlling the size of the unit cell is the volume occupied by the anion. Replacing a proton (with OHO *ca* 2.5 Å) by silver (OAgO *ca* 4.8 Å) might—by increasing the size of the anion—be expected to produce a significantly larger unit cell. However, the hydrogen dinitrate anions do occupy a larger volume, through disorder, than they would in an ordered arrangement, and if the silver dinitrate anions are ordered then the difference in cell dimensions might not be so large.

Assuming a linear sequence O—X—O in the dinitrate ions, then for X = H the O...O distance is known[11] at 2.5 Å, and given a Ag—O(nitrate) distance[5] of 2.4 Å (the smallest of several) then the O...O distance is 4.8 Å, nearly twice that of hydrogen dinitrate. The O...O line lies parallel to the *ac* plane and so expansion would not affect the *b* axis. For *trans*-$[Rhpy_4Cl_2]X(NO_3)_2$ (X = H and Ag) expansion is 0.18 Å in *a* and 0.25 Å in *c*, as against X = H, but there is contraction by 0.17 Å in *b* from X = H to X = Ag.

The isomorphous series found are indicated in Table 10.

Most of these relationships are not too unexpected, particularly when the only difference is at the metal centre. What is surprising is that the 4-picoline silver dinitrate complexes do not form an isomorphous group. Perhaps they are (like so many coordination compounds) polymorphic, and it happens that different phases have been produced; the nitrate infrared bands do indicate that the structures of the anions may differ.

Table 10. Isomorphous relationships

trans-$[Rh(4\text{-}pic)_4Br_2]NO_3 \cdot 3AgNO_3$

[a] This compound exists in two phases.
[b] The second phase.

The infrared spectrum of silver dinitrate (see Fig. 3) in *trans*-$[Rhpy_4Cl_2]Ag(NO_3)_2$ is, not unexpectedly, quite different from that of free nitrate, being more akin to hydrogen dinitrate but with fewer bands.

A nitrate group with D_{3h} symmetry has four vibrational modes, three of which are IR active. Coordinating a single nitrate group lowers its symmetry from D_{3h} to C_{2v} or C_s species. This means that there are (at least potentially) six active bands and additionally an X—ONO_2 mode.[55-57] The coordination modes of nitrato-groups have been reviewed by Addison and his colleagues[56] and Rosenthal.[57] However, no features of the spectra were found to be sufficiently reliable to distinguish consistently between them. With two nitrate groups coordinated to the same centre, the situation is exacerbated because the variety of species and number of vibrations is greater. However, some indication of the structure and geometry of $Ag(NO_3)_2^-$ can be obtained from its spectrum.

First, the nitrate bands derived from $\nu_3(E')$ are narrow with half-widths of 30 cm^{-1} at 1439 cm^{-1} and 20 cm^{-1} ar 1279 cm^{-1}. In contrast, broad bands are found in the spectra of $AgNO_3$ and $KAg(NO_3)_2$, the half-widths being 65 cm^{-1} at 1386 cm^{-1}, and 395 cm^{-1} over the three $\nu_{N=O}$ bands, respectively. Each nitrate in these structures[5,58,59] binds together two or three silver atoms into chains. The lengths of the Ag—O bonds are between 2.37 and 2.70 Å. The narrow bands we find for the present anion indicate that it does not have a chain structure but is probably monomeric. The broad bands of hydrogen dinitrate are either hydrogen bond modes or out of plane deformation modes of nitrate; its nitrate stretching modes are comparatively narrow.

Secondly, the ν_3 mode of free nitrate is split [see Table 11] into two components, at 1438 and 1281 cm^{-1}. Thus the symmetry of the nitrate in the silver dinitrates is lower than D_{3h} namely C_s or C_{2v}.

Thirdly the band at 1281 cm^{-1} is further split. If this results from nitrate–nitrate coupling across silver, then the molecule cannot contain a centre (otherwise coupling would give rise to two bands, one IR active and the other Raman active only).

There are no bands found above 230 cm^{-1} that can be associated with Ag—O stretching modes.

All this, and isomorphism with *trans*-$[Rhpy_4Cl_2]H(NO_3)_2$ tend to confirm that the silver dinitrate anion has the same structure as hydrogen dinitrate.

The case of the 4-picoline complexes is more

Table 11. Infrared bands due to silver dinitrate in *trans*-$[RhL_4Cl_2]Ag(NO_3)_2$

L =	py	py-d5
$\nu_{N=O}$	1438s	1439s
$\nu_{N=O}$	1281s[a]	1279s[a]
ν_{N-O}	1024m	1027m
ν_{NO_3}	816w	817w
δ_{NO_2}	733w	733w

[a] Doublet.

difficult to resolve. The table of IR bands has been deposited with the Editor. Unfortunately bands from 4-picoline occur where some of the nitrate bands would be expected. Further it is not known to what extent loss of solvent changed the spectrum of those compounds.

In each compound except *trans*-$[Rh(4\text{-pic})_4Cl_2]NO_3 \cdot 4AgNO_3$, for which no spectrum was recorded, the ν_3 mode of nitrate is split into ν_s and ν_{as} components by 70–81 cm^{-1}, and its band width is increased over that of *trans*-$[Rhpy_4Cl_2]Ag(NO_3)_2$. The two monosilver nitrate salts each have one component of the split ν_3 band further split, but these splittings are on different components. These salts may require solvent (in the lattice, on a ligand, or even coordinated to the silver) to maintain their structure.

The splitting pattern of all these 4-picoline complexes is similar in form to that of *trans*-$[Rhpy_4Cl_2]Ag(NO_3)_2$, and so similar constraints must apply to the symmetry of the nitrate. The structures, however, of the $[Ag(ONO_2)_2]^-$ moieties must all be quite different from that in the pyridine complex because the primary splitting of ν_3 is by comparison quite small, while the secondary splitting (coupling between the two nitrate units linked to silver) is quite large.

Coordination of silver to halide (to give a silver halide molecule as ligand) as Poulenc envisaged[6] is unlikely for these compounds because the Rh—X/L band system remains unchanged from that of the nitrate salt. However, there are a number of facts which should encourage the search for intact silver halide molecules as ligands.

(i) Halide (X) bridges are increasingly common; (where say M = W^{III})

$$(M—X—M)^{(n-1)+}.$$

The structures of solid silver halides contain the elements

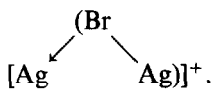
$$(Ag—X—Ag)^+$$

so that the "average" situation

$$(M—X—Ag)^{n+}$$

is to be expected, as in mixed halides of silver and transition metals.

The "inverse" or "metallo-" complexes $(Ag_2Br)^+$ and the like (responsible for the solubility of silver halides in excess of aqueous silver salt solutions) may, of course, be regarded as a silver halide ligand coordinated to a silver ion



(ii) Many complexed pseudo-halides form bridges to other metal ions as in

$$\{[Fe(CN)_6]Hg(CN)_2\}^{3-}$$

and

$$[(H_3N)_5Co(NCS)Ag]^{3+}.$$

(iii) Silver ions often promote the solvolysis of halide coordinated to kinetically inert metal ions, e.g. Co(III)—Cl, presumably via $[Co—Cl—Ag]^{3+}$ intermediates, some of which may have reasonable lifetimes.

(iv) Werner isolated compounds like *trans*-$[Co(en)_2Cl_2]Cl \cdot AgCl$ which he believed to contain silver chloride ligands. However, we reformulated Poulenc's very similar 1 : 1 adduct of silver bromide, "*trans*-$[Rhpy_4Br(BrAg)]Br_2$" as *trans*-$[Rhpy_4Br_2][AgBr_2]$.

Finally, we extend the present comparison between two-coordinated silver ion and two-coordinated proton to other systems. There are many linear species $[MX_2]^+$ for M = H^+ or Ag^+ and X = an uncharged Brønsted base, like water, pyridine, or pyridine-N-oxide. Similarly, for $[MY_2]^-$, for both H^+ and Ag^+ as M, there are isolable derivatives for Y = halide or NO_3^- as in the present work. For Y = $(RCO_2)^-$ [where, with R = CH_3, we have a 24-electron system, isoelectronic with $(ONO_2)^-$], the species $\{(RCOO)_2H\}^-$ are very well-known. The corresponding dicarboxylato-argentates(I) seem not to have been isolated, though they certainly exist. In aqueous media, silver ion remains in solution at pH > 7 when acetate is present, "through formation of $[Ag(OOC \cdot CH_3)_2]^-$".[60]

In view of Emsley's work on the remarkably stable mixed species $[RCOO \cdot H \cdot F]^-$, where R = H or CH_3, we could expect mixed species like $[Ag(\underline{O}NO_2)(OOC \cdot R)]^-$ and $[AgF(\underline{O}NO_2)]^-$ to have reasonable stability.

Abstract—The reaction of a warm ethanolic solution of [Ni(SALSMeTSC-H)Py]Cl·0.5Py (SALSMeTSC = salicylaldehyde S-methylisothiosemicarbazone) with salicylaldehyde and acetylacetone (HACAC), yielded the corresponding square-planar complexes [Ni(SAL_2SMeTSC-2H)] (**A**) and [Ni(SALACACSMeTSC-2H)] (**B**) (SAL_2SMeTSC, and SALACACSMeTSC = quadridentate 2O2N ligand: N(1),N(3)-*bis*(salicylidene)-S-methyl-isothiosemicarbazide, and acetylacetone N(1)-salicylidene-S-methylisothiosemicarbazone, respectively). An X-ray analysis of complex **B** showed that in the reaction of the starting complex with HACAC a rearrangement of the salicylaldehyde moiety takes place (while the C—N(3) bond of the azomethine group is ruptured) and its binding to the N(1) nitrogen. At the same time, HACAC is simultaneously bonded to the liberated N(3)-nitrogen of the hydrazine fragment. Crystal data for the complex B ($NiC_{14}H_{15}N_3O_2S$) are: $M_r = 348.0$, orthorhombic, space group $Pna2_1$, $a = 7.484(3)$, $b = 21.995(8)$, $c = 8.866(3)$ Å; $V = 1459.44$ Å^3, $Z = 4$, $F(000) = 720$, $Dc = 1.58$ g cm^{-1}, $Do = 1.56$ g cm^{-1}, $\mu(MoK\alpha) = 14.45$ cm^{-1}. The structure was solved by the heavy-atom method and refined anisotropically to an R value of 0.078 for 1174 non-zero reflections. The complex molecules are planar, the Ni—Ni distance of nearest molecules being about 3.76 Å. The compounds have been characterized by elemental analysis as well as by IR and electronic spectra.

It has been shown[1,2] that in the presence of some ions, such as VO(II), Ni(II), Cu(II) and Fe(III) a template condensation reaction takes place between salicylaldehyde thiosemicarbazone and its S-alkyl derivatives, yielding the complexes of these metal ions with the quadridentate (2O2N) ligand, N(1),N(3)-*bis*(salicylidene)-S-alkylisothiosemicarbazide, HO-C_6H_4-CHN(3)N(2)C(-SR)-N(1)CH-C_6H_4-OH, SAL_2SRTSC. To our knowledge, there has been no report on the preparation of metal complexes with the ligands which would contain some other carbonyl compound instead of one salicylaldehyde moiety. Therefore, the objective

* Author to whom correspondence should be addressed.

of this work was to investigate the conditions for the synthesis and to determine the structure of the [Ni(SALACACSMeTSC-2H)] complexes, where SALACACSMeTSC is acetylacetone N(1)-salicylidene-S-methylisothiosemicarbazone. Also, we propose here a novel procedure for the synthesis of the earlier described Ni(II) complex with N(1),N(3)-*bis*(salicylidene)-S-methylisothiosemicarbazide, [Ni(SAL_2SMeTSC-2H)].[1]

EXPERIMENTAL

Chemicals and methods

The starting complex [Ni(SALSMeTSC-H)Py] Cl·0.5Py was prepared according to the procedure described earlier.[3] Salicylaldehyde and acetylacetone (HACAC) were puriss grade ("Fluka").

Nickel was determined as *bis*(dimethylglyoximato)-nickel(II), while C, H and N were determined by standard micro-methods.

Magnetic measurements were performed by Gouy balance, and melting points were determined by Kofler apparatus with no correction. IR (KBr pellet) and solution electronic spectra ($C \sim 4 \times 10^{-5}$ mol/dm^3 in EtOH and Py) were obtained on a Perkin–Elmer 457 and on a Unicam SP 800 spectrophotometer, respectively.

Structure solution of complex **B**

Crystal data: $M_r = 348.0$, formula $NiC_{14}H_{15}N_3O_2S$, orthorhombic, Laue symmetry mmm, $a = 7.484(3)$, $b = 21.995(8)$, $c = 8.866(3)$ Å; $V = 1459.44$ Å^3, $Z = 4$, $F(000) = 720$ $Dc = 1.58$ g cm^{-1}, $Do = 1.56$ g cm^{-1}, $\mu(MoK\bar{\alpha}) = 14.45$ cm^{-1}. Systematic extinctions: $0kl$ for $k+1 = 2n+1$, $h0l$ for $h = 2n+1$, ($h00$ for $h = 2n+1$, $0k0$ for $k = 2n+1$ and $00l$ for $l = 2n+1$) define the possible space-groups Pnam (No. 62) or $Pna2_1$ (No. 33). Since $Z = 4$ and the molecule does not have the required symmetry ($\bar{1}$ or m) for Pnam, $Pna2_1$ was chosen and shown to be correct by the subsequent successful structure analysis. The density was measured by flotation in benzene/methyl iodide. Preliminary data on lattice parameters, crystal symmetry and space group were determined from rotation and Weissenberg diffraction patterns. Accurate cell dimensions and X-ray intensity data were measured on a PHILIPS PW 1100 computer-controlled four-circle diffractometer using graphite monochromatized MoK$\bar{\alpha}$ radiation ($\lambda = 0.71069$ Å) and the ω–2θ scan technique. Unit cell parameters were refined from measurements on 14 carefully centred reflections. Intensities were collected in the range $0 < 2\theta < 50°$, h: 0–9, k: 0–26, l: 0–10. A total of 1195 independent reflections were measured of which 1174 with $I > 3\sigma(I)$ were considered as observed and were used in the structure analysis. All intensities were corrected for Lorentz and polarization factors but no absorption correction was applied.

The intensity statistics confirmed the non-centrosymmetric space group (theoretical values are given in parentheses): $\langle E \rangle = 0.885$ (0.886); $\langle E^2 \rangle = 1.000$ (1.000); $\langle |E^2 - 1| \rangle = 0.748$ (0.736). The structure was solved by the heavy-atom method; the positions of the Ni atoms are found from a three dimensional Patterson function. The positions of the non-hydrogen atoms were determined by subsequent Fourier maps. The structure was refined with full-matrix least-squares calculations using anisotropic temperature factors. The final agreement index was $R = 0.078$. A correction for extinction was not applied. Atomic scattering factors including the corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography.[4] Final atomic coordinates, thermal parameters and a list of Fo/Fc values were deposited as supplementary material; copies are available on request. Bond distances and bond angles are given in Table 1.

Preparation of complexes

[Ni(SAL_2SMeTSC-2H)] (**A**): 0.50 g of [Ni(SALSMeTSC-H)Py] Cl·0.5Py[3] was dissolved by heating in 5 cm^3 of EtOH to which was then added 1.0 cm^3 of salicylaldehyde. The red solution was heated mildly with stirring for about 10 min and left at room temperature for about 12 h. The obtained needle-like crystals of cherry-red colour were filtered off and washed with the EtOH–Et_2O (1 : 1) mixture, and finally with Et_2O. Yield: 0.30 g. Found: Ni, 15.6; C, 52.1; H, 3.3; N, 11.2. Calc. for [Ni(SAL_2SMeTSC-2H)]: Ni, 15.9; C, 51.9; H, 3.5; N, 11.3%.

[Ni(SALACACSMeTSC-2H)] (**B**): This complex was prepared in an analogous way, i.e. by the reaction of 1.0 g of the starting complex, dissolved in 10.0 cm^3 of EtOH and by adding 3.0 cm^3 of HACAC. The red solution was heated for about 30 min with reflux. After keeping the solution for several days at room temperature, the dark-red crystals were filtered off and washed carefully with the EtOH–Et_2O (1 : 1) mixture and with Et_2O. Yield: 0.25 g. Found: Ni, 16.7; C, 48.6; H, 4.2; N, 12.4. Calc. for [Ni(SALACACSMeTSC-2H)]: Ni, 16.9; C, 48.3; H, 4.3; N, 12.1%.

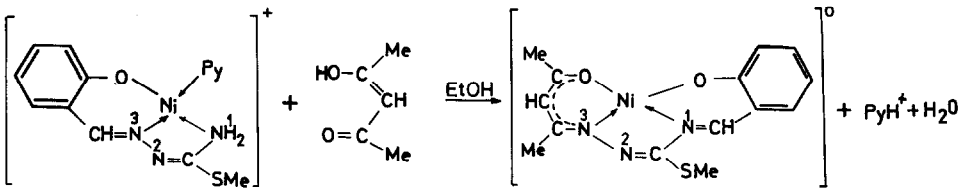
RESULTS AND DISCUSSION

Synthesis and general characteristics of complexes

It is well known from the literature,[5-7] that thiosemicarbazide, $H_2N(3)—N(2)HC(=S)—N(1)H_2$, is condensed with monocarbonyl compounds solely via the hydrazine nitrogen N(3), while the amide nitrogen N(1) does not enter such reaction. However, it has been shown recently[1] that this nitrogen atom can, under special reaction conditions, take part in similar reactions. Thus, the method of template condensation of salicylaldehyde thiosemicarbazone and salicylaldehyde itself, in a basic medium and in the presence of VO(II), Ni(II) and Cu(II) yielded the complexes of general formula $M'[M(SAL_2TSC\text{-}3H)]\cdot nH_2O$ (M' = Na, K; M = VO(II), Ni(II), Cu(II) and SAL_2TSC = quadridentate ligand $HO—C_6H_4—CHNNC(—SH)NCH—C_6H_4—OH$).[1] The compounds obtained can react with CH_3I giving the corresponding complexes of the non-electrolyte type $[M(SAL_2SMeTSC\text{-}2H)]$.[1] It has been established that the above condensation reaction in the case of Ni(II) can proceed only in an alkaline medium (KOH or NaOH). However, in the present work we have shown that $[Ni(SAL_2SMeTSC\text{-}2H)]$ can be prepared in another way, with no OH^- ions present in the solution.

The reaction of hot ethanolic solution of $[Ni(SALSMeTSC\text{-}H)Py]Cl\cdot 0.5Py$[3] (SALSMeTSC = salicylaldehyde S-methylisothiosemicarbazone) and salicylaldehyde appeared to be the route for obtaining the desired complex. Such a course of the reaction can be explained by the coordination of salicylaldehyde S-methylisothiosemicarbazone from $[Ni(SALSMeTSC\text{-}H)Py]Cl\cdot 0.5Py$ which is also established, apart from the oxygen of the deprotonated OH group and the hydrazine nitrogen, via the nitrogen atom of the amide group.[3] The configuration formed is favourable for the occurrence of the template condensation reaction which is in addition catalysed by the coordination effect of the NH_2 group.

With the aim to employ the same condensation reaction for preparation of the complexes with an



Scheme 1.

asymmetric quadridentate ligand containing some other carbonyl compound, we have tried out (under same conditions) the reaction of acetylacetone with the above Ni(II) complex. It appeared, as concluded from an X-ray analysis of the resulting compound, that HACAC has not entered the condensation reaction with the non-condensed amide group. Instead, an unexpected rearrangement of the salicylaldehyde moiety took place, accompanied by its binding to the azomethine nitrogen, and preceded by the rupture of the C—N bond. At the same time HACAC was bound to the newly liberated nitrogen atom of the hydrazine fragment N(3). The general reaction can be represented by Scheme 1.

Such a course of the reaction can be explained by the difference in reactivity of the corresponding hydrazine and amide group of thiosemicarbazide (TSC) and S-methylisothiosemicarbazide (SMeTSC), respectively, as well as by different condensation capabilities of aldehydes and ketones. Namely, it is well known that the condensation reactions with NH_2 groups proceed more readily with aldehydes than with ketones, and the hydrazine group of both TSC and SMeTSC is more reactive than the amide NH_2 group.*

With regard to the nature of the compound obtained and the ligand, respectively, it can be concluded that the rupture of the bond salicylidene–hydrazine moiety [followed by the bonding of the latter to the amide nitrogen N(1)] is energetically preferable to the formation of an ACAC—N(1) bond.

Both complexes are well soluble in common organic solvents, (DMF, $CHCl_3$, C_6H_6, MeOH, EtOH, Me_2CO), less soluble in Et_2O and insoluble in water.

Their molar conductivities are close to zero, which is in agreement with their coordination formulae.

As it could be expected, complex **A** exhibits greater thermal stability (m.p. = 297°C), compared to complex **B** (m.p. = 208°C).

Finally, the complexes are diamagnetic, both crystalline and in solution, which also confirms their square-planar structure.

Descriptions of the structure of complex **B**

The shape of the molecule, atomic numbering scheme and the packing of the molecules are indi-

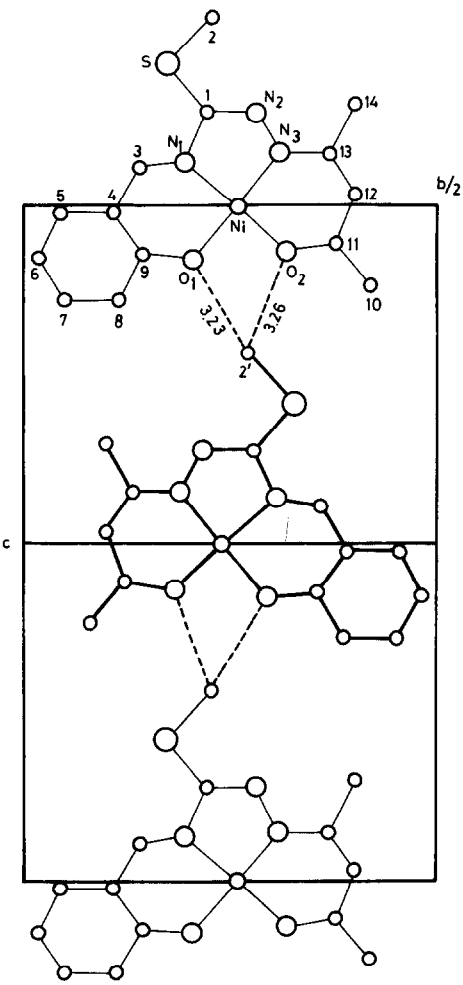


Fig. 1. Arrangement of molecules in two asymmetric units viewed along the *a* axis. The thin lines represent molecules with $a \approx 0$, and the thick lines those with $a \approx 0.5$. Van der Waals contacts are in Å.

* Apparently, the latter difference disappears under special reaction conditions (alkaline medium, presence of a suitable transition metal ion) when, due to the template effect, the condensation of TSC with salicylaldehyde takes place via the two terminal nitrogen atoms.[1]

cated in Fig. 1. The neutral complex molecules are almost planar, in which the ligand is the quadridentate (2O2N) doubly deprotonated acetylacetone N(1)-salicylidene-S-methylisothiosemicarbazone. The ligand coordination around the nickel atom is square-planar with a deviation from the best-plane not exceeding 0.01 Å (compare Table 2). The distances Ni—N(1) and Ni—N(3) of 1.824 and 1.818 Å respectively, agree well with those found in similar compounds having square-planar coordination around the Ni atom. The distance Ni—O(1) (1.852 Å) and Ni—O(2) (1.836 Å) are in good agreement with the corresponding values observed in the structure of ammine(salicylaldehyde 4-phenylthiosemicarbazonato)nickel(II).[8] In the present structure the salicylidene fragment of the ligand is bonded via the amide nitrogen N(1) to the S-methylisothiosemicarbazide moiety instead, as it would be expected, via the hydrazine nitrogen N(3). Such a configuration of salicylidene and S-methylisothiosemicarbazide was found in some transition metal complexes with the similar ligands[9–11] in which two salicylidene fragments were coupled to both N(1) and N(3). The bond distances and bond angles found in the salicylidene and S-methylisothiosemicarbazide fragments of the title compound are in good agreement with the corresponding values from the above references. The bond distances C(1)—N(1) (1.411 Å) and C(1)—N(2) (1.324 Å) indicate a partial delocalization of the electronic density within the carbazide fragment of the ligand. In this case the delocalization is realized in an opposite way with respect to the similar π-electronic delocalization (in the same moiety) of some transition metal complexes with different derivatives of S-methylisothiosemicarbazones in which the ligands appear in an imido form.[12] In the deprotonated acetylacetone fragment, an asymmetric delocalization of electronic charge takes place. As a result, the C—C bond lengths are 1.399 and 1.397 Å, while the C—N and C—O bond distances are 1.343 and 1.265 Å, respectively. The observed C—CH_3 bond lengths are 1.513 and 1.490 Å. These values correspond to those observed in the *bis*(acetylacetone)Ni(II) dihydrate.[13]

The quadridentate ligand chelating the nickel atom forms two (acetylacetoneimine and salicylidene) six-membered, and one (S-methylisothiosemicarbazide) five-membered ring. The ligand molecule as a whole lies approximately in one plane with the largest deviation from the best-plane of 0.06 Å (compare Table 2) for the carbon atom of the thiomethyl group. The S—C(2) bonding is in the *trans*-position with respect to the C(1)—N(1) bond.

The ligand molecules are mutually linked by van der Waals contacts in the layers perpendicular to the *b* axis (Fig. 1). Van der Waals contacts are realized via methyl carbon and both oxygens |C(2′)H_3...O(1) = 3.23 Å, C(2)H_3...O(2) = 3.27 Å|.

These intermolecular contacts are slightly shorter compared to the sum of van der Waals radii of the methyl group (2.0 Å) and oxygen (1.4 Å).[14] The shortest Ni—Ni distance of neighbouring complexes is 3.76 Å.

IR spectra

The character of the IR spectra is in concordance with the established structure of the ligands and complexes. Their prominent feature is the absence of the ν(OH) and ν(NH) vibrations in the region 3600–3050 cm^{-1}. On the other hand, in the region 1615–1510 cm^{-1} there are five strong bonds which, apart from ν(C=C) vibrations of the benzene ring, can be ascribed to the valence vibrations ν(C=O), ν(C=N) and ν(C=N).[15] The three strong and clearly split bands appearing at 1440–1370 cm^{-1} are characteristic of $\delta(CH_3)$ of the acetylacetone moiety,[15] as well as of δ(Cγ—H).[16] The only significant band appears in the spectrum of complex

[a] In EtOH.
[b] In Py. Molar extinction coefficient (ε, $dm^3\ mol^{-1}\ cm^{-1}$) in parentheses.

A at about 1450 cm^{-1}, which makes the principal difference in the appearance of the spectra of the two compounds. This is in agreement with the absence of the acetylacetone moiety in complex **A**, since this band is obviously due to the skeleton vibrations of the benzene ring. The band in the spectrum of complex **B** is overlapped with $\delta_{as}(CH_3)$ and $\delta(C\gamma—H)$ vibrations.[16] The strong band at about 1160 cm^{-1} in both the spectra is due to $\nu(C_{Ar—O})$ of the coordinated phenolic hydroxyl. Finally, the bands of medium intensity at 750 cm^{-1} can be unambigously ascribed to the 1,2-substituted benzene ring, i.e. to the out-of-plane vibrations of four neighbouring hydrogen atoms.[17]

Electronic spectra

The position and intensity of *d–d* bands ($\sim$ 20.000 cm^{-1} for **A**, and $\sim$ 21.000 cm^{-1} for **B**) in the electronic absorption spectra of the complexes (Table 3) recorded in EtOH and Py, suggest that the square-planar structure is also preserved in the solution.[18] The practically identical position of the bands obtained in both solvents, as well as the absence of lower energy bands ($<$ 15.000 cm^{-1})[19,20] indicate the lack of Ni—Py interactions, i.e. the coordination number of Ni(II) has not been changed even in a solvent of strong donor character, such as pyridine. The explanation should be based on a very strong ligand field of both ligands so that the alteration of electronic structure of Ni(II) ion, i.e. of its spin state, would require a larger amount of energy than it would obtain on account of an axial coordination with solvent molecules.

A further support to the square-planar structure of the complexes in the solution is their dark-red colour, as well as their established diamagnetic properties.

FORMATION OF CYANIDE COMPLEXES OF COBALT(II) AND MANGANESE(II)

EFRAIM AVŞAR* and BETÜL BAŞARAN

Department of Chemistry, Technical University of Istanbul, Maslak, 80 626 Istanbul, Turkey

(*Received* 3 *March* 1987; *accepted* 5 *May* 1987)

Abstract—The formation of complexes of the cyanide ion with Co(II) and Mn(II) has been studied potentiometrically in an aqueous sodium perchlorate medium of unit ionic strength at 298 K. Studies of the equilibria in the cobalt(II)–cyanide system show that at least one strong mononuclear complex exists, while in the manganese(II)–cyanide system two mononuclear complexes can be formed in the concentration range studied.

Despite the large number of studies carried out so far[1–7] to indicate the number and nature of complexes formed when cyanide is added to an aqueous solution of cobalt(II) salts, our knowledge is by no means complete. A common opinion is that a strong fifth mononuclear complex exists in cobalt(II) cyanide solutions; but no value for the formation constant seems to have been evaluated. Besides, to the best of our knowledge no equilibrium studies dealing with the formation of cyanide complexes of manganese(II) have ever been reported.

The aim of the present work was to determine the step-wise complex formation equilibria in the cyanide systems of Co(II) and Mn(II).

Potentiometry has been the main technique used for studying the complex formation in aqueous solution.[8] Potentiometric measurements may be applied to a central ion-ligand system if a suitable electrode is available. Here, the most suitable method for ligand determination seems to be pH and/or direct [L], i.e. free ligand, measurements in a buffer of the ligand ion and the corresponding acid by using both glass and cyanide-specific electrodes. From such measurements the free ligand concentration [L] and the average ligand number $\bar{n}$ can be found.[9] All measurements in this study have been carried out at 298.15 K in an aqueous medium of ionic strength $I = 1.0$ M with sodium perchlorate as an inert electrolyte.

EXPERIMENTAL

Chemicals

Co(II) perchlorate solution was prepared from $Co(ClO_4)_2 \cdot 6H_2O$ (Fluka, purum). Mn(II) perchlorate was made by dissolving Mn(II) carbonate (Fluka, purum) in perchloric acid (Merck, p.a.) and recrystallizing several times. Co(II) and Mn(II) were analysed as before.[9] The free acid concentrations in the stock solutions have been determined potentiometrically. The perchloric acid (Merck, p.a.) solutions were standardized against borax. Sodium perchlorate was prepared and analysed as described before.[10] Sodium cyanide (Merck, p.a.) solutions were prepared daily. The NaCN solutions were standardized with a standard $AgNO_3$ solution. Oxygen-free nitrogen was used for deaeration. The Ag, AgCl electrodes were prepared as described previously.[11]

Apparatus and procedure

A Metrohm E580 ion-activity-meter and/or a Metrohm E500 digital pH meter equipped with a Metrohm EA-306-CN ion-specific electrode and a Radiometer type G202 C glass electrode have been used for the potentiometric measurements. The slopes of both the electrodes have been checked repeatedly and found to be 59.2 ± 0.2 mV. The reproducibility in the measurements was usually within ± 1 mV for the Co(II)–CN^- system, but

much better, ±0.4 mV, for the Mn(II)–CN^- system. All solutions in the cobalt(II)–cyanide system were de-oxygenated by purging with purified nitrogen for about 15 min before titrations. A magnetic stirrer was used for mixing. The e.m.f.s of the following cell were measured.

$$-RE//C_M\ M\ Me(ClO_4)_2, C_L\ M\ NaCN,$$
$$C_H\ M\ HClO_4, NaClO_4$$
$$\text{to } I = 1\ M/\text{glass of cyanide electrode} +$$

where

$$RE// = Ag, AgCl/0.025\ M\ NaCl,$$
$$0.975\ M\ NaClO_4/1.00\ M\ NaClO_4/.$$

Here, Me denotes Co or Mn. Both the cyanide and glass electrodes were used in the Co(II)–CN^- system, while in the Mn(II)–CN^- system, measurements were performed with a glass electrode. The measurements were arranged as titrations where the solutions in the right-hand half-cell were obtained by adding a known volume v (cm^3) of a ligand solution to V_0 (cm^3) of metal perchlorate solution. Special attention has been paid to obtain reliable measurements. The precipitate of $Co(CN)_2$ is slightly soluble; therefore the measurements were performed at very low cobalt ion concentrations, *ca* 10^{-4} M, in order to avoid the precipitation. The e.m.f.s have been read within as short a time as possible after each addition. All solutions used in the cobalt(II)–cyanide system have been carefully de-oxygenated and kept under an inert atmosphere during the measurements.

Calculations

The step-wise formation constants have been evaluated both graphically and numerically. The graphical method has been described elsewhere.[9,11] The numerical calculations have been carried out by using different programs designed by Sandell.[12] In order to calculate the formation constants from these measurements, it is necessary to know the acidity constant of HCN under the same conditions. This has therefore been determined in separate measurements and found to be $K_a = (1.12 \pm 0.01)\ 10^{-9}$ M.

RESULTS AND DISCUSSION

Co(II)–*cyanide system*

Potentiometric titrations were carried out on five different C_M, i.e. 0.245, 0.490, 0.633, 0.980 and 1.960 mM at constant acid concentrations of 0.0468, 0.0537, 0.217, 0.0277 and 0.0554 mM, respectively. A free ligand ion concentration up to ~ 1 mM could be reached in the measurement. Thus, the possible formation of a hexacyanide could have been studied.

Both the graphical and numerical evaluations of constants clearly indicate the formation of more than one complex, and the mononuclear pentacyanide complex strongly dominates the complex formation. Furthermore, these calculations show that both $\beta_1 = 0$ and $\beta_6 = 0$. The graphical calculations indicate the existence of ML_3, ML_4 and ML_5 mononuclear complexes. Another one, namely ML_2, might be present but no significant value could be obtained. In the numerical calculations, on the other hand, the fifth complex is well established. However, it is not possible to decide with certainty the sufficiency of the complex ML_5 alone to describe the experimental material. However, in all models to be tested ML_5 has to be included. Nevertheless calculations showed that the introduction of the the third, or fourth, complex gives a much better fit to experimental data. For a model containing ML_4 and ML_5 $\beta_4 = (1.2 \pm 1.8)\ 10^{18}\ M^{-4}$ and $\beta_5 = (1.0 \pm 0.8)10^{23}\ M^{-5}$ are found. Another calculation by considering ML_3 and ML_5 gave a better fit with the results of $\beta_3 = (5 \pm 4)10^{13}\ M^{-3}$ and $\beta_5 = (1.0 \pm 0.6)10^{23}\ M^{-5}$. Thus, introducing the third, or fourth, complex gives a better fit but increases the uncertainties in the estimates. On the other hand, including the three mononuclear complexes, such as $ML_3+ML_4+ML_5$, $ML_2+ML_3+ML_5$ etc. or taking account of all the possible combinations of the probable six complexes always results in very large errors. Moreover, some runs with polynuclear complexes and/or hydrolytic species such as $ML_5(OH)$, have been performed but no estimates could ever be obtained. Such combinations should thus be discarded. This means that the experimental data can adequately be described by just two parameters.

Table 1.

Method	β_1	β_2	β_3	β_4	β_5	β_6
Graphical	0	$\sim < 5 \times 10^8$	$< 2 \times 10^{14}$	$< 6 \times 10^{19}$	$(5 \pm 2)10^{23}$	0
Numerical	0	0	$(5 \pm 4)10^{13}$	0	$(1.0 \pm 0.6)10^{23}$	0

The results of these calculations are shown in Table 1. Obviously, only the value of β_5 is well established. The errors given in the numerical calculations correspond to confidence limits at the 99.9% level of significance.

Since the best fit to the potentiometric data is obtained with the model including only ML_3 and ML_5, this has been accepted to be the best representation of this system. The distribution of the complexes ML_3 and ML_5 as a function of [L], calculated from the formation constants, is shown in Fig. 1(a).

Table 2. Over-all formation constants of the Co(II)– and Mn(II)–cyanide systems at 298.15 K and $I = 1.0$ M: errors given correspond to confidence limits at the 99.9% level of significance

System	j	β_j (M^{-j})
Co(II)–cyanide	3	$(5\pm4)10^{13}$
	5	$(1.0\pm0.6)10^{23}$
Mn(II)–cyanide	1	75 ± 11
	2	$(2.3\pm0.5)10^{3}$

Mn(II) *cyanide system*

Titrations were performed with four different values of C_M, namely 10, 20, 30 and 40 mM. Higher metal ion concentrations were used without any precipitations, which permit the study of the system in a wider range of concentration. The acid concentrations, constant during the titrations, were 10 mM for $C_M = 10$ mM, 20 and 40 mM for $C_M = 20$ mM, 15 mM for $C_M = 30$ mM, 20 and 40 mM for $C_M = 40$ mM. A free ligand ion concentration up to $\simeq 80$ mM could have been reached in these measurements. Higher free ligand concentrations were not allowed due to a blue precipitate of the hexacyanide complex.[13] No systematic deviations could be observed when both C_M and C_H were varied, which shows that neither polynuclear nor acid complexes seem to exist.

The mononuclear complexes are formed in the concentration range studied. The consecutive formation constants were evaluated both graphically[8] and numerically by a high-speed computer using the data program UNINUX.[12] Both methods gave the same estimates: $\beta_1 = 75\pm11$ M^{-1}, $\beta_2 = (2.3\pm0.5)\,10^3$ M^{-2}. The distribution curves of the complexes are shown in Fig. 1(b), and the results of this work are collected in Table 2.

The cyanide system of Co(II) shows an unusual course of complex formation, in which a strong pentacoordinate is dominating. Potentiometric data indicates further the formation of complexes in small quantities before the main pentacyanide. The experimental difficulties do not allow the studies of other complex equilibria in a wider range of concentrations. However, the formation of the third complex can be detected with a formation constant of the order of 10^{13} M^{-3}. In this respect, the Co(II)–CN^- system is reminiscent of another cyanide system, i.e. Ni(II)–CN^-. Also in this system a very strong complex of tetracyanide with $\beta_4 = 1.16\times10^{31}$ M^{-4} was found, while the formation of other complexes could have been discarded.[14]

Comparing with Co(II) complexes, Mn(II)-cyanides have markedly lower stabilities. This, of course, is expected as all Mn(II) complexes show the same trend. In the range of cyanide concentration studied

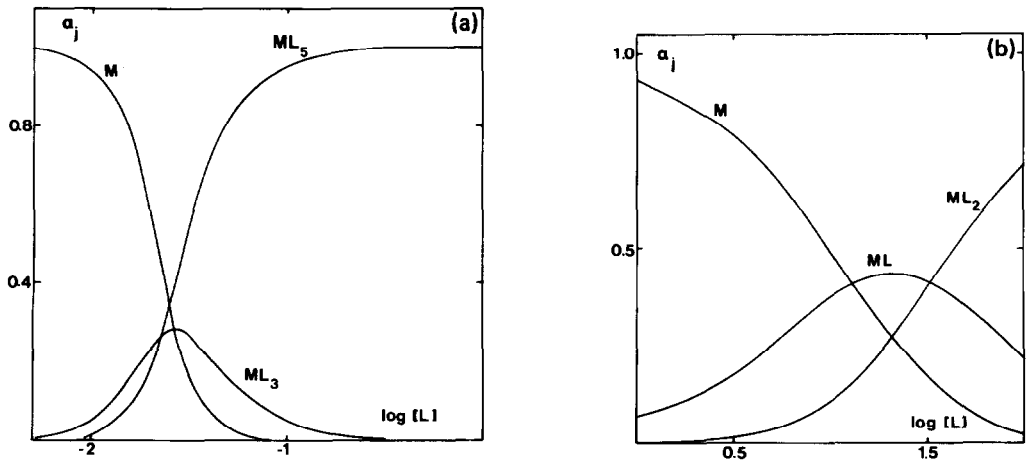

Fig. 1. Distribution of (a) cobalt(II) and (b) manganese(II) between the different ML_j complexes with varying cyanide ion concentrations ([L] in mM).

only the formation of the first two complexes takes place in appreciable amounts. Addition of further cyanide causes a blue precipitate of the hexacoordinate complex,[13] which changes colour on storing. The cyanide ligand can be bonded to a metal ion essentially by covalent bonds. Most metal cyanide complexes have metal-carbon rather than metal-nitrogen bonds. As a very soft ligand the cyanide forms strong complexes with the most transition-elements.

SYNERGISTIC COMPLEXES OF URANYL ION WITH 1-PHENYL-3-METHYL-4-ACETYL-PYRAZOLONE-5 AND SOME OXO-DONORS

M. S. NAGAR, P. B. RUIKAR and M. S. SUBRAMANIAN*

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-400085, India

(*Received* 17 *February* 1987; *accepted* 11 *May* 1987)

Abstract—Complexes of uranyl ion with 1-phenyl-3-methyl-4-acetyl-pyrazolone-5(PMAP) and various oxo-donors such as aliphatic sulphoxides [R_2SO, where R = *i*-C_5H_{11}(DISO), *n*-C_6H_{13}(DHSO), *n*-C_7H_{15}(DSSO), *n*-C_8H_{17}(DOSO), *n*-C_9H_{19}(DNSO), *n*-$C_{10}H_{21}$(DDSO), *n*-$C_{11}H_{23}$(DUDSO) and *n*-C_4H_9(DBUSO)] tributylphosphate (TBP) and tri-*n*-octyl phosphine oxide (TOPO) have been synthesised and characterized. Analytical data establish that they have the stoichiometry $UO_2(PMAP)_2X$ where X is the oxo-donor. The IR spectra of the sulphoxide complexes in the S—O stretching region indicate that the ligands R_2SO are O-bonded. The methyl protons of the pyrazole ring and acetyl group in the PMAP ligand are equivalent giving rise to a single sharp peak in the PMR spectra, whereas in the synergistic complexes with the oxo-donors, two deshielded peaks of equal intensity are observed which indicate the non-equivalence of the methyl groups. The peak which is more deshielded has been ascribed to the methyl of the acetyl group. The higher deshielding of these methyl protons arises due to the transfer of electron density to the metal atom on complexation.

4-aroyl pyrazolones, such as 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5(PMBP) are being increasingly used as extractants for several metal ions[1–10] in view of their relatively lower cost[11] and their ability to extract metal ions from relatively acidic solutions.[2,6,12] This has resulted in the investigation of extraction of several metal ions by various workers. However, relatively little is known about the stabilities and structure of metal chelates of pyrazolones.

We have been investigating the synthesis, infrared and NMR spectra of solid synergistic complexes of uranyl ion with pyrazolones and oxo-donors such as sulphoxides and phosphorus oxides.[13] Rao and Arora[14] have reported the synthesis and infrared spectra of uranyl-PMBP adducts with tributyl phosphate(TBP) and tri-*n*-octyl phosphine oxide (TOPO). Recently, Okafor[15] has isolated the lanthanide chelates of PMAP and investigated their spectroscopic properties. The present paper reports on the synthesis, characterization, infrared and PMR spectra of synergistic complexes of uranyl ion with PMAP and the oxo-donor aliphatic sulphoxides and tributyl phosphate and tri-*n*-octyl phosphine oxide.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Reagents

All chemicals used were of B.D.H./A.R. grade. PMAP was synthesised by a modified Jensens' method[16] described by Okafor and recrystallized from hexane to obtain yellow crystals of the enol form m.p. = 67°C, C = 66.6%, H = 5.6%, N = 12.9%; required for $C_{12}H_{12}O_2N_2$, m.p. = 67°C, C = 66.8%, H = 5.6%, N = 13.0%. All the sulphoxides were prepared by a general method reported earlier for the synthesis of long chain aliphatic sulphoxides.[17] TOPO was obtained from Koch Light Co. and used as such. TBP was purified and distilled by the usual procedure.

Preparation of the complexes

The complexes were prepared by solvent extraction of 50 cm^3 of uranyl nitrate solution (1 mM) at a pH 2 with 50 cm^3 of benzene solution containing 2 mM of PMAP and 1 mM of the neutral oxo-donor. The benzene layer was dried with anhydrous sodium sulphate, evaporated to dryness in a rotary evaporator and the product recrystallized twice from *n*-hexane.

Characterization of the complexes

Table 1 summarises the analytical data of the complexes. Melting points were determined using an automatic melting point apparatus, Mettler FP-61. Carbon and hydrogen were determined by microanalysis using the empty tube combustion method described by Belcher and Spooner.[18] Sulphur was by combustion in an oxygen filled flask and conductometric titration of the sulphate in neutral solution with standard barium acetate solution in alcohol–water medium. Uranium was determined by back-extracting from benzene, a weighed amount of the complex with 5 N sulphuric acid, passing through a Jones' reductor to convert to U(IV) and titrating with standard cerium(IV) solution using ferroin as indicator. It was also obtained from the weight of the oxide residue (U_3O_8) after C—H combustion. Infrared spectra were measured in Nujol mulls between CsI discs in the range of 4000–200 cm^{-1} using a Perkin–Elmer 577 infrared grating spectrophotometer. Proton magnetic resonance spectra were measured in $CDCl_3$ with a Varian EM-360, 60 MHz NMR spectrophotometer using 0.1 M solutions and TMS as internal standard.

RESULTS AND DISCUSSION

A few typical bands in the infrared spectra of these complexes have been assigned empirically

(Table 2). These indicate a small shift of the carbonyl vibration indicating chelation. The S=O stretching frequency in the sulphoxide adducts has been observed as a strong band in the region of 960–970 cm^{-1}. Since these are reduced with respect to the free sulphoxides, it has been concluded that the bonding is through the oxygen atom of the sulphoxide. A band at 1083 cm^{-1} and another at 1210 cm^{-1} have been ascribed to the P=O stretching frequencies in the TOPO and TBP complexes respectively. In all these complexes, the O—U—O asymmetric stretch has been observed as a strong band at 910–920 cm^{-1}. This is lower than the frequency observed at about 950 cm^{-1} in ionic uranyl compounds indicating the presence of the uranyl group in the complexes. In all these complexes a band at 485–490 cm^{-1} which is absent in the free PMAP ligand is observed and this has been attributed to the U—O (pyrazolone) stretching frequency. This compares with the assignment made by Okafor for the M—O stretching frequency of lanthanide chelates of PMAP.[15] Another band at 390–400 cm^{-1} which is absent in the free ligand has been ascribed to the M—O(oxo-donor) stretching frequency. No correlation of this frequency with the base strength of the oxo-donor has been observed. Strong bands at 755 and at 1080 cm^{-1} have been assigned to the νCH and CH in-plane deformation modes respectively as observed by Okafor for lanthanide chelates of PMAP.

In the PMR spectra, two sets of signals of the phenyl protons are observed due to the ortho protons and *m,p* protons in the synergistic complexes of PMAP and oxo-donors (Table 3). The chemical shift of the *ortho* protons occurring at 8.45 ppm shows significant deshielding as compared to the PMAP ligand (7.85 ppm) whereas no shift is observed in the case of the *m,p* protons. This can be attributed to the bonding site being nearer to the *ortho* protons of the phenyl ring. The methyl protons of the pyrazole ring and those of the acetyl group give only a single signal at 2.44 ppm in the PMAP ligand. However, in the synergistic complexes, they are deshielded with respect to the ligand and occur as two sharp separate signals at 2.60 and 2.85 ppm. The latter is ascribed to the methyl protons of the acetyl group as it is more deshielded with respect to the methyl protons of the pyrazole ring due to the transfer of electron density to the metal on coordination. The single peak corresponding to the enolic proton occurring at 11.3 ppm in PMAP disappears in the synergistic complexes on the formation of the chelate. The alpha methylene protons of the sulphoxide groups (Table 4) in these complexes show the expected multiplet (8 lines) at 3.15 ppm corresponding to the ABX_2

pattern as observed in complexes with TTA as the chelating ligand.[19,20] In the $UO_2(PMAP)_2 \cdot TBP$ complex however, these protons are observed as a quartet occurring at 4.24 ppm due to coupling with the adjacent P-31 nuclei. The methyl protons of the oxo-donor are found to occur at much higher fields of 0.85 ppm compared to those of the methyl protons of pyrazolone due to the inductive effect of the adjacent methylene groups. In addition, these peaks appear as triplets with a J value of 5–7 Hz due to coupling by the adjacent methylene protons whereas the pyrazolone methyls occur only as single sharp peaks in these complexes.

CONCLUSIONS

Solid synergistic complexes of uranyl ion with PMAP and oxo-donors have the stoichiometry, $UO_2(PMAP)_2 \cdot X$ where X is the oxo-donor. These are similar to the PMBP systems in which the oxo-donor binds giving a possible coordination number of seven for uranium.

EFFECT OF COUNTERCATIONS IN CATALYTIC PHOTOOXIDATION OF ISOPROPYL ALCOHOL BY DECATUNGSTATE ISOPOLYANION

KENJI NOMIYA,* SEIICHIRO MATSUBARA, KIYOTSUGU YAMASHITA and MAKOTO MIWA

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 6 *April* 1987; *accepted* 5 *May* 1987)

Abstract—By utilizing homogeneous decatungstate solution, we have found a novel catalyst system for photooxidation of isopropyl alcohol under excess of O_2. The decatungstate with countercation ratio of K : TBA (tetrabutylammonium) = 3 : 1 shows an activity about double that of the homogeneous K or TBA salt of decatungstate. A new redox cycle considering the ion-pair between decatungstate and countercations is proposed.

Under excess of O_2, a catalytic photooxidation of isopropyl alcohol to acetone, initiated by irradiation (> 300 nm) of the charge-transfer bands of decatungstate isopolyanion $[W_{10}O_{32}]^{4-}$ proceeds in conjunction with a redox cycle of the polyanion between oxidized (pale yellow) and $2e^-$-reduced (blue) forms.[1–3] The reoxidation of $2e^-$-reduced species is attained by reaction with O_2. Recently we have found spectrophotometrically for homogeneous solution containing K or TBA salt that the relative velocity of redox cycle is markedly influenced by the countercations, i.e. a photoreduction of polyanion proceeds faster for the K salt than for the TBA salt, but a reoxidation of the reduced polyanion by reaction with O_2 proceeds slower for the K salt than for the TBA salt.[2] In spite of such a difference, however, the conversion of isopropyl alcohol to acetone and the catalytic turnover are almost unchanged for the two salts. In order to seek a more active catalyst using decatungstate, we have studied the photooxidation of isopropyl alcohol by mixed-countercation species of decatungstate, $K_n(TBA)_{4-n}[W_{10}O_{32}]$, under excess of O_2.

EXPERIMENTAL

All chemicals used were of analytical grade. $K_4[W_{10}O_{32}]\cdot 4H_2O$ and $(TBA)_4[W_{10}O_{32}]$ were prepared as previously described.[1,2] Solvent was used as a 1 : 1 mixture of CH_3CN and water (pH 2.5, H_2SO_4). A sample solution (50 cm^3) was prepared using two decatungstate salts at a constant concentration of $[W_{10}O_{32}]^{4-}$ (2×10^{-3} mol dm^{-3}) containing various molar ratios of K : TBA (4 : 0, 3.5 : 0.5, 3 : 1, 2.5 : 1.5, 2 : 2, 1 : 3, 0 : 4), into which isopropyl alcohol (0.4 mol dm^{-3}) as a substrate and benzene (0.24 mol dm^{-3}) as an internal reference for gas chromatography had been added. Apparatus for the photoreaction, comprising of a 75-W mercury lamp (SHL 100-UV, Toshiba Corporation) for an external irradiation and 75 cm^3 Pyrex reaction-flask, was described elsewhere. Actinometry was performed by irradiation with 2-hexanone and the light intensity was 1.0×10^{-4} einstein h^{-1}. Decrease of substrate and production of acetone during irradiation (> 300 nm) under excess of O_2 were monitored by TCD gas chromatography (Shimadzu GC-8A) on a PEG 20M glass-column (3 m) and the data were treated by Chromatopak (Shimadzu C-R3A). The formation of reduced decatungstate under N_2 and the reoxidation of it by reaction with O_2 were monitored by a spectrophotometer (Hitachi-340).

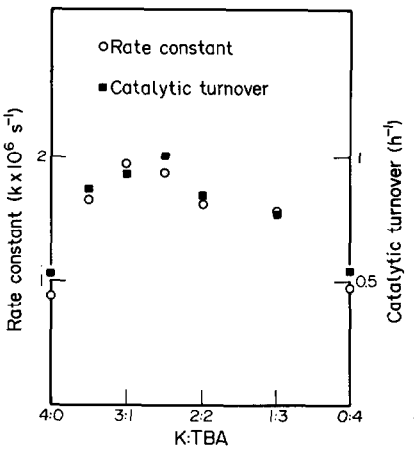

Fig. 1. Relation of the countercation-ratio of decatungstate to the rate constant of decreasing isopropyl alcohol determined by the assumed first-order kinetics and to the catalytic turnover per hour for production of acetone. Conditions: [decatungstate] = 2×10^{-3} mol dm^{-3} and [isopropyl alcohol] = 0.4 mol dm^{-3} in 50 cm^3 solution containing benzene as an internal reference for gas chromatography. Solvent: 1:1 mixed media of Ch_3CN and water (pH 2.5, H_2SO_4).

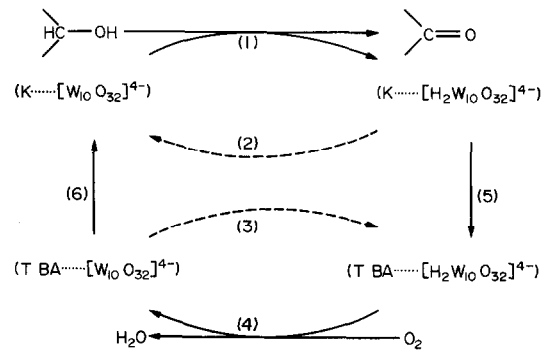

Fig. 2. Proposed redox cycle of decatungstate for catalytic photooxidation of isopropyl alcohol.

RESULTS AND DISCUSSION

Since the stoichiometry between consumed isopropyl alcohol and produced acetone is retained, side-reactions do not need to be considered. For each countercation ratio of decatungstate, the rate constant for decreasing isopropyl alcohol deter-

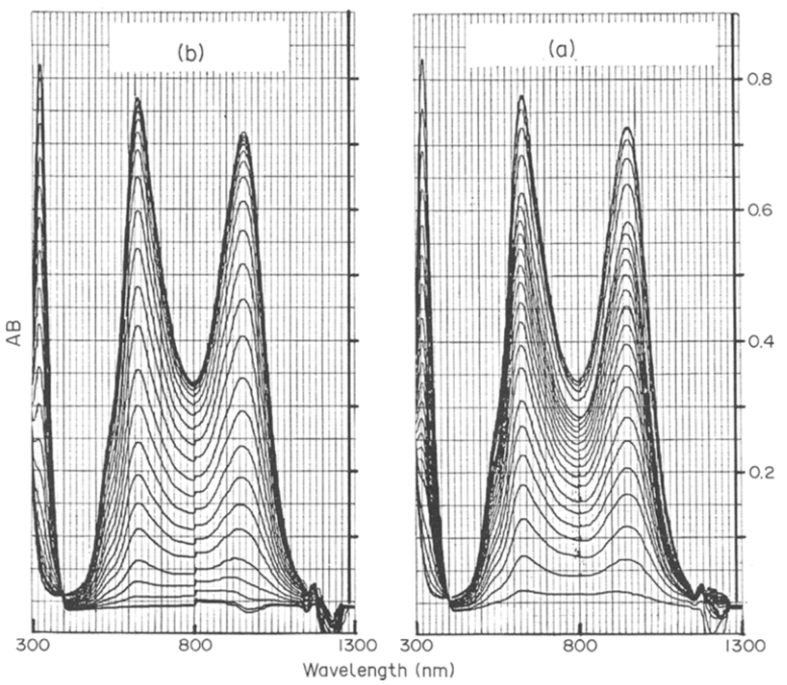

Fig. 3. Absorption spectral changes of photoreduced decatungstate under N_2 (a) and of reoxidation process of reduced decatungstate by reaction with O_2 (b). Irradiation is performed for the decatungstate with the cation-ratio K : TBA = 3 : 1 ([decatungstate] = 6.25×10^{-5} mol dm^{-3}), isopropyl alcohol (5×10^{-3} mol dm^{-3}) and benzene (1.6×10^{-3} mol dm^{-3}) in the 1 : 1 mixed media of CH_3CN and water (pH 2.5, H_2SO_4). The spectra in (a) are recorded for 18 min each after 1-min irradiation and then for each after 5-min irradiation. The spectra of reoxidation (b) are recorded after exposure to air of the solution of saturated photoreduced species obtained in the experiment of (a).

mined by the assumed first-order kinetics and the catalytic turnover, or the molar ratio of decatungstate to produced acetone, per hour are depicted in Fig. 1. Significant effects by countercations are seen in the cases, other than when the K:TBA ratio is 4:0 and 0:4. Such mixed-cation systems show a higher activity about 1.5–2 times than that of the decatungstate with homogeneous countercation composition. A maximal activity is especially observed when the countercation ratio is 3 : 1–2.5 : 1.5. These facts could not be explained by the redox cycle of only a polyanion-moiety, but by the cycle of an ion-pair, or an outer-sphere complex between decatungstate and countercations.

In Fig. 2, we propose a new redox cycle involving ion-pairs with countercations. The paths (1) and (3) show the photoreduction of decatungstate and the paths (2) and (4) the reoxidation of reduced decatungstate by reaction with O_2. $(K\ldots[W_{10}O_{32}]^{4-})$ and $(TBA\ldots[W_{10}O_{32}]^{4-})$ represent the ion-pair of oxidized decatungstate, and $(K\ldots[H_2W_{10}O_{32}]^{4-})$ and $(TBA\ldots[H_2W_{10}O_{32}]^{4-})$ the ion-pair of $2e^-$-reduced decatungstate. For the homogeneous K salt, the redox cycle consists of paths (1) and (2), and for the homogeneous TBA salt, it consists of paths (3) and (4). It has been spectrophotometrically evident that the paths (1) and (4) proceed faster than those of (2) and (3).[2] For the mixed-countercation system, the paths (1)–(5)–(4)–(6) form a new redox cycle, where the paths (5) and (6) are assumed as a process comprising of a rearrangement of countercations.

Figure 3 shows the absorption spectral changes of photoreduction of decatungstate with a K : TBA ratio of 3 : 1 during irradiation under N_2 and of the reoxidation of saturated $2e^-$-reduced decatungstate by exposure to air. These spectra show that both of these processes are well balanced. They markedly contrast to recently reported spectra for homogeneous K or TBA salt, where both processes are unbalanced.[2] The proposed redox cycle is consistent with these spectral changes.

SYNTHESIS AND RING INVERSION OF THE FIRST HAFNOCENE DITELLUROLENE CHELATE: $[(\eta^5\text{-}C_5H_5)_2Hf(1,2\text{-}Te_2C_6H_4)]$

TH. KLAPÖTKE,* H. KÖPF and P. GOWIK

Institut für Anorganische und Analytische Chemie, Technische Universität Berlin, D-1000 Berlin 12, F.R.G.

(*Received* 23 *April* 1987; *accepted* 11 *May* 1987)

Abstract—$[(cp)_2Hf(1,2\text{-}Te_2C_6H_4)]$ (**1**) (cp = η^5-C_5H_5) was obtained from $[(cp)_2HfCl_2]$ and equivalent amounts of $1,2\text{-}(LiTe)_2C_6H_4$ as the first hafnocene ditellurolene metallacycle and the last missing member of the widely investigated subgroup IV metallocene dichalcogenolene chelate complexes of the type $[(cp)_2M(1,2\text{-}X_2C_6H_4)]$ (M = Ti, Zr, Hf; X = S, Se, Te). Hafnocene benzene-1,2-ditellurolate (**1**) was shown by temperature-dependent ^1H NMR spectroscopy to exist in toluene solution in an envelope conformation, the five-membered $HfTe_2C_2$ chelate ring undergoing rapid inversion at room temperature.

Metallocene heterocycles of subgroup IV with S,S-[1–6] and Se,Se-coordinated[7–8] benzene-1,2-dichalcogenolato chelate ligands have been synthesized. Recently there were reports about the preparation of the analogous tellurium derivatives of the titanocene[9] and zirconocene[10] systems using different reaction routes and that no metallacycle could be obtained analogous to the synthesis of the Zr complex when the metal was Hf.[10] We now report on the synthesis and spectroscopic characterization of hafnocene benzene-1,2-ditellurolate (**1**), the first example of a Te containing hafnocene metallacycle and the last missing member of the metallocene ditellurolene chelates of subgroup IV.

The reaction in an argon atmosphere and exclusion of air and moisture of hafnocene dichloride $[(cp)_2HfCl_2]$[11] (5.14 mmol) with $1,2\text{-}(LiTe)_2C_6H_4$[12] (5.19 mmol) in 200 cm^3 tetrahydrofurane (thf)/ether (1:1) at −78°C afforded the desired hafnocene ditellurolene metallacycle (**1**) as a deep red solid, sensitive towards air and moisture (Scheme 1). The product was recrystallized from dry toluene and gave **1** in 37% yield with satisfactory elemental analysis and spectroscopic results in agreement with the expected theoretical values: IR (KBr) $\tilde{\nu}$: ν (CH, cp) 3105, ω (CC, cp) 1435, δ (CH, cp) 1010, γ (CH, cp) 800, γ (CH, 1,2-C_6H_4) 720 cm^{-1}; ^1H NMR (toluene-d_8): 8.30–6.75 (m, 4H, 1,2-C_6H_4), and 5.74 (s, 10H, cp) ppm; MS (EI, 70 eV, 180°C) *m/z*: 640 (46%) M^+, 564 (20) $M^+-C_6H_4$, 512 (25) M^+-Te, 436 (19) $M^+-C_6H_4-Te$, 384 (60) M^+-2 Te, 308 (100) $M^+-Te_2C_6H_4$, 243 (11) $M^+-Te_2C_6H_4-cp$, 178

Table 1. ^{1}H NMR data[a] and activation parameters of $[(cp)_2M(1,2\text{-}X_2C_6H_4)]$

M	X	δ (cp) (ppm)	T_c (°C)	$\Delta\nu$ (Hz)	$\Delta G_c^{\ddagger}$ (kJ mol^{-1})	Ref.
Ti	Te	5.76	−38	10.0	51	9
Zr	Te	5.96[b]	−30	20.9	51	10
Hf	Te	5.74	−50	9.4	48	present work
Hf	Se	5.46	−75	—	—	8
Hf	S	5.46	−64	20.0	45	6

[a] Solvent: $CD_3C_6D_5$; [b] cp = η^5-^{t}BuC$_5$H$_4$.

(28) Hf^+; (values given relate to ^{178}Hf and ^{128}Te); Fp: 225°C, decomposition. **1** reacts with halides such as bromine, dissolved in thf, or hydrogen halides as with hydrogen chloride saturated benzene yielding the corresponding hafnocene dihalides (Scheme 1).

In the dynamic ^{1}H NMR spectrum the singlet due to the ten equivalent cp protons at room temperature was subject to a coalescence phenomenon at a lower temperature and was split into two sharp singlets of equal intensity at temperatures below −50°C (Fig. 1). From this result an envelope conformation of the five-membered chelate ring, folded along the Te---Te axis and undergoing rapid inversion at room temperature, can be derived (Fig. 2). The activation parameters of the chelate ring inversion of **1** and the analogous titanocene and zirconocene derivatives as well as those of the S or Se coordinated hafnocene complexes are given in Table 1. With regard to an estimation of the error of these $\Delta G_c^{\ddagger}$ values (±13%) surprisingly there is no significant connection between this activation parameter and the central atom or the coordinating chalcogen atom.

Abstract—The reactions of $(n\text{-}Bu_4N)_2Re_2Cl_8$ with the bidentate bridging phosphine ligands (L—L) = $Ph_2PC{\equiv}CPPh_2$ or *trans*-$Ph_2PCH{=}CHPPh_2$ in methanol–conc. HCl give the salts $(n\text{-}Bu_4N)_2[(Re_2Cl_7)_2\{\mu\text{-}(L—L)\}]$, the first examples of quadruply bonded dirhenium(III) anions of the type $[Re_2Cl_7L]^-$. Their spectroscopic properties and reactivity have been examined.

The octahalodirhenate(III) anions $[Re_2X_8]^{2-}$ (X = Cl or Br) react with monodentate phosphine ligands (PR_3) to form the neutral quadruply-bonded species $Re_2X_6(PR_3)_2$, and from thence to the lower valent complexes $Re_2X_5(PR_3)_3$ (Re—Re bond order 3.5) or $Re_2X_4(PR_3)_4$ (Re—Re bond order 3) depending upon the reducing propensity of the phosphine ligand.[1] In no instance has a salt of the intermediate monoanionic mono-substituted type $[Re_2X_7(PR_3)]^-$ been isolated. We report for the first time the isolation of such species as present in the salts $(n\text{-}Bu_4N)_2[(Re_2Cl_7)_2\{\mu\text{-}(L—L)\}]$ (**1**), in which L—L is the bidentate bridging phosphine $Ph_2PC{\equiv}CPPh_2$(dpa) or *trans*-$Ph_2PCH{=}CHPPh_2$ (*t*-dppee).

$(n\text{-}Bu_4N)_2[Cl_4ReReCl_3\{\mu\text{-}(L—L)\}Cl_3ReReCl_4]$

L—L = $Ph_2PC{\equiv}CPPh_2$ (**1a**)

L—L = *trans*-$Ph_2PCH{=}CHPPh_2$ (**1b**)

A representative recipe is as follows.‡ A mixture of $(n\text{-}Bu_4N)_2Re_2Cl_8$[2] (0.20 g, 0.175 mmol), dpa (0.09 g, 0.228 mmol) and 10 cm^3 of methanol, to which 10 drops of conc. HCl had been added, was stirred at room temperature for one day. The resulting insoluble purple precipitate was filtered off, washed with methanol, hexanes, diethyl ether and dried *in vacuo*; yield 0.17 g (91%). Found: C, 34.1; H, 4.6; Cl, 22.9. Calc. for $C_{58}H_{92}Cl_{14}N_2P_2Re_4$: i.e. $(n\text{-}Bu_4N)_2[(Re_2Cl_7)_2\{\mu\text{-}(Ph_2PC{\equiv}CPPh_2)\}]$: C, 32.9; H, 4.4; Cl, 23.4. The slightly high C and H microanalyses reflect the difficulty of purifying such an insolublc complex.§

A similar procedure gave $(n\text{-}Bu_4N)_2[(Re_2Cl_7)_2\{\mu\text{-}(trans\text{-}Ph_2PCH{=}CHPPh_2)\}]$ as a green solid in a yield of 86%.

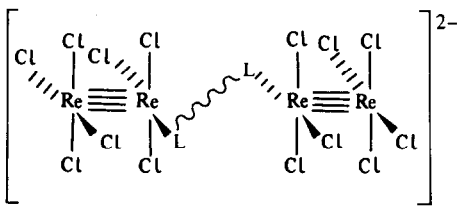
Although both complexes display very limited solubility properties we were, nonetheless, able to adequately characterize them although neither could be obtained in single crystal form. We favor a structure such as that depicted below in which the individual dirhenium units retain the eclipsed

† Author to whom correspondence should be addressed.

‡ Bis(diphenylphosphino(acetylene (dpa) and *trans*-1,2-bis(diphenylphosphino)ethylene (*t*-dppee) were purchased from Strem Chemicals and used as received. Solvents used in the preparation of complexes were of commercial grade and were thoroughly deoxygenated prior to use. All reactions were performed in a nitrogen atmosphere using standard vacuum line techniques.

§ When the reaction which gave this complex was carried out in methanol in the absence of conc. HCl, a brown solid precipitated. Although this product has not yet been fully characterized, it is not $Re_2Cl_6(dpa)_2$.

rotational geometry of the parent $[Re_2Cl_8]^{2-}$,[1] (see Structure 1).



The electronic absorption spectrum of **1a**, recorded as a Nujol mull, has a band at ~ 740 nm, assigned to the $\delta \rightarrow \delta^*$ transition,[1] weak absorptions at ~ 540 and 480 nm, and more intense features at 390 and 325 nm. In CH_2Cl_2 solution, the spectrum is very similar to this, with absorptions (relative intensities in parentheses) at 730(9), ~ 540(2), ~ 470(2), 380sh(13) and 315(34) nm. The Nujol mull spectrum of (**1b**) shows the $\delta \rightarrow \delta^*$ transition at 735 nm, a weak band at ~ 570 nm, a shoulder at ~ 410 nm and an intense absorption at 290 nm. Although (**1a**) and (**1b**) decompose in CH_3CN (*vide infra*), the ^1H NMR spectrum of a freshly prepared solution of (**1a**) in CD_3CN shows proton resonances due to the dpa ligand and *n*-Bu_4N^+ cation in the expected intensity ratio of 1 : 2.

Further evidence for the identity of these salts as derivatives of the quadruply bonded Re_2^{6+} core was obtained from reactions with monodentate phosphines. (**1a**) reacts with PEt_3 in ethanol to form $Re_2Cl_4(PEt_3)_4$ in 55% yield, while $PMePh_2$ and $PEtPh_2$ under these same conditions form $Re_2Cl_5(PMePh_2)_3$ and $Re_2Cl_5(PEtPh_2)_3$, respectively, in yields of ~ 80%. These yields are similar to those in which $Re_2Cl_5(PMePh_2)_3$ and $Re_2Cl_5(PEtPh_2)_3$ are formed (90% and 75%, respectively) from $(n\text{-}Bu_4N)_2Re_2Cl_8$.[3] (**1b**) shows this same reactivity behavior; it forms $Re_2Cl_4(PEt_3)_4$ in 68% yield and $Re_2Cl_5(PMePh_2)_3$ in 85% yield. These products, which are the ones expected from such a quadruply bonded Re_2^{6+} starting material,[3] were identified on the basis of their spectroscopic and electrochemical properties.[3,4]

Of special note is the reaction of (**1a**) with PPh_3 in hot ethanol. An excess of PPh_3 affords an almost quantitative yield of green insoluble $Re_2Cl_6(PPh_3)_2$ (94%), whereas 2 equivs of PPh_3 gives $Re_2Cl_6(PPh_3)_2$ (49%) and from the filtrate a mixture of dpa and $(n\text{-}Bu_4N)_2Re_2Cl_8$.† These observations imply that the following reactions are occurring:

(1) $[Re_2Cl_7(\mu\text{-dpa})Re_2Cl_7]^{2-} + 2PPh_3 \rightarrow Re_2Cl_6(PPh_3)_2 + (n\text{-}Bu_4N)_2Re_2Cl_8 + dpa$

(2) $(n\text{-}Bu_4N)_2Re_2Cl_8 + 2PPh_3 \rightarrow Re_2Cl_6(PPh_3)_2 + 2n\text{-}Bu_4NCl.$

In this same context we have observed that (**1a**) reacts slowly with CH_3CN to give $(n\text{-}Bu_4N)_2Re_2Cl_8$ (36% yield of isolated product) together with an as yet unidentified blue Re_2^{6+} complex (λ_{max} at 656 nm for its $\delta \rightarrow \delta^*$ transition). When the latter reaction is carried out at room temperature in the presence of an excess of *n*-Bu_4NCl for 2 h, the blue salt $(n\text{-}Bu_4N)_2Re_2Cl_8$ can be precipitated in quantitative yield upon the addition of an excess of diethylether. The yield of pure recrystallized product (from methanol/conc. HCl) was ~ 80%. These reactions not only confirm the structural identity of (**1a**) but, furthermore, demonstrate the lability of the μ-dpa ligand.

The cyclic voltammogram (CV) of (**1a**) in 0.1 M *n*-Bu_4NPF_6 (TBAH)-CH_2Cl_2 shows a pair of closely spaced couples at $E_{1/2} \simeq -0.31$ V and -0.43 V vs Ag/AgCl (Fig. 1) which signify that the reductions of the two dpa-coupled Re_2^{6+} cores occur at different potentials.[5] A similar phenomenon is seen in the CV of (**1b**) with $E_{1/2}$ values of $\simeq -0.40$ V and -0.52 V vs Ag/AgCl. These potentials are, as expected, intermediate between those for the one-electron reductions of $Re_2Cl_6(PR_3)_2$[1,4] and $[Re_2Cl_8]^{2-}$.[1,6,7] When acetonitrile is added to a solution of (**1a**) in 0.1 M TBAH-CH_2Cl_2, the CV changes with time and shows the formation of $[Re_2Cl_8]^{2-}$ ($E_{1/2} \simeq +1.5$ V and $E_{1/2} \simeq -0.93$ V vs Ag/AgCl)[6,7] together with a couple at $\simeq -0.7$ V which must be associated with another Re_2^{6+} species.

Studies on the chemistry of these systems

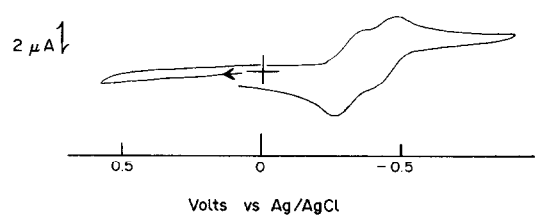


Fig. 1. Cyclic voltammogram (recorded at $v = 200$ mV s^{-1} using a Pt-bead electrode) for a 0.1 M *n*-Bu_4NPF_6-CH_2Cl_2 solution of $(n\text{-}Bu_4N)_2[(Re_2Cl_7)_2(\mu\text{-dpa})]$. For each of the closely spaced couples at $E_{1/2} = -0.31$ V and -0.43 V, the peak separations ΔE_p ($= E_{p,a} - E_{p,c}$) are $\simeq 100$ mV. Under our experimental conditions the ferrocenium/ferrocene reference standard had $E_{1/2} = +0.47$ V.

† The dissociation of dpa in this reaction under non-acidic conditions is in marked contrast to the reaction of $(n\text{-}Bu_4N)_2Re_2Cl_8$ with dpa in methanol to give (**1a**) which requires the presence of HCl.

are continuing. We note that the reaction of *trans*-dppee with $(n\text{-}Bu_4N)_2Re_2Cl_8$ in methanol–conc. HCl to give (**1b**) is different from that with chelating *cis*-dppee. In the latter case, cleavage of the Re≡Re bond predominates to give *trans*-$[ReCl_2(dppee)_2]Cl$.[8]

LOSS OF WATER AND HYDROGEN CYANIDE FROM AQUOPENTAMMINECOBALT(III) HEXACYANOFERRATE(III)

J. E. HOUSE, Jr.* and FADZILAH MOHD TAHIR

Department of Chemistry, Illinois State University, Normal, IL 61761, U.S.A.

(*Received* 4 *March* 1987; *accepted* 27 *May* 1987)

Abstract—Previous studies on the non-isothermal decomposition of $[Co(NH_3)_5H_2O][Fe(CN)_6]$ showed that H_2O and three molecules of HCN are lost simultaneously but the results of the isothermal studies reported here show that these processes can be partially separated. It was found that the first reaction involves the loss of H_2O and two molecules of HCN and the second reaction results in the loss of an additional molecule of HCN. Kinetic studies have been performed and kinetic parameters are reported here and possible mechanisms are discussed.

Since our initial proposal of a defect-diffusion mechanism for solid state reactions,[1] numerous dehydration reactions have shown the utility of this description for such reactions.[2] Many of the reactions similar to that first reported by Haim *et al.*[3]

$$[Co(NH_3)_5H_2O][Co(CN)_6](s) \rightarrow [(NH_3)_5Co\text{-}NC\text{-}Fe(CN)_5](s)+H_2O(g) \quad (1)$$

have been studied by Ribas and co-workers.[2] These reactions include the dehydration of double complex salts containing two different metals. Our TGA study of the process shown in eqn (1) showed that it follows first order kinetics and has an activation energy of 232 ± 40 kJ mol^{-1}[4] while Simmons and Wendlandt reported 239 kJ mol^{-1}. However, an isothermal study on the reaction showed it to be a first order process with an activation energy of 144 kJ mol^{-1}.[5] Other complexes of this type which have been studied include $[Co(NH_3)_5H_2O][Cr(NCS)_6]$, $[Co(NH_3)_5H_2O][Cr(CN)_6]$, and $[Co(NH_3)_5H_2O][Fe(CN)_6]$.[4,7] Ribas and co-workers have also studied a series of complexes of the type $[M(NH_3)_5H_2O][Co(CN)_6]$ where M is Co(III), Rh(III) or Ir(III).[8] These can be dehydrated without further decomposition. In the case of $[Co(NH_3)_5H_2O][Fe(CN)_6]$ the study using TGA showed that H_2O and three molecules of HCN per molecule of complex were lost in a single reaction. Analysis of the data showed that the reaction is second order with an activation energy of 224 ± 8 kJ mol^{-1}.[4] Since the behavior of $[Co(NH_3)_5H_2O][Fe(CN)_6]$ is so different from that of other hexacyanometallates, we have studied this decomposition using isothermal techniques in an effort to separate the dehydration reaction from the loss of HCN and to determine the kinetic parameters for the processes. This report presents the results of that work.

EXPERIMENTAL

The $[Co(NH_3)_5H_2O][Fe(CN)_6]$ was prepared by mixing equal numbers of mols of $[Co(NH_3)_5H_2O]Br_3$ amd $K_3[Fe(CN)_6]$ in equal volumes of water.[4] After the precipitate of $[Co(NH_3)_5H_2O][Fe(CN)_6]$ formed, it was removed by filtration, washed with water, absolute ethanol and ether. The product was allowed to dry in air for two days.

Kinetic studies were performed using a Perkin–Elmer Thermogravimetric System model TGS-2. Samples were contained in platinum pans and were heated at constant temperature in a dry nitrogen atmosphere with a flow rate of 20 cc min^{-1}. Carrying out the first reaction at low temperature (100–

* Author to whom correspondence should be addressed.

120°C) resulted in the loss eventually of H_2O and two molecules of HCN per molecule of complex. When higher temperatures were used (180–195°C), an additional molecule of HCN was lost. The fraction of the reaction complete, α, was obtained by measuring the mass loss with time. Each reaction was studied at several temperatures. The data were analyzed by fitting the data to 14 kinetic models for solid state reactions.[9]

RESULTS AND DISCUSSION

The results of mass loss studies on $[Co(NH_3)_5H_2O][Fe(CN)_6]$ heated isothermally show that a partial separation of the loss of H_2O and HCN can be effected. While TGA studies showed that three molecules of HCN per molecule of complex were lost during dehydration,[4] prolonged heating at temperatures of 100–120°C results in a mass loss corresponding to the reaction:

$$[Co(NH_3)_5H_2O][Fe(CN)_6](s) \rightarrow [(NH_3)_3Co(NH_2)_2NCFe(CN)_3](s) + H_2O(g) + 2HCN(g). \quad (2)$$

The solid product appears to have one CN and two NH_2 bridges. This reaction is different from that indicated earlier by non-isothermal techniques where H_2O and three molecules of HCN were lost.[4] Heating the complex which had already lost H_2O and two HCN molecules at 185–195°C resulted in the loss of one molecule of HCN per molecule of complex:

$$[(NH_3)_3Co(NH_2)_2NCFe(CN)_3](s) \rightarrow [(NH_3)_2Co(NH_2)_3NCFe(CN)_2](s) + HCN(g). \quad (3)$$

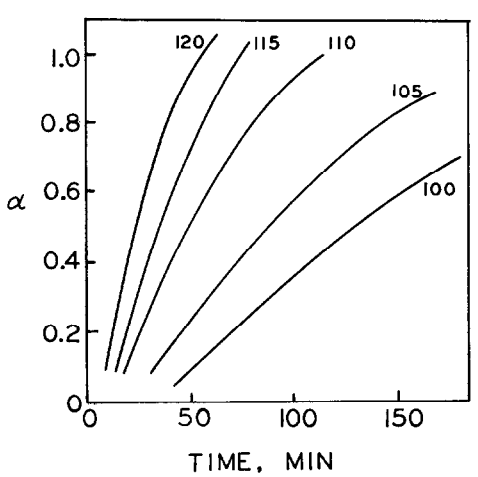

Fig. 1. Extent of reaction vs time for loss of H_2O and two molecules of HCN [eqn (2)].

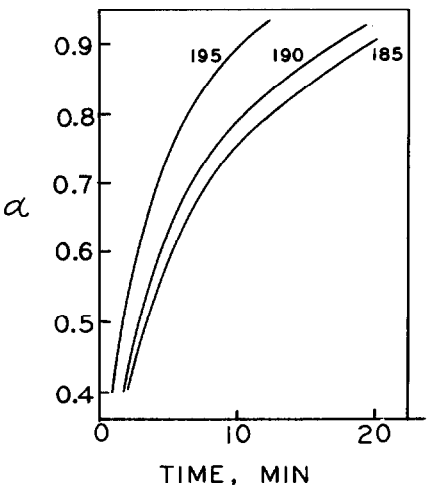

Fig. 2. Extent of reaction vs time for loss of the third molecule of HCN [eqn (3)].

Consequently, it is possible to perform kinetic studies on both of the reactions that are shown in eqns (2) and (3). Figures 1 and 2 show the plots of α, the fraction of reaction complete vs time for the reactions shown in eqns (2) and (3), respectively. These curves are characteristic of solid state reactions of this type.

The usual analysis of the kinetics of solid state reactions involves representing some function of α as a function of time. Theoretical models result in fourteen commonly used functions.[9] Fitting the α, t data for the first reaction to these models results in the best fit being the function $f(\alpha) = 1-(1-\alpha)^{1/2}$. This function corresponds to a two dimensional diffusion controlled process. As far as the physical process is concerned, the diffusion controlled mechanisms frequently result when gaseous products are lost. Although the rate law provides some indication of this aspect of the mechanism, it does not give insight as to how the H_2O and HCN are lost from the coordination spheres.

Analysis of the α and time data shown in Fig. 1 using the rate law $f(\alpha) = 1-(1-\alpha)^{1/2}$ yields the rate constants shown in Table 1. Applying the Arrhenius

Table 1. Rate constants for the reaction shown in eqn (2)

Temperature (°C)	k (min^{-1})	Uncertainty in k	Corr. coeff.
100	3.128×10^{-3}	3.364×10^{-5}	09993
105	4.623×10^{-3}	5.102×10^{-5}	0.9992
110	8.362×10^{-3}	5.812×10^{-5}	0.9998
115	13.911×10^{-3}	4.065×10^{-4}	0.9983
120	18.346×10^{-3}	2.068×10^{-4}	0.9998

equation to these rate constants leads to an activation energy of 113 ± 7 kJ mol^{-1} and a pre-exponential factor of 2.19×10^{13} min^{-1}. This value for the activation energy is much smaller than the 224 ± 8 kJ mol^{-1} found from non-isothermal measurements when H_2O and three molecules of HCN are lost.[4]

The second reaction, the loss of the third HCN, gave the best fit to the data when $f(\alpha) = -\ln(1-\alpha)$, which corresponds to the unimolecular growth controlled mechanism. It would be expected that this process would be unimolecular since the last molecule of HCN lost is probably the result of an intramolecular process in $[(NH_3)_3Co(NH_2)_2NCFe(CN)_3]$. Apparently, in this case, diffusion of the HCN from the solid product is not the rate-controlling process. The structure of the product, $[(NH_3)_2Co(NH_2)_3NCFe(CN)_2]$, would be of interest since it may contain Fe^{3+} with a coordination number of four.

Analysis of the α and time data shown in Fig. 2 for the loss of the third molecule of HCN yields the data shown in Table 2. These rate constants yield an activation energy of 96.8 kJ mol^{-1}. This reaction takes place readily at the temperatures used but could not be studied successfully at lower temperatures. Because of this, only a narrow range of temperatures could be employed and relatively few data points were obtainable, especially at the higher temperatures. As a result, the error limits are large for this activation energy, being about ± 40 kJ mol^{-1}. The pre-exponential factor for the reaction is 7.28×10^9 min^{-1}. It is interesting to note that the sum of the activation energies for the two reactions studied here, about 210 kJ mol^{-1}, is within experimental error of the 224 ± 8 kJ mol^{-1} found for the loss of the H_2O and three HCN molecules studied as a single process using TGA.[4]

Table 2. Rate constants for reaction shown in eqn (3)

Temperature (°C)	k (min^{-1})	Uncertainty in k	Corr. coeff.
185	0.1046	2.148×10^{-3}	0.9983
190	0.1177	2.424×10^{-3}	0.9985
195	0.1802	7.415×10^{-3}	0.9975

This work has shown that by using isothermogravimetry it is possible to study the loss of H_2O and two molecules of HCN from $[Co(NH_3)_5H_2O][Fe(CN)_6]$ in one step and the loss of the third HCN in another. The first step follows a rate law for a two dimensional diffusion controlled process, perhaps because three molecules of gaseous products are produced. The second process does not follow such a rate law and that may be a reflection of the fact that only one HCN is lost and the rate is not diffusion limited.

ANNOUNCEMENTS

FIFTH INTERNATIONAL SYMPOSIUM ON THE EFFECT OF TIN UPON MALIGNANT CELL GROWTH

18–20 JULY 1989
BRUSSELS, BELGIUM

ORGANIZATION

Chairman Marcel Gielen (Free University of Brussels V.U.B.) is being assisted by a Local Organizing Committee and an International Scientific Committee. The Symposium will be supported by the Free Universities of Brussels, industrial sponsors, government sources, the Federation of the European Chemical Societies and the Belgian Chemical Societies.

DATE AND LOCATION

The Fifth International Symposium on the Effect of Tin upon Malignant Cell Growth will be held in Brussels, Belgium from Tuesday to Thursday, 18–20 July 1989. The scientific sessions of the symposium will take place on the campus of the Free University of Brussels V.U.B.

SCOPE

The technical sessions of the symposium will be concerned with the synthesis and characterization, *in vitro* and *in vivo* activity, fate in living organisms, mechanisms of action, physiological effects, toxicity, experimental and clinical therapeutics, and pharmacology of tin-based anti-tumour drugs.

ACCOMMODATION

Inexpensive housing will be available in single rooms of the Free University of Brussels dormitories.

SOCIAL PROGRAMMES

A welcoming reception will be held on Tuesday evening. A banquet and special events are planned for the symposium participants and their guests.

YOUNG SCIENTISTS

Participation of young scientists will be especially encouraged through reduced registration fees for graduate students and post-doctoral research associates, and by Conference Fellowships. Details will be included in the second circular.

PRE-REGISTRATION

Individuals interested in receiving the second circular describing the symposium, to be mailed in July 1988, are asked to complete and return the preliminary registration form **before 1 May 1988.** The second circular will contain a list of the major speakers, final registration forms, instructions for preparing and submitting abstracts, housing information, special events and social activities.

All correspondence should be addressed to: **5th TUC, Prof. Dr Marcel Gielen, Free University of Brussels V.U.B., AOSC Unit, 8G512, Pleinlaan 2, B-1050 Brussels, Belgium.** Phone: (2) 6413279.

SIXTH INTERNATIONAL CONFERENCE ON THE ORGANOMETALLIC AND COORDINATION CHEMISTRY OF GERMANIUM, TIN AND LEAD

23–28 JULY 1989
BRUSSELS, BELGIUM

ORGANIZATION

Chairman Marcel Gielen (Free University of Brussels V.U.B.) is being assisted by a Local Organizing Committee and an International Scientific Committee. The Symposium will be supported by the Free Universities of Brussels, industrial sponsors, government sources, the Federation of the European Chemical Societies (124th event of FECS) and both Belgian Chemical Societies.

DATE AND LOCATION

The 6th ICCC GeSnPb will be held in Brussels, Belgium from Sunday to Friday, 23-28 July 1989. The scientific sessions of the symposium will take place on the campus of the Free University of Brussels V.U.B.

SCOPE

The technical sessions will be concerned with theoretical, structural, mechanistic and synthetic aspects of the chemistry of these elements, together with applications in areas including agriculture, biology/medicine, catalysis, electronics, environmental, polymer and solid-state chemistry, and organic synthesis.

ACCOMMODATION

Inexpensive housing will be available in single rooms of the Free University of Brussels dormitories.

SOCIAL PROGRAMMES

A welcoming reception will be held on Sunday evening. A banquet and special events are planned for the symposium participants and their guests.

YOUNG SCIENTISTS

Participation of young scientists will be especially encouraged through reduced registration fees for graduate students and post-doctoral research associates, and by Conference Fellowships. Details will be included in the second circular.

POLYHEDRON REPORT NUMBER 22

FROM METALLABORANES TO TRANSITION METAL BORIDES: THE CHEMISTRY OF METAL-RICH METALLABORANE CLUSTERS

CATHERINE E. HOUSECROFT

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

CONTENTS

INTRODUCTION

This report is aimed at highlighting the syntheses, structures, bonding and chemistry of metallaboranes which exhibit a metal to boron ratio of greater than or equal to one; that is, metallaboranes possessing equal numbers of metal and boron atoms, or else, possessing more metal nuclei than boron nuclei in their framework. Several classes of compounds are excluded from the review. These exclusions are monometallic borohydride complexes of type $L_xM[BH_4]_y$,[1] complexes in which the source of boron is an organo-borane or -borate ligand, and metallocyclic complexes. Excellent reviews covering the area of metallaboranes with emphasis on the boron-rich cluster compounds have recently been presented by Kennedy.[2] Comprehensive surveys have also been compiled by Shore *et al.*[1] and Grimes.[1] A review of boron containing metallocycles has been provided by Herberich.[3]

In the last few years, metallaborane chemistry has developed rapidly. In particular, the prolific results from Greenwood *et al.*[2] illustrate the extent to which metallaborane cluster chemistry has expanded, and a diversity of fascinating structural types has now been characterized. Perturbation

of a borane cage by a metal fragment is thus well documented. On the other hand, cluster chemistry exhibits a plethora of transition metal aggregates with a very rich associated chemistry, a fair proportion of which involves organic ligands of one type or another. In most of these transition metal-hydrocarbon clusters, the metal nuclei outnumber the organic carbon centres in a given cluster core. Despite the adjacent position of boron to carbon in the periodic table, there are only limited examples of metal hydrocarbon complexes which have metallaborane analogues.[4] As is now quite commonly exemplified, transition metal–carbon interactions extend to metal carbide (i.e. bare carbon) clusters.[5,6] Carbon is not the only naked hetero-atom encapsulated within a transition metal framework; for example, metal nitride,[7] oxide,[8] and phosphide[9] clusters have been characterized. And yet, the trail from a boron-rich metallaborane to a metal-rich metallaborane or a discrete metal boride cluster is only now beginning to be laid.

BOROHYDRIDE (BH_4^-) COMPLEXES

There are several unusual borohydride complexes which deserve a mention because each exhibits a BH_4^- ligand coordinated to multi-metal centres. On the basis of infra-red data, it is proposed that $[(Ph_3P)_4Cu_2BH_4]^+$ [Fig. 1(a)] contains a borohydride ligand bridging through two hydrogens to

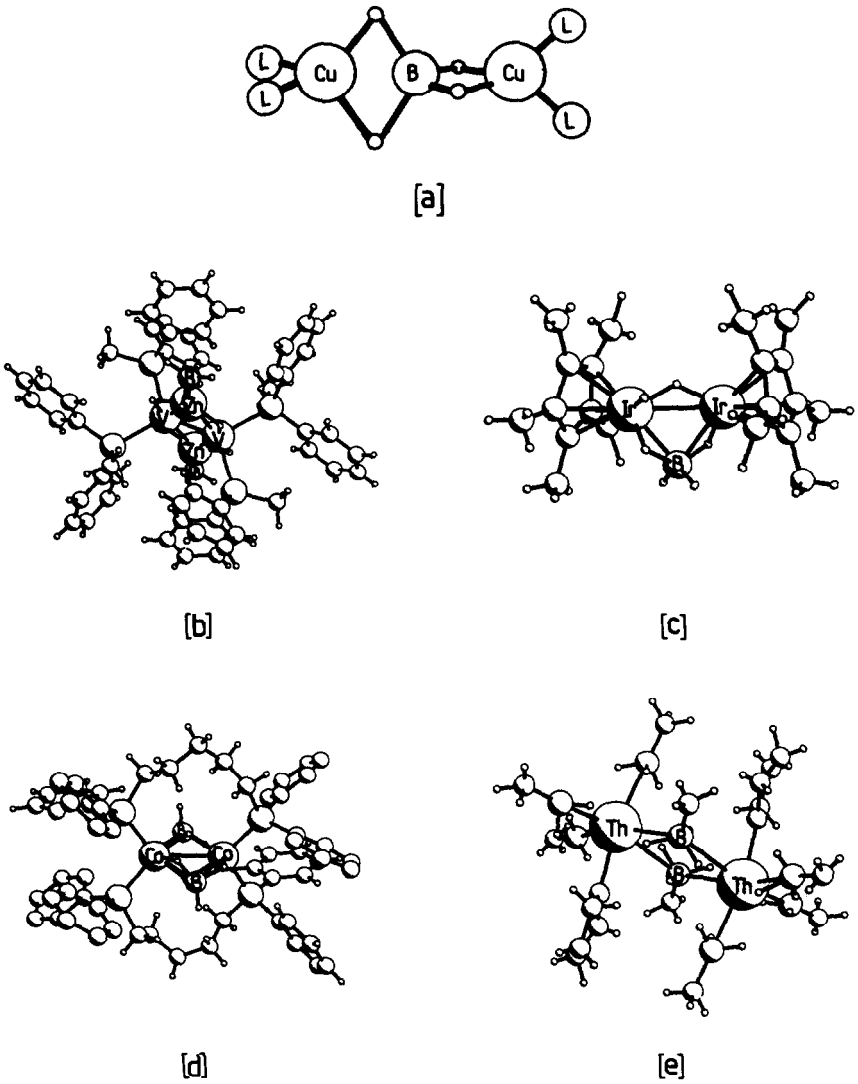

Fig. 1. (a) Proposed structure of $[L_4Cu_2BH_4]^+$;[10] (b) Molecular structure of $V_2Zn_2H_4(BH_4)_2(PPh_2Me)_4$;[11] (c) Molecular structure of $[(C_5Me_5)Ir]_2H_3(BH_4)$;[12] (d) Molecular structure of $Co_2(BH_4)_2(Ph_2P[CH_2]_5PPh_2)_2$;[13] (e) Molecular structure of $\{Th(BH_3CH_3)_4\}_2 \cdot THF$.[14]

each of two copper centres.[10] Although clearly not a "cluster" compound, this complex is of interest because it exemplifies a borohydride ligand in which there are no terminal hydrogen atoms. This is an unusual feature for ligated BH_4^-. A hydrogen-rich borohydride derivative, $V_2Zn_2H_4(BH_4)_2(PPh_2Me)_4$, [Fig. 1(b)] has been made in 50% yield from the reaction of $\{V_2(\mu\text{-}Cl)_3(THF)_6\}_2Zn_2Cl_6$ with PPh_2Me and BH_4^-.[11] The structure is described in terms of two $Zn(BH_4)^+$ units interacting with a divanadium polyhydride anion rather than as containing BH_4^- ligands interacting with a cationic metal centre. Another polyhydride complex containing a borohydride ligand is $\{(C_5Me_5)Ir\}_2H_3(BH_4)$,[12] [Fig. 1(c)]. The complex has the unusual feature that the borohydride ligand bridges between two metal atoms thereby making the complex "metal-rich" as regards the metal to boron atom ratio. In addition, whereas it is usual for bridging and terminal hydrogen atoms in coordinated BH_4^- ligands to undergo exchange on the NMR timescale, those in $\{(C_5Me_5)Ir\}_2H_3(BH_4)$ do not. Nor do the iridium associated metal hydrides exchange with the Ir—H—B bridge hydrogen atoms. Bridging of two metal centres by BH_4^- has also been observed in $Co_2(BH_4)_2(Ph_2P\{CH_2\}_5PPh_2)_2$[13] [Fig. 1(d)], and the related methyltrihydroborate complexes $\{Th(BH_3CH_3)_4\}_2 \cdot L$ (L = OEt_2; THF),[14] [Fig. 1(e)]. It is interesting to ponder whether or not these complexes can be usefully classified as clusters rather than as simple coordination complexes. For example, in $Co_2(BH_4)_2(Ph_2P[CH_2]_5PPh_2)_2$, counting each CoL_2 unit as a one electron cluster fragment and breaking down each borohydride ligand into a cluster BH unit plus three *endo*-hydrogen atoms provides six electron pairs for cluster bonding. On the basis of PSEPT,[15] the Co_2B_2 core is predicted to be a *nido*-cluster, either a tetrahedron or an open butterfly (internal dihedral angle of 140° for an ideal homonuclear cage). However, the observed Co_2B_2 core has an internal dihedral angle of 170° if one defines the Co—Co vector to lie along the butterfly hinge; i.e. the four atoms are virtually coplanar. In addition, the Co—Co distance of 2.869 Å is too long to be considered a bonding interaction. Presumably, the deviation from an obvious cluster bonding picture may be a steric consequence of the bidentate phosphine ligands. Nonetheless, the compound $Co_2(BH_4)_2(Ph_2P[CH_2]_5PPh_2)_2$ does seem to present us with an appropriate bridge from borohydride ligand complexes to clusters.

CLUSTERS WITH METAL:BORON RATIO 1:1

The air and light sensitive diiron–diboron cluster $Fe_2(CO)_6B_2H_6$ has been prepared from the reaction of $Fe(CO)_5$ and B_5H_9 in yields of less than 10%.[16] This ferraborane is also a by-product in the reaction of $Fe(CO)_5$, $BH_3 \cdot THF$ and $LiBEt_3H$ in hexane, (0°C for 3 h), followed by acidification,[17] and in the reaction of $[Fe(CO)_4COCH_3]PPN$ with $BH_3 \cdot THF$ (1 : 3 equivalents) in hexane at 60°C followed by acidification.[18] Formulation is deduced from mass spectroscopic data and a proposed structure is given on the basis of infra-red and multinuclear NMR spectra. Initially, 100 MHz room temperature NMR results were interpreted as being consistent with a diborane-like fragment interacting with a diiron hexacarbonyl unit [Fig. 2(a)].[16] The structure recently proposed for $Fe_2(CO)_6B_2H_6$ [Fig. 2(b)] is postulated from Mössbauer spectroscopic data and the results of a 300 MHz variable temperature ^1H NMR study.[17] The resonances at δ −10.3 and 0.2, originally[16] assigned to four equivalent Fe—H—B protons and two terminal B—H protons respectively, are now observed to be the coalesced signals of three Fe—H—B protons (two at δ −15.6 and one at δ −12.9) and one terminal B—H proton (δ 2.3), and of one terminal B—H hydrogen (δ 2.3), and one bridge B—H—B proton (δ −2.4) respectively.[17] The electronic structure of $Fe_2(CO)_6B_2H_6$ has been probed by UV–photoelectron spectroscopy and by extended Hückel and Fenske–Hall quantum chemical techniques. [The geometrical structure assumed for the calculations is that shown in Fig. 2(a).] The results permit a comparison between the bonding in $Fe_2(CO)_6B_2H_6$ and $Fe_2(CO)_6S_2$,[19] and suggest a greater $Fe_2(CO)_6^{\delta+}B_2H_6^{\delta-}$ charge separation than $Fe_2(CO)_6^{\delta+}S_2^{\delta-}$ separation (1.16 vs 0.07 electrons by the Fenske-Hall method). The results also imply that the B—B bond should exhibit significant Lewis basicity. Indeed, in the more recently postulated structure [Fig. 2(b)], the B—B bond is "protonated". Deprotonation of $Fe_2(CO)_6B_2H_6$ by methanol/PPNCl or methanol/Ph_4AsCl leads to the removal of an Fe—H—B rather than a B—H—B bridging proton. Two isomeric anions are proposed [Fig. 2(c)].[17]

Cobaltaboranes provide examples of *closo*-metal-rich metallaboranes containing equal numbers of metal and boron atoms. The air-stable solids 1,2,3-$\{(C_5H_5)Co\}_3B_3H_5$[20–22] and $[(C_5H_5)Co]_4$

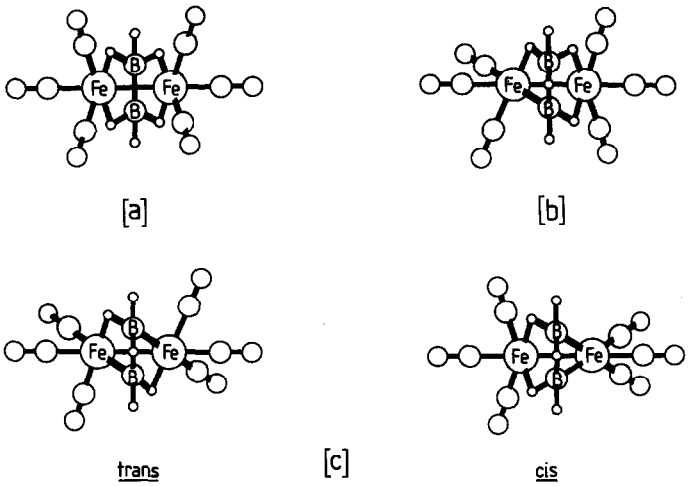

Fig. 2. Proposed structures of $Fe_2(CO)_6B_2H_6$ (a) Ref. 16; (b) on the basis of low temperature 300 MHz ^1H NMR;[17] (c) proposed structures of *trans*- and *cis*-isomers of $[Fe_2(CO)_6B_2H_5]^-$.[17]

B_4H_4[21-23] are minor products of the reaction of $[B_5H_8]^-$ with cobalt(II) chloride and $[C_5H_5]^-$. Interestingly, however, the pentamethylcyclopentadienyl analogues of these clusters have not been detected in an analogous reaction using $[C_5Me_5]^-$ in place of $C_5H_5^-$.[21] The structure[20] of 1,2,3-$\{(C_5H_5)Co\}_3B_3H_5$ [Fig. 3(a)] consists of staggered B_3 and Co_3 triangles which make up an octahedron. Each boron atom is therefore adjacent to two cobalt and two boron atoms. The same

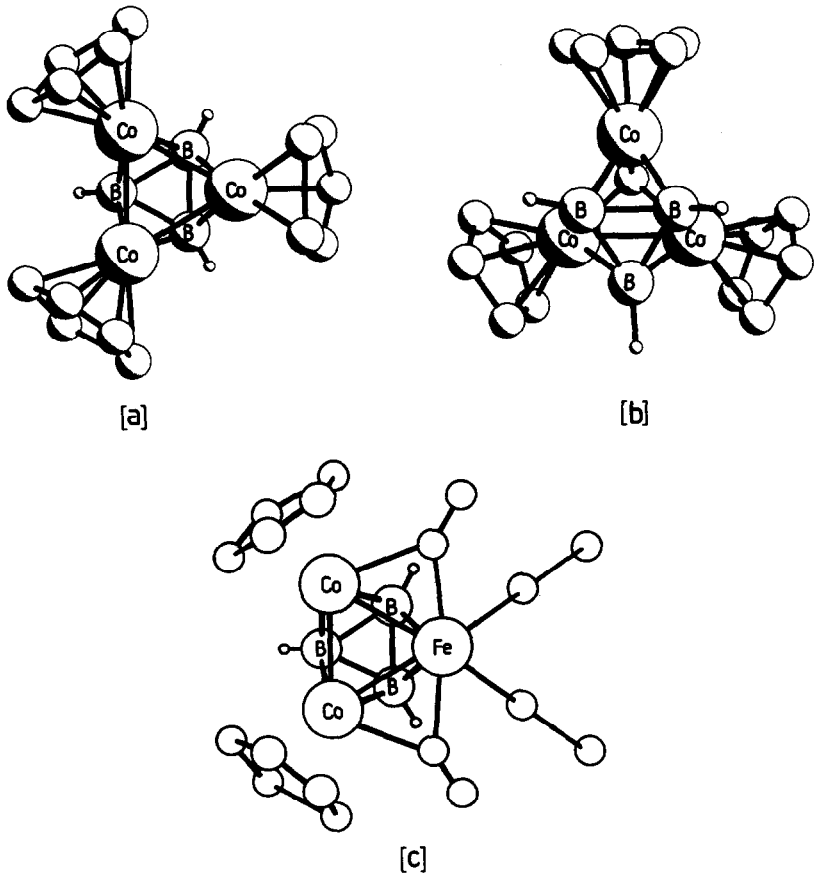

Fig. 3. Molecular structures of the cobaltaboranes (a) 1,2,3-$[(C_5H_5)Co]_3B_3H_5$;[20] (b) 1,2,3-$[(C_5H_5)Co]_3B_3H_3(\mu_3\text{-}CO)$;[24] (c) 1,2,3-$[(C_5H_5)Co]_2Fe(CO)_4B_3H_3$ (proposed).[26]

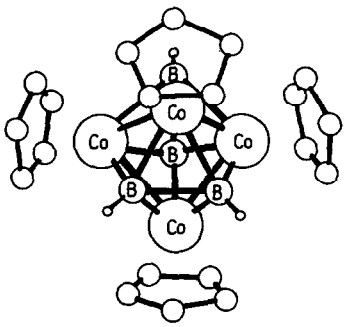
cluster core is present in 1,2,3-$\{(C_5H_5)Co\}_3B_3H_3(\mu_3\text{-}CO)$[24,25] [Fig. 3(b)], which is prepared in 2.7% yield by reacting cobalt vapour and cyclopentadiene with B_5H_9. The source of the cluster-bound CO is unproven but may originate either from metal oxide impurities in the cobalt powder used in the reaction, or from THF used to extract the products. When the preparation is carried out in the presence of carbon monoxide, the yield of 1,2,3-$\{(C_5H_5)Co\}_3B_3H_3(\mu_3\text{-}CO)$ rises to 6.4%.[24] In 1,2,3-$\{(C_5H_5)Co\}_3B_3H_5$, it is deduced from ^1H and ^{11}B NMR spectroscopy and electron difference maps that the two non-terminal protons occupy disordered bridging sites along the three Co—Co edges.[20] The two electrons provided by the two *endo*-hydrogens in 1,2,3-$\{(C_5H_5)Co\}_3B_3H_5$ are donated by the μ_3-carbonyl ligand in $\{(C_5H_5)Co\}_3B_3H_3(\mu_3\text{-}CO)$. Just as the *endo*-hydrogen atoms are associated with the metal atoms, so too is the carbonyl ligand. There is, however, no suggestion that the two clusters interconvert in the presence of H_2 or CO respectively. This type of interconversion is exemplified for another pair of metal-rich metallaboranes, $[Fe_3(CO)_9BH_4]^-$ and $[Fe_3(CO)_{10}BH_2]^-$, described below.

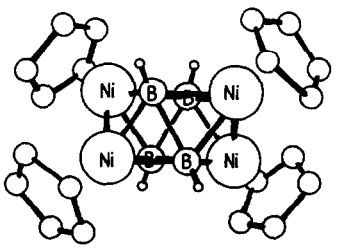
1,2,3-$\{(C_5H_5)Co\}_2Fe(CO)_4B_3H_3$ is prepared by the photochemically initiated reaction of 2-$(C_5H_5)CoB_4H_8$ with $Fe(CO)_5$.[26] The structure [Fig. 3(c)] of this mixed metal cluster is deduced from spectroscopic data and assumed to be related to that of 1,2,3-$[(C_5H_5)Co]_3B_3H_5$. Two bridging carbonyl ligands are invoked to provide the molecular twofold symmetry required by the NMR spectra.

$\{(C_5H_5)Co\}_4B_4H_4$ and $\{(C_5H_5)Ni\}_4B_4H_4$ are the highest nuclearity (i.e. total metal plus boron nuclei) metal-rich metallaboranes yet reported. The cobaltaborane is among the products of the reaction of $Na[B_5H_8]$ with excess $CoCl_2$ and $Na[C_5H_5]$ carried out in THF below 20°C.[27] It is a green, air-stable solid. The brown, air-stable $\{(C_5H_5)Ni\}_4B_4H_4$ is a product of the reaction of $Na[B_5H_8]$ with nickelocene in cold THF in the presence of one equivalent of sodium amalgam.[28]

$\{(C_5H_5)Co\}_4B_4H_4$[23] and $\{(C_5H_5)Ni\}_4B_4H_4$[29] both exhibit closed cages, although they are not isostructural. From Fig. 4, it is apparent that the cobalt atoms in $[(C_5H_5)Co]_4B_4H_4$ occupy sites of high connectivity, whereas the nickel atoms in $[(C_5H_5)Ni]_4B_4H_4$ occupy sites of low connectivity on the dodecahedral skeleton. The $(C_5H_5)Co$ and BH fragments in $\{(C_5H_5)Co\}_4B_4H_4$ can contribute a total of eight electron pairs to cluster bonding (i.e. one pair short of the number required by PSEPT for a *closo* dodecahedral cluster structure). On the other hand, the cluster fragments of



[a]



[b]

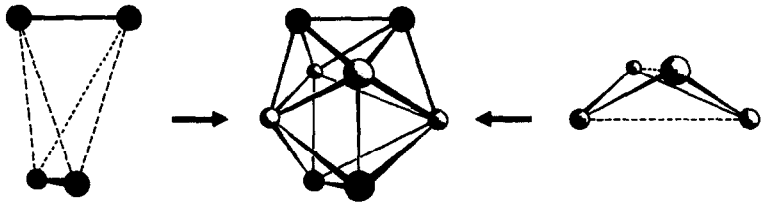

Fig. 5. Schematic representation of the combination of elongated and flattened tetrahedra to generate a D_{2d} dodecahedron.

$\{(C_5H_5)Ni\}_4B_4H_4$ provide ten electron pairs, (i.e. one pair in excess of the PSEPT requirement). An extended Hückel analysis of the dodecahedral cluster in terms of its formation from the interpenetration (Fig. 5) of two tetrahedra, one flattened and one elongated, has been used to rationalize this structural difference.[30] Since the energies of the metal fragment orbitals are always lower than the energies of the BH fragment MO's, the metal–boron cluster bonding orbitals will exhibit more metal than boron character. Thus, the metal will tend to be predominant in the cluster bonding. If the metal fragments occupy the vertices designated by the flattened tetrahedron, then the electron requirement will reflect those of that tetrahedron; i.e. eight cluster bonding pairs are available in $\{(C_5H_5)Co\}_4B_4H_4$ and so the cobalt atoms define the flattened tetrahedron. In $\{(C_5H_5)Ni\}_4B_4H_4$, the electron pair availability fits the needs of the elongated tetrahedron. Alternatively, Wade[31] had demonstrated that the degeneracy of the highest occupied molecular orbitals of the parent dodecahedral cluster $B_8H_8^{2-}$ (which is *closo* with nine cluster bonding electron pairs) allows flexibility in the number of bonding electrons required. Single occupancy of the degenerate set leads to the "normal" *closo* cluster. In $\{(C_5H_5)Co\}_4B_4H_4$, the degenerate MO set is left unoccupied and becomes, therefore, the LUMO of the complex. In $\{(C_5H_5)Ni\}_4B_4H_4$, both these MO's are fully occupied. Wade[31] has explained this in terms of the charge distribution over the cluster surface; the nickel fragment is a three electron donor and will occupy the site of low connectivity which corresponds to the site of highest electron density in the parent $B_8H_8^{2-}$.

A cluster which categorises as "pseudo metal-rich" is 4,6-$\{(C_5H_5)Co\}_2$-3,5-$S_2B_2H_2$.[32] The "pseudo" description is used here only because the sulphur atoms might be seen as isoelectronic main group replacements for BH_3 units in the hypothetical parent metallaborane $\{(C_5H_5)Co\}_2B_4H_8$. 4,6-$\{(C_5H_5)Co\}_2$-3,5-$S_2B_2H_2$ has an interesting *nido*-structure based on a pentagonal bipyramid (Fig. 6). Six-vertex eight electron pair carboranes and metallaboranes tend to adopt pentagonal pyramidal structures. The structure of 4,6-$\{(C_5H_5)Co\}_2$-3,5-$S_2B_2H_2$ illustrates a vacancy at a low rather than a high connectivity site on the parent polyhedron (inset in Fig. 6). This is attributed to a maximising of the Co···Co and S···S separations.

CLUSTERS WITH METAL:BORON RATIO 3:2

The presence of two boron atoms together in a cluster brings to mind derivatives of B_2H_6. A cluster involving B_2H_6 interacting with a diiron fragment has been described above. B_2H_6 interacting

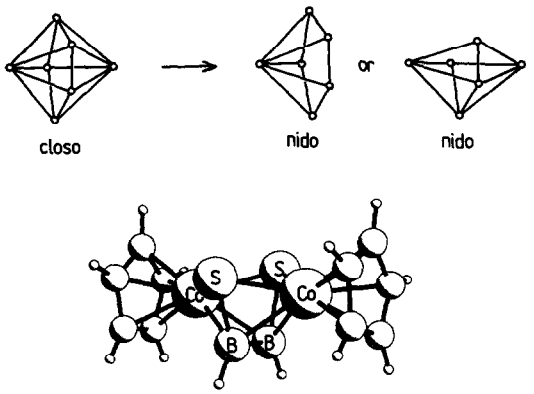

Fig. 6. Molecular structure of 4,6-$[(C_5H_5)Co]_2$-3,5-$S_2B_2H_2$.[32]

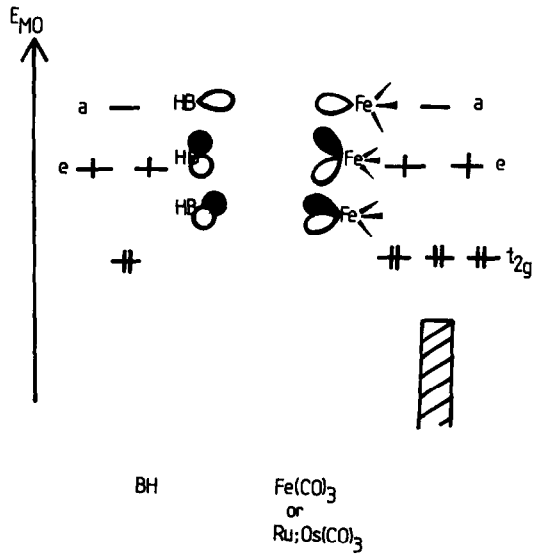

Fig. 7. Comparison of the frontier molecular orbitals of BH and $M(CO)_3$ (M = Fe, Ru, Os) cluster fragments. Energy scales are arbitrary.

with a trinuclear metal framework has been reported for $Ru_3(CO)_9B_2H_6$.[33] The reaction of $Ru_3(CO)_{12}$ with sodium borohydride in refluxing THF leads to a mixture of metal cluster products, two of which are boron-containing. On the basis of spectroscopic data, these are formulated as $Ru_3(CO)_9B_2H_6$ and $Ru_4(CO)_{12}BH_3$. The latter cluster is discussed along with its iron analogue in detail below. No NMR data were recorded for $Ru_3(CO)_9B_2H_6$ and hence, no structural assignment was made.[33] At this stage, it is useful to apply the isolobal analogy; BH and C_{3v} $M(CO)_3$ (M = Fe, Ru, Os) fragments each provide two cluster bonding electrons and exhibit frontier orbitals of the same symmetry. This is schematically represented in Fig. 7. Thus, the bonding requirements of a BH fragment in a cluster may be mimicked by an $M(CO)_3$ fragment. By comparing $Ru_3(CO)_9B_2H_6$ with the related metallaboranes $Fe(CO)_3B_4H_8$[34] and $Fe_2(CO)_6B_3H_7$[18,35] and by considering its parentage as arising from B_5H_9,[36] several isomeric structures can be postulated based on a *nido*-square pyramidal geometry (Fig. 8). It is interesting that no iron analogue of $Ru_3(CO)_9B_2H_6$ has

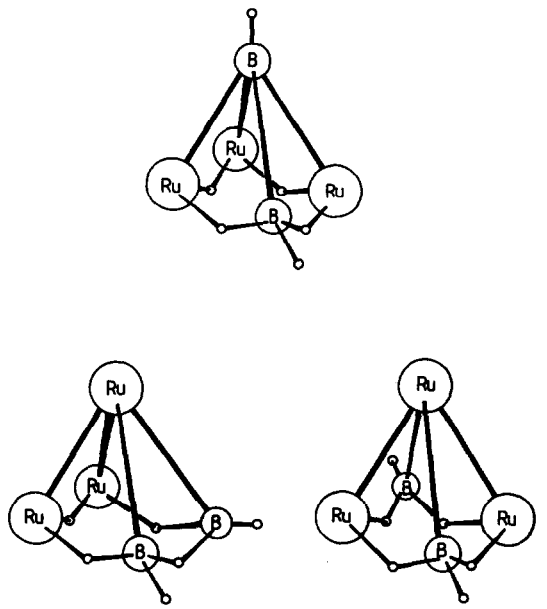

Fig. 8. Possible isomers for $Ru_3(CO)_9B_2H_6$ based on a square pyramid.

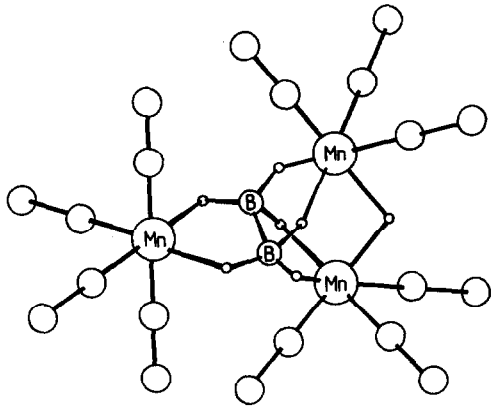

Fig. 9. Structure of $HMn_3(CO)_{10}B_2H_6$.[37]

been characterized to date and that $Fe_3(CO)_9B_2H_6$ remains an elusive member of the $\{Fe(CO)_3\}_x\{BH\}_{5-x}H_4$ series of metallaboranes.

$HMn_3(CO)_{10}B_2H_6$ has been structurally characterized and exhibits an ethane-like diborane fragment bridging between three manganese carbonyl units (Fig. 9).[37] Hydrogen atoms were not refined in the crystal structure but infrared data indicate an absence of terminal BH bonds and the presence of Mn—H—B bridges. Six Mn—H—B bridging protons are suggested on the grounds of equivalent Mn—B bond distances (mean value 2.30(2) Å) and from electron-counting arguments.[37] The presence of the bridging hydrogen atoms also allows each of the metal atoms to maintain an octahedral environment. A broad ^1H NMR resonance at δ −19 is attributed to the Mn—H—Mn bridging hydrogen atom in $HMn_3(CO)_{10}B_2H_6$, but no signals due to the boron associated protons are reported.

CLUSTERS WITH METAL:BORON RATIO 2:1

Upon entering this category of metallaborane cluster, we are truly considering clusters which are "metal-rich". Exemplars of this class are scarce. Recently, the cluster $\{(C_5H_5)Co\}_4B_2H_4$ (Fig. 10) has been structurally characterized.[38] The compound is prepared in 16% yield by the reaction of $(Ph_3P)Co(C_5H_5)(Et_2C_2)$ with $BH_3\cdot THF$ in toluene at 60°C. It is a member of the class of cobaltaboranes $\{(C_5H_5)Co\}_x\{BH\}_{6-x}H_2$,[20,22,27,39,40] but is the first member of the series in which metal atoms outnumber boron atoms in the skeleton. The compound is also noteworthy because of its relationship to the tetrametal acetylene complex, $Co_4(CO)_{10}C_2H_2$.[41] The Co_4X_2 (X = B or C) core is common to both $\{(C_5H_5)Co\}_4B_2H_4$ and $Co_4(CO)_{10}C_2H_2$ with the two main group atoms being adjacent to one another within the octahedral skeleton. The preparation of $\{(C_5H_5)Co\}_4B_2H_4$ illustrates a novel use of $BH_3\cdot THF$.[38,42] The borane acts as a dual reagent, removing phosphine and acetylene ligands from the metal precursor, and then condensing with $\{Co(C_5H_5)\}$ fragments

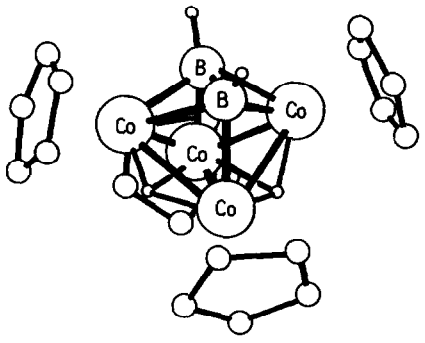

Fig. 10. Molecular structure of $\{(C_5H_5)Co\}_4B_2H_4$.[38]

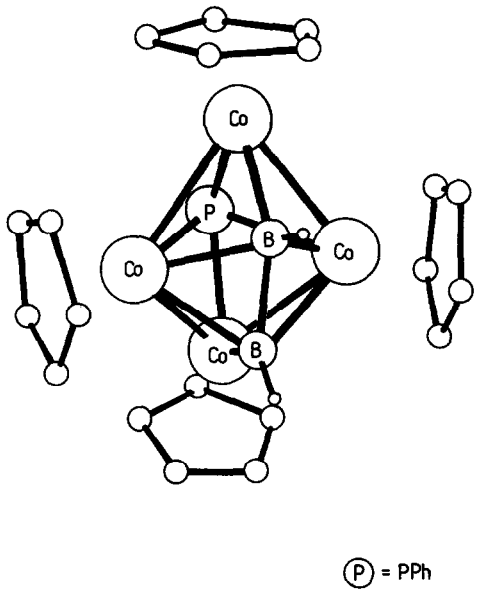

Fig. 11. Molecular structure of 2-Ph-1,3,6,7,2-$\{(C_5H_5)Co\}_4PB_2H_2$.[42]

to form the product cluster. The products formed are sensitive to reaction conditions.[42] Related to $\{(C_5H_5)Co\}_4B_2H_4$ is 2-Ph-1,3,6,7,2-$\{(C_5H_5)Co\}_4PB_2H_2$[42] (Fig. 11). Again, this metallaborane has a close metal-hydrocarbon analogue, *viz.* $Ru_4(CO)_{11}C_2Ph_2PPh$.[43] $\{(C_5H_5)Co\}_4B_2H_4$ and 2-Ph-1,3,6,7,2-$\{(C_5H_5)Co\}_4PB_2H_2$ are seemingly related by the insertion of a PPh unit into a Co—Co bond of, and elimination of two hydrogen atoms from, the former cluster. However, attempts to form 2-Ph-1,3,6,7,2-$\{(C_5H_5)Co\}_4PB_2H_2$ by reacting $\{(C_5H_5)Co\}_4B_2H_4$ with PPh_3 and eliminating two moles of benzene have failed.[42]

Although a metallacarborane rather than a metallaborane, $\{(C_5H_5)(CO)_2W\}_2(CMe)(BHEt)$[44] is worthy of inclusion here, not only because it is metal-rich, but also because its synthesis involves an interesting reduction of the $CH_3C{\equiv}W$ fragment in $(C_5H_5)(CO)_2W{\equiv}CMe$ by $BH_3 \cdot THF$ and subsequent transfer of the ethyl group so-formed onto the boron atom. The structure of $\{(C_5H_5)(CO)_2W\}_2(CMe)(BHEt)$ is shown in Fig. 12. The W—H—B bridging hydrogen atom is an unusual feature.

CLUSTERS WITH METAL:BORON RATIO 3:1

Clusters with metal atoms outnumbering boron atoms 3:1 represent a group which has been the subject of detailed bonding analyses and reactivity studies. However, until recently, only one such reported metal–boron cluster had been reported. This was the tricobalt derivative $Co_3(CO)_9BNEt_3$ (Fig. 13) which is a product of the reaction of $[Co(CO)_4]^-$ with BBr_3 in the presence of a

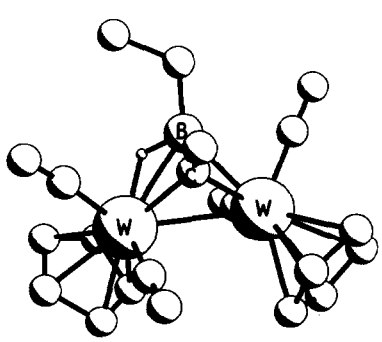

Fig. 12. Molecular structure of $\{(C_5H_5)(CO)_2W\}_2(CMe)(BHEt)$.[44]

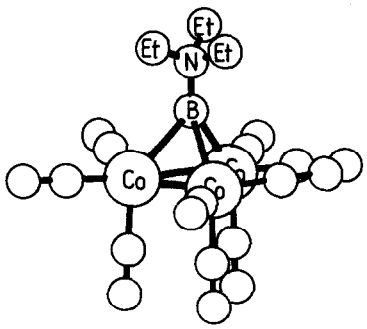

Fig. 13. Proposed structure of $Co_3(CO)_9BNEt_3$.[45]

stoichiometric amount of triethylamine:

$$3[Co(CO)_4]^- + BBr_3 + NEt_3 \xrightarrow{C_6H_6} Et_3NBCo_3(CO)_9 + 3Br^- + 3CO.$$

The nature of the cluster was determined by cryoscopic weight measurements.[45] No structural confirmation of this type of trimetalmonoboron cluster geometry was available until Shore *et al.* characterized $(\mu\text{-H})_3Os_3(CO)_9BCO$[46] [Fig. 14(a)]. The preparation of $(\mu\text{-H})_3Os_3(CO)_9BCO$ is interesting because it formally involves the insertion of boron into an Os—CO bond, but the success of the reaction depends on the presence of catalytic amounts of $BH_3 \cdot NEt_3$. The proposed mechanism is represented in Fig. 15.[46] $(\mu\text{-H})_3Os_3(CO)_9BCO$ is air-stable and is obtained in 85% yield. However, when $BH_3 \cdot THF$ replaces $BH_3 \cdot NEt_3$, a fascinating boroxine derivative, $[(\mu\text{-H})_3Os_3(CO)_9CO]_3B_3O_3$, containing pendant cluster units surrounding a central boroxine ring, is produced along with $(\mu\text{-H})_3Os_3(CO)_9BCO$.[46,47] Transformations at the boron-attached carbonyl in $(\mu\text{-H})_3Os_3(CO)_9BCO$ have been explored[46,48-50] and are summarized in Fig. 16. The unique carbonyl ligand is subject to nucleophilic substitution by PMe_3 to yield exclusively $(\mu\text{-H})_3Os_3(CO)_9BPMe_3$. There is no indication that phosphine substitution at the metal centres competes with substitution at the boron atom.[46,48] An indirect route is used to produce $(\mu\text{-H})_3Os_3(CO)_8(PPh_3)BCO$ from $(\mu\text{-H})_3Os_3(CO)_9BCO$.[48] Reaction of $(\mu\text{-H})_3Os_3(CO)_8(PPh_3)BCO$ with PMe_3 produces a mixture of $(\mu\text{-H})_3Os_3(CO)_9BPMe_3$

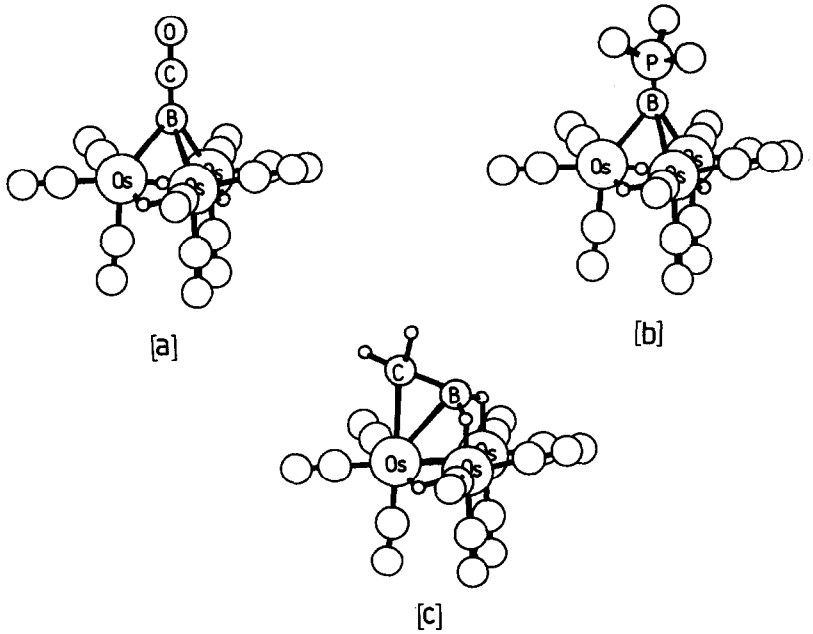

Fig. 14. Molecular structures of (a) $(\mu\text{-H})_3Os_3(CO)_9BCO$;[46] (b) $(\mu\text{-H})_3Os_3(CO)_9BPMe_3$;[48] (c) $(\mu\text{-H})_3Os_3(CO)_9B{=}CH_2$.[49]

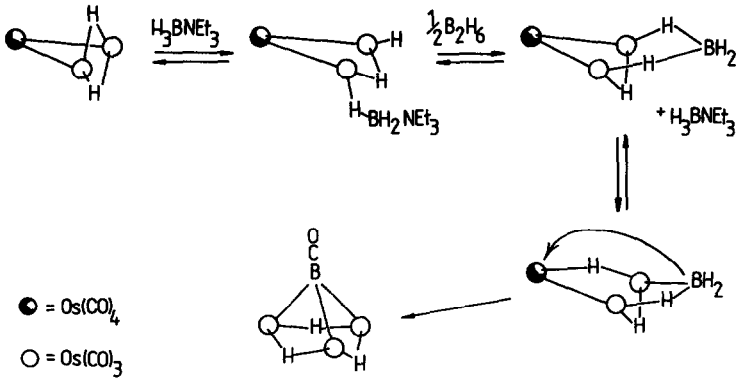

Fig. 15. Proposed mechanism for the formation of $(\mu\text{-H})_3Os_3(CO)_9BCO$.[46]

and $(\mu\text{-H})_3Os_3(CO)_8(PPh_3)BPMe_3$. Kinetic studies on this system suggest that the incoming nucleophile initially attacks the boron atom, resulting in tetrahedral cage opening at an Os—B bond to give a "butterfly" intermediate which subsequently closes, extruding either a CO or a PPh_3 ligand.[48]

UV–photoelectron spectroscopic and Fenske–Hall quantum chemical studies of the clusters $(\mu\text{-H})_3Os_3(CO)_9BCO$ and $(\mu\text{-H})_3Os_3(CO)_9BPMe_3$ have recently been made.[51] The results indicate that the boron is acting as a "pseudo-metal atom". In a comparison between $(\mu\text{-H})_3Os_3(CO)_9BCO$ and $(\mu\text{-H})_2Os_3(CO)_9CCO$, it is shown that the energies of the BCO molecular orbitals are better matched to those of the trimetal fragment than are those of the CCO fragment. This results in their being greater interaction between the metal framework and the BCO unit than between the metal triangle and the CCO fragment. An important observation is that the MO calculations provide evidence for a synergic interaction between the boron and its carbonyl ligand. Again, this suggests a metal-like boron atom.

Reaction of $(\mu\text{-H})_3Os_3(CO)_9BCO$ with $BH_3 \cdot THF$ (Fig. 16) yields an unprecedented triosmium borylidene carbonyl cluster, $(\mu\text{-H})_3Os_3(CO)_9B{=}CH_2$,[49] which can be likened to a trimetal vinylidene system, $(\mu\text{-H})_2Os_3(CO)_9C{=}CH_2$.[52] A comparison of the bonding of the $B{=}CH_2$ and $C{=}CH_2$ fragments to a trimetal framework has been made.[49] It is worth pointing out one salient feature of the structure of $(\mu\text{-H})_3Os(CO)_9B{=}CH_2$ as compared to other characterized $(\mu\text{-H})_3Os_3(CO)_9BX$ clusters: $(\mu\text{-H})_3Os_3(CO)_9B{=}CH_2$ alone exhibits both Os—H—Os and B—H—Os bridges whereas $(\mu\text{-H})_3Os_3(CO)_9BCO$ and $(\mu\text{-H})_3Os_3(CO)_9BPMe_3$ exhibit solely Os—H—Os bridging hydrogen atoms. Presumably, reorientation of the B—X ligand from a vertical (as in X = CO or PMe_3) position to a tilted position (as in X = CH_2) results in a rehybridization of orbitals at the boron

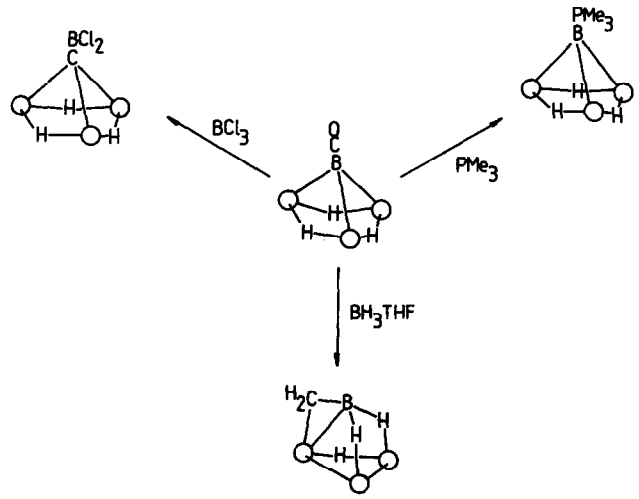

Fig. 16. Reactions of the cluster bound BCO unit in $(\mu\text{-H})_3Os_3(CO)_9BCO$.[46,48–50]

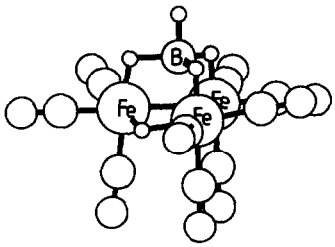

Fig. 17. Molecular structure of $Fe_3(CO)_9BH_5$.[53,54]

atom and a redistribution of electron density on the cluster surface in the hypothetical $[Os_3(CO)_9BX]^{3-}$ anion. The protons will tend to migrate to the regions of highest electron density.

The triiron–borane clusters $(\mu\text{-H})Fe_3(CO)_9BH_4$ and $(\mu\text{-H})Fe_3(CO)_{10}BH_2$, and their conjugate bases $[(\mu\text{-H})Fe_3(CO)_9BH_3]^-$ and $[(\mu\text{-H})Fe_3(CO)_{10}BH]^-$, have been studied in detail. $(\mu\text{-H})Fe_3(CO)_9BH_4$ is prepared by the reaction of two equivalents of $BH_3\cdot THF$ with $[Fe(CO)_4COCH_3]Na$ in THF at 65°C. After acidification, $(\mu\text{-H})Fe_3(CO)_9BH_4$ is produced in 5% yield. The ferraborane has been structurally characterized (Fig. 17).[53,54] The mode of bonding of the borane fragment is particularly interesting. It may be envisaged as the first example of a $\mu_3\text{-}BH_4$ ligand binding to three metal centres via three M—H—B bridges. On the other hand, the 300 MHz variable temperature ^1H NMR spectrum[54] illustrates that three of the borane ligand's four hydrogen atoms are intimately associated with the Fe_3B cluster core while one hydrogen remains terminally attached to the boron atom. This suggests that the $[BH_4]^-$ fragment has lost its ligand identity. There are two separate fluxional processes involving the cluster *endo*-hydrogen atoms in $(\mu\text{-H})Fe_3(CO)_9BH_4$. At −100°C, the protons are static. Warming to −50°C renders the three Fe—H—B protons equivalent, while further warming to 80°C allows exchange of all four *endo*-hydrogen atoms.

Deprotonation of $(\mu\text{-H})Fe_3(CO)_9BH_4$ is readily accomplished with weak bases.[54] Infra-red, multinuclear NMR and Mössbauer spectra indicate that an Fe—H—B bridging proton is removed in preference to either the Fe—H—Fe or terminal protons [Fig. 18(a)]. The terminal BH would not be the expected site of deprotonation since this would leave an exposed boron lone pair, radially

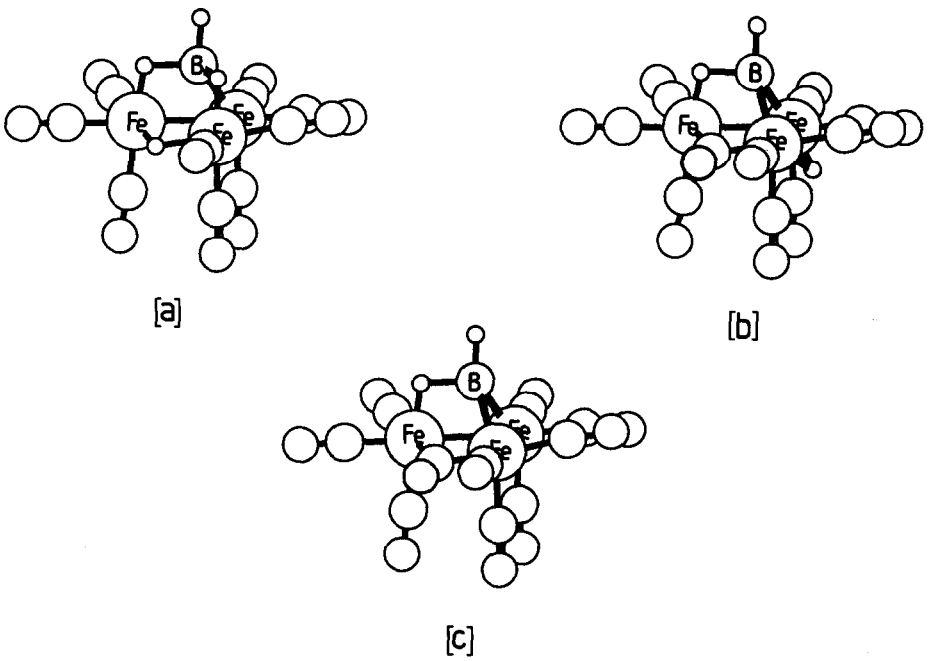

Fig. 18. Proposed structures of (a) $[Fe_3(CO)_9BH_4]^-$; (b) $Fe_3(CO)_{10}BH_3$; (c) $[Fe_3(CO)_{10}BH_2]^-$.[54,57]

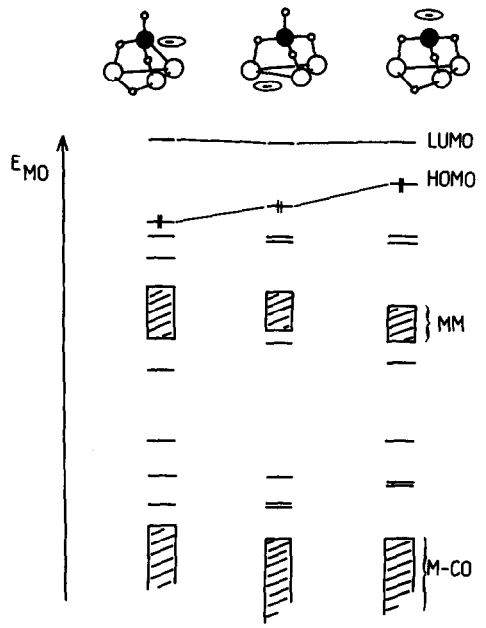

Fig. 19. Comparison of the molecular orbital energies of some isomers of $[Fe_3(CO)_9BH_4]^-$.[55]

disposed and pointing out from the cluster. The relative stabilities of several possible isomers of $[(\mu\text{-}H)Fe_3(CO)_9BH_3]^-$ can be probed by comparing the HOMO–LUMO energy separation obtained from Fenske–Hall calculations.[55] However, it should be noted that the calculations are known to artificially favour M—H—B over M—H—M bridging sites.[56] Figure 19 compares the energies of the MO's of some isomers and we note that the calculations appear to predict a structure in line with experimental observations.

If the conditions of synthesis for $(\mu\text{-}H)Fe_3(CO)_9BH_4$ are modified by adding two equivalents of $Fe(CO)_5$, the favoured product is $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$ [Fig. 18(b)].[57] $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$ is related to $(\mu\text{-}H)Fe_3(CO)_9BH_4$ via the formal replacement of two hydrogen atoms, (each a one electron donor), by a bridging carbonyl ligand, (a two electron donor). Spectroscopic evidence shows that, on going from $(\mu\text{-}H)Fe_3(CO)_9BH_4$ to $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$, two hydrogens "migrate" from Fe—H—B edges on to the trimetal framework and are placed by an edge bridging carbonyl ligand. This migration is a formalism only. The transformation is reported not to take place experimentally; $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$ does not react with H_2 to give $(\mu\text{-}H)Fe_3(CO)_9BH_4$, nor does $(\mu\text{-}H)Fe_3(CO)_9BH_4$ react with CO to give $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$.[57]

In contrast to $(\mu\text{-}H)Fe_3(CO)_9BH_4$, $(\mu\text{-}H)Fe_3(CO)_{10}BH_2$ deprotonates via loss of the Fe—H—Fe proton [Fig. 18(c)].[57] Interestingly, although neutral $(\mu\text{-}H)Fe_3(CO)_9BH_4$ is reported not to react with CO to eliminate hydrogen gas, $[(\mu\text{-}H)Fe_3(CO)_{10}BH]^-$ can be formed in 80% yield by the passage of CO through a solution of $[(\mu\text{-}H)Fe_3(CO)_9BH_4]^-$ at 45°C.[58]

The reactivity of $PPN[(\mu\text{-}H)Fe_3(CO)_9BH_3]$ towards Lewis bases[58] is illustrative of two features. Firstly, it indicates the factors which control whether the incoming nucleophile attacks the boron centre or a metal atom. Secondly, it emphasises the competition between ligand substitution and cluster fragmentation, a problem which Pöe has described as the "Achilles' heel" of cluster substitution.[59] For the Lewis bases H_2O and NEt_3, the expected affinity for boron over a metal centre is observed. However, for $PhMe_2P$, there are three competing reaction pathways as illustrated in Fig. 20. Interestingly, the phosphine substituted product observed in path A is a result of hydrogen, and not CO, elimination. When $PPN[(\mu\text{-}H)Fe_3(CO)_{10}BH]$ reacts with one equivalent of $PhMe_2P$, substitution of a carbonyl ligand is observed as the only reaction. The kinetics of the reaction of $PPN[(\mu\text{-}H)Fe_3(CO)_9BH_3]$ with $PhMe_2P$ show that the reaction is first order with respect to both cluster and Lewis base.[58]

The special significance which the *endo*-hydrogen atoms impart to $[(\mu\text{-}H)Fe_3(CO)_9BH_3]^-$ is noted not only in the reaction of this ferraborane anion with phosphine, but also in its reactivity towards

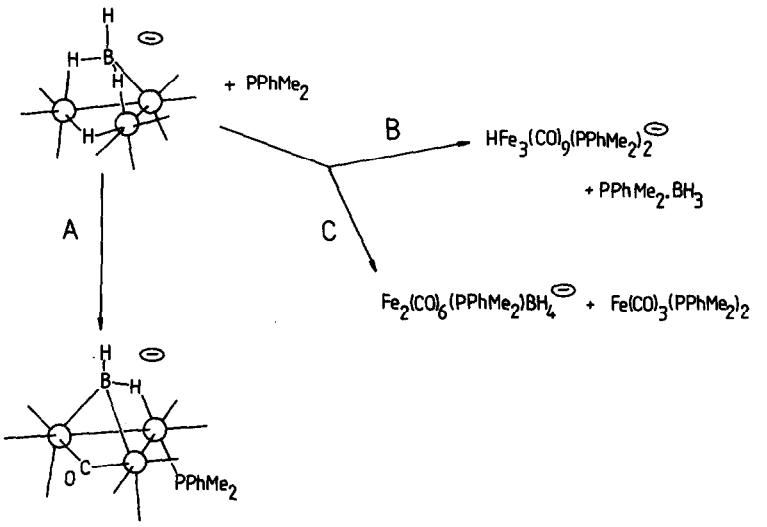

Fig. 20. Competitive pathways for the reaction of $PhMe_2P$ with $[Fe_3(CO)_9BH_4]^-$; pathway **A** is favoured at low concentrations of $PhMe_2P$, while pathways **B** and **C** compete at high $[PhMe_2P]$.[58]

$Fe_2(CO)_9$. The expansion of the triiron cluster to a tetrairon cluster $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ is achieved by reacting $PPN[(\mu\text{-H})Fe_3(CO)_9BH_3]$ with two equivalents of $Fe_2(CO)_9$ at room temperature.[56,60] The mild conditions, heterogeneous nature of the reaction mixture, and fact that the cluster reaction takes place quantitatively, are remarkable. The stoichiometry of the reaction has been fully established:

$$[(\mu\text{-H})Fe_3(CO)_9BH_3]^- + 2Fe_2(CO)_9 \rightarrow [(\mu\text{-H})Fe_4(CO)_{12}BH]^- + H_2 + 3Fe(CO)_5.$$

The cluster building sequence is schematically illustrated in Fig. 21. This cluster construction closely parallels a geometrical description and molecular orbital fragment analysis of $(\mu\text{-H})Fe_4(CO)_{12}CH$[61] which is isoelectronic with $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$. The metallaborane $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ will be discussed in the section, metal : boron ratio of 4 : 1.

Alkylated derivatives of $(\mu\text{-H})Fe_3(CO)_9BH_4$ are major products of the reaction of $Fe(CO)_5$, $BH_3 \cdot THF$ and $Li[BEt_3H]$ in hexane.[54] The methylated derivative of $(\mu\text{-H})Fe_3(CO)_{10}BH_2$, $(\mu\text{-H})Fe_3(CO)_{10}BH(CH_3)$, (Fig. 22) is also formed, but in low yield. Significantly higher yields of the alkylated species $(\mu\text{-H})Fe_3(CO)_9BH_3R$ are obtained if one equivalent of $Fe_2(CO)_9$ is initially present in the reaction mixture.[62] Orange, air-sensitive $(\mu\text{-H})Fe_3(CO)_9BH_3R$ ($R = CH_3$, C_2H_5) is a crystalline solid at room temperature. It is interesting that this particular synthetic route does not produce the all hydrogenated ferraborane, $(\mu\text{-H})Fe_3(CO)_9BH_4$. Separation of the methyl and ethyl derivatives (Fig. 23) has not been achieved.[62] Both derivatives display similar spectroscopic characteristics; the ^{11}B NMR resonances are at δ 22.1 (R = Me) and δ 25.4 (R = Et), while the ^1H NMR resonances are indistinguishable for the two derivatives.[55] The effect of substituting an alkyl group for a terminal hydrogen atom on the boron is to lower the energy barrier to *endo*-hydrogen mobility. Whereas for R = H, the limiting low temperature 300 MHz ^1H NMR spectrum shows that all *endo*-hydrogen motion is frozen out, for R = Me or Et, the three Fe—H—B protons remain equivalent

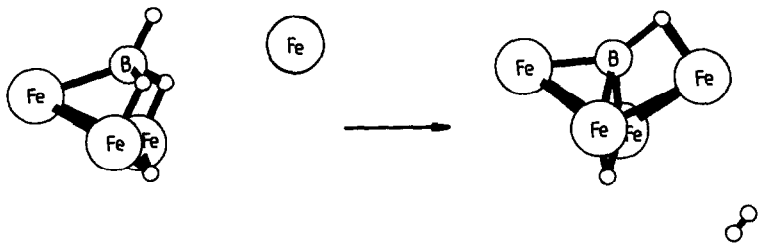

Fig. 21. A schematic representation of the expansion of $[Fe_3(CO)_9BH_4]^-$ to $[HFe_4(CO)_{12}BH]^-$ via the elimination of H_2.[56,60]

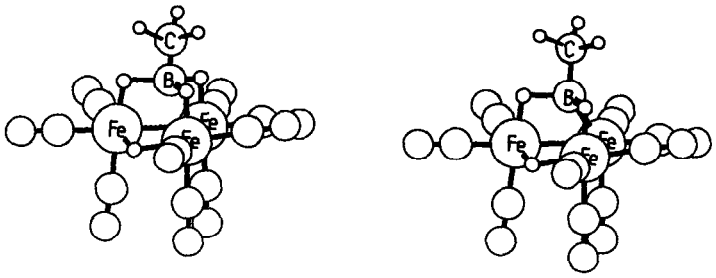

Fig. 22. Proposed structures of $Fe_3(CO)_{10}BH_2(CH_3)$ and $[Fe_3(CO)_{10}BH(CH_3)]^-$.[58]

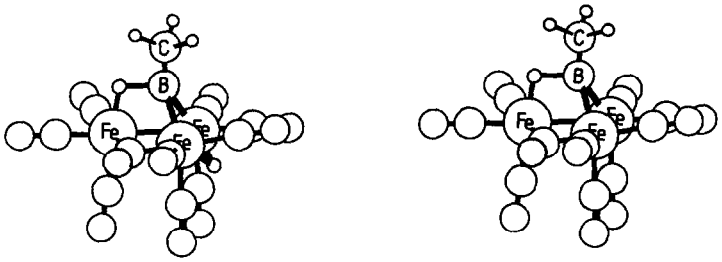

Fig. 23. Proposed structures for $Fe_3(CO)_9BH_4(CH_3)$ and $[Fe_3(CO)_9BH_3(CH_3)]^-$. The ethyl derivatives have the same structures with C_2H_5 replacing CH_3.[54]

at $-80°C$ despite there being two geometrical positions (Fig. 24). This equivalence could be due either to exchange of the Fe—H—B protons themselves, or to scrambling of the Fe—H—Fe proton around the triiron base of the cluster. As with $(\mu\text{-H})Fe_3(CO)_9BH_4$, deprotonation of $(\mu\text{-H})Fe_3(CO)_9BH_3R$ takes place readily at an Fe—H—B site.[54]

$(\mu\text{-H})Fe_3(CO)_{10}BH(CH_3)$ displays similar NMR spectral properties to the hydrogenated parent cluster $(\mu\text{-H})Fe_3(CO)_{10}BH_2$.[58] It deprotonates readily, as does the parent, by loss of an Fe—H—Fe bridging proton (Fig. 22).

CLUSTERS WITH METAL:BORON RATIO 4:1

The formation of $PPN[(\mu\text{-H})Fe_4(CO)_{12}BH]$ via a designed cluster expansion reaction was described above. Historically, the conjugate acid, $(\mu\text{-H})Fe_4(CO)_{12}BH_2$, was the first fully char-

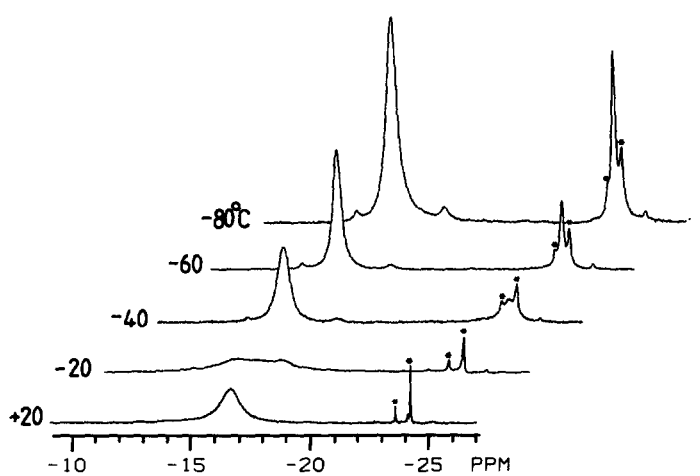

Fig. 24. 300 MHz variable temperature ^1H NMR in CD_2Cl_2 for $Fe_3(CO)_9BH_4R$ (R = Me, Et).[55] Signals labelled * are due to $H_3Fe_3(CO)_9CR$.

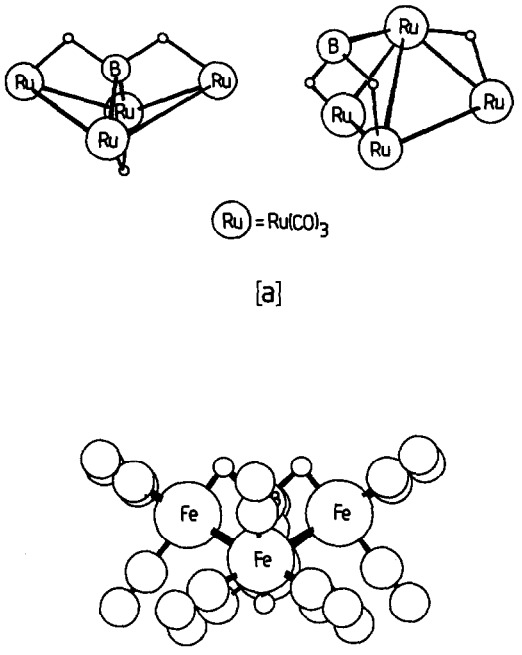

Fig. 25. (a) Proposed structures of $HRu_4(CO)_{12}BH_2$[33] and (b) molecular structure of $HFe_4(CO)_{12}BH_2$.[63,64]

acterized four-metal monoboron cluster.[63,64] A few years earlier, the ruthenium analogue, (μ-H)$Ru_4(CO)_{12}BH_2$ was reported[33] to accompany $Ru_3(CO)_9B_2H_6$ as a minor product in the reaction of $Ru_3(CO)_{12}$ with Na[BH_4]. Two structures [Fig. 25(a)] were proposed for (μ-H)$Ru_4(CO)_{12}BH_2$ on the basis of mass spectroscopic and ^{1}H NMR data. No ^{11}B NMR data were reported. One of the proposed structures for (μ-H)$Ru_4(CO)_{12}BH_2$ was confirmed by X-ray analysis for the ferraborane analogue [Fig. 25(b)].[63,64] In (μ-H)$Fe_4(CO)_{12}BH_2$, the boron atom interacts with a butterfly of four iron atoms (internal dihedral angle 114°), and lies only 0.3 Å above a line joining the two wing-tip metal atoms. All hydrogen atoms are *endo* with respect to the cluster. These structural observations tend to suggest that the boron atom should be described as being *interstitial* with respect to the metal atoms. Note that the BH_2 group is isoelectronic with CH, N and O^+, all of which have been characterized in interstitial environments within butterfly arrays of metal atoms.[7,8,65] The interstitial nature of the boron atom in (μ-H)$Fe_4(CO)_{12}BH_2$ is further indicated by the results of Fenske–Hall MO calculations.[64]

Mono-deprotonation of (μ-H)$Fe_4(CO)_{12}BH_2$ by loss of an Fe—H—B proton takes place readily in the presence of a weak base to form the conjugate base, [(μ-H)$Fe_4(CO)_{12}BH]^-$.[56] Several hours' exposure to triethylamine[55] deprotonates PPN[(μ-H)$Fe_4(CO)_{12}BH$] to the dianion.[66] With *n*-butyl lithium, stepwise deprotonation of (μ-H)$Fe_4(CO)_{12}BH_2$ to the trianion is achieved (Fig. 26).[66] This occurs via alternate loss of Fe—H—B and Fe—H—Fe protons. The replacement of an Fe—H—B interaction by a direct Fe—B interaction as one moves along the series (μ-H)$Fe_4(CO)_{12}BH_2$ to [(μ-H)$Fe_4(CO)_{12}BH]^-$ to $[Fe_4(CO)_{12}BH]^{2-}$ to $[Fe_4(CO)_{12}B]^{3-}$ has a significant effect both on the chemical shift (see Appendix I) and the line width of the ^{11}B NMR resonance.[66] $[Fe_4(CO)_{12}B]^{3-}$ is isoelectronic with $[Fe_4(CO)_{12}C]^{2-}$[67] and is the first example of a transition metal cluster exhibiting an exposed boron atom; i.e. it is a discrete metal boride cluster.

The *endo*-hydrogen atoms of the monoanion, [(μ-H)$Fe_4(CO)_{12}BH]^-$, are fluxional at room temperature on the 300 MHz NMR timescale. A comparison[56] between the fluxional processes that operate in [(μ-H)$Fe_4(CO)_{12}BH]^-$ and the isoelectronic and isostructural cluster (μ-H)$Fe_4(CO)_{12}CH$[68] indicates that exchange of the Fe—H—Fe and Fe—H—X (X = B or C) is more facile for the ferraborane than for the iron hydrocarbyl complex. At low temperatures, the ^{13}C NMR spectrum of (μ-H)$Fe_4(CO)_{12}CH$[65] exhibits equivalence of the two wing-tip $Fe(CO)_3$ units. This can

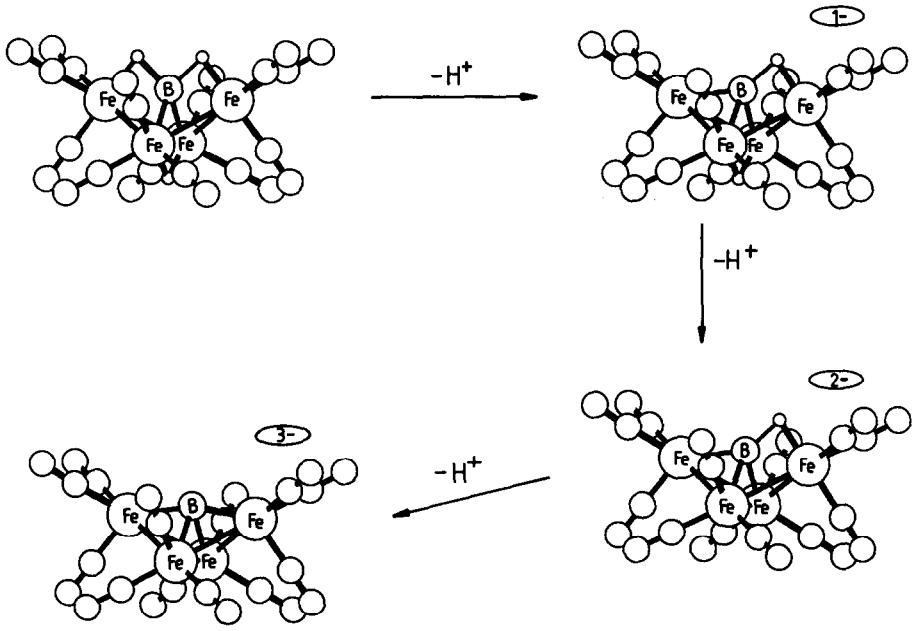

Fig. 26. Stepwise deprotonation of $HFe_4(CO)_{12}BH_2$ leading to $[Fe_4(CO)_{12}B]^{3-}$.[66]

be explained by a process such as a "flip" of the Fe—H—C bridge proton between the two equivalent wing-tip iron-carbon sites. An analogous process in $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ has a higher activation energy and is not observed in this case. It is concluded that in $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$, the Fe—H—B proton is more strongly bound to the iron atom than to the carbon atom, whereas in $(\mu\text{-H})Fe_4(CO)_{12}CH$, the Fe—H—C proton is more closely associated with the carbon than with the iron atom.[56]

The reactivity of $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ towards Lewis bases has been studied.[56,69] With one equivalent of $PhMe_2P$, $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ reacts smoothly via an associative mechanism to give the monosubstituted derivative $[(\mu\text{-H})Fe_4(CO)_{11}(PhMe_2P)BH]^-$. A further equivalent of phosphine leads to $[Fe_4(CO)_{10}(PhMe_2P)_2BH_2]^-$ (again via an associative mechanism), but its formation is accompanied by significant cluster fragmentation. In both the mono- and di-phosphine substituted derivatives, multinuclear NMR data evidence that substitution occurs at an equatorial site on a wing-tip iron atom. The relative stability of this versus other sites is illustrated using extended Hückel MO calculations.[56] It is noteworthy, firstly, that in going from $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ to $[(\mu\text{-H})Fe_4(CO)_{11}(PhMe_2P)BH]^-$, the activation barrier to *endo*-hydrogen exchange is raised; secondly, in going from $[(\mu\text{-H})Fe_4(CO)_{11}(PhMe_2P)BH]^-$ to $[Fe_4(CO)_{10}(PhMe_2P)_2BH_2]^-$, the stable locations for the *endo*-hydrogens change from being one Fe—H—B and one Fe—H—Fe to both protons occupying Fe—H—B bridge sites (Fig. 27). The *endo*-hydrogen atoms play an important role in

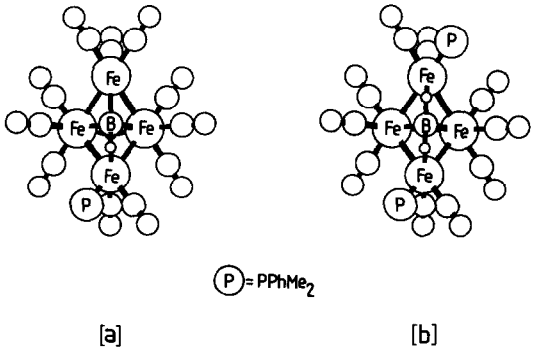

Fig. 27. Proposed structures for (a) $[HFe_4(CO)_{11}(PhMe_2P)BH]^-$ and (b) $[Fe_4(CO)_{10}(PhMe_2P)_2BH_2]^-$.[56,59]

"absorbing" changes in electronic charge which occur at the wing-tip iron atoms as a result of phosphine substitution.[56]

CLUSTERS WITH METAL:BORON RATIO 5:1

The isolobal relationship between H^+ and $AuPR_3^+$[70,71] has been exploited in order to increase the metal to boron ratio in $(\mu\text{-H})Fe_4(CO)_{12}BH_2$ from 4:1 to 5:1; $PPN[(\mu\text{-H})Fe_4(CO)_{12}BH]$ reacts with one equivalent of $AuPPh_3Cl$ at room temperature in CH_2Cl_2 to give $(\mu\text{-H})Fe_4(CO)_{12}(AuPPh_3)BH$.[72] The structure shown in Fig. 28 is proposed on the basis of spectroscopic data. Little change occurs in the ^{11}B NMR chemical shift upon going from $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ to $(\mu\text{-H})Fe_4(CO)_{12}(AuPPH_3)BH$; it has previously been noted that, unlike association with protons, association of the boron atom with $AuPR_3$ fragments causes minimal perturbation to the ^{11}B NMR shift.[73] This fact, in conjunction with the observation of ^1H NMR shifts at δ −7.4 (Fe—H—B) and

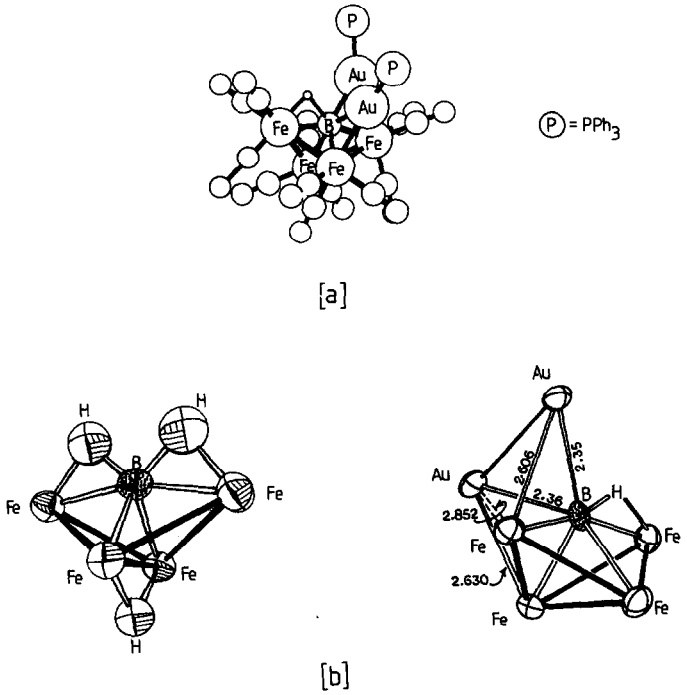

Fig. 29. (a) Molecular structure of $Fe_4(CO)_{12}(AuPPh_3)_2BH$[73,74] and (b) comparison of the Fe_4BH_3 core structure of $HFe_4(CO)_{12}BH_2$ with the Fe_4Au_2BH core of $Fe_4(CO)_{12}(AuPPh_3)_2BH$.

−24.9 (Fe—H—Fe), indicates that $(\mu\text{-H})Fe_4(CO)_{12}(AuPPH_3)BH$ retains the cluster core structure of $(\mu\text{-H})Fe_4(CO)_{12}BH_2$ with a $AuPPh_3$ unit replacing one Fe—H—B bridging proton.

CLUSTERS WITH METAL:BORON RATIO 6:1

Until 1986, the only discrete cluster reported to contain six metal atoms and one boron atom was $Co_6(CO)_{16}B$.[45] This cluster is produced either by the reaction of $Co_2(CO)_8$ with BBr_3 at 60°C, or by treatment of $Co_2(CO)_8$ with 8–10 atmospheres of B_2H_6. Characterization was by elemental analysis and infrared spectroscopy only.

The reaction of $[(\mu\text{-H})Fe_4(CO)_{12}BH]^-$ with excess $AuPPh_3Cl$ in CH_2Cl_2 leads to the high yield formation of $Fe_4(CO)_{12}(AuPPh_3)_2BH$.[73,74] In view of the isolobal analogy between H^+ and $AuPPh_3^+$, one might have expected the cluster structure of $Fe_4(CO)_{12}(AuPPh_3)_2BH$ to mimic that of $Fe_4(CO)_{12}BH_3$. However, the crystallographically characterized isomer of this compound possesses an unprecedented M_6X cluster core [Fig. 29(a)] with one $AuPPh_3$ fragment bridging an Fe(hinge)—B edge and one bridging an Fe(wing)—B edge of the parental Fe_4B cluster core.[73,74] A comparison between the core structures of $Fe_4(CO)_{12}(AuPPh_3)_2BH$ and $Fe_4(CO)_{12}BH_3$ is made in Fig. 29(b). A comparative molecular orbital analysis of the bonding in the two compounds has been made.[74] Certainly, the spatial requirements of the *endo*-hydrogen atom in $Fe_4(CO)_{12}(AuPPh_3)_2BH$ must be responsible for the observed distortion from the symmetrical octahedral M_6 skeleton which encapsulates a carbon atom (isoelectronic with BH) in the related compounds $[Fe_6(CO)_{16}C]^{2-}$[75] and $Fe_4(CO)_{12}(AuPEt_3)_2C$.[76] The two phosphorus environments in $Fe_4(CO)_{12}(AuPPh_3)_2BH$ were not originally observed in the 36 MHz ^{31}P NMR spectrum.[73] However, recent 162 MHz ^{31}P NMR variable temperature studies illustrate that the two phosphorus environments can be frozen out.[72]

It is pertinent to illustrate at this point how molecular orbital calculations can use the known heavy atom structure of a neutral cluster to aid in the location of hydrogen atoms which are not refined in a structure determination. For example, in the crystallographic determination of $Fe_4(CO)_{12}(AuPPh_3)_2BH$, refinement allows the cluster geometry to be known with certainty.[73,74] We can consider the hypothetical anion $[Fe_4(CO)_{12}(AuPPh_3)_2B]^-$ to have the refined core structure of the neutral $Fe_4(CO)_{12}(AuPPh_3)_2BH$. Thus the HOMO of this anion should exhibit a region of high electron density (Lewis basicity) at the site of protonation. Figure 30 illustrates this feature.[55] ($CuPH_3$ fragments are used to model $AuPPh_3$ units in the calculations.[74]) It is, however, crucial to remember that this procedure in *no way* predicts the structure of the real anion, $[Fe_4(CO)_{12}(AuPPh_3)_2B]^-$, but rather uses the known heavy atom structure of the neutral cluster to predict the location of the *endo*-hydrogen in the neutral complex.

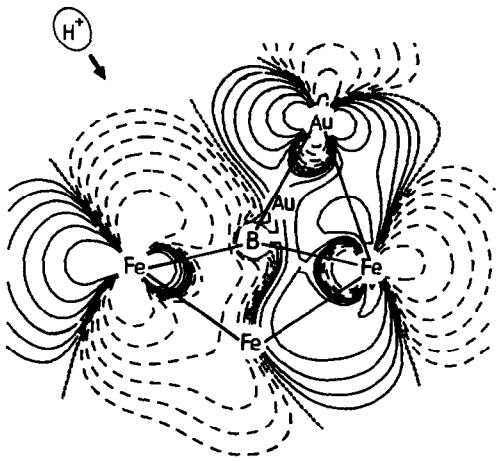

Fig. 30. Amplitude contour plot of the HOMO of $[Fe_4(CO)_{12}(CuPH_3)_2B]^-$ used to model $[Fe_4(CO)_{12}(AuPPh_3)_2B]^-$; the anion has a hypothetical structure derived from the crystallographically refined positions of the non-hydrogen atoms in $Fe_4(CO)_{12}(AuPPh_3)_2BH$. The plot is in the plane containing wing-tip iron atoms, boron atom and Fe(wing)—B bridging gold(I) fragment and shows only core atoms. The other core atoms are projected onto the plane of the plot. The largest contour is 0.05 electron au^{-3}, and each succeeding contour differs from the last by a factor of 2.

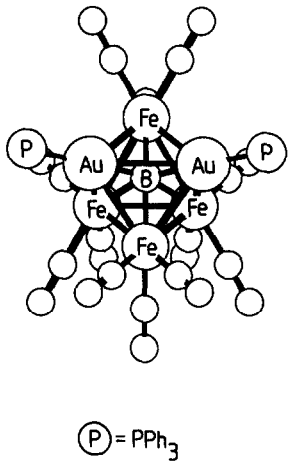

Fig. 31. Proposed structure of $[Fe_4(CO)_{12}(AuPPh_3)_2B]^-$.[72]

Deprotonation of $Fe_4(CO)_{12}(AuPPh_3)_2BH$ with triethylamine leads to a single anionic product.[72] The extreme downfield ^{11}B NMR shift (δ 192) indicates that the boron atom is interacting directly with all four iron atoms. This, in conjunction with a single, temperature invariant ^{31}P NMR resonance suggests that, once rid of the steric requirements of the proton, $[Fe_4(CO)_{12}(AuPPh_3)_2B]^-$ becomes isostructural with its isoelectronic analogue $Fe_4(CO)_{12}(AuPPh_3)_2C$, rather than retaining the distorted octahedral structure found in $Fe_4(CO)_{12}(AuPPh_3)_2BH$. Thus, a boridic environment is proposed for $[FE_4(CO)_{12}(AuPPh_3)_2B]^-$ (Fig. 31).

CONCLUSIONS

The aim of this article has been to illustrate recent developments in the field of metal-rich metallaboranes and this particular survey is timely in view of the burgeoning number of publications in this area. The transition from metallaboranes to discrete metal boride clusters is being made and there should now follow a wealth of new and exciting chemistry. It is many years since Lipscomb pointed out the analogies between borane clusters and bulk metal boride systems.[77] The links between the two extremes are now beginning to be understood.

ESR STUDY ON THE REACTIONS OF IRON CARBONYLS WITH NITRO AND NITROSOPARAFFINES. A MECHANISM OF THE REDUCTIVE CARBONYLATION OF NITRO COMPOUNDS

Yu. A. BELOUSOV* and T. A. KOLOSOVA

A. N. Nesmeyanov Institute of Organoelement Compounds, USSR Academy of Sciences, 28 Vavilov Str., 117813 Moscow, U.S.S.R.

(*Received* 26 *March* 1987; *accepted* 27 *April* 1987)

Abstract—The interaction of $Fe_n(CO)_m$ (n and m equal 1 and 5, 2 and 9, 3 and 12, respectively) with 2-methyl-2-nitrosopropane and sodium salts of nitromethane and nitrocyclohexane was studied. The initial stages of the process, following the activating complex-formation, involves redox disproportionation to give rise to the radical Fe(I) carbonyl complexes and radical anions $Fe_2(CO)_8^-$ (**I**) $Fe_3(CO)_{11}^-$ (**II**), $Fe_4(CO)_{13}^-$ (**III**) and $Fe_3(CO)_{12}^-$ (**IV**). Also, radical anions **I–IV** are formed in the interaction of salts of carbonyl ferrate anions $Na_2Fe(CO)_4 \cdot 1.5$ diox and $PPN_2[Fe_n(CO)_{m-1}]$ (where PPN = $(PPh_3)_2N^+$), with nitro- and nitroso-tert-butane.

Radical anions **I–III** act as catalytically active species in the coordination sphere of which the nitro compounds undergo a successive deoxygenation to nitrene radical complexes with their subsequent carbonylation to isocyanates. A scheme of the reductive carbonylation is proposed.

Reactions of iron carbonyls with nucleophilic agents and bases have been under study for more than 60 years. Owing mainly to the studies of Hieber and coworkers[1,2] it is known that these reactions represent redox disproportionation whose thermodynamics are controlled by formation of Fe(II) salts with the carbonyl ferrate anion Fe(-II) as the counterion. The bi- and trinuclear iron carbonyl complexes were often isolated as intermediates.[3] These complexes contain a variety of fixed products resulting from the conversions of the parent substrates. The complexes were considered to be intermediate catalytic species[4,5] in the carbonylation of nitro[5] and a variety of other nitrogenated compounds[6–8] catalysed with metal, particularly iron carbonyls.

However, only little attention has been paid in these studies to the redox disproportionation of the carbonyls, and its catalytic role has not been disclosed.

On the other hand, electrochemical, ESR and ion cyclotron resonance studies gave evidence of the paramagnetic radical ions of iron carbonyls having a formal charge on metal (-I), such as $Fe_2(CO)_8^-$ (**I**), $Fe_3(CO)_{11}^-$ (**II**), $Fe_4(CO)_{13}^-$ (**III**) and $Fe_3(CO)_{12}^-$ (**IV**). They are generated either by means of the traditional reducing agents or electrochemically.[9–13]

However, these studies do not trace relations between radical anions **I–IV** and redox disproportionation of the iron carbonyls either.

One of the present authors has shown for the first time that such radical anions of iron carbonyls result from the one-electron transfer at the first stage of redox disproportionation of the iron carbonyls under the effect of the nitrogenous nucleophiles, anions of azoles,[14] and that these radical anions are catalytically active species where the reduction of the nitro compounds takes place.[15] The purpose of the present study is to discuss this problem.

EXPERIMENTAL

ESR spectra were taken with an ERS-221 (ZWG DDR) instrument in an X-range with a 100 kHz

* Author to whom correspondence should be addressed.

modulation. The reactions were conducted directly in an ampoule placed in the ESR spectrometer cavity with the equimolar reagents ratio of *ca.* 10^{-1} M of THF and toluene. When using 2-methyl-2-nitrosopropane as the spin trap, its concentration was *ca.* 10^{-3} M. The samples were conditioned in a vacuum of 10^{-4} torr by freeze–pump–thaw cycles by the use of THF and toluene dehydrated over benzophenone ketyl, or nitromethane dehydrated over 4 Å molecular sieves. All the studies using 2-methyl-2-nitrosopropane were made in the dark.

Syntheses of the parent compounds

All the syntheses were carried out in an argon atmosphere. Potassium and sodium nitrites were those commercially available, without preliminary purification. The iron pentacarbonyl was purified by sublimation. The iron pentacarbonyl $^{57}Fe(CO)_5$[16] as well as $Na_2Fe(CO)_4 \cdot 1.5diox$,[17] $PPN_2[Fe_2(CO)_8]$,[18,19] $PPN_2[Fe_3(CO)_{11}]$,[20] $PPN_2[Fe_4(CO)_{13}]$,[21] $PPN[Fe(CO)_3NO]$,[22] $PPN(NO_2)$,[23] t-C_4H_9NO,[24] $FcPF_6$ where Fc is ferricenium,[25] $Fe_2(CO)_6(N\text{-}t\text{-}Bu)_2$, $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$, $Fe_2(CO)_6[(t\text{-}BuN)_2CO]$[26] and t-BuNCO[27] were synthesized by the known methods. The sodium salts of the nitro compounds were obtained from the corresponding nitro compounds and sodium hydride in THF.

RESULTS AND DISCUSSION

1. *Reactions of the iron carbonyls* $Fe(CO)_5$ *and* $Fe_3(CO)_{12}$ *with the sodium salts of nitromethane and nitrocyclohexane*

Iron pentacarbonyl is known to interact with aliphatic nitro compounds under the effect of ultraviolet irradiation, radiolysis or high temperatures. If in reactions with iron carbonyls the sodium salts of nitro compounds are used (thereby increasing the basicity of the reagents) the reactions in THF at room temperature for the most inert iron carbonyl, *viz.* pentacarbonyl, will terminate in no more than a few minutes. When the reaction takes place directly in the ESR spectrometer cavity at −80°C, one can observe a successive formation of radical anions **I–IV** whose g-factors are in good agreement with those reported by Krusic *et al.*[10] Note that these four radicals are always formed in the reactions, irrespective of which iron carbonyl is used initially. The only difference is the order in which they are formed as well as the rate of their accumulation and consumption at the different reaction stages.

Starting with $Fe_3(CO)_{12}$, the order in which the radical anions appear is as follows: **IV, II, I, III.**

In addition to these species, reactions of iron pentacarbonyl gave a series of radicals with the corresponding signals: a broadened singlet ($g = 2.0461$) from **V** which was formed at the initial reaction stages; a broad signal ($g = 2.0327$) from **VI**; a 1 : 2 : 3 : 2 : 1 quintet ($g = 2.0217$ and $a_N = 1.6$ G) from **VII** and broadened singlet ($g = 2.0182$) from **VIII**. A 1 : 3 : 6 : 7 : 6 : 3 : 1 heptet ($g = 1.9914$ and $a_N = 4.7$ G) from **IX** is also detectable (see Table 1), probably $Fe(CO)(NO)_3^{\cdot}$.[28]

We believe that the earlier proposed scheme[14] of redox disproportionation of iron carbonyls under the effect of anionic nucleophiles is applicable to nitro compound salts, as well. For the reaction with iron pentacarbonyl the following scheme can be written down:

$$Fe(CO)_5 + (R_2CNO_2)^- \rightleftharpoons [Fe(CO)_{5-n} \cdot (R_2CNO_2)]^-$$

$$[Fe(CO)_{5-n} \cdot (R_2CNO_2)]^- + Fe(CO)_5 \xrightarrow[-CO]{} [Fe(CO)_4 \cdot (R_2CNO_2)]^{\cdot} + Fe(CO)_5^- \quad (1)$$

$$R = H, -R-R- = -(CH_2)_5-.$$

The ambiguity of the n value (0 or 1) is caused by the order in which one or another process, i.e. CO group elimination or electron transfer, takes place. A detailed discussion of the interaction of iron carbonyls with Lewis bases will be given elsewhere.[29]

The resulting $Fe(CO)_5^-$ is unstable.[30] It interacts with the iron pentacarbonyl to yield radical anions **I–IV**, i.e. Fe(-I) compounds. Thereby the reductive part of the iron carbonyl redox disproportionation is realized.

Among the Fe(I) species $Fe(CO)_3(NO)^{\cdot}$ **(VI)** can be regarded as a reliably identified radical. At −60°C the corresponding signal exhibits a structure typical of a 1 : 1 : 1 unresolved triplet with a Lorenzian line shape to give, as reported elsewhere,[31] $a_N = 2.1$ G. The labelled ^{57}Fe yields a doublet on the iron, $a_{^{57}Fe} = 7.9$ G.

Radical **VI** was also obtained by us via an alternative synthesis, by the reaction:

$$PPN[Fe(CO)_3(NO)] + Fc^+PF_6^- \rightarrow Fe(CO)_3(NO)^{\cdot} + Fc. \quad (2)$$

It is detected at −80°C at the initial reaction stages. The extended reaction time gives rise to the other radicals with a multiplet structure of the signals in this region, whose superposition impedes spectrum interpretation.

Using 2-methyl-2-nitrosopropane as the spin trap

Table 1. ESR data on the reactions of iron carbonyls with nitro and nitrozoparaffines[a,b]

Radical number	Radical structure[c]	g-factor[d]	Hyperfine splitting constants (Gauss)[e] a_N	$a_{(x)}$	Reaction number

makes it possible to detect the spin adduct of this radical, $(CO)_3(NO)Fe—N(O^{\cdot})—t\text{-Bu}$ (X), $g = 2.0040$. The signal has a triplet-of-triplets structure ($a_{N_1} = 16.9$ G, $a_{N_2} = 0.65$ G) (see Fig. 1). When using $^{57}Fe(CO)_5$, one can observe a doubling on a single Fe atom, $a^{57}_{Fe} = 1.7$ G. The final structure of this radical was confirmed by an alternative synthesis in the reaction of PPN[$Fe(CO)_3NO$] with $Fc^+PF_6^-$ in the presence of *t*-BuNO. It should be noted that the literature reports on the spin adducts isoelectronic to radical X, e.g. $ClFe(CO)_4—N(O^{\cdot})—t\text{-Bu}$, $g = 2.0049$, $a_N = 16.0$ G in $CHCl_3$.[32]

The absence of an organic substituent at the nitrogen atom in the resultant radical $Fe(CO)_3NO^{\cdot}$ has made it possible to assume that the formation of the Fe(I) complexes involves a cleavage of the C—N bond in the nitro compound salt.

The cleavage of this bond in nitro compounds is observed in reactions with sodium alcoholates, leading to the formation of a nitrite ion.[33] In reactions with iron carbonyls such a cleavage is likely due to the fact that during the disproportionation an inorganic coordination sphere is formed first around Fe^+ and then Fe^{2+}. Therefore we decided to carry out ESR studies of the reactions of the iron pentacarbonyl with the nitrites such as $Kat^+NO_2^-$, where $Kat^+ = Na^+$, K^+ and PPN^+. Concerning a set of radical products, this reaction turned out to be close to that with the nitro paraffine salts. The formation and consumption of radicals **I–IV** as well as **VI–VIII** is the same for the two reactions (see Table 1).

However, these reactions differ at the initial stages. In reactions with nitrites, radical **V** is absent but instead a strong 1 : 1 : 1 triplet ($g = 2.0376$ and $a_N = 13.2$ G) from **XI** is observed.

Moreover, there appears the radical $Fe(CO)_2(NO)_2^+$ ($g = 2.0286$, $a_N = 2.8$ G) (a 1 : 2 : 3 : 2 : 1 quintet), also obtained via an alternative synthesis by the reaction $Fe(CO)_2(NO)_2 + Fc^+PF_6^- \rightarrow Fe(CO)_2(NO)_2^+ + Fc$.

The reaction of the carbonyls with the nitrite ion as the nucleophile will occur as follows:

$$Fe(CO)_5 + NO_2^- \rightarrow [Fe(CO)_{5-n} \cdot NO_2]^-$$

$$[Fe(CO)_{5-n} \cdot NO_2]^- + Fe(CO)_5 \xrightarrow[-CO]{} [Fe(CO)_4 \cdot NO_2]^{\cdot} + Fe(CO)_5^- \quad (3)$$

$$\xrightarrow[FeCO_5]{} Fe_2(CO)_8^-, Fe_3(CO)_{11}^-, Fe_3(CO)_{12}^-$$

$$n = 0 \text{ or } 1.$$

* Dark reactions.

Fig. 1. ESR-signal from $(CO)_3(NO)FeN(O^{\cdot})—t\text{-Bu}$ (X) in THF at +20°C.

Thus we assume that the structure of radical **V** appearing at the initial stages is $[Fe(CO)_4(R_2CNO_2)]^{\cdot}$ in Scheme 1, and that of radical **XI**–$[Fe(CO)_4 \cdot NO_2]^{\cdot}$ in Scheme 3. Then the appearance of $Fe(CO)_3NO^{\cdot}$ in reactions with the nitroparaffin salts can be explained as follows:

$$[Fe(CO)_4 \cdot (R_2CNO_2)]^{\cdot} \rightarrow [Fe(CO)_4 \cdot NO_2]^{\cdot} \rightarrow Fe(CO)_3NO^{\cdot}. \quad (4)$$

After losing the CO groups and oxidation, the radical $Fe(CO)_3NO^{\cdot}$ in Scheme (4) converts to the Fe(II) complexes. This process is responsible for the thermodynamics of the iron carbonyl redox disproportionation.

Thus the interaction of the nitroparaffin salts with the iron carbonyls represents a redox process accompanied by the appearance of radical anions **I–IV** and Fe(+I) complexes. The formation of the latters coordination sphere involves the cleavage of the C—N bond in the nitro compounds.

2. *Reactions of the iron carbonyls* $Fe(CO)_5$ *and* $Fe_3(CO)_{12}$ *with 2-methyl-2-nitrosopropane**

Nitroso compound complexes are considered to be intermediates during the reductive carbonylation of nitro compounds.[5,34] However, usually the reduction proceeds to immediately reach the lower states of nitrogeneous derivative oxidation.

Therefore it was advisable to study the reactions of the iron carbonyls with nitroso compounds. Used as such a compound was 2-methyl-2-nitrosopropane which also acts as the spin trap.

The reaction of $Fe_3(CO)_{12}$ with 2-methyl-2-nitrosopropane in THF yielded initially the radicals **IV** and **II** as well as two nitroxyl radicals, *viz.* $(t\text{-Bu})_2NO^{\cdot}$ (**XIII**), giving a triplet ($g = 2.0060$, $a_N = 15.4$ G at 20°C[35]) and the spin adduct **X** which has already been detected by us in reactions with the nitroparaffin salts.

Thus, as in the case of the nitroparaffin salts, the interaction of $Fe_3(CO)_{12}$ with *t*-BuNO can be described by the redox disproportionation scheme:

$$Fe_3(CO)_{12} + t\text{-BuNO} \rightleftharpoons [Fe_3(CO)_{12-n} \cdot (t\text{-BuNO})]$$

$$[Fe_3(CO)_{12-n} \cdot (t\text{-BuNO})] + Fe_3(CO)_{12} \xrightarrow[-CO]{} [Fe_3(CO)_{11} \cdot t\text{-BuNO}]^{+} + Fe_3(CO)_{12}^{-}$$

$$[Fe_3(CO)_{11} \cdot t\text{-BuNO}]^{+} \rightarrow Fe(CO)_3(NO)^{\cdot} + t\text{-Bu}^{\cdot}$$

$$Fe_3(CO)_{12}^{-} \xrightarrow{-CO} Fe_3(CO)_{11}^{-}$$

$$Fe(CO)_3(NO)^{\cdot} \xrightarrow{t\text{-BuNO}} (CO)_3(NO)Fe{-}N(O^{\cdot}){-}t\text{-Bu}$$

$$t\text{-Bu}^{\cdot} \xrightarrow{t\text{-BuNO}} t\text{-Bu}_2NO^{\cdot} \qquad (5)$$

As in the case of the nitroparaffin salts, the cleavage of the C—N bond during the formation of the Fe(I) coordination sphere is typical of the nitroso compounds, as well. The reaction of 2-methyl-2-nitrosopropane with iron pentacarbonyl in THF or toluene differs greatly from the previous one. At 20°C the reaction has a fairly long induction period, *ca.* 20 min. At the end of this period the spectra begin to show the rapidly growing signals from $Fe(CO)_3NO^{\cdot}$ and $t\text{-BuNO}^{-}$ ($g = 2.0060$, $a_N = 10.7$ G) (**XIV**).[35] Then the signals from the radicals $t\text{-Bu}_2NO^{\cdot}$ and $(CO)_3(NO)FeN(O^{\cdot})\text{—}t\text{-Bu}$ appear. Low intensity signals from $t\text{-BuNOH}^{\cdot}$ ($g = 2.0060$, $a_N = 13.1$ G, $a_H = 10.7$ G) (**XV**) can also be detected (see Table 1). In this case an appreciable amount of radical anions, primarily **IV**, appear at the terminal reaction stages or, if the reaction starting at 20°C is allowed to occur overnight at −196°C.

Such a difference in the behaviour of iron pentacarbonyl as compared to that of dodecacarbonyl can be explained by considering the fact that the one-electron reduction of the nitroso compound to the radical anion ($E_{1/2\,red} = -1.36$ V in acetonitrile[36]) is more facile than that of pentacarbonyl ($E_{1/2\,red} = -1.64$ to -1.77 V in THF). For iron dodecacarbonyl $E_{1/2\,red} = -0.32$ V in THF so that in Scheme 5 the carbonyl itself undergoes reduction.

Thus the redox disproportionation in the reaction of iron pentacarbonyl with 2-methyl-2-nitrosopropane can be described as follows: in Scheme 6b $Fe(CO)_5$ should be replaced by *t*-BuNO so that

$$Fe(CO)_5 + (t\text{-BuNO})_2 \rightarrow [Fe(CO)_{5-n} \cdot (t\text{-BuNO})_2] \qquad (6a)$$

$$[Fe(CO)_{5-n} \cdot (t\text{-BuNO})_2] + t\text{-BuNO} \rightarrow [Fe(CO)_{5-n} \cdot t\text{-BuNO}]^{+} + t\text{-BuNO}^{-} \qquad (6b)$$

Then the second limiting stage occurs in which the charges become separated. It is this fact which is responsible for the prolonged induction period.

In principle, the reaction can be catalysed by impurity-type nucleophiles, e.g. water, or by the effect of light. In this case the induction period is much shorter. In the absence of these factors the dimer $(t\text{-BuNO})_2$ is likely to act as the nucleophile. Radical cation **XVI** appearing at stage 6b has $g = 2.0222$ and $a_N = 2.8$ G (1:2:3:2:1).

These are not the only differences. Then the decomposition of $t\text{-BuNO}^{-}$ occurs to yield $t\text{-Bu}_2NO^{\cdot}$:[35]

$$t\text{-BuNO}^{-} \rightarrow t\text{-Bu}^{\cdot} + NO^{-} \qquad (6c)$$

$$t\text{-Bu}^{\cdot} + t\text{-BuNO} \rightarrow t\text{-Bu}_2NO^{\cdot}. \qquad (6d)$$

The resulting nitrosyl anion NO^{-} triggers the already known scheme of the $Fe(CO)_5$ redox disproportionation under the effect of the anionic nucleophile. The scheme is distinguished by the fact that as long as the trap is not exhausted, the formation of the radical anion $Fe(CO)_5^{-}$ and, hence, the remaining radical anions **I**–**IV**, remains inhibited:

$$Fe(CO)_5 + NO^{-} \xrightarrow[-CO]{} Fe(CO)_3(NO)^{-} \qquad (6e)$$

$$Fe(CO)_3(NO)^{-} + Fe(CO)_5 \xrightarrow[-CO]{} Fe(CO)_3(NO)^{\cdot} + Fe(CO)_5^{-} \qquad (6f)$$

$$Fe(CO)_5^{-} + t\text{-BuNO} \rightarrow Fe(CO)_5 + t\text{-BuNO}^{-} \qquad (6g)$$

$$Fe(CO)_3(NO)^{\cdot} + t\text{-BuNO} \rightarrow (CO)_3(NO)Fe{-}\underset{\displaystyle O^{\cdot}}{\overset{\displaystyle |}{N}}{-}t\text{-Bu}. \quad (6h)$$

It should be noted that after the induction period (Scheme 6b) the process goes in a chain mode which is effected through the decomposition and formation of tBuNO^{-} (Schemes 6g and 6c, respectively).

If $Fe(CO)_5$ is taken in an excess amount relative to t-BuNO, then after the reduction of the whole of the nitroso compound one can observe the consumption of the appearing **XIII**. This is likely due to the reduction of this species to the hydroxylamine anion ($E_{1/2\,red} = -1.63$ V in acetonitrile[37]).

Thus this scheme can be regarded as an alternative mechanism of the redox disproportionation of the iron carbonyls, by which the organic substrate is reduced and the whole of the Fe(0) from $Fe(CO)_5$ passes to Fe(I).

Such a mechanism is likely to take place if the telomerization is initiated by iron pentacarbonyl in the presence of, e.g. CCl_4 ($E_{1/2\,red} = -0.71$ to -0.78 V[38]), assuming that CCl_4, in this process, is similar to t-BuNO. So stage 6c for CCl_4 is presented in the form:

$$[CCl_3 \ldots Cl]^{-} \rightarrow CCl_3^{\cdot} + Cl^{-}. \quad (6c')$$

In this case one can clearly understand the role of cocatalysts such as nucleophilic agents (amines, dimethyl formamide, etc.[39]) which afford the redox disproportionation of iron pentacarbonyl at the initial stages of the process.

Thus the initial stage in the mechanism of the reductive carbonylation of the nitro and nitroso compounds is represented by the process of the redox disproportionation of the iron carbonyls under the effect of nucleophilic agents. As this takes place, depending on the ratio of the reduction potentials for a given iron carbonyl and an organic substrate, the redox process occurs either with the formation of the Fe(I) and Fe(−I) carbonyl complexes or Fe(I) complexes alone and reduction of the organic substrate. Therefore the thermodynamics of such reactions is controlled, in the long run, by the redox process.

3. *Reactions of carbonyl ferrate anions with nitro- and nitroso-tert-butane*

The interaction of iron carbonyls[26] and carbonyl ferrate anions[40,41] with nitro compounds is known to give rise to the nitro group reduction products such as amines, isocyanates and ureas.

On the other hand, it follows[42] that the iron carbonyl radical anions **IV** and **II** resulting from the one-electron reduction exhibit a very labile coordination sphere and can participate in the ETC and NCE processes in which their CO groups are partially substituted by such stable ligands as phosphines. However, these studies have not revealed such an important property of the iron carbonyl radical anions as their deoxygenating catalytic activity. One of us has shown that the iron carbonyl radical anions **I**–**IV** appearing at the stage of iron carbonyl redox disproportionation reduce the nitro- and nitroso compounds.[15] This section is devoted to a more detailed study of the catalytic function of the iron carbonyl radical anions in the reductive carbonylation of the nitro and nitroso compounds as well as their deoxygenating function.

For this purpose we have studied the processes in which the iron carbonyl radical anions are generated by an independent method, *i.e.* oxidation of the corresponding carbonyl ferrate anions with a ferricenium cation[10] to be then reacted with the nitro- and nitroso compounds such as tertiary nitroso- and nitrobutane:

$$Fe_n(CO)_{m-1}^{2-} \xrightarrow{Fe^{+}PF_6^{-}} Fe_n(CO)_{m-1}^{-} \xrightarrow{BuNO_x} \quad (7)$$

$$n = 1, m = 5; n = 2, m = 9; n = 3, m = 12; n = 4, m = 14, x = 1, 2.$$

However, oxidation with ferricenium (Scheme 7) gives rise to a fast uncontrollable formation of the iron carbonyls $Fe(CO)_5$ and $Fe_3(CO)_{12}$, whose interaction with the nitrogeneous compounds yields side processes. Another inconvenience is the fact that the strong signals appearing at the initial stages of the processes from the initially formed iron carbonyl radical anions **I**, **II**, **IV** prevents the weak signals of the other species being clearly identified.

A different method in which the nitro- or nitroso compounds themselves were used as the oxidants for the carbonyl ferrate anions turned out to be preferred. However, it should be noted that for the tertiary nitrobutane this method is applicable to the reaction with the mono- and binuclear carbonyl ferrate anions ($x = 2$, $n \leqslant 2$) whereas for 2-methyl-2-nitrosopropane, probably to that with the trinuclear carbonyl ferrate anion ($x = 1$, $n \leqslant 3$).

Such behaviour of the carbonyl ferrate anions in reactions with the nitro- and nitroso compounds can be readily understood based on the redox potentials of the carbonyl ferrate anions, iron carbonyl radical anions and organonitrogen radical anions (E_M^{2-}, E_M^{-} and E_L^{-}, respectively, in Fig. 2).

If the E_M^{2-} value of the carbonyl ferrate anions is more negative than that of the t-BuNO$_2^{-}$ ($E_{L^{-}} = -1.62$ to -1.77 V),[36] the process will take place

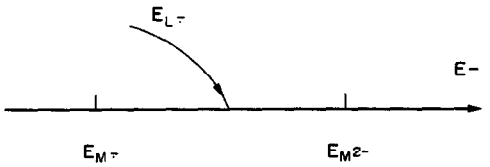

Fig. 2. The comparative scale of redox potentials of carbonyl ferrate radicals (M^-), organic ligands (L^-) and carbonyl ferrate anions (M^{2-}).

as follows:

$$Fe_n(CO)_{m-1}^{2-} + t\text{-}BuNO_x \rightarrow Fe_n(CO)_{m-1}^{-} + t\text{-}BuNO_x^{-}. \quad (8)$$

This gives rise to the radical anions of the corresponding carbonyl ferrate anions. This holds for $Fe(CO)_4^{2-}$ whose E_M^{2-} value, as reported by different authors,[11,12] lies in the range between -1.64 and -1.77 V. If the process takes place directly in the ESR cavity, the first stage will give the signals of the corresponding iron carbonyl radical anions and in some cases those of the nitroso and nitro compounds.

t-$BuNO^-$ (**XIV**) and *t*-$BuNO_2^-$ (**XVII**) (Table 1) are formed in reactions of the corresponding compounds with $Na_2Fe(CO)_4 \cdot 1.5$ diox. Note that in the case of *t*-$BuNO^-$ at the initial stages of the process one can observe the temperature-dependent ion-pair equilibrium *t*-$BuNO^-$ ... solv. ... $Na^+ \rightleftharpoons$ *t*-$BuNO^-$ ... Na^+. At -60°C there appears a triplet of quadruples (a_N = 12.1, a_{Na} = 1.5 G), and at 0°C, a triplet (a_N = 12.3 G).

Due to the fact that the rate of formation of the radical anions by Scheme 8 depends on the relationship between the parent carbonyl ferrate anion and nitrogen containing compound, the further stages of the process of the reduction of R-NO_x (x = 1, 2) may be different, therefore first we shall concentrate on the discussion of the particular cases.

(1) The reaction of $Na_2Fe(CO)_4 \cdot 1.5$ diox with *t*-BuNO proceeds vigorously. The first stages of the process, between -80 and -60°C, give rise to the iron caronyl radical anions **I**, **IV**, **II** and *t*-$BuNO^-$. Then the nitroxyl radical (g = 2.0063, a_N = 15.8–15.7 G (**XVIII**)) and (g = 2.0054, a_N = 16.7 G (**XIX**) are formed. In the middle of the process one can observe the accumulation of the radicals with a triplet splitting on the nitrogen atom (g = 2.0267, a_N = 1.8 G (**XX**) and g = 2.0251, a_N = 2.3 G (**XXI**) (Fig. 3)), the former slowly passing to the latter. One of the products of their further conversions is likely to be a radical (g = 2.0365) generating a broad singlet (ΔH = 4.6 G at -80°C) (**XXII**).

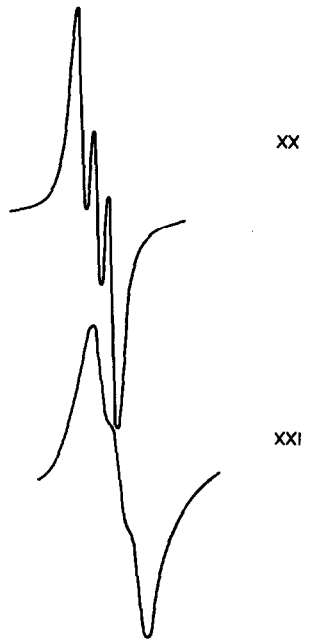

Fig. 3. ESR-spectra of radicals **XX** and **XXI** in THF at -80°C.

If *t*-BuNO is present in an excessive amount, then the terminal stages of the process will show in the ESR spectra at room temperature the presence of signals from *t*-$Bu_2NO^{\cdot}$ and **X** alone, resulting from the reaction of *t*-BuNO with $Fe(CO)_5$ (Schemes 6a–h), appearing during oxidation of the carbonyl ferrate anions.

(2) The reaction of $Na_2Fe(CO)_4 \cdot 1.5$ diox with *t*-$BuNO_2$ is also rather vigorous. At the first instant at -80°C one can observe the formation of the iron carbonyl radical anions **I**, **II**, **IV** and a strongly broadened triplet (g = 2.0060, a_N = 25.4 G), from **XVII**, probably as a result of the ion pair interaction of *t*-$BuNO_2^-$ with Na^+. The spectrum also shows the presence of a broad triplet (**XXIII**) (g = 2.0037, a_N = 15.5 G) and a broad signal (g = 2.0054) from **XXIV**. At the later stages of the process the spectrum begins showing two more nitroxyl radicals (g = 2.0036, a_N = 16.7 G) (**XXV**) and (g = 2.0053, a_N = 16.7 G (**XIX**)) as well as the three earlier mentioned signals from **XX**–**XXII**.

(3) The reactions of $(PPN)_2[Fe_2(CO)_8]$ with *t*-BuNO and *t*-$BuNO_2$ occur much more slowly than the first two processes. In the first case signals from the iron carbonyl radical anions **I**, **II**, **IV**, a weak signal from **XX**, a triplet of triplets in the nitroxyl region (g = 2.0062, a_{N_1} = 15.7 G, a_{N_2} = 2.3 G (**XXVI**)), and a doublet of triplets from **XV** are detected in the spectra. The reaction with tertiary nitrobutane gives signals from the iron carbonyl

radical anions **I, II, IV** as well as very weak signals from t-$Bu_2NO^{\cdot}$.

(4) The reaction of $(PPN)_2[Fe_3(CO)_{11}]$ is only possible with t-BuNO. Initially there appears the iron carbonyl radical anions **II, I, IV** and radical **XX**, a triplet of triplets ($g = 2.0059$, $a_{N_1} = 14.0$ G, $a_{N_2} = 2.0$ G (**XXVII**)). Then one can observe the appearance of t-$Bu_2NO^{\cdot}$ and t-$BuNOH^{\cdot}$.

(5) The reaction of $(PPN)_2[Fe_4(CO)_{13}]$ with t-BuNO when kept for a long time at room temperature gives a signal from radical **XXVII** and a weak signal from **IV**.

In other words, the reduction of the nitro- and nitroso-tertbutane in these reactions involves the formation of the radical products which can be divided into three groups:

First, the known nitroxyl radicals[35] ($g = 2.0059$–2.0063), typical of the reduction of 2-methyl-2-nitrosopropane.

Second, the hitherto unknown unstable radicals, whose g-factors (2.0036–2.0054) and hyperfine splitting constants (15.5–17.7) also lie in the nitroxyl region. Due to the fact that these radicals do not appear at the first stages of the reaction of the iron carbonyl radical anions **I–IV** with t-BuNO, then, they represent, in all likelihood, the spin adducts not of these anions themselves but rather their conversion products.

Third, the hitherto unknown nitrogen-containing radicals ($g = 2.025$–2.036).

To establish the structure of the radicals belonging to the second and third groups, we have conducted an additional series of reactions, i.e. the reduction of the diamagnetic complexes $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$, $Fe_2(CO)_6(N\text{-}t\text{-}Bu)_2$, $Fe_2(CO)_6[(N\text{-}t\text{-}Bu)_2CO]$ on a sodium mirror in the presence of the spin trap, t-BuNO, at -80°C, in THF. These complexes are products of the reaction of $Fe_2(CO)_9$ with t-$BuNO_2$.[26]

(a) Initially the reduction of $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$ gives rise to a quintet ($g = 2.0135$, $a_N = 1.8$ G (**XXVIII**)) which then rapidly disappears. This is followed by the formation of radical anions **II, IV, I** and a strong triplet from **XX** which then, upon temperature increase to -40°C, converts to **XXI**.

In the presence of the spin trap the signal from **XXVIII** passes to a triplet of triplets ($g = 2.0054$, $a_{N_1} = 14.8$ G, $a_{N_2} = 2.3$ G (**XXIX**)). Also, the spectrum shows the presence of signals from **XIX**.

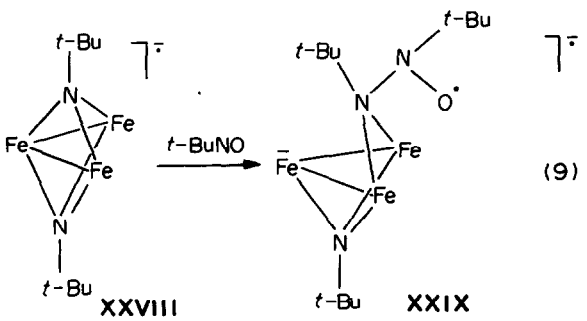
(b) The reduction of $Fe_2(CO)_6(N\text{-}t\text{-}Bu)_2$ results in the appearance of signals from **I, II, IV**. Initially there is also a quintet ($g = 2.0335$, $a_N = 2.9$ G (**XXX**)), part of which lies on the shoulder of the strong signal from **I**.

The reduction in the presence of t-BuNO yields spin adduct **XXV**.

(c) At the first stages of the reduction of $Fe_2(CO)_6[(N\text{-}t\text{-}Bu)_2CO]$ at -80°C it is possible to detect a broad quintet-type signal ($g = 2.0084$, $a_N = 8.2$ G (**XXXI**)). At the later stages there will appear two broadened singlets ($g = 2.0287$ ($\Delta H = 2.8$ G) (**XXXII**) and $g = 2.0417$ ($\Delta H = 4.6$ G) (**XXXIII**)).

Thus the initial stages of the reduction give rise to the radical anions of the corresponding complexes $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2^{-}$ (**XXVIII**), $Fe_2(CO)_6(N\text{-}t\text{-}Bu)_2^{-}$ (**XXX**) and $Fe_2(CO)_6[(N\text{-}t\text{-}Bu)_2CO]^{-}$ (**XXXI**) having an extra electron.

Further conversion of the system goes either through elimination of the ligands or rearrangement of the iron cluster skeleton. In the presence of the spin trap it may happen that the unpaired electron is localized on the organic ligand which, upon interaction with the trap, forms a spin adduct. In this case a closed electron shell is formed on the metallo fragment. This fact may be attributed to the appearance of the second group of radicals ($g = 2.0037$–2.0054). Thus, for example:



XXVIII **XXIX** (9)

CO-ligands are ommitted in the Schemes 9, 11.

Here one can observe a hyperfine splitting at two nitrogen atoms. The formation of the spin adduct is also possible by means of the addition of the spin trap to the CO group with no secondary splitting in this case.

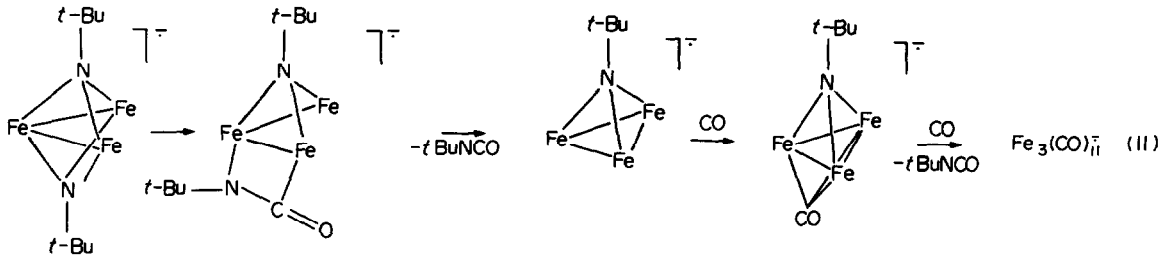
The intensive triplet from **XX** as a result of the reduction of $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$ is attributed by us to the formation of a comparatively stable iron carbonyl trinuclear radical anion containing a single nitrene fragment. It is likely that it appears as a result of the structural rearrangement of the trinuclear cluster with elimination of the nitrene fragment.

Based on the published data concerning the transformation of the diamagnetic complexes

$$Fe_3(CO)_8L(NPh)_2 \xrightarrow{CO} Fe_3(CO)_{10}(NPh) \qquad (10)$$

where L = C(Ph)OEt,[43] as well as on the fact that in our case the reduction of $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$ on the sodium mirror involves a rapid exchange of the CO ligands to give the iron carbonyl radical anions

IV, II, I, it can be assumed that the formation of XX and its conversion to XXI take place as follows:



XXVIII XX XXI II

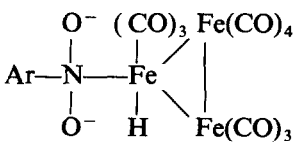
Such a rearrangement of the coordination sphere in the form of a butterfly-trigonal bipyramid is assumed to take place in the trinuclear iron carbonyl complexes with phosphene ligands.[43] It is likely that radical XXI is formed from XX as a result of a variation in metallo fragment nuclearity.

An attempt to pass through this scheme in the reverse direction, i.e. using $Fe_3(CO)_{11}^{-}$ and *t*-BuNO to detect compounds XX and XXI is of little success because the appropriate signals lie on the shoulder of the intensive signal from I appearing from II due to their mutual conversions. However, the signals from XX and XXI become detectable if the ampoule containing the iron carbonyl $Fe_n(CO)_m$, where $n = 1$, $m = 5$; $n = 2$, $m = 9$; $n = 3$, $m = 12$, and tert-butyl-isocyanate BuNCO is irradiated with a filament lamp at −80°C. In this case it is possible to control the intensity growth of signal from I.

Thus the appearance of radicals XX and XXI in the reactions of carbonyl ferrate anions with tertiary nitro- and nitrosobutane as well as in those of the iron carbonyls with tert-butyl isocyanate indicate that isocyanate is formed as a result of carbonylation of the nitrene radical complexes. These in turn are obtained during the reduction of the nitro and nitroso compounds in the coordination sphere of the iron carbonyl radical anions.

4. *The catalytic role of the iron carbonyl radical anions* I–IV. *Scheme of the reductive carbonylation*

Schemes for the reduction of nitro and nitroso compounds with iron carbonyls or carbonylferrate anions have been put forward by some authors.[6,40,41] In this case the reduction process initially goes owing to the CO groups of a certain intermediate carbonyl complex, these groups being oxidized to CO_2. The role of such a complex is assigned, for example, to the adduct of the type



However, these schemes can be constructed assuming the appearance of either a coordinatively unsaturated iron carbonyl species which is short of two electrons to complete its electronic configuration, ($Fe(CO)_4$), or those with an O—Fe bond. But the existence of such intermediates in solution is most unlikely.

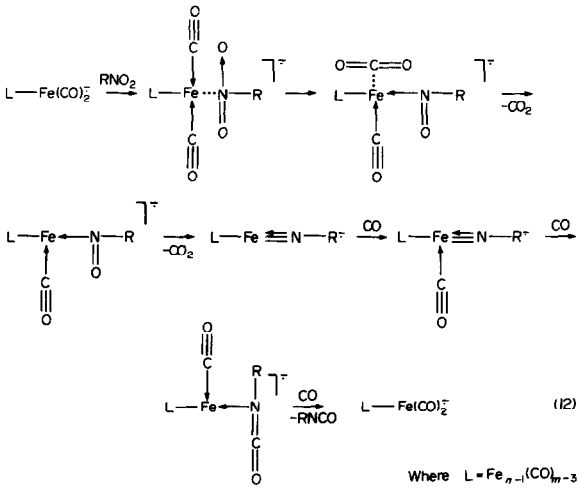
In our hypotheses we used the following facts.

First, the conditions of the nitro compound reduction coincide with those when the radical anions I–IV are formed either due to the redox disproportionation of the iron carbonyls or oxidation of the carbonyl ferrate anions.

Second, the resultant iron carbonyl radical anions I–III have an open electronic shell containing 33, 47 and 59 cluster valence electrons, respectively. Radical anion IV contains 49 electrons but it can readily and reversibly convert to II in the CO elimination. This ensures the lability of the coordination sphere, and the resultant activity of the ligand exchange process.[42]

Third, the reduction of the nitro and nitroso compounds involves the formation of similar intermediate radical species XX and XXI as is the case in the reaction of the iron carbonyls with *t*-BuNCO as well as in the reduction of the diamagnetic nitrene complex $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$.

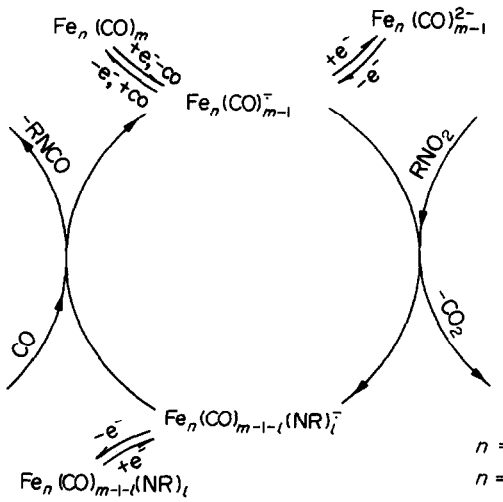
The totality of these facts makes it possible to put forward the following scheme:



The scheme illustrates the case when the coordination sphere of the iron carbonyl cluster contains a nitro compound molecule. The initial stages of the process consist of a successive reduction of the nitro compound coordinated to the iron carbonyl radical anion, through the nitroso compound to the nitrene complexes. The reduction is realized through the coordinated CO groups which are abstracted in the form of CO_2. Then, if the process goes in the catalytic mode, the intermediate complexes undergo carbonylation to yield isocyanates and the parent iron carbonyl radical anions.

The addition of the second nitro compound molecule in the process of reduction is responsible for the appearance of a variety of intermediate radical species similar to **XVIII, XIX, XXIII–XXVII** as well as formation of diazo compounds as the final products.

If the reaction is carried out at the stoichiometric quantities of the reagents, the reduction of the nitrogen-containing ligand can terminate after the nitrene structures have been formed, which, by loosing an unpaired electron, convert to the well known diamagnetic complexes $Fe_2(CO)_6(N\text{-}t\text{-}Bu)_2$, $Fe_2(CO)_6[(t\text{-}BuN)_2CO]$ and $Fe_3(CO)_9(N\text{-}t\text{-}Bu)_2$. This leads to the withdrawal of the nitrene species out of the catalytic cycle.



(13)

$n = 2,\ m = 9,\ l = 2$
$n = 3,\ m = 12,\ l = 1, 2$

It should be pointed out that the electron-deficient negatively charged species **I–III** are catalytically active. However the electron-deficiency can be lost during the catalytic process on the successive addition of the CO ligands as, for example, is the case with the transition

$$Fe_3(CO)_{11} \xrightarrow{CO} Fe_3(CO)_{12}.$$

Nevertheless, the electron-excessive system can be rearranged into an electron-deficient one. This is possible, first, when the excess electron goes towards the ligand. As this takes place, a new bond, e.g. CO—NR, RN—NR, between the coordinated ligands can be formed or such ligands, e.g. RNH, can be reduced. Usually the reaction medium should contain proton donors.

Second, the rearrangement can be effected at the expense of the cluster skeleton, by cleaving the Fe—Fe or Fe—N bonds. The ability of the iron carbonyl radical anions to be rearranged in such a way is also responsible for their catalytic activity.

Schemes 12 and 13 explain the conversions occurring in an aprotic medium, therefore the final products contain isocyanates and diazo compounds. More complicated processes take place in a proton medium where, along with $Fe_n(CO)^-_{m-1}$, their protonated analogues $HFe_n(CO)_{m-1}$ are formed,[44] which are expected to participate in the reduction processes to yield amines, formamide and various urea derivatives.

CONCLUSIONS

The interaction of the iron carbonyls with the nitro and nitroso compounds therefore depends on the following factors.

The initial stages of the process consist of the activating complex formation of the iron carbonyls and Lewis bases, then occurs the redox stage and, as a result of a one-electron transfer, there appears the radical Fe(I) complexes and the iron carbonyl radical anions **I–III** which are just these species that control the catalytic properties of the iron carbonyl–base system.

The iron carbonyl radical anions **I–III** that are capable of a fast exchange in the coordination sphere can deoxygenate the nitro and nitroso com-

pounds to nitrene complexes and then undergo carbonylation to give isocyanates.

We believe that the disclosed deoxygenation and carbonylation ability is of the same nature. This permits, using the same principles, to study a variety of processes involving iron carbonyls, such as carbonylation of various nitrogen-containing compounds (amines, azines, diazo compounds),[6,7] and olefins,[45] telomerization,[39] Fischer–Tropsch process,[46] formation of bi- and trinuclear chalcogene and nitrogen-containing compounds of carbonyl complexes.[3,47] Based on the new conceptions it is possible to provide a fresh approach to the catalytic effect of the iron carbonyls in WGSR and understand the conflicting information.[48,49] We believe that here, as in the case of the nitro compounds, water deoxygenation to H_2 occurs in a catalytic cycle, similar to that presented in Scheme 13 where RNO_2 should be replaced by H_2O. Note that along with the radical anions **I–III** their protonated analogues can also participate in this process.

(*Received* 16 *February* 1987; *accepted* 11 *May* 1987)

Abstract—This paper reports on some complexes of lanthanum(III) and europium(III) with the title ligand (H_5L) which possesses two similar coordination sites: mononuclear and homo- and hetero-dinuclear species are described. The isolated compounds have the formulas $[M(H_2L)\cdot 3H_2O]$, $[M_2LNO_3\cdot 4H_2O]$, (M = La, Eu); $[MM'LOH\cdot nH_2O]$ (M = Fe, M′ = La, $n = 2$; M = Eu, M′ = La, $n = 4$). In addition $[Li_2LaL\cdot 3H_2O]$ and $[CuLaL\cdot 3H_2O]$ have also been obtained. Relevant IR and visible spectral data and magnetic moment values are given and discussed.

Research on polynuclear complexes has increased in recent years, stimulated by the large interest developed in areas such as metallo-enzymes, heterogeneous catalysis and physicochemical properties. A large series of heterobinuclear complexes containing compartmental ligands and *d*- or *f*-block metal ions have been reported by reaction of the pure mononuclear chelates with the required metal salt.[1] To our knowledge, few papers concerning polynuclear chelates of these ligands with lanthanides(III) ions have been reported.[2]

This work reports the synthesis and characterization of mononuclear and binuclear complexes of lanthanide(III) ions with a new binucleating ligand with two similar coordination sites. Homobinuclear complexes of this ligand with transition metals of the *d*-series have already been reported.[3]

EXPERIMENTAL

The ligand 1-oxy-2,6-di[(*N*,*N*-biscarboxymethyl) aminomethyl]-4-chlorobenzene(H_5L) was prepared according to the literature method.[4]

Preparation of the mononuclear complexes

The ligand (1 mmol) was suspended in methanol (40 cm^3) and then LiOH (3 mmol) was added. The lanthanide(III) nitrate (1 mmol), dissolved in methanol (80 cm^3), was added dropwise with stirring to the clear solution. The resulting mixture precipitated the product either immediately or after heating the solution on a steam bath. In each case the solution was refluxed for 4 h, filtered, and the precipitate washed several times with methanol and diethyl ether and then dried *in vacuo* over P_4O_{10}.

Preparation of the homobinuclear complexes

Homobinuclear complexes were prepared by two general methods:

(a) The ligand (1 mmol) and LiOH (5 mmol) dissolved in methanol (80 cm^3) was added dropwise to the lanthanide(III) nitrate (2 mmol) dissolved in the same solvent (40 cm^3). The resulting mixture was heated for 4 h and a precipitate was obtained. It was filtered, washed several times with methanol and dried *in vacuo* over P_4O_{10}.

(b) The mononuclear chelate (1 mmol) was suspended in methanol and lithium hydroxide (2 mmol) was added. After a clear solution was obtained, the appropriate metal salt (1 mmol) dissolved in methanol was added. The resulting mixture was heated under stirring for 4 h. A precipitate was formed, filtered and washed with methanol and diethyl ether, and then dried *in vacuo* over P_4O_{10}.

[a] Magnetic moments are given per atom.

Preparation of the heterobinuclear complexes

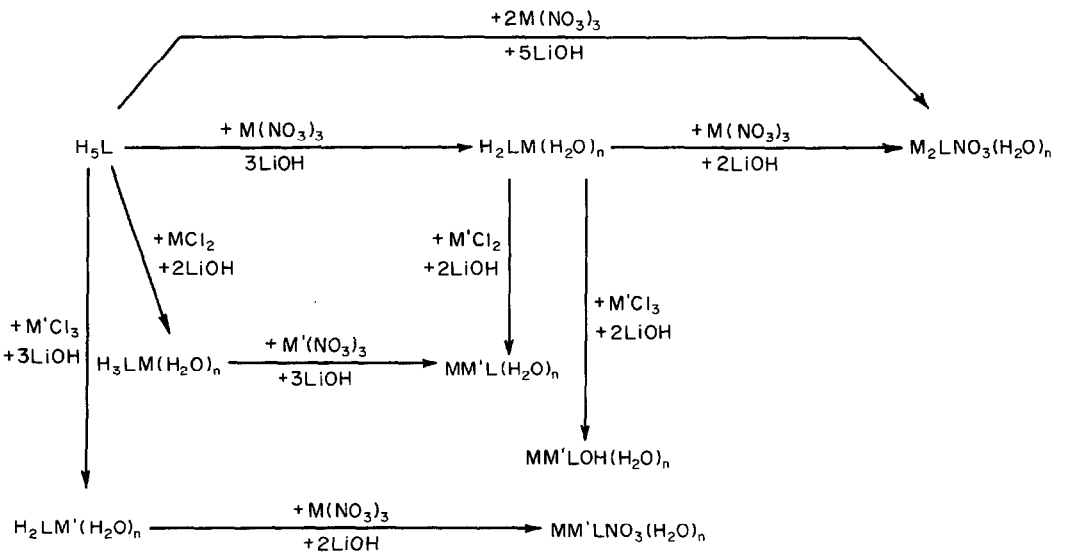
The heterobinuclear complexes were prepared according to method (b) above.

Chemical and physical measurements

Elemental analyses were performed in the microanalytical laboratory of the Department of Inorganic Chemistry. Infrared spectra were obtained by a Perkin–Elmer model 580 spectrophotometer on samples suspended in a KBr matrix or mulled with mineral oil. Electronic spectra were carried out on a Cary 17 spectrophotometer in aqueous solution. Magnetic susceptibilities were measured by the Faraday method by using an Oxford instrument; the apparatus was calibrated with $Nien_3(ClO_4)_2$.

RESULTS AND DISCUSSION

The interactions of metal salts with 1-oxy-2,6-di[(*N*,*N*-biscarboxymethyl)aminomethyl]-4-chlorobenzene (H_5L) in methanol are illustrated in Scheme 1. The mononuclear Eu(III) and La(III) complexes were prepared by stoichiometric reaction of the ligand with the lanthanide(III) nitrate. Their formulation as $[H_2LLn(H_2O)_3]$ is supported by analytical and spectroscopic data. The IR spectra shows a broad band at 3400 cm^{-1} corresponding to the ν(OH) of the water bound to the cation. The strong band at about 1590 cm^{-1} in both the compounds is assigned to the coordinated carboxylate groups, while the uncoordinated ones were found at 1730 cm^{-1}. The weak band observed at 1285 cm^{-1} in the free ligand, which shifts to about



Scheme 1. Reaction pathways of the metal salts with the ligand in methanol.

1295 cm^{-1} in the chelates, is assigned to the phenolic (CO) group. This small shift may be ascribed to the delocalization of electronic density from the oxygen atom to the lanthanide(III) ion resulting in a slight ionic character of the Ln—O bond and consequently in a slight increase in the ν (CO) frequency.

Homo- and hetero-binuclear complexes have been obtained. The former can be prepared by reacting either the ligand with metal nitrate in a molar ratio of 1:2 or the mononuclear chelate with a stoichiometric amount of the metal salt. The latter complexes were synthesized by successive steps; the preparation of the mononuclear complex and then its reaction with the second metal salt.

The homobinuclear compounds present different infrared spectra than those of the corresponding mononuclear chelates. The absorption peak due to the coordinated carboxylic groups is found at 1590 cm^{-1} for $[Eu_2LNO_3(H_2O)_4]$ and 1600 cm^{-1} for $[La_2LNO_3(H_2O)_4]$. The band due to uncoordinated carboxylic groups is absent. The phenolic C—O stretching vibration, which occurs at 1295 cm^{-1} in the mononuclear chelates, lies at the same frequency in the binuclear chelates (about 1300 cm^{-1}). The strong absorptions found at 1490–1470 and 1300–1280 cm^{-1} in the nitrato complexes indicate that the nitrate group acts as a bidentate ligand towards the metal atoms (Fig. 1), a result which is in agreement with the conductivity values in methanol ranging from 10 to 30 mhos at concentrations 10^{-3} M.

The heterobinuclear complexes, prepared from the mononuclear compound (Scheme 1), show a broad band at 3400 cm^{-1}, which corresponds to the ν(OH) of the coordinated water. The strong band observed at about 1600 cm^{-1} is assigned to the characteristic asym. mode of the coordinated carboxylic groups. The phenolic C—O vibration is

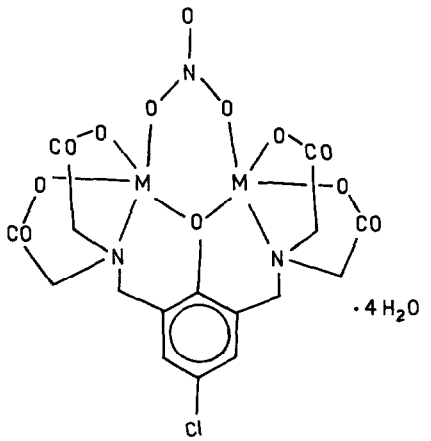


Fig. 1. Proposed coordination geometry of the binuclear complexes.

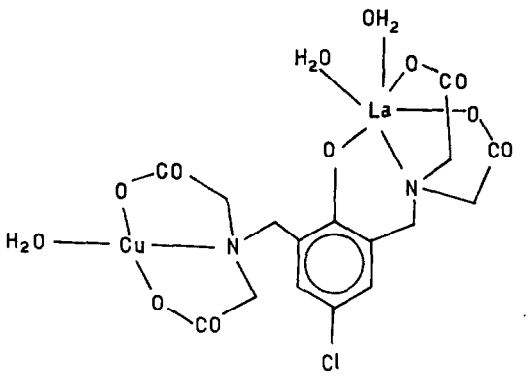

Fig. 2. Proposed coordination geometry of the $CuLaL \cdot 3H_2O$ complex.

found at 1290–1295 cm^{-1}, that is the same frequency of the mononuclear lanthanide complexes.

The purple Fe/La complex dissolved in aqueous solution gives an electronic spectrum (λ_{max} = 515 nm) similar to that observed for the iron(III) complex with N-(*o*-hydroxybenzyl)-N-(carboxymethyl) glycine[5] and the mononuclear iron complexes with analogous ligand.[6] Its magnetic moment (5.87 BM) is that expected for isolated high spin iron(III) complexes with an octahedral geometry. The electronic spectrum of the Cu/La complex, in aqueous solution (λ_{max} = 740 nm) and its low magnetic moment at room temperature (1.67 BM) suggest a pseudo-tetrahedral coordination geometry around the copper atom[7] (Fig. 2). The value of the magnetic moment is similar to that of an isolated copper(II) ion and hence magnetic exchange between two copper atoms in different molecules can probably be ruled out. To confirm this, we are carrying out variable temperature measurements of its susceptibility. The Eu/La complex shows a magnetic moment close to that of the mononuclear Eu(III) complex indicating that the environment of the Eu ion is not affected by the presence of the second ion.

As conclusion, it is in our opinion that the binuclear complexes are monomeric species similar to the di-iron complex with an analogous ligand, whose molecular structure has been resolved by X-ray analysis,[6] even if the possibility of oligomerisation could not definitively be excluded.

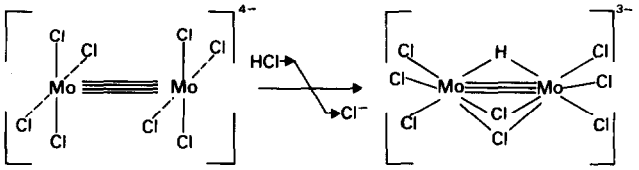
(*Received* 23 *February* 1987; *accepted* 11 *May* 1987)

Abstract—The kinetics of the oxidative addition of hydrochloric acid (6–12 M) to the quadruply bonded $Mo_2Cl_8^{4-}$ ion, **1**, to produce the triply bonded hydride $Mo_2(\mu\text{-}H)(\mu\text{-}Cl)_2(Cl)_6^{3-}$, **2**, are first order in the concentration of the acid, and first order in the Mo_2^{4+} reactant. The rate is strongly affected by axial coordination. At lower acid concentrations (< 6 M) the reaction is complicated by hydrolysis. The hydride **2** and the analogous nonachlorodimolybdate $Mo_2(\mu\text{-}Cl)_3Cl_6^{3-}$, **3**, undergo a two-electron reduction by chromous chloride in HCl (6M) to give **1**; the Mo_2^{6+}/Mo_2^{4+} couple catalyzes the anaerobic oxidation of Cr(II) to Cr(III).

The Redox chemistry of dinuclear clusters is of interest[1] and can be accomplished chemically or electrochemically. Molybdenum compounds are receiving special attention in this context because of the involvement of the metal in many chemical and biochemical reactions.[2] One-electron proton addition to the quadruply bonded (configuration $\sigma^2\pi^4\delta^2$) octachlorodimolybdate anion $Mo_2Cl_8^{4-}$, **1**, is a well established reaction[3] yielding the formally triply bonded [configuration $(a')^2(e')^4$] bioctahedral hydride, $Mo_2(\mu\text{-}H)(\mu\text{-}Cl)_2Cl_6^{3-}$, **2**.



(1)

The molybdenum hydride **2** was first isolated[4] by treating $Mo_2(acet)_4$ with 12 M HCl at 60°C. It has also been obtained photochemically[5] and electrochemically[6] from 6 M HCl solutions of **1**. Aqueous acidic solutions of **2** and also of the isostructural[7] nonachlorodimolybdate $Mo_2(\mu\text{-}Cl)_3Cl_6^{3-}$, **3**, undergo heterogeneously[8] (amalgamized zinc) a two-electron reduction to give **1**. By contrast, electrochemical reduction[4,6] of **2** and **3** in 6 M HCl produce, respectively, **3** and **2**, instead of **1**. There are several mechanistic studies of proton addition on mononuclear metallic centres,[9] but none on metal–metal multiple bonds which we know of. In this paper we describe the kinetics and discuss the mechanism of reaction (1) and also report the homogeneous reduction of **2** and **3** by chromous chloride in HCl solutions to give **1**.

EXPERIMENTAL

The potassium salts of $Mo_2Cl_8^{4-}$, $Mo_2HCl_8^{3-}$ and the ammonium salt of $Mo_2Cl_9^{3-}$ were prepared by

* Author to whom correspondence should be addressed.

the literature methods.[4,10,11] Experiments were performed under oxygen-free nitrogen or argon. Solvents were thoroughly degassed by freeze pumping. All reagents were of analytical grade and purified before use. Chromous chloride was supplied by Ventron and all other compounds by Fluka. Samples for kinetic measurements were prepared on a thermostated Schlenk tube and the resulting clear solution was quickly transferred via a stainless tube and under positive argon pressure to a (previously purged by argon) 1 cm spectrophotometric cell. Microanalyses were performed in this laboratory and at the Research Centre, Demokritos. Electronic spectra were recorded with a Hitachi and a Carry 17.

Reaction of tripotassium 1,1-*trichloro*-2,2,2-*trichloro*-μ-*hydrido*-*bis*-μ-*chloro*-*dimolybdenum*(III) *with* $CrCl_2$

Into a solution (10 cm^3 HCl 6 M) of $K_3Mo_2HCl_8$ (0.105 g, 0.17 mmol) and KCl (0.012 g, 0.17 mmol) is added slowly a solution (10 cm^3 HCl 6 M) of $CrCl_2$ (0.085 g, 0.68 mmol) at room temperature with stirring. The colour of the solution darkens to deep green–brown and gas evolution (H_2) is observed. The mixture was left to react for *ca.* 2 h, the solvent was removed *in vacuo* at room temperature, and the residues were extracted with tetrahydrofuran (20 cm^3). The deep green solution was removed by filtering and the red residue was washed with small portions of tetrahydrofuran until they remained colourless, dried *in vacuo*, and identified by analysis and spectroscopy to be $K_4Mo_2Cl_8$. Yield, 97% based on $Mo_2HCl_8^{3-}$.

Reaction of tris-n-*tetrabutylammonium*-1,1,1-*trichloro*-2,2,2-*trichloro*-*tris*-μ-*chloro*-*dimolybdenum* (III) *with* $CrCl_2$

Into a solution (20 cm^3 HCl 6 M) of a mixture of $[(n\text{-}C_4H_9)_4N]_3Mo_2Cl_9$ (0.363 g, 0.34 mmol) and $(n\text{-}C_4H_9)_4NCl$ (0.363 g, 0.34 mmol) is added a solution (20 cm^3 HCl 6 M) of $CrCl_2$ (0.17 g, 1.36 mmol) at room temperature with stirring. The mixture was left to react for *ca.* $2\frac{1}{2}$ h and treated as described above. The red product was identified as $[(n\text{-}C_4H_9)_4N]_4Mo_2Cl_8$. Yield, 95% based on $[(n\text{-}C_4H_9)_4N]_3Mo_2Cl_9$.

RESULTS AND DISCUSSION

In aqueous solutions $K_4Mo_2Cl_8$ is unstable; it hydrolyzes within a few minutes and the initial red colour becomes brown–yellow. Hydrolysis is slower in hydrochloric acid solutions, the extent of the equilibrium

$$Mo_2Cl_8^{4-} \underset{+Cl^-}{\overset{-Cl^-}{\rightleftharpoons}} Mo_2Cl_{8-x}(H_2O)_x^{4-x} \qquad (2)$$

depending on the acid concentration. The development of the spectra in 6 M and 0.5 M HCl is given in Figs 1 and 2, respectively.

The reaction taking place in 6 M HCl, where hydrolysis is limited is given by eqn (1). The structures of **1** and **2** are assumed to be the same as those determined in the solid.[12,13] The presence of isosbestic points in Fig. 1 indicates that at 6 M HCl $Mo_2HCl_8^{3-}$ is the only appreciably absorbing product. In contrast, at 0.5 M HCl there is no isosbestic point, presumably because of hydrolysis. Never-

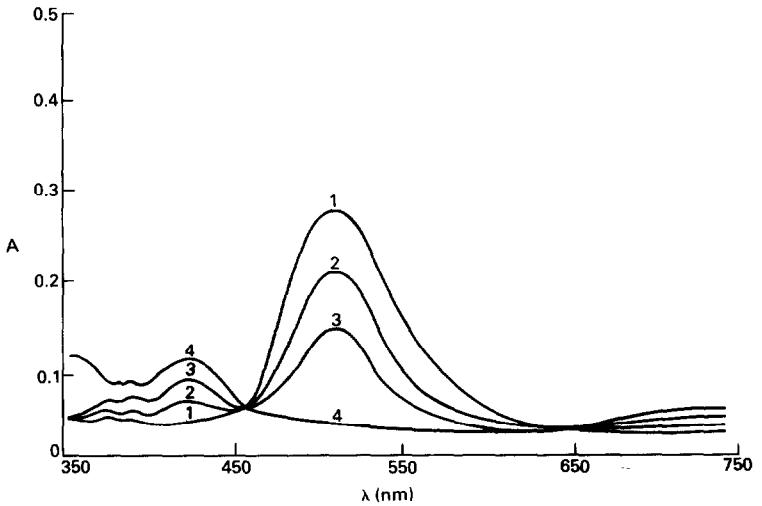


Fig. 1. Spectral changes of a $K_4Mo_2Cl_8$ (3×10^{-4} M) solution in 6 M HCl at 25°C, recorded after 1, 2 and 48 h.

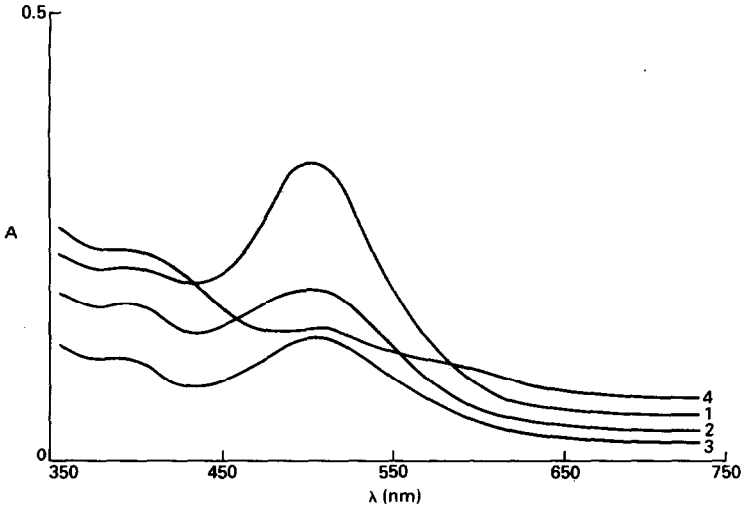

Fig. 2. Spectral changes of a $K_4Mo_2Cl_8$ (6.5×10^{-2} M) solution in 0.5 M HCl at 25°C recorded after 1, 2 and 72 h.

theless here too there is no shift in the peak at 520 nm but the peak of the products (at *ca.* 420 nm in 6 M HCl) is shifted. Accordingly the reaction was followed by monitoring the absorption at 520 nm. The complexity at low acid and the relative simplicity at high acid is also reflected in the kinetics (Fig. 3). At low acid concentrations there is an initial decrease in absorbance, again attributed to hydrolysis. In the acid concentration range between 3–6 M, this initial stage is clearly shown, but it is not too extensive and it does not seem to much influence the subsequent (first order) part, which is attributed to oxidative addition similar to that shown in eqn (1) but with participation of hydrolyzed species. In this acid range the slope of the linear part increases with increasing acid concentration. At lower acid (0.5–3 M) hydrolysis and/or condensation have rates comparable to oxidative addition, the results are not reproducible, and the final absorption at *ca.* 420 nm is relatively small (Fig. 2). In the acid range between 6–12 M, the plots do not have non-linear initial parts (Fig. 4) and the first order kinetics are attributed to reaction (1). In this range the quadruple bond absorption at 520 nm disappears, being replaced by the triple bond absorption at 420 nm. The dependence

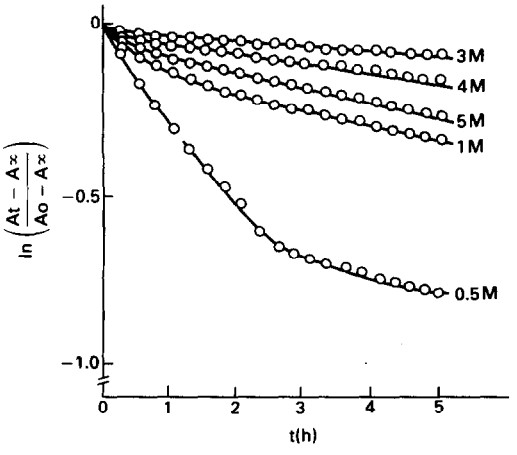

Fig. 3. First order plots in HCl 0.5–5 M at 25°C.

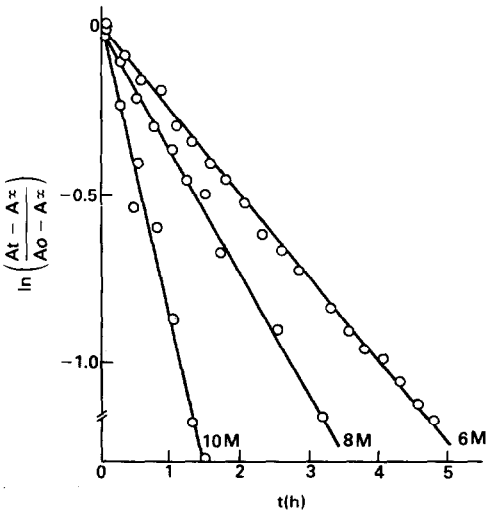

Fig. 4. Typical first order plots (6, 8 and 10 M HCl), at 25°C.

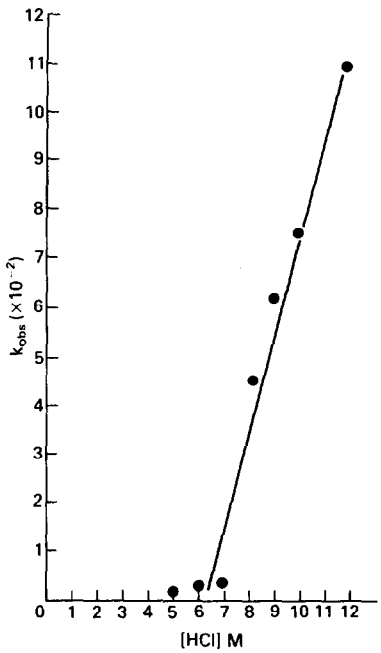

Fig. 5. Dependence of the observed pseudo-first order rate constant on the concentration of HCl.

of the first order rate constant on acid for [HCl] $\geqslant$ 3 M is shown in Fig. 5. Above 6 M the plot is linear, below this concentration it is not, and the rates are relatively slow, because of the postulated participation of hydrolyzed species. Within experimental error the addition of 2 M KCl to a solution of **1** in 2 M HCl had no measurable effect. Addition of KCl or NaCl at higher acid concentrations is limited by solubility. However, hydrogen ion concentration can be changed considerably by addition of p-toluenesulfonic acid (PTSH). The spectrophotometric results are shown in Fig. 6. The rate constant for the disappearance of **1** at 25°C, in 6 M HCl, 6 M PTSH is 2.5×10^{-4} s^{-1} whereas at 6 M HCl it is only 3.3×10^{-5} s^{-1}. The results indicate that the rate determining step in the formation of the hydride **2** is the addition of the proton to the quadruple bond. The activation probably originates in the reorganization involved, including some rotation around the molecular axis and a lengthening of the metal–metal bond. However, the destabilization caused by the approach of the positive charge and the removal of bonding electron density eventually leads to the breaking of the δ-bond which is replaced by three bridges, albeit not without considerable weakening as indicated by the dramatic increase in bond length,[12,13] from 2.139 Å to 2.780 Å. At lower acid where some of the chloride ligands have been replaced by water molecules complete destruction of the multiple bond prevails.[14] The rate constant in 6 M HCl and 6 M PTSH is considerably smaller compared to the value (Fig. 6) 1.9×10^{-3} s^{-1} at 12 M HCl. The difference could partly be attributed to medium effects but a more plausible explanation is that it is caused by the axial coordination of the negatively charged chloride ligands, which causes a weakening of the metal–metal bond, and a simultaneous increase of the proton nucleophilicity of **1**. The increase in bond length caused by axial coordination is well known.[15] With the non-complexing PTS^- some of the chloride ligands are replaced by water molecules, which are decreasing the nucleophilicity. An analogous effect is

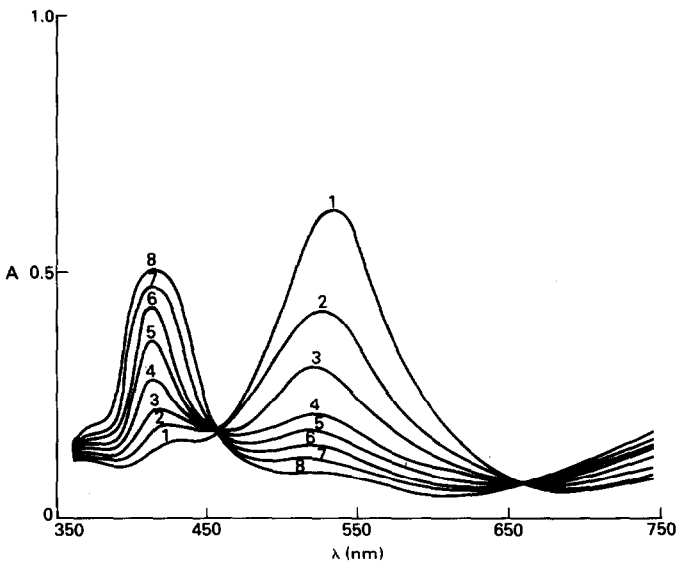

Fig. 6. Spectral changes of a $K_4Mo_2Cl_8$ (10^{-4} M) solution in a mixture of HCl (6 M) and PTSH (6 M) recorded at 10 min intervals.

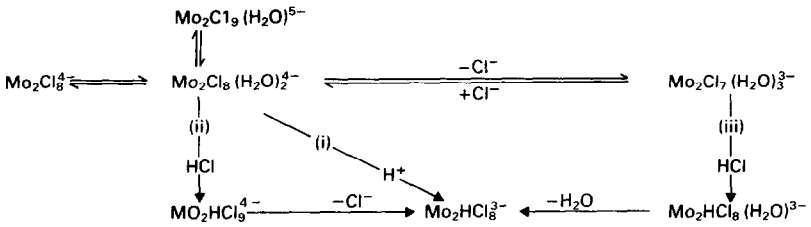

Scheme 1. Proposed pathways of the formation of $Mo_2HCl_9^{3-}$ from $Mo_2Cl_8^{4-}$ by proton oxidative addition.

expected at lower acid concentrations. The *bis*-end coordinated aqua adduct $Mo_2Cl_8(H_2O)_2^{4-}$ can be isolated[12] in 6 M HCl but not from 12 M HCl,[9] whereas the anion $Mo_2Cl_9(H_2O)^{5-}$, where one water molecule is replaced by chloride, has been structurally characterized as the pyridinium salt.[15b] The implication is that apart from hydrolysis the following equilibrium occurs,

$$Mo_2Cl_8(H_2O)_2^{4-} \underset{-Cl^-}{\overset{+Cl^-}{\rightleftharpoons}} Mo_2Cl_9(H_2O)^{5-}. \quad (3)$$

Thus, the mechanism can be summarized as in Scheme 1.

The formation of the hydride **2** can be simply viewed as the protonation of the quadruple bond of **1** and subsequent fast rearrangement [path(i)] or as step-wise addition of HCl across the metal–metal bond producing $Mo_2HCl_9^{4-}$, followed by loss of chloride ion and chloride bridge formation [path (ii)]. At lower acid concentration HCl is added to the metathetical derivative[16] $Mo_2Cl_7(H_2O)^{3-}$ [path (iii)]. The last route has been proposed for the corresponding bromide.[17] At this stage it is not possible to distinguish between paths (i) and (ii).

The mechanistic scheme just described is further supported by observations made with the anion $W_2Cl_8^{4-}$, which is transformed[18] into the corresponding hydride, $W_2HCl_8^{3-}$, much easier (at $-10°C$). The difference in the reactivity[19] can be attributed to the higher energy of the HOMO of W_2^{4+}, compared to Mo_2^{4+}, which implies that bonding electrons are more accessible and the disruption of the weaker δ-bond easier. A similar effect has also been demonstrated by comparing the reaction[20] of benzoic acid with $Mo_2X_4(PR_3)_4$, which yields $Mo_2X_2(PR_3)_2(OOCPh)_2$, with the reaction[21] of this compound with $W_2Cl_2(PBu^n_3)_4$, which gives $W_2Cl_2(PBu^n_3)_2(OOCPh)_2(\mu\text{-H})(\mu\text{-Cl})$ resulting from facile oxidative addition of the generated HCl to the initially formed $W_2Cl_2(PBu^n_3)_2(OOCPh)_2$.

The hydride **2** is stable in 6 M HCl (peak at 420 nm, $\varepsilon = 1082$) whereas Cr(II) is oxidized to Cr(III):

$$Cr^{2+} + H^+ \rightarrow Cr^{3+} + \tfrac{1}{2}H_2. \quad (4)$$

Reactions (1) and (4) depend on the acid concentration and under the above conditions reaction (1) is completed in *ca.* 48 h and (4) in *ca.* 3 h.

When thoroughly deoxydenated freshly prepared

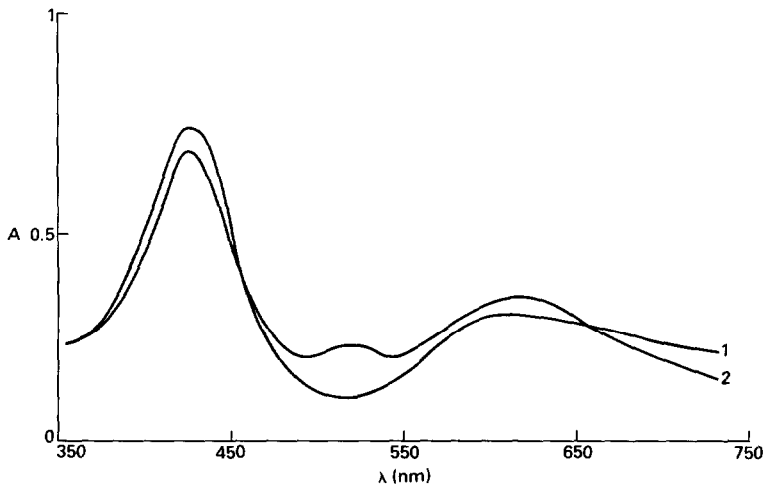

Fig. 7. Spectra of a mixture of $K_3Mo_2HCl_8$, 8.5×10^{-5} M and $CrCl_2$, 3.4×10^{-4} M in 6 M HCl at 25°C; (a) after 15 min from the start of the reaction, (b) after 1 h.

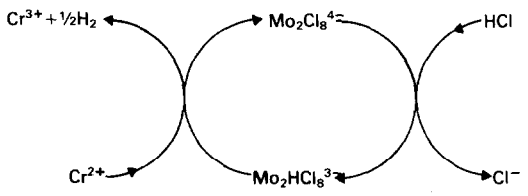

Scheme 2.

HCl 6 M solutions of an excess of chromous chloride and a mixture of $K_3Mo_2HCl_8/KCl$ are mixed at room temperature the colour changes from light yellow–green to dark green–brown and gas evolution (H_2) is observed. The reaction can be followed spectrophotometrically, Fig. 7. The absorbance at 420 nm due to the hydride **2** diminishes whereas a new peak attributed to **1** appears and chromium(II) is oxidized to chromium(III). The reaction taking place is

$$Mo_2HCl_8^{3-} + 2Cr^{2+} + H^+ \rightarrow Mo_2Cl_8^{4-} + 2Cr^{3+} + H_2 \quad (5)$$

but the measured stoichiometry is little more than two Cr^{2+} ions for each $Mo_2HCl_8^{3-}$, because of the parallel reaction (4). There is also a peak at 615 nm attributed to a mixture of $[Cr(H_2O)_5Cl]^{2+}$ and $[Cr(H_2O)_4Cl_2]^+$ which absorbs[22] at 605 and 635 nm, respectively. A similar mixture is obtained in reaction (4). At the end of reaction (5) the solvent is removed *in vacuo*, the residues are extracted with tetrahydrofuran leaving behind a red solid identified as **1**; the green filtrate contains Cr(III) in the form of the dichloro-complex (peaks at 445 and 640 nm). In HCl the product **1** is converted back to **2**, hence the dimolybdenum couple participates in the cycle shown (Scheme 2). With $[(n\text{-}C_4H_9)_4N]_3Mo_2Cl_9$ the reaction is similar yielding **1** and Cr(III).

The Mo_2^{6+} core effectively oxidizes Cr(II) to Cr(III) thus comparing to the behaviour of the olefinic and acetylenic compounds,[23,24] except that here the bond order increases rather than decreases, from three to four.

The system is of interest and it it desirable to pay more attention to its mechanistic aspects in order to establish:

(i) The mechanism of reaction (1).

(ii) Whether the electron transfer in reaction (5) occurs via a chloride bridged activated complex (inner sphere) or by direct metal–metal interaction (Mo—Cr).

(iii) How the bridges over the molybdenum ions open and the implications to homogeneous catalysis.

(*Received* 3 *March* 1987; *accepted* 27 *May* 1987)

Abstract—Electrophilic deuteration of *closo*-[1-$CB_{11}H_{12}$]$^-$ in the DCl/D_2O system confirmed the expected order of reactivity on individual skeletal atoms, decreasing in the series B(12) > B(7–11) > B(2–6) > C(1). In contrast, electrophilic B-substitution of *closo*-[1-$CB_{11}H_{12}$]$^-$ with H_2NOSO_3H is consistent with the preference of the B(7)-substitution to suggest a different mechanism for almost exclusive formation of 7-H_3N-*closo*-1-$CB_{11}H_{11}$. 7-Me_3N-*closo*-1-$CB_{11}H_{11}$ was isolated along with the remaining 2- and 12-Me_3N-1-$CB_{11}H_{11}$ isomers as side products of the thermal decomposition of [$BH_2(NMe_3)_2$]$^+$[*nido*-7-$CB_{10}H_{13}$]$^-$ at 270°C, which is inconsistent with a specific insertion of the $BNMe_3$ fragment into the open face of *nido*-[7-$CB_{10}H_{13}$]$^-$. Nevertheless, clean ^{10}B-insertion was observed in the reactions of $Et_3N^{10}BH_3$ with both *nido*-[7-$CB_{10}H_{13}$]$^-$ and 7-Me_3N-*nido*-7-$CB_{10}H_{12}$ to give respectively *closo*-[1-$CB_{11}H_{12}$]$^-$ and [1-Me_2N-1-$CB_{11}H_{11}$]$^-$ labelled by ^{10}B exclusively at the B(2) site. Cage rearrangement was observed, however, in the reaction of 7-Me_3N-8-$PhCH_2$-*nido*-7-$CB_{10}H_{11}$ with Et_3NBH_3 under similar conditions to produce only the 1-Me_3N-7-$PhCH_2$-1-$CB_{11}H_{10}$ *closo*-isomer.

Recently, we have reported[1] electrophilic substitution reactions of the *closo*-[1-$CB_{11}H_{12}$]$^-$ anion (Fig. 1) with halogens, leading to multiple substitution of the B(7–12) atoms with chlorine and bromine, and to the substitution at the B(7,12) sites with iodine. Acid-catalyzed reaction of [1-$CB_{11}H_{12}$]$^-$ with dimethyl sulphoxide[1] proceeded exclusively on the B(12) atom to produce *closo*-12-Me_2S-1-$CB_{11}H_{11}$ as the main product. With respect to relative rates of halogenation in the series of isoelectronic 12-vertex *closo*-compounds, the decrease in reactivity in the order [$B_{12}H_{12}$]$^{2-}$ > [$CB_{11}H_{12}$]$^-$ > $C_2B_{10}H_{12}$ can be clearly estimated. The skeletal carbon, bearing a partial net positive charge, reduces the reactivity towards electrophilic reagents. Previous work has shown that, apart from the disproportionation of *nido*-[7-$CB_{10}H_{13}$]$^-$ at higher temperatures,[2] the *closo*-[1-$CB_{11}H_{12}$]$^-$ anion and its C-amine derivatives can be prepared by more convenient one-boron insertion into the framework of *nido*-7-L-7-$CB_{10}H_{12}$ compounds[1–3] (L = H^-, H_3N and Me_3N). This paper reports some new aspects of this insertion reaction along with some supplementary results on electrophilic substitution reactions of *closo*-[1-$CB_{11}H_{12}$]$^-$.

EXPERIMENTAL

Physical measurements

The ^{11}B (64.18 MHz) and two-dimensional (2-D) ^{11}B–^{11}B NMR spectra were recorded on a Varian XL-200 spectrometer in hexadeuterioacetone, chemical shifts are given in δ (ppm, referenced to $BF_3 \cdot OEt_2$, positive shifts downfield). 2-D ^{11}B–^{11}B

* Author to whom correspondence should be addressed.

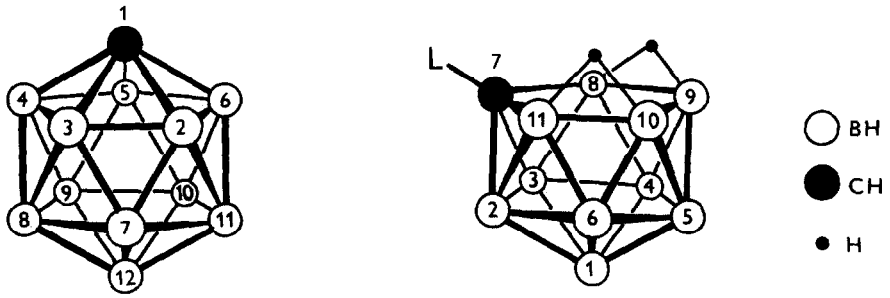

Fig. 1. Simplified structure and numbering system of *closo*-$[1\text{-}CB_{11}H_{12}]^-$ anion and *nido*-7-L-7-$CB_{10}H_{12}$ compounds.

NMR spectra were produced on selected samples via procedures described elsewhere.[4] The following short notation of the off-diagonal interactions (cross peaks) found in 2-D spectra is used: boron atoms found to interact with the observed boron atom (on diagonal) are given in brackets with right superscripts (s—strong, m—medium, w—weak, 0—zero interaction) indicating relative intensities of the cross peaks observed. ^1H (60 MHz) NMR spectra were obtained on Tesla BS-467 equipment in hexadeuterioacetone, chemical shifts are given in δ (ppm, referenced to TMS). Mass spectra were collected at 70 eV using a GC/MS HP-5989 device. TLC was performed on Silufol (silica gel on aluminium foil; detection by I_2 vapour followed by $AgNO_3$ spray) in 1:3 acetonitrile–chloroform. Melting points were determined in sealed capillaries under nitrogen and are uncorrected.

Chemicals

Diethyl ether and tetrahydrofuran were distilled with $NaAlH_2(OC_2H_4OCH_3)_2$ prior to use and other solvents were purified by standard distillation procedures. A concentrated solution of DCl in D_2O was prepared by the absorption of dry DCl, generated in the reaction of benzoyl chloride with D_2O (Merck, 99.9%) at 120–140°C, in D_2O. Compounds 7-L-7-$CB_{10}H_{12}$ (L = H_3N or Me_3N),[5–7] $[1\text{-}CB_{11}H_{12}]^-$,[3] 6-$PhCH_2B_{10}H_{13}$,[8] $[BH_2(NMe_3)_2]^+I^-$,[9] and $Et_3N^{10}BH_3$[10] were prepared by literature methods. Other commercially available chemicals were reagent grade and were used as purchased.

Syntheses

Except where otherwise indicated, all syntheses were conducted under an inert atmosphere. Operations connected with solvent evaporations were performed *in vacuo* on a standard rotatory evaporator.

Deuteration of closo-$[1\text{-}CB_{11}H_{12}]^-Na^+$. A NMR tube was charged with a 1 M D_2O-solution of $[1\text{-}CB_{11}H_{12}]^-Na^+$ (*ca.* 3 cm^3) prepared as in the following experiment. The solution was acidified by three drops of concentrated DCl/D_2O and the ^{11}B NMR spectrum was monitored in 15 min, 1 h, 2 h, and 24 h intervals. The H–D exchange rate on individual B-atoms was estimated by monitoring the collapse of the two low-field doublets into singlets (Fig. 2). The final product of the exchange

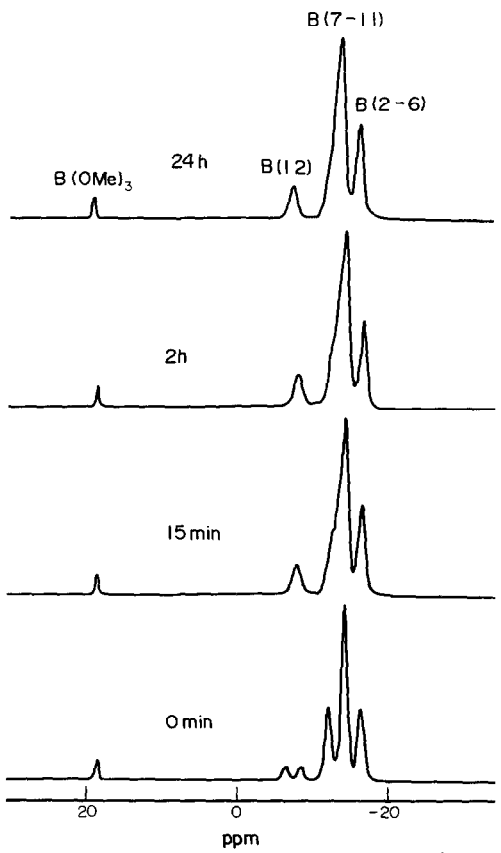

Fig. 2. Proton-coupled ^{11}B NMR spectra of the *closo*-$[1\text{-}CB_{11}H_{12}]^-Na^+/DCl/D_2O$ system in different time intervals.

was [7,8,9,10,11,12-D_6-1-$CB_{11}H_6$]$^-$Na$^+$; connectivities from the 2-D ^{11}B–^{11}B NMR spectrum: B(12) [B(7–11)^s], B(7–11) [B(2–6)^s, B(12)^m], B(2–6) [B(7–11)^s].

7-H_3N-1-$CB_{11}H_{11}$. The [1-$CB_{11}H_{12}$]$^-$$NMe_3H^+$ salt (2.2 g; 0.01 mol) was treated with aqueous 1 M NaOH (10 cm^3) at 50°C, the solution was filtered and the trimethylamine evolved was removed *in vacuo*. The residual solution was extracted with ether (30 cm^3) and the organic layer was separated and evaporated. The semi-solid residue (hydrated [1-$CB_{11}H_{12}$]$^-$Na$^+$) obtained after removing the solvents, was dissolved in water (50 cm^3), acidified with acetic acid to pH 6 and treated with H_2NSO_3H (7.0 g; 0.06 mol). The mixture was heated at 80°C for 10 h, cooled to an ambient temperature and the unreacted [1-$CB_{11}H_{12}$]$^-$ was precipitated with 3 M aqueous $Et_3N \cdot HCl$. The white precipitate was isolated by filtration, washed with water and vacuum-dried to recover 1.5 g (59%) of [1-$CB_{11}H_{12}$]$^-$$NEt_3H^+$, as assessed by ^{11}B NMR. The clear filtrate was extracted with ether (2 × 20 cm^3) and the ether layer was evaporated, leaving a white solid which was recrystallized from benzene (20 cm^3) and vacuum-dried to give 0.25 g (39%) of 7-H_3N-1-$CB_{11}H_{11}$; m.p. > 280°C; R_F 0.25; *m/z* 161; ^{1}H NMR: δ 6.54 [s, 3H, H_3N], 2.51 [s, 1H, H(1)]; ^{11}B NMR: δ_B −5.28 [s, 1B, B(7)], −6.90 [d, 1B, J(BH) 156, B(12)], −13.60 [d, 2+2B, 136, B(8,11)/B(9,10)], −16.79 [d, 2+2B, 164, B(2,3)/B(4,6)], −19.41 [d, 1B, 160, B(5)]. As assessed by ^{11}B NMR, the product was slightly contaminated by the 12-H_3N-isomer (singlet at δ_B −0.60).

closo-7-Me_3N-1-$CB_{11}H_{11}$. A sample of 7-H_3N-1-$CB_{11}H_{11}$ (0.2 g; 1.25 mmol) was dissolved in 5% sodium hydroxide (10 cm^3) and the resultant solution was treated with dimethyl sulphate (0.8 cm^3; 8.4 mmol). The mixture was stirred at room temperature for 1 h to deposit white material and treated with concentrated ammonia (5 cm^3) for 0.5 h. The product was isolated by filtration, washed with water, vacuum-dried and dissolved in 1:1 dichloromethane/benzene. The solution was slowly reduced in volume to *ca.* 10 cm^3 to precipitate white crystals which were filtered, washed with benzene (*ca.* 5 cm^3) and vacuum-dried to afford 0.2 g (75%) of 7-Me_3N-1-$CB_{11}H_{11}$; m.p. 268–270°C; R_F (benzene) 0.20; *m/z* 203; ^{1}H NMR: δ 3.08 [s, 9H, Me_3N], 2.59 [s, 1H, H(1)]; ^{11}B NMR: δ_B 2.57 [s, 1B, B(7)], −7.39 [d, 1B, 138, B(12)], −13.89 [d, 2+2B, 166, B(8,11/9,10)], −16.98 [d, 2+2B, 152, B(2,3/4,6)], −18.65 [d, 1B, 151, B(5)], the unresolved signals assigned to B(8,11/9,10) and B(2,3/4,6) were partially resolved in the "window area" of the 2-D spectrum. Connectivities from 2-D ^{11}B–^{11}B NMR: B(7) [B(12)^m, B(8,11)^s, B(2,3)^s], B(12) [B(7)^m, B(8,11/9,10)^s], B(8,11/9,10) [B(12)^s, B(7)^s, B(2,3/4,6)^s, B(5)^s], B(2,3/4,6) [B(7)^s, B(8,11/9,10)^s, B(5)^s], B(5) [B(2,3/4,6)^s, B(9,10)^s].

Thermal decomposition of nido-[7-$CB_{10}H_{13}$]$^-$[$BH_2(NMe_3)_2$]$^+$. The title salt (2.65 g; 0.01 mol), prepared by the precipitation of 0.2 M aqueous *nido*-[7-$CB_{10}H_{13}$]$^-$Na$^+$ (50 cm^3) with [$BH_2(NMe_3)_2$]$^+$I$^-$ (2.6 g; 0.01 mol), was heated *in vacuo* at 270°C for 3 h in a reaction flask equipped with a glass sublimation tube. The white sublimate and residual solids were digested with dichloromethane (2 × 20 cm^3) and the resultant mixture was filtered. Silica gel (5 g) was added to the filtrate and the solids obtained after removing the solvent were placed onto a column (2.5 × 30 cm) packed with silica gel. Benzene developed three main fractions of R_F 0.42, 0.25 and 0.20 (checked by TLC in benzene) which were evaporated, washed with hexane and vacuum-dried. The first fraction (0.36 g; 18%) was identified as *closo*-12-Me_3N-1-$CB_{11}H_{11}$; m.p. 163–164°C; *m/z* 203; ^{1}H NMR: δ 2.92 [s, 9H, Me_3N], 4.49 [s, 1H, H(1)]; ^{11}B NMR: δ_B 7.73 [s, 1B, B(12)], −12.43 [d, 5B, 148, B(7–11)], −17.23 [d, 5B, 160, B(2–6)]; connectivities from 2-D ^{11}B–^{11}B NMR: B(12) [B(7–11)^s], B(7–11) [B(2,6)^s, B(12)^s], B(2–6) [B(7–11)^s]. The product from the second fraction, (0.1 g; 5%) was identified as *closo*-2-Me_3N-1-$CB_{11}H_{11}$; m.p. 206–207°C; *m/z* 203; ^{1}H NMR: δ 3.22 [s, 9H, Me_3N], 4.71 [s, 1H, H(1)]; ^{11}B NMR: δ_B 19.02 [s, 1B, B(2)], −3.15 [d, 1B, 147, B(12)], −11.15 [d, 2B, 157, B(7,11)], −14.72 [d, 5B, 157, B(3–6,9)], −19.59 [d, 2B, 154, B(8,10)]; connectivities from 2-D ^{11}B–^{11}B NMR: B(2) [B(3–6,9)^m, B(7,11)^s], B(12) [B(7,11)^w, B(8,10)^s, B(3,6/4,5/9)^w], B(7,11) [B(8,10)^s, B(12)^w, B(2)^s, B(3,6/4,5/9)^m], B(3,6/4,5/9) [B(7,11)^m, B(8,10)^s, B(12)^w], B(8,10) [B(3,6/4,5/9)^s, B(7,11)^s, B(12)^s]. The third fraction was identified from ^{11}B NMR as 7-Me_3N-1-$CB_{11}H_{11}$, which was characterized in the preceding experiment. The dichloromethane insoluble portion was treated with boiling 5% potassium hydroxide (30 cm^3) and filtered. The filtrate was precipitated with 1 M tetramethylammonium chloride, the white solid was isolated by filtration and recrystallized from aqueous acetone to recover 1.3 g (59%) of *closo*-[1-$CB_{11}H_{12}$]$^-$$NMe_4^+$, as assessed from ^{11}B NMR.[3]

^{10}B-*insertion into nido*-[7-$CB_{10}H_{13}$]$^-$. A mixture of [7-$CB_{10}H_{13}$]$^-$Cs$^+$ (2.7 g; 0.01 mol) and $Et_3N^{10}BH_3$ (6.8 g; 0.06 mol) was heated at 200°C for 6 h and the triethylamine evolved was removed by distillation. After being cooled to room temperature, the mixture was treated with a mixture of ethanol (50 cm^3) and concentrated hydrochloric acid (30 cm^3). After the initial exothermic reaction

had ceased, the mixture was heated at 80°C for an additional 4 h, diluted with water (100 cm^3), filtered with activated charcoal and extracted with ether (2 × 30 cm^3). The ether layer was evaporated with water (15 cm^3) and the remaining aqueous solution was precipitated with 1 M NMe_4Cl (10 cm^3). The precipitate was isolated by filtration, washed with water and recrystallized from aqueous acetone to give 1.2 g (55%) of *closo*-[2-^{10}B-1-$CB_{10}H_{12}$]$^-$ NMe_4^+ (for ^{10}B and ^{11}B NMR spectra see Fig. 3).

^{10}B *Insertion into nido*-7-Me_3N-7-$CB_{10}H_{12}$. A mixture of 7-Me_3N-7-$CB_{10}H_{12}$ (1.9 g; 0.01 mol) and $Et_3N^{10}BH_3$ (2.8 g; 0.02 mol) was heated at 200°C for 4 h to evolve hydrogen and triethylamine. After being cooled to room temperature, the mixture was decomposed with a mixture of ethanol (50 cm^3) and concentrated hydrochloric acid (30 cm^3) as in the preceding experiment. The solids were decanted and treated with 10% NaOH (30 cm^3) and the alkaline solution was filtered. The filtrate was stirred with dimethyl sulphate (7.6 g; 0.06 mol) for 1 h and the excess dimethyl sulphate was removed by adding concentrated ammonia (10 cm^3) under stirring for 0.5 h. The white product was isolated by filtration and recrystallized from acetone to obtain 0.8 g (42%) of *closo*-1-Me_3N-2-^{10}B-1-$CB_{10}H_{11}$; ^{11}B NMR: δ_B −7.40 [d, 1B, 141, B(12)], −13.65 [d, 5B, 140, B(7–11)], −15.07 [d, 4B, B(3–6)].

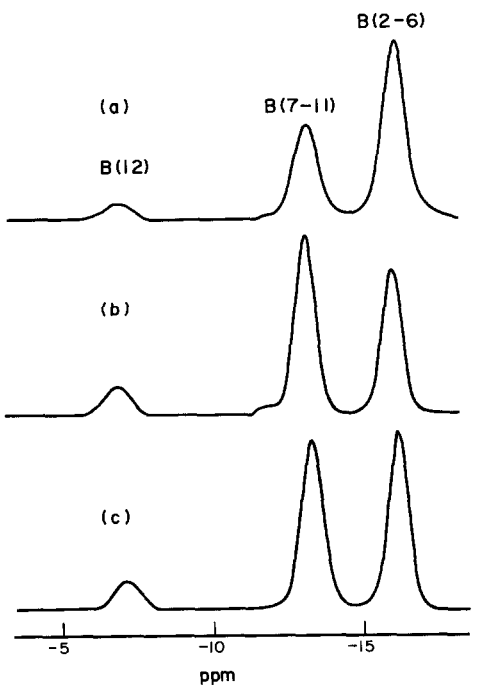

Fig. 3. (a) $^{10}B\{^1H\}$ NMR spectrum of the *closo*-[2-^{10}B-1-$CB_{10}H_{12}$]$^-$ anion; (b) $^{11}B\{^1H\}$ NMR spectrum of *closo*-[2-^{10}B-1-$CB_{10}H_{12}$]$^-$; (c) $^{11}B\{^1H\}$ NMR spectrum of the *closo*-[1-$CB_{11}H_{12}$]$^-$ anion with natural isotopic abundance.

nido-8-$PhCH_2$-7-Me_3N-7-$CB_{10}H_{11}$. A solution of *nido*-6-$PhCH_2B_{10}H_{13}$ (3.2 g; 0.015 mol) in hexane (30 cm^3) was added to a solution of sodium cyanide (2.2 g; 0.045 mol) in water (30 cm^3) and the mixture was stirred for 2 h. The aqueous layer was separated, cooled to 0°C and acidified with dilute (1 : 5) hydrochloric acid (30 cm^3). The deposited white solid was washed with water and vacuum-dried to afford 3.0 g (83%) of 8-$PhCH_2$-7-H_3N-7-$CB_{10}H_{11}$; R_F 0.5; m.p. > 280°C; ^{1}H NMR: δ 7.12 [m, 5H, Ph], 5.43 [s, 3H, H_3N], 2.45 [m, 2H, CH_2], −3.25 [br.s, 2H, μH]; ^{11}B NMR: δ_B −1.18 [d+s, 1+1B, B(5/8)], −8.48 [d, 1B, 147, B(3)], −10.68 [d, 1+1B, 132, B(2/11)], −21.46 [d, 1B, 168, B(9)], −23.02 [d, 1B, 169, B(10)], −26.04 [d, 1B, 149, B(1)], −31.01 [d, 1B, 147, B(4)], −33.86 [d, 1B, 148, B(6)]. The product was dissolved in 5% potassium hydroxide (40 cm^3) and dimethyl sulphate (8.5 cm^3; 0.09 mol) was added dropwise under stirring for 1 h. The precipitate was isolated by filtration, washed with water (100 cm^3) and vacuum-dried to obtain 3.2 g (75% based on 6-$PhCH_2B_{10}H_{13}$ consumed) of 8-$PhCH_2$-7-Me_3N-7-$CB_{10}H_{11}$; R_F 0.71; m.p. 266–268°C; *m/z* 283; ^{1}H NMR: δ 7.15 [m, 5H, Ph], 3.38 [s, 9H, Me_3N], 2.50 [q, 2H, CH_2], −3.35 [br.s, 2H, μH]; ^{11}B NMR: δ_B 0.62 [d, 1B, 140, B(5)], −3.18 [s, 1B, B(8)], −8.20 [d, 1B, 163, B(3)], −11.16 [d, 1B, 165, B(2)], −13.75 [d, 1B, 153, B(11)], −19.76 [d, 1B, 146, B(9)], −24.12 [d, 1B, 138, B(10)], −26.52 [d, 1B, 144, B(1)], −30.90 [d, 1B, 149, B(4)], −33.83 [d, 1B, 152, B(6)]; connectivities from 2-D ^{11}B–^{11}B NMR: B(5) [B(9)^m, B(10)^s, B(1)^s, B(4)^m, B(6)^s], B(8) [B(3)^o, B(4)^s, B(9)^m], B(3) [B(8)^o, B(2)^s, B(1)^m, B(4)^m], B(2) [B(3)^s, B(11)^m, B(1)^s, B(6)^o], B(11) [B(2)^m, B(6)^s, B(10)^s], B(9) [B(5)^m, B(10)^s, B(4)^m], B(10) [B(5)^s, B(9)^s, B(6)^s, B(11)^s], B(1) [B(5)^s, B(3)^m, B(2)^m, B(4)^m, B(6)^s], B(4) [B(5)^m, B(8)^s, B(3)^m, B(9)^m, B(1)^s], B(6) [B(5)^s, B(2)^o, B(11)^s, B(1)^s].

closo-[1-Me_2N-7-$PhCH_2$-1-$CB_{11}H_{10}$]$^-$$NMe_4^+$. A mixture of *nido*-7-$Me_3N$-8-$PhCH_2$-7-$CB_{10}H_{11}$ (3.0 g; 0.011 mol) and Et_3NBH_3 (5 cm^3; 0.04 mol) was heated at 220°C for 5 h under distillation until the trimethylamine evolved. After being cooled to room temperature, the mixture was treated with a mixture of methanol (10 cm^3) and dilute (1 : 5) hydrochloric acid (30 cm^3) and refluxed for 3 h. The resulting mixture was alkalised with solid sodium hydroxide under cooling, filtered, and the filtrate was extracted with two portions of ether (30 cm^3). The ether was removed from the organic layer by evaporation and the residual aqueous solution was precipitated with 1 M NMe_4Cl (20 cm^3). The white precipitate was filtered, washed with water (20 cm^3) and recrystallized from methanol to give 2.9 g (78%) of *closo*-[1-Me_2N-7-$PhCH_2$-1-

$CB_{11}H_{10}]^-NMe_4^+$; R_F 0.40; ^{1}H NMR: δ 7.03 [m, 5H, Ph], 3.43 [s, 12H, NMe_4^+], 3.06 [s, 6H, NMe_2], 2.25 [m, 2H, CH_2]; ^{11}B NMR: δ_B −4.78 [s, 1B, B(7)], −10.56 [d, 1B, 131, B(12)], −14.16 [d, 2+2B, 148, B(2,3/8,11)], −15.29 [d, 2+2B, B(4,6/9,10)], −17.94 [d, 1B, 164, B(5)]; connectivities from 2-D ^{11}B–^{11}B NMR: B(7) [B(12)^m, B(2,3/8, 11)^s], B(12) [B(7)^m, B(2,3/8,11)^s, B(4,6/9,10)^s], B(2,3/8,11) [B(7)^s, B(12)^s, B(4,6/9,10)^s], B(4,6/9,10) [B(12)^s, B(2,3/8,11)^s, B(5)^m], B(5) [B(4,6/9,10)^m]. The product (1.2 g; 2.85 mmol) was shaken with ether (10 cm^3) and dilute (1:3) hydrochloric acid (20 cm^3) until the solid had disappeared. The ether was removed from the organic layer by evaporation and the solid was dissolved in 5% potassium hydroxide (30 cm^3). The mixture was methylated with dimethyl sulphate (0.7 cm^3: 7.4 mmol) under stirring for 1 h and the excess dimethyl sulphate was removed by treatment with concentrated ammonia (5 cm^3) for 15 min. The white precipitate was isolated by filtration, vacuum-dried and recrystallized from benzene to afford 0.8 g (96%) of *closo*-1-Me_3 N-7-$PhCH_2$-1-$CB_{11}H_{10}$; R_F 0.65; m.p. 165–167°C; *m/z* 293; ^{1}H NMR: δ 7.05 [M, 5H, Ph], 3.37 [s, 9H, Me_3N], 2.19 [m, 2H, CH_2]; ^{11}B NMR: δ_B −2.82 [s, 1B, B(7)], −6.33 [d, 1B, 141, B(12)], −12.86 [d, 2+2B, 150, B(4,6/9,10)], −14.15 [d, 2B, 149, B(8,11)], −15.47 [d, 2B, 167, B(2,3)], −18.56 [d, 1B, 154, B(5)].

RESULTS AND DISCUSSION

Previously reported results[1] suggested the following order of reactivity towards electrophilic substitution on individual cage atoms of the *closo*-[1-$CB_{11}H_{12}]^-$ anion (Fig. 1): B(12) > B(7–11) > B(2–6) > C(1). The observed course of the acid-catalyzed deuteration of the latter anion in the DCl/D_2O system, monitored by the ^{11}B NMR spectrum (Fig. 2), is in agreement with this presumption. The H–D exchange occurs primarily at the B(12) position with subsequent exchange at the B(7–11) equatorial belt to give the B(7–12) hexadeuterated compound as a final product. The reaction is in agreement with the results of the electrophilic deuteration of *closo*-1,2-$C_2B_{10}H_{12}$ occurring on boron atoms nonadjacent to carbon.[11]

A different result was obtained, however, in an attempt to introduce amine functionality directly onto the *closo*-[1-$CB_{11}H_{12}]^-$ cluster in its reaction with excess hydroxylamine-*O*-sulphonic acid in weakly acidic solution. The reaction affords *closo*-7-H_3N-1-$CB_{11}H_{11}$ contaminated with a small amount of the 12-H_3N-1-$CB_{11}H_{11}$ isomer. On the other hand, the observed, even though a little surprising enhanced reactivity at B(7), which is indicative of a different substitution mechanism, is comparable to the reported[12,13] less favoured equatorial substitution of the *closo*-$[B_{10}H_{10}]^{-2}$ anion by the H_3N group under similar conditions. The compound 7-H_3N-1-$CB_{11}H_{11}$ can be smoothly methylated in alkaline medium to give its N-trimethyl derivative, *closo*-7-Me_3N-1-$CB_{11}H_{11}$.

All of the three possible B-substituted Me_3N-derivatives of the general formula *closo*-Me_3N-1-$CB_{11}H_{11}$ were isolated as side products of the thermal decomposition of the $[BH_2(NMe_3)_2]^+[7\text{-}CB_{10}H_{13}]^-$ salt at 270°C to produce the parent *closo*-$[1\text{-}CB_{11}H_{12}]^-$ as the main product. The relative ratio of the 2-, 7- and 12-Me_3N-1-$CB_{11}H_{11}$ derivatives isolated is *ca.* 3:1:10, respectively. The described reaction represents another interesting way of boron insertion into open borane clusters, however, the found type of insertion is inconsistent with the expected regioselective entry of the B-NMe_3 fragment into the open pentagonal face of the *nido*-$[7\text{-}CB_{10}H_{13}]^-$ anion (Fig. 1); this process should produce exclusively *closo*-2-Me_3N-1-$CB_{11}H_{11}$. Since 1-Me_3N-1-$CB_{11}H_{11}$ and 7-Me_3N-1-$CB_{11}H_{11}$ do not undergo thermal rearrangement at 320°C for 10 h, the thermal migration of the exohedral substituent seemingly does not account for the observed course of the reaction.

Nevertheless, this result prompted us to examine boron insertion reactions in more detail. In comparison with the preceding reaction, the results of ^{10}B-insertion reactions of $Et_3N^{10}BH_3$ with both *nido*-$[7\text{-}CB_{10}H_{13}]^-$ and *nido*-7-Me_3N-7-$CB_{10}H_{12}$[14,15] at 200°C are in good agreement with the respective formation of $[1\text{-}CB_{11}H_{12}]^-$ and 1-Me_3N-1-$CB_{11}H_{11}$ (on methylation of the $[1\text{-}Me_2N\text{-}1\text{-}CB_{11}H_{11}]^-$ intermediate), both labelled by ^{10}B exclusively at the B(2) site, as documented via ^{10}B and ^{11}B NMR spectra (Fig. 3). The spectra indicate clearly the desired ^{10}B-enrichment on the B(2–6) equatorial belt, which is in agreement with a clean ^{10}B insertion into the open pentagonal face of the eleven-vertex nido-system.

The Et_3NBH_3 insertion approach has also been employed in a similar reaction conducted on *nido*-7-Me_3N-8-$PhCH_2$-1-$CB_{10}H_{11}$. Unlike the preceding case, only the *closo*-1-Me_3N-7-$PhCH_2$-1-$CB_{11}H_{10}$ derivative has been obtained instead of the 2-$PhCH_2$-isomer expected on applying the insertion scheme outlined above. The result is compatible with a regioselective cage rearrangement which manifests the steric effect of the two bulky Me_3N and $PhCN_2$-exohedral substituents at vicinal positions.

The constitution of all isolated compounds of both *nido*-7-L-7-$CB_{10}H_{12}$ and *closo*-$[1\text{-}CB_{11}H_{12}]^-$ series was established unambiguously from ^{1}H and

^{11}B NMR spectra. From the known cage geometries, the 2-D ^{11}B–^{11}B NMR spectra were interpreted and the resonances in the 1-D spectra assigned to specific boron nuclei. In the relevant connectivity schemes (see Experimental), most adjacent borons gave rise to the cross peaks observed in the 2-D spectra, even though the results are complicated due to the overlap of closely spaced resonances in a few cases.

Acknowledgement—The authors wish to thank Dr Z. Weidenhoffer for the mass spectral measurements.

Abstract—Treatment of *bis*(dibenzylideneacetone)palladium with trimethylphosphine under a carbon monoxide atmosphere gives the title complex in good yield. X-ray crystallography has shown the structure of the complex to consist of an octahedron of palladium atoms which is bicapped by two further palladium atoms in an asymmetric fashion. Seven of the eight palladium centres carry terminal trimethylphosphine ligands. Two face-bridging and six edge-bridging CO molecules complete the ligand shell.

Clusters of zerovalent palladium carrying carbonyl and phosphine ligands, $Pd_n(CO)_x(PR_3)_y$, are known for nuclearities n ranging from 3–23.[1] Although all are synthesised under very similar and mild conditions, the process of cluster formation appears to be highly sensitive to the palladium source and the reaction medium. For example, the carbonylation of $Pd(NO_2)_2(PPh_2Me)_2$ in dichloromethane gives $Pd_4(CO)_5(PPh_2Me)_4$,[2] and $Pd(\eta^1,\eta^3\text{-}C_8H_{12})(PMe_3)$ generates $Pd_7(CO)_7(PMe_3)_7$,[3] while $Pd(OAc)_2$ in H_2O/Ac_2O or dioxane results in the synthesis of $Pd_{12}(CO)_{17-x}(PR_3)_{5+x}$ ($x = 0, 2$)[4] and of $Pd_{10}(CO)_{12}(PBu^n_3)_6$,[5] respectively. We report here the high-yield preparation and the crystal and molecular structure of a new member of this family, $Pd_8(CO)_8(PMe_3)_7$ (**1**).

EXPERIMENTAL

Preparation of $Pd_8(CO)_8(PMe_3)_7$

To a solution of 1.75 g (3.04 mmol) *bis*(dibenzylideneacetone)palladium[11] in 40 cm^3 dry dichloromethane under nitrogen was added 0.31 cm^3 (3.0 mmol) trimethylphosphine at room temperature. CO was bubbled through this solution for 1 min and the colour of the mixture changed from yellow–brown to maroon. Stirring was continued for 1 h under 1 bar CO. After removal of volatiles the residue was washed with 4×10 cm^3 diethylether, leaving a dark-red powder which was recrystallized from dichloromethane–diethylether to give 400 mg of **1** (0.24 mmol, 65%). Shiny deep red-to-black plates suitable for X-ray diffraction were obtained by the slow evaporation of a dichloromethane solution of **1** through a rubber septum.

X-ray crystallography

The crystal used for X-ray work was mounted under nitrogen in a thin-walled glass capillary. The orientation matrix and associated cell dimensions and intensity data were obtained at 291 K following previously described procedures,[12] using an Enraf–Nonius CAD4 diffractometer operating in the ω–2θ scan mode and graphite monochromatised Mo-K_α radiation [λ(Mo-K_α) = 0.71069 Å]. The structure was solved by direct methods (SHELXS86),[13] developed via difference synthesis and refined via

* Authors to whom correspondence should be addressed.

full matrix least squares, with scattering factor data taken from reference 14. During the refinement process it became clear that some of the PMe_3 groups were orientationally disordered and it was possible to refine the carbon atoms in the isotropic mode only. Pd and P atoms were treated anisotropically. Crystallographic data were as follows: $Pd_8(CO)_8(PMe_3)_7$, $M_r = 1607.83$, orthorhombic, $a = 11.106(4)$, $b = 11.248(2)$, $c = 42.302(4)$ Å, $V = 5284.1$ Å^3, space group $P2_12_12_1$, $Z = 4$, $d_c = 2.02$ g cm^{-3}, $\mu = 26.5$ cm^{-1}. 5258 intensities measured, 5221 unique and 4080 observed [$F_o > 3\sigma(F_o)$]. The final R, R_w values were 0.055 and 0.064 respectively, with weights $\omega = 1/[\sigma^2(F_o) + 0.0003F_o^2]$. Final atomic parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Treatment of a solution of *bis*(dibenzylideneacetone)palladium in dichloromethane with one equivalent of trimethylphosphine under a CO atmosphere at room temperature gives black–purple crystals of the title complex (**1**) in 60–70% yield. The infrared spectrum of solid **1** (Nujol mull) indicates the presence of bridging and the absence of terminal CO ligands (ν_{CO} 1763 (m), 1775 (m), 1803 (sh), 1810 (s), 1843 (m), 1878 (s) cm^{-1}); a simpler spectrum is observed in dichloromethane solution (ν_{CO} 1817 (s), 1877 (m) cm^{-1}). The presence of PMe_3 ligands is indicated by bands at 1281 (m) and 955 (vs) cm^{-1}.

The structure of (**1**) was elucidated by X-ray diffraction. Six of the eight palladium atoms are arranged to form a regular octahedron. The two remaining Pd atoms cap two opposite triangular faces of the octahedron and interact with the same octahedral vertex Pd atom [Pd(1)] which, as a consequence, is the only metal centre of the cluster not to carry a terminal PMe_3 ligand. Two of the eight carbonyl ligands bridge the two octahedral faces adjacent to those capped by palladium; the others are edge-bridging. The structure and atomic numbering scheme are given in Fig. 1; selected bond lengths and angles are collected in Tables 1 and 2.

The octahedral core of the cluster is subject to only minor distortions due to a shortening of CO bridged edges (on average 2.78 vs 2.85 Å). The shortest Pd—Pd distances are found between the singular octahedral atom Pd(1) and the two capping atoms Pd(7) and Pd(8). The capping is highly asymmetric; one Pd—Pd interaction between each cap and the core is significantly weaker than the other

two, with an average Pd—Pd bond length of 3.18 Å between the capping atoms and two mutually opposite octahedral vertices.

This asymmetry of bonding of the capping palladium units is reflected in the Pd—C distances of the triply bridging CO ligands. Three sets of significantly different Pd—C bond lengths are observed, from the shortest (2.04 Å) between C(1,2) and the Pd atoms least involved in bonding to a capping metal [Pd(2,4)], to the longest towards Pd(1) (> 2.3 Å). Two of the six edge-bridging CO ligands, C(3) and C(4), also show a strong tendency towards a face-bridging position and are inclined towards Pd(3) and Pd(5), i.e. the Pd(2)—C(3)—Pd(6) plane deviates by 47.9° from the Pd(2)—Pd(4)—Pd(6) plane (48.1° for the Pd(4)—C(4)—Pd(6) plane), while angles of 0° would have been expected for truly edge-bridging

ligands. However, the Pd(3)—C(3) and Pd(5)—C(4) distances of 2.63 and 2.67 Å are too long to be interpreted as bonding interactions.

For steric reasons, the trimethylphosphine ligands coordinated to Pd(3) and Pd(5) are bent out of the octahedral "equatorial" plane towards Pd(6) by 37.7 and 37.2°, respectively, while P(2) and P(4) are slightly inclined towards Pd(1) below this plane by 3.7 and 8.4°, respectively.

The cluster possesses 110 cluster valence electrons (CVE) and its geometry is in agreement with this electron count.[6,7] Examples for octanuclear 110 CVE clusters are very limited; the dianion $[Os_8(CO)_{22}]^{2-}$ (**2**),[8] the mixed-metal cluster $Os_6Pt_2(CO)_{17}(C_8H_{12})_2$ (**3**)[9] and the carbide cluster $[Re_8C(CO)_{24}]^{2-}$[10] have been structurally characterized. A comparison of the structure of **1** with that of the isoelectronic Os cluster $[Os_8(CO)_{22}]^{2-}$ (**2**)[8] reveals significant differences in the distribution of metal–metal bond lengths (Fig. 2). While both in **1** and **2** the shortest interactions are those between the basal octahedron vertex and the two capping atoms, in **2** each of these caps forms a nearly regular tetrahedron with its three neighbours in the octahedral core and the longest Os—Os distances are found not between capping and core atoms but for the non-CO bridged vertices between the apical and two equatorial Os atoms of the octahedral core. Asymmetric capping as observed in **1** is a feature typical of d^{10} metal centres and is found to varying degrees in the mixed-metal Os_6Pt_2 cluster **3**[9a] (Fig. 2) as well as in $Pd_7(CO)_7(PMe_3)_7^3$ and $Pd_{10}(CO)_{12}(PBu^n_3)_6^5$* (Fig. 3). It has been argued[3,6]

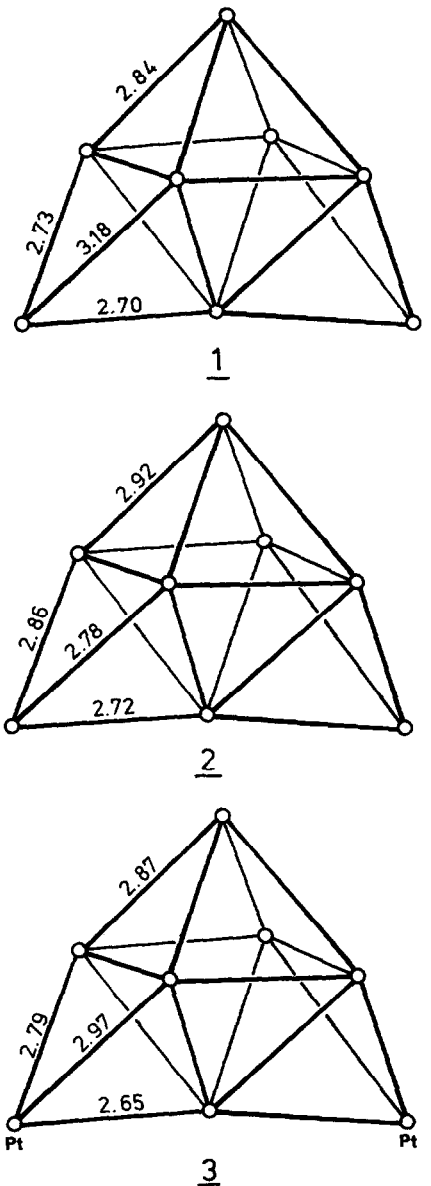

Fig. 2. Comparison of the structures of the octanuclear 110 CVE clusters $Pd_8(CO)_8(PMe_3)_7$ (**1**), $[Os_8(CO)_{22}]^{2-}$ (**2**) and $Os_6Pt_2(CO)_{17}(C_8H_{12})_2$ (**3**) (bond lengths in Å).

* By contrast, asymmetric-face capping Pd units are absent from $Pd_{23}(CO)_{22}(PEt_3)_{10}$, which consists of a four-fold edge bridged Pd_{19} octahedron in a cubic close packed arrangement.[1] The Pd_8 geometry of (**1**) may be regarded as part of a Pd_{19} structure.

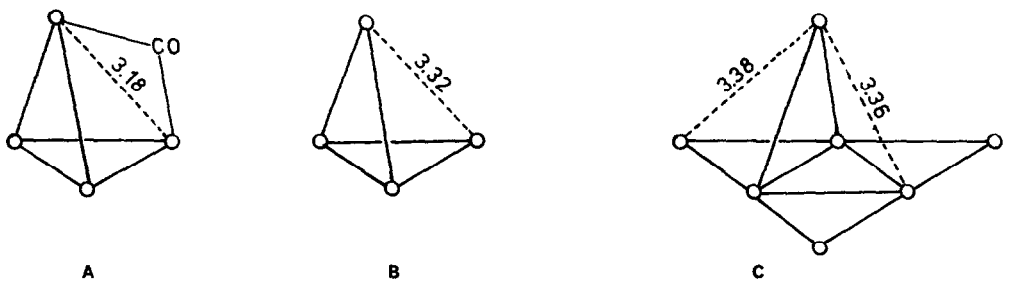

Fig. 3. Partial structures of $Pd_7(CO)_7(PMe_3)_7$[3] (**A**), $Pd_{10}(CO)_{12}(PBu^n_3)_6$[5] (**B**), and $Pd_{23}(CO)_{22}(PEt_3)_{10}$[1] (**C**), illustrating two types of asymmetric face capping (**A**,**B**) and the only example of symmetrical edge bridging (**C**) palladium.

that the reason for metal–metal bond lengthening as observed in **1** lies in the energetic separation between the metal *p* orbitals from the *s* and *d* levels which increases as one moves across the transition series towards heavier elements. A high energy (relative to *d* levels) would make the *p* orbitals less available for bonding, resulting in a deficiency of metal–metal bonding MO's in the cluster and an occupation of low-lying antibonding MO's and consequently a distortion of the cluster geometry.

SPECTROPHOTOMETRIC STUDY OF THE COMPLEXATION EQUILIBRIA OF COBALT(II) WITH 4-(5′-METHYL-3′-ISOXAZOLYLAZO)-RESORCINOL AND DETERMINATION OF COBALT(II)

Z. SOSA, J. P. PÉREZ TRUJILLO, J. J. ARIAS and F. GARCÍA MONTELONGO*

Department of Analytical Chemistry, University of La Laguna, 38204-La Laguna, Spain

(*Received* 24 *April* 1987; *accepted* 27 *May* 1987)

Abstract—The reaction of cobalt(II) with 4-(5′-methyl-3′-isoxazolylazo)-resorcinol (MIAR) in 4% v/v ethanol–water medium at $I = 0.1$ M ($NaClO_4$) was investigated spectrophotometrically. Graphical and numerical calculation methods were used to establish the equilibria in solution and to evaluate the stability constant of the complexes formed ($\log\beta_{101} = 7.48 \pm 0.06$, $\log\beta_{111} = 12.77$ max 12.99, $\log\beta_{102} = 16.41 \pm 0.07$). The optimum conditions for the spectrophotometric determination of Co(II) with MIAR were established and the method applied to its determination in some low alloy steels and hydrofining catalysts.

Heteroazo-phenols and -naphthols have been widely used as chromogenic reagents and metallochromic indicators for many metal ions,[1,2] but in general little attention has been paid to study their complexation equilibria in solution.

In a previous paper[3] the acid–base behaviour, Table 1, of 4-(5′-methyl-3′-isoxazolylazo)-resorcinol (MIAR) as well as its complexation equilibria with cadmium(II) were studied.

The present paper deals with the spectrophotometric study of the complexation equilibria of MIAR and Co(II), the species in solution and their stability constants established by graphical and numerical calculation methods, and a method is developed for the spectrophotometric determination of cobalt, which is applicable to its determination in some low alloy steels and hydrofining catalysts.

EXPERIMENTAL

4-(5′-methyl-3′-isoxazolylazo)-resorcinol (MIAR) 10^{-3} M solution in absolute ethanol. Standard 10^{-1} M $Co(ClO_4)_2$ solution prepared from cobalt nitrate by perchloric acid treatment and standardized complexometrically.[4] A hexamine/$HClO_4$ buffer solution (pH = 7.5) was used as indicated. The ionic strength, I, of the solution was kept constant at 0.1 m ($NaClO_4$).

Analytical reagent grade chemicals and de-ionized water were used throughout with no further purification.

The pH measurements were carried out with a Radiometer PHM64 digital pH-meter with a glass–calomel combination electrode. Absorption measurements were made on a Hitachi Perkin–Elmer 200 recording spectrophotometer provided with 1 cm matched quartz cells. Measurements were performed at 25 ± 0.1°C. Calculations were carried out on a Digital VAS/VMX 11/780 (V.4) computer.

Table 1. Optical characteristics of MIAR species (4% v/v ethanol–water, $I = 0.1$ M $NaClO_4$)

Species	λ_{max} (nm)	ε (l mol^{-1} cm^{-1})	pKa
H_2R	365	18,351	pKa_3 5.51
HR^-	385	26,171	pKa_4 10.52
R^{2-}	463	29,244

Spectrophotometric determination of cobalt

To the sample, 8.75–30.00 μg of cobalt(II) in a 25 cm^3 measuring flask, 5 ml of 10^{-3} M MIAR, 5 cm^3 of hexamine/$HClO_4$ buffer solution (pH = 7.5), 1 cm^3 of 2.5 M $NaClO_4$ was added and made up to volume with de-ionized water. After 5 min the absorbance was measured at 465 nm against a reagent blank.

Spectrophotometric determination of cobalt in low alloy steels and hydrofining catalysts

1 g amounts of the steel or catalyst were weighed accurately and treated with 30 cm^3 of HCl (1 : 1) and 5 cm^3 of concentrated HNO_3 in the case of the steel, and with 30 cm^3 of HCl (1 : 1) in the case of the catalyst, heated in a water-bath until dissolved and then taken almost to dryness. The residue was redissolved and made up to 100 cm^3 in a calibrated flask with 6 M HCl. Suitable aliquots were analysed as described above, iron being previously removed with di-*iso*-propyl ether.

RESULTS AND DISCUSSION

Solutions containing 4-(5′-methyl-3′-isoxazolylazo)-resorcinol, MIAR and Co(II) show an orange colouration over a wide pH range. The absorption spectra as a pH function of the MIAR–Co solutions where $C_{Co}/C_R = 20/1$, Fig. 1, show at the greatest acid pHs an absorption maximum that corresponds to the free reagent and at pH ⩾ 5 an absorption maximum is defined at 465 nm, indicative of the complex species formed.

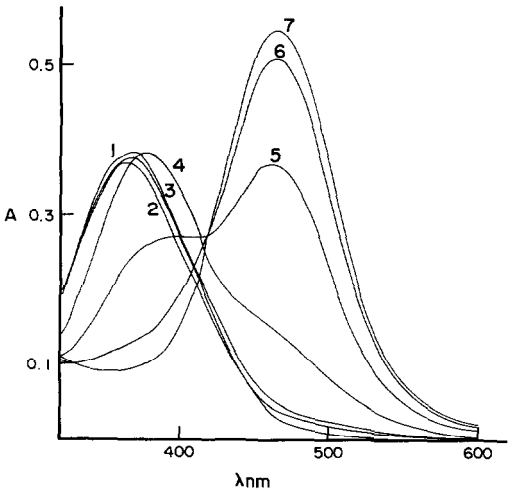

Fig. 1. Absorption spectra of the system Co(II)–MIAR. $C_R = 2.10^{-5}$ M; $C_{Co} = 4.10^{-4}$ M; $I = 0.1$ M ($NaClO_4$); 4% (v/v) ethanol–water; pH = (1) 2.86, (2) 3.96, (3) 4.76, (4) 5.27, (5) 6.25, (6) 6.80, (7) 7.30.

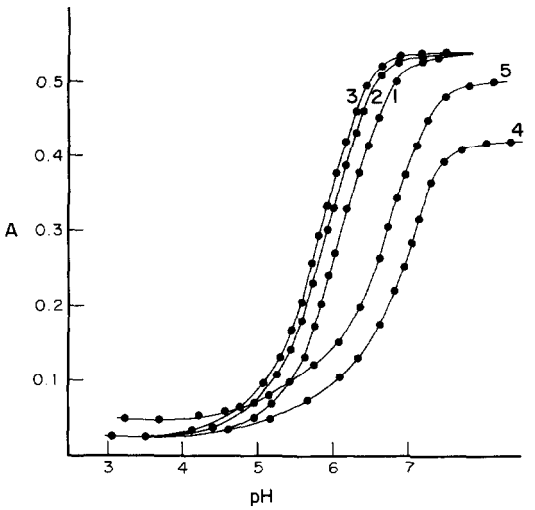

Fig. 2. Absorption–pH curves for the system Co–MIAR. $C_R = 2.10^{-5}$ M, $I = 0.1$ M ($NaClO_4$); 4% (v/v) ethanol–water; 465 nm; C_R/C_{Co} = (1) 1/20, (2) 1/40, (3) 1/60, (4) 1/1, (5) 5/1.

The absorbance–pH curves, at 465 nm, for solutions with different C_{Co}/C_R ratios, Fig 2, show that the complexation begins at pH ≃ 5 and stabilizes at pH ⩾ 6.5.

The stoichiometry, determined at pH = 7.5 and 465 nm by the continuous variations and the molar ratio methods, indicated the formation of a 1 : 2, Co : R species, Fig. 3.

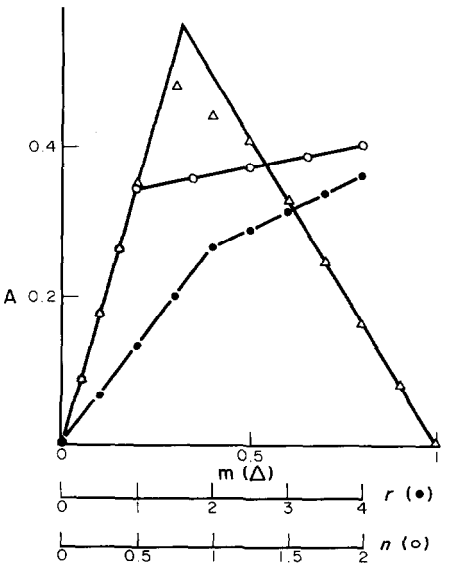

Fig. 3. Stoichiometry of the Co(II)–MIAR system. $I = 0.1$ M ($NaClO_4$); pH = 7.5; 4% (v/v) ethanol–water; 465 nm; (1) $m = C_{Co}/C_R + C_{Co}$; $C_t = 4.10^{-5}$ M, (2) $n = C_{Co}/C_R$; C_R = const. = 2.10^{-5} M, (3) $r = C_R/C_{Co}$; C_{Co} = const. = 10^{-5} M.

Comparison of the absorption spectra in the presence of oxidants or reducers confirmed the presence of cobalt(II) in the complex.

In order to calculate the formation constant of the complex a method of graphical analysis of the A–pH curves derived from that of Sommer *et al.*[5] was used. In accordance with the range of pHs in which complexation took place and the pK_a values of the reagent, it could be admitted that the H_2R and HR^- species of the reagent were those that took part in the complexation reactions, written as follows

$$Co^{2+} + mH_2R \overset{K_{1am}}{\rightleftharpoons} CoH_aR_m + nH^+ \qquad (a = 2m-n) \quad (A)$$

$$Co^{2+} + mHR^- \overset{K_{1bm}}{\rightleftharpoons} CoH_bR_m + pH^+ \qquad (b = m-p) \quad (B)$$

to which the following set of equations can be applied:

$$\log \frac{(AZ - C_R\bar{\varepsilon}_R)(\varepsilon Z - m\bar{\varepsilon}_R)^m}{(C_M\varepsilon Z - C_M m\bar{\varepsilon}_R - AZ + C_R\bar{\varepsilon}_R)(C_R\varepsilon - mA)^m} = \log K + n\,\mathrm{pH} \quad (1)$$

$$\frac{C_R}{A} = \frac{m}{\varepsilon} + \frac{1}{\varepsilon K^{1/m}} \times \left[\frac{(AZ - C_R\bar{\varepsilon}_R)(\varepsilon Z - m\bar{\varepsilon}_R)^m |H^+|^n}{A^m(C_M\varepsilon Z - C_M m\bar{\varepsilon}_R - AZ + C_R\bar{\varepsilon}_R)}\right]^{1/m} \quad (2)$$

where

$$Z = |H^+|/Ka_3 + 1 + Ka_4/|H^+|;$$

$$\bar{\varepsilon}_R = \varepsilon_2 \frac{|H^+|}{Ka_3} + \varepsilon_1 + \varepsilon_0 \frac{Ka_4}{|H^+|}$$

ε_2, ε_1, ε_0 and ε are the molar absorptivities of species H_2R, HR^- and R^{2-} of the reagent and the complex, respectively.

Upon applying the logarithmic equation for $m = 2$, straight lines with a slope of value four were obtained for pH > 6 for the first equilibrium and a value of two for the second equilibrium, indicating that the species formed was CoR_2, while the points of pH > 6 were not in alignment. The fact that not all the points were alligned within a straight line indicated the possible existence of more than one complex species in solution.

Once the values of m, n, and p became known, eqn (2) was applied for pH > 6. The results obtained for equilibrium B are presented in Table 2, where it is observed that the values of K_{102} and ε_{102} for the species CoR_2 are slightly different for solutions with metal excess than in equimolar and excess reagent solutions.

The numerical calculation method was next applied, using the LETAGROP–SPEFO programme.[6] In this treatment, we initially divided the experimental data into two parts: one corresponding to the solutions in excess of metal ion and the other to the equimolar and excess reagent solutions the most suitable model was defined and then applied to the whole of the experimental data.

The data presented in Table 3 indicate that for the ratios in excess of metal ion and in accordance with the values of U and $\sigma(A)$ the fit to a model of a single species is not correct, even with the species CoR_2. The best fit was achieved for a model formed by the species CoHR, CoR and CoR_2, although the constant of the species CoHR was not well defined. The results obtained for the equimolar and excess reagent ratios also indicate that the best fit is obtained with the three-species model deduced in the previous calculations.

Table 2. Values of log K and ε for the system Co-MIAR calculated by graphical methods

Equation	C_R/C_M	Straight line[a]	ε_{102}	$\log K_{102}$

CoR	0.252×10^{-2}	0.007	7.48 ± 0.06	30,811 ± 191
CoR_2			16.41 ± 0.07	50,704 ± 313

The values obtained for the formation constants and molar absorptivities of the different complex species that form the most suitable model are given in Table 3.

In accordance with the values obtained for the whole of the experimental data and using the HALTAFALL programme,[7] the distribution diagrams of species for the proposed model at different metal–ligand ratios, were established as clearly seen in Fig. 4 the slight concentration of the CoHR species justifies the fact that its stability constant is not well defined by mathematical calculation.

The results obtained evidence the limitations presented by applying the graphical method to the study of complexation equilibria in which mixtures of complexes in solution co-exist.

Spectrophotometric determination of cobalt with MIAR

The complex CoR_2, the predominant species in excess of reagent, at pH = 7.5 and 465 nm conforms to Beer's law between 0.12 and 1.65 ppm, according to the equation:

$$A = 9.3 \times 10^{-4} + 0.659|Co^{2+}(ppm)| \quad c.c = 0.999$$

Table 4. Spectrophotometric determination of cobalt with MIAR in the presence of foreign ions, $|Co^{2+}|$ taken = 0.235 ppm, pH = 7.5, λ = 465 nm

|interferent|/|$[Co^{2+}]$|	interference

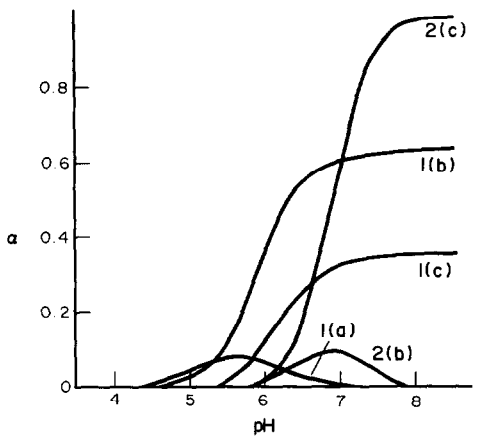

Fig. 4. Distribution diagram of species for Co–MIAR system calculated by HALTAFALL programme, (a) CoHR, (b) CoR, (c) CoR_2; C_{Co}/C_R = (1) 60/1, (2) 1/5.

with 3.89×10^4 as molar absorptivity and 0.23–1.18 ppm as optimum concentration range in accordance with the Ringbom graph with 1.8% as photometric error.

From the statistical study carried out with ten samples each containing 0.235 ppm of cobalt, 0.233 ppm was obtained as the mean value, with a standard deviation of 3.24×10^{-3} and a relative error of 1% (P = 0.05).

The results obtained upon studying the interferences originated by different cations and anions in the determination of cobalt are presented in Table 4.

The method developed was applied to the determination of cobalt in a low alloy steel, Artillería J-5 (4.935% Co), containing Ni and Cu in amounts smaller than those of Co, after previous removal of iron with di-*iso*-propyl ether, and to a hydrofining catalyst, Hydrobon HS-9 (3.23% Co), with recoveries of 4.92% and 3.22%, respectively, as mean values of three determinations.

(*Received* 28 *April* 1987; *accepted* 27 *May* 1987)

Abstract—Mononuclear amide rhodium and iridium complexes of the formulae M(LH)(COD) and M(LH)(CO)(PPh_3) (M = Rh, Ir; COD = 1,5-cyclooctadiene; LH = deprotonated *Z*-*N*-phenyl, *β*-(amino)-4-methylstyryldiphenylphospha-1 λ^5-azene) are described. The related amine ionic compounds $[M(COD)(LH_2)]ClO_4$, $[Rh(CO)_2(LH_2)]ClO_4$, $[Rh(CO)(PPh_3)(LH_2)]ClO_4$, $[M(COD)(LH_2)][M(Cl)_2(COD)]$ and $[Rh(CO)_2(LH_2)][Rh(Cl)_2(CO)_2]$ have also been obtained.

There has been an increasing interest in the chemistry of amide complexes of rhodium[1–9] and iridium.[4–11] In this context, we have recently reported the preparation of new dinuclear rhodium[3,7] and iridium[7] amide complexes containing the deprotonated diaminenaphthalene group, in which the ligand is bound to the two metals in a bridging and chelating manner, as well as dinuclear rhodium(I) complexes with phenyl(2-pyridyl)amido ligands.[9] Following our studies, we report here the synthesis of new chelated rhodium and iridium complexes derived from primary *Z*-*β*-enaminophospha-λ^5-azene (Fig. 1). This ligand can be easily deprotonated with bases to give amide compounds. Furthermore, the ligand contains a phospha-λ^5-azene group which in coordination chemistry has not received extensive attention.[11]

EXPERIMENTAL

Reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. $[Ir(\mu\text{-OMe})(COD)]_2$,[12] $[Rh(\mu\text{-OMe})(COD)]_2$,[12] $[Ir(\mu\text{-Cl})(COD)]_2$[13] and $[Rh(\mu\text{-Cl})(COD)]_2$[14] and LH_2[15] were prepared as previously reported. IR spectra were recorded on a Perkin–Elmer 783 spectrophotometer. Elemental analyses were carried out with a Perkin–Elmer 240B microanalyzer. Conductivities were measured at 20°C with *ca.* 4×10^{-4} M acetone solutions using a Philips PW 9509 conductimeter. Molecular weights were measured in *ca.* 10^{-3} M chloroform solutions with a Perkin–Elmer 115 osmometer.

Preparation of M(LH)(COD) *complexes*

The M(LH)(COD) (M = Rh, Ir) compounds were prepared by reaction of $[M(\mu\text{-OMe})(COD)]_2$ with LH_2 in dichloromethane. In a typical procedure, $[Rh(\mu\text{-OMe})(COD)]_2$ (50 mg, 0.1 mmol) was added to a solution of LH_2 (84 mg, 0.2 mmol) in dichloromethane. The mixture was allowed to react for 30 min, after which the solution was evaporated to dryness to leave a yellow solid. Yield 83 mg (67%).

Preparation of $M(LH)(CO)(PPh_3)$ *complexes*

The $M(LH)(CO)(PPh_3)$ (M = Rh, Ir) complexes were prepared by similar methods. In a typical procedure, carbon monoxide was bubbled through a solution of Rh(LH)(COD) (255 mg, 0.4 mmol) in dichloromethane for 30 min, after which PPh_3 (108 mg, 0.4 mmol) was added. The solution was stirred for 30 min, then concentrated and addition of hexane gave a yellow precipitate, which was filtered off, washed with hexane and air-dried. Yield 262 mg (82%).

Preparation of $[M(COD)(LH_2)]ClO_4$ *complexes*

The $[M(COD)(LH_2)]ClO_4$ complexes were prepared by similar methods. As a typical example, a mixture of $[Rh(\mu\text{-Cl})(COD)]_2$ (40 mg, 0.08 mmol) and $AgClO_4$ (33 mg, 0.16 mmol) in acetone was stirred for 30 min. The AgCl was filtered off and LH_2 (66 mg, 0.16 mmol) was added to the filtrate. After concentration of the solution, the addition of diethyl ether gave a yellow precipitate, which was filtered off, washed with diethyl ether and air-dried. Yield 23 mg (20%).

Preparation of $[Rh(CO)_2(LH_2)]ClO_4$

Carbon monoxide was bubbled through a solution of $[Rh(COD)(LH_2)]ClO_4$ (100 mg, 0.14 mmol) in dichloromethane for 30 min. The yellow solution was concentrated and diethyl ether was added to yield a yellow solid, which was filtered off, washed with diethyl ether and air-dried. Yield 64 mg (69%).

Preparation of $[Rh(CO)(PPh_3)(LH_2)]ClO_4$

PPh_3 (85 mg, 0.32 mmol) was added to a solution of $[Rh(CO)_2(LH_2)]ClO_4$ (213 mg, 0.32 mmol) in dichloromethane. The solution was stirred for 30 min, then concentrated and addition of diethyl ether gave a yellow precipitate which was filtered off, washed with diethyl ether and air-dried. Yield 247 mg (86%).

Preparation of $[M(COD)(LH_2)][M(Cl)_2(COD)]$ *complexes*

The $[M(COD)(LH_2)][M(Cl)_2(COD)]$ complexes were prepared by similar methods. In a typical procedure, $[Rh(\mu\text{-Cl})(COD)]_2$ (60 mg, 0.12 mmol) was added to a solution of LH_2 (50 mg, 0.12 mmol) in dichloromethane and the solution was left to react for 15 min. The solution was concentrated and addition of hexane gave a yellow precipitate which was filtered off, washed with hexane and air-dried. Yield 62 mg (58%).

Preparation of $[Rh(CO)_2(LH_2)][Rh(Cl)_2(CO)_2]$

$[Rh(\mu\text{-Cl})(CO)_2]_2$ (40 mg, 0.1 mmol) was added to a solution of LH_2 (42 mg, 0.1 mmol) in dichloromethane. The solution was left to react for 30 min, after which the solution was concentrated and addition of hexane gave a yellow precipitate which was filtered off, washed with hexane and air-dried. Yield 57 mg (70%).

RESULTS AND DISCUSSION

Reaction of *Z-N*-phenyl, *β*-amino-4-methylstyryldiphenylphospha-1 λ^5-azene (LH_2) with $[M(\mu\text{-OMe})(COD)]_2$ (M = Rh, Ir) leads to the formation of the chelated amide complexes M(LH)(COD), according to the following equation:

$$[M(\mu\text{-OMe})(COD)]_2 + 2LH_2 \rightarrow 2M(LH)(COD) + 2MeOH.$$

As we have previously reported,[7] the methoxy dimers are good starting materials for the preparation of amide complexes via deprotonation of an amine ligand.

Treatment of M(LH)(COD) with carbon monoxide gives the $M(LH)(CO)_2$ complexes as can be deduced by the presence of two metal carbonyl bands of approximately equal intensity in the IR spectra, typical of *cis*-dicarbonylated complexes [$\nu(C{\equiv}O)$: 1990, 2060 cm^{-1} (M = Rh); 1965, 2040 cm^{-1} (M = Ir)]. The $M(LH)(CO)_2$ complexes have not been isolated due to their solubility in aprotic solvents. Reaction of $M(LH)(CO)_2$ with PPh_3 leads to the displacement of one CO ligand and subsequent formation of $M(LH)(CO)(PPh_3)$.

IR spectra (Table 1) show the presence of ν(N—H) bands from the deprotonated ligand and ν(P=N) bands in the region 1102–1110 cm^{-1} corresponding to the phospha-λ^5-azene group, whose frequency drops to around 200 cm^{-1} confirming the coordination of the P=N group as a two electron

nitrogen donor.[16,17-18] Furthermore, molecular weight measurements on the complexes in chloroform solution by vapour pressure osmometry confirm the mononuclear formulation.

The $[M(COD)(LH_2)]ClO_4$ (M = Rh, Ir) complexes are obtained by reaction of LH_2 with $[M(COD)(acetone)_x]ClO_4$, prepared *in situ* by reacting $[M(\mu\text{-Cl})(COD)]_2$ with $AgClO_4$ in acetone. $[Rh(COD)(LH_2)]ClO_4$ reacts with carbon monoxide to give $[Rh(CO)_2(LH_2)]ClO_4$, which on treatment with PPh_3 leads to the formation of $[Rh(CO)(PPh_3)(LH_2)]ClO_4$. The coordinated amine group ($-NH_2$) in $[Rh(CO)_2(LH_2)]ClO_4$ can be easily deprotonated by treatment with a methanol solution of potassium hydroxide leading to the amide complex $Rh(LH)(CO)_2$; this reaction can be reversed by addition of perchloric acid, according to the following equation:

$$[Rh(CO)_2(LH_2)]ClO_4 \underset{HClO_4}{\overset{KOH/MeOH}{\rightleftharpoons}} Rh(LH)(CO)_2.$$

Reaction of $[M(\mu\text{-Cl})(COD)]_2$ (M = Rh, Ir) with LH_2 in dichloromethane results in the formation of the ionic pair $[M(COD)(LH_2)][M(Cl)_2(COD)]$. Similarly reaction of $[Rh(\mu\text{-Cl})(CO)_2]_2$ with LH_2 in dichloromethane gives $[Rh(CO)_2(LH_2)][Rh(Cl)_2(CO)_2]$. The latter complex can also be obtained by treatment of $[Rh(COD)(LH_2)][Rh(Cl)_2(COD)]$ with carbon monoxide. It shows four metal carbonyl bands in the IR spectrum corresponding to $[Rh(CO)_2(LH_2)]^+$ (ν(C≡O) = 2020, 2085 cm^{-1}) and $[Rh(Cl)_2(CO)_2]^-$ (ν(C≡O) = 1990, 2070

cm^{-1}).[19–21] These reactions are analogous to that found with chelating bidentate nitrogen donor ligands,[19–21] and support the tendency of this ligand to act as a chelate due to the stability conferred by the formation of a six membered ring with a π electronic delocalization. Analytical and physical data for the ionic complexes are given in Table 2.

THE ^{1}H NMR SPECTRA OF 8-QUINOLINOLATO COMPLEXES OF Mn(III)

PHILIPPA ADDY, DENNIS F. EVANS* and QUERO DE SOUZA

Inorganic Chemistry Laboratories, Imperial College of Science and Technology, London SW7 2AY, U.K.

(*Received* 28 *April* 1987; *accepted* 27 *May* 1987)

Abstract—^{1}H NMR spectra are reported for *tris*(8-quinolinolato)manganese(III), *tris*(2-methyl-8-quinolinolato)manganese(III) and mixtures of *tris*(acetylacetonato)manganese(III) and *tris*(8-quinolinolato)manganese(III). In the latter case, mixed complexes are formed in equilibrium, with only one of the three possible isomers of acetylacetonato *bis*(8-quinolinolato)manganese(III) being present in detectable amounts. The spectra were assigned making extensive use of selective deuteriation.

There has been considerable interest recently in complexes of Mn(III), partly because a number of enzymes contain manganese in this oxidation state.[1] One technique for studying Mn(III) complexes is ^{1}H NMR spectroscopy. Although a number of low-spin porphyrin complexes have recently been characterized,[2,3] and the low-spin $Mn(CN)_6^{3-}$ anion has been known for some considerable time, the great majority of Mn(III) complexes are high-spin.[4] Species of this type which have been studied by ^{1}H NMR spectroscopy include those with β-diketones,[5,6] tropolones,[7] porphyrins,[8–10] and some sulphur-bonding ligands.[11] In general, the ^{1}H NMR resonances have moderate bandwidths.

The present work is concerned with the ^{1}H NMR spectra of complexes derived from 8-quinolinol (8-hydroxyquinoline), i.e. *tris*(8-quinolinolato)manganese(III), $Mn(hq)_3$, *tris*(2-methyl-8-quinolinolato)manganese(III) and 8-quinolinolatoacetylacetonato mixed species. The rather complex spectra were assigned with the extensive use of selective deuteriation.

EXPERIMENTAL

Trisacetylacetonato manganese(III) ($Mn(acac)_3$). This was prepared by the method of Bhattacharjee and Chaudhuri.[12]

$Mn(hq)_3$[13]—To a solution of $Mn(acac)_3$ (0.89 g, 0.0025 mol) in ethanol (30 cm^3) was added 8-quinolinol (1.45 g, 0.01 mol) dissolved in ethanol (20 cm^3). After 1 h at *ca.* 4°C, the crystals were filtered off, washed with ethanol and dried *in vacuo*. The coordinated ethanol[14] was finally removed by heating at 170–180°C for 1 h. Yield 0.92 g (75%). The deuteriated complexes were prepared similarly, using a molar ratio 8-quinolinol-d_n: $Mn(acac)_3$ of 3.5 : 1.

Tris(2-*methyl*-8-*quinolinolato*)*manganese*(III). This was prepared as described by Burns *et al.*[14] or from $Mn(acac)_3$ and excess 2-methyl-8-quinolinol in ethanol.

Selective ring deuteriation of 8-*quinolinol*

Except where otherwise stated, materials were sealed in glass tubes of appropriate wall-thickness in an Ar atmosphere, and the selectivity of deuteriation was $\geqslant$ 90%.

8-*quinolinol*-$d_{5,7}$. 8-quinolinol (1 g, 6.9×10^{-3} mol), D_2O (5 cm^3) and *either* triethylamine (0.5 cm^3, 3.5×10^{-3} mol) *or* NaOD (0.14 g, 3.5×10^{-3} mol) were heated at 100°C for 24 h. The solution was saturated with CO_2, the solid filtered off, washed with H_2O, and dried *in vacuo* over $CaCl_2$. Yield 0.72 g (70%).

To distinguish between the five and seven positions, 8-quinolinol (0.5 g), 38% DCl (2.4 cm^3) and D_2O (2.4 cm^3) were heated in a screw-top vial at *ca.* 95°C for 48 h. The ^{1}H NMR spectrum of the solution after dilution with an equal volume of D_2O showed that the ratio $[H_7]/[H_5]$ was *ca.* 2.3, with the other ring protons being unaffected. The solution

* Author to whom correspondence should be addressed.

was made slightly alkaline with $NaOH_{aq}$ and the product isolated as above. Yield 0.36 g (70%).

8-*quinolinol*-$d_{2,5,7}$. 8-quinolinol (0.6 g) and D_2O (5 cm^3) were heated at 218°C for 24 h. After cooling, the solid was filtered off and dried as above. Yield 0.43 g (70%).

8-*quinolinol*-$d_{2,3,4,5,6,7}$. 8-quinolinol HCl (0.7 g, obtained by adding HCl gas in diethyl ether to a solution of 8-quinolinol in diethyl ether) and D_2O (12 cm^3) were heated at 255°C for 4–6 days. After cooling, $NaHCO_3$ (0.4 g) dissolved in a little water was added to precipitate the product. Yield 0.36 g (62%).

The largest amount of residual protium was at the six position.

To characterize H_6 further, Na (0.17 g, 7.4×10^{-3} mol) was added in portions to D_2O (5 cm^3) with cooling and in an Ar atmosphere, followed by 1.0 g (6.9×10^{-3} mol) of 8-quinolinol. The mixture was heated in a rocking stainless steel bomb under Ar for *ca.* 1 h at *ca.* 200°C. The contents were diluted with a little H_2O, filtered to remove some debris caused by attack on the stainless steel, and the filtrate adjusted with HCl_{aq} to pH 7. Yield 0.62 g (60%). The ^1H NMR spectrum showed that all ring protons were largely deuteriated, with the exception of H_6.

To distinguish between H_3 and H_4, a solution similar to that used to prepare 8-quinolinol-$d_{2,3,4,5,6,7}$ was heated at 250–255°C for 24 h only. The ^1H NMR spectrum (DCl solution) of the deuteriated product so obtained showed that the ratio $[H_4]/[H_3]$ was *ca.* 3.5.

8-*quinolinol*-$d_{2,3,4,6}$. 8-quinolinol-$d_{2,3,4,5,6,7}$ (0.4 g), H_2O (10 cm^3) and NaOH (0.11 g) were heated at 100°C for 24 h and the product isolated as for 8-quinolinol-$d_{5,7}$.

$2CD_3$-8-*quinolinol*-$d_{5,7}$. The preparation was similar to that for 8-quinolinol-$d_{5,7}$, using NaOD and $2CH_3$-8-quinolinol. In addition to H_5 and H_7, the CH_3 group was almost completely deuteriated. Yield 85%.

Mn(acac-d_1)$_3$. Acetylacetone (1.1 g) dissolved in D_2O (10 cm^3) was left overnight. Finely powdered AnalaR $KMnO_4$ (0.25 g) was added with vigorous stirring. After 10 min the crystals were filtered off, washed with water and dried *in vacuo*. Yield 0.4 g. ^1H NMR and mass spectroscopy showed that the isotopic purity was *ca.* 85%.

Mn(acac-d_6)$_3$. Acetylacetone-d_8[15] (1.2 g) dissolved in H_2O (10 cm^3) was left overnight, and the procedure for Mn(acac-d_1)$_3$ was then followed. The isotopic purity was *ca.* 93%.

The ^1H NMR spectra of the manganese complexes were measured at 250 MHz on a Bruker WM-250 FT spectrometer, and the deuteriated 8-quinolinols similarly or at 90 MHz on a Perkin–Elmer R32 spectrometer.

RESULTS AND DISCUSSION

The ^1H NMR spectrum of Mn(hq)$_3$ is shown in Fig. 1, and indicates that the complex exists as the meridional isomer, since in the facial isomer all three rings are equivalent. The *mer* configuration is also found in the solid state for Mn(hq)$_3$[16] and Cr(hq)$_3$[17] from X-ray studies, and for Al(hq)$_3$,[18,19] Ga(hq)$_3$,[19] Co(hq)$_3$[18] and Rh(hq)$_3$[18] from ^1H NMR spectroscopy. The spectrum was assigned by studying deuteriated samples of Mn(hq)$_3$, prepared from 8-quinolinol which had been selectively deuteriated in all six ring positions. The ^1H NMR spectrum[20] of 8-quinolinol in $CDCl_3$ solution (220 MHz) shows some overlap of the ring resonances. However, by

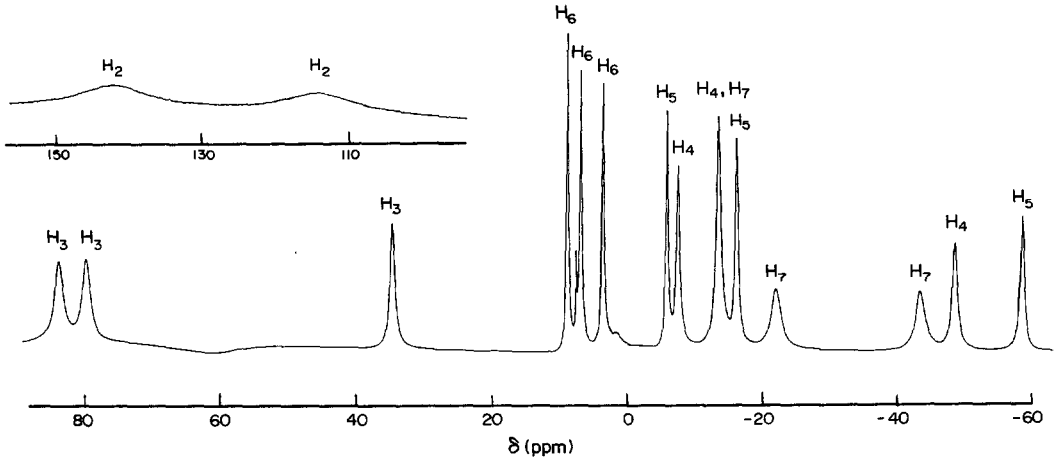

Fig. 1. The ^1H NMR spectrum of Mn(hq)$_3$ in $CDCl_3$ at 301 K.

using, where necessary, solutions in D_2O containing NaOD or DCl, complete resolution could be obtained even at 90 MHz. Standard techniques for the deuteriation of aromatic compounds were used,[21,22] i.e. heating 8-quinolinol with D_2O under neutral, acid or alkaline conditions (see Experimental Section). Since the ^{1}H NMR spectrum of a deuteriated 8-quinolinol was compared with that of the complex prepared from it, highly selective deuteriation was not required. In the present work, the minimum value for $[H_x]/[H_y]$, where x and y are two positions to be distinguished, was greater than 2, although smaller ratios would have been adequate.

Table 1 presents the observed chemical shifts. The only omission is one resonance from H_2, which could not be located. It can be seen that the chemical shifts for the three rings vary greatly, with two resonances for each proton lying close together, and the third considerably up-field. This could be explained by a large pseudo-contact contribution. However, for other Mn(III) complexes the general conclusion is that pseudo-contact shifts are comparatively small[5,9] and it seems more likely that the observed variations are largely due to differing σ- and π-delocalization of the metal d electrons onto the ligands.[23]

The linewidths of the proton resonances vary greatly (Fig. 1). Two coupling mechanisms can contribute to the linewidths, dipolar broadening (proportional to r^{-6}, where r is the distance between the manganese nucleus and the proton) and scalar broadening. Calculations using a molecular model suggest that the linewidths are largely, though not entirely, governed by the dipolar mechanism. This is also found for other Mn(III) complexes,[9] and can enable probable assignments to be made in the absence of selective deuteriation experiments.

The ^{1}H NMR spectrum of *tris*(2-methylquinolinolato)manganese(III) could be largely assigned [in conjunction with that for $Mn(hq)_3$] from the line positions and widths. An ambiguity concerning H_4 and H_5 was resolved by measuring the spectrum of the complex obtained from $2CD_3$-8-quinolinol-$d_{5,7}$ which also enabled two partly overlapped CH_3 resonances to be located unambiguously. The results are given in Table 1.

Mixed 8-quinolinolato-acetylacetonato manganese(III) *complexes*

Figure 2 shows the ^{1}H NMR spectrum of a solution prepared from $Mn(hq)_3$ and $Mn(acac)_3$. From the complexity of the spectrum it is clear that ligand

exchange has occurred to give mixed complexes in equilibrium with $Mn(hq)_3$ and $Mn(acac)_3$ (δ CH_3 25.2 ppm, δ CH 18.2 ppm). A solid analysing as $Mn(acac)(hq)_2$ has been reported by Yamaguchi and Sawyer.[24] The possible isomers for $Mn(acac)_2hq$ and $Mn(acac)(hq)_2$ are shown in Table 2 together with the number of resonances expected for each isomer. To assign the spectrum shown in Fig. 2, the ^1H NMR spectra of $Mn(acac)_3$, $Mn(acac\text{-}d_1)_3$ (deuteriated in the CH groups), $Mn(acac\text{-}d_6)_3$ (deuteriated in the CH_3 groups), $Mn(hq\text{-}d_6)_3$ and $Mn(hq\text{-}d_{2,3,4,6})_3$ were studied in various combinations. By a comparison of the three spectra obtained from $Mn(hq\text{-}d_6)_6$ mixed with $Mn(acac)_3$, $Mn(acac\text{-}d_1)_3$ and $Mn(acac\text{-}d_6)_3$, all the CH_3 resonances in the mixed complexes could be characterized. It was only possible to locate one acac CH resonance of a mixed complex (at $\delta = 28.4$ ppm), with the other presumably being overlapped. The spectrum of a mixture of $Mn(acac\text{-}d_6)_3$ and $Mn(hq\text{-}d_{2,3,4,6})_3$ enabled the H_5 and H_7 resonances in the mixed complexes to be picked out and confirmed that only one of the three possible isomers of $Mn(acac)(hq)_2$ was present in any detectable amount, i.e. either isomer *A* or *B*. The H_5 and H_7 resonances were distinguished by their relative linewidths (see above).

Resonances from the two mixed isomers $Mn(acac)_2hq$ and $Mn(acac)(hq)_2$ could be distinguished on intensity grounds. For a solution initially equi-

Table 2. Possible isomers of $Mn(acac)_2hq$ and $Mn(acac)(hq)_2$ and expected ^1H NMR spectra

		Expected resonances	Relative intensity
$Mn(acac)_2hq$			
		4 CH_3	3
		2 CH(acac)	1
		6 hq	1
$Mn(acac)(hq)_2$			
A		1 CH_3 1 CH 6 hq	6 1 2
B		1 CH_3 1 CH 6 hq	6 1 2
C		2 CH_3 1 CH 12 hq	3 1 1

molar in $Mn(acac)_3$ and $Mn(hq)_3$, we have $[Mn(acac)_2hq] = [Mn(acac)(hq)_2]$. As confirmation, some spectra were recorded with different initial ratios of $Mn(acac)_3$ and $Mn(hq)_3$ or deuteriated analogues.

A number of other hq resonances in the mixed complexes could be tentatively assigned on the basis of their line positions and widths. The final assignments are given in Fig. 2 and Table 1. Quantitative intensity measurements showed that in the equilibrium $Mn(acac)_3 + Mn(hq)_3 \rightleftharpoons Mn(acac)_2hq + Mn(acac)(hq)_2$, the mixed complexes were favoured. In a solution initially 0.05 M in both $Mn(acac)_3$ and $Mn(hq)_3$, the ratio of the concentrations of the mixed isomers to those of $Mn(acac)_3$ and $Mn(hq)_3$ was *ca.* 1.6.

(*Received* 5 *May* 1987; *accepted* 2 *June* 1987)

Abstract—A new bidentate ligand {2-(diphenylphosphino)ethyl}benzylamine (DPEBA) was synthesized and characterized based on the IR, mass and ^{1}H, ^{13}C and ^{31}P NMR spectra. Various complexes of platinum group metal ions and Ni(II) and Co(II) ions with the ligand were synthesized. Reaction of $RuCl_2(PPh_3)_3$ or $RuCl_2(Me_2SO)_4$ with the ligand DPEBA, resulted in formation of a penta-coordinate, Ru(II) species of the composition $[RuCl(DPEBA)_2]Cl$. Carbonylation of $[RuCl(DPEBA)_2]Cl$ gave an octahedral carbonyl complex of the type $[RuCl(CO)(DPEBA)_2]Cl$. The reaction of $RuCl_3 \cdot 3H_2O$ or $RuCl_3(AsPh_3)_2MeOH$ with a twofold excess of the ligand gave an octahedral Ru(III) cationic species $[Ru(DPEBA)_2Cl_2]Cl$. Carbonylation of the Ru(III) complex gave rise to a carbonyl complex $[RuCl(CO)(DPEBA)_2]Cl_2$. The ligand DPEBA reacts with cobalt(II) chloride in methanol to give the 1 : 1 complex $[Co(DPEBA)Cl_2]$. A series of Rh(I) complexes $[Rh(DPEBA)_2Cl]$, $[RhCl(CO)(DPEBA)]$ and $[Rh(DPEBA)_2]Cl$ were synthesized by the reaction of DPEBA with $RhCl(PPh_3)_3$, $RhCl(CO)(PPh_3)_2$ and $[Rh(COD)Cl]_2$, respectively. Reaction of $[Ir(COD)Cl]_2$ and $IrCl(CO)(PPh_3)_2$ with the ligand DPEBA, gave the square-planar complexes $[Ir(DPBA)_2]Cl$ and $[Ir(DPEBA)(CO)Cl]$, respectively. Octahedral cationic complexes of the type $[M(DPEBA)_2Cl_2]Cl$ (M = Rh(III), Ir(III)) were synthesized by the reaction of the ligand DPEBA and rhodium and iridium trichlorides. Reaction of $NiCl_2 \cdot 6H_2O$ with DPEBA in 1 : 2 molar equivalents, in boiling butanol gave an octahedral neutral complex $[Ni(DPEBA)_2Cl_2]$ which readily rearranges to the square-planar complex $[Ni(DPEBA)_2]Cl_2$ in methanol. Reaction of Pd(II) and Pt(II) chlorides with DPEBA gave square-planar, cationic complexes of the type $[M(DPEBA)_2Cl]Cl$ (M = Pd, Pt). All the complexes were characterized on the basis of their analytical and spectral data.

Recently we have synthesized transition metal complexes of bi- and poly-dentate ligands[1–4] containing mixed donor atoms like N, P, As and O, because of their increasing importance in the area of catalysis.[5–7] Bidentate ligands with one weak and one strong donor site have been a subject matter of many reports.[8] These ligands can act both as chelating ligands as well as bridging ligands with metal ions and readily provide a coordination site for the incoming substrates by the displacement of the weak donor atom. This factor, the susceptibility of the weak donor site to displacement by the incoming substrate along with the stability of the catalyst precursor in the absence of the substrate by chelate effect, has a tremendous utility in the field of homogeneous catalysis.[9–11]

In this paper we report the synthesis of one such

* Author to whom correspondence should be addressed.

ligand {2-(diphenylphosphino)ethyl}benzylamine (DPEBA) which contains a set of mixed donor atoms N and P. This ligand has been synthesized and characterized by ^{1}H, $^{13}C\{^{1}H\}$ and $^{31}P\{^{1}H\}$ NMR spectra and mass spectra. The ligand DPEBA was used in the synthesis of Ni(II), Co(II) and platinum group metal complexes which were characterized by analytical and spectral data.

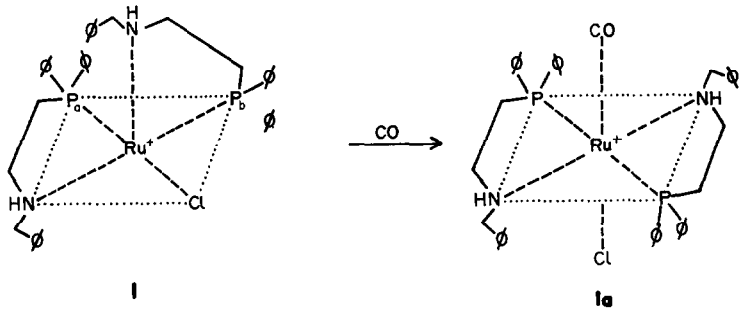
RESULTS AND DISCUSSION

The mixed donor bidentate ligand DPEBA is soluble in almost all organic solvents. The infrared spectrum of the ligand exhibits a characteristic ν(N—H) at 3300 cm^{-1} and a band of the quaternary ammonium salt was observed at 2800 cm^{-1} in addition to the other ligand absorptions.

The ^{1}H NMR spectrum of DPEBA, exhibits resonances from the phenyl protons around δ 7.5. The resonance of the protons of the CH_2CH_2 bridge are observed as multiplets centred at δ 2.8 (CH_2 protons attached to amine centre) and δ 4.2 (-CH_2 protons attached to diphenylphosphino group), due to the interaction of the neighbouring methylene protons and also by the ^{31}P nuclear spin. Two singlets at δ 3.5 and δ 1.7 were assigned to the CH_2 protons of the benzyl group and the N—H proton, respectively. The $^{31}P\{^{1}H\}$ NMR spectrum of the ligand exhibits a singlet at δ −19.3 in $CHCl_3$. The $^{13}C\{^{1}H\}$ NMR spectrum of DPEBA exhibits two well defined doublets at δ 48.3 and δ 22.5. The more downfield doublet is assigned to the methylene carbon of the CH_2CH_2 bridge attached to phosphorus, with larger $^{1}J(C—P) = 30.5$ Hz and the other doublet with $^{2}J(C—P) = 17.1$ Hz, can be assigned to the methylene carbon attached to nitrogen. A singlet at δ 56.7 is assigned to the methylene carbon CH_2 of the benzyl group. Two well defined multiplets in the range δ 129.4–131.4 are assigned to the aromatic carbons of the diphenylphosphino moiety and the phenyl of the benzyl group. The mass spectral fragmentation of the ligand DPEBA is presented in the experimental section and shows general features similar to those reported earlier on some polytertiary phosphines, arsines and phosphinoarsines[12,13] and confirms the above formulation of the ligand.

Metal complexes of the ligand DPEBA

Ru(II) *and* (III) *complexes of DPEBA*. The reaction of $RuCl_2(PPh_3)_3$ or $RuCl_2(Me_2SO)_4$ with the ligand DPEBA in 1 : 2 molar ratio gave rise to the five-coordinate, cationic Ru(II) species [RuCl(DPEBA)$_2$]Cl (**1**). Complex **1** exhibits conductivity consistent with a 1 : 1 electrolyte[14] (Table 1). A band at 310 cm^{-1} in the far-infrared spectrum is assigned to ν(Ru—Cl). Complex **1** can exist in square-pyramidal or trigonal-bipyramidal geometries. The $^{31}P\{^{1}H\}$ NMR spectrum of **1** is however consistent with a square-pyramid geometry (structure **I**). The



I **Ia**

^{31}P NMR spectrum exhibits two doublets at δ 45.9 and 42.9 (Table 2) indicating the presence of two magnetically non-equivalent phosphorus atoms. Based on this spectrum all the other isomers with equivalent phosphorus atoms can be ruled out as they would give rise to a singlet. The other trigonal-bipyramidal isomer where one of the phosphorus atoms lies in the equatorial plane and the other in an axial plane can also be excluded on the basis of the chemical shift values. In this isomer one expects a large chemical shift difference between the two ^{31}P resonances.[2] Based on the chemical shift values a square-pyramidal geometry in which one of the phosphorus atom is *trans* to Cl (doublet at δ 45.9) and the other *trans* to N (doublet at δ 42.9) can be proposed for the complex (Structure **I**). The $J(P_a–P_b)$ value of 39 Hz is also typical for the coupling constant of non-equivalent phosphorus nuclei *cis* to one another in ruthenium(II)-tertiary phosphine complexes.[15,16]

Carbonylation of complex **1** yielded an octahedral carbonyl species [Ru(DPEBA)Cl(CO)]Cl **1a**. Complex **1a** is a 1 : 1 electrolyte (Table 1) and exhibits an intense CO infrared absorption band at 1940 cm^{-1}. The $^{13}C\{^{1}H\}$ NMR spectrum displays a sin-

Table 1. Analytical and other physical data for metal complexes

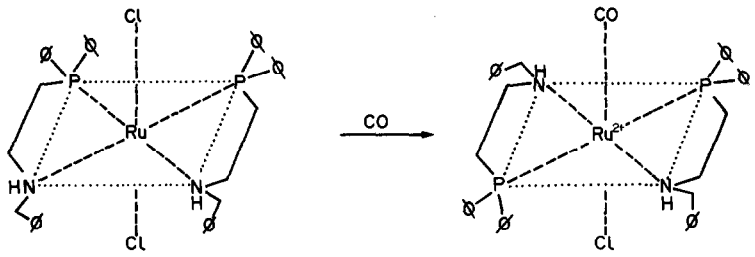
[c] Found values are given in parentheses.

glet at δ 196.2 indicative of a coordinated carbonyl group. The $^{31}P\{^1H\}$ NMR spectrum of **1a** exhibits a singlet at δ 20.3 which is typical of the presence of *trans* phosphorus atoms (Structure **Ia**).

Interaction of $RuCl_3(AsPh_3)_2MeOH$ or $RuCl_3 \cdot 3H_2O$ with the ligand DPEBA in 1 : 2 molar equivalents resulted in the formation of the cationic Ru(III) complex $[Ru(DPEBA)_2Cl_2]$ (**2**). Complex **2** is a 1 : 1 electrolyte (Table 1) and exhibits a magnetic moment of 1.98 μ_B corresponding to one unpaired electron as expected for a low-spin, Ru(III) species. The *trans* coordination of the chloride is indicated by the presence of a single (Ru—Cl) band at 326 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum of **2** exhibits a rather broad singlet at δ 37.2 due to the paramagnetic nature of the complex. Based on the ^{31}P chemical shift value an octahedral geometry in which the phosphorus atoms of the ligand DPEBA lie *cis* to each other is proposed (Structure **II**).

Carbonylation of **2** in MeOH–CH_2Cl_2 solvent gave the carbonyl complex $[RuCl(CO)(DPEBA)_2]Cl_2$ (**2a**) by the displacement of one of the chlorines present in **2**. Complex **2a** is a 1 : 2 electrolyte (Table 1) and its infrared spectrum gave the ν(CO) band at 1940 cm^{-1}. The $^{13}C\{^1H\}$ NMR spectrum of **2a** exhibits the resonance of CO at δ 208.0. The $^{31}P\{^1H\}$ NMR spectrum of **2a** exhibits a more upfield broad singlet at δ 20.2 indicating a *trans* geometry for the two coordinated phosphorus atoms of the ligands (Structure **IIa**) unlike that of **2** where the phosphorus atoms are *trans* to a N donor group. The magnetic susceptibility of com-



II IIa

plex **2a** gave a value of 1.95 μ_B corresponding to a low spin t_{2g}^5 Ru(III) complex. The oxidation state of ruthenium (+3) in the complex is also supported by the further downfield shift of the CO resonance at δ 208.0 indicative of a weaker Ru(III)—CO bond.

Co, Rh and Ir complexes of DPEBA. The reaction of $CoCl_2 \cdot 6H_2O$ and DPEBA in refluxing methanol, gave the greenish-blue, neutral, high-spin complex $[CoCl_2(DPEBA)]$ (**3**). The complex is a non-electrolyte (Table 1), with chlorides coordinated to the metal ion as evidenced by the presence of ν(Co—Cl) at 366 and 322 cm^{-1}. The electronic spectrum of **3** in dichloromethane is consistent with a tetrahedral geometry. The band at 707 nm in the visible region is assigned to the $^4A_2(F) \rightarrow {}^4T_1(P)(\nu_3)$ transition,[17] which is split into a number of components indicating a considerable deviation from the T_d symmetry. The magnetic moment, 4.41 μ_B also corroborates a tetrahedral, high spin, cobalt(II) species, with paramagnetism nearer to the spin-only value.[18,19] No $^{31}P\{^1H\}$ signal for complex **3** was obtained. Based on the above spectral data a tetrahedral geometry is proposed for complex **3**.

The reaction of the ligand DPEBA with $RhCl(PPh_3)_3$, $[RhCl(COD)]_2$ and $[IrCl(COD)]_2$

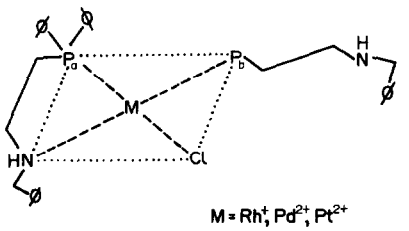
[c] See the text.

resulted in the formation of $[Rh(DPEBA)_2Cl]$ **4**, $[Rh(DPEBA)_2]Cl$ **5** and $[Ir(DPEBA)_2]Cl$ **6**, respectively. Complex **4** is a non-electrolyte, whereas **5** and **6** are 1 : 1 electrolytes (Table 1). A band at 330 cm^{-1} in the IR spectrum of **5** is assigned to ν(Rh—Cl).

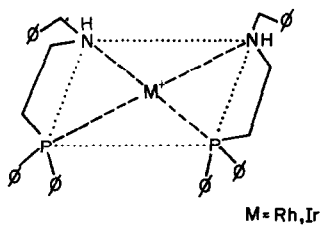
The $^{31}P\{^1H\}$ NMR spectrum of **4** displays an AMX type of spectrum with a pair of doublets of doublets (Table 2) indicating the presence of two non-equivalent phosphorus atoms and also suggests that one of the ligands DPEBA, which is potentially bidentate, is coordinated to the metal ion through its phosphorus donor atom only and the other donor atom N being free as shown in Structure **III**.



III

Based on the chemical shift, the doublet of doublets at δ 34.7 can be attributed to the phosphorus atom (P_a) *trans* to Cl and the other doublet of doublets at δ 21.0 is assigned to the phosphorus atom (P_b) of the unidentate DPEBA. The larger downfield chemical shift δ 20 of P_a in comparison to P_b is due to the involvement of P_a in a five-membered ring and also the *trans* disposition to Cl.[20] The $^1J(Rh—P_a)$ and $^1J(Rh—P_b)$ coupling constant values of about 115 Hz and the $^2J(P_a—P_b)$ of 25 Hz are in agreement with the earlier reported work[21] and confirm the square-planar geometry as shown in (**III**).

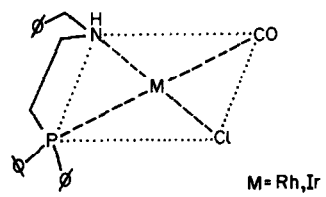
The $^{31}P\{^1H\}$ NMR spectra of complexes **5** and **6**, however, display doublets at δ 52.7 (with $^1J(Rh—P) = 154$ Hz) for complex **5** and a singlet at δ −22.04 for complex **6** (Table 2). The ^{31}P NMR spectral data of **5** and **6** support the coordination of all the donor atoms to the metal ions with *cis* phosphorus as shown in **IV**.



IV

Complex [RhCl(CO)(DPEBA)] **7** and [IrCl(CO)(DPEBA)] **8** were synthesized by the interaction of one equivalent of the ligand DPEBA with the complexes $MCl(CO)(PPh_3)_2$ (M = Rh, Ir). Complexes **7** and **8** exhibit intense infrared absorptions at 1970 and 2020 cm^{-1} respectively, indicative of the coordinated CO. The ν(Rh—Cl) and ν(Ir—Cl) are observed at 348 and 325 cm^{-1} in complexes **7** and **8**, respectively.

The $^{31}P\{^1H\}$ NMR spectra (Table 2) displays a doublet at δ 27.7 for complex **7** with $^1J(Rh—P) = 126$ Hz and a singlet at δ −7.2 for complex **8**, respectively. A square-planar geometry with phosphorus either *trans* to Cl or CO can therefore be proposed. However the chemical shift values suggest that the phosphorus is *trans* to a CO group[15] (Structure **V**).



V

The Rh(III) and Ir(III) complexes $[MCl_2(DPEBA)_2]Cl$ (M = Rh **9**, Ir **10**) show conductance values indicative of 1 : 1 electrolytes. The ν(Rh—Cl) and ν(Ir—Cl), in **9** and **10** are observed at 310 and 340 cm^{-1}, respectively. The $^{31}P\{^1H\}$ NMR spectra of **9** and **10** exhibits a doublet at δ 8.7 with $^1J(Rh—P) = 86$ Hz and a singlet at δ −22.9, respectively. An octahedral geometry with a *cis* disposition of phosphorus atoms and *trans* chlorides is proposed for **9** and **10**.

The $^{31}P\{^1H\}$ NMR data (Table 2) of complexes **4**, **5**, **7** and **9** reveal the fact that the $^1J(Rh—P)$ of Rh(I) complexes are larger than the $^1J(Rh—P)$ coupling values of Rh(III) complexes as was observed earlier.[22] The $^1J(Rh—P)$ in Rh(I) complexes are of the order 115–154 Hz whereas it is around 86 Hz in the Rh(III) complex. The ^{31}P NMR chemical shifts of coordination complexes are generally observed downfield as compared to that of the free ligand due to the strong σ-donor bond from phosphorus to metal with a small d_π–d_π back donation. However in the case of iridium complexes **6**, **8** and **10** the chemical shift (δ) values are observed at higher field values particularly for the complexes **6** and **10** where the chemical shifts are observed at δ −22.0 and −22.9 respectively.

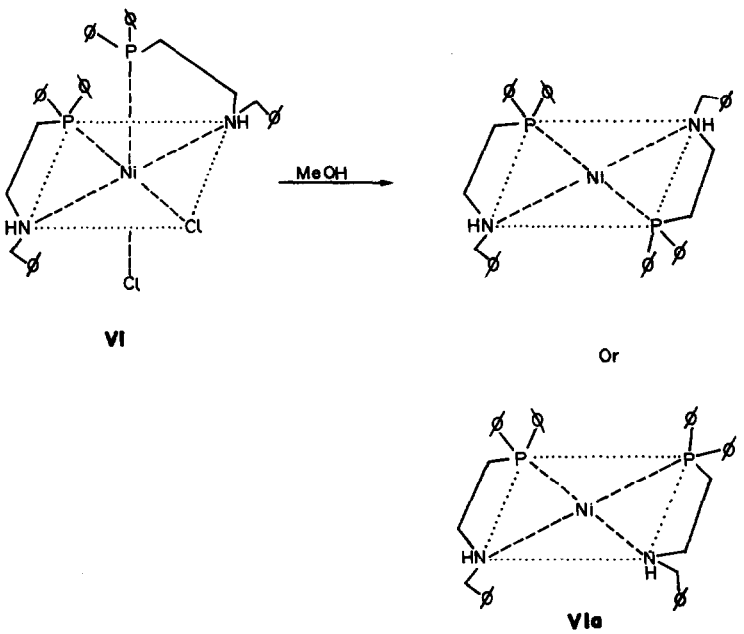
The $^{31}P\{^1H\}$ chemical shifts of the third transition series of elements are usually close to the free ligand value or at values more upfield to that of the free ligand.[23] The upfield shift in the δ values can be accounted in terms of a weak metal phosphorus σ-bond and a strong metal to ligand d_π–d_π back bonding interaction.[24,25]

Ni(II), Pd(II) *and* Pt(II) *complexes of DPEBA.* The reaction of $NiCl_2 \cdot 6H_2O$ with the ligand DPEBA in boiling butanol gave a deep blue, neutral, octahedral 1 : 2 complex $[Ni(DPEBA)_2Cl_2]$ (**11**). The presence of a ν(Ni—Cl) band at 321 cm^{-1} is due to the *trans* chlorides.

The electronic spectrum of **11** in acetone displays three bands at 635, 560 and 325 nm, which are assigned to $^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions, respectively, characteristic of an octahedral, Ni(II) species. When complex **11** is dissolved in methanol the deep-blue colour of the complex rapidly changes to a bright red colour and the electronic spectrum of this solution exhibits a single absorption band at 414 nm, which can be attributed to a square-planar Ni(II) species **11a** derived from a change of the octahedral Ni(II) geometry to a diamagnetic square-planar geometry. The change from **11** to **11a** can be brought about by slow addition of methanol to the acetone solution **11** and observe the decrease in the intensities of the peaks in the UV-Vis spectrum at 635, 560 and 325 nm and simultaneously the increase in the intensity of 414 nm. This change is further corroborated by studying the conductivity (Table 1) and $^{31}P\{^1H\}$ NMR of **11** and **11a**. The complex **11** is neutral, whereas **11a** is a 1 : 2 electrolyte. The $^{31}P\{^1H\}$ NMR spectrum of **11** in acetone at room temperature does not give a well resolved spectrum but at −30°C it gives a singlet at δ 62.3. This large chemical shift may be due to the disposition of the two phosporus atoms *trans* to Cl (Structure **VI**). The $^{31}P\{^1H\}$ NMR spectrum of **11a** in methanol displays a sharp singlet but at a much higher field of δ 29.18 when compared to that for **11**, suggesting the equivalence of the phosphorus atoms in either a *cis* or a *trans* configuration as shown in **VIa**. The square-planar complex **11a** is not converted back to **11** on the addition of acetone.

Interaction of K_2MCl_2 (M = Pd, Pt) with the ligand DPEBA in a 1 : 2 molar equivalents in water–acetone mixture give rise to cationic complexes of the type $[MCl(DPEBA)_2]Cl$ (M = Pd **12**; Pt **13**). The 1 : 1 electrolytic nature of these complexes and the presence of ν(M—Cl)[26] at 325 and 310 cm^{-1} in **12** and **13** support the configuration of the complexes **12** and **13** as shown above. The $^{31}P\{^1H\}$ NMR of both complexes **12** and **13** confirm the unidentate nature of one of the DPEBA ligands coordinated to the metal ion. The ^{31}P NMR spectrum of **12** exhibits two doublets at δ 47.3 and 13.0 indicating the presence of two non-equivalent phosphorus atoms. The doublet at δ 47.3 can be assigned to phosphorus atom (P_a) (Structure **III**) *trans* to Cl and associated in a five-membered ring.[27] The doublet at δ 13.0 can be assigned to the phosphorus atom (P_b) of the ligand DPEBA acting in a monodentate fashion with the nitrogen end free. The $J(P_a–P_b)$ value of 39.2 Hz is also typical of *cis*-phosphorus atoms and the square-planar geometry is assigned as shown in **III**.

The $^{31}P\{^1H\}$ NMR spectrum (Fig. 1) of complex **13** displays two doublets at δ 34.0 and −0.99 with ^{195}Pt satellites confirming the unidentate nature of



VI **VIa**

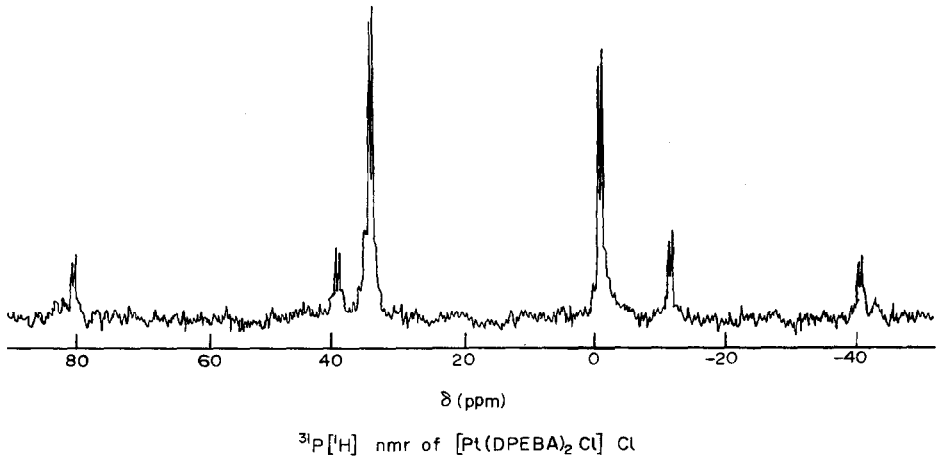


Fig. 1. $^{31}P\{^{1}H\}$ NMR spectrum of $[PtCl(DPEBA)_2]Cl$.

one of the two ligands DPEBA. The former doublet at δ 34.0 can be assigned to P_a of the ligand DPEBA involved in a five-membered ring(III) and the latter δ −0.99 to the P_b of the unidentate ligand. The $^{1}J(Pt—P_a)$ value of 3768 Hz and $^{1}J(Pt—P_b)$ of 3259 Hz are typical of a phosphine *trans* to chloride and *trans* to an amine, respectively.[28,29] The $^{2}J(P_a–P_b)$ of 18 Hz is also typical of mutually *cis* phosphines[29] as shown in (**III**).

The ^{31}P NMR chemical shifts (δ) (Table 2) of all the complexes reveal that there is a good correlation between the size of the metal ion and chemical shifts. In the group Co, Rh, Ir and Ni, Pd, Pt the coordination chemical shifts are largest for the first member of the triad and decreases in the order Co > Rh > Ir and similarly Ni > Pd > Pt as the size increases and electronegativity decreases. It was also observed that the chemical shift values decrease in the order Ru(III) > Rh(III) > Ir(III).

EXPERIMENTAL

The Ru(III), Ir(III) and Rh(III) trichloride trihydrates, K_2PdCl_4 and K_2PtCl_4 were obtained from Johnson Matthey (U.K.) or Alfa Inorganics (U.S.A.). The ligand triphenyl-phosphine was purchased from Strem Chemicals Inc. (U.S.A.). The complexes $RuCl_2(PPh_3)_3$,[30] $RuCl_2(Me_2SO)_4$,[31] $RuCl_3(AsPh_3)_2MeOH$,[27] $RhCl(PPh_3)_3$,[32] $RhCl(CO)(PPh_3)_2$,[33] $IrCl(CO)(PPh_3)_2$[33,34] and $[M(COD)Cl]_2$ (M = Rh, Ir[35]) were synthesized by published procedures. Ethanolamine, benzyl chloride and thionyl chloride were of Analar reagent grade and were used without further purification. All solvents used in this work were of reagent grade and were purified and dried before use. All the preparations were carried out under an atmosphere of nitrogen. Microanalysis, melting points, infrared spectra, conductivity and magnetic susceptibility measurements were done as reported.[36] Proton NMR spectra of the ligand DPEBA was recorded on a Bruker 270 MHz spectrometer in $CDCl_3$. The Carbon-13 NMR spectra of the ligand was recorded on a Jeol FX100 spectrometer operating at 24.99 MHz in $CDCl_3$ using TMS as an external reference. Phosphorus-31 NMR spectra of the ligand and complexes were taken in the indicated solvents (Table 2) with a Jeol FX100 spectrometer operating at 40.3 MHz in the Fourier transform mode with proton noise decoupling and a deuterium lock. The samples were placed in a 10 mm NMR tube and a capillary with deuterium oxide was placed in for the lock. Phosphoric acid (85%) was used as an external standard. The electronic spectra of complexes were measured on a Shimadzu UV240 spectrophotometer. Molecular weight and mass spectral measurements of the ligands were done as reported earlier.[2]

Microanalytical data, conductivity, melting point and magnetic susceptibility data of the ligand and complexes were presented in Table 1. The $^{31}P\{^{1}H\}$ NMR spectral data are presented in Table 2.

Synthesis of the ligand DPEBA. The new bidentate ligand {2-(diphenylphosphino)ethyl}benzylamine (DPEBA) was synthesized employing the reaction as shown in Scheme 1.

$$PhCH_2Cl + H_2NCH_2CH_2OH \xrightarrow[\text{ethanol}]{K_2CO_3} PhCH_2N(H)CH_2CH_2OH$$

a

$$\mathbf{a} \xrightarrow[\text{(ii) 10\% NaOH}]{\text{(i) } SOCl_2} PhCh_2N(H)CH_2CH_2Cl$$

b

$$\mathbf{b} + KPPh_2 \cdot 2diox \xrightarrow{1,4\text{-dioxane}} PhCH_2N(H)CH_2CH_2PPh_2$$

c

$$\mathbf{c} + HCl \xrightarrow{methanol} PhCH_2N(H)CH_2CH_2PPh_2 \cdot HCl$$

(Ph = C_6H_5, diox = dioxane)

The compound $PhCH_2N(H)CH_2CH_2OH$, **a** was prepared by the reaction of benzyl chloride (51.8 g, 0.41 mol) with ethanolamine (25.0 g, 0.41 mol) and potassium carbonate (29.5 g, 0.20 mol) in 100 cm^3 of absolute alcohol. The halide **b** was obtained[37] by the reaction of **a** with thionyl chloride in a 1 : 1 ratio in the form of a quaternary ammonium salt which on treatment with 10% NaOH gave the free amine **b** as an insoluble oil. A dioxane solution of the above oil (dried over Na_2SO_4 prior to its use) was added dropwise with stirring to an orange–red suspension of $KPPh_2$[38] in dioxane, in a stoichiometric amount under cold conditions (15–20°C). The reaction mixture was then allowed to reflux for 1 h. During the course of reaction a sharp decolouration of the orange–red colour occurred. The reaction contents were then poured into ice-water to get a crude oil **c** which was then separated and stirred with 2N HCl in 20 ml of methanol to get a white crystalline precipitate **d**. The ligand **d** was recrystallized from methanol–petroleum ether mixture with a yield of about 65%; m.p. 98–100°C; mol.wt. 355.5(calculated), 350(experimental, osmometric in chloroform). Found: C, 70.6; H, 6.4; N, 3.8. Calc. for $C_{21}H_{23}PNCl$: C, 70.9; H, 6.5; N, 3.9%.

Preparation of complexes

(1) *Chloro (bis (2 - (diphenylphosphino) ethyl) benzylamine) ruthenium* (II) *chloride*, $[RuCl(DPEBA)_2]Cl$. The complex $RuCl_2(PPh_3)_3$ (0.15 g, 0.16 mmol) and the ligand DPEBA (0.17 g, 0.47 mmol) were refluxed for 12 h in acetone. During the course of the reaction the original brown colour of the solution changed to red. The solution was then reduced to a small volume and diethyl ether added to get a pinkish-red complex which was filtered, washed with benzene and recrystallized from a dichloromethane–diethyl ether mixture. Yield: 71%. Alternatively, the same complex was obtained by the reaction of DPEBA and $RuCl_2(Me_2SO)_4$ in benzene. When carbon monoxide was passed through a MeOH—CH_2Cl_2 solution of $[RuCl(DPEBA)_2]Cl$ the colour of the solution immediately changed to green to give a carbonyl complex of the composition $[RuCl(CO)(DPEBA)_2]Cl$.

(2) *Dichloro(bis(2-(diphenylphosphino)ethyl)benzylamine) ruthenium* (III) *chloride*, $[Ru(DPEBA)_2Cl_2]Cl$. The ligand DPEBA (0.841 g, 1.14 mmol) dissolved in 10 cm^3 of methanol was added to a refluxing methanolic solution of $RuCl_3 \cdot 3H_2O$ (0.2 g, 0.38 mmol). After refluxing the solution for an additional 6 h, the reddish complex was filtered, washed with methanol, diethyl ether and dried *in vacuo*. Yield: 63%. Alternatively, the same complex was obtained by the reaction of DPEBA with $RuCl_3(AsPh_3)_2MeOH$ in benzene. When CO was bubbled through a MeOH—CH_2Cl_2 solution of $[RuCl_2(DPEBA)_2]Cl$, a brown carbonyl complex of the composition $[RuCl(CO)(DPEBA)_2]Cl_2$ resulted.

(3) *Dichloro* (2 - (*diphenylphosphino*) *ethyl*) *benzylamine*) *cobalt* (II), $[Co(DPEBA)Cl_2]$. A solution of the ligand DPEBA (0.45 g, 1.26 mmol) dissolved in methanol was added to a refluxing methanolic solution of $CoCl_2 \cdot 6H_2O$. The colour of the solution changed to greenish-blue immediately. After refluxing the solution for 6 h it was concentrated to a small volume by a vacuum rotary evaporator and the complex precipitated by the addition of diethyl ether. The greenish-blue complex was filtered, washed with CCl_4, diethyl ether and dried *in vacuo*. The complex was recrystallized from a dichloromethane–diethyl ether mixture. Yield: 70%.

(4) *Chloro (bis (2 - (diphenylphosphino) ethyl) benzylamine) rhodium* (I), $[Rh(DPEBA(_2Cl]$. The complex $RhCl(PPh_3)_3$ (0.15 g, 0.16 mmol) and the ligand DPEBA (0.15 g, 0.324 mmol) in 30 cm^3 of benzene were refluxed for 12 h. The solution was concentrated to a small volume and diethyl ether added to get a yellow precipitate which was filtered, washed with CCl_4, diethyl ether and recrystallized from a methanol–diethyl ether mixture. Yield: 78%.

(5) (*Bis* (2 - (*diphenylphosphino*) *ethyl*) *benzylamine*) *rhodium* (I) *chloride*, $[Rh(DPEBA)_2]Cl$. The complex $[Rh(COD)Cl]_2$ (0.15 g, 0.30 mmol) and the ligand DPEBA (0.43 g, 1.21 mmol) were refluxed for 7 h in acetone. The solution was then concentrated to a small volume and by the addition of diethyl ether the precipitated complex was

filtered, washed with diethyl ether and recrystallized from a dichloromethane–*n*-hexane mixture. Yield: 55%.

(6) *(Bis (2 - (diphenylphosphino) ethyl) benzylamine) iridium* (I) *chloride*, $[Ir(DPEBA)_2]Cl$. The ligand DPEBA (0.27 g, 0.75 mmol) was added to a refluxing benzene solution of $[Ir(COD)Cl]_2$ (0.13 g, 0.19 mmol). After refluxing the solution for 6 h, the yellow crystalline complex separated was filtered and washed with benzene. Yield: 78%.

(7) *Chlorocarbonyl(2-(diphenylphosphino)ethyl) benzylamine)rhodium*(I), [RhCl(CO)(DPEBA)]. The ligand DPEBA (0.15 g, 0.42 mmol) dissolved in 10 cm^3 of benzene was added to a refluxing benzene solution of $RhCl(CO))(PPh_3)_2$ (0.29 g, 0.42 mmol). After refluxing the solution for 6 h, the solution was cooled and a yellow crystalline complex was obtained. The complex was filtered, washed with benzene, diethyl ether and dried *in vacuo*. Yield: 84%.

(8) *Chlorocarbonyl(2-(diphenylphosphino)ethyl) benzylamine) iridium* (I), [IrCl(CO)(DPEBA)]. To a suspension of $IrCl(Co)(PPh_3)_2$ (0.24 g, 0.31 mmol), the ligand DPEBA (0.11 g, 0.31 mmol) was added and refluxed for 6 h. The solution was concentrated to a small volume by a rotary vacuum evaporator. The addition of diethyl ether gave a yellow complex which was filtered, washed with CCl_4 and recrystallized from a methanol–diethyl ether mixture. Yield: 65%.

(9) *Dichloro (bis (2 - (diphenylphosphino) ethyl) benzylamine)rhodium*(III)*chloride*, $[RhCl_2(DPEBA)_2]$ Cl. To a refluxing methanolic solution of $RhCl_3 \cdot 3H_2O$ (0.17 g, 0.63 mmol), the ligand DPEBA (0.67 g, 1.80 mmol) was added and the solution further refluxed for 10 h. The solution was then evaporated to a small volume on a rotary vacuum evaporator and diethyl ether added to get a yellow crystalline complex. The compound was filtered, washed with diethyl ether and recrystallized from a dichloromethane–*n*-hexane mixture. Yield: 72%.

(10) *Dichloro(bis(2-(diphenylphosphino)ethyl)benzylamine)iridium*(III)*chloride*, $[IrCl_2(DPEBA)_2]$ Cl. A mixture of 0.1 g (0.28 mmol) of $IrCl_3 \cdot 3H_2O$ and the ligand DPEBA (0.31 g, 0.85 mmol) in ethanol was refluxed for 6 h. During the course of the reaction the colour of the solution changed to pale-yellow. The solution was concentrated to a small volume by a vacuum rotary evaporator and the complex precipitated by the addition of diethyl ether. The pale-yellow complex was filtered, washed with water, CCl_4 and recrystallized from a dichloromethane–*n*-hexane mixture. Yield: 55%.

(11) *Dichloro (bis (2 - (diphenylphosphino) ethyl) benzylamine) nickel* (II), $[NiCl_2(DPEBA)_2]$. A mixture of hydrated nickel(II) chloride (0.20 g, 0.84 mmol) and the ligand DPEBA (0.59 g, 1.6 mmol) were refluxed in 30 cm^3 of degassed butanol for 4 h. A deep-blue crystalline complex was obtained, which was filtered, washed with hot butanol and diethyl ether and dried *in vacuo*. Yield: 85%.

(12) *Chloro(bis(2-(diphenylphosphino)ethyl)benzylamine)palladium*(II)*chloride*, [PdCl(DPEBA)]Cl.

(13) *Chloro(bis(2-(diphenylphosphino)ethyl)benzylamine)platinum*(II)*chloride*, [PtCl(DPEBA)]Cl. For the preparation of **12** and **13** aqueous solutions of K_2PdCl_4 (0.1 g, 0.31 mmol) and K_2PtCl_4 (0.2 g, 0.48 mmol) were added separately to a refluxing acetone solution of the ligand DPEBA (0.61 g, 0.61 mmol and 0.34 g, 0.96 mmol). The solutions after refluxing for 3 h were evaporated to dryness by a rotary vacuum evaporator to get pale-yellow complexes of the composition [PdCl(DPEBA)]Cl **12** and [PtCl(DPEBA)]Cl **13**. The complexes were filtered, washed with diethyl ether and recrystallized from a dichloromethane–diethyl ether mixture. Yield: 75% **12**; 60% **13**.

(*Received* 16 *March* 1987; *accepted* 24 *June* 1987)

Abstract—A series of early transition metal organometallic derivatives containing the ancillary ligand 2,6-diphenylphenoxide (OAr–2,6Ph_2) have been synthesized. Compounds of stoichiometry Ti(OAr–2,6Ph_2)$_2$(R)$_2$ (R = CH_3, CH_2SiMe_3, CH_2Ph and Ph) and Ti(OAr–2,6Ph)$_3$(R) (R = CH_3, CH_2SiMe_3) are obtained by treating the corresponding homoleptic alkyl, TiR_4, with the required amount of phenol, HOAr–2,6Ph_2. For the Group 5 metals Nb and Ta, the methyl derivatives M(OAr–2,6Ph_2)$_2$(CH_3)$_3$ and M(OAr–2,6Ph_2)$_3$(CH_3)$_2$ are obtained via methylation of the corresponding chloro-aryloxides. Besides routine spectroscopic characterization the diphenyl Ti(OAr–2,6Ph_2)$_2$(Ph)$_2$ and mono-alkyl Ti(OAr–2,6Ph_2)$_3$(CH_2SiMe_3) have been structurally characterized by X-ray diffraction techniques. Both molecules contain a pseudo-tetrahedral environment about the titanium atom with short 1.794(3)–1.806(2) Å, Ti—O distances and large, 153–179°, Ti—O—Ar angles. The Ti—C distances appear normal for these types of compounds.

The last few years have seen a considerable research effort into the study of the inorganic and organometallic chemistry associated with 2,6-dialkylphenoxide, (OAr) and 2,6-dialkylthiophenoxide, (SAr) ligation. In the case of the phenoxide ligands a diverse range of chemistry has been supported.[1–4] The related thiophenoxide ligands have also been extensively used with a wider range of transition metals to generate systems of possible relevance to biological thiolate environments.[5–8] Following our work on the sterically very demanding 2,6-di-*tert*-butylphenoxide ligand which has been shown to sometimes undergo the mild activation of the aliphatic carbon-hydrogen bonds of the *tert*-butyl groups,[9,10] we have begun an investigation of the ligand 2,6-diphenylphenoxide on similar metal systems.[11] This ligand has the possibility of forming related six-membered metallacycle rings, albeit this time via activation of an aromatic CH bond. Recent work by our group on molybdenum has confirmed this postulate.[12] We wish to report here our synthesis of a number of Group

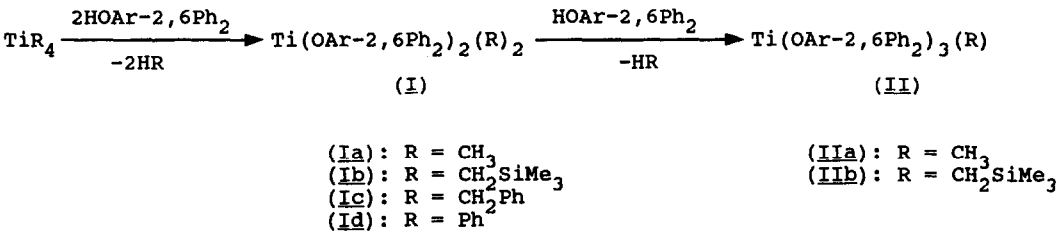


Scheme 1.

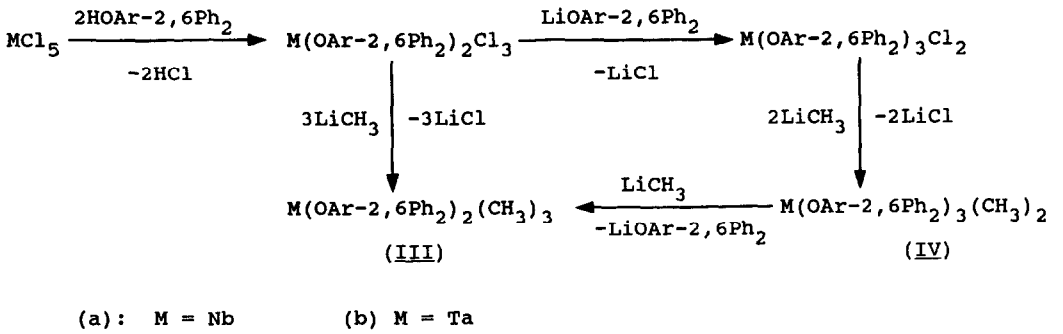
4 and Group 5 metal organometallic derivatives of this ligand as well as their structural and spectroscopic properties. While this work was in progress we became aware that some related studies were being carried out by Dilworth and coworkers[13,14] to complement the interesting work they had previously completed on the related 2,6-diphenylthiophenoxide group.[5]

RESULTS AND DISCUSSION

Synthesis of compounds

Two general synthetic strategies for the synthesis of organometallic derivatives containing 2,6-diphenylphenoxide ligation were employed. The first involved the treatment of homoleptic alkyls of titanium and zirconium[15] with the parent phenolic reagent in hydrocarbon solvents. This resulted in the sequential protonolysis of alkyl groups to directly generate mixed alkyl, phenoxides of this ligand. For zirconium the treatment of $Zr(CH_2SiMe_3)_4$ with HOAr–2,6Ph_2 led to the rapid replacement of all alkyl groups and formation of sparingly soluble $Zr(OAr–2,6Ph_2)_4$ in essentially quantitative yields. However, with titanium alkyls the substitution reaction was more controlled and allowed the synthesis in moderate yields of a number of compounds of general formulae $Ti(OAr–2,6Ph_2)_2(R)_2$ (**I**) and $Ti(OAr–2,6Ph_2)_3(R)$ (**II**) (Scheme 1). The tetra-alkyl substrate TiR_4 was either isolated ($R = CH_2SiMe_3$) or else generated *in situ* ($R = CH_3$, CH_2Ph, Ph) before being reacted with HOAr–2,6Ph_2. The phenoxide derivatives (**I**) and (**II**) were thermally much more robust than the corresponding homoleptic alkyls, undergoing little noticeable decomposition either in the solid state or hydrocarbon solution at 20–30°C over periods of weeks. These deep red or yellow crystalline materials proved only slightly soluble in hexane but much more soluble in aromatic hydrocarbon solvents.

For the Group 5 metals niobium and tantalum a synthetic route via the mixed chloro, phenoxide intermediates was investigated (Scheme 2). Treatment of the pentahalides MCl_5 (M = Nb, Ta) with HOAr–2,6Ph_2 (2 equivalents) in benzene led to the corresponding trichlorides $M(OAr–2,6Ph_2)_2Cl_3$ in good yields. It was then found possible to further substitute one more chloride ligand by using LiOAr–2,6Ph_2, again in hydrocarbon solvents, to yield the dihalide derivatives. Treatment of these halide substrates with the alkylating agent $LiCH_3$ resulted in the formation of the corresponding methyl compounds, $M(OAr–2,6Ph_2)_2(CH_3)_3$ (**III**) and $M(OAr–2,6Ph_2)_3(CH_3)_2$ (**IV**) as yellow (M = Nb) or colorless (M = Ta) crystalline solids (Scheme 2). Treatment of the dimethyl species (**IV**) with excess $LiCH_3$ resulted initially in the formation of (**III**) with loss of LiOAr–2,6Ph_2, but on extended



Scheme 2.

exposure decomposition, presumably via formation of $M(CH_3)_5$, took place. This reactivity pattern is similar to that found for other 2,6-di-alkylphenoxide complexes of these metals.[1]

Spectroscopic properties

Some selected NMR data are collected in Table 1. As is to be expected the ^1H and ^{13}C NMR spectra of the 2,6-diphenylphenoxide ligand itself are not very informative, all resonances being grouped in the δ 6–7.5 ppm and δ 110–160 ppm regions. However, the ligand does have some influence on the NMR resonances of other groups contained in the metal coordination sphere. This is a consequence of the phenyl substituents of the aryloxide ligand which, due to their associated diamagnetic anisotropy, tend to shield some of the proton and carbon nuclei of adjacent groups. This effect was also noticed in dimolybdenum amido and tantalum alkylidyne derivatives of this ligand.[11] Table 1 contains some selected ^1H and ^{13}C NMR data for the organometallic compounds obtained in this study. Hence, considering the methyl derivatives one finds that the M-CH_3 protons resonate at values of δ 0.53 (**Ia**), −0.41 (**IIa**), 0.09 (**IIIa**), −0.26 (**IIIb**), 0.18 (**IVa**) and −0.21 ppm (**IVb**) compared to values of δ 1–2 ppm typically found for methyl derivatives of these metals containing other 2,6-dialkylphenoxide ligands. Similar upfield shifts of the resonances of other protons in the alkyl ligands are also evident (Table 1).

Solid state structures of $Ti(OAr\text{–}2,6Ph_2)_2(Ph)_2$ (**Id**) *and* $Ti(OAr\text{–}2,6Ph_2)_3(CH_2SiMe_3)$ (**IIb**)

In order to more fully characterize the coordination properties of the 2,6-diphenylphenoxide ligand in these systems, X-ray diffraction analyses of the diphenyl compound (**Id**) and mono-trimethylsilylmethyl derivative (**IIb**) were carried out. Although a complete data set was also collected on the trimethyl $Ta(OAr\text{–}2,6Ph_2)_2(CH_3)_3$, the structure proved impossible in our hands to solve.[16] Attempts to solve the structure of the niobium analogue by Dilworth and co-workers were also unsuccessful.[13] Figures 1 and 2 contain the ORTEP views of (**Id**) and (**IIb**) respectively while Tables 2 and 3 contain some selected bond distances and angles. The diphenyl compound (**Id**) was found to contain one molecule of benzene per unit cell. It can be seen that both compounds (**Id** and **IIb**) contain a pseudo-tetrahedral arrangement of oxygen and carbon atoms about the titanium metal center. The five Ti—O distances lie in the narrow range of 1.794(3)–1.806(2) Å and can be compared with distances of 1.780(3) and 1.781(3) Å in $Ti(OAr\text{–}2,6Pr^i_2)_4$[17] and 1.782(8), 1.802(7) and 1.810(9) in $Ti(OAr\text{–}2,6Bu^t_2)_3I$.[18] In the less crowded diphenyl (**Id**) the Ti—O—Ar angles are 153.0(3) and 162.2(3)° while in the much more sterically congested $Ti(OAr\text{–}2,6Ph_2)_3(CH_2SiMe_3)$ (**IIb**) this angle opens up to values of 164.6(2), 170.7(2) and 179.1(2)°. These latter values are on average significantly larger than found in the stoichiometrically related iodide compound $Ti(OAr\text{–}2,6Bu^t_2)_3I$; 155.2(4), 158.2(4) and 159.1(4)°.[18]

The short Ti—O distances found in these compounds are consistent with the presence of considerable oxygen-*p* to metal-*d* π-bonding. The almost linear Ti—O—Ar angles also can be attributed to this effect and are characteristic of the coordination of 2,6-dialkylphenoxide ligands to early transition metal centers[19] and allow some relief of the steric congestion at the metal caused by the bulky substituents. Similar structural

features were reported by Dilworth for $Ti(OAr\text{–}2,6Ph_2)_2Cl_2$.[13] The Ti—C(phenyl) distances of 2.070(5) and 2.106(5) Å in $Ti(OAr\text{–}2,6Ph_2)_2(C_6H_5)_2$ (**Id**) are slightly shorter than the distance of 2.272(14) Å reported for the metallocene derivative $Cp_2Ti(C_6H_5)_2$.[20] The Ti—C distance of 2.051(4) Å in (**IIb**) is also slightly shorter than found in the mono-cyclometallated complex $Ti(OC_6H_3Bu^t CMe_2CH_2)(OAr\text{–}2,6Bu^t_2)(CH_2SiMe_3)(py)$, 2.131(6) Å.[9] However, we do not believe these shorter distances in these derivatives of 2,6-diphenylphenoxide are significant.

EXPERIMENTAL

All reactions were carried out under an atmosphere of dry, oxygen-free nitrogen using standard Schlenk and glove box techniques. Solvents were distilled under nitrogen from sodium benzophenone and stored under nitrogen. The halides $TiCl_4$, $NbCl_5$ and $TaCl_5$ were obtained commercially (Alfa) as was 2,6-diphenylphenol ($HOAr\text{–}2,6Ph_2$, Aldrich). ^1H and ^{13}C NMR spectra were recorded on a Varian Associates XL-200 spectrometer. Microanalyses were obtained in-house at Purdue University.

Preparations

Due to similarities of the procedures used full details of the synthesis of only representative compounds will be given. Considerable difficulty in obtaining good microanalyses of derivatives of 2,6-diphenylphenoxide was experienced. Typically carbon percentages were suppressed probably due to the formation of metal carbides. However, full microanalytical data that were obtained on all new compounds are reported.

$Ti(OAr\text{–}2,6Ph_2)_2(CH_3)_2$ (**Ia**). To a solution of $IMgCH_3$ (0.11 mol) in diethylether (250 cm^3) cooled to −78°C was slowly added $TiCl_4$ (0.026 mol) in hexane (15 cm^3). The resulting yellow mixture con-

taining $Ti(CH_3)_4$ was stirred for 1 h at −78°C before $HOAr\text{–}2,6Ph_2$ (13.9 g, 2 equiv per Ti) was added slowly as a toluene (50 cm^3) solution. The color of the mixture darkened to orange and methane was evolved. After being allowed to warm slowly to room temperature, all solvent was removed *in vacuo* to yield a dark solid residue. Extraction of the residue with a 50/50 hexane/benzene mixture and evaporation gave the crude product as an off-yellow crystalline powder. Recrystallization with hexane and cooling to −15°C gave the pure product as lemon–yellow crystals. Yield = 6.28 g (42%). Found: C, 79.7; H, 5.5. Calc. for $TiC_{38}H_{32}O_2$: C, 80.3; H, 5.7%.

cm^3) was added solid $HOAr\text{–}2,6Ph_2$ (1.24 g, 2 equiv) with vigorous stirring. The resulting mixture was stirred overnight before the solvent was removed *in vacuo* to yield the crude product as a yellow powder. The compound can be readily recrystallized from saturated hexane solution on cooling as large yellow blocks. Yield = 1.08 g (60%). Found: C, 73.2; H, 7.0. Calc. for $TiC_{44}H_{48}O_2Si_2$: C, 70.8; H, 6.7%.

$Ti(OAr\text{–}2,6Ph_2)_2(CH_2Ph)_2$ (**Ic**). An essentially identical procedure used for (**Ia**) except using $ClMgCH_2Ph$ (0.16 mol) and $TiCl_4$ (0.04 mol) yielded the di-benzyl (**Ic**) as deep-red crystals from hexane. Yield = 24.6 g (84%). Found: C, 80.9; H, 5.7. Calc. for $TiC_{50}H_{40}O_2$: C, 83.3; H, 5.5%.

$Ti(OAr\text{–}2,6Ph_2)_2(Ph)_2 \cdot C_6H_6$ (**Id**). Addition of $HOAr\text{–}2,6Ph_2$ (14.8 g, 2 equiv) to a preformed solution of $TiPh_4$ (PhMgBr, 0.12 mol; $TiCl_4$, 0.03 mol) using the procedures outlined for (**Ia**) above yielded a dark brown mixture. The crude product was purified by recrystallization from hexane/benzene mixture as large yellow blocks. Yield = 3.5 g (17%). Found: C, 82.2; H, 5.5. Calc. for $TiC_{48}H_{36}O_2 \cdot C_6H_6$: C, 84.1; H, 5.5%.

$Ti(OAr\text{–}2,6Ph_2)_3(CH_3)$ (**IIa**). A yellow solution of $Ti(OAr\text{–}2,6Ph_2)_2(CH_3)_2$ (**Ia**) (0.5 g) and $HOAr\text{–}2,6Ph_2$ (0.22 g) in toluene (10 cm^3) was stirred at 25°C. Methane evolution occurred, but no color change was evident. After 30 min the solution was cooled slowly to yield the product as yellow crystals. Yield = 0.50 g (73%). More product could be obtained on cooling the mother liquor. Found: C, 81.4; H, 5.2. Calc. for $TiC_{55}H_{42}O_3$: C, 82.7; H, 5.3%.

$Ti(OAr\text{–}2,6Ph_2)_3(CH_2SiMe_3)$ (**IIb**). A mixture of $Ti(CH_2SiMe_3)_4$ (1.0 g) and $HOAr\text{–}2,6Ph_2$ (1.86 g, 3 equiv) in toluene (30 cm^3) was refluxed for 4 h. The solvent was removed to give the crude product as a yellow powder which was recrystallized from a toluene/hexane mixture. Yield = 0.6 g (27%). Found: C, 79.6; H, 6.0. Calc. for $TiC_{58}H_{50}SiO_3$: C, 80.8; H, 5.8%.

$Nb(OAr\text{–}2,6Ph)_2(Cl_3)$. A solution of $HOAr\text{–}2,6Ph_2$ (18.16 g) in benzene was added slowly to a solution of $NbCl_5$ (9.96 g) also in benzene. The resulting mixture was stirred for 3 h before the solvent, along with generated HCl, was removed *in vacuo* to leave the crude product as an orange solid. Recrystallization from a saturated toluene solution gave the pure product. Yield = 24.0 g (94.4%). Found: C, 62.5; H, 4.3; Cl, 14.2. Calc. for Nb, $C_{36}H_{26}O_2Cl_3$: C, 62.7; H, 3.8; Cl, 15.4%.

$Ta(OAr\text{–}2,6Ph_2)_2Cl_3$. This was obtained as a yellow solid using an identical procedure using $TaCl_5$ instead of $NbCl_5$. Found: C, 56.9; H, 3.9; Cl, 12.2. Calc. for Ta, $C_{36}H_{26}O_2Cl_3$: C, 55.6; H, 3.4; Cl, 13.7%.

$Nb(OAr\text{–}2,6Ph_2)_3Cl_2$. Addition of $LiOAr\text{–}2,6Ph_2$ (0.37 g) to a solution of $Nb(OAr\text{–}2,6Ph_2)_2Cl_3$ (1.0 g) in benzene gave a yellow–orange suspension. After being stirred overnight the mixture was filtered and the filtrate stripped to yield the crude product as a yellow–orange solid. (Recrystallization from saturated hexane solutions gave the pure product.) Yield = 1.25 g (96.2%). Found: C, 72.3; H, 4.6; Cl, 7.1. Calc. for $NbC_{54}H_{39}O_3Cl_2$: C, 72.1; H, 4.4; Cl, 7.9%.

$Ta(OAr\text{–}2,6Ph_2)_3Cl_2$. An identical procedure using $Ta(OAr\text{–}2,6Ph_2)_2Cl_3$ gave the product as a pale yellow solid. Found: C, 64.2; H, 4.4; Cl, 8.7. Calc. for $TaC_{54}H_{39}O_3Cl_2$: C, 65.6; H, 4.0; Cl, 7.2%.

$Nb(OAr\text{–}2,6Ph_2)_2(CH_3)_3$ (**IIa**). Slow addition of $LiCH_3$ (190 mg, 3 equiv) to a solution of $Nb(OAr\text{–}2,6Ph_2)_2Cl_3$ (2.0 g) in benzene causes a lightening of the solution from orange to pale yellow. Filtration and removal of the solvent *in vacuo* gave the product as a yellow powder. Recrystallization from hexane yielded the pure products as well formed yellow crystals. Yield = 1.1 g (68.1%). Found: C, 70.7; H, 5.4. Calc. for $NbC_{39}H_{35}O_2$; C, 74.5; H, 5.6%.

$Ta(OAr\text{–}2,6Ph_2)_2(CH_3)_3$ (**IIIb**). An identical procedure using $Ta(OAr\text{–}2,6Ph_2)_2Cl_3$ yielded (**IIb**) as well formed, white blocks from hexane. Found: C, 65.0; H, 5.1. Calc. for $TaC_{39}H_{35}O_2$: C, 65.3; H, 4.9%.

$Nb(OAr\text{–}2,6Ph_2)_3(CH_3)_2$ (**IVa**). Obtained from

$Nb(OAr\text{–}2,6Ph_2)_3Cl_2$ and $LiCH_3$ (2 equiv) in benzene. Recrystallized from hexane on cooling. Found: C, 78.3; H, 5.4. Calc. for $NbC_{56}H_{45}O_3$: C, 78.3; H, 5.3%.

$Ta(OAr\text{–}2,6Ph_2)_3(CH_3)_2$ (**IVb**). Obtained by reacting $Ta(OAr\text{–}2,6Ph_2)_3Cl_2$ with $LiCH_3$ (2 equiv) in benzene. An identical procedure to that used for (**IIa**) yielded the product as a white crystalline solid. Found: C, 70.3; H, 4.7. Calc. for $TaC_{56}H_{45}O_3$: C, 71.0; H, 4.8%.

Crystallographic studies

Crystal data are summarized in Table 4. One of the structures was determined at the Indiana University Molecular Structure Center while the second was determined in-house at Purdue.

$Ti(OAr\text{–}2,6Ph_2)_2(Ph)_2 \cdot C_6H_6$ (**Id**). General operating procedures and a listing of programs have been published previously.[21] A suitable small crystal was selected and transferred to the goniostat for characterization and data collection. Attempts at cooling the crystal to our usual operating temperature of −150°C resulted in fracturing of the crystal, possibly due to a phase transition. At about −94°C the crystal was stable, and this temperature was used for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited monoclinic symmetry and extinctions corresponding to the space group $P2_1/c$.

The structure was solved by direct methods, all non-hydrogen atoms were readily located after some initial difficulty resulting from the placement of the Ti atom almost on a twofold screw axis. After initial refinement the hydrogen atoms were located

and refined. The full matrix least-squares refinement was completed using anisotropic thermal parameters on all non-hydrogen atoms and isotropic thermal parameters on the hydrogen atoms. The final difference map was essentially featureless, the largest peak was 0.6 e/Å. The asymmetric unit contained one molecule of benzene solvent. The atoms in the solvent are numbered C(52) through to C(57).

$Ti(OAr\text{–}2,6Ph_2)_3(CH_2SiMe_3)$ (**IIb**). A suitable crystal was located and mounted in a 0.5 mm capillary surrounded by epoxy resin. Data collection and refinement were carried out using the standard procedures of the Purdue Crystallographic facility.[11]

Hydrogens were located such that the hydrogen–carbon bond was 0.95 Å and the angles were correct. For methyl groups, one hydrogen was located in the Fourier map, its position was idealized, and the remaining hydrogen positions were calculated based on it. Hydrogen temperature factors and positions were not refined.

(*Received* 9 *April* 1987; *accepted* 2 *June* 1987)

Abstract—It is shown in the present work that hexagonal and tetragonal forms of Rh(I) *bis*-4,4′-diisocyanobiphenyl chloride polymers containing stacks of rhodium ions in the integral +1 state show *d*-electron delocalization in one dimension along Rh^+—Rh^+ chains at and below ambient temperature at atmospheric pressure.

Although most organometallic solids are insulators,[1] their structural and electronic properties can be modified by overlap of metal orbitals[2] or π-ligand orbitals[3] to allow formation of conduction bands. In the present study on rhodium diisocyanide polymers, both types of overlap may contribute towards the overall electronic conductivity.

Hexagonal and tetragonal rhodium(I) *bis* 4,4′-diisocyanobiphenyl chloride polymers ($[Rh(CN\text{-}C_6H_4\text{-}C_6H_4\text{-}NC)_2]^+Cl)_n$, have been prepared from the reaction of 4,4′-diisocyanobiphenyl[4] with tetracarbonyl di-μ-chloro dirhodium.[5,6,7] These and similar polymers have shown catalytic hydrogenation properties[8,9] as well as electrical[10] and photoconductivities.[11]

Powder X-ray diffractometry on these materials has revealed ordered structures of "graphite-like" two-dimensional laminae with interlayer separations of 3.54 and 3.40 Å for the hexagonal[6] and tetragonal[10] modifications respectively. Interlayer spacing of this order (3–4 Å) are found in many planar molecule charge-transfer salts.[3] For the materials reported here, the interplanar spacings most probably arise from overlap of electron density between adjacent ligand sheets and rhodium(I) ions. Both structural modifications of the rhodium polymer satisfy all of the preconditions necessary for one-dimensional metals,[12] and the interplanar spacing is at about the maximum critical distance (i.e. 3.44 Å+a contribution for polarizability) required for delocalization of electrons within Rh—Rh bonded systems[13] provided that vertical alignment of Rh^+ ions is present.

A band found in the electronic spectra of both structural forms of the material at ~ 700 nm has been attributed to an $a_{1g}(d_z^2) \rightarrow a_{2u}(p_z, \pi^*)$ transition (which shifted from 520 nm because of overlap of adjacent metal–metal d_z^2 orbitals[14]), providing the first evidence for Rh—Rh interactions therein.[5,6] However, to date, the existence of one-dimensional molecular metals in these compounds has not been proved conclusively. The applicability of Raman spectroscopy to the study of weak metal–metal interactions has been well detailed[15] and a weak Raman-active band has been detected at 130 cm^{-1} for the rhodium polymers discussed here. This band

* Author to whom correspondence should be addressed.

is attributed to a symmetric Rh—Rh stretching vibration and is reported here for the first time as further evidence for direct metal–metal interactions in these polymeric solids. The weak intensity of this band together with its low vibration frequency in the Raman spectrum (a band at 170 cm^{-1} had previously been detected for νRh—Rh in rhodium(II) acetate[16]) indicate that only a weak metal–metal interaction is present here.

We find that both hexagonal and tetragonal polymers exhibit weak paramagnetism; this is surprising, as a fully spin-paired d^8 ground state electronic configuration would have been predicted for Rh^+ in D_{4h} symmetry. This unpaired spin electron density probably arises from either paramagnetic rhodium impurities or from donation of electron density from the antibonding σ-lone pair on the C atom from ArNC to the metal. A shift of 24 cm^{-1} has been observed for the νC≡N stretching mode in the infrared spectra of the ligand after complexation and this confirms that net electron donation occurs from the ligand to the metal (and not the reverse) for these particular polymeric solids.

The unpaired electron spin density on the rhodium centres proved to be amenable to detection by electron paramagnetic resonance spectroscopy; three EPR spectra of the hexagonal and tetragonal polymers are shown in Fig. 1. Both polymeric solids exhibit EPR spectra with two peaks. The peak at $g \approx 2.00$ is attributed to unpaired electron density on the rhodium ions and the peak at the larger g value is thought to be due to delocalized electron density in the material's solid state conduction bands. Similar conduction electron EPR spectra to those shown in Fig. 1 have been reported for colloidal metal particle sols[17] and for the molybdenum hexafluoride intercalated graphite samples[18] and the peak assignments given are consistent with those suggested here. Samples of tetratolyl isocyano rhodium(I) perchlorate, prepared by the action of tolyl isocyanide on rhodium trichloride in the presence of sodium perchlorate,[19] gave no detectable EPR signal. For this reason it is thought unlikely that the EPR spectra recorded for the two polymers here result from spin-orbital coupling within paramagnetic rhodium centres in an anisotropic field.

Temperature-dependent EPR studies in the range 78 to 420 K show that the total integrated peak area decreases with temperature and that the conduction band is the most susceptible peak of the two to changes in temperature. At room temperature, calibration of the EPR spectra gave total spin densities of 4.55×10^{-4} for each Rh site in the hexagonal polymer and 1.36×10^{-4} for each Rh site in the tetragonal polymer. The values obtained for the conduction–electron spin densities at room temperature for the same species were 1.8×10^{20} spins per mol for the hexagonal polymer and 4.9×10^{18} spins per mol for the tetragonal polymer.

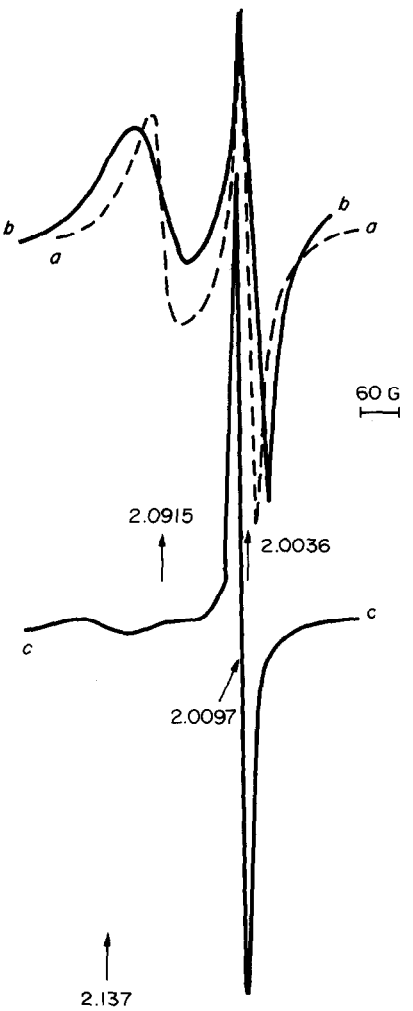

Fig. 1. EPR spectra of Rh(I) *bis*-diisocyanobiphenyl chloride polymers obtained on a Varian EPS3 instrument in air: (a) in the hexagonal configuration at 78 K shows two peaks (g = 2.0915, 45 G and g = 2.0036, 40 G), (b) in the hexagonal configuration at 333 K also shows two peaks (g = 2.0915, 85 G and g = 2.0036, 60 G), and (c) in the tetragonal configuration at 333 K, which shows two peaks (g = 2.137 72 G and g = 2.0097, 5 G).

The "dark" electrical conductivities of polycrystalline samples of the two different polymers were determined in a low-pressure conductivity cell[20] and show $\sigma_{hex} > \sigma_{tet}$ (2×10^{-6} ohm^{-1} cm^{-1} and 1×10^{-7} ohm^{-1} cm^{-1} respectively). This is in agreement with the results obtained from EPR spectroscopy. The intrinsic electrical conductivities of both of these polymers had been interpreted previously in terms of a summation of intralayer and interlayer contributions.[10] However, infra-red spectral data indicate that electron transfer may occur one way only, from the ligands to the metal and

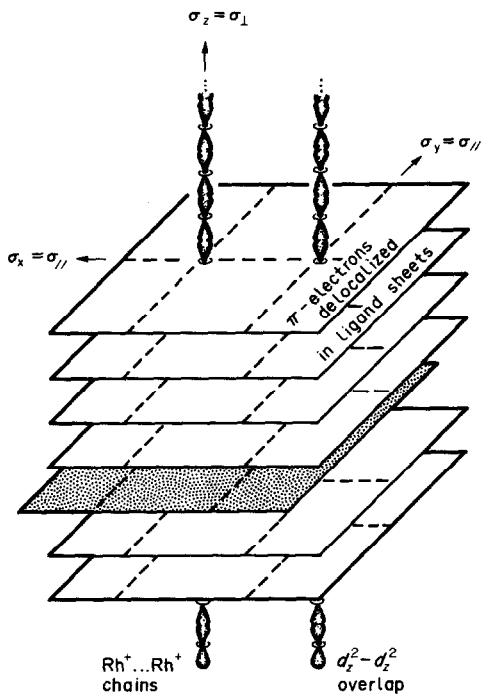

Fig. 2. Electronic conductivity of Rh(I) *bis*-diisocyanobiphenyl chloride polymers. $\sigma_\parallel$ denotes conductivity within (or parallel to) diisocyanobiphenyl sheets. $\sigma_\perp$ denotes conductivity perpendicular to these sheets which predominantly involves d_z^2–d_z^2 overlap of Rh^+ centres (in essentially integral +1 oxidation states) forming Rh^+—Rh^+—Rh^+ chains which are broken only by translational defects resulting in a mismatch of Rh^+—Rh^+ ions in adjacent laminae (mismatched sheet breaking Rh^+—Rh^+—Rh^+ chain is shaded). – – – denotes the diisocyanobiphenyl ligands between Rh^+ centres in the laminae involving π-bond delocalization).

EPR shows no peak splitting due to coupling of unpaired electron density on the rhodium centres with nitrogen atoms in the ligands. In the light of the results reported here, it may be concluded that the intralayer contribution $\sigma_\parallel$ (see Fig. 2) to the total electrical conductivity must be very small when compared with the interlayer contribution $\sigma_\perp$ (see Fig. 2).

Total numbers of unpaired electrons per rhodium site suggest that the overall oxidation state of the rhodium ions present in these materials is $(1 \pm x)$, where x is a factor which takes into account the electron donating power of the ligands as well as the effects of interlayer electronic delocalization within the solid state.

As mentioned earlier, the Rh—Rh distance in these polymers is very close to the critical limiting distance for delocalization of *d*-electrons. Thus for either of the two systems considered here only a relatively small stacking fault (i.e. translational dislocation) would be required to disrupt the one-dimensional metallic character (see Fig. 2). The electronic charge is able to move freely along the *straight* Rh^+—Rh^+—Rh^+ segments but requires an activation energy input to hop over from one chain to the next. The kinetics involved in electron transfer of this kind are critical in defining the level of electronic conduction in this a similar class of material[21] and are dependent upon relaxation rates along the metal atom and chain lengths. Further research is being carried out in this area to define and modify the magnetic and electronic properties in this and related one-dimensional systems.

Acknowledgement—The authors thank Johnson Matthey Ltd., for the loan of rhodium trichloride. I.F.-J. acknowledges the financial support of N.C.R.D. (Israel) for parts of this research programme.

(*Received* 16 *March* 1987; *accepted June* 1987)

Abstract—The reaction between $BiCl_3$ and two equivalents of $Na[(C_5H_4Me)Fe(CO)_2]$ affords the title complex, $[\{(C_5H_4Me)Fe(CO)_2\}_2BiCl]_3$, containing a planar six-membered Bi_3Cl_3 ring in which each bismuth is bonded to two chlorine atoms and two $(C_5H_4Me)Fe(CO)_2$ fragments.

Organotransition metal complexes containing transition metal–bismuth bonds are uncommon. Examples of known complexes include $[Bi\{Co(CO)_4\}_3]$,[1] $[Bi\{Ir(CO)_3\}_3]$,[2] $[W_3Bi_2(CO)_{15}]$,[3] $[W_2(CO)_8(\mu\text{-}\eta^2\text{-}Bi_2)(\mu\text{-}Bi(Me)W(CO)_5)]$[4] and recently a range of iron carbonyl–bismuth clusters has been reported by Whitmire *et al.*[5] As part of a study of such systems, we have investigated the reaction of the cyclopentadienylirondicarbonyl anion with bismuth trichloride, since there appear to be no literature reports of transition metal–bismuth complexes containing the cyclopentadienyl ligand.

Treatment of a THF solution of $BiCl_3$ with two equivalents of $[(C_5H_5)Fe(CO)_2]^-$ in THF at room temperature produces a deep emerald green solution from which, after filtration and recrystallization from THF/hexane, dark green crystals of **1a** can be isolated in moderate yield. Analogous reactions involving the alkylated cyclopentadienyl ligands, C_5H_4Me and C_5Me_5, afford the derivatives **1b** and **1c** respectively. ^1H and ^{13}C NMR† analysis of **1a–c** indicated a single cyclopentadienyl environment while infra-red spectroscopy revealed only terminal carbonyl absorptions.† However, since these data gave little indication as to the nature of **1a–c**, a single crystal X-ray diffraction study of **1b** was undertaken, the result of which is shown in Fig. 1 and Table 1.‡ The molecule consists of a planar six-membered Bi_3Cl_3 ring in which each bismuth atom is bonded to two chlorine atoms (mean Bi–Cl = 2.907 Å) and two $(C_5H_4Me)Fe(CO)_2$ fragments (mean Bi–Fe = 2.680 Å) as represented in the diagram. Each bismuth atom resides in a tetrahedral environment but this is considerably distorted, as evidenced by the large Cl–Bi–Cl angles (153.2

and 154.9°), which in turn leads to a small angle at each chlorine (86.0 and 84.4°). These distortions are probably a result of a stereochemically active lone pair on each bismuth, which presumably lies in the Fe_2Bi plane and bisects the Cl–Bi–Cl angle. An alternative explanation invoking Bi—Bi interactions, which might result in similar distortions, is considered unlikely due to the large internuclear separation (mean Bi···Bi = 3.944 Å). Typical Bi—Bi distances in complexes containing mutually bonded dibismuth fragments range from 2.796 to 3.092 Å[3,4,5d] while in the cluster $[Bi_4Fe_4(CO)_{13}]^{2-}$,[5b] containing a tetrahedron of bismuth atoms, the Bi—Bi separations range from 3.140 to 3.473 Å, these being associated with some degree of Bi–Bi interaction. The Bi—Bi distance in bismuth metal is 3.10 Å.[6] The $(C_5H_4Me)Fe(CO)_2$ fragments are arranged such that the cyclopendienyl ligands are chemically equivalent, consistent with the observed solution NMR properties of **1a–c**. The carbonyls, however, fall into two sets; six pointing in towards the centre of the Bi_3Cl_3 ring and six pointing out. The observation of only one carbonyl resonance in the ^{13}C NMR spectrum of **1a** and **1b** implies an exchange process in solution at room temperature (presumably rotation about the Fe—Bi bonds). In **1c**, however, two CO signals are observed, consistent with a static structure in solution, possibly due to hindered rotation resulting from the increased size of the C_5Me_5 ligands.

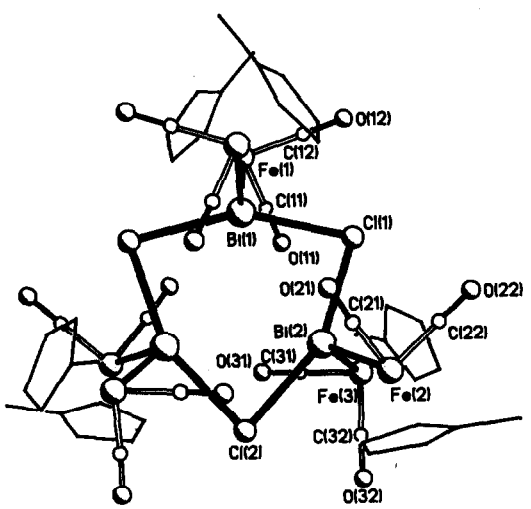

Fig. 1. A diagram of the molecular structure of **1b** showing the atom numbering scheme adopted, except for the C_5H_4Me ligands. A crystallographic two-fold axis passes through Bi(1) and Cl(2).

The structure of **1b** is formally derived from a cyclotrimerization of $\{(C_5H_4Me)Fe(CO)_2\}_2BiCl$ fragments resulting from a Lewis acid–base interaction between bismuth and a second chlorine. The Lewis acidity of tricoordinate bismuth is well known and a similar interaction occurs in the related chloro-bismuthinidene complex, **2**.[7] Fur-

BOOK REVIEW

Preparative Polar Organometallic Chemistry Vol. 1. By Lambert Brandsma and Hermann D. Verkruijsse. Springer, Berlin, 1987. ISBN 3-540-19616-4, 240pp., DM 78.

This book is the first in a new organometallic series and is devoted to polar organometallics derived from *sp*2 compounds. The first chapter discusses the use of strong bases such as alkali metal amides, metal dialkyl amides and alkyllithiums. Aspects such as reagent stability, solvent purification, additives such as HMPA, safety precautions and practical tips are all covered. In chapter two the general reactivities of polar organometallics are discussed, with detailed reference to alkylation, acylation, halogenation, etc. These two first chapters form an excellent introduction to synthesis using strong bases and organometallics, and are illustrated with plenty of examples and full experimental procedures in the style of "Organic Syntheses".

The remainder of the book then describes the preparation and reactions of *sp*2 organometallics derived from four main groups: olefins and allenes, hetero-substituted unsaturated systems, hetero-aromatics and aromatics. In each section a general introduction is followed by full experimental procedures for preparation of a variety of products. Three useful indexes allow rapid location of a particular metallation reaction, or type of functionalization and over 240 references are included.

The book serves both as an excellent reference collection of organometallic preparations and as an informative lab. manual useful for researchers in all areas of synthetic chemistry.

^{17}O AND ^{14}N NMR STUDIES OF THE Co(II), Cu(II) AND Mn(II) COMPLEXES OF L-PROLINE IN AQUEOUS SOLUTION

EFSTATHIOS D. GOTSIS* and DANIEL FIAT†

Department of Physiology and Biophysics, University of Illinois College of Medicine at Chicago, P.O. Box 6998, Chicago, IL 60680, U.S.A.

(*Received* 27 *May* 1986; *accepted after revision* 17 *March* 1987)

Abstract—The ^{17}O and ^{14}N paramagnetic transverse relaxation time and chemical shift of proline as well as of water, in aqueous solutions of Co(II), Cu(II) and Mn(II) were measured as a function of pH, temperature, and metal ion concentration. The relaxation results were fitted to a theoretical equation linking the Swift–Connick equation to the stability constants of the major complexes in equilibrium. Stability constants for the major complexes of the three ions in this work were determined, along with thermodynamic parameters for some of the complexes. Two complexes of Co(II) were detected directly by ^{17}O NMR at basic pH, and were assigned to $CoPro_2$ and $CoPro_3^-$. The hyperfine coupling constant for these two complexes, A/h, was determined directly from the isotropic shift and was found to be -0.63 and -0.31 MHz, respectively. $CoPro_2$ could be detected in the pH range 6–12, for Co(II) concentrations greater than 0.04 M, and its chemical shift was around 700 ppm downfield from free proline, at 300 K. $CoPro_3^-$ was detected only at pH 11, in the temperature range 275–284 K, with a chemical shift of 390 ppm downfield from free proline.

Transition metal ion complexes of amino acids and their equilibria in aqueous solution have been the subject of a number of investigations.[1–5] Among the various methods, ^1H and ^{13}C NMR have been used extensively, with varying success. Both the ^1H and the ^{13}C nuclei, though, are not involved directly in the binding to the paramagnetic ions, and consequently there is an inevitable attenuation of the paramagnetic effects arising from the greater distances to the paramagnetic center. On the other hand, both ^{17}O and ^{14}N nuclei are binding sites, and as such they should manifest the effects of the paramagnetic ions in a more pronounced way. The above considerations, together with an overwhelming lack of ^{17}O and ^{14}N NMR studies of transition metal ion complexes with amino acids, led us to the undertaking of this work.

The inherent difficulties associated with ^{17}O NMR, due to the low natural abundance of the ^{17}O nucleus (0.037%), low sensitivity and broad spectral lines resulting from an effective quadrupolar relaxation mechanism, are difficult to overcome without isotopic enrichment.[6] The above difficulties, coupled with the requirement of a high-power transmitter and probe (not standard equipment in most laboratories) and rather expensive isotopic enrichment, had kept ^{17}O NMR from realizing its full potential.

Of the three metal ions in this work, the Co(II)–Proline complexes have been investigated the least. The only stability constants that could be found in the literature[7–9] were for $CoPro^+$ and $CoPro_2$, thus comparison with literature cannot be made for the remaining complexes.

EXPERIMENTAL

For the ^{17}O NMR measurements, proline enriched to 30% ^{17}O at the carboxyl site by methods described previously,[10–11] was used after being passed through a chelex column twice, for further

* Present address: Department of Chemistry, University of Illinois at Chicago, P.O. Box 4348, Chicago, IL 60680, U.S.A.

† Author to whom correspondence should be addressed.

purification. For ^{14}N NMR, commercially available L-proline was used as bought from the manufacturer.

The NMR measurements were obtained using two spectrometers: a Bruker CXP-180 high-power spectrometer, operating in the Pulsed Fourier Transform mode at frequencies of 24.4 and 13.0 MHz for ^{17}O and ^{14}N NMR, respectively, and a home-made NSF-250 high-power spectrometer at the Regional NMR Center of the University of Illinois in Champaign-Urbana, operating in the Pulsed Fourier Transform mode at frequencies of 33.926 and 18.075 MHz for ^{17}O and ^{14}N NMR, respectively. Whenever appropriate, many measurements were performed on both spectrometers, to determine possible field effects, as well as to ascertain reproducibility of results.

Normally, 2,000–10,000 scans were sufficient for a well-resolved spectrum, and typical spectroscopic parameters were a spectral width of 50 kHz, pulse width for a 90° pulse of 10 μs, pulse delay of 10 μs, recycle delay of 70 ms and 4k spectral points for signal averaging.

Experimental errors in both ^{17}O and ^{14}N NMR shifts are within ± 0.5 ppm for narrow lines (20–400 Hz), and no more than ± 2.0 ppm for broader lines. The accuracy of the measured linewidths is within $\pm 5\%$.

A Bruker temperature control unit, with the thermocouple external to the sample, was used to monitor the temperature of the samples to within ± 0.5 K, with the CXP-180 spectrometer, whereas a Varian Associates temperature control unit operating along the same principles was employed with the NSF-250 spectrometer. In both cases, a minimum time of 15 min was allowed for the temperature to equilibrate each time is was changed.

The pH of the solutions was adjusted by the addition of NaOH or HCl and measured on a Corning model 125 pH meter, equipped with a combined electrode. The pH of the solution was measured before and after spectral acquisition, and, if different, the average value was recorded, provided that the variation was small.

Stock solutions of $CoCl_2$, $CuCl_2$ and $MnCl_2$ were prepared from salts of the ions that were dried at 105°C, for 36 h. The concentration of proline was determined by weighing an amount of dried in vacuum powder of proline, and whose purity was checked with an amino acid analyzer. The amino acid analyzer was used at least twice for each sample. The accuracy of the calculated concentration of proline is estimated to be within $\pm 10\%$, to allow for humidity that was inevitably absorbed by the hydrophilic proline, as well as other measuring errors.

THEORETICAL

A. *Chemical exchange*

The Bloch equations were modified by McConnell[12] to take into account the effects of chemical exchange between different magnetic environments. The McConnell equations were subsequently applied to the limiting conditions of a predominant diamagnetic site (the bulk water), in chemical exchange with one or more paramagnetic sites at considerably lesser concentrations (aqueous complexes of paramagnetic ions), by Swift and Connick.[13] In addition to the predominance of the diamagnetic site, chemical exchange among the paramagnetic sites was considered negligible to a first approximation, thus simplifying the solution of the modified Bloch equations. As a result, analytical expressions for the paramagnetic relaxation rate, $1/T_{2p}$, and chemical shift, $\Delta\omega_a$, of the diamagnetic site in the presence of the paramagnetic ions can be derived. For the benefit of the reader, a discussion of the Swift and Connick equations will follow, for they are an integral part of the theoretical treatment of our data.

The paramagnetic relaxation rate, $1/T_{2p}$, and the paramagnetic chemical shift, $\Delta\omega_a$, were found by Swift and Connick to be:

$$1/T_{2p} = \sum_{j=b}^{n} \frac{1}{\tau_a} \frac{T_{2j}^{-2} + (\tau_j T_{2j})^{-1} + \Delta\omega_j^2}{(\tau_j^{-1} + T_{2j}^{-1})^2 + \Delta\omega_j^2} \qquad (1)$$

and

$$\Delta\omega_a = -\sum_{j=b}^{n} \frac{1}{\tau_a \tau_j} \frac{\Delta\omega_j}{(\tau_j^{-1} + T_{2j}^{-1})^2 + \Delta\omega_j^2} \qquad (2)$$

where τ_a is the lifetime of the nucleus in the predominant diamagnetic site, τ_j is the lifetime of the nucleus in each of the paramagnetic sites, T_{2j} is the transverse relaxation time of the nucleus in the paramagnetic site and $\Delta\omega_j$ is the frequency difference, in rads/s, between the bulk and each of the paramagnetic sites.

In the special case of only one paramagnetic site exchanging with the diamagnetic site, eqs (1) and (2) can be reduced to simpler ones:

$$1/T_{2p} = \frac{1}{\tau_a} \frac{T_{2m}^{-2} + (\tau_m T_{2m})^{-1} + \Delta\omega_m^2}{(\tau_m^{-1} + T_{2m}^{-1})^2 + \Delta\omega_m^2} \qquad (3)$$

and

$$\Delta\omega_a = -\frac{1}{\tau_a \tau_m} \frac{\Delta\omega_m}{(\tau_m^{-1} + T_{2m}^{-1})^2 + \Delta\omega_m^2} \qquad (4)$$

where the subscript m refers to the paramagnetic site.

Some distinctions about the mechanism of transfer of the paramagnetic effects to the bulk can now

be made, depending on the relative size of T_{2m} and $\Delta\omega_m$. Thus, if $T_{2m}^{-2} \gg \Delta\omega_m^2$, it is referred to as the "T_{2m}" mechanism, whereas in the opposite case it is referred to as the "$\Delta\omega_m$" mechanism. In each case we further distinguish between slow and fast exchange, depending on the magnitude of the exchange rate, $1/\tau_m$. The following limiting equations describe all possible cases.

(1) The "$\Delta\omega_m$" mechanism:

$\Delta\omega_m^2 \gg T_{2m}^{-2}$, and eqs (3) and (4) become:

$$1/T_{2p} = (1/\tau_a)[\Delta\omega_m^2/(\tau_m^{-2}+\Delta\omega_m^2)] \tag{5}$$

and

$$\Delta\omega_a = -(1/\tau_a\tau_m)\Delta\omega_m/(\tau_m^{-2}+\Delta\omega_m^2). \tag{6}$$

We can now distinguish two cases, depending on the rate of chemical exchange, $1/\tau_m$. Thus, for $\Delta\omega_m^2 \gg \tau_m^{-2}$,

$$1/T_{2p} = 1/\tau_a = p_m/\tau_m \tag{5a}$$

and

$$\Delta\omega_a = (\tau_a\tau_m\Delta\omega_m)^{-1} \tag{6a}$$

where p_m is the ratio of the number of nuclei in the paramagnetic site divided by that of the bulk.

For $\tau_m^{-2} \gg \Delta\omega_m^2 \gg (T_{2m}\tau_m)^{-1}$,

$$1/T_{2p} = p_m\tau_m\Delta\omega_m^2 \tag{5b}$$

and

$$\Delta\omega_a = -p_m\Delta\omega_m. \tag{6b}$$

(2) The "T_{2m}" mechanism:

$T_{2m}^{-2} \gg \Delta\omega_m^2$, which results in:

$$1/T_{2p} = p_m/(\tau_m+T_{2m}) \tag{7}$$

and

$$\Delta\omega_a = -p_m\Delta\omega_m T_{2m}^2/(\tau_m+T_{2m})^2. \tag{8}$$

Again, we distinguish two cases, depending on the rate of chemical exchange, $1/\tau_m$, with respect to $1/T_{2m}$. For $T_{2m}^{-2} \gg \tau_m^{-2}$,

$$1/T_{2p} = 1/\tau_a = p_m/\tau_m \tag{7a}$$

and

$$\Delta\omega_a = -p_m\Delta\omega_m(T_{2m}/\tau_m)^2. \tag{8a}$$

For $\tau_m^{-2} \gg T_{2m}^{-2}$,

$$1/T_{2p} = p_m/T_{2m} \tag{7b}$$

and

$$\Delta\omega_a = -p_m\Delta\omega_m. \tag{8b}$$

Granot and Fiat[14] have distinguished one more case in the "$\Delta\omega_m$" mechanism. If $(\tau_m T_{2m})^{-1} \gg T_{2m}^{-2}$, $\Delta\omega_m^2$ then,

$$1/T_{2p} = p_m/T_{2m}. \tag{5c}$$

In this last case, the exchange is very rapid, so that the term $(\tau_m T_{2m})^{-1}$ becomes important and it can no longer be ignored in eq. (5).

The temperature dependence of τ_m is given by the Eyring equation,[15] indicative of first-order exchange processes:

$$\tau_m = (h/kT)\exp(\Delta H\dagger/RT-\Delta S\dagger/R) \tag{9}$$

where $\Delta H\dagger$ and $\Delta S\dagger$ are the enthalpy and entropy of activation for the first-order reaction of exchange between the diamagnetic and paramagnetic sites.

The frequency difference between the paramagnetic and diamagnetic sites is given by:

$$\Delta\omega_p = \Delta\omega_a+\Delta\omega_m. \tag{10}$$

The temperature dependence of $\Delta\omega_p$ and its relationship to the hyperfine coupling constant, A/h, is given by the equation of Bloembergen:[16]

$$(\Delta\omega_p/\omega) = -S(S+1)A(\gamma_e/\gamma_n)/3kT \tag{11}$$

where S is the spin of the paramagnetic ion, γ_e and γ_n are the magnetogyric ratios of the free electron and the nucleus under consideration, respectively, and the other constants have their usual meaning. At the point of intersection of the two limiting cases of $\ln T_{2p}$ vs $1/T$, $\Delta\omega_m\tau_m = 1$. Thus, having determined τ_m from the slow exchange region of $\ln T_{2p}$ vs $1/T$, eq. (5a), one can determine $\Delta\omega_m$, and consequently A/h from eq. (11). Such parameters were determined for aqueous complexes of several transition metal ions,[17-20] with considerable accuracy.

B. *Paramagnetic relaxation*

The relaxation of the ^{17}O and ^{14}N nuclei in a paramagnetic complex could occur by dipolar and hyperfine interactions with the unpaired electrons of the paramagnetic ion[17,21-23] in addition to their quadrupolar relaxation, and the transverse relaxation rate, $1/T_{2m}$, is given by:

$$1/T_{2m} = (1/T_{2m})_{DP}+(1/T_{2m})_{HF} \tag{12}$$

where DP stands for dipolar and HF for hyperfine:

$$(1/T_{2m})_{DP} = (1/15)[S(S+1)g^2\beta^2\gamma_n^2/r^6] \times (B+C+D+D+E+F) \tag{13}$$

and

$$(1/T_{2m})_{HF} = (1/3)S(S+1)(2\pi A/h)^2(G+H). \tag{14}$$

The terms A, B, C, D, E, F, G and H are given

by:

$$B = 4\tau_1$$

$$C = \tau_2/[1+(\omega_n-\omega_e)^2\tau_2^2]$$

$$D = 3\tau_1/(1+\omega_n^2\tau_1^2)$$

$$E = 6\tau_2/(1+\omega_e^2\tau_2^2)$$

$$F = 6\tau_2/[1+(\omega_n+\omega_e)^2\tau_2^2]$$

$$G = \tau_1$$

$$H = \tau_2/[1+(\omega_n-\omega_e)^2\tau_2^2]$$

where τ_1 and τ_2 are correlation times characterizing the interactions, r is the distance between the nucleus and the unpaired electrons and ω_n and ω_e are the nuclear and electronic precessional frequencies, respectively. The rest of the terms have their usual meaning.

Equations (13) and (14) can be further simplified, considering the relative size of ω_n, ω_e and the correlation times, τ_1 and τ_2. Thus, since $\omega_e \gg \omega_n$ and $\omega_n^2\tau^2 \ll 1$, eqs (13) and (14) become:

$$(1/T_{2m})_{DP} = (1/15)[S(S+1)g^2\beta^2\gamma_n^2/r^6] \times [7\tau_1+13\tau_2/(1+\omega_e^2\tau_2^2)] \quad (15)$$

and

$$(1/T_{2m})_{HF} = (1/3)(2\pi A/h)^2S(S+1) \times [\tau_1+\tau_2/(1+\omega_e^2\tau_2^2)]. \quad (16)$$

Similar equations[17,23] exist for T_{1m}:

$$1/T_{1m} = (1/T_{1m})_{DP}+(1/T_{1m})_{HF} \quad (17)$$

where,

$$(1/T_{1m})_{DP} = [(2/15)S(S+1)g^2\beta^2\gamma_n^2/r^6] \times [3\tau_1+7\tau_2/(1+\omega_e^2\tau_2^2)] \quad (18)$$

and

$$(1/T_{1m})_{HF} = (2/3)S(S+1)(2\pi A/h)^2[\tau_2/(1+\omega_e^2\tau_2^2)]. \quad (19)$$

C. *Quadrupolar relaxation*

The ^{17}O quadrupolar relaxation ($I = 5/2$) in the extreme motional narrowing limit is given by the following equation:[23]

$$(1/T_2)_q = (3/125)(1+\eta^2/3)(e^2qQ/\hbar)^2\tau_c \quad (20)$$

where η is the asymmetry parameter, $e^2qQ/\hbar$ is the quadrupolar coupling constant and τ_c is the rotational correlation time.

D. *Complex equilibria*

For aqueous solutions of amino acids or peptides, containing small quantities of paramagnetic ions, such that [L] ≫ [M], where L and M refer to the ligand amino acid or peptide and metal ion, respectively, the complex equilibria in solution can be described by the general equation:[24]

$$pM^{2+}+qH^+ + rL^{y-} \overset{\beta_{pqr}}{\rightleftharpoons} M_pH_qL_r^{(2p+q-yr)}. \quad (21)$$

β_{pqr} is the overall stability constant for each metal ion complex:

$$\beta_{pqr} = [M_pH_qL_r]/([M]^p[H]^q[L]^r). \quad (22)$$

Since the concentration of the metal ions in this work is much smaller than that of the ligands, the probability for polymeric species is negligible and only monomeric species are considered with $p = 1$. L-Proline can exist in three forms: the ionic form, L^-, with $q = 0$, the zwitterionic form, $HL^{\pm}$, with $q = 1$, and the cationic form, H_2L^+, with $q = 2$. Considering that there are two possible binding sites per amino acid, and assuming hexa-coordinated complexes of the metal ions in this work, there can be up to three amino acids per metal ion. Thus $r = 1$, 2 or 3.

From the mass balance equation for $[M]_{total}$ and $[L]_{total}$ we get:

$$[M] = [M]_{total}\Big/\left(1+\sum_q\sum_r\beta_{1qr}[H]^q[L]^r\right) \quad (23)$$

and

$$[L] = [L]_{total}\Big/\left(1+\sum_q\beta_{0q1}[H]^q\right). \quad (24)$$

Thus, by calculating $[L^-]$ as a function of pH (easily accomplished with the aid of the Henderson–Hasselbalch equation), one can calculate the free metal ion concentration, provided that the stability constants are known and consequently the concentration of each of the complexes in solution. The validity of the above approximation has been tested by Beattie *et al.*[5] with an iterative solution of the complete mass balance equations using the method of Ingri and Sillén.[25] We can now combine the complex equilibria equations with the Swift–Connick equation and get:

$$1/T_{2p} = \sum_q\sum_r p_{1qr}f(\tau, T_2, \Delta\omega)_{1qr} \quad (25)$$

where τ_{1qr}, $(T_2)_{1qr}$ and $\Delta\omega_{1qr}$ refer to the lifetime, transverse relaxation time and frequency difference, in rads/s, from the free ligand, for each of the complexes. p_{1qr} is the ratio of the number of exchanging nuclei in each of the complexes divided by the number of nuclei in the free ligand. Since the free ligand concentration is much larger than the concentration of any of the complexes, the total concentration of

the ligand in solution is being taken as the concentration of the free ligand, to a first approximation. Thus,

$$p_{1qr} \approx r[MH_qL_r]/[L]_{total}. \quad (26)$$

Since $[MH_qL_r] = \beta_{1qr}[M][H][L]$, we can now substitute in (25) and get:

$$1/T_{2p} = \sum_q \sum_r r[M][H]^q[L]^r \beta_{1qr} f(\tau, T_2, \Delta\omega)_{1qr}/[L]_{total}. \quad (27)$$

Substituting eq. (23) into (26) for [M], we get:

$$1/T_{2p} = \frac{([M]/[L])_{total} \sum_q \sum_r r\beta_{1qr}[H]^q[L]^r f(\tau, T_2, \Delta\omega)_{1qr}}{\left(1+\sum_q \sum_r \beta_{1qr}[H]^q[L]^r\right)}. \quad (28)$$

Equation (28) thus links the paramagnetic relaxation rate, $1/T_{2p}$, of the free ligand, to the stability constants of all possible complexes and their perspective NMR parameters. Thus, it is possible to determine the stability constants of the complexes through a multi-parameter fit of the experimental relaxation data to eq. (28). In this work, the variation of the stability constants and NMR parameters was done semi-manually, starting with published values of stability constants (whenever possible), and having the computer determine $1/T_{2p}$ for any given combination of parameters. The best fits were then determined graphically, and the correlation coefficients were found to be in the range 0.97–0.99.

E. *The solvent signal*

In addition to the relaxation results for the free proline, there is a second set of data that indirectly gives information about the degree of formation of the various complexes, namely the paramagnetic relaxation rate of H_2O:

$$1/T_{2p} = p_m f(\tau_m, T_{2m}, \Delta\omega_m) \quad (29)$$

where p_m is the ratio of the bound water molecules divided by the number of molecules in the bulk water:

$$p_m = n_{eff}[M]_{total}/(55.5 - n_{eff}[M]_{total}). \quad (30)$$

Since $[M] \ll 55.5$, p_m is approximated by:

$$p_m \approx n_{eff}[M]_{total}/55.5. \quad (31)$$

In a pure aqueous solution of the metal ions in this work, n_{eff} is 6, assuming a hexa-coordinated structure.[17-20] In the presence of the amino acid, though, some of the water molecules in the metal ion complexes get replaced by the amino acid, reducing, thus, the effective number of coordinated water molecules. Consequently, the paramagnetic relaxation rate of water is reduced in a predictable way, since it depends linearly on n_{eff} and also on $f(\tau_m, T_{2m}, \Delta\omega_m)$. Thus in general n_{eff} can be calculated from the ratio of the paramagnetic relaxation of water in the presence and absence of proline, respectively:

$$n_{eff} = [6(1/T_{2p})^*/(1/T_{2p})] \times [f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)] \quad (32)$$

where the asterisk denotes the presence of proline in the solution, and all parameters subscripted by m are weighted average quantities over the various complexes in which water can be bound.

Equation (32) can be useful only when $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)$ is known, or assumptions can be made about its magnitude. Assuming that $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m) = 1$, however, simplifies eq. (32) to:

$$n_{eff} = 6(1/T_{2p})^*/(1/T_{2p}) \quad (32a)$$

which is the equation that we have used in plotting the experimental results. The validity of this approximation will be discussed in a subsequent section.

Another way of calculating n_{eff} is by taking the weighted average of the number of water molecules in each complex, i.e.

$$n_{eff} = (1/[M]_{total})\{6[M(H_2O)_6]^{2+} + 5[MHL^{2+} \cdot 5H_2O] + \cdots + 1[MHL_3 \cdot H_2O]\}$$

which can be written in compact form as:

$$n_{eff} = (1/[M]_{total}) \sum_q \sum_r (6+q-2r)[MH_qL_r]. \quad (33)$$

Assuming that the concentrations of the complexes are known (i.e. the stability constants are known) one can calculate the effective coordination number of water molecules per metal ion, n_{eff}, in two ways: from eqs (32a) and (33). A good agreement between the results of the two equations will assure that the assumption made to get eq. (32a) is valid, and/or the stability constants are correct. Alternatively, divergence of the results of eqs (32a) and (33) means that the assumption that $[f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)] = 1$ is not valid and/or the stability constants used in eq. (33) are not correct. A further discussion of these points will follow in the next section.

RESULTS AND DISCUSSION

A. *The* Co(II)-*proline system*

(1) ^{17}O *NMR*. The pH dependence of the paramagnetic transverse relaxation rate of proline, $1/T_{2p}$, at 300 K, for a solution containing 0.13 M proline and 7.7 mM $CoCl_2$ (Solution A) is depicted in Fig. 1. The experimental results were least-squares fitted to eq. (28), and the stability constants and NMR parameters for each complex are given in Tables 1 and 2. Unlike other amino acids, for which several stability constants have been reported, the only stability constants for Co(II)–proline complexes that could be found in the literature were K_1 and β_2, for $CoPro^+$ and $CoPro_2$, respectively,[7–9] which are included in Table 1 for comparison. The following equations define the stability constants for all complexes assumed to exist in non-negligible concentrations:

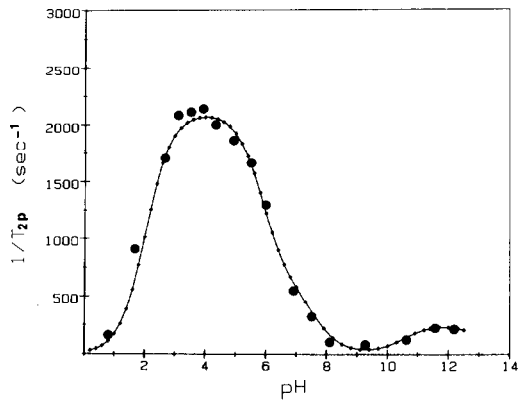

Fig. 1. Dependence of the ^{17}O paramagnetic transverse relaxation rate of proline upon the measured pH of a solution containing 0.126 M L-Proline and 7.7 mM $CoCl_2$ (Solution A). The experimental points were recorded at 24.4 MHz, 300 K and the dotted line is the least-squares fit of the experimental points to eq. (28), with the constants of Tables 1 and 2.

[b] Ref. 9.
[c] From ^{14}N NMR measurements.

First-order dissociation of $CoPro^+$ and $CoPro_2$ cannot be a major source of broadening, because of the long lifetimes of complexes of this type (in the order of 10^{-1} to 10^{-2} s),[9,26] thus their contribution to the relaxation rate of proline was neglected, to a first approximation. (A rough calculation shows that the contribution of these two complexes to $1/T_{2p}$ is less than 0.5 Hz, certainly negligible.) Incidentally, the small deviation of the experimental points from the theoretical line in the pH range 3–5 is due to copper impurities that are found in the titrating base. As will be seen in the Cu(II)–proline results, very large broadening is observed in the pH range 3–4 for comparatively small copper concentrations.

Taking the existence of $Co(HPro)_2^{2+}$ into account was dictated by the value of n_{eff} in the acidic pH range, Fig. 2. Without $Co(HPro)_2^{2+}$, an unreasonably large stability constant for $CoHPro^{2+}$ would have to be assumed to justify a value of about 5 for n_{eff} at pH 4–5. Similar considerations were also made in the case of glycine and alanine[27] for Co^{2+} but not for Cu^{2+} and Mn^{2+}, for which the best fits were obtained without considering the complex $M(HL)_2^{2+}$ as a major species. The solid circles in Fig. 2 were determined from eq. (32a). The deviation from the dotted line [eq. (33)] shows clearly that $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m) = 1$ is not a good assumption for $n_{eff} < 5$. In fact, $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)$ was found to vary nonlinearly from 1 at very acidic pH to about 5 at pH 8, (Solution C, data not included).

Figure 3 shows the distribution of all Co^{2+}-containing species in Solution A, as a function of pH, constructed with the stability constants of Table 1. The existence of $CoHPro_3$ was postulated on the fact that the zwitterionic form of proline is predominant in the pH range 3–10, thus eq. (IV) should be considered. The best fit for $1/T_{2p}$ could be obtained with $\log k'_3 = 0.11$, but there is an uncertainty of ± 0.15 associated with the above value, due to the small paramagnetic broadening in the pH range where $CoHPro_3$ reaches its maximum concentration. The distribution of $CoHPro_3$ follows that of $CoPro_2$, except in the high pH range where the concentration of the zwitterion of proline diminishes and reaction (IV) is negligible.

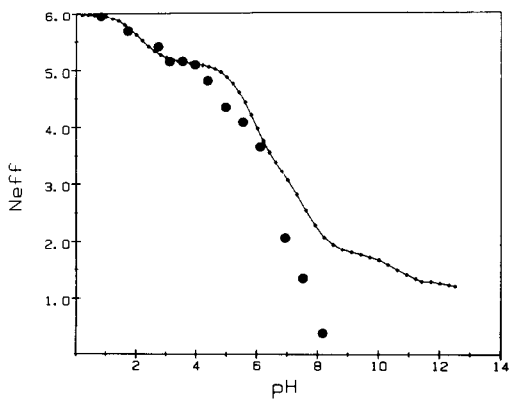

Fig. 2. Dependence of the effective coordination number of water upon pH, for Solution A. The solid circles represent the experimental data calculated from eq. (32a), while the dotted line is the theoretical prediction of eq. (33).

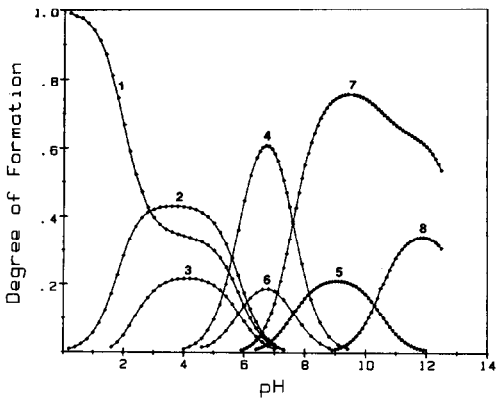

Fig. 3. Dependence of the relative concentration of all Co^{2+}-containing species upon pH, for Solution A. All curves were constructed with the stability constants of Table 1. 1 is the free Co^{2+}, 2, 3, 4, and 5 are the protonated complexes $CoHPro^{2+}$, $Co(HPro)_2^{2+}$, $CoHPro_2^+$ and $CoHPro_3$, respectively, whereas 6, 7 and 8 are the bidentate complexes $CoPro^+$, $CoPro_2$ and $CoPro_3^-$, respectively.

Second-order processes were neglected, but the shorter lifetimes calculated from the ^{14}N NMR data for $CoPro_3^-$ at basic pH indicate that second-order exchange does play a role when the concentration of the free ligand is larger than 0.5 M. The low concentration of proline in Solution A, though, justifies neglecting of second-order effects, included in:

$$1/\tau_m = k_1 + k_2[Pro^-] \tag{34}$$

with k_2 defined by:

$$CoPro_r + (Pro^-)^* \overset{k_2}{\rightleftharpoons} CoPro^*_{(r-1)}Pro + Pro^-. \tag{35}$$

The reaction of the type shown in eq. (35) has been considered in several ^1H NMR studies of amino acids and metal ions.[5,28,29]

The relatively small paramagnetic broadening in the basic pH range, where $CoPro_3^-$ is the predominant species, indicates the formation of strong coordination bonds between proline and Co^{2+}, with a slow rate of chemical exchange on the NMR time scale. From the temperature dependence of T_{2p}, the enthalpy and entropy of activation for the first-

order process (V) were calculated along with the lifetime of $CoPro_3^-$ and its hyperfine coupling constant, A/h, are presented in Table 2.

Figure 4 contains several ^{17}O spectra of Solution B at various pH values. In addition to free proline, a second signal can be seen at around 700 ppm from free proline. Considering the stoichiometry of the solution in the pH range 7–12 this signal was assigned to $CoPro_2$. The concentration of $CoPro_2$ determined from the relative areas of the signals (compared to the signal of water that was considered as constant to a first approximation) reaches a maximum at pH 9.5, and then decreases slightly above that pH. The concentration of free proline, on the other hand, decreases dramatically above pH 9, reflecting the formation of $CoPro_3^-$. Note that the total concentrations of proline and Co^{2+} in Solution B are 0.28 and 0.055 M, respectively, thus at basic pH where $CoPro_2$ and $CoPro_3^-$ are the predominant complexes, more than half of the proline is bound to Co^{2+}. Of course, the Swift and Connick equations are not expected to hold true in this case, because the condition of a predominant diamagnetic case is not met. The high concentration of Co^{2+}, though, was necessary in order to make detection of $CoPro_2$ possible.

The minimum linewidth of $CoPro_2$ (1,700 Hz) occurs in the pH range 6–8 and it is taken to be the natural linewidth of $CoPro_2$ (no contributions from chemical exchange to it). This assumption is substantiated by $T_1 = 0.19$ ms that was determined for $CoPro_2$ at pH 9, which corresponds to about 1,700 Hz. Above pH 8, the linewidth of $CoPro_2$ increases non-linearly with pH (from 1900 Hz at pH 9 to 3700 Hz at pH 11.7). The long lifetime of $CoPro_2$ (2.5×10^{-2} s)[9] rules out the importance of first-order exchange. Second-order exchange broadening of $CoPro_2$ must then be considered and that is given by:

$$1/T_{2p} = k_2[Pro^-] \tag{36}$$

whereas the second-order broadening of free proline is given by:

$$1/T_{2p} = k_2[CoPro_2][Pro^-]/[Pro]_{total}. \tag{37}$$

Comparing eqs (36) and (37) it is obvious that the second-order broadening of $CoPro_2$ is greater than that of free proline by a factor of $[Pro]_{total}/$

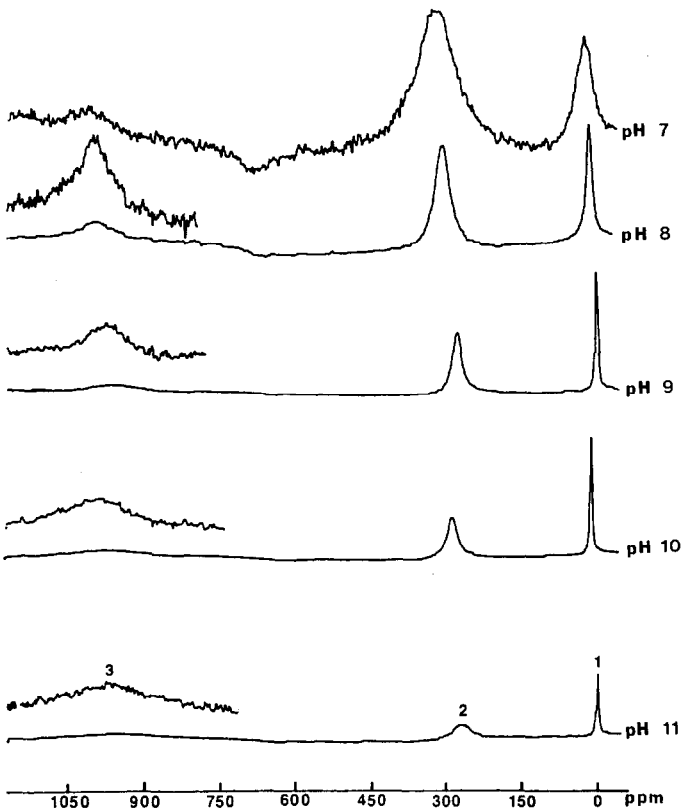

Fig. 4. ^{17}O NMR spectra of a solution containing 0.28 M proline and 55 mM $CoCl_2$ (Solution B), At several pH values. The spectra were recorded at 24.4 MHz, 300 K, with a spectral width of 50 KHz, pulse width of 10 μs, delay time of 10 μs, recycle delay of 70 ms and with 4k spectral points for signal acquisition.

[$CoPro_2$]. For Solution A at pH 11.7, this factor is about 40, thus if second-order exchange broadens the free proline signal by 20 Hz, $CoPro_2$ would be broadened by 800 Hz, certainly non-negligible.

The question that must be answered is whether the signal that was assigned to $CoPro_2$ is the weighted average of all ^{17}O nuclei in $CoPro_2$ or is it due only to the non-coordinated carbonyl oxygens in that complex. The "narrow" linewidth of 1,700 Hz suggests that the quadrupolar interaction be the principal mechanism of relaxation. In fact, if one uses eq. (33) with $\eta = 0.45$,[30] $e^2qQ/h = 10.2$ MHz determined from the ^{17}O quadrupolar splittings of [^{17}O]urea dissolved in a lyotropic liquid crystal (M. I. Burgar and D. Fiat, unpublished data), and $\tau_c = 7.6 \times 10^{-11}$ s calculated from the Moniz–Gutowski–BPP equation[31,32] (taking $d = 1$ g/cm^3) the quadrupolar relaxation rate is expected to be 7860 s^{-1}, larger than the observed value of 5340 s^{-1}. This estimate shows that the quadrupolar relaxation alone can account for the observed relaxation rate of $CoPro_2$. It also shows that the correlation time calculated from the Moniz–Gutowski–BPP equation is longer than what one calculates from the quadrupolar relaxation rate, a finding that has been reported quite often.[31,33,34]

The contribution of the dipolar and hyperfine mechanisms to the relaxation rate of $CoPro_2$ can be determined from eqs (15) and (16), respectively, provided that the hyperfine coupling constant, correlation times and the distance between the ^{17}O nucleus and Co^{2+} are known. The hyperfine coupling constant was determined from the observed paramagnetic shift of $CoPro_2$ and was found to be -6.3×10^5 Hz. The correlation time for the aqueous and methanol complexes of Co^{2+} was taken to be the electronic relaxation time, which at 298 K was found to be 7×10^{-13} s.[18,19] Using this value for the electronic relaxation time in the case of $CoPro_2$ is not necessarily a good assumption (in view of the negative charge of the carboxylate group of each proline molecule) but it should serve as a guide since no better estimate could be found. The distance between the metal ion and the non-coordinated carbonyl oxygen was taken to be 4 Å, in line with similar values measured for complexes of proline with Mn^{2+} and Cu^{2+} (3.99 and 4.04 Å, respectively).[4,35] With these values, eqs (15) and (16) give 4 and 27 s^{-1}, respectively, for the dipolar and hyperfine contributions to the relaxation rate of $CoPro_2$.

The predominance of the quadrupolar mechanism and the small hyperfine coupling constant of $CoPro_2$ support the hypothesis that the signal arises from the non-coordinated carbonyl oxygens in $CoPro_2$ (one from each proline molecule). The paramagnetic shift of $CoPro_2$ was taken to be the difference of the observed chemical shift of $CoPro_2$ from that of the carbonyl oxygen of methyl ester (970 and 350 ppm, respectively), rather than from the signal of free proline, which is the weighted average signal of a double bonded and a single bonded carboxylic oxygen exchanging rapidly with respect to the NMR time scale. Thus the methyl ester carbonyl oxygen seems to be a better-suited reference in the present case.

Figure 5 shows the pH dependence of the paramagnetic chemical shift, $\Delta\omega_a$, of proline in Solution A. The decline from pH 3 to 4 is probably due to experimental error (at this pH the broadest lines are observed, with an uncertainty of ± 2.0 ppm). A plateau is more likely to reflect the concentration profile of $CoHPro^{2+}$ and $Co(HPro)_2^{2+}$ in this pH range, and the additional shift from pH 4–7 is apparently due to the formation of $CoHPro_2^+$ in this pH range. Thus, the paramagnetic chemical shift also reflects the distribution of the complexes as a function of pH.

Figures 6 and 7 show the temperature dependence of T_{2p} of free proline in Solution C, at pH 3 and 6, respectively. In this pH range, where the monodentate complexes $CoHPro^{2+}$ and $Co(HPro)_2^{2+}$ predominate, both the slow and the fast exchange regions are accessible in the temperature range of 274–370 K. Incidentally, room temperature falls in the intermediate exchange region, where maximum broadening occurs, and neither the slow nor the fast exchange approximation is valid for $1/T_{2p}$. At the point of intersection of the slow and fast exchange curves in Figs 6 and 7, $\Delta\omega_m\tau_m = 1$, and eq. (5) reduces to:

$$1/T_{2p} = (1/2)p_m/\tau_m. \tag{38}$$

The above simplification serves as a useful con-

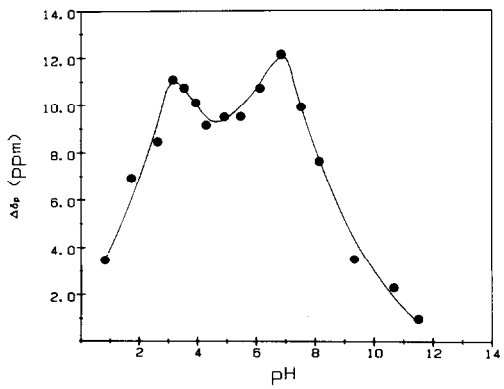

Fig. 5. Dependence of the ^{17}O paramagnetic chemical shift of proline upon pH, for Solution A, 300 K and a spectrometer frequency of 24.4 MHz.

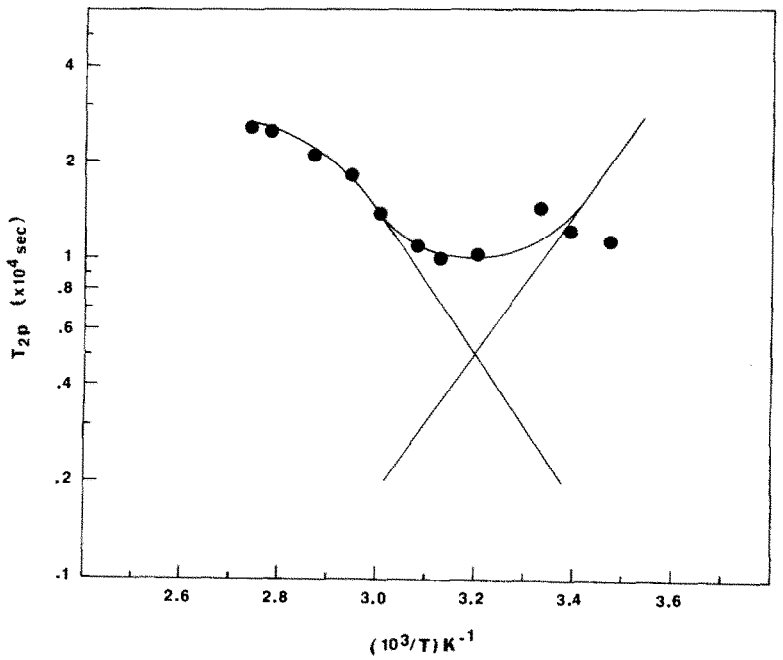

Fig. 6. Dependence of the ^{17}O paramagnetic transverse relaxation time of proline upon inverse temperature at pH 3, for a solution containing 0.3 M proline and 22 mM $CoCl_2$ (Solution C). The data were recorded at 33.926 MHz.

straint on the data analysis: the slow and fast exchange approximation lines intersect at a point at exactly half the experimental value at that temperature.

If an average p_m is assumed, i.e. including $CoHPro^{2+}$, $Co(HPro)_2^{2+}$ and $CoHPro_2^+$, an average value of A/h for these three complexes can be calculated. Unfortunately, although the relative distribution of these complexes can be determined at a given temperature by a least-squares fitting of eq. (28) to the experimental paramagnetic relaxation data, the temperature dependence of the stability constants and the rate of chemical exchange are not known, thus the relative contribution of each complex to the overall relaxation rate, $1/T_{2p}$, as a function of temperature, cannot be assessed. As a result, only an average value (or at best some estimates) for all thermodynamic parameters, as

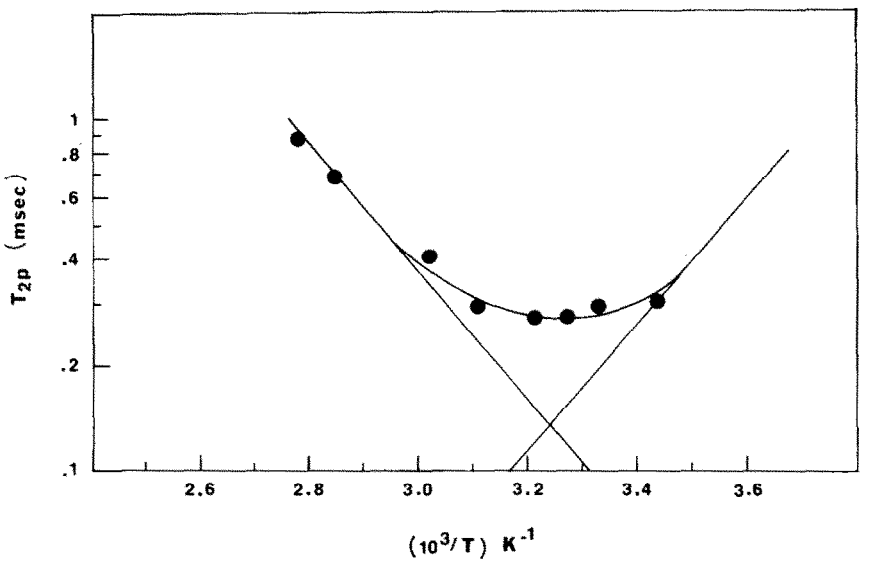

Fig. 7. Dependence of the ^{17}O paramagnetic transverse relaxation time of proline upon inverse temperature, in Solution C, at pH 6 and at a spectrometer frequency of 33.926 MHz.

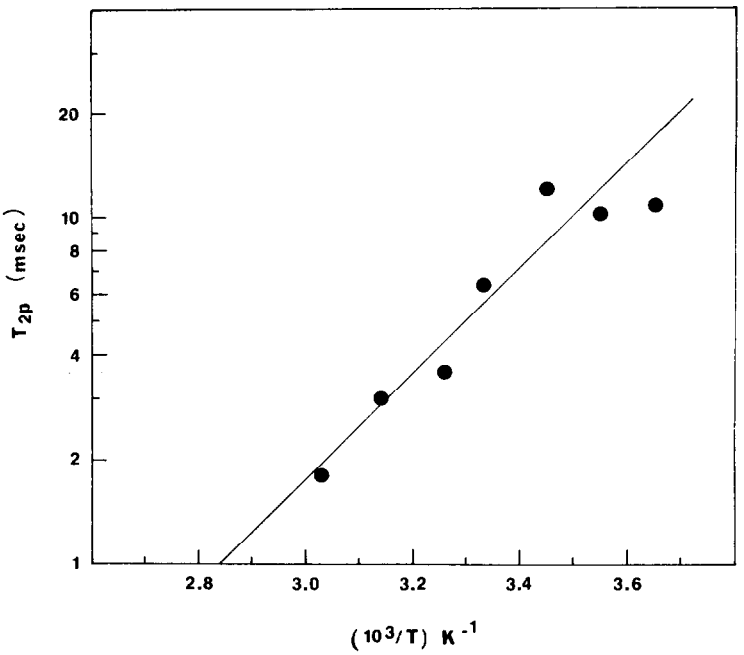

Fig. 8. Dependence of the ^{17}O paramagnetic transverse relaxation time of proline upon inverse temperature, at pH 11, for a solution containing 0.26 M proline and 0.01 M $CoCl_2$ (Solution D). Spectrometer frequency is 33.926 MHz.

well as for the hyperfine coupling constant, A/h, can be determined.

Figure 8 shows the temperature dependence of T_{2p} of proline for Solution D, at pH 11. Only the slow exchange region is accessible in the temperature range 275–330 K. The deviation from linearity at the lower temperatures is probably due to a non-linear increase in the viscosity of the solution. From the slow exchange region, the lifetime of $CoPro_3^-$, the enthalpy and entropy of activation of the first-order exchange of this complex are determined and shown in Table 2.

(2) ^{14}N *NMR results.* Figure 9 shows the pH dependence of the ^{14}N transverse paramagnetic relaxation rate, $1/T_{2p}$, of proline for Solution E and F, containing Co^{2+} and Cu^{2+}, respectively. The complete lack of broadening below pH 8 is consistent with the ^{17}O results, indicating that the first-order exchange in reaction (V) and second-order exchange [eq. (35)] are responsible for the observed broadening in the basic pH region. Thus, ^{14}N NMR can be used as a complementary method to ^{17}O NMR, but alone it lacks the wealth of information provided by ^{17}O NMR. The broadening of the proline signal above pH 9 follows the formation of $CoPro_3^-$. Thus, the temperature dependence of T_{2p} at high pH, can provide the thermodynamic parameters associated with reaction (V), to a first approximation, i.e. neglecting second-order effects. Table 2 summarizes the results obtained from both ^{17}O and ^{14}N NMR experiments.

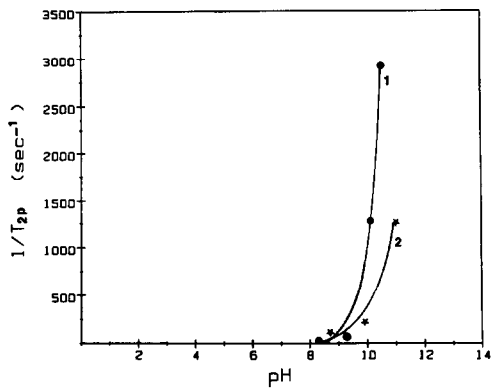

Fig. 9. Dependence of the ^{14}N paramagnetic transverse relaxation rate of proline upon pH, for Solution E (1.5 M proline and 0.02 M $CoCl_2$) and Solution F (1.0 M proline and 1.0 mM $CuCl_2$), at 300 K. The spectrometer frequency was 18.075 MHz.

B. *The* Cu(II)-*proline system*

(1) ^{17}O *NMR results.* Figure 10 shows the pH dependence of the ^{17}O paramagnetic transverse relaxation rate, $1/T_{2p}$, of proline for Solution G, at 300 K. The dotted line was constructed through eq. (28), with the stability constants of Table 3 and the NMR parameters of Table 4.

Figure 11 shows the distribution of all Cu(II)-containing species in Solution G, as a function of

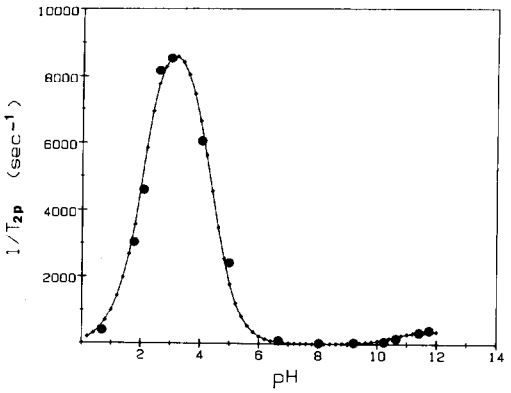

Fig. 10. Dependence of the ^{17}O paramagnetic transverse relaxation rate of proline upon the measured pH of a solution containing 0.25 M proline and 0.3 mM $CuCl_2$ (Solution G). The experimental points were recorded at 24.4 MHz, and 300 K, and the dotted line is the least-squares fit of the experimental points to eq. (28), with the constants of Tables 3 and 4.

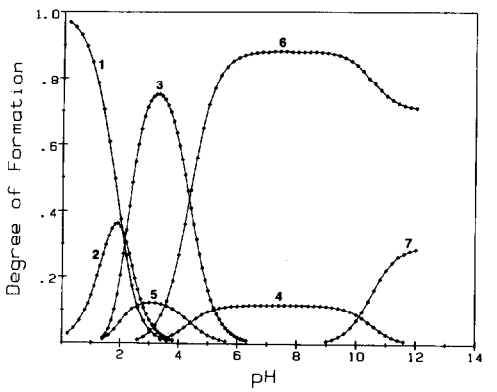

Fig. 11. Dependence of the relative concentration of all Cu^{2+}-containing species upon pH, for Solution F. All curves were constructed with the stability constants of Table 3. 1 is the free Cu^{2+}, 2, 3 and 4 are the protonated complexes $CuHPro^{2+}$, $CuHPro_2^+$ and $CuHPro_3$, respectively, and 5, 6 and 7 are the bidentate complexes $CuPro^+$, $CuPro_2$ and $CuPro_3^-$, respectively.

Table 3. Log of stability constants of the major Cu(II)–proline complexes in aqueous solution[a]

Complex	Constant	This work	Ref. 2	Ref. 36	Ref. 37
$CuHPro^{2+}$	k'_1	0.85	0.98 ± 0.27		
$CuHPro_2^+$	k'_2	1.39	1.10 ± 0.19		
$CuHPro_3$	k'_3	−0.05			
$CuPro^+$	K_1	8.70	8.69	8.76	8.72
$CuPro_2$	β_2	16.34	16.03	16.31	16.35
$CuPro_3^-$	β_3	16.54			

[a] The stability constants of this work were determined at 300 K, while those of Ref. 2 were recorded at 310 K. The remaining constants are reported at 298 K.

Table 4. Thermodynamic and NMR parameters of the Cu(II)–proline complexes in aqueous solution[a]

Complex	$f(\tau_m, T_{2m})$ (s^{-1})	τ_m (s)	$\Delta H\dagger$ (Kcal/mol)	$\Delta S\dagger$ (e.u.)
$CuHPro^{2+}$	2.68×10^6			
$CuHPro_2^+$	2.17×10^6			
$CuHPro_3$	2.5×10^4			
$CuPro^+$	3.0[b]			
$CuPro_2$	5.9[b]			
$CuPro_3^-$	1.68×10^5	1.2×10^{-6}[c]	5.8[c]	−14.0[c]

[a] All parameters are calculated at 300 K.

[c] From ^{14}N NMR.

pH, constructed with the stability constants of Table 3. For comparison, the stability constants reported by other investigators are also given in Table 3. The overall good agreement confirms the validity of the method used in this work.

The n_{eff} data of water could not be used in this case, due to the small paramagnetic broadening of the water signal, for the concentration of $CuCl_2$ used in this work. Considering the experimental uncertainty of ± 5 Hz associated with narrow lines, and the total paramagnetic broadening of 20 Hz, the uncertainty in n_{eff} was $\pm 0.25 \times 6$ or ± 1.5, totally unacceptable.

The values of $f(\tau_m, T_{2m}, \Delta\omega_m)$ associated with each Cu(II)–Proline complex are one to three orders of magnitude larger than those of the corresponding Co(II)–Proline complexes. The relevant mechanism of transfer of the paramagnetic effects of Cu(II) to the bulk is the "T_{2m}" mechanism, given by eq. (7). Thus, either the rate of chemical exchange in cases of slow exchange, or the transverse relaxation rate of the complexes in cases of fast exchange, are one to three orders of magnitude larger than those of the corresponding Co(II)–proline complexes. This is also the case with the aqueous complexes of the aforementioned metal ions.[13] The Jahn–Teller interactions that characterize the coordination of Cu^{2+} cause the formation of elongated octahedral complexes, with unequal equatorial and axial coordination, whereas the complexes of Co(II) are distinguished by regular octahedral symmetry, with all six coordination sites equivalent. Thus, the long electronic relaxation times of Cu^{2+}, coupled with possible interconversion of the axial and equatorial coordination sites, may be the principal reasons for the apparent short NMR relaxation times and/or lifetimes of its complexes.

The relaxation results in the basic pH region are completely different from those in the Cu(II)–Glycine and Cu(II)–Alanine systems, in which cases the broadening in the basic pH was larger than that in the acidic pH.[27] This result must be due to the cyclic structure of proline and the fact that it is a more basic amino acid (pK_a of proline is an order of magnitude larger than that of glycine and alanine). Consequently, $CuPro_3^-$ is more tightly bound than $CuGly_3^-$ or $CuAla_3^-$, and as a result it has a longer lifetime. The overall result is less broadening of the free proline signal in the basic pH.

The stability constant that was determined for $CuHPro_3$ suffers from the same uncertainty as that of $CoHPro_3$, for the reasons discussed previously, but its overall effect on the stability constants of the other species in the pH range that it exists was minimal. Thus, omitting $CuHPro_3$ from the fitting would require slightly different stability constants for $CuHPro_2$, $CuPro_2$ and $CuPro_3^-$ to obtain a good fit, but the resulting best fit had a smaller correlation coefficient than the best fit obtained including $CuHPro_3$. Thus $CuHPro_3$ was included in the fitting.

(2) ^{14}N *NMR results.* The pH dependence of the ^{14}N paramagnetic transverse relaxation rate of proline, $1/T_{2p}$, for Solution F, is depicted in Fig. 9. As in the case of the Co(II)–Proline system, there is no broadening in the acidic and neutral pH, but only in the basic pH, following the formation of $CuPro_3^-$. Thus, no information could be provided in the acidic and neutral pH, limiting, therefore, ^{14}N NMR as a self-sufficient method in ion binding studies with amino acids.

Figure 12 depicts the temperature dependence of the ^{14}N paramagnetic transverse relaxation time of proline at pH 11, for Solution H. The thermodynamic parameters derived from the temperature dependence of τ_m of $CuPro_3^-$ are given in Table 4. Slow exchange characterizes the Cu(II)–Proline system for the entire temperature range of 275–360 K. At the lower end of the temperature range, the non-linear increase in the viscosity of the solution causes additional broadening, and that explains the deviation from linearity.

C. *The* Mn(II)*-proline system*

(1) ^{17}O *NMR results.* Figure 13 shows the pH dependence of the ^{17}O paramagnetic transverse relaxation rate of proline, for Solution I. The dotted line is the least-squares best fit of the experimental results to eq. (28). The stability constants and NMR parameters are shown in Table 5. The small deviation from the theoretical line around pH 3 is caused by the inevitable contamination of the solution with copper impurities, that despite all precautions persist in the titrating base. As it was seen in the previous section, copper causes the largest broadening around pH 3. While one can reduce the amount of impurities in the solution by extreme caution, some trace of the copper impurity will always persist for all practical applications.

The most striking difference from the Co(II)–proline and Cu(II)–proline systems lies in the fact that one species predominates in the pH range 0–8, namely $MnHPro^{2+}$. The spherical symmetry in the electronic charge density of Mn^{2+}, resulting in small stability constants of its complexes, is the reason that $MnHPro^{2+}$ is the predominant species in the pH range 0–8.

The distribution of the Mn(II)–proline complexes as a function of pH, for the same Solution H, is given in Fig. 14. The same types of complexes that

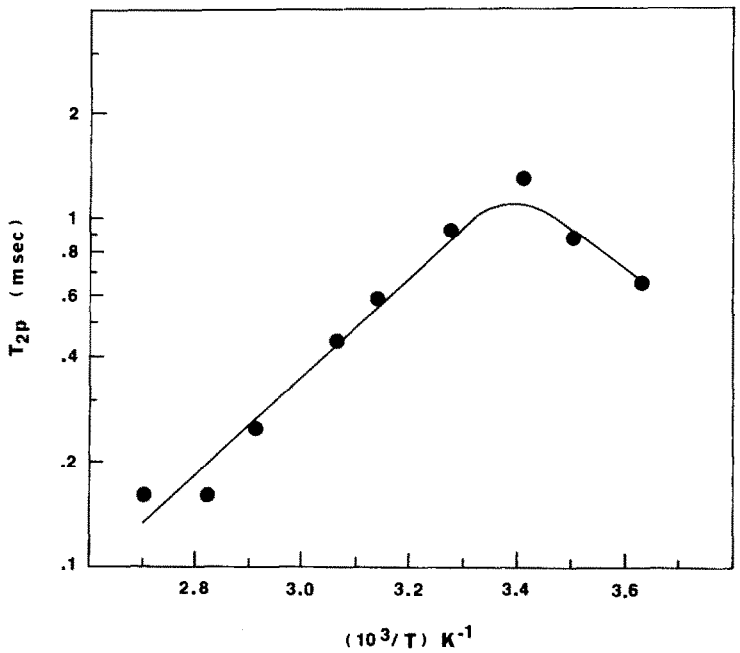

Fig. 12. Dependence of the ^{14}N paramagnetic transverse relaxation time of proline upon inverse temperature, for a solution containing 1.5 M proline and 2.0 mM $CuCl_2$ (Solution H), at pH 11. The spectrometer frequency was 18.075 MHz.

were discussed in previous sections also exist in the Mn(II)–proline system, except that their maximum concentration is shifted to much higher pH. The stability constants reported by Childs and Perrin[2] were used almost unchanged, as can be seen from Table 5, and this confirms the validity of the overall method used in this work.

Figure 15 shows the pH dependence of n_{eff} of water for Solution I. Since there are only two Mn(II)-containing species in the pH range 0–8, namely $Mn(H_2O)_6^{2+}$ and $MnHPro^{2+}$ ($5H_2O$), and assuming $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m) \approx 1$, then the stability constant of $MnHPro^{2+}$ can be calculated easily from n_{eff}, since the concentrations of both free Mn^{2+} and $MnHPro^{2+}$ are deduced from n_{eff}:

$$[MnHPro^{2+}]/[Mn(H_2O)_6] = (6-n_{eff})/(n_{eff}-5) \quad (39)$$

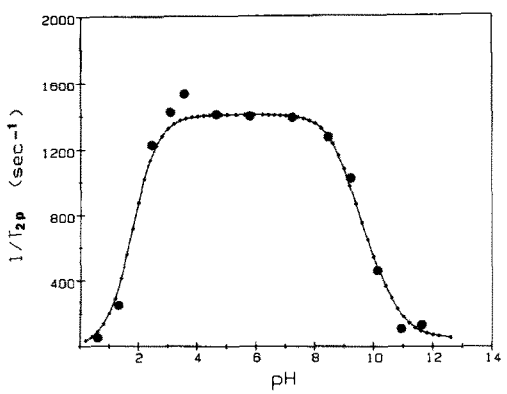

Fig. 13. Dependence of the ^{17}O paramagnetic transverse relaxation rate of proline upon the measured pH of a solution containing 0.08 M proline and 0.34 mM $MnCl_2$ (Solution I), at 300 K. The experimental points were recorded at 24.4 MHz and the dotted line is the least-squares fit of the experimental points to eq. (28), with the constants of Tables 5 and 6.

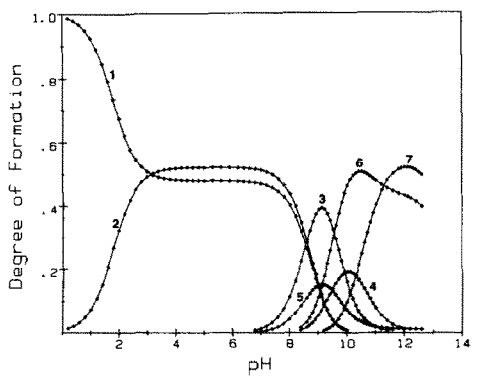

Fig. 14. Dependence of the relative concentration of all Mn^{2+} containing species upon pH, for Solution I, at 300 K. All curves were constructed with the stability constants of Table 5. 1 is the free Mn^{2+}, 2, 3, and 4 are the protonated complexes $MnHPro^{2+}$, $MnHPro_2^+$ and $MnHPro_3$, respectively, whereas 5, 6 and 7 are the bidentate complexes $MnPro^+$, $MnPro_2$ and $MnPro_3^-$, respectively.

Table 5. Log stability constants of the major Mn(II)–proline complexes and NMR parameters in aqueous solution[a]

Complex	$f(\tau_m, T_{2m})$ (s^{-1})	Constant	This work	Ref. 2	
$MnHPro^{2+}$	6.03×10^5	k'_1	1.15	1.50 ± 0.12	
$MnHPro_2^+$	1.82×10^5	k'_2	1.53	1.74 ± 0.21	
$MnHPro_3$	1.10×10^3	k'_3	0.17 ± 0.13		
$MnPro^+$		K_1	2.84	2.84	3.34[b]
$MnPro_2$		β_2	5.53	5.53	5.5[c]
$MnPro_3^-$	1.78×10^4	β_3	6.74	6.74

[c] Taken from Ref. 7.

and

$$k'_1 = [HPro^+]^{-1}(6-n_{eff})/(n_{eff}-5). \quad (40)$$

Needless to say that one need not see the signal of proline to derive the stability constant for $MnHPro^{2+}$, for only the signal of water in the absence and presence of proline at constant Mn^{2+} concentration is required. Thus, non-enriched proline is sufficient for such a task. The excellent agreement between the theoretical and experimental values of n_{eff} in Fig. 15 justifies the assumption that when only one water molecule is replaced by an amino acid in an aqueous complex of a metal ion, $f(\tau_m, T_{2m}, \Delta\omega_m)$ for the remaining water molecules is not changed drastically with respect to that in $M(H_2O)_6^{2+}$.

The temperature dependence of the paramagnetic transverse relaxation time of proline at pH 11, where $MnPro_3^-$ predominates, showed that conditions of fast exchange prevail in the temperature range 275–330 K. In this range, $1/T_{2p} = p_m/T_{2m}$, thus the transverse relaxation time of $MnPro_3^-$ can be calculated. At 33°C, T_{2m} was found to be 6.18 μs, from which a correlation time of 1.4×10^{-10} s was calculated, taking a value of 1.97×10^{-8} cm derived by Henry *et al.*[4] from ^{13}C NMR data. Henry *et al.* also report a value of 1.28×10^{-10} s for the rotational correlation time of $MnPro_3^-$, at the same temperature, which is in good agreement with our value. At 60°C, though, they report a value of 4.6×10^{-11} s, while at the same temperature we calculated a value of 8.4×10^{-11} s for the rotational correlation time of $MnPro_3^-$, almost two times longer. No clear explanation exists other than possible experimental error, either theirs or ours.

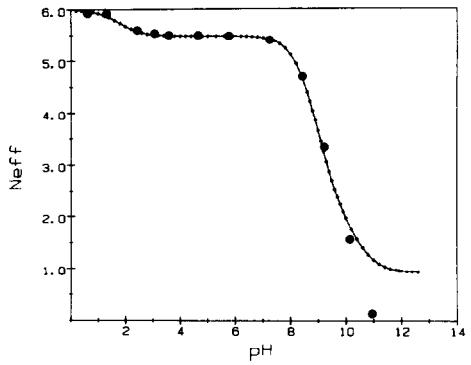

Fig. 15. Dependence of the effective coordination number of water upon pH, for Solution H. The experimental points were calculated from the ratio of the paramagnetic transverse relaxation rate of water in the presence and absence of proline, respectively, and the dotted line is the prediction of eq. (33).

CONCLUSIONS

This work showed that the combination of ^{17}O and ^{14}N NMR can be a powerful probe in ion binding studies of amino acids and information not afforded easily by any other method can be extracted from such studies. Thus, stability constants, hyperfine coupling constants and the corresponding thermodynamic parameters characterizing the dynamical behavior of the metal ion complexes can be determined from the ^{17}O and ^{14}N NMR studies.

With regard to the complexes of proline, in particular, the stability constants of $CoHPro^{2+}$, $Co(HPro)_2^{2+}$, $CoHPro_2^+$ $CoHPro_3$ and $CoPro_3^-$ were determined for the first time, in this work. Furthermore, the direct observation of $CoPro_2$ and $CoPro_3^-$ allowed the accurate determination of the hyperfine coupling constant, A/h, of these complexes, as well as the characterization of the

mechanism of interaction between the unpaired electrons of Co^{2+} and the ^{17}O nucleus.

^{17}O AND ^{14}N NMR STUDIES OF THE Co(II), Cu(II) AND Mn(II) COMPLEXES OF GLYCINE IN AQUEOUS SOLUTION

EFSTATHIOS D. GOTSIS* and DANIEL FIAT†

University of Illinois College of Medicine at Chicago, Department of Physiology and Biophysics, P.O. Box 6998, Chicago, IL 60680, U.S.A.

(*Received* 27 *May* 1987; *accepted* 29 *June* 1987)

Abstract—The ^{17}O and ^{14}N paramagnetic relaxation rates and chemical shifts of glycine as well as of water, in aqueous solutions of Co(II), Cu(II), and Mn(II) were measured as a function of pH, temperature and metal ion concentration; the relaxation results were fitted to a theoretical equation linking the Swift–Connick equation to the stability constants of all major complexes in equilibrium. As a result, the stability constants of all major complexes were determined, and from the temperature-dependent measurements the thermodynamic parameters for some of these complexes were also calculated. In addition to the bidentate complexes ML^+, ML_2 and ML_3^-, monodentate complexes of the type MHL^{2+} and $M(HL)_2^{2+}$, mixed complexes of the type MHL_2^+ and MHL_3 were also considered. In the case of the Cu(II)–glycine system at pH > 12 two additional species were considered, namely $ML_2(OH)^-$ and $ML_2(OH)_2^{2-}$, suggested by the drastic reduction of the paramagnetic broadening in that pH range.

Glycine is the smallest and structurally simplest of all amino acids and its complexes with transition metal ions in aqueous solution have been the subject of a number of investigations.[1–5] Use of ^{17}O NMR however has been conspicuously absent, especially if one considers that the carboxylic oxygen is a potential binding site and should therefore be a sensitive probe to assess the paramagnetic effects. Similarly, the amino nitrogen is also a potential binding site, thus a combination of ^{17}O and ^{14}N NMR should be a good probe to use for ion binding studies. The above considerations, led us to the undertaking of this work.

Of the three metal ions in this work, Cu(II) has certainly attracted most of the attention, not only in NMR but in ESR studies as well.[6,7] Mn(II) complexes of glycine have also received attention, but Co(II) complexes of glycine have not been studied as thoroughly. For example, no information could be found in the literature for $CoHG^{2+}$, $Co(HG)_2^{2+}$, $CoHG_2^+$, and $CoHG_3$. The stability constants for these species were determined in this work.

EXPERIMENTAL

For the ^{17}O NMR measurements, glycine enriched to 30% ^{17}O at each carboxyl site by methods described previously,[8,9] was used after being passed through a chelex column twice, for further purification. For ^{14}N NMR, commercially available glycine was used as bought from the manufacturer.

The NMR measurements were obtained on a Bruker CXP-180 high-power spectrometer, at 24.4 and 13.0 MHz for ^{17}O and ^{14}N NMR, respectively, and a home-made NSF-250 spectrometer at the Regional NMR Center of the University of Illinois in Champaign-Urbana, at 33.926 and 18.075 MHz respectively. Whenever appropriate many measurements were performed on both spectrometers, to determine possible field effects, as well as to ascertain reproducibility of results. Most measurements were repeated at least twice.

Typical spectroscopic parameters were a spectral width of 20 kHz, pulse width for a 90° pulse of 10 μs, pulse delay of 25 μs, recycle delay of 110 msec and 4k spectral points for signal acquisition.

Experimental errors in both ^{17}O and ^{14}N NMR shifts are within ± 0.5 ppm for narrow lines (20–300 Hz), and no more than ± 2.0 ppm for broader

* Present address: Department of Chemistry, University of Illinois at Chicago, P.O. Box 4348, Chicago, IL 60680, U.S.A.

† Author to whom correspondence should be addressed.

lines. The accuracy of the measured linewidths is within ±5%.

The pH of the solutions was adjusted by the addition of NaOH or HCl and measured on a Corning Model 125 pH meter, equipped with a combined electrode. The pH of the solution was measured before and after spectral acquisition, and, if different, the average value was recorded, provided that the variation was small.

The purity of the enriched glycine was checked with an amino acid analyzer. The amino acid analyzer was used at least twice for each sample. The accuracy of the calculated concentration of glycine is within ±10%, to allow for all measuring errors.

The ^{17}O chemical shifts are reported (unless otherwise stated) with respect to external water, at the same temperature. The dependence of the chemical shift of water upon inverse temperature was found to be linear in a wide temperature range, thus the chemical shift at any temperature could be extrapolated from the linear plot. ^{14}N chemical shifts were measured with respect to external NH_4NO_3.

THEORETICAL

(A) *Chemical exchange*

The effect of chemical exchange between a predominant diamagnetic site (the bulk) and a much less concentrated paramagnetic site (the coordination sphere of the metal ions) on the relaxation rate and chemical shift of the bulk has been determined by Swift and Connick,[10] along the lines of the McConnell[11] equations. A detailed description of the Swift–Connick equations and their connection to the stability constants of all complexes in solution was given in a previous paper,[12] thus only a brief summary of the equations used in this work will follow here.

The paramagnetic relaxation rate, $1/T_{2p}$, and the paramagnetic chemical shift, $\Delta\omega_a$, were found by Swift and Connick to be:

$$1/T_{2p} = \sum_{j=b}^{n} \frac{1}{\tau_a} \frac{T_{2j}^{-2} + (\tau_j T_{2j})^{-1} + \Delta\omega_j^2}{(\tau_j^{-1} + T_{2j}^{-1})^2 + \Delta\omega_j^2} \quad (1)$$

and

$$\Delta\omega_a = -\sum_{j=b}^{n} \frac{1}{\tau_a \tau_j} \frac{\Delta\omega_j}{(\tau_j^{-1} + T_{2j}^{-1})^2 + \Delta\omega_j^2} \quad (2)$$

where τ_a is the lifetime of the nucleus in the predominant diamagnetic site, referred to as the bulk henceforth, τ_j is the lifetime of the nucleus in each of the paramagnetic sites, T_{2j} is the transverse relaxation time of the nucleus in the paramagnetic site, and $\Delta\omega_j$ is the frequency different, in rads/s, between the bulk and each of the paramagnetic sites.

The temperature dependence of τ_j is given by the Eyring equation:[13]

$$\tau_j = (h/kT)\exp(\Delta H\dagger/RT - \Delta S\dagger/R) \quad (3)$$

where $\Delta H\dagger$ and $\Delta S\dagger$ are the enthalpy and entropy of activation for the first-order reaction of exchange between the diamagnetic and paramagnetic sites.

The temperature dependence of $\Delta\omega$ and its relationship to the hyperfine coupling constant, A/h, is given by the equation of Bloembergen:[14]

$$(\Delta\omega/\omega) = -S(S+1)A(\gamma_e/\gamma_n)/3kT \quad (4)$$

where S is the spin of the paramagnetic ion, γ_e and γ_n are the magnetogyric ratios of the free electron and the nucleus under consideration, respectively, and the other constants have their usual meaning.

(B) *Complex equilibria*

For aqueous solutions of amino acids or peptides, containing small quantities of paramagnetic ions, such that $[L] \gg [M]$ (ligand and metal ion concentrations, respectively), the complex equilibria in solution can be described by the general equation:[15]

$$pM^{2+} + qH^{+} + rL^{y-} \underset{}{\overset{\beta_{pqr}}{\rightleftharpoons}} M_pH_qL_r^{(2p+q-yr)} \quad (5)$$

where β_{pqr} is the overall stability constant for each metal ion complex:

$$\beta_{pqr} = [M_pH_qL_r]/([M]^p[H]^q[L]^r). \quad (6)$$

From the mass balance equation for $[M]_{total}$ and $[L]_{total}$ we get:

$$[M] = [M]_{total} \Big/ \left(1 + \sum_q \sum_r \beta_{1qr}[H]^q[L]^r\right) \quad (7)$$

and

$$[L] = [L]_{total} \Big/ \left(1 + \sum_q \beta_{0q1}[H]^q\right). \quad (8)$$

The validity of the above approximation was tested by Beattie *et al.*[1] by an iterative solution of the complete mass balance equations using the method of Ingri and Sillen.[16] Combining the complex equilibria equations with the Swift–Connick equation we get:

$$1/T_{2p} = \frac{([M]/[L])_{total} \sum_q \sum_r r\beta_{1qr}[H]^q[L]^r f(\tau, T_2, \Delta\omega)_{1qr}}{\left(1 + \sum_q \sum_r \beta_{1qr}[H]^q[L]^r\right)}. \quad (9)$$

Equation (9) links the paramagnetic relaxation rate, $1/T_{2p}$, of the free ligand, to the stability constants of all possible complexes and their NMR parameters. Thus, it is possible to determine the stability constants of the complexes through a multi-parameter fit of the experimental relaxation data to eqn (9). The correlation coefficients of the final fitted lines were found to be in the range of 0.97–0.99.

(C) *The solvent signal*

In addition to the data of glycine, a second set of data indirectly gives information about the degree of formation of the various complexes, namely the paramagnetic relaxation rate of H_2O:

$$1/T_{2p} = p_m \frac{1}{\tau_m} \frac{T_{2j}^{-2} + (\tau_j T_{2j})^{-1} + \Delta\omega_j^2}{(\tau_j^{-1} + T_{2j}^{-1})^2 + \Delta\omega_j^2} = p_m f(\tau_m, T_{2m}, \Delta\omega_m) \quad (10)$$

where p_m is the ratio of the bound water molecules divided by the number of molecules in the bulk water:

$$p_m = n_{\text{eff}}[M]_{\text{total}}/(55.5 - n_{\text{eff}}[M]_{\text{total}}). \quad (11)$$

Since $[M] \ll 55.5$, p_m is approximated by:

$$p_m \approx n_{\text{eff}}[M]_{\text{total}}/55.5. \quad (12)$$

In a pure aqueous solution of the metal ions in this work, n_{eff} is 6, assuming a hexa-coordinated structure.[11,17–19] In the presence of the amino acid, though, some of the water molecules in the metal ion complexes get replaced by the amino acid, reducing, thus, the number of sites coordinated to water. n_{eff} can be calculated from the ratio of $1/T_{2p}$ of water in the presence and absence of the amino acid, respectively:

$$n_{\text{eff}} = [6(1/T_{2p})^*/(1/T_{2p})]/[f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)] \quad (13)$$

where the asterisk denotes the presence of the amino acid in the solution. The above equation is useful if $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)$ is known or assumptions about its magnitude can be made. Assuming it to be 1, eqn (13) reduces to:

$$n_{\text{eff}} = 6(1/T_{2p})^*/(1/T_{2p}). \quad (13a)$$

Another way of calculating n_{eff} is by taking the weighted average of the number of water molecules in each complex, i.e.

$$n_{\text{eff}} = (1/[M]_{\text{total}}) \sum_q \sum_r (6+q-2r)[MH_qL_r]. \quad (14)$$

Equation (14) is of course the correct equation to use, provided that the stability constants of the complexes are known, but equation (13a) has some limited usefulness under conditions which will be discussed in a subsequent section.

(D) *Second-order exchange*

In addition to first-order exchange, the linewidth of free glycine may be broadened by second-order chemical exchange with some of the complexes. Such a process can be described by the following equation:

$$ML_r + {}^*L^- \overset{k_r}{\rightleftharpoons} ML^*_{(r-1)}L + L^-. \quad (15)$$

The lifetime of the ligand in ML_r can be determined from:

$$\tau_m = (k_1 + k_r[L^-])^{-1} \quad (16)$$

where k_1 is the first-order rate constant and k_r is the second-order rate constant involving the species ML_r.

It is obvious that second-order exchange leads to concentration-dependent lifetimes, thus one can reach fast exchange not only by raising the temperature, as is done with first-order exchange, but also by increasing the pH. The effects of second-order exchange broadening are described by the following equation:

$$(1/T_{2p})^{**} = k_2[ML_r][L^-]/[L]_{\text{total}} \quad (17)$$

where the double asterisk indicates second-order exchange broadening. Equation (17) must be added to eqn (9) whenever second-order exchange processes are considered.

RESULTS AND DISCUSSION

(A) *The* Co(II)*–glycine system*

(1) ^{17}O *NMR.* The pH dependence of the paramagnetic transverse relaxation rate, $1/T_{2p}$, of glycine at 300 H, for Solution A, is depicted in Fig. 1. The dotted line is the least-squares best fit of eqn (9) to the experimental results, with the stability constants of Table 1, and the NMR parameters of Table 2. The following equations define the stability constants of the major complexes of glycine considered in this work, using the notation of Childs and Perrin,[2] except in (II), (IX) and (X):

$$M^{2+} + HG^+ \overset{k_1'}{\rightleftharpoons} MHG^{2+} \quad (I)$$

$$M^{2+} + 2HG^+ \overset{k_2''}{\rightleftharpoons} M(HG)_2^{2+} \quad (II)$$

$$MG^+ + HG^+ \overset{k_2'}{\rightleftharpoons} MHG_2^+ \quad (III)$$

Table 1. Log of stability constants of the major Co(II)–glycine complexes in aqueous solution

Complex	Constant	This work	Ref. 23	Ref. 29	Ref. 30
$CoHG^{2+}$	k'_1	0.76			
$Co(HG)_2^{2+}$	k''_2	1.02			
$CoHG_2^+$	k'_2	1.04			
$CoHG_3$	k'_3	−0.45			
CoG^+	K_1	4.96	4.51	5.23	5.5
CoG_2	β_2	9.18	8.16	9.25	9.0
CoG_3^-	β_3	10.43	10.43		11.3

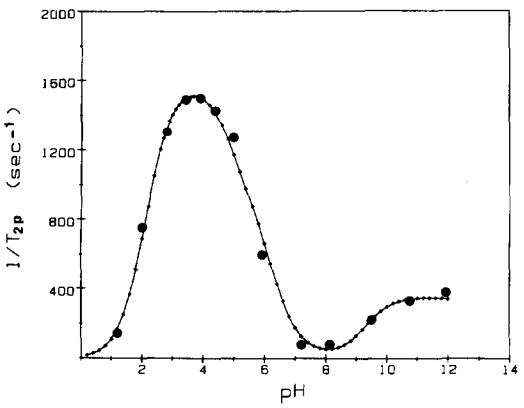

Fig. 1. Dependence of the ^{17}O paramagnetic transverse relaxation rate of glycine upon the measured pH of a solution containing 0.31 M glycine and 5.0 mM $CoCl_2$ (Solution A). The experimental points were recorded at 24.4 MHz, 300 K, and the dotted line is the least-squares best fit of the experimental points to eqn (9), with the constants of Tables 1 and 2.

$$MG_2 + HG^+ \overset{k'_3}{\rightleftharpoons} MHG_3 \quad \text{(IV)}$$

$$MG_2 + G^- \overset{K_3}{\rightleftharpoons} MG_3^- \quad \text{(V)}$$

$$M^{2+} + G^- \overset{K_1}{\rightleftharpoons} MG^+ \quad \text{(VI)}$$

$$M^{2+} + 2G^- \overset{\beta_2}{\rightleftharpoons} MG_2 \quad \text{(VII)}$$

$$M^{2+} + 3G^- \overset{\beta_3}{\rightleftharpoons} MG_3^- \quad \text{(VIII)}$$

$$MG_2 + OH^- \overset{K_{OH}}{\rightleftharpoons} MG_2(OH)^- \quad \text{(IX)}$$

$$MG_2 + 2OH^- \overset{K_{2OH}}{\rightleftharpoons} MG_2(OH)_2^{2-} \quad \text{(X)}$$

where M stands for Co^{2+}, Cu^{2+} or Mn^{2+}. Equations (IX) and (X) were used only in the Cu(II)–glycine system.

The low n_{eff} for water in the acidic pH, Fig. 2, suggested that the existence of $Co(HG)_2^{2+}$ be taken

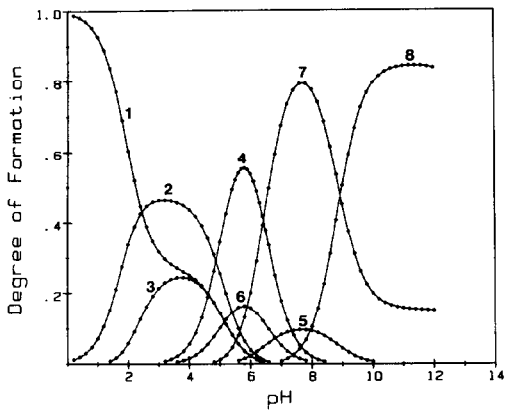

Fig. 3. Dependence of the relative concentration of all Co^{2+}-containing species upon pH, for Solution A. All curves were constructured with the stability constants of Table 1. (1) Is the free Co^{2+}; (2), (3), (4) and (5) are the protonated complexes $CoHG^{2+}$, $Co(HG)_2^{2+}$, $CoHG_2^+$ and $CoHG_3$, respectively; whereas (6), (7) and (8) are the bidentate complexes CoG^+, CoG_2 and CoG_3^-, respectively.

into account, otherwise an unreasonably large stability constant for $CoHG^{2+}$ would have to be assumed in order to fit the acidic pH data, but then the relaxation results at neutral pH were overestimated. Similar conclusions were drawn from the Co(II)–proline, and to a lesser degree the Co(II)–alanine systems.[20]

The agreement between theoretical and experimental values of n_{eff} requires that $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)$ of water as a function of pH remain unchanged, and of course the correct stability constants of the complexes. The first condition can be met approximately in the pH range 0–4, in which $f(\tau_m, T_{2m}, \Delta\omega_m)/f^*(\tau_m, T_{2m}, \Delta\omega_m)$ was found to be 1 ± 0.15, whereas values as high as 5 were found at pH 8 for a solution containing proline[21] and Co^{2+}. The second condition is expected to be met throughout the pH range, within the accuracy of the present method.

Figure 3 shows the distribution of all Co^{2+}-containing species as a function of pH, constructed with the stability constants of Table 1. The existence of $CoHG_3$ was postulated on the fact that the zwitterionic form of glycine is predominant in the pH range 3–8, thus reaction (IV) should be taken into account. The best fit for $1/T_{2p}$ was obtained with $k'_3 = 0.3$, but there is an uncertainty of ± 0.25 associated with the above value, due to the small paramagnetic broadening in the pH range 7–9 where this species reaches its maximum concentration.

The distribution of $CoHG_3$ follows that of CoG_2, as can be seen in Fig. 3, except in the high pH range where the concentration of the zwitterionic form of glycine diminishes and reaction (IV) is negligible.

The relatively small paramagnetic broadening in the basic pH range, where CoG_3^- is the predominant species, is indicative of the slow rate of chemical exchange. Hammes and Steinfeld[4] report a value of $3.8 \times 10^3\ s^{-1}$ for the rate constant of CoG_3^-, whereas we found $7.1 \times 10^3\ s^{-1}$ with ^{17}O NMR and an even higher value with ^{14}N NMR. Pearson and Lanier[5] report a first-order rate constant of $5.7 \times 10^3\ s^{-1}$, and a second-order constant of $4.8 \times 10^3\ M^{-1}\ s^{-1}$ from ^1H NMR studies. With these constants at pH 11, a total rate constant ($1/\tau_m = k_1 + k_2[L^-]$) of $7.14 \times 10^3\ s^{-1}$ for $[L] = 0.3$ M that was used for our ^{17}O NMR measurements, and $10.5 \times 10^3\ s^{-1}$ for $[L] = 1.0$ M that was used for the ^{14}N NMR measurements. Certainly, both the ^{17}O and ^{14}N NMR results are in excellent agreement with the results of Pearson and Lanier. Thus, since the concentrations used in the ^{17}O NMR experiments are not particularly large, in the range of 0.1–0.3 M, the assertion that second-order mechanisms do not contribute appreciably to the observed broadening is basically valid. With the second-order constant of Pearson and Lanier, the second-order contribution to the observed broadening would range from 8 to 20%, for concentrations of glycine ranging from 0.1 to 0.3 M, at pH 11. The lifetimes for CoG_3^- reported in Table 2 are then the combined effects of both first- and second-order exchange processes, especially those derived from the ^{14}N measurements.

Figure 4 shows the pH dependence of the paramagnetic chemical shift of glycine for Solution A, at 300 K. The first peak in the pH range 3–4 reflects

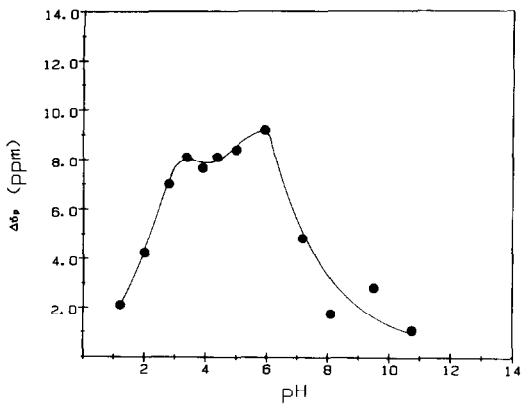

Fig. 4. Dependence of the ^{17}O paramagnetic chemical shift of glycine upon pH, for Solution A, 300 K and a spectrometer frequency of 24.4 MHz.

the maximum concentration of $CoHG^{2+}$ and $Co(HG)_2^{2+}$, whereas the additional shifts in the pH range 4–6 are due to $CoHG_2^+$, as can be seen from Fig. 3. The small paramagnetic shifts at basic pH are due to the slow exchange with CoG_3^-. Thus, the paramagnetic chemical shift does reflect the distribution of the complexes as a function of pH, in harmony with the relaxation results.

Figure 5 shows the temperature dependence of T_{2p} of free glycine at pH 3, for Solution B. At this pH, the monodentate complex $CoHG^{2+}$ predominates, and $Co(HG)_2^{2+}$ makes a small contribution (less than 15% of the total broadening of the free glycine at 300 K is due to $Co(HG)_2^{2+}$). As can be seen in Fig. 5, both the slow as well as the fast exchange regions are accessible in the temperature range of 274–335 K. Incidentally, room temperature falls in the intermediate exchange rate, where maximum broadening occurs, and neither the slow nor the fast exchange approximation is valid for $1/T_{2p}$. At the point of intersection of the slow and fast exchange approximation lines in Figs 5 and 6, $\Delta\omega_m\tau_m = 1$, and eqn (5) reduces to:[22]

$$1/T_{2p} = (1/2)p_m/\tau_m. \tag{18}$$

The above constraint was used to draw the slow and fast exchange approximation lines, for the point of intersection must be half the experimental value at that same temperature.

The hyperfine coupling constant of $CoHG^{2+}$, calculated from the intersection of the slow and fast exchange limits in Fig. 5 is approximately the same as that obtained for $CoHPro^{2+}$ and $CoHAla^{2+}$ ($+1.2\pm0.2$ MHz).[12,20] The enthalpy and entropy

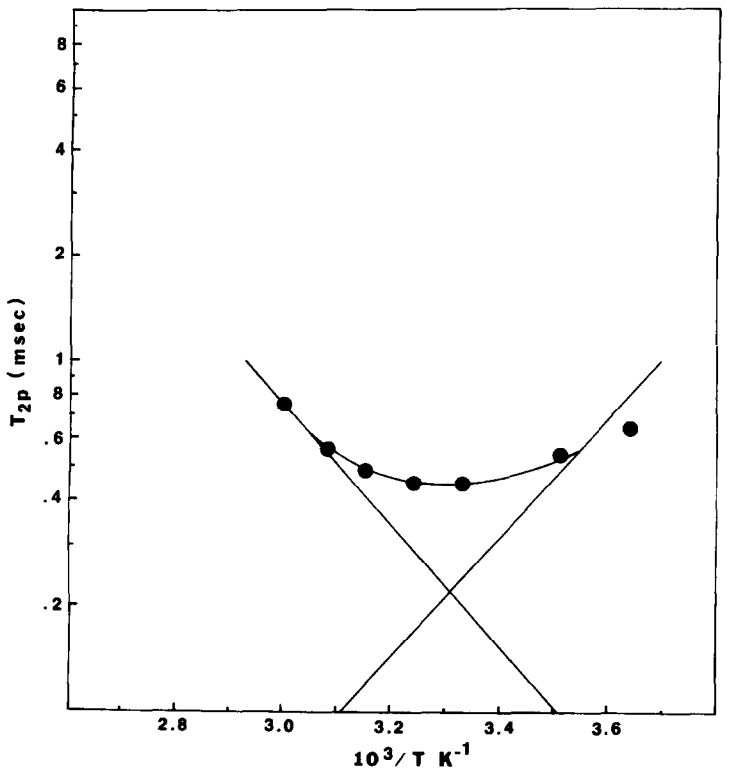

Fig. 5. Dependence of the ^{17}O paramagnetic transverse relaxation time of glycine upon inverse temperature at pH 3, for a solution containing 0.115 M glycine and 5.0 mM $CoCl_2$ (Solution B). The data were recorded at 24.4 MHz.

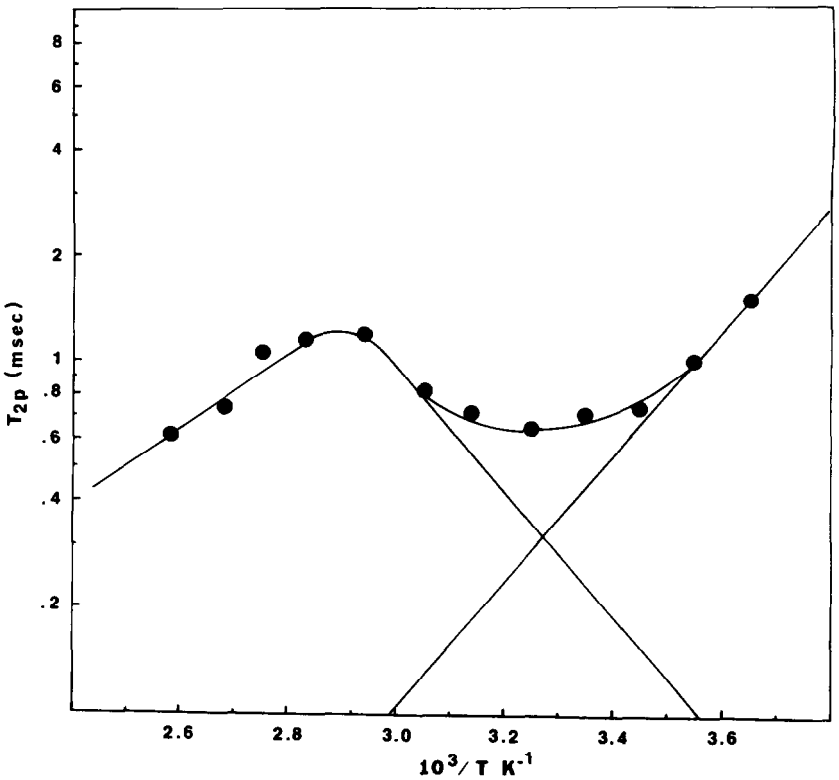

Fig. 6. Dependence of the ^{17}O paramagnetic transverse relaxation time of glycine upon inverse temperature, in a solution containing 0.19 glycine and 10.0 mM $CoCl_2$ (Solution C), at pH 6.1 and a spectrometer frequency of 33.926 MHz.

of activation for the first-order dissociation of $CoHG^{2+}$ were also calculated from the slow exchange region of Fig. 5 and are also included in Table 2. The values, though, were calculated from the total paramagnetic relaxation time (to which $Co(HG)_2^{2+}$ makes a contribution), thus $\pm 25\%$ uncertainty is to be expected with those values.

Figure 6 depicts the dependence of T_{2p} of glycine upon inverse temperature, for Solution C, at pH 6. At this pH, $CoHG_2^+$ is the predominant complex and it causes the observed broadening. This complex is similar to CoG_2 with respect to the number of negatively charged carboxylic oxygens per Co^{2+}, but one glycine molecule is bound only through the oxygen site. The hyperfine coupling constant, A/h, for $CoHG_2^+$ is in the order of 0.7 MHz, a value similar to that of CoG_2 that could be determined directly from the chemical shift of that complex, and its lifetime was found to be about 10^{-5} s. The high-temperature bend from linearity in Fig. 6 may be due to an increased contribution from CoG^+ and CoG_2, which was neglected at low temperatures because of their long lifetimes at those temperatures.[23]

Although much effort was made to detect directly CoG_2, as it was done easily for the corresponding complex in the Co(II)–proline system,[12] we were successful only once, at pH 10. The signal was detected at the same frequency that $CoPro_2$ was detected, but it was much broader (around 6,000 Hz, as opposed to about 2,000 Hz recorded for $CoPro_2$), making detection difficult. The lack of reproducibility of results, then, makes the single observation suspect, and the possibility of an artifact cannot be excluded entirely, although the usual tests for determining whether a signal is "real" or not were performed and proven to be positive.

(2) ^{14}N *NMR results.* The pH dependence of the ^{14}N transverse paramagnetic relaxation rate, $1/T_{2p}$, of glycine for Solution D is depicted in Fig. 7. Broadening occurs only above pH 7, indicating that the first- and second-order exchange processes with CoG_3^- are responsible for the observed broadening. Thus, ^{14}N NMR can be used as a complementary method to ^{17}O NMR, for the information that it offers is limited in the basic pH only, where the amino nitrogen binds directly to the metal ion. From the temperature dependence of T_{2p} at pH 11 (Fig. 8), the thermodynamic parameters describing CoG_3^- were determined. Those results are shown in Table 2. Note the shorter lifetime for CoG_3^- calculated from ^{14}N NMR, compared to that deter-

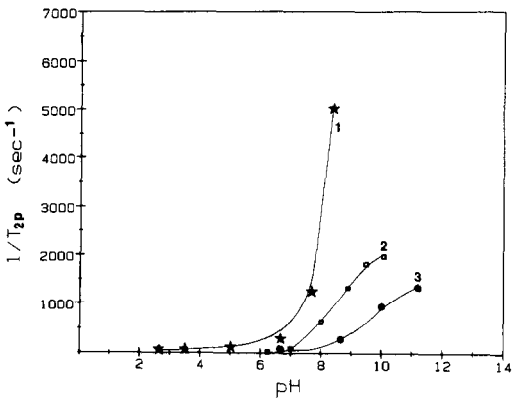

Fig. 7. Dependence of the ^{14}N paramagnetic transverse relaxation rate of glycine upon pH, for Solutions D (1.0 M glycine and 0.01 M $CoCl_2$), E (1.0 M glycine and 1.0 mM $CuCl_2$), and F (1.0 M glycine and 1.0 mM $MnCl_2$), at 300 K. The spectrometer frequency was 18.075 MHz.

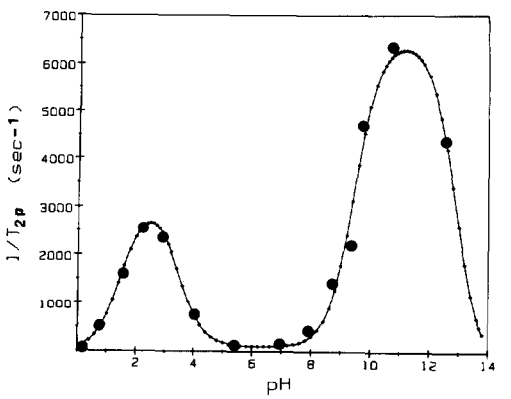

Fig. 9. Dependence of the ^{17}O paramagnetic transverse relaxation rate of glycine upon the measured pH of a solution containing 0.29 M glycine and 0.2 mM $CuCl_2$ (Solution G). The experimental points were recorded at 24.4 MHz, 300 K, and the dotted line is the least-squares best fit of the experimental points to eqn (9), with the constants of Tables 3 and 4.

mined from ^{17}O NMR, as a result of a greater contribution from second-order exchange to the total rate constant, arising from the higher concentration of glycine used in the ^{14}N NMR measurements.

(B) *The* Cu(II)*–glycine system*

(1) ^{17}O *NMR results.* Figure 9 shows the pH dependence, at room temperature, of the ^{17}O paramagnetic transverse relaxation rate, $1/T_{2p}$, of gly-

CuG_3^-	β_3	15.43	15.43	
$CuG_2(OH)^-$	K_{OH}	1.46		
$CuG_2(OH)_2^{2-}$	K_{2OH}	1.56		

cine for Solution G. The dotted line is a least-squares best fit of eqn (9) to the experimental relaxation results, with the stability constants of Table 3 and the NMR parameters of Table 4. $Cu(HG)_2^{2+}$ was not considered as a major species, and there was no compelling evidence to the contrary. The paramagnetic relaxation rate of water could not be used in the case of Cu^{2+} because it was too small for the concentrations used in this work. Typically, the maximum broadening of the water signal in the presence of Cu^{2+} was about 20 Hz. Given the ±5 Hz uncertainty in the linewidth of water, the uncertainty in n_{eff} was $\pm(5/20) \times 6 = \pm 1.5$, totally unacceptable.

The Cu(II)–glycine system has been the subject of several authors, with particular emphasis on ^1H NMR, ESR as well as potentiometric studies.[1,2,6,7,24,25] In this work we have extended our studies to the entire pH range 0–14, for the decrease of the broadening above pH 11.5 indicated the formation of complexes involving OH^-. The best fit was obtained by considering two additional complexes in the basic pH, namely $CuG_2(OH)^-$ and $CuG_2(OH)_2^{2-}$, with the stability constants defined in eqns (IX) and (X), respectively.

Table 3 contains some values from the literature, for comparison, particularly those from Beattie *et al.*[1] and Childs and Perrin.[2] There are several interesting comparisons that can be made to the studies of Beattie *et al.* First, the minimum broadening that they observed in their ^1H paramagnetic relaxation rate was around pH 4, and the broadening above pH 4 was assigned to second-order processes with CuG_2, and first-order processes with CuG_3^-. Our ^{17}O paramagnetic relaxation data show a minimum broadening in the pH range 6–8, in which CuG_2 is the predominant species. The ^{17}O paramagnetic relaxation in the acidic pH follows closely the concentration profiles of $CuHG^{2+}$ and $CuHG^+$ and their first-order dissociation. The results at basic pH were fitted by considering the first-order dissociation of CuG_3^- and second-order exchange broadening with CuG_2. A second-order rate constant of $1.5 \times 10^7\ M^{-1}\ s^{-1}$ (taken from Beattie *et al.*[1]) was used, whereas a value of $2.27 \times 10^6\ s^{-1}$ was used for $f(\tau_m, T_{2m})$ of CuG_3^-. Note that the stability constants for CuG_2 and CuG_3^- are identical to those determined by Beattie *et al.* (Table 2).

Pearson and Lanier[5] have reported a second-order rate constant of $8.2 \times 10^6\ M^{-1}\ s^{-1}$ for CuG_2,

Table 4. Thermodynamic and NMR parameters of the Cu(II)–glycine complexes in aqueous solution[a]

Complex	$f(\tau_m, T_{2m})$ (s^{-1})	τ_m (s)	$\Delta H\dagger$ (Kcal/mole)	$\Delta S\dagger$ (e.u.)
$CuHG^{2+}$	3.40×10^6			
$CuHG_2^+$	1.85×10^6			
$CuHG_3$	2.71×10^5	1.1×10^{-6}	7.5	−12.3
CuG^+	23[b]			
CuG_2	120[b]			
CuG_3^-	2.27×10^6			

[a] All parameters are calculated at 300 K.
[b] Taken from Ref. 26.

whereas Nagypal *et al.*[25] determined a value of 7.7×10^7 M^{-1} s^{-1}. Using the value of Nagypal *et al.* and assuming that the broadening at pH 11 is due entirely to the second-order exchange with CuG_2, a broadening of 14,870 s^{-1} is predicted, while the experimental value is 6,270 s^{-1}. Clearly, the second-order rate constant of Nagypal *et al.* is overestimated by a factor of more than two. The value reported by Beattie *et al.* seems to be in better agreement without ^{17}O NMR results.

In the pH range 6–8, though, neither first- nor second-order exchange with CuG_2 could justify the relaxation results. If the existence of $CuHG_3$ were not taken into account, the observed broadening would have to be assigned to CuG_2, and an unreasonably short lifetime for this complex would be calculated from the relaxation results (in the order of 10^{-5} s). This value is two to three orders of magnitude shorter than values reported for complexes of this type,[26] thus first-order exchange with CuG_2 has to be excluded as a major source of broadening. On the other hand, if second-order exchange with CuG_2 was considered as the major source of broadening, then a value of 20 s^{-1} is calculated at pH 7.3 with $k_2 = 1.5 \times 10^7$ M^{-1} s^{-1} (Beattie *et al.*[1]), whereas the experimental value is about 160 s^{-1}. Thus if one calculates the second-order rate constant from the relaxation results at neutral pH ignoring the existence of $CuHG_3$, a value of 1.2×10^8 M^{-1} s^{-1} is calculated, which is in total disagreement with the relaxation results at basic pH. Clearly, CuG_2 alone cannot justify the relaxation results at neutral pH, thus the existence of $CuHG_3$ seems to be fairly well-established. Incidentally, the existence of $CuHG_3$ was suggested by Beattie *et al.*,[1] in view of their ^1H relaxation results at neutral pH, and some spectrophotometric evidence.

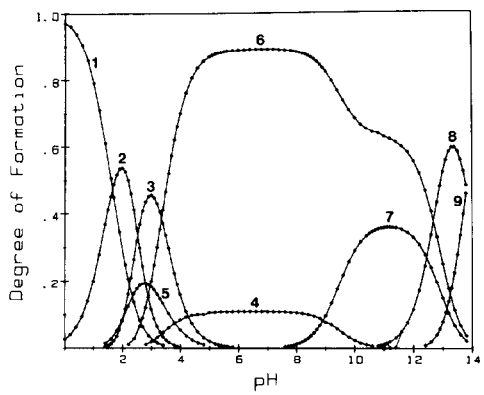

Fig. 10. Dependence of the relative concentration of all Cu^{2+}-containing species upon pH, for Solution G. All curves were constructed with the stability constants of Table 3. (1) Is the free Cu^{2+}; (2), (3) and (4) are the protonated complexes $CuHG^{2+}$, $CuHG_2^+$ and $CuHG_3$, respectively; (5), (6) and (7) are the bidentate complexes CuG^+, CuG_2 and CuG_3^-, respectively; (8) and (9) refer to the complexes $CuG_2(OH)^-$ and $CuG_2(OH)_2^{2-}$, respectively.

The dependence of T_{2p} of glycine upon inverse temperature, in Solution H at pH 7.3, is depicted in Fig. 11. The deviation from linearity at the lower end of the temperature range is probably due to non-linear viscosity effects. Since the major source of broadening at this pH was shown to be $CuHG_3$, and enthalpy and entropy of activation for the first-order dissociation of this complex were found to be 7.5 Kcal/mole and -12.3 e.u., respectively, and its lifetime at 300 K was found to be *ca.* 10^{-6} s.

The second maximum around pH 11, Fig. 9, reflects the concentration profile of CuG_3^-, Fig. 10. The decrease of the concentration of CuG_3^- above pH 11 is due to the formation of $CuG_2(OH)^-$, initially, and $CuG_2(OH)_2^{2-}$ at even higher pH. The stability constant for CuG_3^- used was $K_3 = 1.7$, as determined by Beattie *et al.* James and Williams[27] have reported $K_3 = 2.95$, but most authors have failed to determine K_3, including Childs and Perrin,[2] with whom we are in fairly good agreement for most of the stability constants.

A pH dependence of $1/T_{2p}$ at 323 K (not shown) produced reduced broadening in the pH range 0–7 (with respect to the results at 300 K), whereas above pH 7, the broadening was more pronounced. These results indicate that conditions of fast exchange prevail in the acidic pH range where the monodentate complexes predominate, whereas in the basic pH where the first-order dissociation of CuG_3^- and the second-order exchange with CuG_2 are responsible for the observed broadening, conditions of slow exchange prevail. (Both first- and second-order rate constants increase with increasing temperature).

(2) ^{14}N *NMR results.* The pH dependence of the ^{14}N paramagnetic transverse relaxation rate of glycine, for Solution E, are depicted in Fig. 7. The small broadening in the pH range 5–7 is indicative of second-order exchange with CuG_2, for the first-order dissociation of $CuHG_3$ cannot be a major source of broadening to the ^{14}N nucleus. The steep increase above pH 7 is the combined result of the first-order dissociation of CuG_3^- and the increasing contribution of the second-order exchange with CuG_2. Very broad lines at high pH prevented us from extending the measurements to higher pH. Thus, the ^{14}N relaxation results provide an additional source of information about the complexes, but the lack of information in the acidic pH limits ^{14}N NMR as a self-sufficient method in the entire pH range.

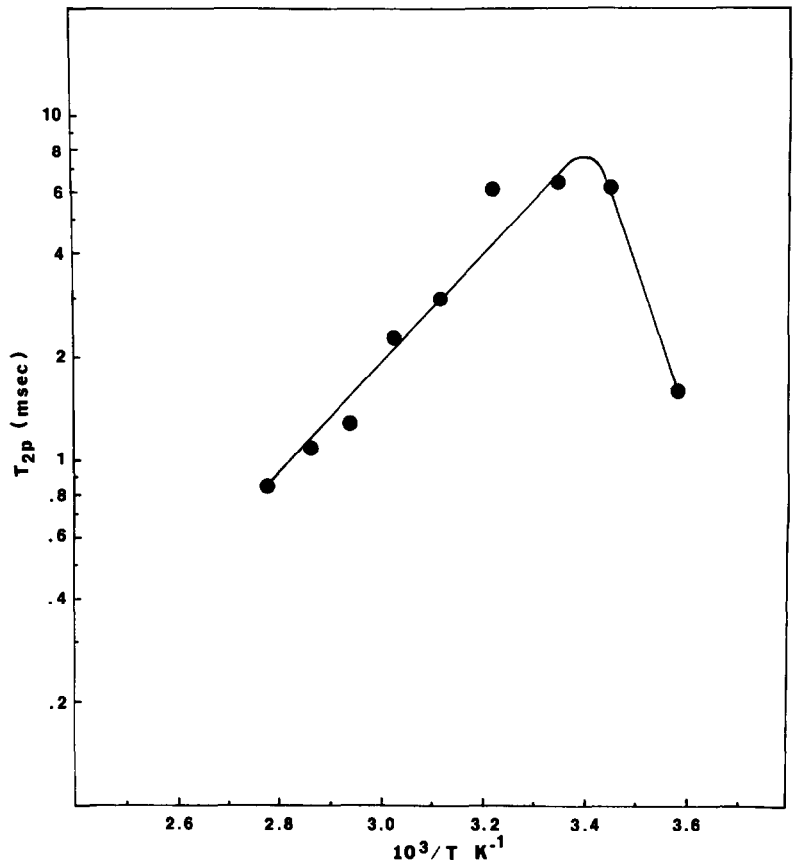

Fig. 11. Dependence of the ^{17}O paramagnetic relaxation time of glycine upon inverse temperature, in a solution containing 0.19 M glycine and 1.0 mM $CuCl_2$ (Solution H), at pH 7.3. The spectrometer frequency was 33.926 MHz.

(C) *The* Mn(II)–*glycine system*

(1) ^{17}O *NMR results.* Figure 12 shows the pH dependence of the ^{17}O paramagnetic transverse relaxation rate of glycine, for Solution I, at 300 K. The dotted line is the least-squares best fit of eqn (9) to the experimental results and the resulting stability constants and NMR parameters are shown in Table 5.

The most striking difference from the Co(II)–glycine and Cu(II)–glycine systems lies in the fact that one species predominates in the pH range 0–7, namely $MnHG^{2+}$. This is due to the small stability constants of the bidentate complexes, which is characteristic of Mn^{2+}.

The distribution of the Mn(II)–glycine complexes as a function of pH, for the same Solution I, is given in Fig. 13. The same types of complexes that were

Table 5. Log of stability constants of the major Mn(II)–glycine complexes and NMR parameters in aqueous solution[a]

Complex	$f(\tau_m, T_{2m})$ (s^{-1})	Constant	This work	Ref. 2
$MnHG^{2+}$	1.43×10^6	k'_1	0.80	0.64 ± 0.49
$MnHG_2^+$	6.85×10^5	k'_2	0.92	0.80 ± 0.42

MnG_3^-	4.50×10^5	β_3	5.57	5.52

[a] All parameters of this work are reported at 300 K, whereas those of Ref. 2 are reported at 310 K.

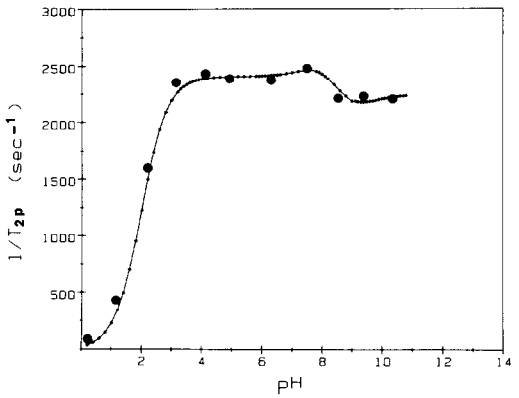

Fig. 12. Dependence of the ^{17}O paramagnetic transverse relaxation rate of glycine upon the measured pH of a solution containing 0.20 M glycine and 0.6 mM $MnCl_2$ (Solution I), at 300 K. The experimental points were recorded at 24.4 MHz and the dotted line is the least-squares fit of the experimental points to eqn (9), with the constants of Table 5.

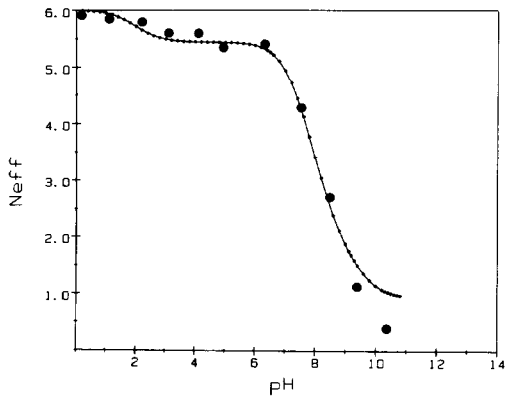

Fig. 14. Dependence of the effective coordination number of water upon pH, for Solution I. The experimental points were calculated from the ratio of the paramagnetic transverse relaxation rate of water in the presence and absence of glycine, respectively, and the dotted line is the theoretical prediction of eqn (14).

discussed in previous sections also exist in the Mn(II)–glycine system, only at much higher pH. The stability constants for the bidentate species in the basic pH were found to be almost identical to those reported by Childs and Perrin,[2] as can be seen from Table 5, and this once more confirms the validity of the overall method used in this work. A fairly good agreement also exists with regard to the values reported by those authors about $MnHG^{2+}$ and $MnHG_2^+$.

Figure 14 shows the pH dependence of n_{eff} of water for Solution I. Since there are only two Mn^{2+}-containing species in the pH range 0–7, namely $Mn(H_2O)_6^{2+}$ and $MnHG^{2+} \cdot 5H_2O$, and assumming that $f(\tau_m, T_{2m})/f^*(\tau_m, T_{2m})$ is approximately 1, then the stability constant of $MnHG^{2+}$ can be calculated easily from n_{eff}, since the concentrations of both free Mn^{2+} and $MnHG^{2+}$ are deduced from n_{eff}:[22]

$$[MnHG^{2+}]/[Mn(H_2O)_6^{2+}] = (6-n_{eff})/(n_{eff}-5) \quad (19)$$

and

$$k'_1 = [HG^+]^{-1}(6-n_{eff})/(n_{eff}-5). \quad (20)$$

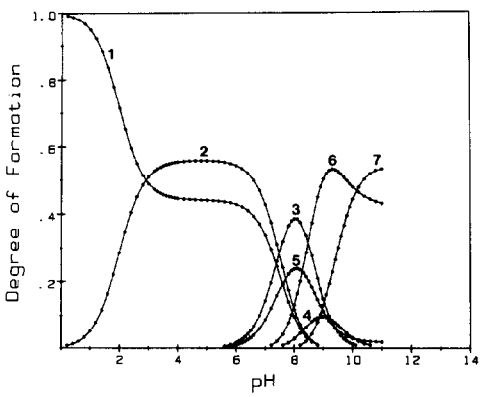

Fig. 13. Dependence of the relative concentration of all Mn^{2+} containing species upon pH, for Solution I, at 300 K. All curves were constructed with the stability constants of Table 5. (1) Is the free Mn^{2+}, (2), (3) and (4) are the protonated complexes $MnHG^{2+}$, $MnHG_2^+$ and $MnHG_3$, respectively, whereas (5), (6) and (7) are the bidentate complexes MnG^+, MnG_2 and MnG_3^-, respectively.

The dependence of T_{2p} of glycine upon inverse temperature, at pH 6.6, where $MnHG^{2+}$ is the predominant complex, showed that conditions of slow exchange prevail at 300 K. The enthalpy and entropy of activation for the first-order exchange of glycine were found to be 5 Kcal/mole and -17 e.u., respectively, and the lifetime of $MnHG^{2+}$ at 300 K was found to be 4×10^{-6} s. At higher temperatures (*ca.* 330 K), conditions of intermediate exchange prevail, at which point $1/T_{2p} = (1/2)p_m/T_{2m}$. T_{2m} can be then calculated from the experimental value of T_{2p}. Taking a value of 10^{-8} s for the electronic relaxation time of Mn^{2+} (a value of 2.18×10^{-8} s was assumed by Henry *et al.*[28] for $MnPro_3^-$) we can get an estimate of the hyperfine coupling constant, A/h, assuming the Fermi contact mechanism to be predominant. With the above assumptions, a value of -0.5 MHz was found for A/h.

Precipitation above pH 11, where MnG_3^- predominates, precluded us from conducting temperature dependent studies at that pH, to derive the thermodynamic parameters for that complex. Even when a lower concentration of Mn^{2+} was used in an attempt to prevent precipitation, it still occurred

at elevated temperatures, after only one hour, thus the results were discarded. Considering the scarcity of enriched materials no further experimentation was attempted.

CONCLUSIONS

The stability constants of all major complexes of glycine in aqueous solutions of Co^{2+}, Cu^{2+}, and Mn^{2+} were determined in this work by utilizing the paramagnetic relaxation rate of glycine as a function of pH. The thermodynamic parameters of some complexes were also determined. The existence of the species MHG_3 was taken into account, and estimates of its stability constant are given. Similarly, the stability constants of $CuG_2(OH)^-$ and $CuG_2(OH)_2^{2-}$ were determined for the first time in this work, along with stability constants for the monodentate complexes of Co^{2+}. Overall, the ^{17}O paramagnetic relaxation of amino acids has been shown to be a fairly reliable method for determining stability constants and certainly the method of choice for determining the dynamical involvement of oxygen in complexes of paramagnetic ions.

Acknowledgements—The authors would like to thank Drs A. Steinschneider and D. Dhawan for labeling and purifying the ^{17}O enriched glycine used in this work. Our long cooperation with the Regional NMR Center at Champaign-Urbana and Dr Eric Oldfield in particular is greatly appreciated. Special thanks to Dr David Wright and Dennis Warrenfeltz, also at Champaign-Urbana. We would also like to thank the RRC Facilities at the University of Illinois at Chicago.

(*Received* 9 *July* 1987; *accepted* 13 *July* 1987)

Abstract—Reactions between diphenyl(vinyl)phosphine and the compounds [FeW(μ-$CC_6H_4Me\text{-}4$)$(CO)_5(\eta^5\text{-}C_5Me_5)$] and [FeMo($\mu$-$CC_6H_4Me\text{-}4$)$(CO)_6(\eta^5\text{-}C_5H_5)$] result in a coupling of the vinyl and *p*-tolylmethylidyne groups at the dimetal centres to produce the $PPh_2 \cdot CH \cdot CH_2 \cdot C(C_6H_4Me\text{-}4)$ fragment, which bridges the metal–metal bonds. This was confirmed by an X-ray diffraction study on [FeW{μ-$PPh_2 \cdot CH \cdot CH_2 \cdot C(C_6H_4Me\text{-}4)$}$(CO)_5(\eta^5\text{-}C_5Me_5)$].

The availability of the compounds [FeW(μ-$CC_6H_4Me\text{-}4$)$(CO)_5(\eta^5\text{-}C_5Me_5)$] (**1**)[2] and [FeMo($\mu$-$CC_6H_4Me\text{-}4$)$(CO)_6(\eta^5\text{-}C_5H_5)$] (**2**)[2] has allowed extensive studies to be made on the reactivity of an alkylidyne ligand when bridging two dissimilar metal centres. For example, both species react under mild conditions with oxygen, sulphur, alkynes or diazomethane. Coupling of these reagents with the alkylidyne groups occurs and new C—O, C—S and C—C bonds are formed.[1–4] The molybdenum complex (**2**),[5] and its tungsten analogue [FeW(μ-$CC_6H_4Me\text{-}4$)$(CO)_6(\eta^5\text{-}C_5H_5)$],[6] also readily react with tertiary phosphines with displacement of a CO group at the iron centre. These studies have led us to investigate reactions of (**1**) and (**2**) with $P(CH:CH_2)Ph_2$ and the results are reported herein. It was anticipated that the phosphine would initially coordinate at the iron atom, with the vinyl group subsequently playing a non-spectator role, the nature of which could not be readily predicted.

RESULTS AND DISCUSSION

Treatment of the iron–tungsten compound (**1**) with $P(CH:CH_2)Ph_2$ in CH_2Cl_2 at ambient temperatures afforded a yellow–orange crystalline complex [FeW{μ-$PPh_2 \cdot CH \cdot CH_2 \cdot C(C_6H_4Me\text{-}4)$}$(CO)_5(\eta^5\text{-}C_5Me_5)$] (**3**). A similar reaction occurred in thf (tetrahydrofuran) between $P(CH:CH_2)Ph_2$ and the iron–molybdenum compound (**2**), yielding a product (**4**) which on the basis of spectroscopic data was evidently structurally similar to (**3**). However, from the ^1H and $^{13}C\text{-}\{^1H\}$ NMR results it was not possible to establish the structures of these compounds, and hence an X-ray diffraction study was carried out on (**3**) for which suitable single crystals were available.

Important structural parameters obtained from the X-ray diffraction study are listed in Table 1 and the structure is shown in Fig. 1. It will be seen that the Fe—W bond is spanned by a $PPh_2 \cdot CH \cdot CH_2 \cdot C(C_6H_4Me\text{-}4)$ fragment in such a manner that the phosphorus atom ligates the iron atom. The μ-$C(C_6H_4Me\text{-}4)$ group is σ bonded to both metal centres and the CH group is σ bonded to the tungsten atom. The latter, as expected, carries the η^5-C_5Me_5 ligand and two carbonyl groups, and the iron atom is coordinated by three essentially orthogonal CO groups.

It is interesting to compare the interatomic distances in (**3**) with those found in some other recently reported iron-tungsten compounds. The Fe—W separation is 2.828(1) Å and is thus long compared with those in [FeW{μ-$C(C_6H_4Me\text{-}4)C(O)O$}$(CO)_5(\eta^5\text{-}C_5Me_5)$] [2.605(1) Å],[1] [FeW($\mu$-$CC_6H_4Me\text{-}4$)$(CO)_5${$HB(pz)_3$}] [{$HB(pz)_3$ = hydrotris(pyrazol-1-yl)borate}, 2.612(2)Å],[6] [NEt_4][FeW(μ-$CC_6H_3Me_2\text{-}2,6$)$(CO)_5(\eta^5\text{-}C_2B_9H_9Me_2)$] [2.600(1) Å],[7]

[FeW{μ - C(C_6H_4Me - 4)C(O)C(Me)C(Me)}$(CO)_5$ (η^5-C_5Me_5)] [2.722(1) Å][4] and [FeW{μ-C(C_6H_4Me-4) C(Me)C(Me)}$(CO)_5$(η-C_5H_5)] [2.720(1) Å].[8]

The μ-C(10)—Fe [2.141(4) Å] and μ-C(10)—W [2.188(4) Å] distances may be compared with the respective μ-C(C_6H_4Me-4)—Fe and μ-C(C_6H_4Me-4)—W separations in [FeW{μ-C(C_6H_4Me-4)C(O)C(Me)C(Me)}$(CO)_5$(η^5-C_5Me_5)] [2.103(6), and 2.193(5) Å],[4] and [FeW{μ-C(C_6H_4Me-4)C(Me)C(Me)}$(CO)_5$(η^5-C_5H_5)] [2.047(6) and 2.194(6) Å].[8] The Fe—P bond [2.248(1) Å] in (**3**) is of very similar length to that [2.184(9) Å] in the dimetal compound [FeW(μ-PPh_2)$(CO)_5$ {$HB(pz)_3$}].[9]

Having established the molecular structure of (**3**) by X-ray diffraction it became possible to interpret the NMR data for this species, and for (**4**) also. Since the latter displayed similar resonances it was evidently isostructural. The ^{13}C-{^1H} NMR spectrum of (**3**) measured at room temperature in CD_2Cl_2–CH_2Cl_2 showed doublet signals for the two CO groups bonded to tungsten [δ 230.1 and 225.3 ppm, with J(PC) 12 and 14 Hz, respectively], and three broad resonances for the $Fe(CO)_3$ fragment (δ 216.5, 213.2 and 212.8 ppm). The latter observation suggested site-exchange of the three CO groups at the iron centre. At −60°C, however, in a ^{13}C spectrum measured in CD_2Cl_2–CH_2Cl_2 the tricarbonyliron group gave rise to three sharp doublet signals at δ 216.5, 213.2 and 212.5 ppm with J(PC) 23, 41 and 30 Hz, respectively. For compound (**4**), the ^{13}C-{^1H} NMR spectrum at ambient temperatures showed five distinct resonances for the CO ligands, each a doublet, at δ 236.5, 235.0 (Mo—CO), 214.7, 212.4 and 210.8 ppm, with J(PC) 10, 15, 24, 44 and 29 Hz, respectively.

The ^{13}C-{^1H} NMR spectra of (**3**) and (**4**) show several peaks in the range *ca* δ 120–155 ppm due to the Ph and C_6H_4 moieties. However, doublet signals in each spectrum characteristic for the μ-CC_6H_4Me-4 group are seen at δ 131.6 ppm with J(PC) 7 Hz. The resonance for the C(H)M (M = W or Mo) group occurs as a doublet in the spectra of both compounds at *ca* δ −8.2 ppm, with J(PC) 7 Hz. The assignment is confirmed by the appearance of ^{183}W satellite peaks [J(WC) 24 Hz] on this resonance in the spectrum of (**3**). In a fully-coupled ^{13}C spectrum of (**4**), measured in $CDCl_3$, the signal for the C(H)Mo group (δ −8.1 ppm) occurs as a doublet

of doublet of doublets [J(PC) 7, J(HC) 150 and 7]. Evidently ^{1}H–^{13}C coupling occurs between C(H)Mo and only one proton of the adjacent CH_2 moiety. The resonance for the latter was not observed in the ^{13}C-{^{1}H} spectrum of (**4**) when measured in CD_2Cl_2–CH_2Cl_2, being masked by the solvent peaks, but is seen in the ^{13}C spectrum (in $CDCl_3$) at δ 54.6 ppm as a triplet [J(HC) 129 Hz] of doublets [J(PC) 14 Hz].

The ^{1}H NMR spectra of (**3**) and (**4**) show the expected three signals for the CH·CH$_2$ fragment. For (**3**), these occur at δ 0.78 [d of d, CH, J(PH) 14, J(HH) 4], 3.05 [d of d of d, CH$_2$, J(PH) 50, J(HH) 15, 4] and 4.50 [d of d, CH$_2$, J(PH)17, J(HH) 15 Hz], while for (**4**) the resonances are at δ 1.76 [d of d, CH, J(PH) 12, J(HH) 4], 3.57 [d of d of d, CH$_2$, J(PH) 50, J(HH) 15, 4] and 4.13 [d of d, CH$_2$, J(HH) 15, 4 Hz].

The μ-PPh$_2$·CH·CH$_2$·C(C$_5$H$_4$Me-4) group present in compounds (**3**) and (**4**) can be visualized as having been formed in a step-wise manner at the dimetal centre. Based on previous observations,[5] it is probable that initially the phosphine coordinates at the iron centres of (**1**) and (**2**), a process which would require release of CO from the latter species. Subsequent addition of the vinyl group to the C═M (Mo or W) bond would produce the M·CH(PPh$_2$)·CH$_2$·C(C$_6$H$_4$Me-4) ring system found in the products. Reaction of the vinyl group present in P(CH:CH$_2$)Ph$_2$ with the μ-alkylidyne groups of (**1**) and (**2**) provides a further demonstration of the reactivity of these heteronuclear dimetal species.

EXPERIMENTAL

All experiments were carried out under nitrogen, using Schlenk tube techniques. Solvents were rigorously dried before use. NMR spectra were recorded with JNM FX 90Q, FX 200 or GX 400 instruments and IR spectra were recorded with Nicolet MX 10 or MX 5 spectrophotometers. For NMR data all chemical shifts are in ppm and coupling constants are in Hz. Phosphorus-31 chemical shifts are positive to high frequency of 85% H_3PO_4 (external). The compounds [FeW(μ-CC$_6$H$_4$Me-4)(CO)$_5$(η^5-C$_5$Me$_5$)] and [FeMo(μ-CC$_6$H$_4$Me-4)(CO)$_6$(η^5-C$_5$H$_5$)] were prepared by methods previously described.[1,2] Light petroleum refers to that fraction of b.p. 40–60°C.

Synthesis of the complexes

(i) Compound (**1**) (0.16 g, 0.26 mmol) in CH_2Cl_2 (20 cm^3) was treated with P(CH:CH$_2$)Ph$_2$ (0.055 g,

0.052 cm^3, 0.26 mmol) and the mixture was stirred at ambient temperatures for *ca* 4 h. The volume was reduced *in vacuo* to *ca* 5 cm^3 and the mixture was chromatographed at 10°C on a Florisil column (3 × 15 cm, 100–200 mesh). Elution with light petroleum–CH_2Cl_2 (3:2) afforded a yellow eluate. Removal of solvent *in vacuo*, followed by crystallization of the residue from CH_2Cl_2–light petroleum (1:5) at −78°C gave yellow–orange *needles* of $[FeW\{\mu\text{-}PPh_2\cdot CH\cdot CH_2\cdot C(C_6H_4Me\text{-}4)\}(CO)_5(\eta^5\text{-}C_5Me_5)]$ (**3**) (0.18 g, 83%) [Found: C, 51.4; H, 4.5%. $C_{37}H_{35}FeO_5PW$ requires C, 53.5; H, 4.3%]. ν_{max} (CO) at 2024s, 1956s, 1948s and 1877w cm^{-1} (in CH_2Cl_2). NMR: ^1H (in CD_2Cl_2), δ 0.78 [d of d, 1 H, CH·P, *J*(PH) 14, *J*(HH) 4], 1.81 (s, 15 h, C_5Me_5), 2.24 (s, 3 H, Me-4), 3.05 [d of d of d, 1 H, CH_2, *J*(PH) 50, *J*(HH) 15 and 4], 4.50 [d of d, 1 H, CH_2, *J*(PH) 17, *J*(HH) 15], 6.97 (m, 4 H, C_6H_4), and 7.29–7.71 (m, 10 H, Ph); $^{13}C\text{-}\{^1H\}$ (in CD_2Cl_2–CH_2Cl_2), δ 230.1 [d, WCO; *J*(PC) 12], 225.3 [d, WCO, *J*(PC) 14], 216.5, 213.2, 212.8 [3 × br s, $Fe(CO)_3$], 154.2–121.8 (C_6H_4, Ph), 131.6 [d, CC_6H_4 Me-4, *J*(PC) 7], 100.5 (C_5Me_5), 21.6 [d, CH_2, *J*(PC) 14], 21.1 (Me-4), 9.5 (C_5Me_5) and −8.2 [d, P·CH, *J*(PC) 7, *J*(WC) 24]; ^{13}C (at −60°C), δ 230.5 [d, WCO, *J*(PC) 12], 224.9 [d, WCO, *J*(PC) 14], 216.5 [d, FeCO, *J*(PC) 23], 213.2 [d, Fe(CO), *J*(PC) 41], 212.5 [d, FeCO, *J*(PC) 30], 131.6 [d, CC_6H_4Me-4, *J*(PC) 7] and −8.2 [d of d, CH·P, *J*(PC) 7, *J*(HC) 159]. In the ^{13}C NMR at −60°C the CH_2 resonance at 51.6 is obscured by a strong solvent peak. $^{31}P\text{-}\{^1H\}$ (in CD_2Cl_2), δ 41.4.

(ii) Compound (**2**) (0.20 g, 0.41 mmol) in thf (50 cm^3) was treated with $P(CH:CH_2)Ph_2$ (0.095 g, 0.45 mmol) at room temperature and the mixture was stirred for 3 h. Solvent was removed *in vacuo* and the brown residue was dissolved in CH_2Cl_2 (2 cm^3) and light petroleum (8 cm^3), and the solution chromatographed on an alumina column (3 × 30 cm, Brockman Activity II). Elution with CH_2Cl_2–light petroleum (1:4) afforded a yellow eluate. Removal of solvent *in vacuo* gave yellow *microcrystals* of $[FeMo\{\mu\text{-}PPh_2\cdot CH\cdot CH_2\cdot C(C_6H_4Me\text{-}4)\}(CO)_5(\eta^5\text{-}C_5H_5)]$ (**4**) (0.22 g, 77%) [Found: C, 57.0; H, 4.2%. $C_{32}H_{25}FeMoO_5P$ requires C, 57.2; H, 3.8%]. ν_{max} (CO) at 2029s, 1996w, 1964vs, 1945w and 1898w(br) cm^{-1} (in CH_2Cl_2). NMR: ^1H (in CD_2Cl_2), δ 1.76 [d of d, 1 H, CH·P, *J*(PH) 12, *J*(HH) 4], 2.27 (s, 3 H, Me-4), 3.57 [d of d of d, 1 H, CH_2, *J*(PH) 50, *J*(HH) 15 and 4], 4.13 [d of d, 1 H, CH_2, *J*(PH) 14, *J*(HH) 15], 5.02 (s, 5 H, C_5H_5), 7.03 [m, 4 H, C_6H_4], and 7.20–7.70 (m, 10 H, Ph); $^{13}C\text{-}\{^1H\}$ (in CD_2Cl_2–CH_2Cl_2), δ 236.5 [d, MoCO, *J*(PC) 10], 235.0 [d, MoCO, *J*(PC) 15], 214.7 [d, FeCO, *J*(PC) 24], 212.4 [d, FeCO, *J*(PC) 44], 210.8 [d, FeCO, *J*(PC) 29], 157.1 [$C^1(C_6H_4)$], 141.0–124.0 (C_6H_4 and Ph), 131.6 [d, CC_6H_4Me-4, *J*(PC) 7], 92.1 (C_5H_5), 21.1 (Me-4) and −8.2 [d, CH·P, *J*(PC) 7]; ^{13}C ($CDCl_3$), δ 54.6 [t of d, CH_2, *J*(HC) 129, *J*(PC) 14] and −8.11 [d of d of d, CH·P, *J*(PC) 7, *J*(HC) 150, 7]; $^{31}P\text{-}\{^1H\}$, δ 43.2 ppm.

X-ray crystallographic data

Red crystals of (**3**) were grown from CH_2Cl_2–light petroleum. Diffraction data were collected on a Nicolet P3 diffractometer at 298 K using a crystal of dimensions *ca* 0.50 × 0.40 × 0.35 mm. Of the 6511 intensities measured (Wyckoff ω-scans, $2\theta \leqslant 50°$), 5389 had $F \geqslant 5\sigma(F)$ and only these were used in the solution and refinement of the structure. Intensity data were corrected for Lorentz, polarization, and X-ray absorption effects. The latter by a procedure based upon azimuthal scan data.[10]

Crystal data for (**3**). $C_{37}H_{35}FeO_5PW$, $M = 830.4$, triclinic, $a = 8.583(3)$, $b = 10.529(4)$, $c = 19.989(8)$ Å, $\alpha = 88.43(3)$, $\beta = 84.58(3)$, $\gamma = 67.66(3)°$, $U = 1663(1)$ $Å^3$, $Z = 2$, $D_c = 1.66$ g cm^{-3}, $F(000) = 824$, space group $P\bar{1}$, $\mu(Mo\text{-}K_\alpha) = 40.5$ cm^{-1}, Mo-K_α X-radiation ($\bar{\lambda} = 0.71069$ Å, graphite monochromator).

The structure was solved, and all non-hydrogen atoms were located, by conventional heavy-atom and difference Fourier methods. Hydrogen atoms were included in calculated positions with fixed isotropic thermal parameters (aryl, CH_2 and CH), or common refined isotropic thermal parameters (methyl). All remaining atoms were given anisotropic thermal parameters. Refinement by blocked-cascade least-squares converged at $R = 0.024$ ($R_w = 0.026$) with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.0005|F|^2]$.* The final electron-density difference synthesis showed no peaks >0.7 e $Å^{-3}$. Scattering factors were from ref. 11. All calculations were carried out on a Data General "Eclipse" computer with the SHELXTL system of programs.[10]

Abstract—The dinuclear complex $[Re_2Cl_2(CO)_6SeCH_2CMe_2CH_2Se]$ has been prepared and characterized in the solid state by X-ray crystallography. Proton NMR spectroscopy has shown the structure to be stereochemically rigid in solution.

Syntheses and structures of complexes of general formula $[Re_2X_2(CO)_6L]$, (X = Cl, Br, I, L = R_2S_2, R_2Se_2) where the open chain ligands bridge two rhenium atoms are now well characterized.[1–3] In the case of the complexes of dialkyl disulphides and diselenides, the chalcogen atoms have been reported to undergo pyramidal inversions.[3] The aims of the present work are to examine whether analogous complexes can be formed with cyclic dichalcogen ligands and to study any stereochemical non-rigidity in solution.

EXPERIMENTAL

The cyclic diselenide $SeCH_2CMe_2CH_2Se$[4] and the dirhenium complex $[Re_2Cl_2(CO)_6(THF)_2]$[5] were prepared by literature methods. The diselenide in excess (0.205 mmol) in chloroform (5 cm^3) was added to a stirred solution of $[Re_2Cl_2(CO)_6(THF)_2]$ (0.155 mmol) in chloroform. After stirring under nitrogen (4 h) the solvent was removed under vacuum from the pale brown solution. Dissolution of the residue in dichloromethane (10 cm^3) and filtration gave a yellow solution to which was added heptane (4 cm^3). Slow cooling to −20°C yielded yellow/brown crystals of $[Re_2Cl_2(CO)_6(SeCH_2CMe_2CH_2Se)]$ (0.088 mmol 57%) (Found: C, 15.9; H, 1.3. Calc: C, 15.7; H, 1.2%). (ν_{CO} 2060, 2038, 1958, 1937 and 1905 cm^{-1}). The mass spectrum gave a complex pattern for $[M]^+$ which corresponded exactly to the computer simulated isotope pattern, with maximum intensity $[M]^+$ at 840.

X-ray crystallography. X-ray diffraction measurements were made on a small crystal, of dimensions approx. $0.16 \times 0.12 \times 0.06$ mm^3, sealed inside a thin-walled glass capillary. Orientation matrix and cell dimensions were determined accurately and intensity data recorded at room temperature with graphite monochromatised Mo-K_α radiation ($\lambda = 0.71069$ Å) using a CAD4 diffractometer and previously detailed procedures.[6]

Crystal data

$C_{11}H_{10}Cl_2O_6Re_2Se_2$, $M = 839.427$, space group $P2_1/n$, $a = 9.9996(16)$ Å, $b = 18.0336(31)$ Å, $c = 10.8639(12)$ Å, $\beta = 111.673(10)°$, $U = 1820.568$ $Å^3$, $Z = 4$, $D_c = 3.06$ g cm^{-3}, μ(Mo-K_α) = 169.3 cm^{-1}. Of the 2461 data measured in the range $1.5 \leqslant \theta \leqslant 22.0°$, 2232 were unique and 1716 observed [$I > 2.5\sigma(I)$]. The structure was solved via interpretation of a Patterson Function followed by standard heavy atom phasing procedures. The intensity data were corrected for absorption (ABSC in SHELX76).[7] Non-hydrogen atoms were refined anisotropically; hydrogens were inserted in idealized positions and assigned group U_{iso} values. The final R, R_w values were 0.0396 and 0.0340 for 230 parameters, with a weighting scheme $w = 1/[\sigma^2(F) + 0.0007F_o^2]$.

Tables of atomic coordinates and displacement factor coefficients, and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies can be obtained on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

There are many parallels between the structural moieties $PtXMe_3$ and $ReX(CO)_3$. The metal centres are isoelectronic, and with similar ligands isostructural products usually result. We have reported the acyclic diselenide $[(PtXMe_3)_2(RSeSeR)]$[8] and Calderazzo and his co-workers[1,2] have reported the corresponding $[\{ReX(CO)_3\}_2(RSeSeR)]$ complexes. The structures of both types of complex show there to be invariably a *trans* relationship between the two ligand organic groups, and there is a synchronous or correlated pyramidal atomic inversion process about the coordinated selenium atoms.[3,9] Notably the activation parameters for these processes are considerably higher for the rhenium comlexes.[3]

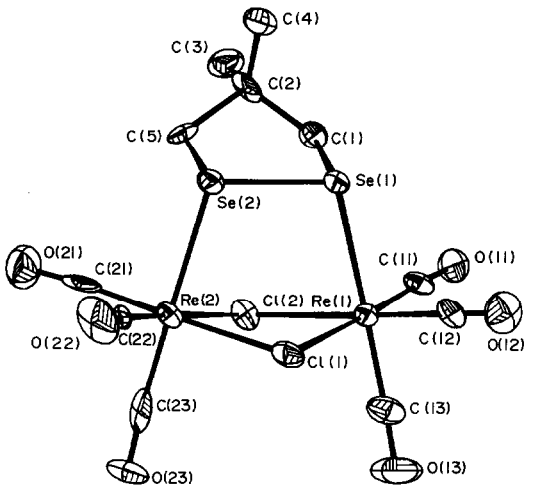

Fig. 1.

The formation of a diselenide complex of Pt(IV) with a *cis* relationship between the two carbon atoms attached to the seleniums of the ligand was achieved with the cyclic diselenide $SeCH_2CMe_2CH_2Se$, and this was found to undergo a synchronous inversion of the selenium atom pairs with an energy about 20 kJ mol^{-1} higher than the usual single site inversion energies.[10]

The displacement of THF from $[Re_2Cl_2(CO)_6(THF)_2]$ by 4,4-dimethyl-1,2-diselenacyclopentane gave a good yield of $[Re_2Cl_2(CO)_6(SeCH_2CMe_2CH_2Se)]$.

This structure is the first example of a bis $ReX(CO)_3$ moiety bridged by a cyclic dichalcogen ligand. The X-ray crystal structure is shown in Fig. 1, and important bond lengths and angles are given in Table 1.

We have been unable to detect, to date, any selenium pyramidal inversion for this species in solution. This is not unexpected as any such process will necessarily involve both Se atoms inverting synchronously. From previous experience with dinuclear Pt(IV) complexes[10] this is a relatively high energy process, and not surprisingly in the present complex is apparently too slow to produce any exchange broadening of the ligand methylene and methyl signals in the high temperature range accessible for our NMR studies.

SYNTHESIS AND CHARACTERIZATION OF A NEW COORDINATION COMPOUND OF GOLD(III) WITH TRIPHENYLARSINE OXIDE(TPAsO)

GONG YUQIU* and XIA SHIHUA

Department of Chemistry, Hangzhou University, Hangzhou, China

(*Received* 6 *May* 1987; *accepted* 19 *June* 1987)

Abstract—A new solid coordination compound of the type 1 : 1 of TPAsO to gold(III) was prepared firstly by means of the extraction method, but only the coordination compound of the type 2 : 1 was obtained by the method of direct synthesis. It was found in polar solvents that the 1 : 1 type coordination compound could transform to that of the 2 : 1 type slowly. By the data of thermoanalyses, a mechanism was suggested for thermal decomposition of the above two coordination compounds.

Potts[1] synthesized a solid coordination compound of the type 2 : 1 of TPAsO to gold(III) more than ten years ago, but he failed to prepare the 1 : 1 type. When researching the extraction behavior of gold(III) with TPAsO, we obtained the new compound of the 1 : 1 type successfully, and the comparison with that of the 2 : 1 type was made. It was discovered that the composition of the solid coordination compound of the 1 : 1 type was the same as that of the extracted species of gold(III) with TPAsO.

EXPERIMENTAL

UV spectra were obtained using a UV-210A type doublebeam UV and visible spectrophotometer. IR spectra were recorded on a Perkin–Elmer 683 spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL FX-90Q spectrometer at 90 Hz. Elemental analyses of carbon and hydrogen were measured with a Perkin–Elmer EA-240C type analyser and gold analyses were carried out by gravimetric methods. The TG/DTA data were recorded on a DT-30 simultaneous thermal analyser, the rate of heating was 10°C per min. Molar conductance were measured with a DDS-11A type conductance meter.

TPAsO was prepared as reported by Shriner,[2] after recrystallizing using 1,2-dichloroethane and petroleum ether, drying in vacuum, the product obtained was white crystals, m.p. = 189°C. Tetrachloroaurate (A.R.) was purchased from the second factory of chemicals in Peking. Other reagents used were of chemical or analytical grade.

Preparation of coordination compounds

Direct synthetic method. 2.43 mmol $HAuCl_4 \cdot 4H_2O$ (dissolved in 10 cm^3 1.0 M HCl) was added to 2.43 mmol, 4.86 mmol and 7.29 mmol TPAsO solutions (dissolved in 10 cm^3 ethanol for each), respectively and yellow products precipitated immediately. After filtering, washing several times with ethanol, pale yellow crystal were obtained for each (Compd **I**).

Extraction method. 2.43 mmol $HAuCl_4 \cdot 4H_2O$ (dissolved in 10 cm^3 1.0 M HCl) were added to 2.43 mmol TPAsO (in 10 cm^3 1,2-dichloroethane). On shaking for a few minutes, the organic phase was separated and solid product was obtained after evaporating the solvent. The solid product was recrystallized by 1,2-dichloroethane and petroleum ether, a deep yellow crystal was obtained after drying in air (Compd **II**).

RESULTS AND DISCUSSION

The elemental analyses and some physical properties of the coordination compounds, which were prepared by the direct synthetic method and the extraction method, are shown in Table 1. From Table 1, it can be seen that the composition of the

[a] Figures in parentheses are calculated ones.

coordination compound obtained by the extraction method was the same as that of the extracted species of gold(III) and TPAsO.[3] However, the attempt to synthesize the 1:1 type solid coordination compound by the direct synthetic method did not succeed. The experiments showed that only the 2:1 type product was obtained when any ratios of TPAsO to gold(III) were used, this might be why Potts could not synthesize the 1:1 type coordination compound.

IR spectra showed the stretching frequency of free As=O bond was at 881 cm^{-1}, but after coordination, this absorption peak shifted to 770 cm^{-1} (Compd **I**) and 745 cm^{-1} (Compd **II**), respectively, and in coordination compound (**I**), the vibrating peaks of hydrogen bonds appeared at 1030 cm^{-1} and 1280 cm^{-1}; but in compound (**II**), a characteristic peak appeared at 2940 cm^{-1}, this might be ascribed to the absorption peak of the hydroxy group (O—H) formed by the bonding of As=O and H^+. Apparently, that is why the stretching frequency of As=O in compound (**I**) was lower than that in compound (**II**) due to the O—H covalent bond formed in coordination compound (**II**).

When dissolving coordination compounds in $CDCl_3$ and TMS as internal references, we discovered the hydrogen proton resonance peak in compound (**II**) was at 6.12 ppm, but the relative resonance peak of compound (**I**) was at 7.40 ppm, this indicated the electron density of the hydrogen proton in compound (**II**) was higher than that of compound (**I**). Apparently, this was because of the formation of an O—H covalent bond between As=O bond and H^+ in compound (**II**). However, only a hydrogen bond was formed between H^+ and two TPAsO molecules, so the proton resonance peak shifted to lower field in compound (**II**). This result was consistent with the conclusion obtained from IR spectra.

The 10^{-4} M solutions of compounds were made using dichloromethane and ethanol as solvents and UV absorption spectra of them were recorded (results shown in Table 2). The absorption curves of the two coordination compounds were almost the same as that of tetrachloroaurate in water, suggesting the $AuCl_4^-$ anionic complex existed in them.[4]

Table 2. UV spectra of coordination compounds λ_{max} (nm), ε (cm^{-1} mol^{-1} l)

Compds	Solvents CH_2Cl_2	C_2H_5OH	H_2O
	$\varepsilon \times 10^{-3}$

(II)	4.08(323)	2.75(321)	
$HAuCl_4$			5.60(313)

[a] Figures in parentheses were maximum absorption peaks.

The solid coordination compounds dissolved in many polar organic solvents, e.g. ethanol, trichloromethane, dichloromethane and 1,2-dichloroethane etc. but did not dissolve in non-polar solvents such as benzene and toluene. The molar conductance values of the two compounds in ethanol and dichloromethane are presented in Table 3.

Table 3. The molar conductance of coordination compounds, Λ_M (Ω^{-1} cm^2 M^{-1}), 25°C

(II)	39.5	40
KNO_3	37.0	[a]

[a] KNO_3 can not dissolve in CH_2Cl_2.

Table 4. TG/DTA analyses of coordination compounds

Compds	Percentage of loss of weight: First loss of weight	Second loss of weight	Total loss of weight
(I)	72.40	6.47	78.87
	(73.50)[a]	(6.45)	(79.93)
(II)	61.30	9.15	70.45
	(60.66)	(9.59)	(70.25)

[a] Figures in parentheses are calculated ones.

From Table 3, it can be seen that the two compounds are 1 : 1 electrolytes.

It must be noted that when the above solutions of compound (II) were left for several days, it was discovered that the molar conductance of it apparently increased. If the solvents were evaporated and the product was recrystallized by ethanol and petroleum ether, a pale yellow crystal was obtained. Elemental analyses of it showed the product was coordination compound (I). It appears that compound (II) could transform gradually in polar organic solvents as follows:

$$2[H(TPAsO)][AuCl_4] \xrightarrow[\text{dichloromethane}]{\text{in ethanol or}} [H(TPAsO)_2][AuCl_4] + HAuCl_4.$$

Thermogravimetric and differential thermal analyses showed coordination compounds had endothermic peaks at 175°C (Compd I) and 152°C (Compd II), respectively, but no loss of weight occurred in the thermogravimetric curves. It was believed that the positions of endothermic peaks were relative to their melting points. The TG/DTA curves of them were almost the same, the first loss of weight was finished between 200–300°C. At 400°C the second loss of weight started and ended at *ca.* 500°C, from then no loss of weight occurred. The final products of thermal decomposition were a yellow powder of gold. By the above experiments, it was suggested that procedures of thermal decompositions of the two compounds could be written as follows:

$$[H(TPAsO)n]AuCl_4 \xrightarrow[(1)]{200\text{–}300^\circ C} Au(CO)Cl \xrightarrow[(2)]{400\text{–}500^\circ C} Au$$

where $n = 1$ or 2.

By the above procedures of thermal decompositions of coordination compounds, theoretical percentage loss of weight for each stage coincided very well with the values measured by experiments (shown in Table 4).

From the results of the above experiments, the structures of the two compounds may be suggested as follows:

Compd I

$$[TPAsO \ldots H^+ \ldots OAsPT]AuCl_4^-.$$

Compd II

$$[TPAsO^+—H]AuCl_4^-.$$

(*Received* 8 *May* 1987; *accepted* 19 *June* 1987)

Abstract—The compounds $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) react with one equivalent of thiourea (tu) in MeOH or *N,N,N′,N′*-tetramethylthiourea (tmtu) in CH_2Cl_2 at room temperature to initially afford the monoacetonitrile compounds $[MI_2(CO)_3(NCMe)L]$ (L = tu or tmtu) which rapidly transform to the isolated iodide bridged dimers, $[M(\mu\text{-}I)I(CO)_3L]_2$ with loss of acetonitrile. Reaction of $[WI_2(CO)_3(NCMe)_2]$ with two equivalents of tu or tmtu gave the expected mononuclear seven-coordinate compounds $[WI_2(CO)_3L_2]$. However, reaction of $[MoI_2(CO)_3(NCMe)_2]$ with two equivalents of tu or tmtu rapidly affords the iodide-bridged dimers $[Mo(\mu\text{-}I)I(CO)_2L_2]_2$ with loss of carbon monoxide from $[MoI_2(CO)_3L_2]$. The low temperature (−70°C) ^{13}C NMR spectrum of $[Mo(\mu\text{-}I)I(CO)_2\{SC(NMe_2)_2\}_2]_2$ suggests the complex is based on two capped octahedra with a carbonyl ligand capping each octahedral face.

Although there are a wide variety of examples of complexes of molybdenum(II) and tungsten(II) containing anionic sulphur ligands such as dithiocarbamates and xanthates: in particular the compounds $[M(CO)_n(S_2CNR_2)_2]$ (M = Mo or W; $n = 2$ or 3; R = Me, Et and ^{i}Pr)[1] hitherto very few seven-coordinate halocarbonyl complexes containing neutral sulphur donor ligands have been reported. Wilkinson and Mannerskantz[2] reported the reaction of the zerovalent complexes $[M(CO)_4(dth)]$ (M = Mo or W; dth = 2,5-dithiahexane) with X_2 (X = Br or I) under controlled conditions to give the seven-coordinate complexes $[MX_2(CO)_3(dth)]$. Also Tsang, Meek and Wojcicki[3] reported the preparation of some seven-coordinate complexes with neutral sulphur donor ligands attached to molybdenum(II) and tungsten(II) such as diphenyl(*o*-methylthiophenyl)phosphine and phenylbis(*o*-methylthiophenyl)phosphine.

Although the zerovalent six-coordinate complexes $[Mo(CO)_3\{SC(NH_2)_2\}_3]$,[4] $[Mo(CO)_3(bipy)\{SC(NH_2)_2\}]$[5] and very recently $[Cr(CO)_5\{SC(NR_2)_2\}]$ (R = H, Me, p-tol or ^{t}Bu)[6] have been previously reported, hitherto there are no examples of seven-coordinate complexes of molybdenum(II) or tungsten(II) containing thiourea as an attached ligand. In this paper we describe the preparation and properties of some new mononuclear and dinuclear seven-coordinate complexes of molybdenum(II) and tungsten(II) containing $SC(NH_2)_2$ or $SC(NMe_2)_2$ as attached ligands.

EXPERIMENTAL

The synthesis and purification of the complexes described were carried out under an atmosphere of dry nitrogen. The compounds $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) were prepared by the published method,[7] and $[M(CO)_6]$, acetonitrile, I_2, $SC(NH_2)_2$ and $SC(NMe_2)_2$ were purchased from commercial sources.

The low temperature (−70°C) ^{13}C NMR spectrum of (7) was recorded on a Bruker WH-400 MHz NMR spectrometer at the University of Warwick (the spectrum was calibrated against tetramethylsilane). Infrared spectra were recorded on a Perkin–Elmer 197 infrared spectrophotometer. Elemental analyses for carbon, hydrogen and nitro-

* Author to whom correspondence should be addressed.

gen were carried out by Mr E. Lewis of the Department of Chemistry, UCNW, on a Carlo Erba Elemental Analyser MOD 1106 (using helium carrier gas). Molecular weight determinations were carried out using Rast's method[8] using camphor as the solvent. Magnetic susceptibilities were determined using a Johnson–Mathey magnetic susceptibility balance.

(3) $[Mo(\mu\text{-}I)I(CO)_3\{SC(NMe_2)_2\}]_2$

To $[MoI_2(CO)_3(NCMe)_2]$ (0.195 g, 0.378 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen was added $SC(NMe_2)_2$ (0.05 g, 0.378 mmol). After stirring the solution for two minutes, filtration and removal of the solvent *in vacuo* gave brown crystals of $[Mo(\mu\text{-}I)I(CO)_3\{SC(NMe_2)_2\}]_2$ (yield = 0.17 g, 80%), which were recrystallized from CH_2Cl_2. Molecular weight for $C_{16}H_{24}N_4I_4Mo_2O_6S_2$: Calc. 1132; found 1062.

Similar reactions of $[MI_2(CO)_3(NCMe)_2]$ with $L = SC(NH_2)_2$ in CH_3OH and $SC(NMe_2)_2$ in CH_2Cl_2 gave the new compounds $[M(\mu\text{-}I)I(CO)_3L]_2$ (1), (2) and (4). Molecular weight for (4): $C_{16}H_{24}N_4I_4W_2O_6S_2$: Calc. 1308; found 1172.

(6) $[WI_2(CO)_3\{SC(NH_2)_2\}_2]$

To $[WI_2(CO)_3(NCMe)_2]$ (0.23 g, 0.381 mmol) dissolved in MeOH (15 cm^3) with continuous stirring under a stream of dry nitrogen was added $SC(NH_2)_2$ (0.058 g, 0.762 mmol). After stirring the solution for 4 min, filtration and removal of the solvent *in vacuo* gave green crystals of $[WI_2(CO)_3\{SC(NH_2)_2\}_2]$ yield = 0.16 g, 62%), which were recrystallized from MeOH.

In a similar reaction, $[WI_2(CO)_3(NCMe)_2]$ with $SC(NMe_2)_2$ in CH_2Cl_2 gave the new compound $[WI_2(CO)_3\{SC(NMe_2)_2\}_2]$ (8).

(7) $[Mo(\mu\text{-}I)I(CO)_2\{SC(NMe_2)_2\}_2]_2$

To $[MoI_2(CO)_3(NCMe)_2]$ (0.195 g, 0.378 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen was added $SC(NMe_2)_2$ (0.1 g, 0.756 mmol). After stirring the solution for 6 min, filtration and removal of the solvent *in vacuo* gave brown crystals of $[Mo(\mu\text{-}I)I(CO)_2\{SC(NMe_2)_2\}_2]_2$ (yield = 0.18 g, 71%), which were recrystallized from CH_2Cl_2. Molecular weight for $C_{24}H_{48}N_8I_4Mo_2O_4S_4$: Calc. 1340, found 1154.

In a similar reaction, $[MoI_2(CO)_3(NCMe)_2]$ with $SC(NH_2)_2$ in MeOH gave the new compound $[Mo(\mu\text{-}I)I(CO)_2\{SC(NH_2)_2\}_2]_2$ (5).

RESULTS AND DISCUSSION

The addition of one equivalent of $SC(NH_2)_2$(tu) or $SC(NMe_2)_2$(tmtu) to $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) at room temperature after rapid filtration and removal of the solvent *in vacuo* gave good yields of the iodide-bridged compounds $[M(\mu\text{-}I)I(CO)_3L]_2$ (L = tu or tmtu). Reaction of two equivalents of tu or tmtu with $[WI_2(CO)_3(NCMe)_2]$ afforded good yields of the mononuclear seven-coordinate compounds $[WI_2(CO)_3L_2]$. Whereas reaction of $[MoI_2(CO)_3(NCMe)_2]$ with two equivalents of tu or tmtu after rapid filtration and removal of solvent *in vacuo* gave good yields of the iodide-bridged dimers $[Mo(\mu\text{-}I)I(CO)_2L_2]_2$ with loss of carbon monoxide. All the complexes (1)–(8) are very air-sensitive in solution and rapidly decompose in the solid state in air. The compounds are also thermally unstable (particularly the iodide-bridged dimers), although they can be stored for several hours in the solid state under nitrogen at 0°C. The thiourea complexes are much less soluble than their tetramethylthiourea counterparts. The complexes are not very soluble in chlorinated solvents such as $CHCl_3$ or CH_2Cl_2 but are much more soluble in MeOH. All the complexes have been characterized by elemental analysis (C, H and N) (Table 1), IR spectroscopy (Table 2) and for the tetramethylthiourea complexes molecular weight studies using Rast's method[8] indicated that the complexes (3), (4) and (7) were dimeric (see Experimental). The magnetic susceptibilities of compounds (1)–(8) were determined and the results showed all the complexes to be diamagnetic.

Reaction of the complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W)[7] with one equivalent of L (L = tu or tmtu) must initially afford the monoacetonitrile complexes $[MI_2(CO)_3(NCMe)L]$ via displacement of acetonitrile probably by a dissociative mechanism since seven-coordinate complexes are highly crowded. This type of complex $[MI_2(CO)_3(NCMe)L]$ has been isolated from the reaction of $[MI_2(CO)_3(NCMe)_2]$ with one equivalent of L (L = PPh_3, $AsPh_3$ or $SbPh_3$)[9] which are good π-acceptor ligands and hence stabilize these seven-coordinate monomers by lowering the electron density on the metal and hence increasing the strength of the M—N bond. Whereas tu and tmtu are better σ-donors and poorer π-acceptors than PPh_3, $AsPh_3$ or $SbPh_3$ and hence the electron density at the metal is greater which weakens the M—N bond. Acetonitrile is mainly a σ-donor ligand and rapid loss of acetonitrile occurs via attack of the iodide lone pair to give the iodide bridged complexes $[M(\mu\text{-}I)I(CO)_3L]_2$.

Reaction of $[WI_2(CO)_3(NCMe)_2]$ with two equi-

[a] Calculated values in parentheses.

valents of tu or tmtu gives the expected mononuclear compounds $[WI_2(CO)_3L_2]$ with facile displacement of two acetonitrile ligands. The molybdenum complex $[MoI_2(CO)_3(NCMe)_2]$ reacts with two equivalents of L and initially gives $[MoI_2(CO)_3L_2]$ which rapidly dimerizes with loss of carbon monoxide to give the iodide-bridged dimers $[Mo(\mu\text{-}I)I(CO)_2L_2]_2$. This tendency for molybdenum complexes of the type $[MoX_2(CO)_3L_2]$ (L = phosphorus donor ligands) to dimerize with loss of carbon monoxide more readily than their tungsten analogues has been previously observed.[10] Molecular weight and magnetic susceptibility measurements on (7) confirm the dimeric nature of this complex (see Experimental).

Most of the previously reported X-ray crystal structures of d^4-seven-coordinate complexes have capped octahedral geometry.[11] It is very likely that the $[WI_2(CO)_3L_2]$ complexes will have a similar geometry since their infrared carbonyl pattern closely resembles the seven-coordinate complexes which have been shown to have capped octahedral geometry from X-ray crystallography.[11] Colton and Kevecordes[12] have shown how low temperature (−70°C) ^{13}C NMR spectroscopy can be used to find out if there is a carbonyl ligand in the capping position in capped octahedral compounds. Unfortunately the low temperature (−70°C) ^{13}C NMR spectra of $[WI_2(CO)_3L_2]$ did not reveal any carbonyl resonances due to instability and low solubility in CD_3OD at low temperature. However, the low temperature (−70°C) ^{13}C NMR spectrum of $[Mo(\mu\text{-}I)I(CO)_2\{SC(NMe_2)_2\}_2]_2$ (recorded in CD_3OD) shows carbonyl resonances at δ = 207.7(s) and 239.6(s) ppm. The low field resonance at δ = 239.6 ppm is highly likely to be due to a carbonyl ligand in the unique capping position. Hence the structure of (7) probably has the two molybdenum atoms in capped octahedral environments with a carbonyl ligand capping a $[MoI_3(CO)\{SC(NMe_2)_2\}_2]$ octahedron. It is interesting to note that Cotton and co-workers[13] recently reported the X-ray crystal structure of $[W(\mu\text{-}Br)Br(CO)_4]_2$ which shows the two tungsten atoms to be in capped octahedral environments with a carbonyl ligand capping a $[WBr_3(CO)_3]$ octahedron, i.e. similar to our suggested structure of (7). We have tried without success to grow crystals of (1)-(8) for X-ray crystallography.

The complexes $[MX_2(CO)_3L_2]$ (M = Mo or W;

ELECTRON PARAMAGNETIC RESONANCE STUDY OF THE REACTIONS OF TETRATHIOMOLYBDATE WITH ROUSSIN SALTS AND ESTERS, AND WITH SOME RELATED IRON NITROSYLS

ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL,* IAN L. JOHNSON and JOHN C. WALTON

Department of Chemistry, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

(*Received* 23 *February* 1987; *accepted* 24 *June* 1987)

Abstract—The tetrathiomolybdate ion $[MoS_4]^{2-}$ reacts in DMF solution with Roussin esters $Fe_2(SR)_2(NO)_4$ (R = Me, Et, *n*-Pr, *i*-Pr, *n*-Bu, *t*-Bu, *n*-C_5H_{11}) to yield the paramagnetic iron nitrosyls $[Fe(NO)_2(SR)_2]^-$ (**1**), $[Fe(NO)_2(S_2MoS_2)]^-$ (**2**) and $[Fe(NO)(S_2MoS_2)_2]^{2-}$ (**3**). The new complexes (**2**) and (**3**) have been characterized by EPR spectroscopy and the assignment to them of constitutions based respectively upon tetrahedral and square pyramidal iron is supported by EHMO calculations. $Fe_2(SPh)_2(NO)_4$ with $[MoS_4]^{2-}$ yields only $[Fe(NO)_2(SPh)_2]^-$, and preformed (**3**) reacts with PhS^- to give firstly EPR-silent species, and then $[Fe(NO)_2(SPh)_2]^-$. The mononitrosyl (**3**) can also be formed by reaction of $[MoS_4]^{2-}$ with $[Fe_4S_3(NO)_7]^-$, $Fe_4S_4(NO)_4$, or $Fe_2I_2(NO)_4$.

We have recently shown[1] that the diamagnetic Roussin esters $Fe_2(SR)_2(NO)_4$ (R = Me, Et, *i*-Pr, *t*-Bu, $PhCH_2$) are readily converted, by means of RS^- to the paramagnetic mononuclear complexes $[Fe(NO)_2(SR)_2]^-$: the formal oxidation state of iron remains as Fe(−I). The characterization[1] of $[Fe(NO)_2(SR)_2]^-$ by EPR spectroscopy has allowed definitive identification of a family of iron–nitrosyl complexes widely[2] observed in animal tissues following administration of certain chemical carcinogens. The primary products of similar reactions of RS^- with the tetra-nuclear nitrosyl cluster $[Fe_4S_3(NO)_7]^-$, in which all the nitrosyl ligands are present[3] as NO^+ and in which the basal $Fe(NO)_2$ groups formally contain Fe(−I) and the apical Fe(NO) group contains Fe(I),[4] are[1] $[Fe(NO)_2(SR)_2]^-$ (from the basal irons) and $[Fe(NO)(SR)_3]^-$ (from the apical iron). Again the initial reaction with RS^- proceeds without change of oxidation state at iron.

However in the presence of the non-chelating RS^- ligands $[Fe(NO)]^{2+}$ groups are[1] fairly rapidly converted to $[Fe(NO)_2]^+$, while in the presence of chelating ligands such as $[Me_2NCS_2]^-$ the reverse transformation of $[Fe(NO)_2]^+$ fragments into $[Fe(NO)]^{2+}$ readily occurs: thus $[Me_2NCS_2]^-$ reacts[1] with both $Fe_2(SMe)_2(NO)_4$ and $[Fe_4S_3(NO)_7]^-$ to yield the well-known paramagnetic complex $Fe(NO)(S_2CNMe_2)_2$, and in this case no paramagnetic dinitrosyl intermediate could be detected. The interconversion of $[Fe(NO)_2]^+$ and $[Fe(NO)]^{2+}$ fragments in mono-nuclear iron–sulphur nitrosyl complexes appears[1] to be common and dependent primarily on the nature of the sulphur ligands present.

In the present paper we present the results of an EPR study of the reactions of the chelating ligand tetrathiomolybdate $[MoS_4]^{2-}$ with a range of Roussin esters $Fe_2(SR)_2(NO)_4$, with the tetra-nuclear species $[Fe_4S_3(NO)_7]^-$ and $Fe_4S_4(NO)_4$, and with $Fe_2I_2(NO)_4$.

RESULTS

Reactions of $Fe_2(SR)_2(NO)_4$, R = *alkyl*

The reactions of $Fe_2(SR)_2(NO)_4$ for R = Me, Et, *n*-Pr, *i*-Pr, *n*-Bu, *t*-Bu and *n*-C_5H_{11} with tetrathiomolybdate all follow a common pattern.

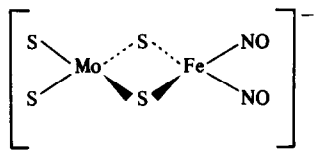
Addition of $[MoS_4]^{2-}$ to $Fe_2(SR)_2(NO)_4$, for R = alkyl as above, in DMF solution such that the overall molar ratio Mo : Fe was 1 : 1 yielded in every

* Author to whom correspondence should be addressed.

case an EPR spectrum showing the presence of three paramagnetic iron–nitrosyl complexes, (**1**)–(**3**): complexes (**1**) and (**2**) were dinitrosyl species and (**3**) was a monitrosyl.

The EPR parameters for (**1**) permitted its identification in each case as a member of the known[1] series $[Fe(NO)_2(SR)_2]^-$. The dinitrosyl complex (**2**) was characterized by $g = 2.027$ and $A(^{14}N) = 2.0$ G, while the mononitrosyl (**3**) was characterized by $g = 2.024$ and $A(^{14}N) = 15.0$ G. When the molar ratio Mo : Fe was increased from 1 : 1 to 5 : 1, the spectra of complexes (**1**) and (**2**) disappeared while the spectrum of (**3**) was enhanced.

The EPR parameters, g and $A(^{14}N)$, for (**2**) were independent of the identity of R in the initial ester $Fe_2(SR)_2(NO)_4$ and hence (**2**) contains no RS group: on the other hand these parameters are very similar to those observed[1] for $[Fe(NO)_2(SR)_2]^-$ and suggest that (**2**) also contains a tetrahedral $S_2Fe(NO)_2$ fragment. We therefore assign the constitution $[Fe(NO)_2(S_2MoS_2)]^-$ to complex (**2**):



(**2**)

This assignment is supported by molecular orbital calculations, discussed below.

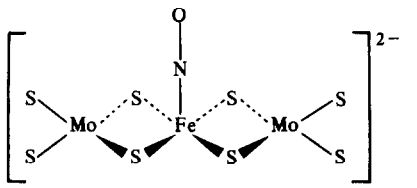
The formation of complexes (**1**) and (**2**) is therefore entirely straightforward, eqs (1) and (2):

$$Fe_2(SR)_2(NO)_4 + 2[MoS_4]^{2-} \rightarrow 2RS^- + 2[Fe(NO)_2(S_2MoS_2)]^- \quad (1)$$
(**1**)

$$Fe_2(SR)_2(NO)_4 + 2RS^- \rightarrow [Fe(NO)_2(SR)_2]^- \quad (2)$$
(**2**)

Nucleophilic displacement of RS^- from $Fe_2(SR)_2(NO)_4$ by $[MoS_4]^{2-}$ yields the complex (**2**), while the known[1] reaction of $Fe_2(SR)_2(NO)_4$ with excess RS^- yields (**1**).

In the presence of a large excess of the chelating ligand $[MoS_4]^{2-}$ both (**1**) and (**2**) are converted to (**3**). The EPR parameters of (**3**) are again independent of the identity of R in the initial $Fe_2(SR)_2(NO)_4$ and closely resemble those of $Fe(NO)(S_2CNMe_2)_2$: in particular both (**3**) and $Fe(NO)(S_2CNMe_2)_2$ have large $A(^{14}N)$ values, 15.0 and 13.6 G respectively in DMF solution. Molecular orbital calculations (discussed below) suggest that these large $A(^{14}N)$ values are characteristic of square pyramidal $Fe(NO)S_4$ species, having a C_{2v} (approximate C_{4v}) symmetry. Hence we assign to complex (**3**) the constitution $[Fe(NO)(S_2MoS_2)_2]^{2-}$: the analogous square pyramidal thiotungstate complexes $[Fe(NO)(S_2WS_2)_2]^{2-}$ and $[Co(NO)(S_2WS_2)_2]^{2-}$ have recently been described.[5]



(**3**)

The formation of (**3**) from (**1**) and (**2**) is entirely analogous to the formation of $Fe(NO)(S_2CNMe_2)_2$ from $Fe_2(SR)_2(NO)_4$ or $[Fe_4S_3(NO)_7]^-$: $[Fe(NO)_2]^+$ fragments are converted into $[Fe(NO)]^{2+}$. The main difference between $[MoS_4]^{2-}$ and $[Me_2NCS_2]^-$ in this content is that no dinitrosyl species analogous to (**2**) were detected[1] in reactions involving $[Me_2NCS_2]^-$.

The relative abundances of complexes (**2**) and (**3**) were temperature dependent; when the Mo : Fe ratio was 1 : 1 and in the temperature range 220–300 K, the relative abundance of (**3**) rose steadily. However at 280 K, complex (**3**) although initially more abundant than (**2**), had a shorter life-time: when the EPR spectrum of such a mixture was monitored continuously at 280 K, the spectrum of (**3**) disappeared within *ca.* 30 min, while that of (**2**) disappeared only after *ca.* 2 h. When species (**2**) and (**3**) had both disappeared, presumably as a result of irreversible conversion to EPR-silent species, there remained only the weak EPR spectra of two mononitrosyl complexes (**4**), having $g = 2.042$, $A(^{14}N) = 3.3$ G, and (**5**) having $g = 2.041$, $A(^{14}N) = 3.4$ G. Of these (**5**) is the more robust and was the sole paramagnetic species detectable in mixtures of $Fe_2(SR)_2(NO)_4$ and $[MoS_4]^{2-}$ after 3 h at 280 K.

The relative abundance of the dinitrosyl complexes of (**1**) and (**2**) was somewhat dependent upon the identity of R, when the Mo : Fe ratio was 1 : 1. For R = *i*-Pr, the dominant dinitrosyl was (**2**) while for R = *t*-Bu the dominant dinitrosyl was (**1**): for other alkyl groups (**1**) and (**2**) were present in rather similar abundance, although accurate measurement of the molar ratio was not possible because of spectral overlaps.

Reactions of $Fe_2(SR)_2(NO)_4$, R = *aryl*

When $[MoS_4]^{2-}$ was added to a DMF solution of $Fe_2(SPh)_2(NO)_4$, to give a molar ratio Mo : Fe of 1 : 1, the weak spectrum of the solvo-complex[1] was rapidly replaced by the spectrum of a dinitrosyl complex, together with a trace only of complex (**3**).

The dinitrosyl had $g = 2.027$, $A(^{14}N) = 2.5$ G and was identical with an authentic sample of $[Fe(NO)_2(SPh)_2]^-$, prepared in the usual way[1] from $Fe_2(SPh)_2(NO)_4$ and PhS^-. The assignment was checked using the reactions of $Fe_2(SPh_2)(^{15}NO)_4$ with PhS^- and $[MoS_4]^{2-}$, both separately and together. The spectrum was independent of temperature in the range 220–320 K. Increase of the ratio Mo : Fe first to 5 : 1 and then to 10 : 1 caused no increase in the abundance of (**3**) but weak features due to complexes (**4**) and (**5**) appeared. The behaviour of $Fe_2(SC_6H_4CH_3\text{-}p)_2(NO)_4$ with $[MoS_4]^{2-}$ was identical: the major product was $[Fe(NO)_2(SC_6H_4CH_3\text{-}p)_2]^-$, $g = 2.027$, $A(^{14}N) = 2.5$ G, with only a trace of complex (**3**). No (**2**) was detected in either reaction.

The very low abundances of complexes (**2**) and (**3**) in the reactions of $Fe_2(S\text{-aryl})(NO)_4$ with $[MoS_4]^{2-}$ may possibly be the result of their reaction with ArS^- to form EPR-silent products. This idea was tested as follows: a solution was prepared, from $Fe_2(SBu^t)_2(NO)_4$ and $[MoS_4]^{2-}$, containing $[Fe(NO)_2(SBu^t)_2]^-$ and $[Fe(NO)(S_2MoS_2)_2]^{2-}$ in roughly equal abundance, and this solution was then titrated in the EPR spectrometer against a DMF solution of PhS^-. Initial aliquots of PhS^- caused the disappearance firstly of $[Fe(NO)_2(SBu^t)_2]^-$ and then of $[Fe(NO)(S_2MoS_2)_2]^{2-}$, followed upon further addition of PhS^-, by the appearance of $[Fe(NO)_2(SPh)_2]^-$. The two complexes initially present apparently reacted with PhS^- to yield EPR silent species, while further addition of PhS^- yielded the EPR active complex $[Fe(NO)_2(SPh)_2]^-$.

Whereas when R = alkyl, $[MoS_4]^{2-}$ competes effectively with RS^- for Fe coordination sites, when R = aryl, RS^- is the more effective ligand. Hence when R = alkyl, complexes (**2**) and (**3**) are generally dominant, but when R = aryl, complex (**1**) is dominant.

Reactions of $[Fe_4S_3(NO)_7]^-$

Addition of $[MoS_4]^{2-}$ to a DMF solution of $Na[Fe_4S_3(NO)_7]H_2O$ to give a 1 : 1 Mo : Fe ratio, yielded a very complex spectrum containing $[Fe(NO)(S_2MoS_2)_2]^{2-}$ and the known[1,6] complexes $[Fe(NO)_2(SH)_2]^-$ and $[Fe(NO)(SH)_3]^-$: $[Fe(NO)(SH)_3]^-$ has[6] $g = 2.020$ and $A(^{14}N) = 5.0$ G. The relative abundances of these three complexes were temperature dependent, varying widely as the temperature was raised from 220 to 320 K, but the changes were fully reversible when the temperature was lowered again to 220 K. At 220 K $[Fe(NO)_2(SH)_2]^-$ was most abundant and $[Fe(NO)(SH)_3]^-$ least: at 240 K, all three species were of similar abundance, but from 260 to 320 K, $[Fe(NO)(SH)_3]^-$ was the most abundant and $[Fe(NO)_2(SH)_2]^-$ the least. At 300 K and above $[Fe(NO)_2(SH)_2]^-$ was scarcely detectable, although it reverted to high abundance when the temperature was lowered to 220 K. Thus the net effect of increasing temperature appears to be to shift the equilibrium of eq. (3) to the right:

$$[Fe(NO)_2(SH)_2]^- \rightleftharpoons [Fe(NO)(SH)_3]^- \quad (3)$$

so providing another example of the very ready interconversion of $[Fe(NO)_2]^+$ and $[Fe(NO)]^{2+}$ fragments. It should be emphasized that with the Mo : Fe molar ratio at 1 : 1, the temperature variation of the EPR spectrum of the $[Fe_4S_3(NO)_7]^-/[MoS_4]^{2-}$ system was entirely reversible.

However when the Mo : Fe ratio was increased to 5 : 1 the effects observed on change of temperature are non-reversible. At 220 K, the EPR spectrum showed the same three species $[Fe(NO)(S_2MoS_2)_2]^{2-}$ (**3**), $[Fe(NO)_2(SH)_2]^-$ and $[Fe(NO)(SH)_3]^-$ as before, together with very weak indications of species (**4**) and (**5**). The spectral variation upon raising the temperature was such that at 320 K only (**3**), (**4**) and (**5**) were detectable. On reducing the temperature to 320 K only (**3**) was detectable and throughout a further temperature cycle 220 → 260 → 220 K, (**3**) was the sole complex detectable by EPR spectroscopy. Thus, as with $Fe_2(SR)_2(NO)_4$ as starting iron complex, so with $[Fe_4S_3(NO)_7]^-$, when high Mo : Fe ratios were employed the equilibria in solution shift so that $[Fe(NO)(S_2MoS_2)_2]^{2-}$ is the dominant paramagnetic species present. As usual,[1] $[Fe(NO)_2(SH)_2]^-$ is formed by attack of HS^- (from hydrolysis of $[MoS_4]^{2-}$) at the basal iron atoms in $[Fe_4S_3(NO)_7]^-$ and $[Fe(NO)(SH)_3]^-$ by attack at the apical iron: in both cases substitution occurs without change of the oxidation state at iron.

Reactions of $Fe_4S_4(NO)_4$

In contrast to the reactions of $Fe_2(SR)_2(NO)_4$ or $[Fe_4S_3(NO)_7]^-$ with $[MoS_4]^{2-}$, the reaction of $Fe_4S_4(NO)_4$ with $[MoS_4]^{2-}$ yielded EPR spectra which were essentially independent of the Mo : Fe ratio between 1 : 1 and 5 : 1.

Immediately after addition of $[MoS_4]^{2-}$ to a DMF solution of $Fe_4S_4(NO)_4$, a complex EPR spectrum appeared. Three species were present: (**3**), $[Fe(NO)_2(SH)_2]^-$ and a new mononitrosyl complex (**6**) characterized by $g = 2.023$, $A(^{14}N) = 13.5$ G, characteristic of a complex having a SOMO σ orbital along the Fe—N—O vector (see Discussion section, below). At 220 K the relative abundances were: $[Fe(NO)_2(SH)_2]^-$ > (**3**) ≃ (**6**): as the tem-

perature was raised the relative abundance of $[Fe(No)_2(SH)_2]^-$ diminished the fastest so that at 280 K the relative abundances were (3) > (6) > $[Fe(NO)_2(SH)_2]^-$, and at 300 K only (3) was detectable, accompanied by traces of (4) and (5). When the temperature was then cycled, thus: 300 → 230 → 300 → 230 K, complex (6) was the only species detectable. After heating to 350 K however and recooling to 220 K, only $[Fe(NO)_2(SH)_2]^{2-}$ remained, all other complexes presumably having undergone irreversible thermal decomposition above 300 K.

Reaction of $Fe_2I_2(NO)_4$

Finally, we have studied the reaction of $[MoS_4]^{2-}$ with $Fe_2I_2(NO)_4$, which, as we have shown[7] previously, reacts readily with sulphur-donor ligands via the intermediacy of mono-nuclear paramagnetic complexes.

A solution of $Fe_2I_2(NO)_4$ in DMF gives[7] a strong EPR spectrum showing the presence of $[Fe(NO)_2]^+$, $Fe(NO)_2I$ and $[Fe(NO)_2I_2]^-$, the first two of which are presumably solvated by DMF to give four-coordination. Upon addition of $[MoS_4]^{2-}$ such that the molar ratio of Mo : Fe was 1 : 1, the original EPR spectrum was immediately replaced, at 220 K, by a spectrum showing primarily (3), but with (2) and $[Fe(NO)_2(SH)_2]^-$ in lesser abundance. As the temperature was raised to 280 K, the relative abundance of (3) increased, although at 300 K the whole spectrum was very weak. On cooling from 300 to 220 K, only $[Fe(NO)_2(SH)_2]^-$ remained. As in the solution derived from $Fe_4S_4(NO)_4$, $[Fe(NO)_2(SH)_2]^-$ is the complex most robust at 300 K.

The EPR parameters of new complexes are collected in Table 1 and the reaction products are summarized in Table 2.

Table 1. EPR parameters of new complexes

Complex	g	$A(^{14}N)$ G^{-1}
$[Fe(NO)_2(S_2MoS_2)]^-$ (2)	2.027	2.0
$[Fe(NO)(S_2MoS_2)_2]^{2-}$ (3)	2.024	15.0
$[Fe(NO)_2(SPh)_2]^-$	2.027	2.5
$[Fe(NO)_2(SC_6H_4CH_3\text{-}p)_2]^-$	2.027	2.5
(4)	2.042	3.3
(5)	2.041	3.4
$[Fe(NO)(SH)_4]^{2-}$ (6)	2.023	13.5
$[Fe(NO)(SH)_3]^-$	2.020	5.0

DISCUSSION

The di-nuclear complex (2), $[Fe(NO)_2(S_2MoS_2)]^-$, is similar in stoichiometry to, but differs in redox level from, the diamagnetic di-anion $[Fe(NO)_2(S_2MoS_2)]^{2-}$ isolated[8] from the reaction $[Fe(S_2MoS_2)_2]^{2-}$ with NO gas, and characterized[8] by X-ray crystallography.

The tri-nuclear complex (3) $[Fe(NO)(S_2MoS_2)_2]^{2-}$, represents a further example of a trimetallic system containing "linear"[9] MoS_2Fe units. Complexes of this previously reported include the Mo—Fe—Fe type,[10] as in $[(S_2MoS_2)FeS_2Fe(SAr)_3]^{3-}$ and the Fe—Mo—Fe type,[11] as in $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$: the present complex (3) contains a Mo—Fe—Mo system, $[(S_2MoS_2)Fe(NO)(S_2MoS_2)]^{2-}$, analogous to the W—Fe—W system[5] $[Fe(NO)(S_2WS_2)_2]^{2-}$.

The large difference in $A(^{14}N)$ values between (3) and $Fe(NO)(S_2CNMe_2)_2$ on the one hand ($A \sim 13$–15 G), and (2) and $[Fe(NO)_2(SR)_2]^-$ on the other ($A \sim 2$–4 G)[1] can be traced to the different forms of the SOMO in these complexes, as determined using EHMO calculations. In each of $Fe(NO)(S_2CNMe_2)_2$ and $[Fe(NO)(S_2MoS_2)_2]^{2-}$, containing square pyramidal $Fe(NO)S_4$ groups, the SOMO is of σ type and it lies along the linear Fe—NO bond, Fig. 1. In contrast, in $[Fe(NO)_2(SR)_2]^-$, of C_{2v} symmetry, the SOMO is

of b_2 symmetry and is of approximately π type with respect to the Fe—N bonds, Fig. 2. The poorer overlap in the SOMO of $[Fe(NO)_2(SR)_2]^-$ prevents spin density from reaching the nitrogens and this is the origin of the much reduced A value.

This simple connection between the $A(^{14}N)$ value and the form of the SOMO allows a more detailed consideration of the assignment of two families of paramagnetic mono-nitrosyl iron complexs observed in earlier work.[1,6] Reaction of *i*-PrSH with $Fe_2I_2(NO)_4$ in THF/Et_3N yields,[6] in addition to $[Fe(NO)_2(SPr^i)_2]^-$, a paramagnetic mono-nitrosyl characterized by $g = 2.040$ and $A(^{14}N) = 13.5$ G, but showing no hyperfine coupling to hydrogen in SR groups: similar species were obtained[1] from the reactions of $Fe_4S_4(NO)_4$ with SH^- or with *t*-BuS^-. The 13.5 G species were tentatively assigned[1,6] a constitution of type $[Fe(NO)(SR)_3]^{x-}$ where $x > 1$. From the foregoing discussion it is clear that these species, of whatever composition, must have a SOMO which is of a σ type along with Fe—N direction.

The second family of mono-nitrosyl complexes observed,[1] of type $[Fe(NO)(SR)_3]^-$, were obtained along with $[Fe(NO)_2(SR)_2]^-$ by reaction of RS^- with $[Fe_4S_3(NO)_7]^-$. If this reaction occurs without any change of oxidation state at iron, then $[Fe(NO)_2(SR)_2]^-$ arises from the basal $[Fe(NO)_2]^+$ groups in $[Fe_4S_3(NO)_7]^-$ and $[Fe(NO)(SR)_3]^-$ from the apical $[Fe(NO)]^{2+}$ group. The magnitude of $A(^{14}N)$ in the complexes $[Fe(NO)(SR)_3]^-$, ranging[1] between 3.9 and 5.0 G, strongly indicates a constitution having a SOMO which is of π type with respect to the Fe—N vector (in iron di-nitrosyl complexes having a π-type SOMO, the observed range of $A(^{14}N)$ is 2.0–6.0 G).

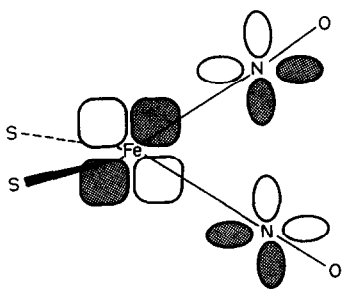

Fig. 2. The SOMO in complexes of types $[Fe(NO)_2(SR)_2]^-$ and $[Fe(NO)_2(S_2MoS_2)]^-$.

EHMO calculations on mononitrosyl complexes of the following constitutions: tetrahedral $[Fe(NO)(SR)_3]^-$, tetrahedral $[Fe(NO)(SR)_3]^{3-}$ and square-pyramidal $[Fe(NO)(SR)_4]^{2-}$ show that while in $[Fe(NO)(SR)_3]^-$ the SOMO is of π type in the Fe—N bond, it is of σ type in the other two complexes. The calculations thus support the assignment[1] of the constitution $[Fe(NO)(SR)_3]^-$ to the low $A(^{14}N)$ mononitrosyls, but cannot distinguish between $[Fe(NO)(SR)_3]^{3-}$ (as suggested earlier[1]) and $[Fe(NO)(SR)_4]^{2-}$ for the $g = 2.040$ complexes. The slow conversion,[1] in the presence of excess RS^-, of $[Fe(NO)(SR)_3]^-$ to the $g = 2.040$ species is perhaps more consistent with a redox reaction, yielding $[Fe(NO)(SR)_3]^{3-}$ and RSSR, than with a simple ligand addition to yield $[Fe(NO)(SR)_4]^{2-}$. If the $g = 2.040$ complexes having $A(^{14}N)$ of 13.5 are on this basis assigned the constitution $[Fe(NO)(SR)_3]^{3-}$, then complex (**6**), formed along with (**3**) and $[Fe(NO)_2(SH)_2]^-$ in the reaction of $[MoS_4]^{2-}$ with $Fe_4S_4(NO)_4$ and having $g = 2.023$ and $A(^{14}N) = 13.5$ G, may be tentatively assigned as square-pyramidal $[Fe(NO)(SH)_4]^{2-}$.

Complexes (**4**) and (**5**) which are formed in low abundance in almost all the systems described in this work, are each on the basis of the foregoing discussion a mononitrosyl species having a SOMO which is of π type with respect to the Fe—N bond, but having a g value rather higher than all other complexes listed in Table 1: these complexes remain at present unidentified, but the possibility that they are ologomeric cannot be excluded. Certainly neither can be assigned as NO, for which $A(^{14}N)$ is 10.6 G.[12]

CONCLUDING REMARKS

We have found ready routes to the formation of the paramagnetic iron nitrosyls (**2**) and (**3**), containing $Fe(\mu\text{-}S)_2Mo$ fragments: these may prove to be useful synthetic intermediates for the construction of diamagnetic oligonuclear mixed iron–molybdenum nitrosyls, analogous to $[Fe_4S_3(NO)_7]^-$ or $Fe_4S_4(NO)_4$.

EXPERIMENTAL

Literature methods were used for the preparation of $Fe_2(SR)_2(NO)_4$[13] and $(NH_4)_2[MoS_4]$:[14] ^{15}N labelled compounds [except for $Fe_2(S\text{-}CH_2Ph)_2(^{15}NO)_4$] were similarly prepared[13] using 99% $Na[^{15}NO_2]$ (MSD Isotopes). DMF of AnalaR quality was dried over barium oxide, distilled under reduction pressure and stored under dry nitrogen.

EPR spectra were measured, in 1 mm quartz capillaries, using a Bruker ER200D spectrometer: di-*t*-butyl nitroxide was used as the standard for the measurement of line positions and diphenyl picryl hydrazyl as the standard in the measurement of intensities. Spectral assignments were confirmed where necessary by the use of ^{15}N labelling: spectral parameters for new species are in Table 1.

Molecular orbital calculations employed the EHMO method.[15,16] Atomic parameters, for a basis set including *d* orbitals for S, Fe, and Mo, and *s* and *p* orbitals only for N and O, were as published.[17] Molecular geometries were based upon those observed[8,18-20] for $[Fe(NO)_2(S_2MoS_2)]^{2-}$, $[Fe(S_2MoS_2)_2]^{3-}$, $Fe(NO)(S_2CNMe_2)_2$ and $[Fe(NO)_2(SPh)_2]^-$.

Bis(μ-toluene-α-thiolato)bis[di(^{15}N*)nitrosyliron]*, $Fe_2(SCH_2Ph)_2(^{15}NO)_4$

$Fe_2(SCH_2Ph)_2(CO)_6$ (0.68 g, 1.3 mmol) was dissolved in DMF (30 cm^3) and $Na[^{15}NO_2]$ (0.50 g, 7.1 mmol) was added. The mixture was stirred at ambient temperature, under nitrogen, and the reaction was monitored by infrared spectroscopy. After 3 h toluene (500 cm^3) was added and the mixture was then filtered through Hyflo-supercel. The filtrate was evaporated to dryness and the residue was dissolved in CH_2Cl_2 (40 cm^3). This solution was washed with nitrogen-flushed distilled water (10×300 cm^3). The organic fraction was dried over Na_2SO_4, filtered and reduced to small volume: addition of an equal volume of ice-cold methanol precipitated the product (yield 40%). The compound was identified by ^1H NMR and by infrared spectroscopy: $\nu(^{15}NO)$ 1745, 1718 cm^{-1}.

ISOTOPIC EXCHANGE REACTIONS BETWEEN IRON–SULPHUR–NITROSYL CLUSTERS AND NITRITE

ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL* and IAN L. JOHNSON

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

(*Received* 26 *May* 1987; *accepted* 24 *June* 1987)

Abstract—The anion $[Fe_4S_3(NO)_7]^-$ undergoes slow exchange with labelled nitrite $[^{15}NO_2]^-$ to yield a product $[Fe_4S_3(^{14}NO)(^{15}NO)_6]^-$ in which complete isotopic exchange has occurred at the basal $Fe(NO)_2$ groups, but with no exchange at the apical Fe(NO) group. The neutral $Fe_4S_4(NO)_4$ reacts rapidly with $[^{15}NO_2]^-$ to give fully exchanged $[Fe_4S_3(^{15}NO)_7]^-$, and it is proposed that the conversion proceeds by fragmentation, followed by complete isotopic exchange and rapid reassembly. The binuclear anion $[Fe_2S_2(NO)_4]^{2-}$ also yields, with $[^{15}NO_2]^{2-}$ in CD_2Cl_2 solution, the fully exchanged $[Fe_4S_3(^{15}NO)_7]^-$, and a mechanism involving successive fragmentation, exchange and reassembly steps is proposed; however in aqueous solution, a clean exchange reaction occurs to give $[Fe_2S_2(^{15}NO)_4]^{2-}$. Neutral binuclear esters $Fe_2(SR)_2(NO)_4$ (R = Me, Et, or Ph) with $[^{14}NO_2]^-$ yield the mononuclear paramagnetic $[Fe(^{14}NO)_2(^{14}NO_2)_2]^-$, and with $[^{15}NO_2]^-$, the analogous $[Fe(^{15}NO)_2(^{15}NO_2)_2]^-$.

We have recently observed,[1] using ^{13}C and ^{15}N NMR spectroscopy, that the nitrosyl ligand in the nitroprusside anion $[Fe(CN)_5^{14}NO]^{2-}$ undergoes rapid and complete isotopic exchange with excess of labelled nitrite, $[^{15}NO_2]^-$. Similar rapid and complete isotopic exchange was observed[2,3] by EPR spectroscopy both for the neutral iron nitrosyl $Fe(NO)(S_2CNMe_2)_2$ and for the two series of anionic complexes $[Fe(NO)_2(SR)_2]^-$ and $[Fe(NO)(SR)_3]^-$, for R = H, Me, Et, *i*-Pr, *t*-Bu, and $PhCH_2$, where the facile replacement of the ligand ^{14}NO by ^{15}NO was of great value in making the assignment of the EPR spectra in the $[Fe(NO)_2(SR)_2]^-$ and $[Fe(NO)(SR)_3]^-$ series.[2,3] In addition, infrared spectroscopy has been used[4] to monitor the isotopic exchange reactions of *cis*- and *trans*-$Fe(NO)(NO_2)(S_2CNEt_2)_2$ with both ^{15}NO and $[^{15}NO_2]^-$. If general, such isotopic exchange reactions would, by removing the need for *de novo* synthesis of isotopically labelled complexes, greatly facilitate the NMR and EPR spectroscopy of metal nitrosyl systems.

We now report the results of a ^{15}N NMR study of the nitrosyl exchange reactions between nitrite and Roussin salts and esters, and some related metal cluster nitrosyls.

RESULTS AND DISCUSSION

$[Fe_4S_3(NO)_7]^-$ *and* $[Fe_4Se_3(NO)_7]^-$

The ^{15}N NMR spectrum of the isotopically labelled Roussin anion $[Fe_4S_3(^{15}NO)_7]^-$ in CD_2Cl_2 solution consists[1] of a singlet at $\delta = +7.7$, due to the apical nitrosyl ligand and an AX spectrum having δ_A +76.1, δ_X +36.0 and $J = 4.3$ Hz, due to the basal $Fe(NO)_2$ groups in which the axial and equatorial nitrosyl ligands are different and distinguishable:[5] we have never observed any exchange processes involving the nitrosyl groups in $[Fe_4S_3(^{15}NO)_7]^-$, either within the basal $Fe(NO)_2$ groups or between basal and apical nitrosyl ligands. When either $Na[Fe_4S_3(^{14}NO)_7]$ was mixed with $Na[^{15}NO_2]$ in D_2O solution or $(PNP)[Fe_4S_3(^{14}NO)_7]$ $[(PNP)^+ \equiv (Ph_3PNPPh_3)^+]$ was mixed with $(PNP)[^{15}NO_2]$ in acetone-d_6 solution such that the overall ratio $^{14}N:{}^{15}N$ was 1:5, no exchange was apparent within 4 h of mixing the solutions. After 3 days in aqueous solution, or 20 days in acetone solution, exchange of the basal nitrosyl ligands was complete, as judged by the

* Author to whom correspondence should be addressed.

sharp AX spectrum due to basal $Fe(^{15}NO)_2$ groups: residual $Fe(^{14}NO)(^{15}NO)$ groups would provide singlets rather than doublets at δ 76 and 36. However, despite the complete exchange of the basal ligands, no exchange at all was detectable for the apical nitrosyl ligand. These observations show that the apical Fe(NO) group, containing formally[6] d^7 Fe(I), undergoes exchange much more slowly than the basal $Fe(NO)_2$ groups which contain formally d^9 Fe(−I): attempts to monitor the exchange reaction of the apical ligands over longer periods of time than 20 days were not conclusive, as the $[Fe_4S_3(NO)_7]^-$ anion begins to decompose after long periods in solution, even under a dinitrogen atmosphere. These observations also confirm very elegantly the lack of exchange between basal and apical nitrosyl ligands.

For the selenium analogue $Na[Fe_4Se_3(NO)_7]$ of Roussin's black salt, we employed sodium salts in aqueous solutions, as these conditions had given the fastest exchange with $[Fe_4S_3(^{14}NO)_7]^-$: when saturated aqueous solutions of $Na[Fe_4Se_3(^{14}NO)_7]$ and $Na[^{15}NO_2]$ were mixed, no exchange at all was detectable after 1 h: the ^{15}N spectrum was monitored at intervals, but it was clear that the rate of decomposition of $Na[Fe_4Se_3(NO)_7]$ comfortably exceeded the rate of any exchange, and at no time did this mixed solution exhibit the characteristic[1] ^{15}N spectrum of the selenium anion $[Fe_4Se_3(^{15}NO)_7]^-$.

$Fe_4S_4(NO)_4$

The cubane-like cluster $Fe_4S_4(^{15}NO)_4$ exhibits[1] a single sharp resonance in its ^{15}N NMR spectrum, at δ 12.8 in CD_2Cl_2 solution. When a solution of $Fe_4S_4(^{14}NO)_4$ in CD_2Cl_2 was mixed with a $(PNP)[^{15}NO_2]$ solution, the ^{15}N NMR spectrum recorded immediately after mixing shows no labelled $Fe_4S_4(NO)_4$ at all, but rather the three chemical shifts characteristic of $[Fe_4S_3(^{15}NO)_7]^-$. When the overall ratio of $^{14}N:{}^{15}N$ was 1:1 the spectrum of the partially labelled $[Fe_4S_3(NO)_7]^-$ comprised three singlets, but when the $^{14}N:{}^{15}N$ ratio was 1:10 the full spectrum of $[Fe_4S_3(^{15}NO)_7]^-$ was observed. As in our previous observations[1,2] on isotopic exchange using $[^{15}NO_2]^-$, the exchange is an equilibrium which is forced effectively to the ^{15}N side by addition of sufficient $[^{15}NO_2]^-$.

The behaviour of $Fe_4S_4(NO)_4$ with nitrite is thus markedly different from that of $[Fe_4S_3(^{14}NO)_7]^-$. First there is a stoichiometric change from $Fe_4S_4(NO)_4$ to $[Fe_4S_3(NO)_7]^-$; secondly, the product has incorporated ^{15}NO ligands at all the sites, rather than at just the basal sites, as for preformed $[Fe_4S_3(^{14}NO)_7]^-$; finally, the overall exchange process is very much faster than in preformed $[Fe_4S_3(NO)_7]^-$. The stoichiometric change is equivalent to that effected by reduction[5,7] of $Fe_4S_4(NO)_4$, and we envisage the transformation of $Fe_4S_4(NO)_4$ to $[Fe_4S_3(NO)_7]^-$ as proceeding via electron transfer[7] leading to cluster fragmentation followed by rapid spontaneous self assembly. If the initial cluster undergoes fragmentation into mono-iron complexes, as occurs with other nucleophiles,[2,6] then the known[2] rapid nitrosyl mobility in $[Fe(NO)]^{2+}$ and $[Fe(NO)_2]^+$ fragments is sufficient to explain our observations on the reaction between $Fe_4S_4(NO)_4$ and $(PNP)[^{15}NO_2]$. It is necessary for the exchange of ^{14}NO ligands with $[^{15}NO_2]^-$ to occur before rather than after the self-assembly process to give $[Fe_4S_3(NO)_7]^-$ in order to rationalize both the rate of the exchange process and the completeness of substitution in the final product $[Fe_4S_3(^{15}NO)_7]^-$.

$[Fe_2S_2(NO)_4]^{2-}$

The red Roussin anion $[Fe_2S_2(NO)_4]^{2-}$ has been characterized[8] by X-ray methods as its $(Me_4N)^+$ salt, in which it has approximately D_{2h} symmetry. The nucleophilic reactivity of the sodium salt in THF solution has also been investigated.[9] In previous work, we observed[1] that analytically pure samples of $(PNP)_2[Fe_2S_2(^{15}NO)_4]$ were rapidly and cleanly converted, in CD_2Cl_2 solution, to $[Fe_4S_3(^{15}NO)_7]^-$ as the only species detectable by ^{15}N NMR spectroscopy. We have now observed that analytically pure $(Et_4N)_2[Fe_2S_2(^{14}NO)_4]$ cleanly undergoes conversion, with $(PNP)[^{15}NO_2]$ in CD_2Cl_2 to $[Fe_4S_3(^{15}NO)_7]^-$, again as the sole product detectable by ^{15}N NMR. Because of the complete isotopic substitution in $[Fe_4S_3(NO)_7]^-$, including the apical nitrosyl ligand, the mechanism for conversion of $[Fe_2S_2(NO)_4]^{2-}$ to $[Fe_4S_3(NO)_7]^-$ probably again involves fragmentation followed by isotopic exchange and finally by spontaneous self-assembly to give the product $[Fe_4S_3(NO)_7]^-$.

However, despite the facile conversion of $[Fe_2S_2(NO)_4]^{2-}$ to $[Fe_4S_3(NO)_7]^-$ in CD_2Cl_2, we have found that reaction of a 2% aqueous solution of $Na_2[Fe_2S_2(^{14}NO)_4]$ with $Na^{15}NO_2$, such that $^{14}N:{}^{15}N$ is 1:10 gives a single sharp resonance, in addition to excess $^{15}NO_2^-$, at δ +37.8, identical with that observed for preformed $Na_2[Fe_2S_2(^{15}NO)_4]$. There was no sign of the characteristic spectrum of $[Fe_4S_3(NO)_7]^-$ nor, in contrast to the behaviour of neutral di-iron complexes $Fe_2(SR)_2(NO)_4$ (see below), was there any evidence for the formation of appreciable concentrations of paramagnetic intermediates.

$Fe_2(SR)_2(NO)_4$

When either of the neutral Roussin esters $Fe_2(SEt)_2(NO)_4$ and $Fe_2(SPh)_2(NO)_4$ was mixed with (PNP)[$^{15}NO_2$] in CD_2Cl_2 solution, the resulting ^{15}N NMR spectrum exhibited only very broad unresolved absorptions, suggestive of the presence of persistent paramagnetic species. This was confirmed by EPR spectroscopy. Reaction of $Fe_2(SR)_2(^{14}NO)_4$ (R = Me, Et or Ph) with (PNP)[$^{14}NO_2$] in CH_2Cl_2 solution gave a strong EPR spectrum, characterized by $g = 2.036$, $A(^{14}N) = 6.5$ G (2N), 2.2 G (2N); the spectral assignment was confirmed by use of $Fe_2(SCH_3)_2(^{15}NO)_4$ and (PNP)[$^{15}NO_2$]. The simplest system which contains two equivalent nitrogen ligands of one type, and two others of a second type is $[Fe(NO)_2(NO_2)_2]^-$, formed as in eq. (1):

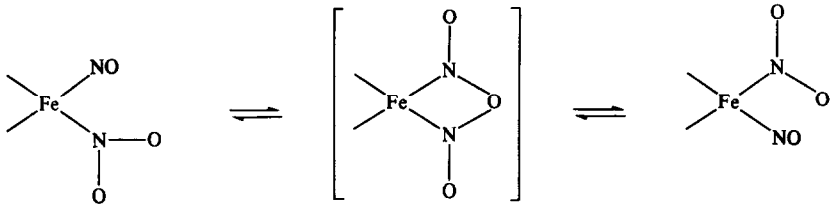
$$Fe_2(SR)_2(NO)_4 + 4NO_2^- \rightarrow 2RS^- + 2[Fe(NO)_2(NO_2)_2]^- \quad (1)$$

This is an example of a more general reaction of Roussin esters with nucleophilic anions, eq. (2):

$$Fe_2(SR)_2(NO)_4 + 4X^- \rightarrow 2RS^- + 2[Fe(NO)_2X_2]^- \quad (2)$$

This has been observed both for X = R'S,[2] and for a wide range of other nucleophiles.[10]

At low temperatures (220 K in DMF or 190 K in acetone) the EPR spectrum of $[Fe(NO)_2(NO_2)_2]^-$ showed two A values, as noted above. However upon raising the temperature by 20–30 K, the g value remained unchanged but the spectrum showed a symmetric pattern of nine lines with mean A value of 4.3 G. This indicated that all the nitrogen nuclei had become equivalent, with an A value which is the average of the two A values (6.5 G and 2.2 G) observed at low temperature, and was thus consistent with a rapid scrambling of the NO and NO_2 ligands, as indicated schematically in eq. (3).



(3)

Such an exchange process can account for the formation of $[Fe(^{15}NO)_2(^{15}NO_2)_2]^-$ from $Fe_2(SR)_2(^{14}NO)_4$ and $[^{15}NO_2]^-$.

Mononuclear iron-nitrosyls

We have noted previously[2] the rapid exchange between $Fe(^{14}NO)(S_2CNMe_2)_2$ and $[^{15}NO_2]^-$, observed by EPR spectroscopy. We have now observed using ^{15}N NMR spectroscopy, rapid exchange between $[^{15}NO_2]^-$ and $Fe(^{14}NO)(^{14}NO_2)(S_2CNMe_2)_2$. Reaction of (PNP)[$^{15}NO_2$] with *cis*-$Fe(^{14}NO)(^{14}NO_2)(S_2CNMe_2)_2$ in CD_2Cl_2 solution with an overall ratio $^{14}NO_x$: $^{15}NO_x$ of 1 : 5 gave two sharp singlets in the ^{15}N spectrum at δ +84.7 and −27.1: we assign these respectively to $^{15}NO_2$ and ^{15}NO ligands in *cis*-$Fe(^{15}NO)(^{15}NO_2)(S_2CNMe_2)_2$. Even after one day at normal temperature, when full equilibration of ^{15}N between the NO and NO_2 ligands should be complete (the half-life for exchange between these ligand at 295 K in $CHCl_3$ solution is less than 1 h[4]), no $^2J(^{15}NFe^{15}N)$ coupling between the ^{15}NO and $^{15}NO_2$ ligands could be resolved. Under the conditions of our experiments, *trans*-$Fe(^{14}NO)(^{14}NO_2)(S_2CNMe_2)_2$ was converted to the *cis*-isomer too rapidly for its exchange reaction with $[^{15}NO_2]^-$ to be studied.

The mononuclear salt (PNP)[$Fe(CO)_3(^{15}NO)$], for which δ is +15.2 in 2% solution in CD_2Cl_2 underwent complete exchange within 3 h with a tenfold molar excess of (PNP)[$^{14}NO_2$]. Whereas the exchange is fast[1] for $[Fe(CN)_5NO]^{2-}$, the corresponding ruthenium analogue $[Ru(CN)_5NO]^{2-}$ showed no rapid exchange.

EXPERIMENTAL

Literature methods were employed for the preparation of (PNP)[$^{15}NO_2$][11] [$(PNP)^+ \equiv (Ph_3PNPPh_3)^+$], (PNP)[$Fe(CO)_3NO$],[11] $Na_2[Fe_2S_2(NO)_4]$, $Na[Fe_4S_3(NO)_7]$,[12] (PNP)[$Fe_4S_3(NO_7)$],[13] $Na[Fe_4Se_3(NO)_7]$,[13] $Fe_4S_4(NO)_4$,[1,7] $Fe_2(SR)_2(NO)_4$[1,13] and $Fe(NO)(NO_2)(S_2CNMe_2)_2$.[4,14] Isotropically labelled materials where required were prepared by appropriate modifications[1] of these procedures, using Na[$^{15}NO_2$] (99% enriched, MSD Isotopes) as a source of ^{15}N. $(Et_4N)_2[Fe_2S_2(NO)_4]$, prepared[8] by reaction of $(Et_4N)OH$ with $Na[Fe_4S_3(NO)_7]$ had C, 34.1; H, 7.2; N, 14.9%: $(Et_4N)_2[Fe_2S_2(NO)_4]$, $C_{16}H_{40}Fe_2N_6O_4S_2$ requires C, 34.5; H, 7.2; N, 15.1%; $(Et_4N)[Fe_4S_3(NO)_7]$, $C_8H_{20}Fe_4N_8O_7S_3$ requires C, 14.6; H, 3.1; N, 17.0%.

All ^{15}N NMR spectra were recorded at 36.51 MHz and 25°C relative to external $CH_3{}^{15}NO_2$ using the Bruker WH-360 spectrometer of the SERC

regional NMR service at the University of Edinburgh: spectral parameters were as described previously.[1] All spectra were recorded using 1% or 2% *w/w* solutions in the appropriate solvent (D_2O, $(CD_3)_2CO$, or CD_2Cl_2).

EPR spectra were recorded in 1 mm quartz capillaries using a Bruker ER200D spectrometer, with di-*t*-butyl nitroxide as the standard for the measurement of line positions.

Acknowledgement—We thank the Ministry of Agriculture, Fisheries and Food for financial support, and Dr D. Reed for help in obtaining the ^{15}N NMR spectra.

STUDIES ON THE CHELATION OF ALUMINIUM FOR BIOLOGICAL APPLICATION—IV. AMP, ADP AND ATP

GRAHAM E. JACKSON* and KUKU V. VOYI

Department of Inorganic Chemistry, Rondebosch 7700, South Africa

(*Received* 28 *April* 1987; *accepted* 10 *July* 1987)

Abstract—Aluminium complexes of AMP, ADP and ATP have been studied at 25°C and an ionic strength of 0.15 mol dm^{-3}, using glass electrode potentiometry. A novel formation function has been used as an aid to the interpretation of the data. For the Al^{3+}/ADP system the major species formed, under the experimental conditions, was ML, while for the Al^{3+}/ATP system the MLH species predominated.

Aluminium is one of the most abundant elements in the earth's crust and its uptake by plants is determined by the pH of the soil, being high in acidic and low in alkaline soil.[1] Aluminium in its pure metallic state is highly reactive but quickly becomes coated with a passive oxide layer. In aluminium cooking utensils this amphoteric layer is solubilized by various foodstuffs.[2] Aluminium compounds are also additives in many common household products. Despite a high dietary intake of aluminium it is of limited toxicity.[3] The reasons for this are two fold (i) the insolubility of its metal hydroxides and (ii) its very high affinity for membrane phosphates.

Notwithstanding the relatively low toxicity of aluminium, this metal-ion has been implicated in "dialysis dementia",[4] phosphate depletion syndrome,[5] Alzheimers disease,[6,7] decreased serum adenosine triphosphate levels[8] and increased prothrombrin times.[9] More recently aluminium(III) has been found to inhibit cholinergic enzyme acetylcholinesterase[10] and influence the activity of a range of phosphatase enzymes.[11,12,13]

In the light of the biomedical interest in aluminium(III) and in particular its interaction with biological phosphates, we have studied, using glass electrode potentiometry, the Al^{3+}, AMP, ADP and ATP systems.

EXPERIMENTAL

Solutions were prepared using distilled deionized and degassed water. All titrations were carried out under an atmosphere of nitrogen which had been successively washed in 15 g of 1,2,3-trihydroxybenzene in 100 cm^3 of 30% KOH, 50% KOH and 150 mmol dm^{-3} NaCl. The ionic strength was maintained at a chloride concentration of 150 mmol dm^{-3} using NaCl. Aluminium stock solutions were prepared from $AlCl_3 \cdot 6H_2O$ and standardized by complexometric titration using EDTA[14] and by a Gran plot[15] for hydrogen ion concentration. NaOH solutions (100 mmol dm^{-3}) were prepared weekly from standard ampoules, under nitrogen and standardized using potassium hydrogen phthalate.

AMP, ADP and ATP (Sigma Chemical Co.) were used without purification. In order to avoid hydrolysis prior to potentiometric measurements, samples of the nucleotides were weighed out as the solid and added to the reaction vessel just prior to performing the titration. The titrations were performed in a double walled vessel, thermostated at 25°C. Potentiometric measurements were made on a Radiometer PHM84 research pH meter equipped with a Metrohm glass electrode and a Ag/AgCl reference electrode with a renewable liquid junction of 150 mmol dm^{-3} NaCl. Because of the relatively slow kinetics of aluminium(III) complexation reactions, data were only collected once an emf drift of

<0.1 mV min^{-1} was established. The data were analysed using the computer program ESTA.[16]

RESULTS AND DISCUSSION

Adenosine-5′-monophosphate

AMP shows two protonation constants, both of which are assigned to the phosphate group. The experimental values compare well with the literature considering the different conditions under which they were obtained. Attempts to measure formation constants for the Al^{3+}–AMP system failed. Under the conditions used in this study no metal complexes were detected before the onset of precipitation. This was so even at a ligand to metal ratio of 7 : 1.

Adenosine-5′-diphosphate

ADP has three protonation sites, of which only two could be titrated above pH 2.0. Agreement with the literature is fair as far as pK_{a2} is concerned (3.81 and 3.93[17]) but poor with respect to pK_{a1}. The concentration of the ligand was kept low to avoid any ring stacking which might occur.[18] The objective function is low, with good statistical agreement between the calculated and experimental results.

Figure 1(a) shows the formation curves for the Al^{3+}/ADP system at different ligand to metal ratios. These are somewhat unusual and require some comment. The horizontal region of the curve from pA 4–7 is an indication of the presence of a ML species. Clearly this is present even at the start of the titration. Below pA = 4, the formation curves begin to fan out, indicating the formation of hydroxy species.

Inspection of the deprotonation curves [Fig. 1(b)] shows that from pH 2.5–5.0, the average number of protons on the complex is zero. Above pH = 5.0 hydroxy species are formed with a final stoichiometry at pH 7 of MLOH. Both these conclusions are consistent with the observations made

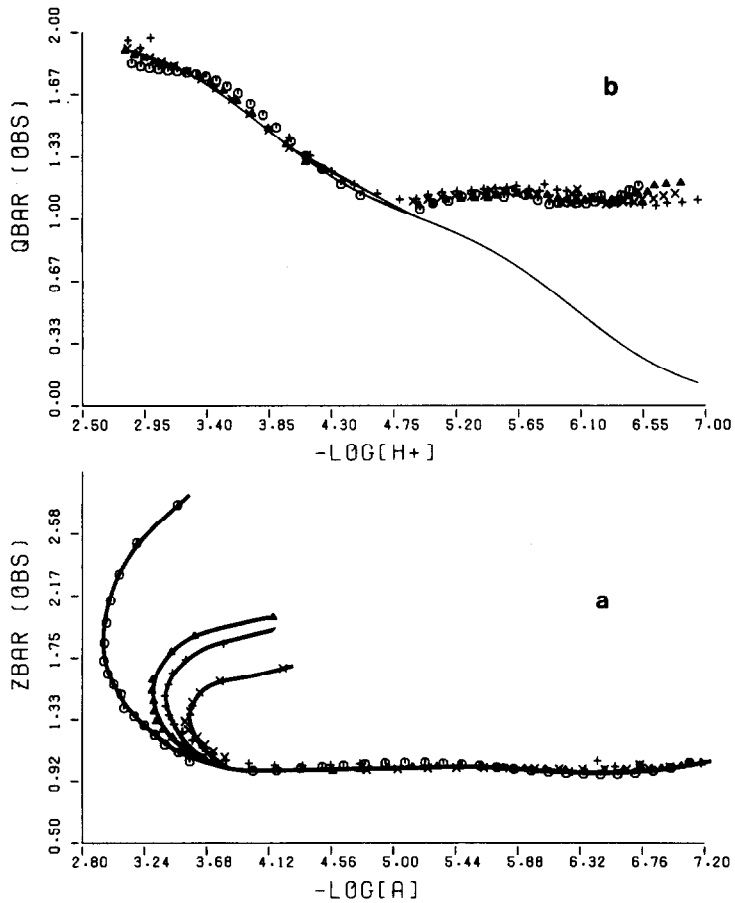

Fig. 1. (a) Experimental formation curves of $\bar{Z}$ vs $-\log$ (free ligand) for the aluminium(III) ADP system at 25°C and 0.15 mol dm^{-3} (Na)[Cl]. The full line represents the theoretical curve obtained using the formation constants given in Table 1. (b) Experimental deprotonation curves of $\bar{Q}$ vs pH. The full line represents the $\bar{n}$ function. ADP : AL^{3+} ratios: 0.0071 : 0.0024, 0.0078 : 0.0038, 0.0081 : 0.0042, 0.0081 : 0.005.

from the formation function. The final set of constants refined from these data are presented in Table 1. In this case, while the standard deviation in the beta values and also the objective function are very good, the statistical R factor is relatively high. The agreement between the theoretical and experimental formation function show this model to be a reasonable description of the data.

Adenosine-5′-triphosphate

This ligand has four protonation sites. Only two have been titrated in this study. The constants obtained after ESTA[16] refinement of the data are presented in Table 1, together with relevant literature values. Once again the agreement is not good. The most likely reason for this discrepancy is the different ionic medium used in the two studies. However, because the theoretical and experimental curves are superimposable and also because the statistical analysis of the data is so good, we have confidence in our results. The pK_a's of the third and fourth protonation sites are below the range (i.e. pH 2.0) of the glass electrode and so could not be determined.

The aluminium formation curves are presented in Fig. 2(a). These are not easily interpreted, but suggest the formation of MLH at pA = 7, followed by deprotonation to ML at pA = 3. The deprotonation function [Fig. 2(b)] is more easily interpreted. At the start of the titration (pH 2.0) $\bar{Q} = 1$ and $\bar{n} = 2$, which implies a stoichiometry of MLH. As the pH is raised deprotonation occurs until at pH 5.0, $\bar{Q} = \bar{n} = 1$ and ML is the major species in solution. Notwithstanding the fact that the presence of only two main species is indicated by the formation function, numerous other species were tested for, using the BETA task of ESTA.[16] No significant improvement in the model was achieved by the inclusion of any of these species and so the simplest model was chosen. The final results obtained are given in Table 1.

Standard deviations in log β are given in parentheses.

Of the three ligands examined in this study, AMP was found to form very weak complexes with aluminium(III). Similar results have been found for other metal ions,[17] where the AMP complexes are considerably less stable than the corresponding ADP and ATP complexes. In this case the AMP complex is so weak that hydrolysis of the aluminium occurs before complexation.

The structure of the Al^{3+}/ATP complex has been studied by NMR[19] and the metal found to coordinate to the β and γ phosphates. The effect of Mg^{2+} on the ^{31}P nmr spectrum of ATP is not as simple but coordination to α and β phosphates is postulated.[20] These observations are consistent with our observation that the Al^{3+}/ADP complex is more stable than the corresponding ATP complex, while the Mg^{2+}/ATP complex is more stable (log $K = 4.22$) than the Mg^{2+}/ADP complex−(log $k = 3.17$).[21] In conclusion the Al^{3+}, ADP and ATP complexes are fairly stable and hence it is very possible that aluminium exerts its pathological potential via coordination to one of these high energy phosphates.

LIQUID–LIQUID EXTRACTION OF TRIVALENT ACTINIDES AND LANTHANIDES WITH 1-PHENYL-3-METHYL-4-TRIFLUOROACETYL PYRAZOLONE-5

J. N. MATHUR and P. K. KHOPKAR*

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400085, India

(*Received* 5 *March* 1987; *accepted* 24 *June* 1987)

Abstract—Extraction of the trivalent actinides Am, Cm and Cf and lanthanides Eu, Tb, Tm and Lu has been studied with 1-phenyl-3-methyl-4-trifluoroacetyl pyrazolone-5(HPMTFP) in chloroform and benzene. The formation of a self-adduct species $M(PMTFP)_3 \cdot HPMTFP$ has been observed with Am, Cm and Eu but only the chelate species $M(PMTFP)_3$ with Cf, Tb, Tm and Lu. The reasons for the formation of a self-adduct species with lighter actinides and lanthanides and not with the heavier ones of the pyrazolones have been discussed.

The extraction of trivalent actinides and lanthanides with β-diketones alone as well as their mixtures with neutral donors has been a subject of great interest.[1–3] A new class of extractants namely 1-phenyl-3-methyl-4-acyl (or aroyl) pyrazolone-5 has found varied applications in the extraction and separation of trivalent metal ions from acidic solutions due to the lower pK_a values of the pyrazolones as compared to those of other β-diketones.[4–9] Freiser *et al.*[6] studied the extraction of lanthanides by pyrazolones having decanoyl or substituted benzoyl (in the 4-position) groups. In a recent study[7] they have used halogen substituted 4-acyl-pyrazolones for the uptake of the lanthanides. Among the halogen substituted pyrazolones, 1-phenyl-3-methyl-4-trifluoroacetyl pyrazolone-5 (HPMTFP) is of particular interest since it has a reasonably low pK_a value (2.73) and extracts the trivalent metal ions from acidic solutions in a much better way as compared to 1-phenyl-3-methyl-4-benzoyl pyrazolone-5 (HPMBP) (pK_a 4.01). In earlier studies we have examined the extraction behaviour of trivalent actinides and lanthanides with HPMBP and 1-phenyl-3-methyl-4-(3 : 5-dinitrobenzoyl) pyrazolone-5 (HDMPP).[8–10] The present study deals with the extraction of trivalent Am, Cm, Cf, Eu, Tb, Tm and Lu with HPMTFP in chloroform and benzene.

EXPERIMENTAL

The tracer solutions of ^{241}Am, ^{244}Cm, Cf (mainly ^{252}Cf), $^{152,154}Eu$, ^{160}Tb, ^{170}Tm and ^{177}Lu were prepared and assayed as described earlier.[11,12] HPMTFP in the keto from (m.p. 144°C) was prepared in this laboratory by the procedure described by Jensen.[13] Chloroform, benzene and the other chemicals used were of A.R. grade. The experimental details of HPMTFP and pH variations were as given in Ref. 9 with an exception that the solutions had to be shaken vigorously (0.5 h) on a wrist shaker and then slow rotation (2 h) as against 1 h slow rotation for the attainment of equilibrium.

RESULTS AND DISCUSSION

In earlier solvent extraction studies with HPMBP and HDMPP[5,8–10] it was observed that equilibrium is attained in 1 h by slow rotation in a thermostated bath, but in the present study with HPMTFP it was not attained even after 2 h. However, equilibrium was attained when the tubes were vigorously shaken for 0.5 h on a wrist shaker and then by slow rotation for 2 h. Freiser *et al.*[7] while using HPMTFP for the extraction of trivalent lanthanides found it necessary to use vigorous shaking for 1 h in order to attain

Table 1. Absorption spectra of HPMTFP as a function of time in chloroform and benzene

Time elapsed	Chloroform Main peak (nm)	Chloroform O.D.	Benzene Main peak (nm)	Benzene O.D.
0.00 h	~ 406	No peak detected	~ 406	No peak detected
4.00 h	406	0.211	406	0.208
23.00 h	411	0.346	413	0.329
28.00 h	412	0.383	414	0.383
4 days	412	0.409	413	0.398
5 days	411	0.411	413	0.364
7 days	411	0.411	413	0.351

equilibrium, whereas with 8-hydroxyquinoline only 0.5 h was sufficient for the same.[14] It is probable that in the HPMTFP systems (similar to the thenoyltrifluoroacetone (HTTA) systems[15]) the keto–enol equilibrium is attained rather slowly. A vigorous and longer shaking probably helps to attain the equilibrium in a comparatively shorter time. The results of absorption spectral studies of HPMTFP dissolved in chloroform and benzene (0.02 M) using a Beckman DU-7 spectrophotometer are given in Table 1. Absence of any peak at 406 nm in the beginning and its subsequent appearance and gradual increase in intensity may be taken as an indication of the slow attainment of the keto–enol equilibrium and is probably one of the reasons for the longer and more vigorous shaking required to reach an equilibrium in this system.

Figure 1 gives the plots of log D (distribution coefficient) vs log[HPMTFP] in chloroform and benzene for different actinides and lanthanides at pH 2.70. In this range of HPMTFP concentration (0.01–0.02 M) straight lines with a slope of 4 are obtained for Am, Cm and Eu and only of 3 for Cf, Tb, Tm and Lu. The lower slope of 3 observed in such plots for heavier actinides and lanthanides (smaller ionic radii) could possibly have arisen due to the increased hydrolysis of these metal ions as was observed earlier in *N*-benzoyl-*N*-phenyl hydroxylamine-trivalent metal ion systems at pH 4.5.[16] The HPMTFP variation experiments carried out with Lu(III) (smallest ionic radius) in the same concentration range of HPMTFP but at a lower pH of 2.03 (HCl) giving a straight line with a slope of 3 only (Fig. 1 lower Lu curve) completely ruled out the possibility of hydrolysis at pH 2.70. Figure 2 shows the plots of log D vs pH at a fixed HPMTFP concentration (0.02 M) in both the diluents. The straight lines with a slope of 3 suggest an inverse third power dependence on the $[H^+]$ for all the

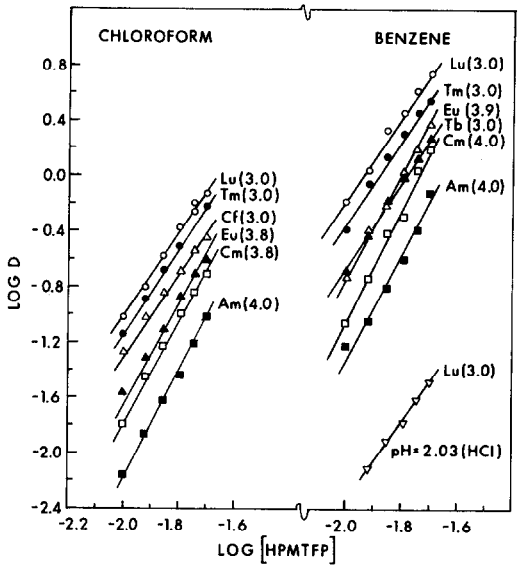

Fig. 1. Variation of log D of trivalent actinides and lanthanides as a function of HPMTFP concentration. Org. phase: 0.01–0.02 M, HPMTFP in chloroform or benzene.

metal ions. The extraction equilibria may, therefore, be represented either by the adduct formation mechanism:

$$M^{3+}_{aq} + 4HPMTFP_{org} \rightleftharpoons M(PMTFP)_3 \cdot HPMTFP_{org} + 3H^+_{aq} \quad (1)$$

where M = Am, Cm or Eu, or by a simple chelate

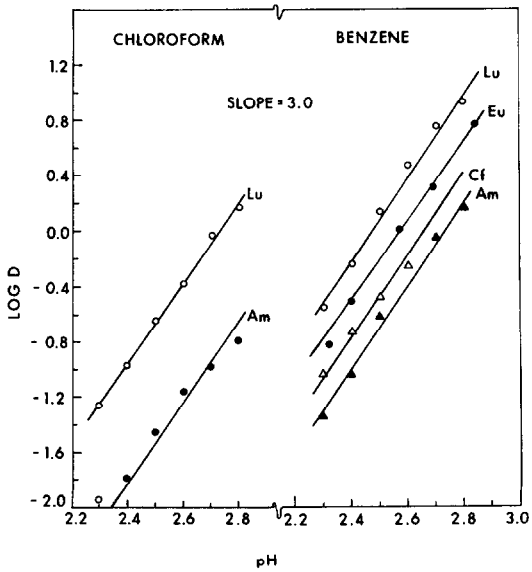

Fig. 2. Variation of log D trivalent actinides and lanthanides as a function of pH.

formation mechanism:

$$M^{3+}_{aq} + 3HPMTFP_{org} \rightleftharpoons M(PMTFP)_{3org} + 3H^{+}_{aq} \quad (2)$$

where M = Cf, Tm or Lu.

In the cases of Am(III) and Eu(III) where the formation of a self-adduct species has been observed, it was decided to carry out the extraction studies at lower HPMTFP concentrations. Figure 3 shows the plots of log D vs log[HPMTFP] for Am(III) and Eu(III) at such HPMTFP concentrations (0.0034–0.0085 M). The straight lines with a slope of 3 suggest the formation of the chelate species $M(PMTFP)_3$ at lower HPMTFP concentrations. Freiser *et al.*[7] have also obtained a slope of 3 in similar plots for Eu(III) extraction by HPMTFP in chloroform at similar low concentrations. As seen from the above experiments it is clear that simple chelates are formed at lower reagent concentrations while the self-adducts $M(PMTFP)^3 \cdot HPMTFP$ are obtained at higher concentrations.

Formation of "self-adduct" species in different metal chelate extraction systems has been established by many workers.[14,17–22] In the chloroform solutions of HPMBP, HDMPP and HPMTFP, it has been observed that (a) with HPMBP, Am, Bk, Cf and Eu are extracted as self-adducts and Cm as a chelate,[9,10] (b) with HDMPP, all these metal ions are extracted as the chelate species[9] and (c) with HPMTFP, Am, Cm and Eu are extracted as self-adducts and Cf, Tm and Lu as chelate species. From the above observations it may be concluded that the formation of a self-adduct species depends mainly on the basicity of the neutral pyrazolone molecule. As seen from the pK_a values (Table 2), the basicity of HDMPP is minimum and it does not form a self-adduct at all. The next in the basicity order being HPMTFP, it forms self-adducts with lighter trivalent actinides and lanthanides whereas with HPMBP (highest basicity) the self-adducts are formed with elements up to Cf (Cm being an exception due to the "tetrad effect").

The formation of a self-adduct species with Am, Cm and Eu and only the chelate species with the rest of metal ions studied in the HPMTFP-chloroform (or benzene) systems could be explained as due to the formation of stronger complexes of the metal ions of higher Z (smaller ionic radii) with $PMTFP^-$ anions in the aqueous phase. This leaves a smaller residual charge (δ^+) on their metal chelate species which is insufficient to attract a less basic HPMTFP molecule. Under similar conditions HPMBP forms a self-adduct species because of its higher basicity.

Table 3 gives the equilibrium constant (K) values of the two phase reactions of the trivalent actinides and lanthanides with HPMTFP in chloroform and benzene. In case of Am, Cm and Eu (all forming a self-adduct) the log K values follow the order Am < Cm < Eu and in the case of other metal ions, where a chelate species is formed the order is Am < Eu < Cf < Tm < Lu. These orders are just

the reverse of the order of ionic radii of these metal ions. In the case of Am and Eu where the experimental data for both the chelate and self-adduct formation was available, the equilibrium constant for the organic phase reaction

$$M(PMTFP)_{3org} + HPMTFP_{org} \rightleftharpoons M(PMTFP)_3 \cdot HPMTFP_{org} \quad (3)$$

has also been calculated. The log K values for Am (1.80) and Eu (1.74) are as expected much lower than the organic phase synergistic constants involving neutral donors.[1,9,10]

Table 2 gives the two-phase equilibrium constant (K) values of Am(III) and Eu(III) with different β-diketones in chloroform along with the pK_a values of the β-diketones. It is evident that the log K values for both these metal ions follow an increasing order (separately for the chelate and self-adduct species) with decrease in pK_a value of the β-diketones. It may be inferred that in the extraction of the trivalent Am and Eu with the above β-diketones, the higher stability of the complexes of β-diketones (in the aqueous phase) does not play an important role (higher pK_a gives higher metal chelate stability) while other factors like ionization and partition coefficient of β-diketones and partition coefficient of the metal chelates are probably of special significance.

(*Received* 19 *March* 1987; *accepted* 24 *June* 1987)

Abstract—Complexes of cobalt(II) with Schiff-bases obtained by condensation of 5-formyl pyrimidine bases with di- or tri-amines have been synthesized and characterized by visible spectroscopy and magnetic susceptibilities. Their catalytic efficiency in the oxidation of 2,6-ditertbutylphenol by molecular oxygen was studied. The molecular structure of a cobalt(III) complex was reported.

Cobalt(II) complexes have been the subject of numerous studies because of their similarities to natural dioxygen carriers[1,2] and also of their ability to catalyze the insertion of oxygen into organic substrates.[3,4] Among them, cobalt phtalocyanines[5] and porphyrins,[6] Co SalN-Medpt,[7] Co acacen[8] and cobaloxime derivatives[9] all form dioxygen adducts and have been found to be efficient catalysts in the oxidation of hindered phenols.

On the other hand, some antibiotics owe their biological activity to their complexing properties towards metal cations such as Fe^{2+} for bleomycin[10] and Cu^{2+} for streptonigrin.[11] Though the detailed mechanisms of their action are not known, it appears well-established that the chelated metal is able to bind molecular oxygen, leading by reduction to an activated species which efficiently induces strand-scissions of DNA.

We describe here the synthesis and characterization of cobalt(II) complexes of a series of Schiff-base ligands derived from the pyrimidine bases, uracil and dimethyl barbituric acid. We present the results of an electrochemical study of these complexes in order to establish a relationship between their structure, their redox potential and their catalytic efficiency in the oxidation of 2,6-ditertbutyl phenol by molecular oxygen. We also report the crystal and molecular structure of a cobalt(III) complex determined by single-crystal X-ray diffraction.

EXPERIMENTAL

Synthesis

The synthesis of the Schiff bases derived from 5-formyl uracil and 5-formyl dimethyl-1,3 barbituric acid was previously described.[12,13] Co Salen, Co Salpen and Co SalN–Medpt were prepared according to known procedures.[14] All complexes were prepared under argon.

Co Urapen

1 mmol of 5-formyluracil was partially dissolved

* Author to whom correspondence should be addressed.

in 20 cm^3 of degassed 95% ethanol. To this suspension was added 0.5 mmol of 1,3 diaminopropane and 0.5 mmol of cobalt acetate dissolved in 10 cm^3 of methanol. The mixture turned violet then pale pink. Heating was maintained for 4 h and the pink precipitate filtered off and dried under argon.

Co Uradpt

2 mmol of Uradpt were partially dissolved in 40 cm^3 of refluxing 95% ethanol. 1 mmol of cobalt acetate in 15 cm^3 of methanol was added to this suspension. After refluxing for 4 h then cooling, the grey–green precipitate was filtered off and dried under argon.

Cobalt complexes with ligands derived from dimethyl barbituric acid

To 0.5 mmol of ligand in 25 cm^3 of methanol was added 1 mmol of NaOH (pellets). After stirring at room temperature for 1 h, 1.1 equivalents of $Co(OAc)_2$ dissolved in 10 cm^3 of methanol were added to the suspension of the ligand and the mixture heated to reflux for 3 h. After cooling, the complex was recovered as a precipitate which was filtered off, washed with degassed methanol and dried under argon.

Co(III) DiMeBardpt OAc

The same procedure described for the preparation of the Co(II) complexes is followed using 30 cm^3 of methanol instead of 5 cm^3. Ater leaving the solution in contact with air, at room temperature for a few days, brown crystals appeared.

In the case of Co DiMeBardpt, only 5 cm^3 of methanol was used due to the greater solubility of this complex.

Electrochemistry

Spectroscopic grade DMSO (Merck) was dried on 0.3 nm molecular sieves. The supporting electrolytes (Fluka), tetraethylammonium perchlorate (TEAP) and tetrabutylammonium hexafluorophosphate (TBH), were dried in a vacuum oven and used without purification. Argon bubbling was used to remove oxygen from tested solutions.

Cyclic voltammetry was performed using an EG and G Princeton applied research model 362 scanning potentiostat.

In all electrochemical experiments, an aqueous saturated calomel electrode (S.C.E.) was used as reference electrode; the reported potential values are accurate to ± 0.02 V. The temperature was controlled at 20 ± 0.5°C.

The concentration of the different complexes was 0.6 mM in DMSO.

X-ray crystal structure of Co DiMeBardpt OAc

Crystals suitable for X-ray diffraction were obtained by evaporation of an ethanolic solution. A small crystal sealed in a Lindemann capillary with a drop of mother liquor was used for data collection and determination of the unit cell parameters.

Crystal data: $(C_{22}H_{30}O_8N_7)Co$, 0.5EtOH. M.W. = 579.46 + 46.07, monoclinic system, space group $P2/n$, $Z = 4$; $a = 14.831(5)$, $b = 9.955(3)$, $c = 20.292(6)$ Å, $\beta = 107.46(3)°$; $V = 2857.92(9)$ $Å^3$, $d_c = 1.40$, $\mu(\text{CuK}\alpha) = 49.92$ cm^{-1}, $F(000) = 1260$.

Data were collected on a Philips PW1100 diffractometer using graphite monochromatized CuKα radiation ($\lambda\text{CuK}\alpha = 1.5418$ Å) and the θ–2θ scan technique. Three standard reflections monitored every 2 h showed loss in intensity and a correction was made for crystal decomposition. A total of 7591 reflections were collected of which 2361 independent ones with $I > 3\sigma(I)$ were considered as observed and used for the structure calculations. The cobalt atom was located from the Patterson function, then Fourier syntheses gave all the other atoms of the molecule. The structure was refined by least-squares method, minimizing the function $\Sigma w(Fo - |Fc|)^2$. An empirical correction for absorption was made[15] reducing the isotropic R factor from 0.134 to 0.107. At the end of the anisotropic refinement, difference Fourier maps showed some hydrogen atoms and the presence of an ethanol solvent molecule. The ethanol atoms displayed high thermal motion, and so the molecule was refined as a rigid group with arbitrary occupation factors of 0.5 and a group isotropic thermal factor.

Hydrogen atoms were introduced at theoretical positions (dC—H = 1.08 Å) with an isotropic temperature factor equivalent to that of the bonded atom.

Final R values were 0.086 ($R = \Sigma(Fo - Fc)/\Sigma Fo$) and 0.0942 [$Rw = \Sigma w^{1/2}|Fo - |Fc||/\Sigma w^{1/2} Fo$ with a weighting scheme $w^{-1} = \sigma^2(Fo) + 0.0186(Fo)^2$], max $\Delta P = 0.76$, min $\Delta P = -0.90$ e $Å^{-3}$ on the final difference Fourier map.

All calculations were performed on a Mini-6 Bull computer using SHELX76[16] with coefficients for analytical approximation to the scattering factor and anomalous corrections from International Tables. Final coordinates, thermal parameters and a list of observed and calculated structure factors

have been deposited as supplementary material with the Crystallographic Data Centre in Cambridge.

Magnetic measurements

Magnetic susceptibility measurements at ambient temperature were performed on polycrystalline samples weighing about 5 mg, with a Faraday-type magnetometer. $HgCo(NCS)_4$ was used as calibrant. The molar susceptibilities were corrected for ligand diamagnetism, using Pascal's constants.

General procedure for the oxidation of 2,6-ditert-butylphenol

To 0.15 mmol of the starting phenol in 5 cm^3 of acetonitrile was added the catalyst (0.015 mmol) in 0.5 cm^3 of DMSO. The solution was stirred in a two-necked flask connected to a gas-burette containing oxygen (pressure 1 atm). At the end of the reaction, the different products were extracted by hexane. The hexane phase was evaporated to dryness and the percentage of the various products evaluated by NMR spectroscopy.

^1H NMR spectra were recorded on a Perkin–Elmer R-32 spectrometer using $CDCl_3$ solutions or DMSO d_6 solutions and $SiMe_4$ as internal reference.

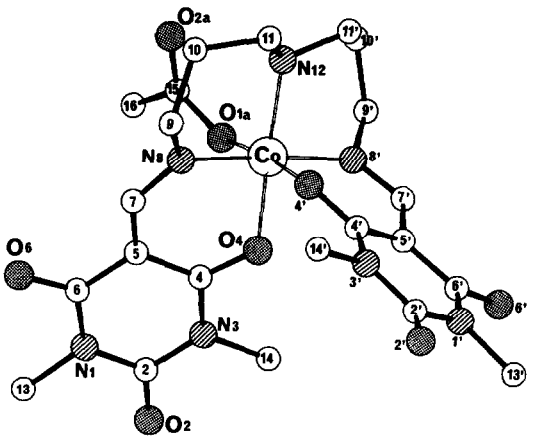

Fig. 1. Structure of Co DiMeBardpt OAc.

RESULTS AND DISCUSSION

(1) *Synthesis*

The cobalt complexes of the Schiff-bases derived from uracil were obtained simply by refluxing a suspension of the ligand in the presence of an equal amount of cobalt acetate. However in the cases of the ligands derived from 1,3-dimethyl barbituric acid, two equivalents of base must be added to accomplish complexation with cobalt(II). Barbituric acid is in fact a much stronger acid (pKa = 4.7) than uracil which is a base. The ligands with their abbreviated notation are shown in the Structures.

(2) *X-ray analysis*

The X-ray analysis establishes that an acetate group was linked to the cobalt atom as shown in Fig. 1. The cobalt atom, surrounded by three nitrogen and three oxygen atoms in two perpendicular planes assumes an octahedral geometry: it lies exactly in the plane of the four atoms: O4, N8, N12 and N8′ of the Schiff base ligand, the atoms O4′ and O1a being respectively 1.876(5) and 1.887(6) Å distance from the central cobalt atom (Table 1). Therefore, the two dimethyl barbituric acid moieties are in a *cis* geometry, the dihedral angle between the pyrimidine rings being 94.3° (Table 2). An intramolecular hydrogen bond bridges the second oxygen atom of the acetate group to the nitrogen atom N12 (O2a—N12 = 2.81 Å, O2a—H12 = 1.79 Å, angle O2a—H12—N12 = 154.5°), making the molecule more rigid.

In the packing of the molecules only Van der Waals contacts are noted. The ethanol molecule is placed in a hole of the crystal and does not establish any hydrogen bond with the complex molecules.

The structure of this complex can be compared to that of the complex formed from the corresponding Schiff-base derived from salicylaldehyde.[17] No significant difference in the geometry around the metal centre appears between the two molecules. As noticed by the authors, the same geometry of the Schiff-base ligand is observed in the peroxy-quinolato cobalt(III) complex[18] and in the binuclear μ-peroxo cobalt(III) complex[19] whereas it is *trans* in the dioxygen complex.[20]

(3) *Characterization of the cobalt complexes*

In addition to the results of elemental chemical analyses, the complexes have been characterized by IR, Visible and U.V. spectral studies and magnetic susceptibility measurements.

(a) IR spectroscopy of all the complexes are similar: they show very strong IR-active bands near 1650–1600 cm^{-1} which are assigned to the conjugated C=N, C=O and C=C stretching vibrations of the amide and imine chelated bonds. Compared to the free ligands these bands are shifted to lower energy in the complexes. Additional bands are also observed at 1695 and 1550 cm^{-1} for DiMeBar type and Ura type complexes respectively.

(b) Due to the low solubility of the various complexes which are not soluble in most organic solvents, we have measured their spectra in DMSO solution (Table 3). The spectra of the Co Salen and Co SalN–Medpt were also measured in chloroformic and DMSO solutions for the sake of comparison. Whatever the solvent, the values of λ max do not vary much and show that Co Salen is square-planar and Co SalN–Medpt is a trigonal bipyramid.[21]

All the complexes with Schiff-bases derived from uracil, Co DiMeBarpen and Co DiMeBardpt exhibit the same type of spectra: a shoulder at $\approx$ 1000 nm and a maximum at 550 nm.

These values are consistent with an octahedral geometry[21] with one or two molecules of DMSO when the ligands are respectively penta- or tetradentate. Co DiMeBaren and Co DiMeBarMeen are probably square-planar as indicated by the absence of absorption at 500 nm. After complexation a bathochromic shift of 20–30 nm was observed in the UV spectra.

(c) Magnetic susceptibility measurements (Table 4) reveal that Co DiMeBaren which probably has a square planar geometry is the only low-spin complex. As indicated by the microanalysis, this complex crystallizes with a molecule of solvent (MeOH) which can be either in the lattice or directly bound to the metal, in which case the axial ligand field would not be increased sufficiently to give a high-spin complex. The other five complexes are high-spin. In the case of Co DiMeBarMeen the presence of two water molecules creates an axial ligand field which is relatively strong compared to the equatorial ligand field and leads to a high-spin complex. As expected the tetrahedral Co Urapen and Co DiMeBarpen and the five coordinate Co Uradpt and Co DiMeBardpt exhibit magnetic moments in the range of 4.2–4.6 BM.

(4) *Electrochemistry*

(a) Cyclic voltammetry. The voltammogram of Co DiMeBaren shows the typical behavior of tetracoordinated cobalt complexes: in the range +0.5 to −1.8 V (vs SCE), a reversible process is seen, including an anodic current peak at +0.15 V and a cathodic one at +0.25 V. Increasing the scan rate does not modify these values. A second anodic current peak is observed at −1.3 V which is associated to a cathodic current peak at −1.2 V, which probably corresponds to the reduction of Co(II) to Co(I).

The voltammograms of pentacoordinate com-

plexes are less simple: we have chosen Co DiMeBardpt as an example. The first redox process [Co(III)/Co(II)] is fast and reversible. Reduction of Co(II) to Co(I) is not observed under the experimental condition used (Pt, DMSO, TEAP). With a graphite electrode which enables the exploration of a larger range of potentials, it is possible to see an anodic current peak at ≈ -1.8 V which probably corresponds to the reduction of Co(II) to Co(I). This process is also reversible but the Co(I) complexes are probably reacting with the solvent leading to an electroactive species which is oxidized at ≈ -1.8 V.

(b) Linear voltammetry. We have compared the values of $E_{\frac{1}{2}}$ of the reference complexes (e.g. Co Salen and Co SalN–Medpt) with those of the Co(II)

Table 3. Visible and near IR spectra of cobalt(II) complexes (nm)

Complex	Solid (KBr)	$CHCl_3$	DMSO

complexes derived from pyrimidine bases (Table 5).

If we first examine the values measured for the complexes with Schiff-bases derived from salicylaldehyde, we can see that the oxidation potential Co(II)/Co(III) is more negative for Co SalN–Medpt than for Co Salen,[22] indicating that Co(II) is more difficult to oxidize in the latter complex. This is probably due to the fact that Co Salen is tetracoordinate in DMSO whereas Co SalN–Medpt is pentacoordinate as shown by visible spectroscopy. This observation agrees well with the results of Basolo,[23] who suggested that the oxidation potential of cobalt(II) is strongly dependent on the electron density at the metal centre. Co Salpen is the least easily oxidized complex probably because of its nearly tetrahedral geometry.

Table 4. Magnetic data of cobalt(II) complexes

	μBM
Co Urapen	4.63
Co Uradpt	4.36
Co DiMeBaren	2.72
Co DiMeBarMeen	4.58
Co DiMeBarpen	4.64
Co DiMeBardpt	4.49

As for the two complexes derived from uracil, the values of the oxidation [Co(II)/Co(III)] and of the reduction [Co(II)/Co(I)] potentials are higher than for Co Salen or Co SalN–Medpt. On the other hand, for a given type of ligand, the reduction of the Co(II) complexes is more difficult than the reduction of the corresponding Cu(II) complexes as noticed previously by Deutsch.[24] The differences observed in the values of $E_{\frac{1}{2}}$ between the two series of complexes, are a consequence of the decreased electron-donating character of the uracil ring compared to the phenoxyl group, therefore making the metal cation more easily reduced and less easily oxidized.

Concerning the complexes derived from dimethyl barbituric acid, the presence of an extra hydroxyl group and two methyl groups on the pyrimidine ring has no great influence on the values of $E_{\frac{1}{2}}$ [Co(II)/Co(III)] compared to those of Co Urapen or Co Uradpt. Except for DiMeBarpen, the values of $E_{\frac{1}{2}}$ [Co(II)/Co(III)] are nearly the same for the three other complexes whether the ligand is tetra- or pentadentate.

Well above in the scale in each series are Co DiMeBarpen and Co Urapen with value of $E_{\frac{1}{2}}$ of $+0.51$ V and > 0.5 V respectively. This is in agreement with the more positive potential for [Co(III)/Co(II)] reduction of Co Salpen compared

Table 5.

Compound	$E_{\frac{1}{2}}$ (V)[a]		% of quinone after 2 h[b]
Co Salen	−0.1;	−1.33	100

[b] Oxidation of 2,6-ditertbutylphenol by mol. O_2 catalyzed by Co(II) compounds. See text for experimental conditions.

to Co Salen, probably reflecting slightly different geometries. We confirm also that the presence of a methyl group on the ethylene bridge has no influence on the stability of Co(II), as already shown by Averill.[25]

(5) *Electron paramagnetic resonance*

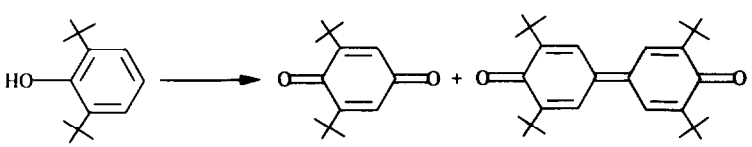
In order to test the ability of these complexes to bind dioxygen, we have measured the ESR spectrum of two complexes: Co Uradpt and Co DiMeBardpt which show similar values of $E_{\frac{1}{2}}$ [Co(II)/Co(III)].

Co Uradpt being soluble only in DMSO, was dissolved in this solvent in the presence of oxygen; whatever the temperature, no signal corresponding to the complex Co—O_2 could be detected. However under the same conditions Co DiMeBardpt shows a change of colour from green (solid) to maroon (solution) and exhibits a weak signal corresponding to the oxygen adduct, that is with eight lines because of the coupling of the cobalt nucleus and the electron from Co—O_2^-. The coupling constant is 15 G, which was already observed for other Co Saldpt complexes.[26,27] When acetonitrile was used instead of DMSO, a much stronger signal was observed. The heights of the lines varied with temperature and reached a maximum at room temperature. Addition of a trace of DMSO to the acetonitrile solution caused a strong decrease of the signal. This demonstrated that DMSO competes with oxygen as a ligand.

Thus, two complexes with very similar values of $E_{\frac{1}{2}}$[Co(II)/Co(III)] behave quite differently towards dioxygen. We will propose a possible explanation in the conclusion. We have also tested their catalytic activity in the oxidation of 2,6-ditertbutyl phenol by molecular oxygen.

(6) *Catalytic oxidation of 2,6-ditertbutyl phenol*

2,6-ditertbutyl phenol is readily oxidized by molecular oxygen in the presence of various cobalt(II) complexes giving only two products: parabenzoquinone (PBQ) and diphenoquinone (DPQ) as shown in the Scheme. We have compared the efficiency of the different cobalt complexes mentioned in this study with that of Co Salen and Co SalN–Medpt under the same standard conditions: 1 atm pressure of oxygen, room temperature, solvent: H_3CC N/DMSO, 10/1 in order to increase the solubility of the complexes, ratio: catalyst/phenol = 0.1.



PBQ DPQ

All complexes are not efficient catalysts (Table 5), but when they are, they exhibit the same high selectivity, the only reaction product being the benzoquinone PBQ. As expected, Co DiMeBardpt which binds O_2 shows an efficiency which is similar to that of good catalysts in this reaction such as Co SalN–Medpt whereas Co Uradpt which does not bind O_2 does not catalyze the reaction.

We noticed also that when the reaction is carried out in pure acetonitrile, the yield in oxidation product become quantitative with Co SalN–Medpt but drops to 70% with Co Salen instead of 100% in the mixture DMSO/CH_3CN (1/10). We interpret these apparently surprising results by assuming that in the case of Co SalN–Medpt, DMSO can act as a sixth ligand, thus preventing the binding of O_2. By contrast, with Co Salen it would act as a fifth ligand thus increasing the ability of the cobalt atom to bind O_2. Although the values of $E_{\frac{1}{2}}$ for Co DiMeBaren and Co DiMeBarMeen are similar, the yields in quinone are very different. This might be due to a lower solubility of Co DiMeBaren under the conditions we have used. The complexes derived from 1,3-propylene diamine (as Co Salpen for instance) are totally inefficient probably due to the high value of their Co(III)/Co(II) potential.

We conclude that complexes which have similar Co(II)/Co(III) redox potential values can exhibit very different catalytic efficiency. The latter is certainly a function of the redox potential but also depends on other factors such as the steric hindrance at the metal centre.[31] One should also bear in mind that these $E_{\frac{1}{2}}$ values concern a complex which is only the precursor of the active catalyst namely the oxygen adduct and that many other cobalt complexes are involved as intermediates in the catalytic oxidation.[28–30] Therefore, it seems very hazardous to establish a direct relationship between $E_{\frac{1}{2}}$ values and the catalytic efficiency of cobalt(II) complexes.

Acknowledgements—We wish to thank Dr J. Huet for the ESR spectra.

MOLYBDENUM–MOLYBDENUM QUADRUPLE BONDS: AN ASYMMETRICALLY SUBSTITUTED DIMER CONTAINING A SINGLE ACETATE BRIDGE. CRYSTAL AND MOLECULAR STRUCTURE OF $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]\cdot PhMe$

(*Received* 30 *March* 1987; *accepted* 24 *June* 1987)

Abstract—$[Mo_2(OAc)_4]$ reacts with three or more equivalents of lithium chloride and PMe_3 in thf to give $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]0.75thf$ (**1**). The IR spectrum of the complex shows Mo—O and Mo—Cl stretches at 350 and 300 cm^{-1} respectively and the ^1H and ^{13}C NMR spectra suggest several species are present in solution. $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]$ converts slowly in thf to $[Mo_2Cl_4(PMe_3)_4]$ and $[Mo_2(OAc)_4]$. The structure of $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]0.5C_6H_5Me$ (**2**) has been determined by single-crystal X-ray diffraction methods. Crystals of the toluene solvate are tetragonal with $a = 20.726(2)$, $c = 11.776(2)$ Å, space group = $I4cm$. The structure was solved by Patterson and Fourier methods and refined to R of 0.035 for the 539 observed data. The molecule contains two metal centres each of which shows 5-fold coordination. The two molybdenum atoms are linked by an acetate bridge and a short Mo—Mo bond of 2.121(3) Å. Remaining coordination sites are occupied on Mo(1) by two Cl and one PMe_3 and on Mo(2) by one Cl and two PMe_3 groups.

Preparations of dinuclear molybdenum(II) complexes containing chloro and phosphine ligands have traditionally used $[Mo_2(OAc)_4]$ as the source material for the molybdenum–molybdenum quadruple bond.[1] Reaction with ammonium chloride to give $(NH_4)_5Mo_2Cl_9\cdot H_2O$ followed by treatment with the phosphine has been the usual route.[2] McCarley *et al.* have reported that $[Mo_2Cl_4(PEt_3)_4]$ could be synthesized by reacting $[Mo_2(OAc)_4]$ with excess Me_3SiCl in the presence of PEt_3.[3] More recently Green *et al.* found that $[Mo_2Cl_2(OAc)_2(P)_2]$ complexes could be prepared by the reaction of $[Mo_2(OAc)_4]$ with two equivalents of Me_3SiCl in the presence of a variety of phosphine ligands.[4] This latter reaction showed that complexes containing both acetate and chloro ligands could be prepared for molybdenum as had been found with rhenium.[5]

The stepwise deacetylation of $[Mo_2(OAc)_4]$ to produce $[Mo_2Cl_4(P)_4]$ complexes can be envisaged to proceed through the following intermediates

$$[Mo_2(OAc)_4] \rightarrow [Mo_2Cl(OAc)_3P] \rightarrow [Mo_2Cl_2(OAc)_2P_2] \rightarrow [Mo_2Cl_3(OAc)P_3] \rightarrow [Mo_2Cl_4P_4].$$

In this sequence only the *mono-* and *tri*-chloro complexes remain to be discovered. We report here results of work in which attempts were made to prepare and characterize these two complexes using PMe_3 as the phosphine ligand. In particular the X-ray structural characterization of a $[Mo_2Cl_3(OAc)P_3]$ complex is presented.

RESULTS AND DISCUSSION

During reactions carried out between Me_3CPLi_2 and $[Mo_2(OAc)_4]$ in the presence of PMe_3 using thf as solvent, we have observed the formation of small quantities of a red–purple complex for which analytical and spectral data indicated a molybdenum compound containing chloro and PMe_3 ligands. Since it was suspected that the chloro ligands resulted from a reaction between $[Mo_2(OAc)_4]$ and lithium chloride present in our solutions of

Me_3CPLi_2, the interaction of these two reagents was studied further.

When $[Mo_2(OAc)_4]$ was reacted with three or more equivalents of LiCl in thf in the presence of PMe_3, the mixture rapidly became purple and lithium acetate was precipitated. The red–purple complex extracted from this reaction mixture had similar spectral properties to the complex formed when the dilithium phosphide reagent was present. Recrystallization of the product from thf gave a complex which analyzed as $[Mo_2Cl_3(OAc)(PMe_3)_3]$ 0.75 thf (**1**). The IR spectrum showed a broad C=O absorption band at 1450 cm^{-1} and there were bands due to PMe_3 and thf at 960 and 855 cm^{-1} respectively. In the far-IR, bands at 350 and 300 cm^{-1} were identified as Mo—O and Mo—Cl stretches respectively.[6] In the ^1H NMR spectrum there were several PMe_3 methyl resonances in the vicinity of 1.8 ppm; a singlet was observed for the acetate methyl carbon and the methylene protons of the thf appeared as multiplets in the vicinity of 1.8 and 3.7 ppm. In the $^{13}C[^1H]$ NMR spectrum there were several resonances present for the PMe_3 methyl carbons and singlets for the acetate methyl carbon as well as the α- and β-carbons of the thf solvate. In addition there were three resonances of different intensity for the acetate group quarternary carbon. The $^{13}C[^1H]$ NMR spectrum thus indicated the presence of several species present in solution.

When the red–purple complex is allowed to stand for long periods in thf (i.e. several weeks) the solution changes colour from purple to blue and molybdenum tetra-acetate precipitates. From the blue–purple solution $[Mo_2Cl_4(PMe_3)_4]$[7,8] and the red–purple complex (**1**) were isolated.

The solvated complex (**1**) was best prepared from $[Mo_2(OAc)_4]$ in thf by the addition of three equivalents of both LiCl and PMe_3. It was also formed when Me_3SiCl was used in place of LiCl. Reactions of $[Mo_2(OAc)_4]$ with one or two equivalents of LiCl and PMe_3 in thf invariably lead to mixtures containing various uncharacterized molybdenum complexes. When $[Mo_2(OAc)_4]$ was reacted with two equivalents of Me_3SiCl and PMe_3 in thf, a pink product was formed which we believe to be $[Mo_2(OAc)_2Cl_2(PMe_3)_2]$ but attempts to obtain pure product by crystallization led only to the red–purple complex.

Crystal structure studies

The crystal structure of the red–purple complex recrystallized from toluene was determined and found to be the toluene solvate, $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]0.5C_6H_5Me$ (**2**). The molecular structure is shown in Fig. 1. It consists of an asymmetric

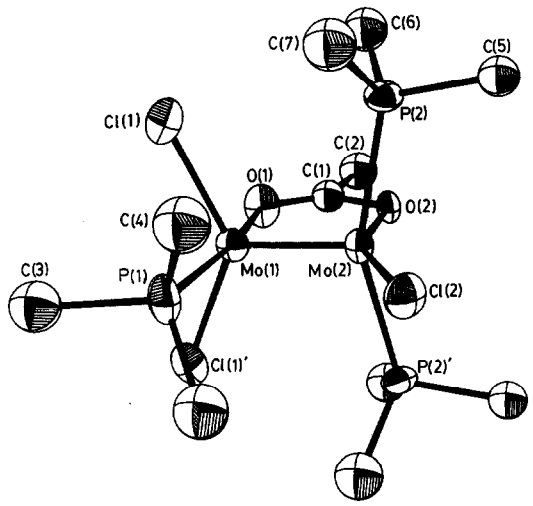

Fig. 1. Molecular structure of $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]0.5PhMe$. Ellipsoids are drawn at the 40% probability level. Hydrogen atoms have been omitted.

dinuclear species in which a single acetate ligand bridges two molybdenum atoms which in turn are joined by a short metal–metal bond of 2.121(2) Å. The remaining coordination sites are occupied on Mo(1) by two Cl and one phosphine and on Mo(2) by one Cl and two phosphine ligands. As a result the donor atoms *trans* to the acetate oxygens are not the same for the two metal centres. Bond distances and angles are given in Table 1. These latter indicate the deviations from ideal 5-fold coordination which occur. At Mo(1) the angles Cl(1)–Mo(1)–Cl(1)′ and P(1)–Mo(1)–O(1) of 134.2(2) and 170.6(6)° respectively, more closely resemble a trigonal bipyramidal geometry whereas P(2)–Mo(2)–P(2)′ (156.2(2)°) and Cl(2)–Mo(2)–O(2) (149.8(5)°) are more indicative of the square pyramidal arrangement.

A comparison of distances and angles observed for (**2**) and other related complexes is given in Tables 2 and 3. The Mo(1)—Mo(2) separation of 2.121(2) Å lies within the range of values (2.086(2)–2.153(6) Å) found for complexes containing a Mo—Mo quadruple bond. These compounds may be further subdivided into complexes either with, or without, an acetate bridge. In complexes in which two or more acetate bridges are present the Mo—Mo separation is a little shorter (2.093(1)–2.113(1) Å) than that observed where no acetate bridges occur (2.130(1)–2.153(6) Å). In (**2**) the Mo—Mo distance of 2.121(3) seems to lie between the two ranges. The Mo(1)—Cl(1) and Mo(2)—Cl(2) distances of 2.420(7) and 2.431(8) Å respectively do not differ significantly from one another despite the differences in their *trans* neigh-

[a] This work.

[b] The 2 C—O distances within the same acetate group follow one another.

[c] The oxygen is involved in an intermolecular bonding interaction.

Arenivar *et al.*[16] that the *trans* effect of a phosphine is greater than that attributed to acetate. However the variation in Mo—P distances in the red isomer of $[Mo_2(O_2CCMe_3)_2Cl_2(PEt_3)_2]$[16] cannot be explained in this way. In (**2**), the Mo(1)—O(1) bond length of 2.14(2) Å is longer than Mo(2)—O(2) (2.06(2) Å) and at least part of the difference can be attributed to the differing *trans* effect exerted by phosphine and Cl. The distances C(1)—O(1) (1.19(4) Å), C(1)—O(2) (1.36(4) Å) appear to differ significantly from one another at the 3σ level suggesting an asymmetry in the bridging acetate. Such an effect has not been observed in the di- and tetra-acetate bridged species listed in Table 3.

Inspection of the bond angles given in Table 3 shows that for each of the three groups Cl—Mo—X, P—Mo—X and O—Mo—X the angles fall into three ranges of decreasing value as X varies from O through P to Cl. If steric effects were solely responsible for this then it is surprising that the P—Mo—Cl angles of 139.8 and 142.2° are observed in the complexes $[Mo_2(OAc)_2Cl_2(PBu_3)_2]$ and $[Mo_2(O_2CCMe_3)_2Cl_2(PEt_3)_2]$ respectively where the smaller angle is associated with the bulkier phosphine group.

The crystal structure determination highlights several features. The complex is the first structurally characterized molybdenum complex containing a single acetate bridge. To retain the Mo^{2+} formalism for each molybdenum atom, O(1) must act as a 2-electron σ-donor to Mo(1). In other chloro-carboxylate complexes, a distinction between bonding modes is not always apparent by inspection or more importantly from structural data. For example in $[Mo_2(OAc)_4]$ the bond lengths observed do not distinguish between the two bonding modes.[15] In the red isomer of $[Mo_2Cl_2(OAc)_2(PBu_3)_3]$ the two longer Mo—O bonds lie *trans* to the phosphorous atoms[16] which suggest that the anion may bind *trans* to the chloride. However, this is not a certainty since a difference in bond length is to be expected due to the trans effect. For $[Re_2Cl_4(\mu\text{-}Cl)(\mu\text{-}O)(\mu\text{-}O_2CEt)(PPh_3)_2]$ (Re^{4+} dimer containing a Re≡Re double bond) in which the oxygen atoms of the single acetate bridge lie *trans* to chloro ligands, the Re—O distances are equivalent at 2.097(11) and 2.092(12) Å.[18] In the present complex (**2**), the Mo(1)—O(1) distance (2.14(2) Å) differs from the Mo(2)—O(2) distance (2.06(2) Å) by just over 3σ which may reflect a significant difference in the two modes of bonding. Further, this is accompanied by a difference in the C—O bond length (1.19(4) and 1.36(4) Å for C(1)—O(1) and C(1)—O(2) respectively) which, although small, is at least consistent with O(2) being involved in π-bonding.

Another feature of the structure is the asymmetry in the molecule. One end contains a *trans* Cl—Mo—Cl structure and the other a *trans* P—Mo—Cl structure. Two of the phosphine ligands are eclipsed which has not been observed in the other chloro-phosphine complexes structurally characterized. As a result of this geometry the P(1)—Mo—O(1) bond angle is widened to 170.6(6)° which compares with 163.9(2) and 165.0(3)° in the orange isomer of $[Mo_2Cl_2(OAc_2)(PEt_3)_2]$ in which phosphine and chloro ligands are *trans* to one another.[16] As a consequence of the acetate bridging mode the Mo(1)—P(1) bond represents a phosphine ligand lying *trans* to a 2-electron oxygen sigma donor. The Mo(1)—P(1) bond length (2.517(9) Å) is similar to that found for the equivalent position in the red isomer of $[Mo_2Cl_2(OAc)_2(PEt_3)_2]$ (2.529(4) Å)[9] but is much shorter than for the *trans* oriented phosphines in $[Mo_2Cl_4(PMe_3)_4]$ (Mo—P bond distances 2.546(1) and 2.544(1) Å).[8]

Analysis of the species formed when the acetate ligands of $[Mo_2(OAc)_4]$ are replaced in a stepwise manner by chloro and phosphine ligands, taking into account the origin of the O=C—O^- function, suggests that the complex characterized is not an intermediate in the transformation of $[Mo_2(OAc)_4]_2$ to $[Mo_2Cl_4(PMe_3)_4]$, but results from an isomerization of one of the stepwise transformed intermediates. The coordination geometry observed about Mo(1) could give rise to the *trans* orientation of ligands in (**a**) and (**b**) [see Fig. (2)] whereas the geometry about Mo(2) could result in the *cis* structures (**c**) and (**d**). The characterized complex itself is likely to give rise to the *trans–cis* structure (**e**). The complex could result from (**f**), being an isomerized product of (**g**), which itself is the stepwise replaced product from the *tris*-acetate (**h**), or from an isomerization of a $[Mo_2Cl_3(\mu\text{-}OAc)(PMe_3)_3]$ product produced by the stepwise replacement of an acetate in a $[Mo_2Cl_2(OAc)_2(PMe_3)_2]$ molecule. The ^{13}C NMR spectrum of the complex indicates that more than one species is present and this suggests that the solution chemistry is more complicated than the solid state structure would suggest.

EXPERIMENTAL

Lithium chloride was dried by heating to 100°C under vacuum for 24 h. Trimethyl phosphine was prepared by a literature method.[19] $[Mo_2(OAc)_4]$ was prepared by refluxing $[Mo(CO)_6]$ in a mixture of acetic acid and acetic anhydride.[20] Tetrahydrofuran (thf) was distilled from sodium hydroanaphthylide. All preparations and manipulations were carried out under dry, oxygen-free nitrogen using standard bench-top air-sensitive techniques.[21]

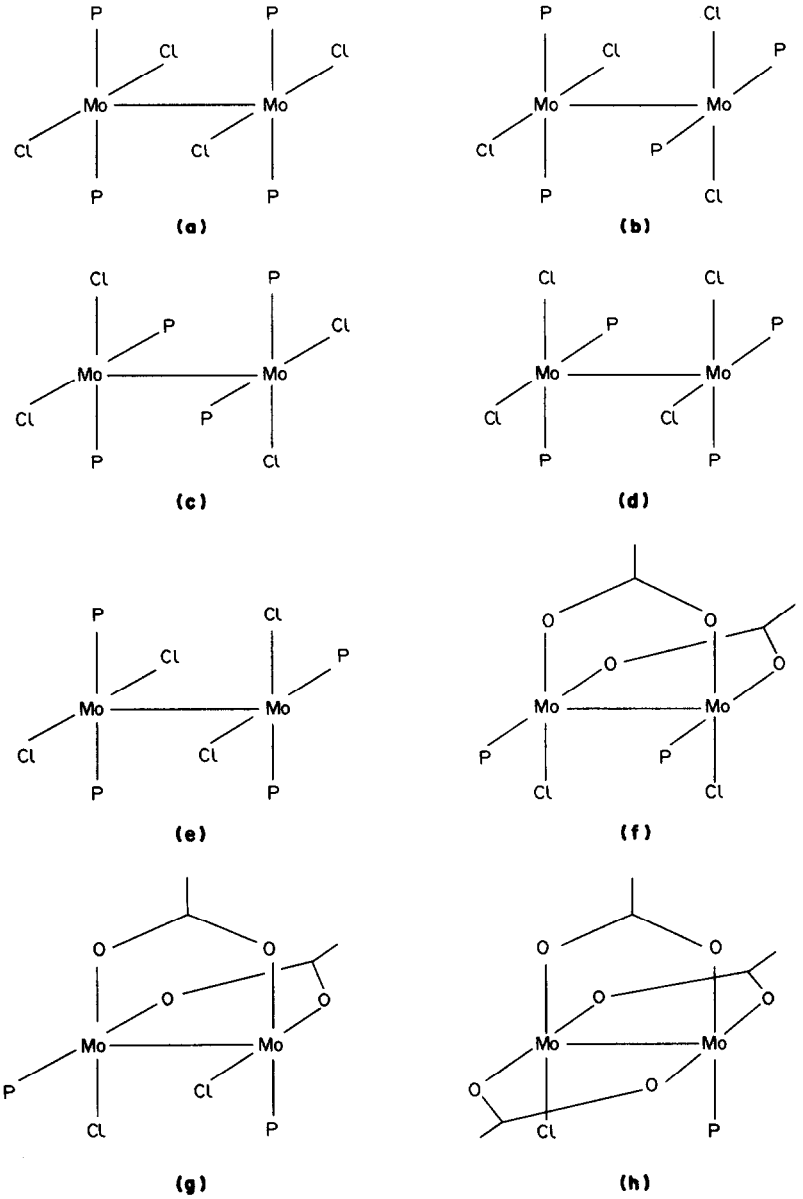

Fig. 2.

IR spectra were recorded on a Perkin–Elmer 597 spectrometer as Nujol mulls between CsI plates. ^{1}H and ^{13}C NMR spectra on a JEOL FX60 spectrometer. Analytical data were obtained by Prof. A. D. Campbell and his associates, University of Otago, New Zealand.

μ - Acetato - trichlorotris (trimethylphosphine) dimolybdenum (II)

Trimethyl phosphine (0.8 cm^3, 7.3 mmol) was added to a suspension of dimolybdenum tetraacetate (1.0 g, 2.3 mmol) in tetrahydrofuran (50 cm^3) and the mixture was stirred rapidly while a suspension of lithium chloride in tetrahydrofuran (30 cm^3) was added. The mixture was stirred for a further 20 h and the solution filtered from the precipitate which was then extracted with tetrahydrofuran (10 cm^3 portions) until the washings were no longer coloured purple. The extracts were combined, filtered and the solvent removed *in vacuo* to give the complex as purple–red crystals. Yield 1.3 g (96%). An analytically pure sample was obtained by dissolving the bulk sample in thf, filtering the solution and reducing the volume until crystallization commenced. On standing, the complex formed as red–purple needles which were filtered, washed with cooled thf (5 cm^3)

and dried *in vacuo*. (Found: C, 26.4; H, 5.6%. $C_{14}H_{36}Cl_3Mo_2O_{2.75}P_3$ (i.e. $[Mo_2Cl_3(\mu\text{-OAc})(PMe_3)_3]$ 0.75 thf requires C, 26.3; H, 5.7%.)

IR (Nujol) bands at 1450s, 1304m, 1285m, 1070m, 1055w, 1030w, 960s, 855m, 740m, 675m, 600w, 350m and 300m cm^{-1}. ^1H NMR ($CDCl_3$) 1.38–1.70 (m, 27H, $3PMe_3$); 1.70–2.0 (m, β Hs, thf); 2.75 (s, 3H, Me); 3.55–3.82 (m, α-Hs, thf). ^{13}C NMR, 10.7, 11.6, 12.2, 13.1, 14.0 (PMe_3); 23.5 (Me); 25.6 (β-Cs, thf); 67.9 (α-Cs, thf); 184.8, 185.7, 186.3 ($-CO_2$).

The complex was dissolved in tolune (30 cm^3) and the volume reduced to *ca.* 5 cm^3. On standing at $-20°$ red–purple crystals of the complex were formed which were filtered and washed with chilled toluene (2 cm^3). The product was crushed to a powder and dried for 3 h under vacuum. (Found: C, 27.1; H, 5.6; P, 14.5%. $C_{14.5}H_{34}Cl_3Mo_2O_2P_3$ (i.e. $[Mo_2Cl_2(\mu\text{-OAc})(PMe_3)_3]$0.5PhMe) requires C, 27.6; H, 5.4; P, 14.7%.)

A sample of the complex (0.5 g) was dissolved in thf (15 cm^3) and the solution allowed to stand at room temperature for several weeks giving a blue solution and a yellow precipitate of $[Mo_2(OAc)_4]$. On crystallization, the filtrate gave rise to the thf solvate of $[Mo_2Cl_3(\mu\text{-OAc})(PMe_3)_3]$ and $[Mo_2Cl_4(PMe_3)_4]$. The complexes were separated manually and identified by spectral comparison with authentic samples.

Crystallographic studies

Crystal data. Compound recrystallized from toluene at $-20°C$, $[Mo_2(\mu\text{-}O_2CMe)Cl_3(PMe_3)_3]$0.5 C_7H_8: $C_{11}H_{30}O_2P_3Cl_3Mo_2$0.5$C_7H_8$, $M = 631.63$, tetragonal, $a = 20.726(2)$, $c = 11.776(2)$ Å, $U = 5059$ Å^3, space group $I4cm$, $Z = 8$, $Dc = 1.66$ g cm^{-1}, $F(000) = 2536$, μ(Mo-$K\alpha$) = 14.8 cm^{-1}.

Data collection. CAD4 diffractometer, Mo-$K\alpha$ radiation (0.71069 Å), graphite monochromator $\omega/2\theta$ scan mode. Crystal ($0.30 \times 0.12 \times 0.11$ mm) sealed under N_2 in a capillary tube, 808 unique data measured ($\theta_{max} = 22°$). The intensities of three standard reflections, monitored during the data collection showed a variation of less than 3.5%; corrections were made for absorption,[22] minimum and maximum correction factors being 0.917 and 1.000 respectively.

Structure solution and refinement. The structure was solved by Patterson and Fourier methods and refined by a full-matrix least-squares technique.[23] The final refinement cycle converged to values of 0.034 and 0.035 for R and Rw respectively for the 121 variables and 539 data for which $F^2 > 3\sigma(F^2)$; the weight, w, is defined as $0.9337/[\sigma^2(F) + 0.001194F^2]$. The compound crystallized as the toluene solvate and disordered sites for the atoms of the solvent molecule were located about the four-fold axis. The six carbon atoms of the aromatic ring were treated as a rigid group (C—C 1.395 Å) for inclusion in the calculations with an occupancy factor of 0.25 but because of the nature of the disorder no attempt was made to include the methyl substituent. Anisoptropic thermal motion was assumed for all atoms other than hydrogen with the exception of C(1), C(2), C(3) and the solvent atoms. All hydrogen temperature factors were fixed at $U = 0.1$ e Å^{-2}. The atomic scattering factors were taken from the tabulations of Cromer and Mann,[24] anomalous dispersion corrections were by Cromer and Liberman.[25] Final atomic coordinates, tables of thermal parameters, hydrogen atom coordinates and lists of Fo/Fc have been deposited with the editor as supplementary material.*

(*Received* 21 *May* 1987; *accepted* 24 *June* 1987)

Abstract—Nine spiroborate complexes (**7–15**) were analyzed by NMR and MS spectroscopy and the characteristic spectra and fragmentation patterns are reported. On the basis of these results, the structure of Meulenhoff's free acid is re-investigated.

There have been considerable studies on reactions between boric acid and diols in connection with the changes of conductivity, acidity and rotatorypolarization.[2] Hermans pointed out that the changes of these physical properties are due to the formation of a spiroborate complex (**1**) which is produced from those reactions in a solution.[3] The first isolation of the spiroborate complex was performed by Böeseken and co-workers[4] who synthesized potassium biscatechol spiroborate (**2**) from the reaction of catechol with potassium borate in water, although they failed to get satisfactory elemental analyses. Later, Meulenhoff confirmed the structure as the spirane type by measurement of the rotatory polarization of some substituted biscatechol spiroborates.[5] Moreover, the free acid (**3**), which is called Meulenhoff's free acid, was reported to be obtained by sublimation of anilinium biscatechol spiroborate (**5**) *in vacuo*.[5] However, the structure of this free acid is still ambiguous and furthermore, NMR and MS spectral analyses of both biscatechol spiroborate and its analogs are little known. In this paper, we describe the structural elucidation of Meulenhoff's free acid on the basis of its spectral data, which are compared with those of its related compounds.

EXPERIMENTAL

All 2-amino-4-methylpyridinium spiroborate complexes (**7–15**) were obtained by our previously reported method.[1] ^{1}H-NMR and ^{13}C-NMR were obtained using Varian T-60 (60 MHz) or EM-90 (90 MHz) and XL-400 (400 MHz) spectrometers, respectively. ^{1}H-NMR spectra of all spiroborates **7–15** were measured in a solution of dimethylsulfoxide-d_6 using tetramethylsilane as an internal standard and all chemical shifts were attributed in a previous paper.[1] Similarly, spiroborates **2** and **5** were also submitted to ^{1}H-NMR and ^{13}C-NMR measurements. MS spectral data were obtained on a JEOL JMS DX-300 (equipped with JMA 3100; ionization voltage, 70 eV) and a JEOL JMS D-100 (ionization voltage, 20 eV) spectrometers.

RESULTS AND DISCUSSION

In a previous study, we reported a new synthesis of 2-amino-4-methylpyridinium biscatechol spi-

* For Part I, see ref. 1.

† Author to whom correspondence should be addressed.

roborate (7) and its analogs (**8–15**) by the reaction of 2-amino-4-methylpyridine borane (**6**) with catechol and its related diols in the presence of orthoester.[1] To confirm the spirane structure, we converted Böeseken's complex **2** into anilinium complex **5** and 2-amino-4-methylpyridinium complex **7** by exchange of potassium cation with the corresponding protonated amines, respectively. When these two spiroborates (**5**) and (**7**) were sublimed *in vacuo* by Meulenhoff's method, the pure starting spiroborates were recovered, respectively, but not the free acid (**3**). Therefore, we used a subliming apparatus as shown in Fig. 1 which is equipped with a dish where concentrated sulphuric acid is poured to remove aniline from gaseous **5**. The sublimation was repeated twice at 140°C below 2 mmHg, and colourless powder was obtained. Hereafter, we used it as Meulenhoff's free acid (MFA). In 1961, Dale and co-workers proposed structure (**4**) instead of structure (**3**) for MFA by speculation about the result that an open structure of a crystalline bis(2,2,5,5-tetramethylhexane-3,4-diol)borate has been confirmed by the presence of an OH absorption band in the infrared (IR) spectrum.[6,7] These facts prompted us to re-examine the structure of MFA by NMR and MS analyses.

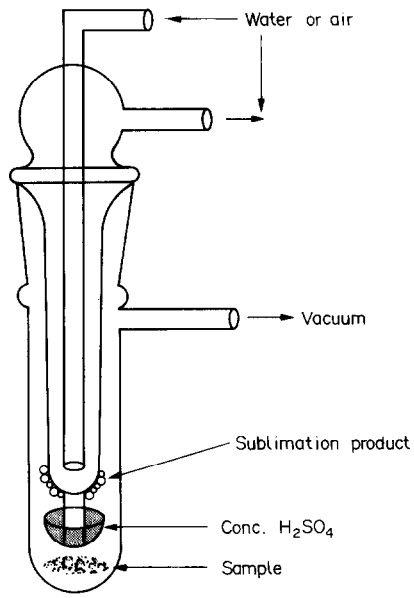

Fig. 1. Subliming apparatus.

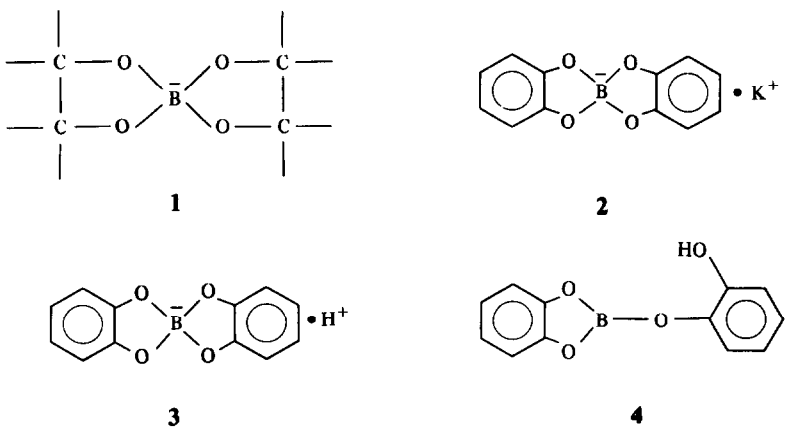
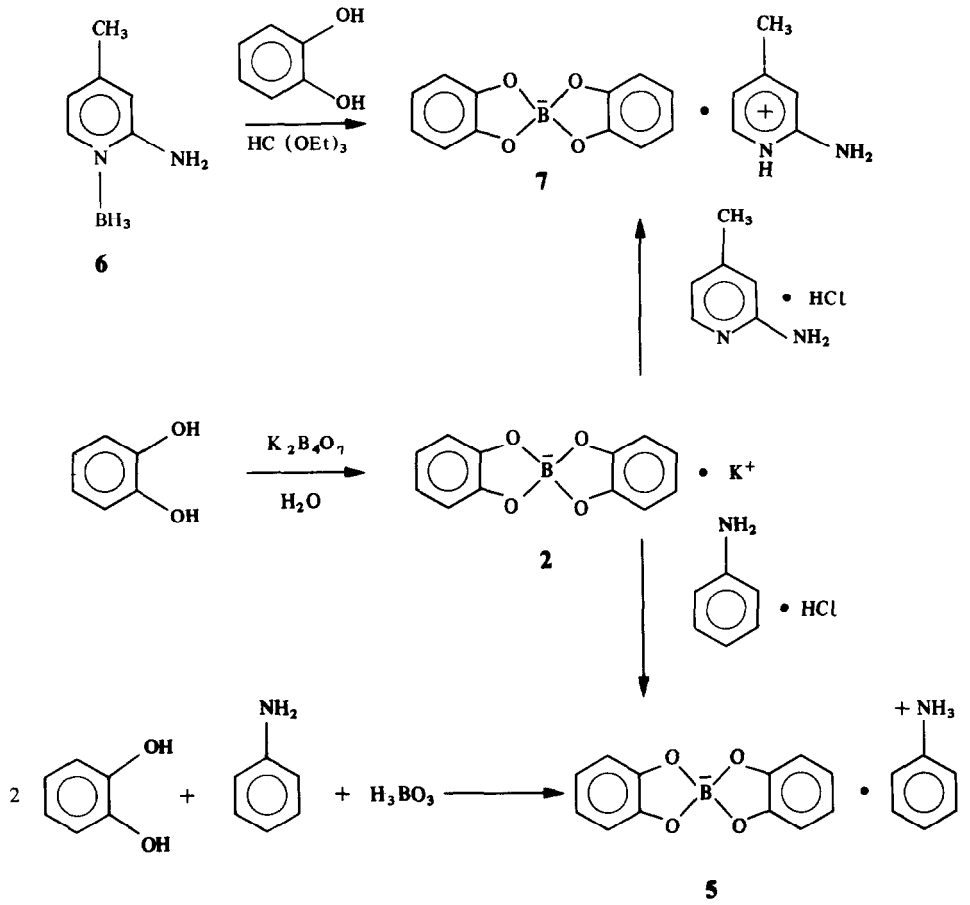
NMR spectra

A few NMR studies have been reported on certain spiroborates,[8,9] but not on biscatechol spiroborate and its analogs. Previously, we measured ^{1}H-NMR of spiroborates **7–15**,[1] and have studied their spectral data as well as those of **2** and **5** and two characteristic phenomena were found. Firstly the signal patterns of anion moieties of the spiroborates **7–15** changed when deuterium oxide was added to the solution and secondly the signal of spirans **2** was unchanged by addition of deuterium oxide. As Fig. 2(a) shows, when the counter cation of the biscatechol spiroborate is potassium ion, the singlet signal at 6.47 ppm due to the atomic protons was unchanged by addition of deuterium oxide, whereas when the counter cation is a protonated amine such as anilinium or 2-amino-4-methylpyridinium, the singlet signal at 6.47 ppm of the anion moiety was partially changed to a multiplet by addition of deuterium oxide. Figures 2(b) and (c) show two other examples. The ratio of the signal at 2.15 ppm to the signal at 2.12 ppm due to methyl protons (6H) of spirans **8** was changed by addition of deuterium oxide. Similarly, the signal at 4.43 ppm due to methylene protons (4H) of spi-



1 **2** **3** **4**

Scheme 1.

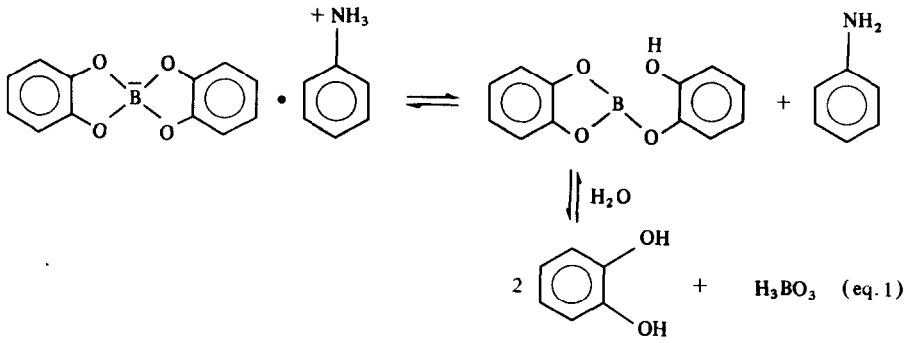


Scheme 2.

rans **11** was clearly changed to a doublet (4.40 and 4.45 ppm) by addition of deuterium oxide. Namely, the proton of anilinium or of the 2-amino-4-methylpyridinium ion would assist hydrolysis of the anion moiety of the spiroborate complex.

Since some spiroborates have already been hydrated in their crystals and also a little amount of water is contained in the NMR solvent, hydrolysis of the spiroborates would occur to a small extent even without adding deuterium oxide. In fact, Fig. 3 shows a small signal of AA′BB′ pattern near the singlet signal at 6.47 ppm at least below 50°C, although deuterium oxide was not added to the solution. The signal of the AA′BB′ pattern coalesced with the singlet signal when the solution was heated above 70°C and after cooling the spectrum again showed the same pattern as that at 32°C. Therefore, the AA′BB′ pattern at 32°C resulted from hydrolysis of the spiroborate where water was contained in the NMR solvent. The equilibrium equation would be expressed as eq. (1).

The ^{13}C-NMR spectrum of spiroborate **2** was



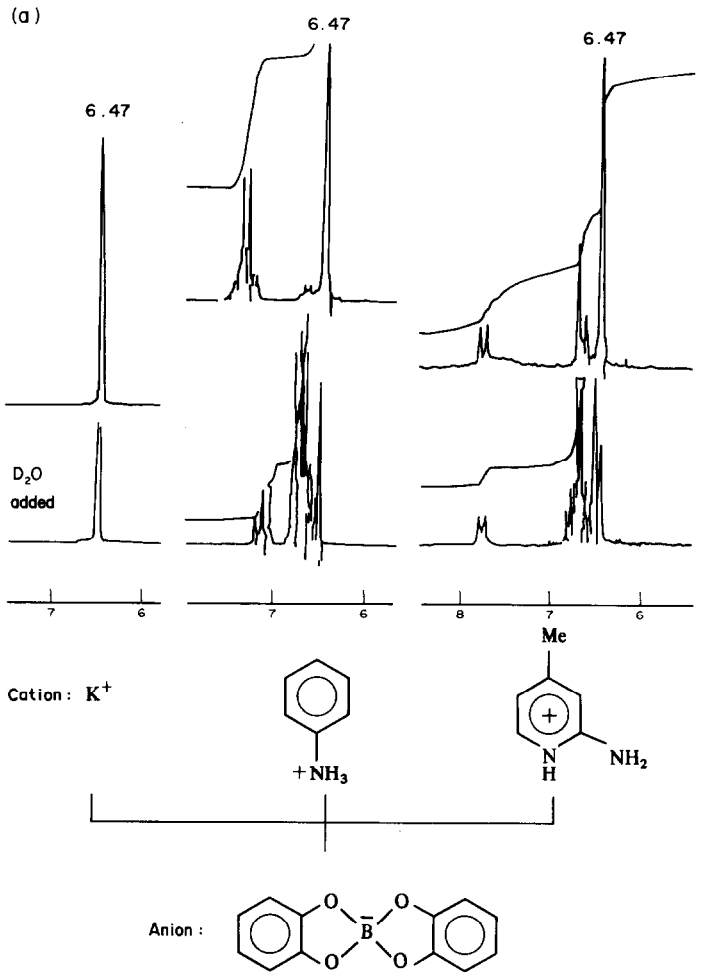


Fig. 2. (a) ^{1}H-NMR spectra of spiroborates 2, 5 and 7 (90 MHz) (deuterium oxide was added in the spectra below). (b) ^{1}H-NMR spectra of spiroborate 8 (90 MHz). (c) ^{1}H-NMR spectra of spiroborate 11 (60 MHz).

compared with that of catechol and Table 1 shows the difference of the chemical shifts between catechol and **2**. Those chemical shifts of **2** were attributed to DEPT and ^{13}C-^{1}H COSY. Clearly, electrons of the oxygen atom of **2** flow into the boron atom because the C-1 signal of **2** shifted to the lower field in the range of 6.28 ppm comparing it with catechol. Magnetic anisotropy of the boron atom was especially observed at C-2.

Table 1. ^{13}C-NMR spectral data (ppm)

Compound	C-1	C-2	C-3
	145.37	115.80	119.41
 •K$^+$	151.65	107.72	117.43
Difference	−6.28	+8.08	+1.98

MS spectra

Tables 2 and 3 show the results of MS analysis of spiroborates **7**–**15**. In compound **7**, for example, when R is defined as a 2-(1,3,2-benzodioxaborolyl) group, typical fragment ions such as RO––OR (*m*/*Z* 346), R—O—R (*m*/*Z* 254), RO––OH (*m*/*Z* 228) and R—OH (*m*/*Z* 136) were observed including the molecular ion peaks of the catechol (*m*/*Z* 110) and 2-amino-4-methylpyridine (*m*/*Z* 108). This fragmentation pattern was in common with other spiroborates **8**, **12** and **13**. On the other hand, as Table 3 shows, *o*-substituted spiroborates **9**, **10** and **11**, and spiroborates with a carboxyl group as the

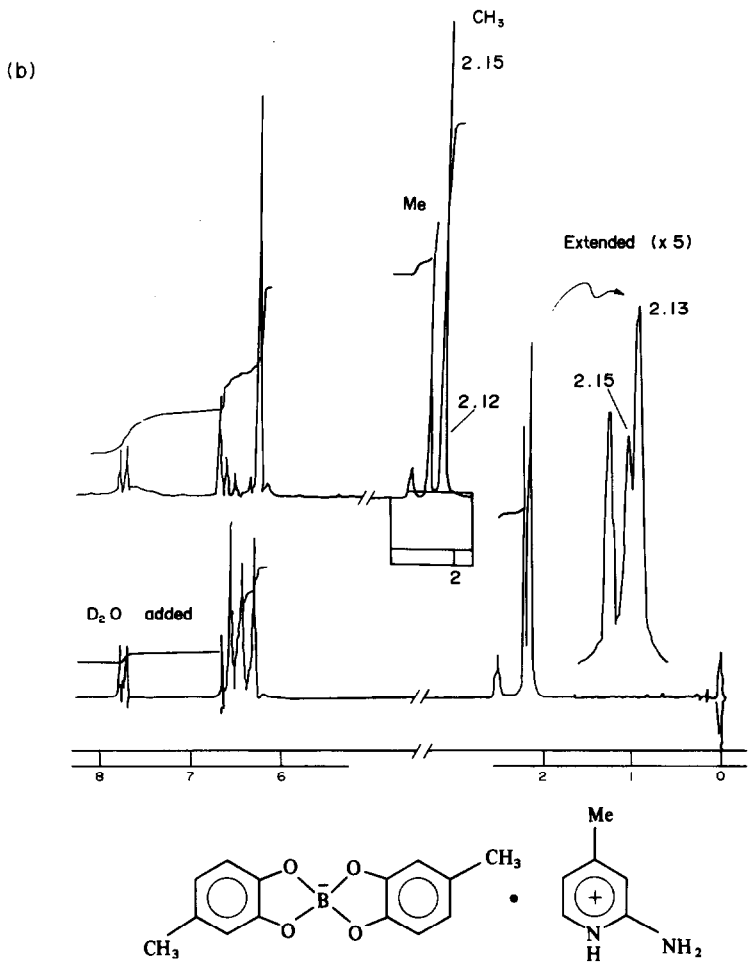

Fig. 2—*continued*

ligand (**14** and **15**) did not afford the characteristic fragmentation pattern of this kind. Especially, **15** did not give any fragment ion of boron contained moiety even by the In Beam method. MS spectrum of **2** was not obtained and this result corresponded with the fact that **2** is hard to combust.[5]

Although relative intensities of these typical fragment ions were dependent on their sample temperature for measurement, the fragment ion of bisdiol trigonal borate (RO––OH) showed the strongest intensity among the boron contained fragment ions in Table 2. It is worth noting that any kind of amine in the protonated counter cation does not affect the MS fragmentation of the spiroborate anion (compare **7** in Table 2 with **5** in Table 4). Therefore, both the characteristic fragmentation pattern and the strongest fragment ion shown in Table 2 could become the clue to clarify whether the structure of a certain borate is spirane or simple trigonal.

Structural elucidation of MFA

On the basis of the above results, we attempted to elucidate the structure of MFA. Table 4 shows the fragment ions of MFA in comparison with those of **5**. Since one of the typical fragment ions, RO––OR (*m*/*Z* 346), was not observed and the relative intensity of the fragment ion R—OH (*m*/*Z* 136) was very strong instead of RO––OH (*m*/*Z* 228), MFA could not be **3**. Interestingly, the molecular ion peak of aniline was observed. Meanwhile, Fig. 4 shows ^{1}H-NMR spectra of MFA where signals of deuterium exchangable protons (7.85 ppm) and aromatic protons of both aniline (7.23–7.60 ppm) and catechol (6.40–6.83 ppm) were observed in addition to an aromatic singlet signal at 6.47 ppm (the left spectra). When treated with deuterium oxide, the spectral patterns were changed to those of aniline (5H, 6.97–7.43 ppm) and catechol (8H, 6.50–6.87 ppm), and the signal at 6.47 ppm disappeared

entirely (the right spectra). These data clearly indicate that aniline cannot be removed from **5** by the sublimation method even over concentrated sulphuric acid. We believe that MFA might be a mixture of catechol, aniline and an unknown compound which would readily be hydrolyzed so that the signal at 6.47 ppm disappeared upon addition of deuterium oxide. Since *o*-phenylene borate like compound **4** is known to be hydrolyzed readily,[10] the unknown compound might be the aniline adduct of compound **4**.

In conclusion, spiroborates of certain kinds derived from catechol and its analogous diols showed characteristic spectra, and especially the proton of the counter cation in the spiroborate complex plays an important role in the ^{1}H-NMR and MS spectroscopic measurements.

(*Received* 21 *May* 1987; *accepted* 24 *June* 1987)

Abstract—A predominantly localized electron pair scheme is outlined for describing the electron distribution and bonding in *closo* borane anions $B_nH_n^{2-}$ and related electron deficient deltahedral clusters, in which a skeletal electron pair is assigned to each vertex, one pair being regarded as delocalized just inside the roughly spherical surface on which the skeletal atoms lie. The scheme gives a clearer picture of the electron distribution than is conveyed by resonating 2- and 3-centre bonds in the polyhedron edges and faces, and allows the bond orders of the polyhedron edge links to be calculated readily. The consequence of formal removal of BH^{2+} units from closo species $B_nH_n^{2-}$ to generate *nido* species $B_{n-1}H_{n-1}^{4-}$ and *arachno* species $B_{n-2}H_{n-2}^{6-}$ is explored, and seen to allow rationalization of two features of such deltahedral-fragment clusters: (i) why a high-connectivity vertex is left vacant and (ii) why the frontier orbitals of such species concentrate electronic charge around their open faces. Moreover, in the case of D_{4h} $B_4H_4^{6-}$ (cf. $C_4H_4^{2-}$) and D_{5h} $B_5H_5^{6-}$ (cf. $C_5H_5^-$), the approach leads directly to the familiar picture for aromatic ring systems in which the highest filled, doubly degenerate π-bonding molecular orbital concentrates electronic charge in rings above and below the polygon on which the skeletal nuclei lie. It also leads to the expectation that *arachno* clusters with non-adjacent vacant vertices will be more stable than those with adjacent vacant vertices.

In previous papers[1,2] in which we have separately discussed the bonding in cluster compounds, we have advocated the use of localized valence shell electron pair schemes for treating the bonding in certain highly symmetrical polyhedral clusters in which the numbers of edges or faces coincide with the numbers of bond pairs available. For example, a regular octahedral arrangement of six bond pairs over the edges of the tetrahedral P_4 molecule allows its bonding to be described in terms of six 2-centre 2-electron (2c2e) bonds, while a tetrahedral arrangement of the four skeletal bond pairs over the faces of the tetrahedral boron halide B_4Cl_4 satisfactorily accounts for its bonding in terms of four 3-centre 2-electron (3c2e) bonds. Similar treatments are possible for the metal–metal bonding in the octahedral clusters $Mo_6Cl_8^{4+}$ (twelve 2c2e edge bonds) and $Nb_6Cl_{12}^{2+}$ (eight 3c2e face bonds). The advantages of these treatments are that they give a clear picture of the symmetrical distribution of the

* Author to whom correspondence should be addressed.

electronic charge in such clusters, and give a useful indication of the strength of the bonding (edges associated with a pair of electrons clearly correspond to bonds of order 1.00; those shared between faces containing 3c2e bonds, effectively acquiring one-third of a bond pair from each such bond, have a bond order of 0.66′).

Closo borane anions $B_nH_n^{2-}$ and related clusters contain too few electrons to allow comparably simple treatments of their bonding. They contain $(n+1)$ skeletal bond pairs with which to hold together their n BH units, which are located at the n vertices of deltahedra with $2(n-2)$ faces and $3(n-2)$ edges (Fig. 1).[2-6] If each skeletal atom was to participate in three skeletal bonds (a condition that must be met if each skeletal atom is to use all four of its valence shell orbitals) then the $(n+1)$ skeletal bond pairs would have to be allocated to three 2c2e edge bonds and $(n-2)$ 3c2e face bonds.[4,7,8] However, none of the polyhedra in Fig. 1 has the appropriate symmetry to allow such a combination of 2c2e and 3c2e bonds to be allocated in a unique manner to match the skeletal symmetry. In each case, a relatively large number of resonance canonical forms has to be considered (e.g. 24 in the case of $B_6H_6^{2-}$, 10 in the case of $B_7H_7^{2-}$) any one of which gives a distorted picture of the actual electron distribution.[9,10] The average number of electrons associated with each type of polyhedron edge is difficult to deduce from such bond schemes, which are therefore rarely used for *closo* clusters, even though 2c2e BH and BB bonds and 3c2e BHB and BBB bonds have been found to be extremely helpful for describing the bonding in *nido* and *arachno* boranes B_nH_{n+4} and B_nH_{n+6} ever since Lipscomb developed his elegant topological treatment of borane bonding a quarter century ago.[7,11]

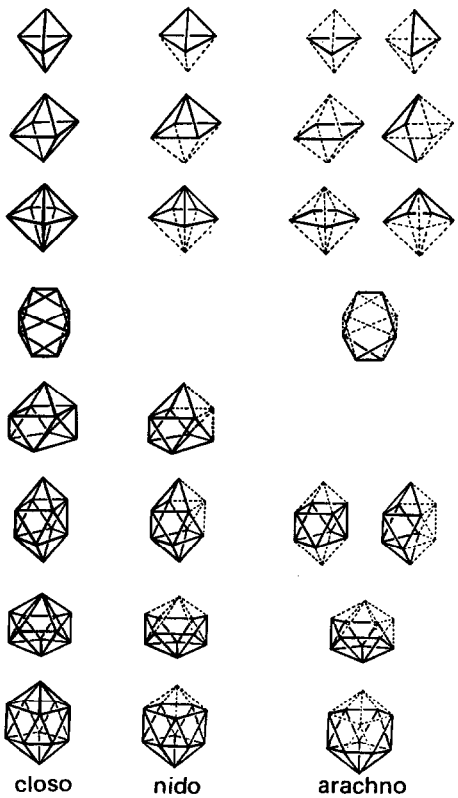

Fig. 1. The deltahedral skeletal structures of *closo* borane anions $B_nH_n^{2-}$ and isoelectronic carboranes $C_2B_{n-2}H_n$, and polyhedral fragment structures of *nido* species $B_{n-1}H_{n+3}$ and *arachno* species $B_{n-2}H_{n+4}$.

Because of the complexity of 2- and 3-centre bond schemes for *closo* borane anions $B_nH_n^{2-}$ and related clusters, it is usual to treat their skeletal bonding in terms of molecular orbital schemes that delocalize the electrons over the whole molecular skeleton.[6,12,13] Such schemes help one understand the numbers of electrons needed, but (like the 2c2e and 3c2e bond schemes) convey little feeling for the electron distribution or the numbers of electrons associated with individual polyhedron edges. It is to overcome this problem that we put forward in this paper a predominantly *localized* electron pair scheme for *closo* clusters that associates a skeletal bond pair with each polyhedron *vertex* as outlined below. This scheme, which we refer to as a "Vertex Electron Pair Scheme" (VEPS), not only conveys a feeling for the electron distribution in deltahedral (*closo*) clusters, but also allows the electron distribution in polyhedral fragment (*nido* and *arachno*) clusters to be deduced easily, reproducing quite well the electron distribution deduced from MO calculations on such clusters. Moreover, it underlines the relationship between *closo* clusters like $B_6H_6^{2-}$ or $B_7H_7^{2-}$ and *arachno* aromatic ring systems like $C_4H_4^{2-}$ or $C_5H_5^-$ respectively.

THE VERTEX ELECTRON PAIR SCHEME (VEPS)

Our approach exploits the fundamental feature of *closo* borane anions $B_nH_n^{2-}$, that each of the n BH units contributes two electrons for skeletal bonding. Since in the cluster it shares these with similar BH units, it is reasonable to suppose that the overall distribution of skeletal electron density over the surface of the polyhedron still leaves each boron atom's share as effectively two electrons centred on the boron nucleus and so on the polyhedron vertex. (Actually, for clusters with more than one type of vertex, the atoms at vertices of low connectivity end up with a slightly greater share—a small fraction of an electron charge—of the skeletal electrons than those at vertices of high connec-

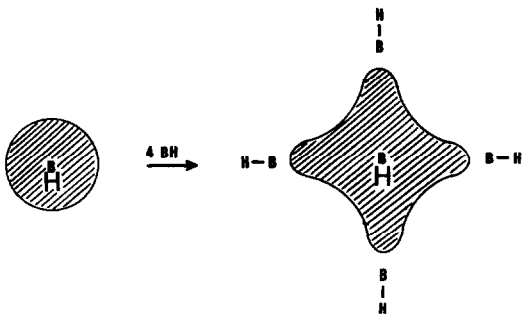

Fig. 2. Polarization of a BH unit's skeletal electron pair by four neighbouring skeletal boron atoms.

tivity.[2,4,9,13,14]) Compared to an isolated BH unit, with its available skeletal electron pair cylindrically symmetrically disposed about the B—H axis, the skeletal pair associated with a BH unit in a cluster will become polarized under the attractive influence of the neighbouring boron nuclei (Fig. 2).

In addition to retaining effective control over two skeletal electrons, each BH unit in a fully symmetrical *closo* cluster anion $B_nH_n^{2-}$ will also acquire a supplementary electronic charge of $-2/n$, that being its share of the extra, $(n+1)$th skeletal electron pair.

This is illustrated schematically in Fig. 3 for

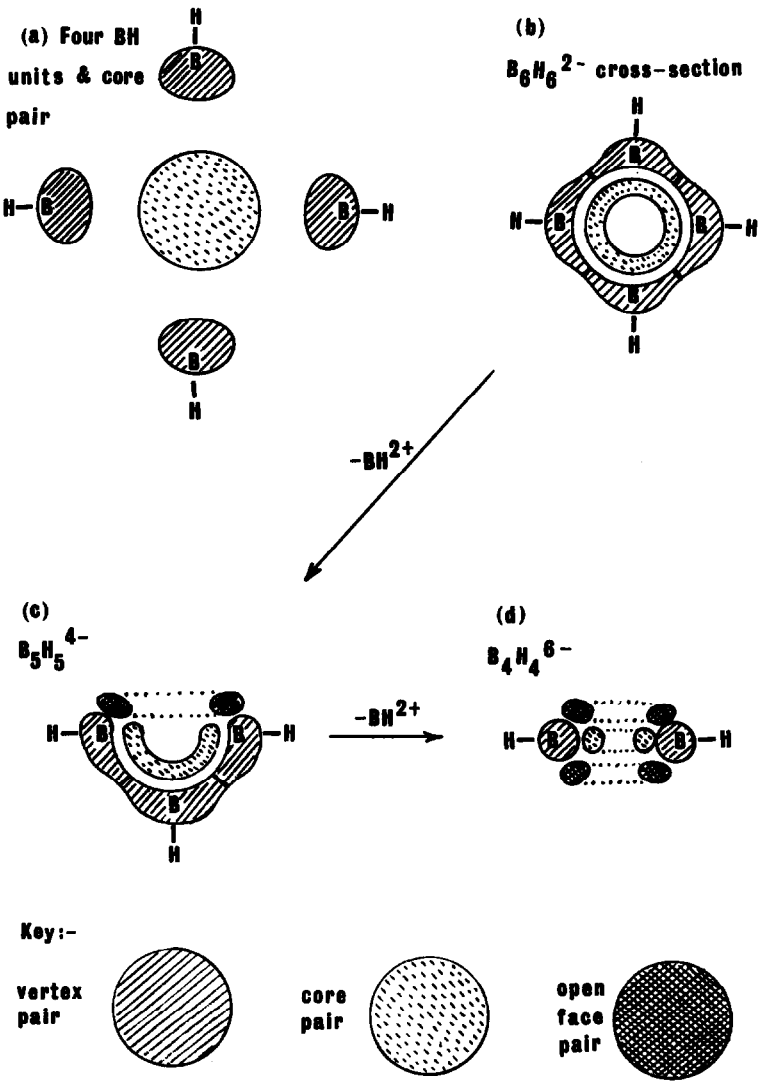

Fig. 3. Distribution of the skeletal electron pairs in O_h $B_6H_6^{2-}$ (illustrated as a cross-section in a B_4 plane) and in the *nido* C_{4v} $B_5H_5^{4-}$ and *arachno* D_{4h} $B_4H_4^{6-}$ derivable therefrom by successive removal of two BH^{2+} units. (a) Four BH units and core-centred pair in exploded form. (b) Cross-section of O_h $B_6H_6^{2-}$ in a B_4 plane. (c) Cross-section of C_{4v} $B_5H_5^{4-}$ in a B_3 plane. (d) Cross-section of D_{4h} $B_4H_4^{6-}$ in a B_2 plane.

$B_6H_6^{2-}$. Figure 3(a) shows a cross-section of this octahedral cluster in exploded form, with four BH units, each contributing a pair of electrons for skeletal bonding, surrounding the extra, $(n+1)$th pair of electrons. When these BH units are brought together [Fig. 3(b)] to the interatomic distances appropriate for $B_6H_6^{2-}$, there are two major consequences for the skeletal electron pairs. Those associated with the BH units acquire the C_{4v} distortion already referred to (Fig. 2), as they are attracted towards adjacent nuclei, while the $(n+1)$th electron pair, which initially may be considered to lie at the cluster centre, spreads out to form an octahedrally distorted spherical shell of electronic charge just inside the sphere on which the boron nuclei lie.

Such a distribution of the skeletal electron pairs, responding to the attractions of the boron nuclei, conveys (in essentially localized electron pair terms) the electron distribution implicit in molecular orbital treatments of *closo* clusters.[7,12-15] Invariably, there is a unique, strongly bonding MO of A symmetry (S^{σ}-type in A. J. Stone's nomenclature[16-18]) resulting from a fully in-phase combination of inward-pointing *sp* hybrid orbitals. This molecular orbital concentrates electronic charge in a roughly spherical shell just inside the sphere on which the boron atoms lie. It is this orbital which is represented by the unique, $(n+1)$th (delocalized) electron pair in our treatment, centred on the middle of the cluster but concentrated near to the boron nuclei. The remaining n bonding MO's all arise primarily from interactions of tangentially oriented p AO's that concentrate electron density on the roughly spherical surface of the polyhedron (illustrated for $B_6H_6^{2-}$ in Fig. 4).[15]

POLYHEDRON EDGE BOND ORDERS

The approach we have outlined can be used to calculate the fractional bond orders of the B—B polyhedron edge bonds of *closo* borane anions $B_nH_n^{2-}$ and related clusters very simply. If each BH unit is allocated $(2+2/n)$ electrons as its share of the $(n+1)$ skeletal electron pairs and it shares these equally between the k 2-centre links it forms to neighbouring boron atoms (where k is the skeletal connectivity—the number of polyhedron edges radiating from the vertex in question), then a polyhedron edge linking two boron atoms of skeletal connectivities k_1 and k_2 can be allocated $(2+2/n)(1/k_1+1/k_2)$, i.e. $2(n+1)(k_1+k_2)/nk_1k_2$ electrons and so has a bond order, $\bar{n}$, of $(n+1)(k_1+k_2)/nk_1k_2$. For octahedral $B_6H_6^{2-}$, for which $n=6$, $k_1=k_2=4$, all edges have formal bond order $7/12=0.58$. For pentagonal bipyramidal $B_7H_7^{2-}$, for which $n=7$, $k_1=4$, $k_2=5$, the axial–equatorial edges have formal bond order of 18/35, i.e. 0.51, while the equatorial edges have a bond order of 4/7, i.e. 0.57. These and other bond orders, $\bar{n}_{VEPS}$, calculated similarly for the various types of edge in *closo* borane anions $B_nH_n^{2-}$ ($n=5$–12) are listed in Table 1, together with the edge lengths L. For comparison, Table 1 also lists some relevant data taken from Refs 10 and 19. These include bond indices I calculated by the Molecular Orbital Bond Index (MOBI) method,[20] and bond orders estimated by two other methods, (i) $\bar{n}_L$, edge bond orders calculated directly from their known lengths L and (ii) $\bar{n}_{2c3c}$, bond orders deduced from the distributions of 2- and 3-centre bonds compatible with their topologies. In comparing them, one should note that the calculated bond indices I integrate to values that *exceed* the numbers of skeletal electron pairs, whereas $\Sigma\bar{n}_{VEPS}$ and $\Sigma\bar{n}_{2c3c}$ equal the numbers of skeletal bond pairs, $(n+1)$. The values of $\bar{n}_{VEPS}$ in Table 1 provide an encouragingly reliable guide to the way the edge bonds vary in strength (and so in length) in these *closo* clusters, though necessarily failing to discriminate between bonds of identical connectivity type that occupy non-equivalent sites (as in the cases of $B_8H_8^{2-}$, $B_9H_9^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{11}H_{11}^{2-}$). However, the values of $\bar{n}_{VEPS}$ underestimate the *extent* to which bonds vary in strength with connectivity, for the reason

[a] Calculated values[19]: these and other values of L, I, $\bar{n}_L$ and $\bar{n}_{2c3c}$ are taken from Refs 10 and 19. Bond orders $\bar{n}_L$ were calculated from bond lengths L[19]; bond orders $\bar{n}_{2c3c}$ were calculated from 2c- and 3c-electron pair bond schemes.[10]

noted above—that the atoms of lower connectivity attract a slightly greater share of the skeletal electronic charge.

NIDO AND *ARACHNO* SPECIES

It is possible to extend our approach to *nido* or *arachno* clusters with shapes that are clearly fragments of the same series of polyhedra as the *closo* boranes. *Nido* boranes B_nH_{n+4} are formally protonated derivatives of hypothetical anions $B_nH_n^{4-}$ whose polyhedral fragment structures (Fig. 1) resemble those of *closo* species $B_{n+1}H_{n+1}^{2-}$, but with one vertex (normally that of highest skeletal connectivity) left vacant. The *nido* anion $B_nH_n^{4-}$ can thus be generated in principle by removal of a BH^{2+} unit from a highly-connected vertex of a parent *closo* species $B_{n+1}H_{n+1}^{2-}$. Figure 3(c) illustrates the consequence of this for the skeletal electrons. The electrons originally associated with the vertex from which BH^{2+} is removed, losing their electrostatic attraction to that vertex, spread out towards the neighbouring nuclei. The core-centred delocalized skeletal pair also moves away from the vacant vertex. The effect of these shifts in the electron distribution is to build up electron density around the open face, with only a marginal increase in electron density elsewhere. Again, this is consistent with the picture conveyed by MO calculations: typically, the HOMO of *nido* clusters concentrates electronic charge around the open face,[2,7,12,16–18,21–26] making this region most suitable for protonation in generating neutral species B_nH_{n+4}. The high connectivity of the vertex vacated is also intelligible in that the ring of electronic charge generated will be stabilized increasingly with the number of nuclei around the open face.

Similar arguments apply to *arachno* clusters B_nH_{n+6} whose skeletal anions $B_nH_n^{6-}$ have shapes formally derivable from *closo* parents $B_{n+2}H_{n+2}^{2-}$ by removal of two BH^{2+} units. Figure 2(d) illustrates this for the removal of a second BH^{2+} unit from a vertex opposite the first vacated. Again, the electron pair originally assigned to the vertex vacated spreads out to form a ring of charge adjacent to the neighbouring nuclei and the core-centred, delocalized skeletal pair likewise relaxes towards those nuclei.

The *arachno* $B_4H_4^{6-}$ species depicted schematically as the end product of these successive removals of two BH^{2+} units from $B_6H_6^{2-}$ is a square planar species, analogous to the cyclobutadiene dianion, $C_4H_4^{2-}$. The rings of electronic charge generated, above and below the plane of the four boron atoms, correspond directly to the electron distribution arising from the doubly degenerate HOMO of a species like $C_4H_4^{2-}$. Similar removal of the axial BH^{2+} units from a pentagonal bipyramidal *closo* parent $B_7H_7^{2-}$ would generate an *arachno* pentagonal species $B_5H_5^{6-}$ (cf. the isoelectronic cyclopentadienide anion $C_5H_5^-$). Again, the electron distribution in rings above and below the $B_5H_5^{6-}$ plane reproduces exactly that appropriate for the doubly degenerate HOMO of an aromatic ring system like $C_5H_5^-$.

The cyclic *arachno* species $B_4H_4^{6-}$ and $B_5H_5^{6-}$ just considered, derived from parent *closo* species $B_6H_6^{2-}$ and $B_7H_7^{2-}$ respectively by removal of two BH^{2+} units from opposite vertices, would clearly be more stable entities than hypothetical alternatives in which the BH^{2+} units were removed from adjacent vertices, since the stabilization of the electron pairs associated with the open face would involve fewer boron nuclei and so be less in the latter case. Indeed, the approach outlined here leads to the prediction that, for *arachno* species in general, the most stable isomer will be that in which *non*-adjacent, high connectivity vertices will be left vacant. Among known

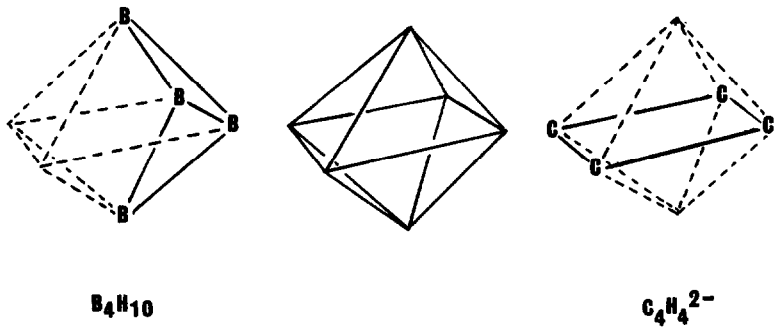

Fig. 5. Alternative skeletal shapes possible for *arachno* species based on an octahedron.

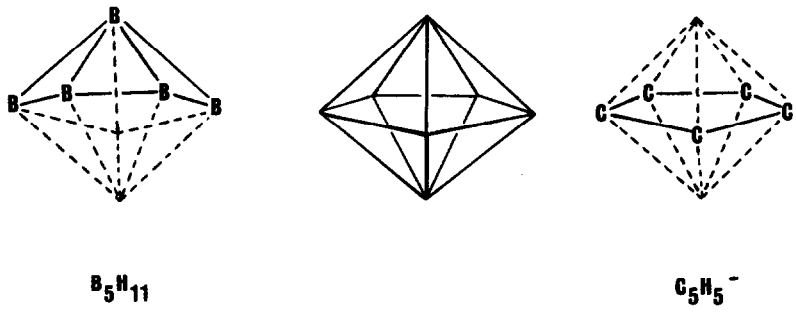

Fig. 6. Alternative skeletal shapes possible for *arachno* species based on a pentagonal bipyramid.

arachno boranes, B_nH_{n+6}, however, the preferred isomer is one that leaves adjacent vertices vacant. Tetraborane(10) B_4H_{10}, for example, has a butterfly-shaped arrangement of its four skeletal boron atoms (Fig. 5) (contrast the square planar shape expected for $C_4H_4^{2-}$) while pentaborane(11), B_5H_{11}, has the nonplanar tent-like shape shown in Fig. 6 (contrast planar $C_5H_5^-$). We shall show elsewhere[26] that EHMO calculations support the qualitative conclusions drawn here, that the more stable skeleton is that with non-adjacent vacant vertices, but that the extra six hydrogen nuclei that *arachno* boranes need to convert their $B_nH_n^{6-}$ frameworks into neutral molecules B_nH_{n+6} are better accommodated if that framework has adjacent *vacant* vertices.

Acknowledgement—The approach outlined here evolved during the tenure of visiting professorial appointments by WWP at Durham and by KW at McMaster. Financial support from the Mednick (WWP) and Hooker (KW) Foundations is gratefully acknowledged.

CHEMICAL BEHAVIOUR OF *o,o'*-DIAMINOAZOBENZENE. SPECTROPHOTOMETRIC DETERMINATION OF Pd(II)

L. VICH, J. M. ESTELA* and V. CERDÁ

(*Received* 3 *June* 1987; *accepted* 24 *June* 1987)

Abstract—A study of several physicochemical and analytical properties of *o,o'*-diaminoazobenzene (DAB) is reported and its chemical behaviour discussed from the point of view of Pearson's theory. DAB has been applied to the determination of palladium by means of a new extractocolorimetric method.

The azocompounds, mainly those derived from benzene and naphthalene, are widely used as analytical reagents.[1–5] Their importance both theoretical and practical, is based on their complexing reactions. The great influence of the donor atoms that are present as substituents in the *ortho* position to the azo group is well known. Among these substituents are the phenolic, carboxyl, amino groups or a heteroatom of the ring, such as nitrogen or sulphur, in the *ortho* position. The azo group also acts as a donor when chelate compounds are formed.

Redox reactions take place in the case of several ions. Thus, with Cr^{2+}, V^{2+} and Ti^{3+} a reduction to the colourless *leuco*form is produced; whereas with dichromate, permanganate, VO_2^+, Fe^{3+} and Tl^{3+} there is an oxidation to *o*- or *p*-quinones under analogous conditions.

Some azo dyes yield, in basic media, adsorption or coprecipitation of coloured chelates on metallic hydroxides whose mechanisms are not well known. These reactions, that can be initially interpreted through adsorption phenomena, in diluted solutions give stoichiometric compounds or coloidal solutions.

One of the main difficulties in the determination of the complexation constants and also in the acid–base dissociation study, is the possibility of aggregation, (usually dimerization), which can easily be produced for concentrations of about 10^{-3} M.[6]

Great efforts were made in order to establish the laws of chemical behaviour of chelates, mainly by Irving and Williams and more recently by Pearson with the theory of hard and soft acids and bases.

A bibliographic review shows that azo compounds with substituents decreasing the basic strength of the ligand have been scarcely studied. Therefore we chose *o,o'*-diaminoazobenzene as an analytical reagent in order to determine its behaviour with metallic ions.

Following Pearson's theory, a decrease of stability is expected for alkaline, alkaline-earth and lanthanide elements, whereas more stable comlexes with divalent transition and platinum family elements will probably be formed.

EXPERIMENTAL

Reagents

o,o'-Diaminoazobenzene was synthesized using the following procedure.† 10.8 g of *o*-phenylendiamine and 4.3 g of methyltrioctylammonium chloride were placed in a round-bottomed flask; 100 cm^3 of benzene and 100 cm^3 aqueous solution

* Author to whom correspondence should be addressed.

† We acknowledge Prof. Mendoza of the Department of Organic Chemistry of the University Autonoma of Madrid for providing the product to initiate this research.

of 50% NaOH added, the mixture was refluxed for 96 h at 60°C. The black precipitate formed was purified by column chromatography using a mixture of benzene and chloroform. A red compound was isolated with a yield of 47%. M.p. 133°C.

Purity of DAB was controlled by thin layer chromatography using several solvents (*Rf* in silicagel 60 F_{254} Merck 0.2 mm : 0.18 chloroform, 0.18 benzene, 0.22 chloroform–benzene 1 : 1, 0.68 chloroform–methanol 9 : 1, 0.75 methanol–water 8 : 2, 0.77 ether, 0.83 methanol, 0.89 ethylacetate). Only one spot was observed. All other chemicals were of analytical grade.

Apparatus

Beckman ACTA CIII spectrophotometer with 1 cm quartz cells. Digital 112 Corning potentiometer with Corning 476051 glass and AgCl/Ag reference electrodes.

Extracto-colorimetric procedure for Pd(II) determination

Place a sample volume in a 100 cm^3 separatory funnel (0.5–5 ppm concentration range) and add 1 cm^3 of DAB 2.8 10^{-3} M in ethanol, 10 cm^3 of Prideaux buffer[7] and deionized water to a final volume of 20 cm^3. Extraction with 10 cm^3 of isoamyl alcohol is performed by shaking for 5 min. Let it settle for 5 min and filter the organic phase through a filter paper. Absorbance is measured at 585 nm using isoamyl alcohol as reference.

Palladium in 5% palladized active carbon determination procedure

Treat 0.1490 g of the sample first with aqua regia, then with HNO_3–H_2SO_4 mixture. Evaporate to dryness and dissolve with diluted HCl. Adjust to pH 2, transfer to a 250 cm^3 flask and dilute with deionized water to the mark. Continue as stated in the extracto-colorimetric proposed method.

RESULTS AND DISCUSSION

Physicochemical properties

Solubilities of DAB in several solvents were determined using the Wittemberg method.[8] This compound is scarcely soluble in water (0.066%), more in alcohols (0.94% isoamylic, 2.50% ethanol and 3.76% methanol) and soluble in MIBK (13.9%). The spectral behaviour of the compound obtained agreed with that expected for DAB (IR: 3460 cm^{-1} NH_2 asym., 3340 NH_2 sym., 3060–3025 C—H ar., 1600 NH_2 bend, 1480–1460 Ø, 1330–1315 N—Ø, 1260–1225 C—H rock, 1140 NH_2 rock, 860 NH_2 twist, 755–745 4H adj. wag.; ^{1}H NMR in $CDCl_3$: 4.20–4.80 ppm NH_2broad, 6.66–6.87 *m* 4H (H_3H_5), 7.17 *d d d* J = 7.5, 7.4 and 1.6 Hz(H_4), 7.68 *d d* 2H J = 8.2, 1.5 Hz (H_6)). UV-visible spectra of DAB were run for several pH values (Fig. 1) in a 50% methanol–water mixture. There is only one maximum in the visible zone: λ_{max} = 440 nm in neutral (ε = 8100) and 0.1 M NaOH media (ε = 7000) and stable for at least 60 min in neutral medium, 24 h, 0.1 M HCl and unstable in 0.1 M NaOH.

Acid-base equilibria

Dissociation constants of DAB were potentiometrically determined. Electrode calibration was performed by the Gran method, titrating HCl with NaOH[9–11] in water at 25.0±0.1°C and I = 0.1 M KCl. Resulting values were refined by means of the MINIPOT program,[12] which allowed us to obtain several parameters necessary for further calculations (pK_w = 13.783±0.001, log j_H = 0.00, log j_{OH} = 0.90, E^0 = 362.95±0.05 mV, g = 59.157, U = 1.60 mV^2, s = 0.22 mV.

DAB was then dissolved in HCl, which also was used to calibrate (*in situ*) the electrodes, and then titrated with NaOH in analogous conditions. Only one constant could be observed. The data resulting from the potentiometric titration were refined by means of the MINIPOT program, which only accepted one protonation constant, log β = 3.24±0.02, E^0 = 362.2±0.1 mV, U = 3.41 mV^2 and s = 0.3 mV.

Reactionability

The analytical behaviour of DAB in 1% ethanol was studied using 59 inorganic ions (1 g l^{-1}) at different pH values: HCl, AcOH, NH_3, NaOH (2N) and neutral media. Positive tests were repeated in the presence of masking agents: fluoride, cyanide, tartrate and EDTA; and extractants: ether, chloroform, toluene, isoamyl alcohol and MIBK both without and with trioctylmethylammonium chloride 5 g l^{-1} which in some cases, enabled extractable ion-pair formation. Results are summarized in Tables 1 and 2, showing that DAB reacts with 16 of the 59 ions. Therefore selectivity is quite good in acid media, sensitivities proved to be high, with p*D*s values ranging between 4–6, the follow-

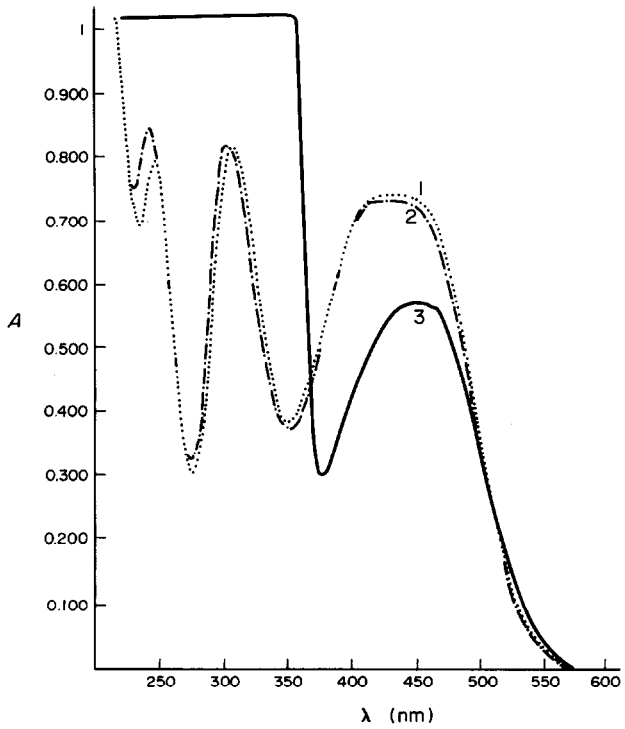

Fig. 1. pH influence on the spectra of DAB (50% MeOH/H_2O): (1) neutral, [DAB] = 9×10^{-5} M; (2) NaOH 0.1 M, [DAB] = 1.04×10^{-4} M; (3) HCl 0.1 M, [DAB] = 2.16×10^{-4} M.

ing giving the greatest: Cu(II), Au(III), Co(II), Fe(III), Pd(II), Ni(II) and Hg(II).

As was initially expected, a shift of the ligand properties to a softer basic behaviour, reacting especially with soft acids, takes place on substituting OH groups by $-NH_2$ in the azocompounds. The use of extractants and/or maskings increases both selectivity and sensibility, effects which have been exploited in further experiments.

Qualitative applications

From the reactionability table, two qualitative tests can be proposed:

(1) *Procedure for* Pd(II) *identification.* Place 0.5 cm^3 of the sample in a test tube (previously neutralized if it is basic), add 0.5 cm^3 of HCl(2N), 0.5 cm^3 of DAB (1% in ethanol) and shake. A violet precipitate shows the presence of Pd(II) ($pD = 4.6$). This sensitivity can be increased to $pD = 6.0$ by means of extraction with isoamyl alcohol. This test is specific.

(2) *Procedure for* Mg(II) *identification.* Place 0.5 cm^3 of neutral sample in a test tube, add 0.5 cm^3 of DAB (1% in ethanol), 0.5 cm^3 of NH_3(2N) and shake. An orange precipitate is produced in presence of Mg(II) ($pD = 5$). In presence of CN^- only Pd(II) interferes.

Quantitative applications

Extracto-colorimetric determination of Pd(II). Both selectivity of the qualitative test and the increase of the sensibility of the extraction procedure, encouraged us to develop a new method for Pd(II) determination. Influence of pH has been studied by using the Prideaux buffer.[7] For different pH values the corresponding spectra of DAB and its Pd(II) complexes can be observed in Fig. 2. Since maxima differences were observed at pH 2 for an analytical wavelength of 585 nm, these values were selected for further experiments. The absorbance of the complex is constant if the molar ratio of DAB to Pd is greater than 2:1. A 1.4×10^{-4} M concentration of DAB was selected. Best results were obtained for an addition order of Pd(II)–DAB–buffer. Although 5 min shaking time was chosen it

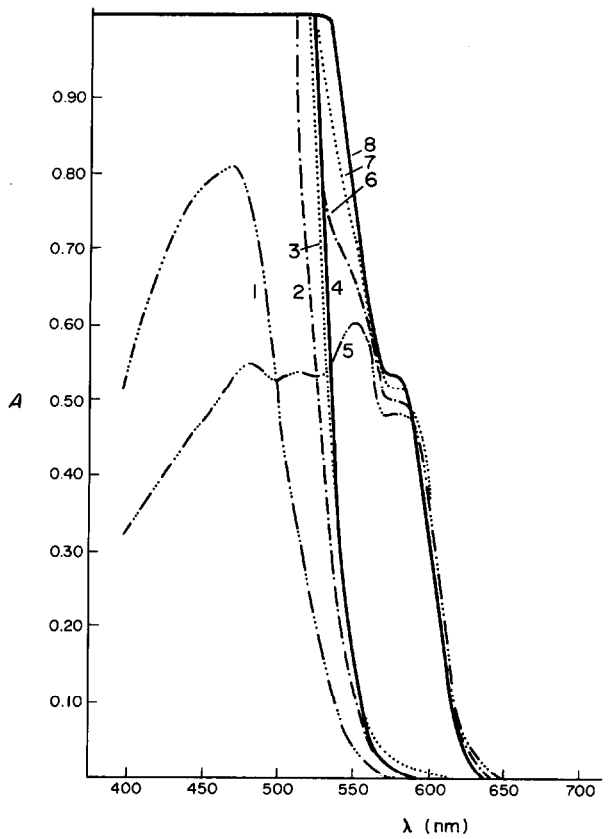

Fig. 2. pH influence on the spectra of DAB and its Pd(II) complex extracted with isoamilic alcohol. [DAB] = 27.8×10^{-5} M; [Pd(II)] = 2.8×10^{-5} M. Curves 1, 2, 3 and 4: DAB reagent at pH 2.1, 3.2, 4.0 and 5.1. Curves 5, 6, 7 and 8: DAB-Pd(II) complex at pH 2.1, 3.2, 4.0 and 5.1.

had no influence on the absorbance values. The absorbance of the extracted complex is constant for at least 90 min.

Stoichiometry of the complex was determined by Job's method, giving 1 : 1 with a molar absorptivity of 16625 l mol^{-1} cm^{-1}. The Lambert–Beer's law is obeyed in the 0.5–5 ppm Pd(II) concentration range, the Ringbom minimum error zone being between 1–5 ppm, where the relative error is 3.3%. Statistical values ($n = 11$, 95% confidence level) were determined with a 3 ppm Pd(II) content; standard deviation 5.83×10^{-3}, average standard deviation 0.0017, C.V. $= \sigma \times 100/x_m = 0.18\%$, $E = \pm t \times \sigma \times 100/x_m = \pm 0.18\%$.

Table 3. Tolerance of different ions in Pd(II) (3 ppm) determination for a 5% photometric error

Ion	Tolerance (ppm)
Au(III)	12
Fe(III)	12
V(V)	25
Hg(II)	100
Cu(II)	12
Co(II)	50
BrO_3^-	100
CrO_4^-	12
NO_2^-	0.75
Tartrate	100
EDTA	100
F^-	100
CN^-	1

In Table 3 the effect of different ions on Pd(II) determination can be observed. Concentrations producing a 5% photometric error are also indicated, 100 ppm was the maximum quantity tested. EDTA, tartrate and fluoride can be used as masking agents.

Palladium in a 5% palladized active carbon was determined by the proposed extracto-colorimetric procedure, using both the standard addition and the calibration curve methods. Results were of 4%, which agree with those of A. A. spectrophotometry.

SPECTROPHOTOMETRIC STUDY OF COMPLEXATION EQUILIBRIA BETWEEN $HCrO_4^-$ AND Cl^- IONS

N. MIRALLES,* A. SASTRE and M. AGUILAR

Departament de Química, Escola Tècnica Superior d'Enginyers Industrials de Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 8 *June* 1987; *accepted* 24 *June* 1987)

Abstract—The complex equilibria between $HCrO_4^-$ and Cl^- ions has been studied spectrophotometrically at a constant ionic strength of 3.0 mol dm^{-3} and the data have been analyzed both graphically and numerically by means of the program LETAGROP-SPEFO (L. G. Sillen and B. Warnquist, *Arkiv. kemi.* 1968, **31**, 377). The experimental results can be explained on the basis of the following reaction:

$$HCrO_4^- + H^+ + Cl^- = CrO_3Cl^- + H_2O \qquad (\log\beta_{11} = 1.37 \pm 0.08).$$

Molar absorptivities of $HCrO_4^-$ and CrO_3Cl^- were also reported.

Preliminary studies on the extraction of chromium(VI) with long chain amines[2] have shown that the distribution of the metal between the aqueous and the organic phase depends principally on the nature of the ionic medium used in the aqueous phase.

When hydrochrloric acid is used the extraction of chromium(VI) is much higher than with other mineral acids,[3–5] probably due to the extraction of the CrO_3Cl^- species. On the other hand, it has been demonstrated that the extraction is higher when the concentration of hydrochloric acid is increased.

The studies by Haight *et al.*,[6] Halloway[7] and Tong and Johnson[8] indicate that the addition of hydrochloric acid, sulphuric acid and phosphoric acid changes the $HCrO_4^-$ absorption spectrum over the range 260–400 nm. It has been assumed that these changes are due to the formation of the species CrO_3Cl^-, $CrSO_7^{2-}$, $H_2CrPO_7^-$ respectively. Dikshitulu *et al.*[9] obtained similar results from kinetic studies of the reduction of chromium(VI) by tellurium(IV). Formation constants of these species were also determined under several experimental conditions.

The present work is a detailed study of formation equilibria of CrO_3Cl^-. This study has been carried out spectrophotometrically at the wavelengths 320, 330 and 340 nm and 25°C. An ionic strength of 3.0 mol dm^{-3} has been utilized which allows a wide variation in chloride concentration.

EXPERIMENTAL

It is known that acid solutions of chromium(VI) in concentration lower than 4×10^{-4} mol dm^{-3} follow the Beer–Lambert law between 320 and 350 nm.[6]

It has been tested experimentally that Beer's law is obeyed in solutions of the following composition: B mol dm^{-3} Cr(VI), 10^{-2} mol dm^{-3} H^+, 3.0 mol dm^{-3} (Na^+, ClO_4^-), where the concentration B of chromium(VI) was kept in the range $1.5\ 10^{-4} \leqslant B \leqslant 7.5\times10^{-4}$ mol dm^{-3}. Values of molar absorptivities ε_{10} for $HCrO_4^-$ were determined from the slope of the straight line obtained by plotting absorbance against chromium(VI) concentration for different wavelengths and these are given in Table 1.

For determining the variation of absorbance as a function of chloride ion concentration, solutions of the following composition were prepared: B mol dm^{-3} Cr(VI), 10^{-2} mol dm^{-3} H^+, C mol dm^{-3} Cl^-, $(3.0-C)$ mol dm^{-3} ClO_4^-, 3.0 mol dm^{-3} Na^+. For each series, the concentration B of chromium(VI) was kept constant and the concentration C was varied between 0 and 3.0 mol dm^{-3}. Values of B were in the range between 2.6×10^{-4} mol dm^{-3}

* Author to whom correspondence should be addressed.

Table 1. Molar absorptivities ε_{10} of $HCrO_4^-$ for different wave lengths

$\lambda = 320$ nm	$\varepsilon_{10} = 817$
$\lambda = 330$ nm	$\varepsilon_{10} = 1156$
$\lambda = 340$ nm	$\varepsilon_{10} = 1466$

and 3.1×10^{-4} mol dm^{-3} for all series. This range allows the neglect of the $Cr_2O_7^{2-}$ and CrO_4^{2-} concentrations.[8]

Reagents and solutions

Sodium perchlorate, Merck p.a., used as ionic medium, was prepared as described previously.[10]

Potassium dichromate, primary standard grade "Baker Analyzed", was dried at 110°C before use. Chromium(VI) solutions were prepared by weighing the appropriate amount of potasium dichromate.

Sodium chloride, Probus, was recrystallized twice in distilled water and the stock solution analyzed using silver nitrate.[11]

Perchloric acid, Merck, p.a. A stock solution of approximate 0.1 mol dm^{-3} was standardized with HgO and NaI.[12]

Equipment

The spectrophotometric measurements were obtained using a visible–UV Perkin–Elmer 554 spectrophotometer, using Hellma K 282/2X 10 × 10 mm cells.

RESULTS AND DISCUSSION

The experimental data have been analyzed both graphically and numerically using the program LETAGROP-SPEFO,[1] in order to determine the formation constant of CrO_3Cl^- as well as the molar absorptivities at different wavelengths.

Graphical treatment

In the experimental conditions employed the following reaction can be assumed:

$$HCrO_4^- + H^+ + Cl^- = CrO_3Cl^- + H_2O \quad (1)$$

with β_{11} being the constant of reaction (1) defined by:

$$\beta_{11} = \frac{[CrO_3Cl^-]}{[H^+][Cl^-][HCrO_4^-]}. \quad (2)$$

Since the hydrogen ion and chloride concentrations were always much higher than chromium(VI) concentrations, it was assumed that the concentration of these species were equal to their stoichiometric concentrations. On the other hand, the chromium concentrations employed were in a region of negligible dimeric species. In such conditions, the absorbance A of the solutions can be written as:

$$A = \varepsilon_{10}[HCrO_4^-] + \varepsilon_{11}[CrO_3Cl^-] \quad (3)$$

where ε_{10} and ε_{11} are the molar absorptivities of $[HCrO_4^-]$ and $[CrO_3Cl^-]$ respectively.

Taking into account eq. (2), the mass balance for chromium(VI) can be written:

$$B = [HCrO_4^-] + [CrO_3Cl^-] = [HCrO_4^-](1 + \beta_{11}[H^+][Cl^-]). \quad (4)$$

By substituting (4) in eq. (3) we obtain:

$$A = \frac{B}{1 + \beta_{11}[H^+][Cl^-]}(\varepsilon_{10} + \varepsilon_{11}\beta_{11}[H^+][Cl^-]). \quad (5)$$

Rearranging eq. (5) it follows:

$$\log\frac{B\varepsilon_{10} - A}{B} \log(\varepsilon_{10} - \varepsilon_{11}) = \log\frac{\beta_{11}[H^+][Cl^-]}{1 + \beta_{11}[H^+][Cl^-]}. \quad (6)$$

Two new variables Y and u can be defined as:

$$Y = \frac{B\varepsilon_{10} - A}{B}\frac{1}{(\varepsilon_{10} - \varepsilon_{11})} \quad (7)$$

$$u = \beta_{11}[H^+][Cl^-]. \quad (8)$$

Substituting eqs (7) and (8) in (6) we get:

$$\log Y = \log\frac{u}{1+u}. \quad (9)$$

By comparison of the experimental data plotted as $\log(B\varepsilon_{10} - A)/B$ vs $\log[Cl^-]$ with the theoretical function $\log Y$ vs $\log u$, the values of β_{11} and ε_{11} can be obtained by reading off the differences:

$$\log\frac{B\varepsilon_{10} - A}{B} - \log Y = \log(\varepsilon_{10} - \varepsilon_{11}) \quad (10)$$

$$\log u - \log[Cl^-] + pH = \log\beta_{11} \quad (11)$$

in the position of the best adjust.

The experimental results as well as the theoretical function $\log Y$ vs $\log u$ in the position of the best adjust are plotted in Figs 1–3 for different wavelengths. Values of β_{11} and ε_{11} are given in Table 2.

Numerical treatment

A refinement of the values of β_{11} and ε_{11} was performed using a version of the general minimizing

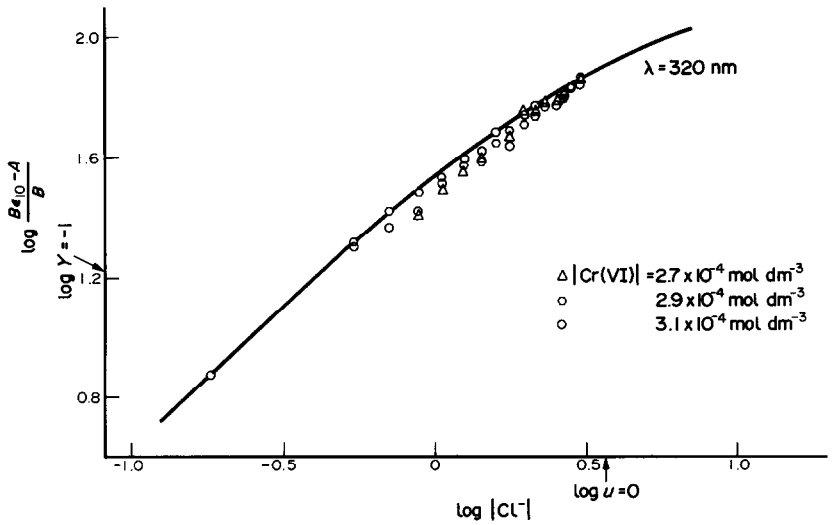

Fig. 1. $-\log(B\varepsilon_{10}-A)/B$ plotted vs $\log[Cl^-]$ at $\lambda = 320$ nm for different chromium(VI) concentration. The full drawn line gives $\log Y$ as a function of $\log u$ in the position of the best adjust.

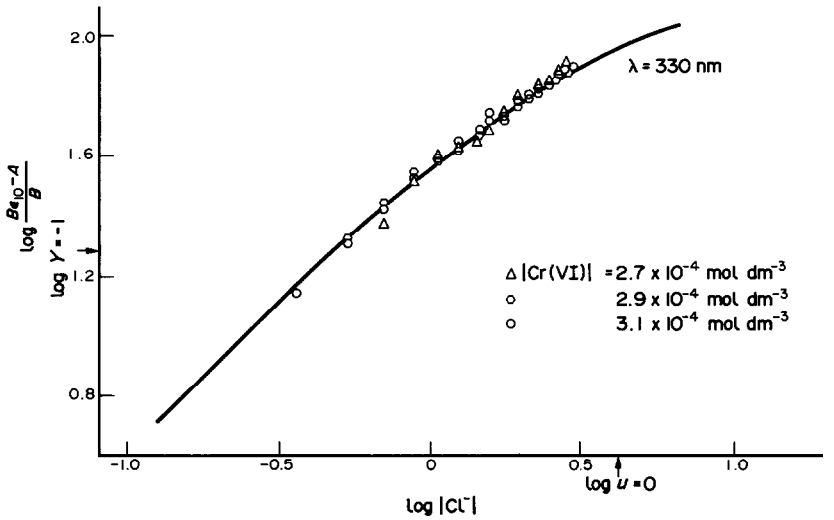

Fig. 2. $-\log(B\varepsilon_{10}-A)/B$ plotted vs $\log[Cl^-]$ at $\lambda = 330$ nm for different chromium(VI) concentration. The full drawn line gives $\log Y$ as a function of $\log u$ in the position of the best adjust.

Table 2. Values of β_{11} and the molar absorptivities ε_{10} and ε_{11} found graphically and numerically

	$\log\beta_{11}$	ε_{10}	ε_{11}	Method

$\log\beta_{11} = 1.37\pm0.08$.

program LETAGROP,[13] especially adapted to the treatment of spectrophotometric data LETAGROP-SPEFO.[1]

As input, experimental data of absorbance at different wavelength, concentrations of chromium(VI) and values of β_{11}, ε_{10} and ε_{11} calculated graphically, were given. The program searches for the best set of constants that would minimize the error square sum defined by

$$U = \sum(A_{calc}-A_{exp})^2 \qquad (12)$$

where A_{exp} is the value of absorbance measured

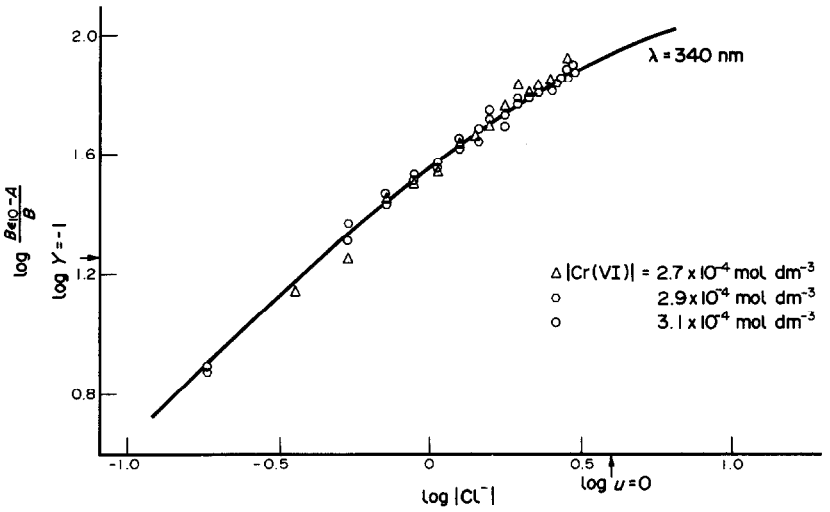

Fig. 3. $-\log(B\varepsilon_{10}-A)/B$ plotted vs $\log[Cl^-]$ at $\lambda = 340$ nm for different chromium(VI) concentration. The full drawn line gives $\log Y$ as a function of $\log u$ in the position of the best adjust.

experimentally and A_{calc} is the calculated A obtained assuming a set of complexes and their formation constants. The program also calculates the standard deviation $\sigma(A)$ defined by:

$$\sigma(A) = \left[\frac{\sum (A_{calc}-A_{exp})^2}{N_p}\right]^{1/2} \qquad (13)$$

where N_p are the number of experimental points.

The fit of the data is illustrated in Fig. 5, where $A_{calc}-A_{exp}$ has been plotted against $[Cl^-]$.

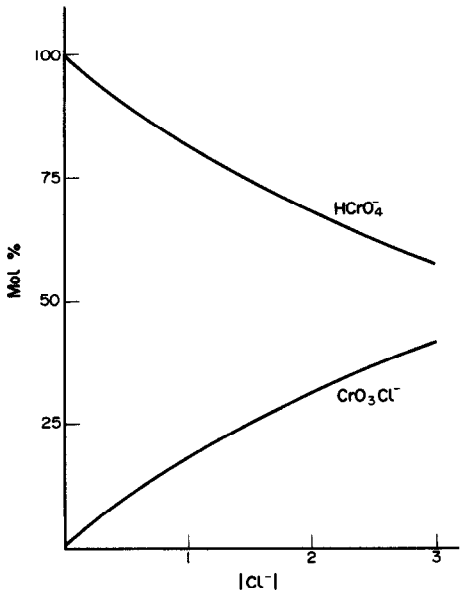

Fig. 4. The mol percent of the different chromium(VI) species as a function of the chloride concentration.

In Table 2 the value of $\log\beta_{11}$, ε_{10} and ε_{11} are given for different methods. It is seen from this table, that normalized curves and least-square methods give, practically the same constants.

The calculations give a value of $\log\beta_{11} = 1.37$. This value could be corrected to 1.0 mol dm^{-3} ionic strength to be compared with the values found in the literature. The activity coefficients γ could be calculated using the extended Debye–Hückel equation[15]

$$\log\gamma = \frac{-z^2 0.511\sqrt{I}}{1+1.5\sqrt{I}} + 0.102z^2 I \qquad (14)$$

where I is the ionic strength and z is the charge of the ion.

From these calculations, it was found that $\log\beta_{11} = 1.04$. As seen the value of the formation constant obtained seems to agree with those found in the literature (Table 3).

REACTION ENTROPY FOR THE ELECTROREDUCTION OF BIS(BIPHENYL)CHROMIUM(I) IN DIFFERENT SOLVENTS

JAN S. JAWORSKI

Department of Chemistry, University of Warsaw, 1 Pasteur Street, 02-093 Warszawa, Poland

(*Received* 27 *April* 1987; *accepted* 29 *June* 1987)

Abstract—The reaction entropy, ΔS_r°, for the electroreduction of bis(biphenyl)chromium(I) has been measured in eight solvents using a non-isothermal cell arrangement. A correlation between the solvent acceptor number and the ΔS_r° values has been observed. The measured reaction entropies are higher than those for ferrocene/ferricenium ion and bis(benzene)chromium(0)/bis(benzene)chromium(I) couples.

The electrochemical reaction entropy, ΔS_r°, i.e. the entropy difference between the reduced and oxidized forms of a redox couple can be obtained from the temperature dependence of the electrode potential using a non-isothermal cell.[1] The ΔS_r° values are suitable for detailed examination of ionic solvation as well as electron-transfer processes and thus, they were reported for numerous transition-metal redox couples and many earlier results were discussed by Hupp and Weaver.[2] Among sandwich complexes the reaction entropy in a variety of solvents was measured only for the two couples: ferrocene/ferricenium ion, Fc/Fc^+,[3] and its derivative.[4] Recently, some entropy data for other metallocenes and bis(benzene)chromium(0)/bis(benzene)chromium(I) couple were also reported.[5] In the same solvent the obtained values were similar, in full agreement with the empirical prediction[2] for redox couples with identical charge numbers and similar radii.

It is interesting to investigate electrochemical reaction entropies for bis(biphenyl)chromium(0)/bis(biphenyl)chromium(I), BCr/BCr^+, for the sake of a possibility to examine the influence of reactant size as well as for a comparison with reaction entropies for Fc/Fc^+, because these two couples have been recently recommended as reference redox systems for the reporting electrode potentials in nonaqueous solvents.[6]

EXPERIMENTAL

Dimethylformamide (DMF), dimethylsulphoxide (DMSO), dimethylacetamide (DMA), propylene carbonate (PC), acetonitrile (ACN) and N-methylformamide (NMF) were purified and dried as described previously.[7–9] Methanol (POCh) (MeOH) and formamide (IE, Windsor) (FA) were purified in a conventional manner.[10] A small amount of NaOH was added to FA to avoid an acidic decomposition of BCr^+ cation. The concentration of bis(biphenyl)chromium tetraphenylborate was 0.5 mM and 0.1 M tetraethylammonium perchlorate (TEAP) was used as the supporting electrolyte.

The reaction entropy was obtained from the temperature dependence of the reversible polarographic half-wave potential using a non-isothermal cell; details have been described previously.[7–9] The reference electrode consisted of a silver wire in a solution containing 0.09 M TEAP and 0.01 M $AgNO_3$ (or $AgClO_4$ in the case of PC) in the solvent of interest,[8] with the exception of measurements in NMF and FA where a silver electrode in ACN was used.

RESULTS AND DISCUSSION

Linear coefficients of temperature variations in the half-wave potentials for the reduction of BCr^+,

$dE_{1/2}/dT$, measured in different solvents and errors determined on the basis of the "Student's" distribution with a confidence level of 0.95 are given in Table 1. The reaction entropies calculated for the one-electron reversible reduction from:

$$\Delta S_r^\circ = F dE_{1/2}/dT \qquad (1)$$

where F denotes Faraday's constant, are positive (Table 1). Similarly, the positive ΔS_r° values were observed[2] for the reduction of other cationic couples due to a greater extent of solvent polarization in the vicinity of an oxidized form with a higher ionic charge.

The inspection of the ΔS_r° values collected in Table 1 indicates that the reaction entropy becomes smaller in protic solvents with molecules associated via hydrogen bonding. The analogous behaviour observed for the Fc/Fc^+ couple[3] and its derivative (*n*-ferrocenemethylene-*p*-toluidine[4]) was rationalized in terms of a significant donor–acceptor interaction between the solvent hydrogens and the cyclopentadienyl rings of the Fc molecule, which has a greater electron density than those of the Fc^+ ion.[3,4] Alternatively, the negative contribution to entropy change arising from the disordering of the original solvent structure by the charged Fc^+ ion was considered.[2,4] The solvent acceptor number, *AN*,[11] was proposed as a measure of both the above effects.[3,4]

Plots of the ΔS_r° values against the solvent acceptor number for BCr/BCr^+ as well as Fc/Fc^+ [3,4] and $(C_6H_6)_2Cr^{0/+}$ [5] couples are shown in Fig. 1. A weighted regression line for BCr/BCr^+ system holds with the correlation coefficient 0.984 and χ^2-test 2.3, which indicates that the deviations from the line are explained completely by experimental errors in the

ΔS_r° values. A similar solvent effect on the reaction entropy for the BCr/BCr^+ and Fc/Fc^+ couples (Fig. 1) is not surprising if one takes into account that differences between the redox potentials for these systems were found[6] to be almost constant in 22 solvents.

On the other hand, in each solvent the highest reaction entropy was found for the largest reactant, BCr/BCr^+. The above result does not agree with the empirical equation proposed by Hupp and Weaver[2] in which the reaction entropy is proportional to the reciprocal of the reactant radius. Differences in the method of the ΔS_r° measurements used in this paper and by Weaver and coworkers are not responsible for that finding. For the oxidation of ferrocene at a dropping mercury electrode in ACN a reaction entropy equal to 47 ± 5 J K^{-1} mol^{-1} has been obtained, in full agreement with Weaver's value of 48 J K^{-1} mol^{-1} determined by cyclic voltammetry and using a different cell and electrodes.[3]

Two alternative explanations for the presented result can be suggested: a difference in short range donor–acceptor interactions with solvent molecules due to a distinct charge distribution on aromatic rings of the considered couples and greater increase in the metal-ring distances during the electroreduction process for the BCr^+/BCr couple. The first possibility corresponds to the observation found[7,12] for systems of organic heteraromatic molecules and their radical-ions, that ΔS_r° values are related to a spin density at a heteroatom in a radical-ion. However, the same number of hyperfine components in ESR spectra of BCr^+ and $(C_6H_6)_2Cr^+$ cations suggests[13] for the former a delocalization of an unpaired electron only on one benzene ring in each biphenyl system. Then, a similar effect of a spin

distribution can be expected for both the considered cations.

Concerning the second possibility it should be added, that a significant contribution to ΔS_r° values proportional to a relative change in the metal–ligand bond distances between the reduced and oxidized species has been recently found[14] for a number of transition-metal redox couples, including aquo ligands and complexes of cobalt. However, we are not in a position to discuss that possibility in detail because for sandwich complexes the metal-ring distances in both oxidation states are not known with sufficient accuracy.

Acknowledgements—The author is grateful to Dr W. Linert, Vienna, for a sample of bis(biphenyl)chromium tetraphenylborate. This work was supported as a part of CPBP 01.15 programme.

EXTRACTION OF Fe(III) BY *n*-DODECANOIC ACID DISSOLVED IN TOLUENE

M. P. ELIZALDE,* J. M. CASTRESANA and A. I. ELORRIAGA

Departamento de Química Analítica, Facultad de Ciencias, Universidad del País Vasco, Apartado 644, 48080 Bilbao, Spain

(*Received* 28 *April* 1987; *accepted* 29 *June* 1987)

Abstract—The extraction of Fe(III) from a nitrate medium of ionic strength 1.0 mol dm^{-3} by *n*-dodecanoic acid (HA) dissolved in toluene has been studied by distribution measurements. Experimental data, treated by different graphical and numerical methods, have been explained assuming the extraction of the species $(FeA_3)_3$ into the organic phase as well as the formation of a Fe(III)–HA complex in the aqueous phase.

The solvent extraction of metal ions by carboxylic acids has aroused a great interest from both theoretical and practical points of view. Being one of the cheapest available kind of extractant reagents, the studies were first focussed on the possibilities of hydrometallurgical applications. Later on, detailed series of studies concerning the distribution equilibria of metal ions were carried out, giving rise to several reviews on the subject reported by Fletcher and Flett,[1] Flett and Jaycock,[2] Ashbrook,[3] Miller,[4] Rice,[5] Brzóska and Rózycki[6] and Yamada and Tanaka.[7] Most of the work basically agrees on the presence of monomer–polymer equilibria between metallic carboxylates, although the complexity of the systems has resulted in serious discrepancies in the composition of the extracted species.

The reported enhancements of the extraction of metals by carboxylic-containing synergic mixtures[8–10] has revealed the importance of having self-consistent data on individual systems in order to explain satisfactorily the results obtained with the mixtures.

With regard to iron(III) extraction, the influence of the diluent and the type of carboxylic acid over the composition of the extracts seems to be open to question since trimers,[11,12] dimers of several compositions[13–15] and monomers[16,17] have been proposed as main organic complexes in different conditions.

In the present work, the study of the extraction of Fe(III) from a nitrate medium by *n*-dodecanoic acid dissolved in toluene has been carried out in order to determine the stoichiometries of the complexes extracted as well as their stoichiometric extraction constants.

EXPERIMENTAL

Reagents

$Fe(NO_3)_3 \cdot 9H_2O$, Merck, p.a., was twice crystallized from distilled deionized water. *n*-Dodecanoic acid, Merck, r.s., was purified by successive recrystallization in ethanol and acetone.[18] Sodium nitrate and toluene, Merck, p.a., were used as supplied. All other chemicals were analytical-reagent grade.

Experimental procedure

Equal volumes (10 cm^3) of both organic and aqueous phases were mechanically shaken in special stoppered test tubes for 4 h. The initial acidity of the aqueous phase was gradually adjusted during the extraction process, always keeping the pH value below 3.3 in order to avoid the evolution of iron(III) hydroxide. Previous experiments showed that, under the conditions used, equilibrium was reached in about 2 h and no changes in the distribution coefficient were noticed up to 12 h after mixing. The concentration of *n*-dodecanoic acid in toluene was varied from 0.100–0.400 mol dm^{-3}. The aqueous phases contained Fe(III) in the concentration range 0.2–1.0 mmol dm^{-3} in $NaNO_3$ (1.0 mol dm^{-3}).

* Author to whom correspondence should be addressed.

After phase separation by centrifugation, the H^+ concentration was measured potentiometrically, using a combined glass electrode. The iron content in both phases was determined by atomic absorption spectroscopy. The iron concentration in the organic solutions was determined by stripping the metal into 1.0 mol dm^{-3} HNO_3. Any data which did not fulfil the mass balance for iron within 5% were rejected.

When necessary, the sodium content in both phases was determined by atomic absorption spectroscopy.

RESULTS

The extraction of iron(III) by *n*-dodecanoic acid (HA) can be described by the following general equilibrium:

$$j\mathrm{Fe}^{3+} + \tfrac{1}{2}(m+n)j(\mathrm{HA})_{2,\mathrm{org}} \rightleftharpoons (\mathrm{FeA}_m(\mathrm{HA})_n)_{j,\mathrm{org}} + mj\mathrm{H}^+ \quad (1)$$

where the known predominance of the carboxylic acid as a dimer in toluene has been considered.[19]

Taking into account that the total concentration of Fe(III) in the organic phase is given by:

$$C_{\mathrm{Fe,org}} = \sum_m \sum_n \sum_j j|(\mathrm{FeA}_m(\mathrm{HA})_n)_j|_{\mathrm{org}} \quad (2)$$

and k_{mnj} being the stoichiometric equilibrium constant for reaction (1), the distribution coefficient of the metal ion can be expressed as:

$$D = C_{\mathrm{Fe,org}}/C_{\mathrm{Fe,aq}} = \sum_m \sum_n \sum_j jk_{mnj}\alpha_{\mathrm{Fe}}^{-1} \times |\mathrm{Fe}^{3+}|^{j-1}|(\mathrm{HA})_2|^{1/2(m+n)j}|\mathrm{H}^+|^{mj} \quad (3)$$

where α_{Fe} is the side reaction coefficient of Fe(III) due to the formation of hydroxo[20] and nitrate[21] complexes in the aqueous phase and can be calculated from the equation:

$$\alpha_{\mathrm{Fe}} = 1 + \beta_1|\mathrm{NO}_3^-| + \beta_{11}|\mathrm{OH}^-| + \beta_{12}|\mathrm{OH}^-|^2 + \beta_{14}|\mathrm{OH}^-|^4 + \beta_{22}|\mathrm{Fe}^{3+}||\mathrm{OH}^-|^2 + \beta_{34}|\mathrm{Fe}^{3+}|^2|\mathrm{OH}^-|^4. \quad (4)$$

In Fig. 1 the experimentally determined $\log D$ values are plotted as a function of equilibrium pH at constant total metal concentration. On the other hand, Fig. 2 shows $\log D$ vs pH data at constant *n*-dodecanoic acid concentration and several C_{Fe} levels.

Both the high slope values, larger than the charge of the metal ion, obtained in the low D range for all the sets of data in Fig. 1 and the shifts to lower pH values of the experimental curves in Fig. 2 when increasing the iron content point to the polimerization of the extracted iron complexes.

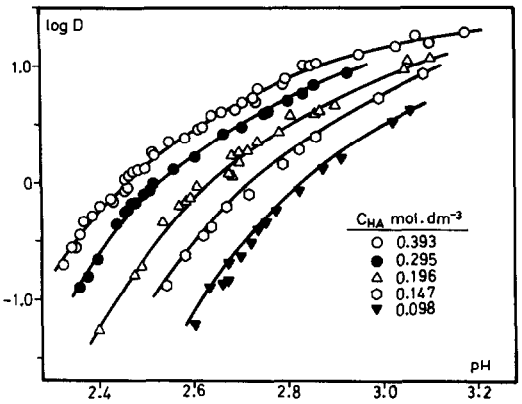

Fig. 1. Extraction of Fe(III) at various *n*-dodecanoic acid concentrations and $C_{\mathrm{Fe}} = 5.0 \times 10^{-4}$ mol dm^{-3}. Continuous lines have been drawn using the equilibrium constants proposed in Table 2.

Each type of data was first considered separately but the whole of the experimental information was subsequently treated both graphically and numerically.

GRAPHICAL TREATMENT

Data at constant iron concentration

An estimation of the polymerization degree of the extracted species can be achieved from the data collected at constant metal iron concentration. Assuming the formation of one single compound in the organic phase, eq. (2) takes the form:

$$\log C_{\mathrm{Fe,org}} = \log jk_{mnj} + \tfrac{1}{2}(m+n)j \times \log|(\mathrm{HA})_2|_{\mathrm{org}} + j(\log|\mathrm{Fe}^{3+}| + m\mathrm{pH}). \quad (5)$$

The function $\log C_{\mathrm{Fe,org}} = f(\log|\mathrm{Fe}^{3+}| + m\mathrm{pH})$ at constant extractant concentration was evaluated

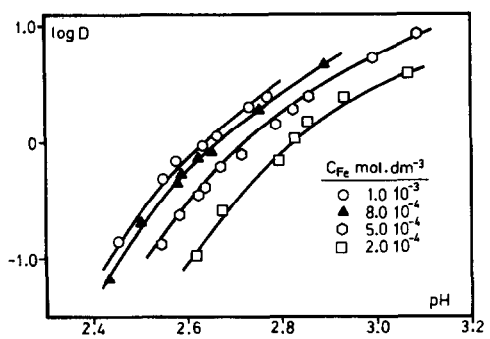

Fig. 2. The effect of total Fe(III) concentration on the extraction with *n*-dodecanoic acid at $C_{\mathrm{HA}} = 0.174 \times$ mol dm^{-3}. Continuous lines have been drawn using the equilibrium constants proposed in Table 2.

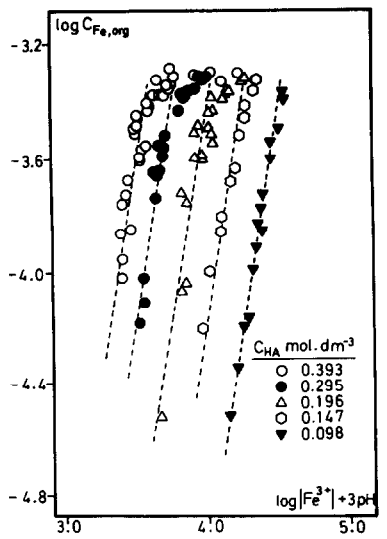

Fig. 3. Plot of the function $\log C_{Fe,org} = f(\log|Fe^{3+}| + 3pH)$ for the experimental data collected at constant total Fe(III) concentrations.

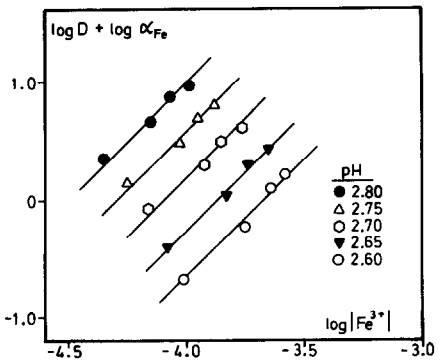

Fig. 4. Plot of the function $\log D + \log \alpha_{Fe} = f(\log|Fe^{3+}|)$ for the experimental data collected at different total Fe(III) concentrations.

for selected integer m values until straight lines were found. $|Fe^{3+}|$ values were calculated from the measured $C_{Fe,aq}$ according to eq. (5) by means of the program SOLGASWATER.[22]

Although in the higher D range deviations from linearity were observed for all the m values tried, linear plots were only found for $m = 3$, and a value of $j = 3$ was deduced from the slopes obtained (Fig. 3). Since straight lines of slope 4.5 were obtained in the plots $\log C_{Fe,org} = f(\log|(HA)_2|_{org})$ at several constant $(\log|Fe^{3+}| + 3pH)$ values, it can be deduced that $n = 0$ and consequently that a trimer of stoichiometry $(FeA_3)_3$ is extracted in the organic phase. From the intercepts of the former plots an extraction constant value of $\log k_{303} = -11.6$ was obtained.

Data at different iron concentration

In order to confirm the validity of the former extraction model, a graphical analysis of the experimental data at constant C_{HR} and different iron concentration (Fig. 2) was performed. Assuming the extraction of a single species, eq. (2) can be reduced to:

$$\log D + \log \alpha_{Fe} = \log k' + (j-1)\log|Fe^{3+}| \quad (6)$$

where, at constant pH values, k' is a conditional extraction constant defined by:

$$\log k' = \log jk_{mnj} + \tfrac{1}{2}(m+n) \times \log|(HA)_2|_{org} + mj\,pH. \quad (7)$$

Figure 4 shows the plots of the function $\log D + \log \alpha_{Fe} = f(\log|Fe^{3+}|)$ at several constant pH values. The straight lines of slope 2.0 ($j = 3$) obtained, further confirm the degree of polymerization of the extracted complex. An extraction constant value of $\log k_{303} = -11.5$, in good agreement with the one deduced from data at constant metal concentration was obtained by plotting the intercepts in Fig. 4 as a function of pH.

Treatment of all the data

The extraction of the species $(FeA_3)_3$ does not explain the whole set of data since deviations from the expected behaviour are found mainly at the highest studied range of extractant concentration. All the graphical analysis performed assuming the extraction of more metallic species, including OH-containing complexes, did not improve the fit to the data. A similar procedure using the highest formation constant values quoted in the literature for the iron(III)-hydroxo complexes confirmed that deviations cannot be attributed only to the presence of these species in the aqueous phase. Moreover, additional experiments showed that coextraction of sodium from the ionic medium, with the resulting decrease of *n*-dodecanoic acid concentration, was negligible in the pH range of the study. Accordingly, a graphical treatment of all the experimental data taking into account the possibility of the formation of iron carboxylate species in the aqueous phase was carried out. The biphasic equilibria for this reaction can be described as:

$$zFe^{3+} + \tfrac{1}{2}(x+y)z(HA)_{2org} \rightleftharpoons [FeA_x(HA)_y]_z + xzH^+. \quad (8)$$

Considering the mass balance equations for iron(III) in both phases:

$$C_{Fe,org} = 3[(FeA_3)_3]_{org} \quad (9)$$

$$C_{Fe,aq} = |Fe^{3+}|\alpha_{Fe} + z[(FeA_x(HA)_y)_z] \quad (10)$$

and the free iron concentration:

$$|Fe^{3+}| = [k_{303}^{-1}[(FeA_3)_3]_{org} \times |H^+|^9[(HA)_2]_{org}^{9/2}]^{1/3} \quad (11)$$

the following expression can be derived by combination of eqs (9), (10) and (11):

$$\frac{(3k_{303})^{1/3}C_{Fe,aq}|(HA)_2|_{org}^{3/2}}{C_{Fe,org}^{1/3}|H^+|^3\alpha_{Fe}} = 1 + zk_{xyz} \times (3k_{303})^{(1-z)/3}|(HA)_2|_{org}^{(1/2)[3+z(x+y-3)]} \times |H^+|^{z(3-x)-3}C_{Fe,org}^{(z-1)/3}\alpha_{Fe}^{-1} \quad (12)$$

where k_{xyz} is the stoichiometric constant for reaction (8).

Experimental functions $[\log C_{Fe,aq} + 3pH - (1/3)\log C_{Fe,org} - \log \alpha_{Fe}] = f[(z(3-x)-3)\log|H^+| + (z-1)/3 \log C_{Fe,org} - \log \alpha_{Fe}]$, at constant extractant concentration and different x and z values, were compared with the theoretical $\log Y = \log(1+X) = f(\log X)$, where Y and X are two normalized variables:

$$Y = (3k_{303})^{1/3}C_{Fe,aq} \times |(HA)_2|_{org}^{3/2}C_{Fe,org}^{-1/3}|H^+|^{-3}\alpha_{Fe}^{-1} \quad (13)$$

and X being the second term in eq. (12).

The best fit was found for $x = 3$ and $z = 2$ (Fig. 5), although it is noteworthy that the goodness of the fit is slightly sensible to changes on the degree of polymerization, z.

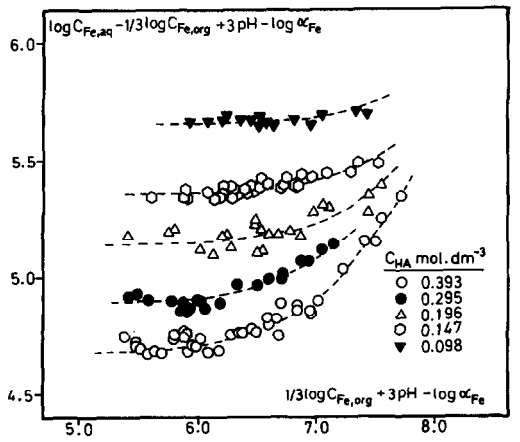

Fig. 5. Positions of best fit between the experimental function $\log C_{Fe,aq} - (1/3)\log C_{Fe,org} + 3pH - \log \alpha_{Fe} = f((1/3)\log C_{Fe,org} + 3pH - \log \alpha_{Fe})$ and the theoretical $\log Y = f(\log X)$.

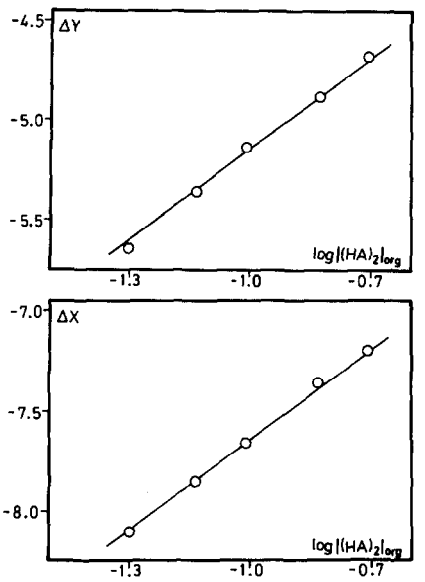

Fig. 6. Plots of the differences ΔY and ΔX as a function of free *n*-dodecanoic acid concentration.

Differences on both axes in the position of best fit between the experimental and the theoretical functions depend on $|(HA)_2|$, according to:

$$\Delta Y = \log Y - [\log C_{Fe,aq} - (1/3)\log C_{Fe,org} + 3pH - \log \alpha_{Fe}] = (1/3)\log 3k_{303} + (3/2)\log|(HA)_2|_{org} \quad (14)$$

$$\Delta X = \log X - [3pH + (1/3)\log C_{Fe,org} - \log \alpha_{Fe}] = 2\log k_{3y2} - (1/3)\log 3k_{303} + \tfrac{1}{2}(2y+3)\log|(HA)_2|_{org}. \quad (15)$$

Plots of these differences as a function of $|(HA)_2|$ are shown in Fig. 6. Since the points fall on a straight line of slope 1.5, it can be deduced that $y = 0$ and therefore the stoichiometry $(FeA_3)_2$ for the aqueous species can be deduced. Values of the constants obtained from the intercepts are given in Table 1.

NUMERICAL TREATMENT

Computer calculations were carried out in order to search for the chemical model which best explains the experimental data as well as to refine the extraction constant values graphically derived. The LETAGROP-DISTR program[23] was used in the calculations, the error square sum being:

$$U = \sum(\log D_{calc} - \log D_{exp})^2 \quad (16)$$

the function chosen for the minimization.

For each model tried, the program finds the set

Table 1. Values of the stoichiometric equilibrium constants obtained by graphical and numerical treatments of all the extraction data

Species	Method	$\log k_{mnj} \pm 3\sigma(\log k)$	$\log k_{xyz} \pm 3\sigma(\log k)$
$(FeA_3)_{3,org}$	Curve fitting	−11.4	
	Letagrop	−11.31 ± 0.04	
$(FeA_3)_{2,aq}$	Curve fitting		−10.1
	Letagrop		−10.01 ± 0.09

of equilibrium constants which gives the minimum value of U (U_{min}) as well as the standard deviation $\sigma(\log D)$, the best model being the one with the lowest values of both U_{min} and $\sigma(\log D)$. The results of the calculations are summarized in Table 2, confirming that the model graphically derived provides the best fit to the data. Table 1 compares the values of the constants obtained by the program and those derived by graphical analysis.

The fit to the data can be observed in Figs 1 and 2, where the continuous lines have been drawn using the equilibrium constants calculated by the program.

CONCLUSIONS

The presence in the organic phase of the unsolvated trimer quantitatively explains the extraction of Fe(III) from 1.0 mol dm^{-3} $NaNO_3$ by *n*-dodecanoic acid dissolved in toluene. Both graphical and numerical treatments of extraction data carried out at different metal ion and extractant concentrations confirm the absence of any other species in the organic phase. This result is in agreement with that obtained by Kholk'in *et al.*[12] and Tanaka *et al.*[11] for the extraction of Fe(III) by *n*-octanoic and *n*-decanoic acids, respectively, and seems to confirm the view of Yamada and Tanaka[7] that monomeric and dimeric iron(III) long chain carboxylates are not realistic in non-polar solvents. The extraction constant value obtained is higher than the one reported by Kholk'in *et al.* for the extraction by *n*-octanoic acid in benzene ($\log k_{303} = -14.63$) and the difference could be qualitatively explained by the higher distribution constant of *n*-dodecanoic in our system.

Deviations of the extraction data in the highest pH range studied can be only quantitatively

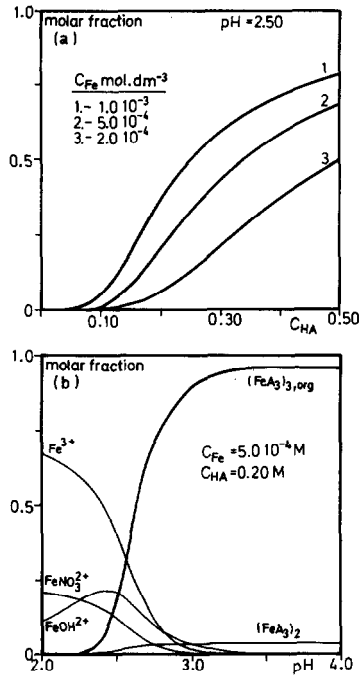

Fig. 7. Distribution diagrams in the system Fe(III)–$NaNO_3$/HA–toluene. (a) Molar fraction of the trimer, $(FeA_3)_3$, in the organic phase as a function of C_{HA} at constant pH and different total metal concentration. (b) Molar fraction of the main species in both phases as a function of pH at constant metal and *n*-dodecanoic acid concentration.

explained by the formation of iron carboxylate complexes of general composition $(FeA_3)_n$. Although the best fit is obtained for $n = 2$, the aggregation degree should be considered only as an average and species with a different n value cannot be disregarded.

Finally, the distribution diagrams in Fig. 7 show the influence of iron concentration on the extraction and the variation of the molar fraction of the main iron-containing species in both phases as a function of pH at constant metal and extractant concentrations. It can be easily appreciated that the aqueous iron carboxylate predominates in the aqueous phase in the range of high extraction, keeping the extraction percentage practically unchanged in a wide pH range.

ALKOXY DERIVATIVES OF TRITHIAZYLTRICHLORIDE

RAY JONES, IVAN P. PARKIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

(*Received* 5 *May* 1987; *accepted* 29 *June* 1987)

Abstract—Reaction of trithiazyltrichloride, $(NSCl)_3$, with NaOR in ROH (R = Me, Et, ^{i}Pr, ^{n}Pr, ^{n}Bu, ^{t}Bu, pentyl, amyl, cyclohexyl, benzyl) gives $(NSOR)_3$. The compounds have been characterized by IR and mass spectroscopy and in the case of R = methyl, (**2a**) and benzyl, (**2e**) by X-ray crystallography. In the structures of both (**2a**) and (**2e**) the S_3N_3 ring adopts a flattened chair cyclohexane conformation with the substituents being axial.

Trithiazyltrichloride, $(NSCl)_3$, (**1**), has been known for many years.[1] It is readily prepared[2] and unlike many other sulphur–nitrogen species, not especially hazardous. However, unlike the related phosphorus–nitrogen ring system, $(PNCl_2)_3$, substitution reactions of (**1**) are not common; with ring cleavage readily occurring. There has recently been a brief report[3] on the use of sodium alkoxides (NaOR; R = Me, ^{i}Pr) in the preparation of $(NSOR)_3$, (**2**), from (**1**). Neither the generality of the reaction nor the structure and properties of (**2**) were described. Here we report on our studies into the preparation of (**2**) for a wide variety of R groups. Vibrational and mass spectroscopy have been used to characterize the compounds. In the cases of R = methyl and benzyl the X-ray crystal structures are reported.

EXPERIMENTAL

General. All reactions were performed under an inert atmosphere of nitrogen or argon using dried solvents. Alcohols were dried over 3 Å molecular sieves and petroleum ether was dried over sodium. Trithiazyltrichloride was prepared by the literature method.[2] IR spectra were recorded as thin films or nujol mulls using a PE497. UV/vis spectra were measured on a Pye SP8-400.

Preparation of $(NSOR)_3$ R = Me, Et, *n*-Pr, *i*-Pr. Sodium (0.6 g, 0.026 mol) was added to the appropriate alcohol (20 cm^3), after dissolution of the metal petroleum ether (5 cm^3) was added and the reaction cooled to 0°C. A slurry of $S_3N_3Cl_3$ (3.0 g, 0.012 mol) in alcohol (20 cm^3) was added over 10 min. The reaction was stirred and allowed to warm to room temperature (2 h) during which time it turned red. The solvent was evaporated under reduced pressure and the oily solid remaining was extracted with *n*-hexane (3 × 20 cm^3). Removal of the *n*-hexane *in vacuo* gave the final products. Analytical and spectroscopic data are in Tables 1 and 2. For R = Me the volume of *n*-hexane was reduced to *ca* 20 cm^3 and the solution cooled to −20°C, Yield 1.4 g, 50%. Crystals of (**2a**) suitable for X-ray crystallography were obtained by slow evaporation of an *n*-hexane solution at 4°C.

R = *n*-Bu, *t*-Bu, *n-pentyl*, *amyl*, *cyclohexyl*. Sodium (0.2 g, 8.7 mmol) was dissolved in the

appropriate alcohol (20 cm^3) and pet. ether (20 cm^3) added. With the solution at 35°C solid $S_3N_3Cl_3$ (1.0 g, 4.0 mmol) was added. Stirring and heating was maintained for 3 h after which time the reaction was worked up as above.

R = *Benzyl.* Sodium (0.23 g, 10 mmol) was dissolved in benzyl alcohol at 0°C. To this solution was added solid $S_3N_3Cl_3$ (0.8 g, 3.2 mmol). After 2 h the alcohol was removed *in vacuo* and the residue extracted with pet. ether (2 × 20 cm^3). The ether solution was reduced to *ca* 20 cm^3 and cooled to −20°C to give the product as crystals suitable for X-ray studies.

Crystal Data. (**2a**), $C_3H_9N_3O_3S_3$, $M = 231.3$, rhombohedral, $a = 12.147(6)$, $c = 11.368(6)$ Å, $U = 1453(1)$ Å^3, space group $R\bar{3}$, $Z = 6$, $D_c = 1.59$ g cm^{-3}, colourless air stable irregular polyhedron, crystal dimensions 0.15 × 0.15 × 0.2 mm. μ(Cu-K$_\alpha$) = 67.8 cm^{-1}, $\lambda = 1.54178$ Å, $F_{(000)} = 720$.

(**2e**), $C_{21}H_{21}N_3O_3S_3$, $M = 459.6$, monoclinic, $a = 9.373(2)$, $b = 13.581(3)$, $c = 17.507(5)$ Å, $\beta = 90.08(2)$, $U = 2229(1)$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.37$ g cm^{-3}, colourless, air stable irregular polyhedron, crystal dimensions 0.16 × 0.18 × 0.15 mm, μ(Cu-K_α) = 32.2 cm^{-1}, $\lambda = 1.54178$ Å, $F_{(000)} = 960$.

Data collections and processing

Nicolet R3m diffractometer, ω-scan method [$2\theta \leqslant 116$ (**2a**) and 100° (**2e**)], graphite monochromated Cu-K_α radiation. 437 and 2198 independent reflections of which 269 and 1692 respectively considered observed [$|F_o| > 3\sigma(|F_o|)$] for (**2a**) and (**2e**), corrected for Lorentz and polarization factors; empirical absorption correction based on 360 azimuthal scans for both data sets.

Structure analysis and refinement

Both structures were solved by direct methods and non-hydrogen atoms refined anisotropically in each case. The methyl group in (**2a**) was treated as a rigid body. The hydrogen atoms in (**2e**) were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters [$U(H) = 1.2U_{eq}(C)$] and allowed to ride on their parent carbons. Refinement was by block-cascade full-matrix least-squares to give for (**2a**) $R = 0.107$, $R_w = 0.122$ ($w^{-1} = \sigma^2(F) + 0.00278F^2$) and for (**2e**) $R = 0.050$, $R_w = 0.053$ ($w^{-1} = \sigma^2(F) + 0.00072F^2$) ($R = \Sigma|(F_o - F_c)|/\Sigma|F_o|$). The maximum residual electron densities in the final ΔF maps were 0.74 and 0.22 e Å^{-3} for (**2a**) and (**2e**) respectively. The mean and maximum shifts/error in the final refinement cycles were for (**2a**) 0.016 and 0.107 and for (**2e**) 0.005 and 0.017. Computations were carried out on an Eclipse S140 computer using the SHELXTL system.[4]*

RESULTS AND DISCUSSION

The *cyclo*-trialkoxytrithiazenes, $(NSOR)_3$, (**2**), are readily prepared by reaction of trithiazyltrichloride with the appropriate sodium alkoxide in alcohol [eq. (1)]. Yields varied between 51 and 10%, with lower yields being obtained in reactions involving bulky alcohols

$$(NSCl)_3 + 3NaOR \rightarrow (NSOR)_3 + 3NaCl. \quad (1)$$

Microanalytical data for those compounds obtained pure is given in Table 1; when using less volatile alcohols it was not possible to free the pro-

* Final positional parameters and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

duct of the parent alcohol even after sustained pumping under high vacuum. Since we found that (**2**) are somewhat thermally unstable they could not be distilled. The reaction does not proceed in solvents other than the parent alcohol. Asymmetrically substituted compounds are also readily prepared. For example, reaction of NaOEt/NaO*i*-Pr (in ethanol/isopropanol) with (**1**) gives all possible products, $S_3N_3(OEt)_n(OiPr)_{3-n}$ (in the statistically expected proportions); observed by ^1H NMR and mass spectrometry.

IR and NMR data for selected compounds are given in Table 2. In (**2**) the ^1H resonances are shifted downfield relative to the parent alcohol. For the observed (*vide infra*) C_{3v} symmetry four ν(SN) vibrations together with ν(SO) and ν(CO) vibrations are expected. Seven characteristic bands are observed. The band at *ca* 1025 cm^{-1} is assigned as ν(CO) because of its sensitivity to the R group. The ν(SO) and ν(SN) vibrations fall between 1000–630 cm^{-1}; although individual assignments are difficult it seems likely that ν(SO) is the lowest frequency band of this group (at around 640 cm^{-1}). The moderate intensity band at *ca* 520 cm^{-1} is probably a ring deformation. The mass spectra consist of weak peaks due to M^+ with the principle fragments being $S_3N_3(OR)_2^+$ and $(S_2N_2OR)^+$. The UV spectra of (**2**) exhibit one absorption centred at 208 nm of moderate intensity ($\varepsilon \approx 1800$ mol^{-1} dm^3 cm^{-1}).

The X-ray crystal structure of (**2e**) (Fig. 1) is analogous to that of (**1**) having a flattened chair-like six-membered ring which is substituted axially. The whole structure has approximate non-crystallographic C_3 symmetry. The bond lengths and angles (Table 3) are not significantly different within the ring suggesting a delocalized system. The SN bond lengths (range 1.588(4)–1.611(4) Å) are shorter than the single bonds in *cyclo*-$S_4(NCH_2Ph)_2$, (**3**), [1.713(4)–1.720(3)][5] and are within statistical significance the same as those in

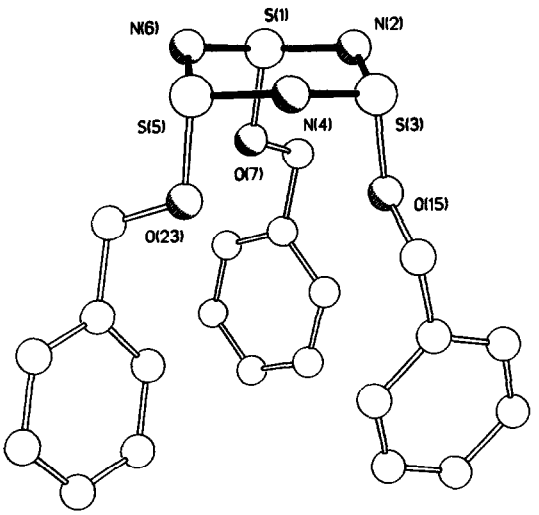

Fig. 1. The X-ray crystal structure of $(NSOBz)_3$, (**2e**).

$(NSCl)_3$.[6] The SNS and NSN angles [range 121.2(3)–122.5(2) and 112.2(2)–113.3(2)°] in (**2e**) indicate trigonal and distorted tetrahedral environments for nitrogen and sulphur respectively. The structure of (**2a**) though of limited accuracy (the determination being carried out close to the melting point) displays the same axial substitution pattern and flattened chair cyclohexane conformation. The errors in the structural parameters preclude any meaningful comparisons. The chair form appears to be general for S(IV) rings[1,6] although β-$(SNOCl)_3$ adopts a distorted boat conformation with the chlorines axial and the oxygens equatorial.[7]

It is interesting to compare the relative planarity of (**2e**) and (**3**) since this may provide an indication of the extent of π-delocalization in (**2**). In (**2e**) the S(1)—S(3)—N(4)—N(6) plane is inclined to the S(1)—N(2)—S(3) and N(4)—S(5)—N(6) planes by 32 and 27° respectively with N(2) and S(5) lying 0.38 and 0.42 Å above and below this plane. In (**3**)

Table 3. Selected bond distance (Å) and angles (°) in $(NSOBz)_3$, (**2e**)

S(3)—O(15)—C(16)	112.8(3)	S(5)—O(23)—C(24)	114.6(3)

the S—S—S—S and S—N—S planes are inclined by 63° whereas the comparable angles in (**1**) are 23 and 18° respectively.* The flattening of the ring in (**1**) and (**2e**) relative to (**3**) is presumably a consequence of a π system based on nitrogen *p* and sulphur *d* orbitals. This type of bonding scheme has been developed previously.[8] The noticeably flattening in the structure of (**1**) relative to (**2e**) is due to the increased steric repulsion between the three chlorine substituents *cf.* the oxygen atoms in (**2e**). In (**1**) the Cl···Cl distances are 3.61, 3.61, and 3.78 Å whilst in (**2e**) the O···O distances are 3.06, 3.13 and 3.17 Å.

The compounds reported here are sulphur–nitrogen analogues of $(PNR_2)_3$ and as such may provide useful starting materials in the synthesis of substituted SN polymers. Further work is under way.

*The equivalent values for the alternative S(1)—N(2)—N(4)—S(5) plane are 30 and 29° and for the N(2)—S(3)—S(5)—N(6) plane are 29 and 28°. In all three instances the larger dihedral angle is associated with the out of plane nitrogen atom.

PREPARATION AND X-RAY CRYSTAL STRUCTURES OF MIXED LIGAND COMPLEXES CONTAINING THE S_3N^- LIGAND

RAY JONES, THOMAS G. PURCELL, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

(*Received* 29 *May* 1987; *accepted* 10 *July* 1987)

Abstract—Reaction of $Hg(S_7N)_2$ with *cis*-$PtCl_2(PR_3)_2$ (PR_3 = PPh_3, PPh_2Me, $PPhMe_2$, PEt_3) in the presence of $Na[PF_6]$ gives $[Pt(S_3N)(PR_3)_2][PF_6]$ in 32–46% yield. The complexes have been characterized by IR, NMR and microanalyses. The X-ray crystal structures of two examples (PR_3 = PPh_2Me and PEt_3) show that the S_3N^- ligand coordinates in a bidentate fashion via two sulphur atoms.

Metalla–sulphur–nitrogen complexes include terminally bonded fragments and stretch from 5 to 8 membered rings.[1,2] We are investigating the stabilization of reactive sulphur–nitrogen anions using transition metal centres for a number of reasons. New insights into the solution equilibria of SN species might be gained; synthetic reagents can be prepared and structurally interesting materials are available. In this latter regard we have recently reported[3] on the synthesis of mixed ligand platinum stacking compounds, $[Pt(S_2N_2H)(PR_3)_2]X$, (**1**) containing the $S_2N_2H^-$ group. There has previously been substantial work on $M(S_2N_2H)_2$ and $M(S_3N)_2$ complexes[4] and it is clear that the $S_2N_2H^-$ and S_3N^- ligand are isoelectronic (NH = S). We have therefore developed a simple synthesis of $[Pt(S_3N)(PR_3)_2][PF_6]$, (**2**), to enable us to investigate the effect of replacement of an NH group by a sulphur atom on the stacking properties of (**1**).

Previously, complexes containing the S_3N^- ligand have been obtained from reactions involving explosive S_4N_4;[4] directly from salts of S_3N^-[5,6] or by *in situ* formation of the anion using base and S_7NH.[7–10] All of these three routes have problems. S_4N_4 is rather hazardous and should be avoided wherever possible. Salts of S_3N^- are not particularly easy to prepare, are air sensitive, equilibrate in solution to S_4N^- and have not been particularly successful in the preparation of Group VIII complexes. The deprotonation reactions of S_7NH are useful but give complex products. Finally, none of these routes has been used in reactions with metal phosphine complexes. Here, we report on the usefulness of the readily prepared and easily handled reagent $Hg(S_7N)_2$ in the synthesis of $[Pt(S_3N)(PR_3)_2]$, (**2**). The X-ray crystal structures of two examples (PR_3 = PPh_2Me and PEt_3) are reported.

EXPERIMENTAL

General experimental procedures and preparation of platinum starting materials were as described previously.[4,11] $Hg(S_7N)_2$ was prepared by the reported method[12] and stored at −18°C in the dark. All reactions were performed under an inert atmosphere (N_2 or Ar) but the work-ups were carried out in air.

Preparation of S_3N^- *complexes.* In a typical reaction $PtCl_2(PPh_3)_2$ (100 mg, 0.126 mmol), $Hg(S_7N)_2$ (86 mg, 0.126 mmol) and $NaPF_6$ (23 mg, 0.136 mmol) were stirred together in dichloromethane (20 cm^3) at room temperature for 24 h. During this time the initial cream suspension turned into a dark purple solution. The solution was filtered through Celite and its volume reduced to *ca* 3 cm^3 before preparative thin layer chromatography (CH_2Cl_2 eluent). The product (r_f 0.3) was extracted from the silica using CH_2Cl_2/thf. After evaporation of this solution, *in vacuo*, to near dryness the orange/brown product was precipitated

using *n*-hexane. Yields, and properties of the complexes are reported in Tables 1 and 2. Samples suitable for X-ray crystallography were obtained by diffusion of hexane into dichloromethane solutions.

Crystal data

2(a) $[Pt(S_3N)(P(C_2H_5)_3)_2][PF_6]$, $M = 686.6$, orthorhombic, $a = 12.540(4)$, $b = 13.754(5)$, $c = 27.542(8)$ Å, $U = 4750(3)$ Å^3, space group *Pcab*, $Z = 8$, $D_c = 1.93$ g cm^{-3}, red air stable truncated octahedron, crystal dimensions $0.2 \times 0.1 \times 0.1$ mm, μ(Cu-$K\alpha$) = 160 cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 2671$.

2(b) $[Pt(S_3N)(PCH_3(C_6H_5)_2)_2][PF_6]\cdot(X_{11})_{0.25}$*, M* = 883.7, monoclinic, $a = 18.759(4)$, $b = 19.168(5)$, $c = 12.498(2)$ Å, $\beta = 124.34(2)$, $U = 3711(1)$ Å^3, space group $C2/c$, $Z = 4$, D_c* = 1.59 g cm^{-3}, red air stable prism, crystal dimensions $0.3 \times 0.2 \times 0.1$ mm, μ(Cu-$K\alpha$)* = 104 cm^{-1}, $\lambda = 1.54178$ Å, $F(000)$* = 1722.

Data collections and processing

Nicolet R3m diffractometer, ω-scan method ($2\theta \leqslant 100°$ for (**a**) and $2\theta \leqslant 116°$ for (**b**)), graphite monochromated Cu-$K\alpha$ radiation. For (**1**) and (**2**): 2003 and 2590 independent measured reflections of which 1915 and 2371 respectively were considered observed ($|F_o| > 3\sigma(|F_o|)$), corrected for Lorentz and polarization factors; numerical absorption corrections (face indexed crystals).

Structure analysis and refinement

Structure (**2a**) was solved by the heavy atom technique and (**2b**) by direct methods. In (**2a**) all the non-hydrogen atoms were located from successive ΔF maps and refined anisotropically. In (**2b**) the structure was initially solved in space-group *Cc*. The thermal ellipsoids for the N(1) and S(2) atoms in the PtS_3N ring indicated the structure to be disordered about the axis passing through the Pt atom and bisecting the P—Pt—P angle. Further inspection of the coordinates of the atoms in the two phosphine ligands showed that they also could be related by this 2-fold axis. The PF_6 anion could also be accommodated on an independent 2-fold axis. Subsequent refinement of the disordered model was carried out in space-group $C2/c$ which though resulting in the expected small increase in R gave significantly improved standard deviations. All non-hydrogen atoms were refined anisotropically with the exception of the 50% occupancy nitrogen atom N(1) and the disordered solvent, for which five carbon atoms were refined isotropically in general positions with occupancies of 25% and one carbon atom was refined isotropically on a crystallographic centre of symmetry with an occupancy of 12.5%.

*Contains a contribution from an unknown disordered solvent fragment refined as $(C_{11})_{0.25}$.

In both structures the PF_6 anions were refined as rigid bodies. The methyl groups were also refined as rigid bodies, all other hydrogen atoms [in (**2a**) and (**2b**)] were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters [$U(H) = 1.2U_{eq}(C)$] and allowed to ride on their parent carbon atoms. Refinement was by block cascade full-matrix least-squares to give for (**2a**) $R = 0.042$, $R_w = 0.034$ ($w^{-1} = \sigma^2(F) + gF^2$, where g converged to a value of less than 0.00001) and for (**2b**) $R = 0.063$, $R_w = 0.067$ ($w^{-1} = \sigma^2(F) + 0.00738F^2$) ($R = \Sigma|F_o - F_c|/\Sigma|F_o|$). The maximum residual electron densities in the final ΔF maps were 0.60 and 1.92 eÅ^{-3} for (**2a**) and (**2b**) respectively. The mean and maximum shifts/error in the final refinement cycles were, for (**2a**), 0.011 and 0.082 and, for (**2b**), 0.002 and 0.026. Computations were carried out on an Eclipse S140 computer using the SHELXTL[13] program system and published[14] scattering factors.

RESULTS AND DISCUSSION

Reaction of $Hg(S_7N)_2$ with $PtCl_2(PR_3)_2$ and $NaPF_6$ at room temperature gives reasonable yields of $[Pt(S_3N)(PR_3)_2][PF_6]$.

$$Hg(S_7N)_2 + PtCl_2(PR_3)_2 + NaPF_6 \rightarrow [Pt(S_3N)(PR_3)_2][PF_6] + HgCl_2$$

The products were characterized by $^{31}P\text{-}\{^1H\}$ NMR and IR spectroscopy and this data together with the microanalytical results are shown in Tables 1 and 2. The driving force for the reaction is the formation of $HgCl_2$ but the mechanism is not obvious. During purification using preparative thin layer chromatography we isolated S_4N_2 as a major side-product. A number of pathways thus seem possible. (1) Decomposition of $Hg(S_7N)_2$ to form S_4N_2 which then reacts with *cis*-$PtCl_2(PR_3)_2$ to give (**2**). (2) Initial formation of a complex containing the S_7N^- ligand which then eliminates sulphur. (3) Formation of S_7N^- which equilibrates to S_4N^-/S_3N^-. We do not favour (3) since the characteristic blue colour of S_4N^- is not observed during the reaction. There has recently been a report on the formation of an S_7N^- complex[10] and this lends some support for (2). Stirring $Hg(S_7N)_2$ overnight (with formation of S_4N_2 as evidenced by TLC) followed by treatment with $PtCl_2(PMe_2Ph)_2$ did not result in formation of (**2**). Direct reaction of sublimed S_4N_2 with $Pt(C_2H_4)(PR_3)_2$ gives $Pt(S_2N_2)(PR_3)_2$. We therefore favour pathway (2).

The $^{31}P\text{-}\{^1H\}$ NMR of (**2**) are AB type with platinum satellites. The magnitudes of $^2J(^{31}P—^{31}P)$ and $^1J(^{31}P—^{195}Pt)$ are appropriate for Pt(II) complexes. Assignment of individual resonances is difficult. Comparison with (**1**) and $Pt(S_2N_2)(PR_3)_2$, (**3**), which are related to (**2**) by replacement of a sulphur atom by an NH group and an N^-, is of interest but not particularly helpful. As was the case with (**1**) and (**3**) there is a linear increase in the magnitude of ^1J on replacing methyl groups by phenyl groups in the phosphines. To be consistent with our previous assignments we tentatively assign δ_A (with the lower ^1J values) to P(1) which is *trans* to S(1). The Pt—P bond lengths are however not crystallographically distinguishable because of disorder problems.

The IR spectra of the complexes are dominated by absorptions due to phosphines. However, in the PEt_3 case two ν(SN) vibrations (1010(sh) 709(m) cm^{-1}), a ν(SS) (529(m) cm^{-1}) and two ν(PtS) (338(w), 320(vw) cm^{-1}) vibrations may be assigned by analogy with $Pt(S_3N)_2$.[4]

The X-ray structures of (**2a**) (Fig. 1) and (**2b**) have been determined. The cations have the expected *cis* square planar geometry. Unfortunately, in each case, disorder about the pseudo two-fold axis (Fig. 2) of the cation precludes any detailed discussion of bond lengths and angles for the sulphur–nitrogen portions of the molecules. The degree of disorder, as evidenced by the thermal elipsoids, is somewhat less in (**2a**) than in (**2b**). Disorder of this type is apparent in a number of other related complexes.[10,15] Comparison with $Cu(S_3N)(PPh_3)_2$ and $PPN[Cu(S_3N)_2]$,[5] neither of which are reported to be disordered, shows an apparent reversal in the lengths of the bonds at nitrogen for (**2a**) relative to the copper complexes [in (**2a**) S(2)—N(1) 1.502(11), N(1)—S(3) 1.632(10) Å; the equivalent distances in

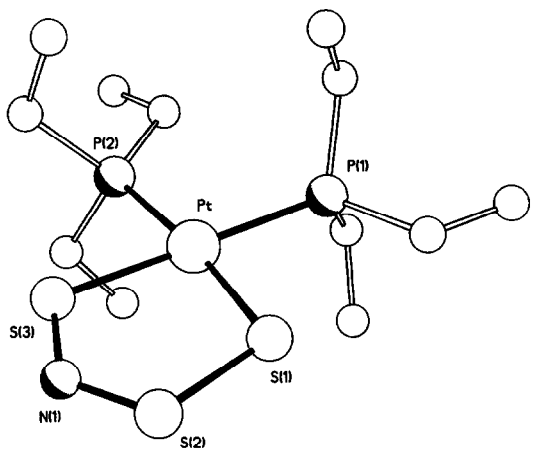

Fig. 1. The X-ray crystal structure of the cation in (**2a**); selected bond lengths and angles S(1)—S(2) 2.034(5), S(2)—N(1) 1.502(11), N(1)—S(3) 1.632(10), Pt—S(1) 2.287(3), Pt—S(3) 2.290(3), Pt—P(1) 2.321(3), Pt—P(2) 2.319(3) Å, S(1)—Pt—S(3) 89.8(1), Pt—S(1)—S(2) 103.6(1), S(1)—S(2)—N(1) 111.7(4), S(2)—N(1)—S(3) 124.8(7), N(1)—S(3)—Pt 110.1(4)°.

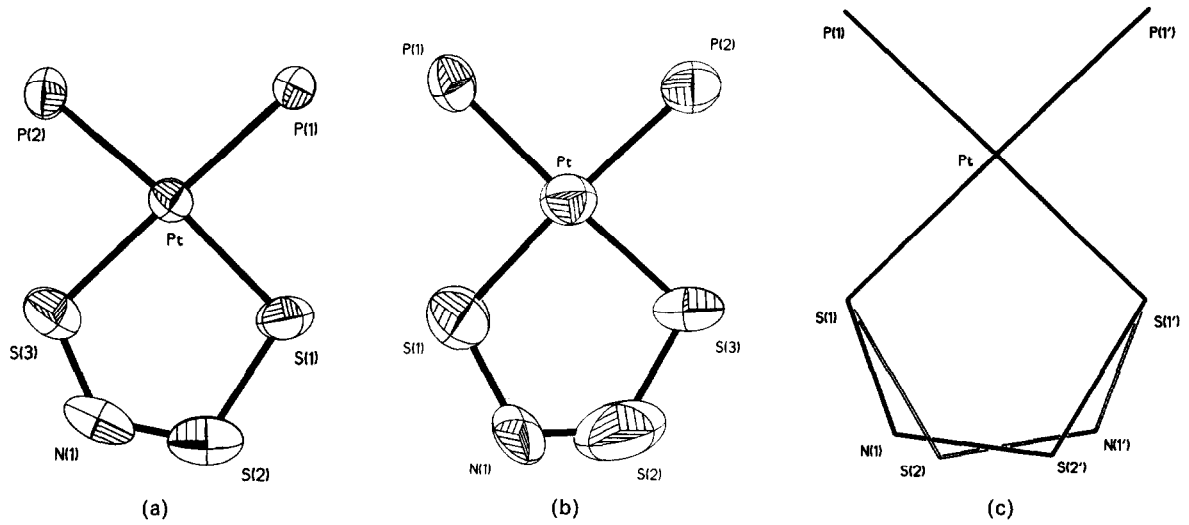

Fig. 2. (a) 50% probability thermal ellipsoid plot of the cation in (**2a**). (b) 50% probability thermal ellipsoid plot of the cation in (**2b**) when refined in space-group *Cc* showing the disorder affecting the metallacycle (carbon atoms omitted for clarity). (c) A line drawing showing the disordered model, refined in space-group *C*2/*c*, for (**2b**) where the two orientations of the ring are related by a crystallographic two-fold axis passing through the Pt atom and bisecting the P—Pt—P angle.

PPN[Cu(S_3N)$_2$] are 1.652(9) and 1.512(11) Å]. This apparent reversal may be an artifact of the disorder present in (**2a, b**), nonetheless, the structures do confirm the gross geometry of the cations to be as expected. The Pt—P and Pt—S bond lengths are as expected for Pt(II) complexes and are not significantly different from those observed in analogous $S_2N_2^{2-}$ and $S_2N_2H^-$ complexes.[11,16] Neither structure shows the type of stacking of cations observed in the isoelectronic $S_2N_2H^-$ complexes, (**1**).

SYNTHETIC POSSIBILITIES OF THE 2,4-PENTANEDIONE-1,2-DIAMINOETHANE SYSTEM: AN OVERALL VIEW

J.-P. COSTES

Laboratoire de Chimie de Coordination du CNRS, Unité n° 8241 liée par convention à l'Université Paul Sabatier, 205, route de Narbonne, 31077 Toulouse Cedex, France

(*Received* 25 *April* 1987; *accepted* 10 *July* 1987)

Abstract—Single condensation of acetylacetone (AcacH) with 1,2-diaminoethane (En) yields the terdentate "half-unit" 7-amino-4-methyl-5-aza-3-hepten-2-one (abbreviated as AEH). In the presence of a metal ion, this ligand leads to the macrocycle 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclo tetradeca-4,6,11,13-tetraene, which can be considered as resulting from the condensation of two molecules of (AcacH) with two molecules of (En). This "half-unit" can also be used to obtain acyclic ligands and complexes made with one (AcacH) molecule and two (En) molecules (1 : 2) or conversely two (AcacH) molecules and one (En) molecule (2 : 1). Using reagents other than (AcacH) and (En), this "half-unit" may yield homo and heterodinuclear complexes, macrocyclic compounds and non-symmetrical tetradentate Schiff bases.

Within the large family of Schiff bases, one of the most frequently named is *N,N'*-ethylene-bis(acetyl acetoneimine) ($BAEH_2$)* [*Cf.* Fig. 1(C)]. It is generally suggested that ($BAEH_2$) is the only product resulting from the reaction of 1,2-diaminoethane with 2,4-pentanedione, whatever the proportion of the two reagents.[1] After deprotonation it may be reacted with divalent metal ions M(II) to yield MBAE complexes.[2–4] It is noteworthy that these complexes may be obtained through different synthetic pathways, such as the reaction of $Ni(En)_2Cl_2$ with (AcacH),[5] that of $Ni(CH_3COO)_2 \cdot 4H_2O$ with an equimolar mixture of (En) and (AcacH), or the reaction of bis(4-amino-3-penten-2-onato)nickel(II) with (En).[6] On the contrary, no reaction occurs on mixing $Ni(Acac)_2 \cdot H_2O$ and (En). This absence of reactivity has been attributed to a $p\pi$-$d\pi$ cyclo conjugation between the metal centre and the 2,4-pentanedionato anion.[7]

It has been reported that $NiCl_2 \cdot 6H_2O$ reacts with a mixture of (En) and (AcacH), in the presence of acetic acid, to yield the compound (**H**).[8] This compound is also obtained by reacting (AcacH) with $Ni(En)_2Cl_2$.[9] In the Au^{3+} chemistry, a similar reaction not only yields the complex (**H**) but also a macrocyclic compound of the (**J**) type.[10] This macrocycle was also synthesized by reaction of (En) with 4-amino-3-penten-2-one[11] or with the thio analog of ($BAEH_2$),[12] subsequent to the activation of the ketone or thioketone functions by Et_3OBF_4. Finally, from a literature survey it appears that the synthetic possibilities of the (En)/(AcacH) system are restricted to the preparation of the (**C**), (**H**) and (**J**) compounds. The diazepine (**F**) resulting from the double condensation of (AcacH) and (En) in strong acidic medium must be added to this list.[13] Furthermore, low yields characterize the reported synthesis of (**H**) and (**J**).

In this paper, our aim is to show that the possibilities of the (En)/(AcacH) system largely exceed these three compounds. This increase is based on the synthesis of the "half-unit" (AEH) [Fig. 1 (**A**)]. We have recently shown that suitable experimental conditions allow for the monocondensation of diaminoethane and 2,4-pentanedione, leading to (AEH), a stable, easily handled compound.[14] A similar approach for 2,4-pentanedione-*ortho*-

*The following abbreviations will be used in this paper: (AcacH) for 2,4-pentanedione, (En) for 1,2-diaminoethane, ($BAEH_2$) for *N,N'*-ethylene-bis(acetylacetoneimine), (AEH) for 7-amino-4-methyl-5-aza-3-hepten-2-one. The less common compounds will be pointed out by letters, as indicated in Fig. 1.

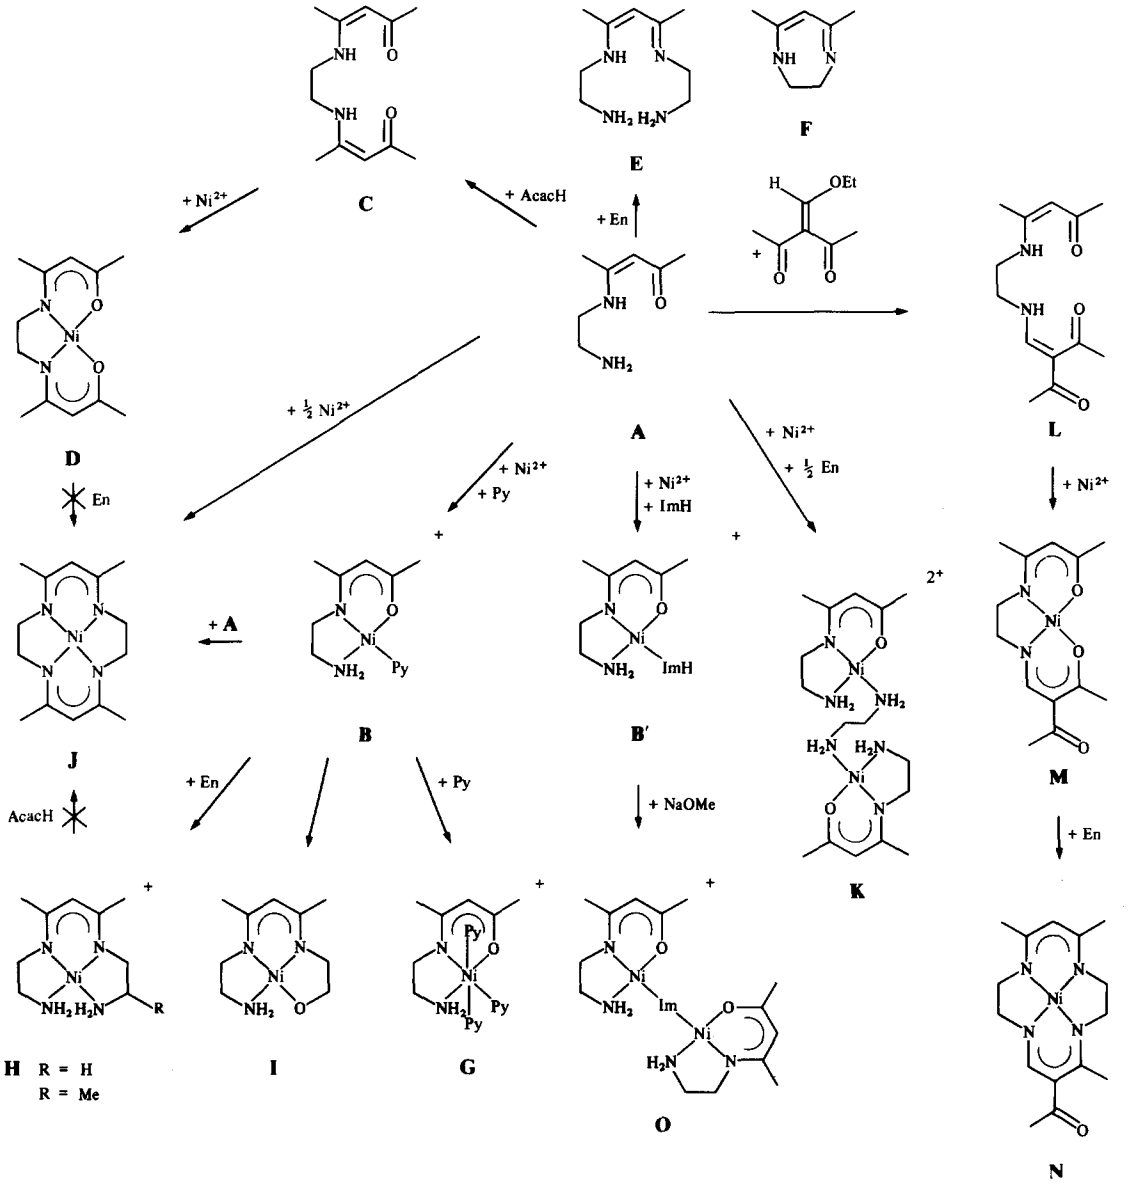

Fig. 1. Synthetic possibilities of the 2-4-pentanedione-1,2-diaminoethane system.

phenylenediamine recently appeared in the literature.[15,16] The authors suggested that the key compound was a monoanil or "half-unit" which, however, was not isolated. The occurrence of such "half-units" was evidenced in the hydrolysis of benzodiazepines[17] also suggested by Nelson[18] in more complicated systems.

RESULTS AND DISCUSSION

Reactivity of the "half-unit" (AEH)

The whole set of reactions made from the free (AEH) or complexed (**B**) ligand appears in Fig. 1.

Chronologically, the first use of (AEH) was to give an easy access to tetradentate non-symmetrical Schiff bases.[19–24] This possibility is illustrated in Fig. 1 by the reaction of (AEH) with 3-(ethoxymethylene)2,4-pentanedione, leading to the ligand (**L**). Its complexed form, (**M**), can subsequently react with (En) to give a functionalized macrocyclic complex, (**N**), in quantitative yield. Such a reaction is governed by the "thermodynamic and kinetic template effect"[24] and also by the inductive effect exerted by the -C(O)Me group. Conversely, complex (**D**), NiBAE, does not react with (En) to give (**J**).

The free (AEH) ligand can lead to ($BAEH_2$) (**C**), the diazepine (**F**) and in low yield, to the ligand (**E**). The most interesting reaction concerns self-

condensation of (AEH) to give the macrocyclic compound (**J**). This reaction necessitates the presence of (AEH), sodium methoxide and Py_2NiCl_2 as a source of nickel ions. The macrocycle is isolated under its complexed form in 30% yield. A mixture of free (AEH) and complex (**B**), where the (AEH) ligand is complexed, also yields the complex (**J**) but with a lower yield. It is interesting to recall here that the reaction of (AEH) with nickel(II) ions in the absence of any base leads to (**D**).

A promising opportunity results from the tridentate nature of (AEH) which cannot saturate the possibilities of coordination at the metal ion. Thus, at least, a second ligand such as pyridine can enter the coordination sphere, as it is the case for complexes (**B**) and (**G**). Interestingly, the second ligand may be (AEH) itself but in this instance, the nature of the resulting products depends on the nature of the metal ions. For cobalt (III), an octahedral complex $[Co(AE)_2]^+$ is obtained while in the case of the nickel(II) ion cyclization occurs, leading to the macrocyclic (**J**) complex. A trinuclear complex, $[(AECu)_3OH]^{2+}$, is isolated in high yield for the copper(II) ion.[25]

In (**B**), substituting pyridine, a monodentate ligand, by bidentate ligands offers new possibilities toward the preparation of dinuclear species such as (**O**) with imidazole[26] or (**K**) with 1,2-diaminoethane. At this stage, the versatility of (En) has to be emphasized. Depending on the experimental conditions, the system $(AEH)/Ni^{2+}/(En)$ can yield either the dinuclear complex (**K**) or the mononuclear species (**H**). In the first case, (En) makes a bridge between two nickel ions, while in the other case one of the two NH_2 groups reacts with the keto function of the (AE) ligand. Substituting 2-aminoethanol for (En) leads to the complex (**I**).

Until now, we have restricted our presentation to the nickel complexes since due to their diamagnetic behaviour they are easily characterized by NMR. Nevertheless, similar reactions work in the case of copper(II): only (**I**) and (**J**) are not obtained. This is not surprising in the case of (**J**) because it has been recently shown in the literature[27] that during the reaction of the free macrocycle with copper salts, the concentration of the macrocyclic complex (**J**) goes through a maximum, then decreases as decomposition takes place in solution. Indirect preparations with other metal ions can be carried out through demetallation of the nickel complexes and complexation by these ions.[28]

Characterization and properties

NMR results (^1H *and* ^{13}C). Free ligands and nickel(II) complexes are easily characterized by NMR (^1H and ^{13}C). The chemical shifts are reported in Tables 1 and 2. The ^1H NMR spectrum of (AEH) presents three singlets (two CH_3 and one CH group), a triplet–quadruplet set (two CH_2 groups) and two large signals attributable to the NH_2 and NH groups, the latter being strongly deshielded ($\delta \sim 11$ ppm). Selective irradiation of this signal changes the quadruplet (CH_2) into a triplet while irradiation of the second CH_2 signal (triplet) changes the quadruplet into a doublet. The appearance of two complex CH_2 signals is quite good evidence for the formation of (AEH) for they clearly show the inequivalence of the two methylene signals resulting from the monocondensation of 2,4-pentanedione with (En). Furthermore, the results of irradiation confirm the tautomeric form (**A**) for the "half-unit", conversely to the first suggestion.[14] The presence of a hydrogen bond —NH···OC— must be responsible for the deshielding of the NH signal. Most probably, the triplet–quadruplet set for the two CH_2 groups is due to the identity of the coupling constants $^3J_{HNCH} = {}^3J_{HCCH} = 6$ Hz.

The ^{13}C NMR spectrum displays seven signals corresponding to the seven types of carbon atoms present in (AEH): attributions were made, based on proton off-resonance decoupling experiments.[29]

The spectra of ligands (**C**), (**F**), (**L**) and that of complex (**D**) are identical to previously published results.[24,30–32]

The ligand (**E**) presents an interesting NMR spectrum. The two singlets related to the CH_3 groups display rather similar shifts (1.98 and 2.00 ppm). These values are consistent with the substitution of the keto function of (AEH) by an imine function. By analogy to (AEH), the triplet at 2.72 ppm, corresponds to the CH_2 group adjacent to the NH_2 functions. A multiplet centred at 3.30 ppm can be considered as resulting from the superposition of a triplet and a quadruplet of the CH_2N and CH_2NH groups, respectively. The other nuclei gave signals at 3 ppm (NH_2, broad signal), 7.75 ppm (NH, triplet) and 7.98 (CH, singlet). Coupling constants $^3J_{HNCH}$ and $^3J_{HNCH}$ are equal to 5 Hz.

NMR data for complex (**B**) have previously been published.[33] Complex (**J**) gives simple spectra: three

[a] Other resonances: 8.71, 7.43, 7.83 (pyridine).
[b] Other resonances: 2.97 (CH_2, diaminoethane), 6.90–7.57 (tetraphenylborate).
[c] Bad resolution.
s: singlet, d: doublet, t: triplet, q: quadruplet, m: multiplet.

singlets for ^{1}H NMR and four singlets for ^{1}H-decoupled ^{13}C spectra. ^{1}H NMR spectra of (**H**) are identical to literature results[9] when R = H, while ^{13}C NMR spectra display three CH_3 signals and two CN signals when R = CH_3. In order to characterize (**K**) by ^{1}H NMR, it is necessary to substitute perchlorate ions by tetraphenylborate ions. Its ^{1}H NMR spectrum is quite similar to that of the (**B**) complex, with a supplementary broad singlet at 2.97 ppm which corresponds to the CH_2+NH_2 groups of the bridge (En).

Infrared results. Complexes (**H**) and (**K**) display four bands between 3320–3080 cm^{-1} due to NH_2 functions whereas two bands are observed in this area for (**B**) complexes (symmetrical and antisymmetrical stretching vibrations). The increase in the number of bands is presumably due to hydrogen bonds between perchlorate ions and NH_2 groups. The two bands at *ca* 1590 and 1520 cm^{-1} may be assigned to the "double bonds" C=O, C=C and C=N. The band at 1590 cm^{-1} which is lacking in the (**J**) spectrum can be confidently attributed to

Table 2. ^{13}C NMR data (numbering as in Fig. 2)

ν(C=O). The broad band at 1090 cm^{-1} and the sharper one at 625 cm^{-1} are attributed to the perchlorate ion (ν_3 and ν_4). The absence of these bands in (**I**) confirms the deprotonation of the OH function of 2-aminoethanol.

A particular case: *the macrocyclic complex* (**J**), 5,7,12,14 - *tetramethyl* - 1,4,8,11 - *tetraaza* - 4,6,11,13 - *cyclotetradecatetraenato* (2-) *Nickel* (II)

The importance of macrocyclic complexes gives a particular interest to (**J**) which is readily prepared from (AEH). Seemingly, (**J**) has been previously prepared by Holm.[11] However, the physical characteristics of the two samples are not fully identical. For instance, our complex appears as a green microcrystalline powder whereas Holm's complex is described as a red–brown powder.

Analytical results agree with the formula $C_{14}H_{22}N_4Ni$ which is also consistent with mass spectra results. The most important peak is centred at 304 a.m.u., with higher isotopic peaks corresponding to the proposed formulation. Secondary peaks are attributable to deprotonated species, particularly those resulting from the loss of two or four protons. This agrees with the data reported by Holm who showed that (**J**) could be converted to a sixteen-electron π complex with a parent peak at 300 a.m.u.[11]

The NMR results (*vide supra*) are in accordance with the proposed structure. Regarding the electrochemical behaviour, (**J**) does not reduce at potentials of *ca* -2.0 V but undergoes apparent one-electron oxidation at -0.094 V (*vs* Ag/AgCl) in our case while the oxidation is reported to occur at $+0.110$ V (*vs* SCE) for the red–brown compound.

The most important difference between these two complexes is the colour but it is quite difficult to link this difference to a spectral modification since diffuse reflectance spectrum of the red–brown one was not reported. In the present case, the large *d-d* band moves from 16,800 cm^{-1} (solid) to 17,700 cm^{-1} (solution in acetone). Such an effect generally arises from a modification of electronic interactions between the next molecules in the solid state[34] and could be the reason for the difference between these two compounds. Another cause could be the conformation of the pentagonal Ni–N–C–C–N-cycles. Known structural studies show that these cycles have a *left* configuration. For (**J**), three stereochemical possibilities: two enantiomers, $\delta\delta$ and $\lambda\lambda$, and one diastereoisomer $\lambda\delta$, can be envisaged. The template effect of the nickel ion, which is essential for the synthesis of (**J**) could favour one of these forms or alter the *left* configuration of the pentagonal cycles. It is noteworthy that a green complex of the (**J**) type prepared from *ortho*-phenylenediamine presents two flat pentagonal cycles. In our case, structural studies of related complexes of the "half-unit"[25,26] point to a *left* configuration for the diamine chain. Furthermore, breaking of the (AEH) ligands may be discarded since this would result in the formation of (**D**) and (**H**) species which, as previously noted, cannot lead to (**J**). Finally, we suggest that the favoured isomer is the $\lambda\lambda$ enantioner.

Surprisingly compound (**J**) which from static susceptibility measurements is diamagnetic, shows an EPR signal in the solid state. Several samples resulting from different preparations present a thin signal (20 G) centred at $g = 2.0027$. The intensity of this signal does not vary even after exposure to air for a long time. This behaviour is similar to that observed for several diamagnetic metallo-phtalocyanins.[35,36] The g value and a peak-to-peak separation of 20 G are suggestive of the occurrence of π-cation radical species.

Conclusion

A view of Fig. 1 shows the prominent part of the "half-unit" (AEH) [(**A**) and (**B**)] to increase the reactive possibilities of the (AcacH)/(En) system. Kinetic and thermodynamic template effects play a major role in this chemistry, as in the synthesis of macrocycles (**N**).

In this article, reactions of the "half-unit" with (AcacH) and (En) deserve a detailed examination. Under its free (**A**) or complexed (**B**) forms, (AEH) reacts with an excess of (AcacH) or (En) to give terdentate compounds with N_2O_2 (**C, D**) or N_4 sites (**E, H**) that do not undergo further reaction to give the (**J**) macrocycle. Furthermore, if (En) is used in stoichiometric ratio and at ambient temperature, we do not observe a condensation reaction but formation of a dinuclear species (**K**). The formation of (**J**) necessitates the use of the preformed (AEH) exclusively, in the presence of nickel ions. These differences of behaviour are justified within the context of the mechanism recently proposed by Melson.[37]

The first step of the process in going from (**B**) to (**H**) could be the formation of a pentacoordinated $(\mathbf{B}.En)^+$ or hexacoordinated $(\mathbf{B}.2En)^+$ adduct in which one or two (En) molecules acting as monodentate ligands would be axially bound to nickel. The second step would involve deprotonation of the coordinated amine by the base, followed by the nucleophilic attack of the deprotonated amine NH^- at the CO group of the ligand to give (**H**). In this instance, the metal plays two important functions:

(i) it is used for orienting the reactant molecules and (ii) it acts as a positively charged centre able to induce suitable polarization of the coordinated amine and keto functions. The choice between a penta- or hexacoordinated intermediate would necessitate a detailed kinetic study, but we can suggest that, considering the preference of the nickel ion for six-coordination, the intermediate is (**B**.2En)$^+$ while in the case of the copper ion, a pentacoordinated intermediate seems more reliable. Such a model explains the autocondensation of (AEH) leading to (**J**). The intermediate species must involve two "half-units" orthogonally arranged around the hexacoordinated nickel. A similar complex has been isolated with cobalt (III).[14] Eventually, the decisive step would be the formation of an unstable penta- or hexacoordinated complex; the impossibility to form such a compound could explain the lack of reaction between (**H**) and (AcacH) or between (**D**) and (En). We found[29] that (**D**) remains diamagnetic in the presence of pyridine, while (**B**) becomes paramagnetic owing to the formation of a hexacoordinated species (**G**).

We can also recall the abnormal properties of the (**J**) macrocycle which need further study and particularly, a structural determination.

EXPERIMENTAL

Microanalyses were preformed by the Service Central de Microanalyses du CNRS, Lyon. Infrared spectra of KBr discs were recorded using a Perkin–Elmer 577 spectrometer, visible spectra using a Cary 14 spectrophotometer. Mass spectra were obtained using a VG Micromass 7070F spectrometer. Proton and ^{13}C NMR spectra were run on a Bruker WH90 using TMS (^1H spectra) and $CDCl_3$ (^{13}C spectra) as internal references. All chemical shifts (^1H and ^{13}C) are given in ppm *vs* TMS using CD_3COCD_3 or $CDCl_3$ as solvent. EPR spectra were obtained on a Bruker 200 TT spectrometer. Polarographic measurements were obtained with a "home-made microcomputer-controlled instrument" according to the following experimental conditions: 10^{-3} M in CH_3CN/Et_4NClO_4 (Fluka) 0.1 M medium; ambient temperature, potential measured *vs* Ag/AgCl (0.1 M KCl) as reference electrode.

Preparations

Some of the compounds and ligands were prepared according to literature processes, *viz.* (AEH),[14] (**B**),[33] (**B′** and **O**),[26] (**C** and **D**),[3,4] (**L, M** and **N**).[24]

(**E**) *ligand.* To an aqueous solution of (AEH) was added another aqueous solution containing one equivalent of (En) and of acetic acid. The mixture was stirred overnight. An aqueous Na_2CO_3 solution then was added and finally chloroform. The organic layer was dried and concentrated. Addition of ether caused a small amount of a precipitate to appear which was then filtered and dried.

(**F**) *ligand.* Addition of NH_4Cl to an alcoholic solution of (AEH) yielded the salt of diazepine (**F, HX**) (70% yield) which was isolated and neutralized to give (**F**).

(**K**) *complexes.* To a solution of (AEH) (7×10^{-3} M) in MeOH (50 cm^3) was added upon stirring the equivalent amount of a MeOH solution of NaOMe. A few minutes later, $NiClO_4 \cdot 6H_2O$ (2.57 g in 20 cm^3 of MeOH), then an (En) solution (3.3×10^{-3} M in 10 cm^3 of MeOH) were added. An orange precipitate appeared readily which was filtered, washed with MeOH and dried (80% yield). Calc. (Found) for $C_{16}H_{34}Cl_2N_6Ni_2O_{10}$: C, 29.2 (29.1); H, 5.2 (5.2); N, 12.8 (12.7); Ni, 17.7 (17.2); Cl, 10.8 (10.7)%.

With $CuClo_4 \cdot 6H_2O$, a similar experimental procedure yielded a blue product (80% yield). Calc. (Found) for $C_{16}H_{34}Cl_2Cu_2N_6O_{10}$: C, 28.7 (28.6); H, 5.1 (5.1); N, 12.6 (12.4); Cu, 19.0 (19.2); Cl, 10.6 (10.5)%.

(**J**) *complex.* To (AEH) (2 g, 1.410^{-2} M) in MeOH (60 cm^3) were added the equivalent amount of NaOMe (1.4×10^{-2} M) and Py_2NiCl_2[38] (2 g, 0.7×10^{-2} M). The mixture was heated for 20 min at 50°C under argon. The solution turned from yellow to red and gave a green precipitate. After cooling and filtration, the precipitate was taken back by boiling toluene and filtered again. After cooling, green microcrystals appeared. They were isolated and dried under reduced pressure (30% yield). This compound could also be obtained using (**B**) and (AEH) according to the procedure of the (**H**) complexes but the yield was lower. Calc. (Found) for $C_{14}H_{22}N_4Ni$: C, 55.3 (54.9); H, 7.2 (7.2); N, 18.4 (18.0); Ni, 19.1 (19.0)%.

(**H**) *and* (**I**) *complexes.* (**B**) (1 g) was suspended in water (30 cm^3). Addition of (En) (0.4 cm^3) and NaOH (0.1 g) caused the solubilization of the nickel complex. The mixture was brought to boiling for 15 min and left to stand overnight. The resulting red crystals were filtered and dried (50% yield). Calc. (Found) for $C_9H_{19}ClN_4NiO_4$: C, 31.7 (31.5); H, 5.6 (5.7); N, 16.4 (16.2)%. Substituting 1,2-diaminopropane for 1,2-diaminoethane yielded a more soluble, red compound (30% yield). Calc. (Found) for $C_{10}H_{21}ClN_4NiO_4$: C, 33.8 (33.5); H, 5.9 (6.0); N, 15.8 (15.6)%.

Use of ethanolamine yielded the red product (**I**). The mass spectrum of this compound gives the par-

ent peak at 241 a.m.u. (100) corresponding to the $C_9H_{17}N_3NiO$ formula while (**H**) complexes do not give such parent peaks in the same experimental conditions. Calc. (Found) for $C_9H_{17}N_3NiO$: C, 44.8 (44.1); H, 7.0 (7.2); N, 17.4 (16.9)%. In the case of [CuAEPy](ClO_4) and (En), a green product appeared (35% yield). Calc. (Found) for $C_9H_{19}ClCN_4O_4$: C, 31.2 (31.2); H, 5.5 (5.6); N, 16.2 (15.9)%.

(*Received* 4 *June* 1987; *accepted* 10 *July* 1987)

Abstract—The title complex, prepared by reacting lead(II) nitrate with a stoichiometric amount of 1-methylimidazoline-2(3H)-thione (mimt) in water, crystallizes in the triclinic space group $P\bar{1}$ with $a = 9.334(2)$, $b = 11.340(4)$, $c = 11.398(3)$ Å, $\alpha = 108.24(2)$, $\beta = 95.69(2)$, $\gamma = 100.27(2)°$ and $Z = 1$. In the solid state, the molecules show an unusual dimeric structure, with the formula $[(mimt)_2(NO_3)_2Pb(\mu\text{-}mimt)_2Pb(NO_3)_2(mimt)_2]$.

Imidazoline-2-thiones are familiar as ligands to a number of metals, including Cr,[1] Co,[2–5] Ni,[6–8] Cu,[9–10] Zn,[4,5,11] Pd,[12] Cd,[4] and Pt[13] complexes which have been well characterized. The coordination behaviour of ligands of this type is of interest as they serve as partial models for the biological imidazoline-2-thione derivative, ergothioneine found in erythrocytes.

Herein, we report the preparation and characterization of a complex of lead(II) with 1-methylimidazoline-2(3H)-thione. An X-ray crystal structure shows that the complex consists of discrete dimeric units with the formula $[Pb_2(C_4H_6N_2S)_6(NO_3)_4]$ per dimer.

EXPERIMENTAL

Preparation of hexakis (1-methylimidazoline-2(3H)-thione)tetrakis(nitrato)dilead(II)

To a hot (70°C) solution of lead(II) nitrate (0.66 g, 2.0 mmol) in water (10 cm^3) was added a hot (70°C) solution of 1-methylimidazoline-2(3H)-thione (Aldrich; 0.69 g, 6.0 mmol) in water (5 cm^3). The resulting green–yellow solution was evaporated to approximately one quarter its original volume, cooled and scratched with a glass rod, whereupon a yellow, microcrystalline solid was deposited. The product was isolated by filtration, washed with a little cold water and dried over anhydrous $CaCl_2$. Yield 0.97 g, 72%. M.p. 148–148.5°C. (Found: C, 21.2; H, 2.7; N, 16.5; Pb, 31.1. $C_{24}H_{36}N_{16}O_{12}Pb_2S_6$ requires C, 21.4; H, 2.7; N, 16.6; Pb, 30.8%.) Crystals suitable for X-ray diffraction studies were grown by slow evaporation of a solution of the complex in water.

Analytical and spectroscopic measurements

Microanalyses were carried out by Butterworth Laboratories Ltd., Teddington, Middlesex, U.K. Melting points were measured using a Gallenkamp MF-370 melting point apparatus and are uncorrected. Infrared spectra were recorded, for samples mulled in liquid paraffin and in hexachlorobutadiene, and held between NaCl plates, in the range 4000–600 cm^{-1} on a Perkin–Elmer PE 297 spectrophotometer. U.V.–visible absorbance measurements were recorded for samples dissolved in water and contained in matched silica cells (path-

* Authors to whom correspondence should be addressed.

length = 1 cm) on a Pye–Unicam SP6-500 spectrophotometer. The ^{1}H NMR spectrum was recorded at 250 MHz on a Bruker AM-250 spectrometer, at 30°C, using a sample dissolved in ^2H_2O, and was referenced to $Na^+(CH_3)_3Si(CH_2)_3SO_3^-$.

Crystal structure determination

Crystal data. $C_{24}H_{36}N_{16}O_{12}Pb_2S_6$, $M = 1347.43$. Triclinic, $a = 9.334(2)$, $b = 11.340(4)$, $c = 11.398(3)$ Å, $\alpha = 108.24(2)$, $\beta = 95.69(2)$, $\gamma = 100.27(2)°$, $V = 1111.9(6)$ Å^3 (by least-squares fit to the setting angles of 25 reflections, $\theta \geqslant 12°$), Mo-K_α radiation ($\lambda = 0.71069$ Å), space group $P\bar{1}$ (No. 2, C_i^1), $Z = 1$, $D_x = 2.01$ g cm^{-3}. Pale cream prisms. Crystal dimensions *ca* $0.6 \times 0.5 \times 0.3$ mm. $F(000) = 648$, μ(Mo-K_α) = 79.6 cm^{-1}.

Data collection and processing. Enraf–Nonius CAD4F diffractometer, $\theta/2\theta$ scan mode. A unique hemisphere of data (h, 0–11, k, −13–13, l, −13–13) totalling 4161 observations, $2 \leqslant \theta \leqslant 25°$ were collected, yielding 3897 independent reflections, of which the 3345 reflections having $I > 3.0\sigma(I)$ were deemed observable and used for structure solution and refinement. The intensities of 3 reflections (016, $\bar{1}\bar{5}5$, and $\bar{3}4\bar{5}$) were monitored during data collection, and a linear decay correction (equivalent to *ca* 10% over 10,000 reflections) was applied to all data. Data were also corrected for Lorentz/polarization effects, and for absorption using the method of Walker and Stuart.[14]

Structure solution and refinement. Patterson and Fourier methods for all non-hydrogen atoms. H atoms included at fixed, calculated positions (methyl C—H 1.084, ring C—H and N—H 1.073 Å). Full-matrix least squares refinement, with all non-hydrogen atoms anisotropic, minimizing $w(|F_o| - |F_c|)^2$ with the weighting scheme $w = 1/\sigma^2(F)$ used and judged satisfactory, gave final discrepancy indices R and R_w of 0.031 and 0.037, respectively. A final difference-Fourier synthesis showed no peaks greater than 1.16 nor less than −1.29 e Å^3, the largest features being in the vicinity of the Pb atom. Scattering factors were taken from ref. 15, with corrections for anomalous dispersion. All calculations were carried out on a Gould–SEL 32/27 minicomputer using the GX suite of programs.[16] Selected bond lengths and interbond angles are given in Table 1.*

RESULTS AND DISCUSSION

The reaction between $Pb(NO_3)_2$ and 1-methylimidazoline-2(3H)-thione (mimt) in water at 70°C gives a yellow product which has been shown by X-ray crystallography to exist in the solid state as discrete dimeric units, $[\{(mimt)_2(NO_3)_2Pb\text{-}(\mu\text{-}mimt)\}_2]$ (Fig. 1) separated by normal van der Waals distances. The two lead atoms in the formula unit are related by a crystallographic centre of symmetry and are bridged by the sulphur atoms of two mimt ligands. The distances between lead and the bridging S atoms are 3.053(2) and 3.195(2) Å; and the Pb—S_b—Pb and S_b—Pb—S_b angles are 82.0(1) and 98.0(1)° respectively, giving a Pb—Pb distance of 4.102(1) Å. Two more mimt ligands are coordinated to the Pb in positions essentially *trans* to the bridging ligands. Thus, S(1)—Pb—S(3) = 165.8(1)° and S(1′)—Pb—S(2) = 170.4(1)°. As expected, the Pb—S bond lengths to the nonbridging mimt ligands are shorter than those to the bridging ligands: Pb—S(2) = 2.850(2) Å and Pb—S(3) = 2.826(2) Å. These distances may be compared with Pb—S distances of *ca* 3.05 Å (bridging) and *ca* 2.96 Å (nonbridging) in a related lead–thiourea complex.[17] The overall geometry of the $\{(mimt)_2Pb(\mu\text{-}mimt)_2Pb(mimt)_2\}$ unit is reminiscent of the core structure found[18] for a nickel ethanethiolate complex, $[Ni_2(SEt)_6]^{2-}$, in that the bridging ligands adopt an *anti* configuration and the thione coordination about lead is distorted square planar. The mimt ligands are unremarkable in geometry compared to that found in 1,3-dimethylimidazoline-2-thione.[19] In particular, the C—S bond lengths in the complex (mean = 1.699(7) Å) are close to that in 1,3-dimethylimidazoline-2-thione (1.696(5) Å), and are indicative of partial C=S character. However, there is clearly some contribution to the electronic structure of the mimt ligand from a canonical resonance form involving a thiolate-type sulphur.[19] In addition, the mimt ligands are all essentially planar, with the greatest deviation from the mean plane defined by the five ring atoms being 0.012(8) Å for C(24).

The coordination sphere of lead is completed by two nitrato groups, one monodentate, the other bidentate, giving an overall coordination number of seven. However, the coordination geometry about lead can be described as distorted octahedral if the bidentate nitrate is considered to occupy a single coordination site. The conventional geometries for seven-coordination[20] are pentagonal bipyramidal, capped octahedral or capped trigonal prismatic:

* Atomic co-ordinates, thermal parameters, full lists of bond lengths and angles, and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

[a] O(CT) is centroid of O(21) and O(22).

none of these geometries adequately describes the irregular stereochemistry found in this complex. This may be due to a stereochemically active lone pair of electrons. However, the geometry is irregular, whatever basis is chosen to describe the coordination polyhedron. Thus, we choose to describe the geometry as distorted octahedral, with the bidentate nitrato ligand occupying a single site. If the mean position of the coordinated oxygen atoms of the bidentate nitrato group is O(CT) then S(1)—Pb—O(CT) = 81.9°, S(1′)—Pb—O(CT) = 83.9°, and S(2)—Pb—O(CT) = 103.6°, values which support our description of the geometry. The appearance of a dimeric unit in the solid-

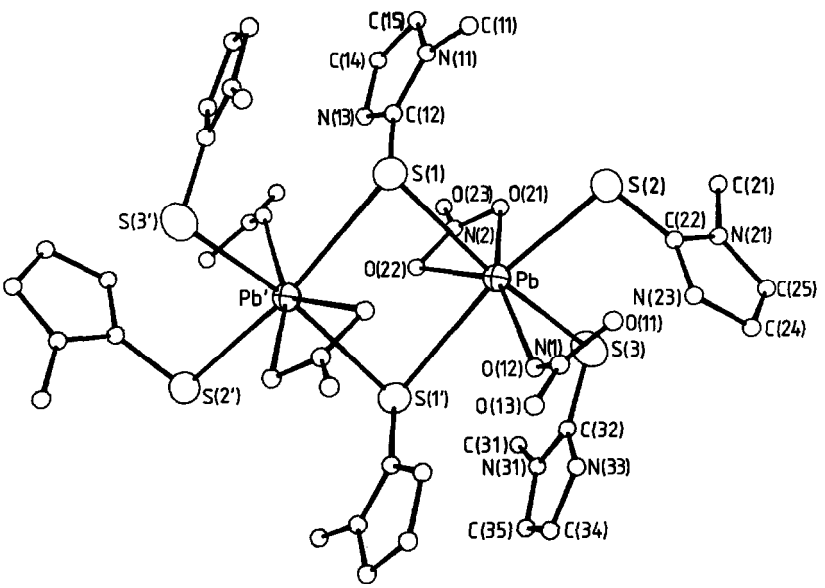

Fig. 1. Molecular structure of $[(mimt)_2(NO_3)_2Pb(\mu\text{-}mimt)_2Pb(NO_3)_2(mimt)_2]$.

state structure was unexpected and is unusual for complexes of this ligand.[1-13] Related complexes of Pb with thiourea (tu) have structures which are almost exclusively one-dimensionally non-molecular.[17] An exception is the triclinic form of $[Pb(tu)_6](ClO_4)_2$,[21] which consists of discrete, distorted octahedral $[Pb(tu)_6]^{2+}$ cations and ClO_4^- anions. Thus, this structure is unusual in being merely dimeric.

Confirmation of the presence of an N—H group in the compound is found in the infrared spectrum, where a fairly weak band is seen at 3150 cm^{-1}, compared with 3120 cm^{-1} in the free ligand. No S—H absorption around 2600 cm^{-1} was detected, confirming the thione tautomer. There are several bands in the region 1000–1500 cm^{-1}, where vibrations of coordinated NO_3^- should occur.[22] However, these are obscured by mimt ligand vibrations in the same region. There is little agreement on the position of C—S stretching vibrations.[23] Several bands in the spectrum might be assigned to this vibration, including one at 740 cm^{-1}.

The title compound dissolves in water to give a yellow solution ($\lambda_{max} = 208$ nm, $\varepsilon = 3.9 \times 10^4$ dm^3 mol^{-1} cm^{-1}; $\lambda_{max} = 255$ nm, $\varepsilon = 4.2 \times 10^4$ dm^3 mol^{-1} cm^{-1} per dimer), which has resonances in its ^1H NMR spectrum at $\delta = 3.58$ ppm (s, CH_3); 6.95 ppm (d, $J = 2.3$ Hz, CH) and 7.03 ppm (d, $J = 2.3$ Hz, CH). This apparent equivalence of the mimt ligands in solution suggests that the dimer does not remain intact in solution, but dissociates—perhaps to form monomeric $[Pb(mimt)_3]^{2+}$ cations.

OXYGEN ABSTRACTION FROM TETRAHYDROFURAN BY MOLYBDENUM–IODIDE COMPLEXES. X-RAY MOLECULAR STRUCTURE OF $[Mo_2(\mu\text{-}O)(\mu\text{-}I)(\mu\text{-}O_2CCH_3)I_2(THF)_4][MoOI_4(THF)]$ (THF = TETRAHYDROFURAN)

F. ALBERT COTTON* and RINALDO POLI

(*Received* 30 *March* 1987; *accepted* 1 *July* 1987)

Abstract—The interaction between $Mo_2(O_2CCH_3)_4$, Me_3SiI and I_2 in THF resulted in oxygen abstraction from the solvent and formation of $[Mo_2(\mu\text{-}O)(\mu\text{-}I)(\mu\text{-}O_2CCH_3)I_2(THF)_4]^+[MoOI_4(THF)]^-$ and $I—(CH_2)_4—I$. The molybdenum complex has been characterized by X-ray diffractometry. *Crystal data*: triclinic, space group $P\bar{1}$, $a = 13.827(3)$ Å; $b = 15.803(7)$ Å; $c = 9.950(3)$ Å; $\alpha = 93.34(4)°$; $\beta = 102.40(2)°$; $\gamma = 90.09(2)°$; $V = 2120(2)$ Å^3; $Z = 2$; $d_{calc} = 2.559$ g cm^{-3}; $R = 0.0476$ ($R_w = 0.0613$) for 370 parameters and 3938 data with $F_0^2 > 3\sigma(F_0^2)$. The metal-metal distance in the cation is 2.527(2) Å and indicates a strong interaction. The magnetic behavior is consistent with the assignment of one unpaired electron to the Mo_2^{7+} core of the cation and one to the d^1 Mo(V) center of the anion. The interaction between $Mo(CO)_6$ and I_2 in THF also results in the formation of 1,4-diiodobutane.

We have recently been investigating the relatively unexplored chemistry of molybdenum–iodide complexes.[1–3] Among other things, we spent some time trying to obtain the tetrahydrofuran adduct of molybdenum(III), $MoI_3(THF)_3$, as this might be expected to be a good starting material for the synthesis of the virtually unknown class of molybdenum(III)–iodide derivatives. We were eventually able to prepare the compound by iodine oxidation of low-valent molybdenum carbonyl derivatives.[3] Among other unsuccessful strategies, we also tried to obtain the above mentioned material by iodine oxidation of quadruply bonded molybdenum(II) iodide dimers, $Mo_2I_4L_4$. This led to the discovery of a quite complex reactivity which involves oxygen abstraction from the solvent and formation of a metal complex with a higher average oxidation state. We report here this chemistry and the X-ray molecular structure of the peculiar molybdenum product.

EXPERIMENTAL

All operations were carried out under an atmosphere of prepurified argon with standard Schlenk-tube techniques. Solvents were dried by conventional methods and distilled under dinitrogen prior to use. Instruments used were as follows: IR, Perkin–Elmer 783; ^{1}H-NMR, Varian XL-200; GC-MS, HP 5995; magnetic susceptibility, Johnson–Matthey JME. $Mo_2(O_2CCH_3)_4$ was prepared as described in the literature,[4] while Me_3SiI was obtained from Aldrich and used as received.

Preparation of $[Mo_2OI_3(O_2CCH_3)(THF)_4][MoOI_4(THF)]$

$Mo_2(O_2CCH_3)_4$ (1.09 g, 2.54 mmol) was suspended in 15 cm^3 of THF and treated with Me_3SiI (1.50 cm^3, 10.5 mmol). Most of the insoluble mo-

* Author to whom correspondence should be addressed.

lybdenum compound, but not all, rapidly dissolved to afford a deep yellow solution. The appearance of the mixture did not change upon brief reflux. Treatment with an additional 0.50 cm^3 of Me_3SiI (3.5 mmol) caused the complete disappearance of the yellow solid. A solution of I_2 (0.43 g, 1.68 mmol) in 15 cm^3 of THF was then added dropwise at room temperature. The solution first turned green and then a dark grey solid started to precipitate. At the end of the addition there was much precipitate, while the supernatant liquid had a dark red color. The product was filtered off, washed with THF and dried *in vacuo*. Yield: 0.91 g [33% with respect to the molybdenum(II) acetate, 100% with respect to I_2 and the stoichiometry of eq. (2), see Discussion]. IR (nujol mull): 2340 w (br), 1265 w, 1440 vs (br), 1380 s, 1345 s, 1055 m, 1025 m, 945 w, 680 s, 620 m, 595 w, 385 s, and 345 s cm^{-1}. $\chi_g = 2.20 \times 100^{-6}$ c g s; $\mu_{eff} = 3.14$ BM [diamagnetic correction (molar) $= -553.1 \times 10^{-6}$ c g s]. A GC-MS analysis of the filtered solution showed the presence of $I—(CH_2)_4—I$ (M^+, $m/e = 310$).

A single crystal for the X-ray analysis was obtained as follows: $Mo_2(O_2CCH_3)_4$ (0.21 g, 0.50 mmol) in THF (5 cm^3) was treated with 0.30 cm^3 of Me_3SiI (2.1 mmol). After brief stirring the mixture was filtered and a solution of I_2 (0.08 g, 0.31 mmol) in 10 cm^3 of *n*-hexane was carefully layered on top of it. A mixture of well-formed black and yellow crystals was produced upon diffusion. A black crystal was used for the subsequent X-ray analysis. A yellow crystal was selected and its cell constants determined from its X-ray diffraction pattern. These correspond to those reported[5] for $Mo_2(O_2CCH_3)_4$. The identity of the black crystals with the grey microcrystalline material obtained in the above described procedure was confirmed by IR analysis.

Reaction between $Mo(CO)_6$ *and* I_2 *in* THF

$Mo(CO)_6$ (4.62 g, 17.5 mmol) was treated with I_2 (6.69 g, 26.4 mmol) in THF (50 cm^3). The mixture was refluxed for 3 days. IR monitoring in the carbonyl stretching region showed the disappearance of the carbonyl starting material (band at 1979 cm^{-1}). The final mixture contained a black insoluble solid, whose nature was not further investigated. After filtration, the solution was reduced in volume by room temperature evaporation at reduced pressure. A dense liquid remained at the end of the treatment. Distillation of this residue under reduced pressure yielded 4.48 g of colorless $I—(CH_2)_4—I$ (b.p. 69–80°C at *ca* 6×10^{-2} mm Hg), identified by IR, ^{1}H-NMR and MS (55% yield with respect to I_2).

X-ray crystallography for $[Mo_2OI_3(O_2CCH_3)(THF)_4][MoOI_4(THF)]$

A single crystal was glued under argon to the inside of a thin-walled capillary and mounted on the diffractometer. The cell constant determination, data collection and reduction were routine. A semi-empirical absorption correction based on the variation of intensity during azimuthal (ψ) scans for nine standard reflections having an Eulerian angle χ close to 90° was applied.[6] The structure was solved with the SHELXS-86[7] direct methods program package and refined by alternating cycles of full-matrix least-squares and difference Fourier maps. An additional absorption correction was applied at the end of isotropic refinement.[8] The agreement factor R was then 0.122. Anisotropic refinement converged at $R = 0.0476$ ($R_w = 0.0613$). The highest peaks in the final difference Fourier map, having a height of > 1 e $Å^{-3}$, were all located at < 1.0 Å distance from the iodine atoms and were attributed to series termination errors and/or deficiencies in the absorption correction. Pertinent crystal data are assembled in Table 1 and selected bond distances and angles are in Table 2.*

RESULTS AND DISCUSSION

We allowed $Mo_2(O_2CCH_3)_4$ to interact with four equivalents of Me_3SiI in THF as solvent, with the hope that this would afford the reactive intermediate $Mo_2I_4(THF)_4$ according to eq. (1).

$$Mo_2(O_2CCH_3)_4 + 4Me_3SiI + 4THF \rightarrow Mo_2I_4(THF)_4 + 4Me_3SiO_2CCH_3. \quad (1)$$

The same strategy has been employed for the preparation of chloride,[9,10] bromide[11] and iodide derivatives[12] of the Mo_2^{4+} core containing phosphine ligands, although higher nuclearity clusters were sometimes obtained.[9] We have evidence that reaction 1 does not proceed to completion when a $Me_3SiI/Mo_2(O_2CCH_3)_4$ ratio of 4:1 is employed. Some molybdenum acetate remains unreacted in these conditions and even the use of an excess of the silyl reagent over the 4:1 ratio results in the formation of a final product where one acetate group is still present. We believe that the incom-

* A full list of bond distances and angles, positional parameters, anisotropic displacement parameters and F_o/F_c data have been deposited with the Editor as supplementary materials. The atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

[c] Quality-of-fit $= [\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

pleteness of reaction 1 is caused by a competitive interaction of Me_3SiI with the solvent (*vide infra*).

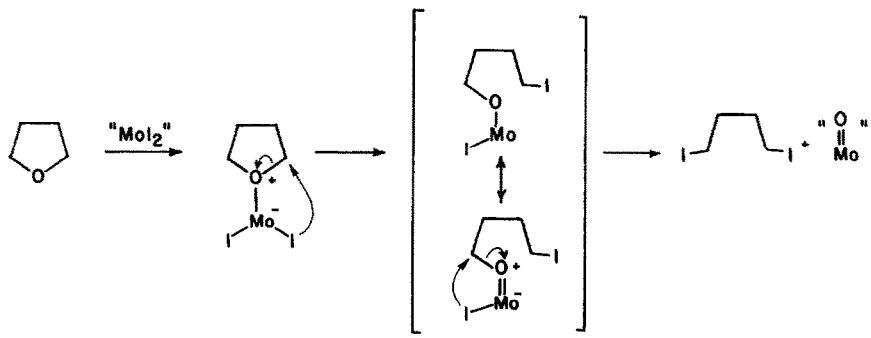
Once the interaction between $Mo_2(O_2CCH_3)_4$ and Me_3SiI is completed, a subsequent treatment with I_2 causes the formation of a precipitate, identified as $[Mo_2(\mu\text{-}O)(\mu\text{-}I)(\mu\text{-}O_2CCH_3)I_2(THF)_4]^+[MoOI_4(THF)]^-$ by X-ray analysis. The stoichiometry of the reaction is represented in eq. (2). The formation of 1,4-diiodobutane has been confirmed by GC-MS analysis.

$$3Mo_2(O_2CCH_3)_4 + 10Me_3SiI + 6I_2 + 14THF \rightarrow 2[Mo_2OI_3(O_2CCH_3)(THF)_4][MoOI_4(THF)] + 10Me_3SiO_2CCH_3 + 4I{-}(CH_2)_4{-}I. \quad (2)$$

We suggest that the oxophilicity and the Lewis acidity of the molybdenum center make a molybdenum-assisted iodide cleavage of THF possible, as shown in Scheme 1.

It is well known that ethers can be cleaved by HI and also by HX (X = Br, Cl) in the presence of Lewis acids such as $ZnCl_2$.[13] Me_3SiI has also been found to be effective in the cleavage reaction of ethers.[14] The room temperature interaction between THF and Me_3SiI in $CDCl_3$ as solvent was reported to take place rapidly with formation of $Me_3Si{-}O{-}(CH_2)_4{-}I$ followed by slow conversion to $I{-}(CH_2)_4{-}I$.[14a] We cannot therefore exclude *a priori* that 1,4-diiodobutane is produced only by interaction of Me_3SiI with THF and that the oxygen atom is then in some way transferred from the silicon to the molybdenum centers. We observe, however, that in our system the molybdenum acetate dimer will compete with THF for the silyl reagent according to eq. (1). The observed fast dissolution of the insoluble $Mo_2(O_2CCH_3)_4$ upon treatment with Me_3SiI indicates that reaction between these two compounds does occur. The competitive interaction between Me_3SiI and THF may, however, account for the incompleteness of reaction 1.

That the molybdenum center is capable of assisting the cleavage reaction of THF by iodide is proved by the result of the interaction between $Mo(CO)_6$ and I_2 in THF. The interaction between $Mo(CO)_6$ and I_2 in a 2:3 ratio in refluxing benzene–toluene



Scheme 1.

is a good synthetic method for anhydrous MoI_3.[15] When, however, we carried out the same interaction in boiling THF [hoping to produce the THF adduct, $MoI_3(THF)_3^3$], significant amounts of 1,4-diiodobutane were obtained together with an uncharacterized black solid, presumably an oxo-iodide of molybdenum.

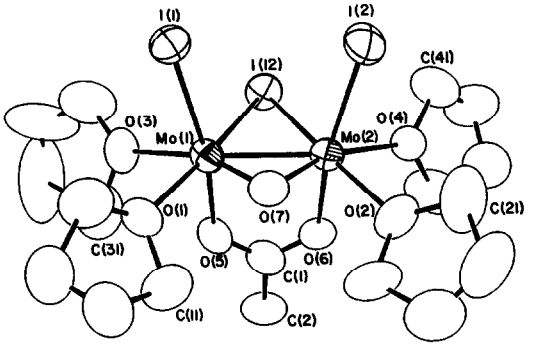

Fig. 1. An ORTEP view of the $[Mo_2OI_3(O_2CCH_3)(THF)_4]^+$ ion.

Molecular structure

A view of the cation is illustrated in Fig. 1, while the anion is shown in Fig. 2. The assignment of the

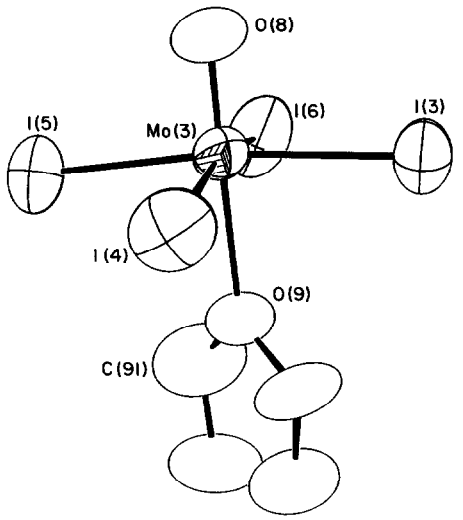

Fig. 2. An ORTEP view of the $[MoOI_4(THF)]^-$ ion.

charge to the two ions is based on the existence in the literature of another salt of the $[MoOI_4L]^-$ anion (L = H_2O).[16] Also, this assignment fits well with the observed magnetic properties of the compound (*vide infra*).

The cation is a dinuclear complex with a distorted edge-sharing bioctahedral arrangement of the ligands. A bridging oxygen atom and a bridging iodine atom are the ligands defining the shared edge. An axially coordinated acetate group also bridges the two metal centers. The coordination spheres are completed by one axial iodide ligand and two equatorial THF groups per molybdenum atom. This cation therefore contains three different bridges between the metal atoms. An identical configuration has been found for the rhenium compound $Re_2OCl_5(O_2CC_2H_5)(PPh_3)_2$,[17] the two metal atoms being bridged there by an oxygen atom, a chlorine atom and a propionato group.

There are several reasons for the deviation of the geometry from the ideal edge-sharing bioctahedral one. The first one is the different bond lengths to the two bridging atoms in the shared edge (average values are given): Mo—(μ-O), 1.87 Å; Mo—(μ-I), 2.734 Å. Another is the close contact between the two axial iodide ligands (I···I: 3.931 Å), which is less than the sum of the van der Waals radii (4.30 Å).[18] These two atoms thus push each other away from the ideal axial positions (the average I—Mo—O angle involving the acetate oxygen atom is 168.6°). The equatorial donor atoms show only slight deviations from the respective least-squares planes. Each molybdenum atom, on the other hand, is displaced away from its own local equatorial plane by 0.140(1) Å towards the axial iodine atom. The two planes form a dihedral angle of 21.2(4)°.

The metal–metal separation of 2.527(2) Å indicates a strong bonding interaction. A Mo_2^{7+} core is present in the cation, with five electrons available for metal–metal bonding. These may be distributed among the orbitals of the dimetal core either in the $\sigma^2\pi^2\delta^1$ or in the $\sigma^2\pi^2\delta^{*1}$ order.[19] In either case a paramagnetism for the ion is expected corresponding to one unpaired electron. A distance of 2.789(1) has been reported for the d^3–d^3 compound $Mo_2Cl_6(dppm)_2$ [dppm = bis(diphenylphosphino) methane], which is believed to have a $\sigma^2\pi^2\delta^{*2}$ configuration. No edge-sharing bioctahedral compound of Mo(IV) with a metal–metal bonding interaction seems to have been reported. The edge-sharing bioctahedral $[Mo_2Cl_{10}]^{2-}$ complex has a metal–metal separation of 3.80 Å, which indicates no bonding interaction.[20] The compound $Mo_2S_2(SCNPr_2)_2(S_2CNPr_2)_2$, however, has been described as containing a double bond between Mo(IV) centers,[21] with a metal–metal distance of 2.705(2) Å. The shorter distance in our compound might then be due to the occupation of the δ orbital by the fifth electron, but it is also possible that the two metals are forced closer to each other by the presence of the small oxo bridge.

The average separation between molybdenum and terminal iodine atoms is a little shorter (2.705 Å) than those involving the bridging iodine atom. These Mo—I bond lengths are shorter than those commonly found for other molybdenum–iodide complexes,[1-3,22] in agreement with the higher oxidation state and the positive charge of the ion. The Mo—(μ-O) distances are slightly shorter than those typical of Mo—(μ-O)—Mo moieties in trinuclear clusters of molybdenum(IV) (the latter being in the 1.91–1.94 Å range)[23] and may indicate some double bond character. The Mo—O distances involving the acetato group (average 2.084 Å) compare with those found in $Mo_2(O_2CCH_3)_4$ (2.10–2.21 Å),[5] while those involving the THF ligands (2.19–2.21 Å) are in the same range found in $MoI_3(THF)_3$.[3]

The anion (see Fig. 2) is a distorted octahedral complex of Mo(V). The structural parameters compare well with those of the very similar anion $[MoOI_4(H_2O)]^-$.[16] The Mo—I distances are longer than those found in the cation (*vide supra*) in spite of the higher oxidation state in the anion. This may be due to the different charge of the two ions. The Mo—O(THF) bond length is also substantially longer in the anion, mainly because of the well-known strong *trans* influence of the oxo group. The molybdenum atom is displaced away from the least-squares plane of the four iodine atoms by 0.265(1) Å, towards the oxo ligand.

A d^1 electronic configuration for the Mo(V) center is present in the anion. The salt $[Mo_2OI_3(O_2CCH_3)(THF)_4][MoOI_4(THF)]$ is therefore expected to have two unpaired electrons, one in the cation and one in the anion. A magnetic susceptibility measurement agrees with this view, as an effective magnetic moment of 3.14 BM is found at room temperature.

RAPID THERMAL HYDROGEN PRODUCTION FROM 2,3-BUTANEDIOL CATALYZED BY HOMOGENEOUS RHODIUM CATALYSIS

DAVID MORTON and DAVID J. COLE-HAMILTON*

Chemistry Department, University of St. Andrews, St. Andrews, Fife KY16 9ST, U.K.

and

JOHN A. SCHOFIELD and ROBERT J. PRYCE

Sittingbourne Research Centre, Shell Biosciences Division, Sittingbourne, Kent, ME9 8HG, U.K.

(*Received* 25 *April* 1987; *accepted* 11 *May* 1987)

Abstract—Thermal production of hydrogen from butane-2,3-diol is achieved with rates of up to 125 catalyst turnovers per hour using the homogeneous rhodium catalysts, $[Rh(bipy)_2]Cl$, $[RhH(P^iPr_3)_3]$ and $[RhCl(PPh_3)_3]$. (bipy = 2,2′-bipyridyl).

High grade fuel oils can be obtained from the hydrogenation of biomass,[1] but the need for external hydrogen has meant that such processes are not generally commercially viable. The ability to produce hydrogen from biomass, or from products that are readily formed from biomass might allow such hydrogenations to be carried out in a one or two stage system without the need for other sources of hydrogen.

One material that can readily be produced by fermentation reactions is butane-2,3-diol and we now report the rapid thermal dehydrogenation of this compound under mild conditions.

Heating butane-2,3-diol with $[Rh(bipy)_2]Cl$, $[RhCl(PPh_3)_3]$ or $[RhH(P^iPr_3)_3]$ in the presence of base produces hydrogen at initial rates corresponding to 66–125 mol of hydrogen per mol of catalyst per hour (Table 1). These rates, which correspond to up to 1.1 l of hydrogen per l of catalyst solution per hour are considerably higher than is normally observed for alcohol dehydrogenation reactions, although comparable to those obtained from high boiling alcohols using $[Ru(PPh_3)_2(CO)(O_2CCF_3)_2]$[2] or from ethanol using $[Rh(bipy)_2]Cl$.[3] The initial fast rates fall slightly after *ca.* 2 h, but sustained hydrogen production at 40–90 turnovers per hour can be achieved for at least 24 h.

Although for $[Rh(bipy)_2]Cl$, similar rates of hydrogen production can be obtained using ethanol as substrate,[3] hydrogen is only produced in very low yields for thermal reactions of ethanol catalyzed by $[RhH(P^iPr_3)_3]$ or $[RhCl(PPh_3)_3]$. We attribute the much higher yields and rates of hydrogen production from butane-2,3-diol to the absence of the facile decarbonylation of alkanals (the products of dehydrogenation of primary alcohols) by rhodium(I) complexes and the stability of the carbonyl species formed towards CO loss. In the case of $[Rh(bipy)_2(CO)]^+$, CO can be lost by water–gas shift type chemistry[3,4] and for $[RhH(CO)P^iPr_3)_2]$, CO can be lost photochemically, accounting for the activity of $[RhH(P^iPr_3)_3]$ for photochemical decomposition of primary alcohols.[5]

Since butane-2,3-diol is a secondary alcohol, the possible reaction products, acetoin and butane-2,3-

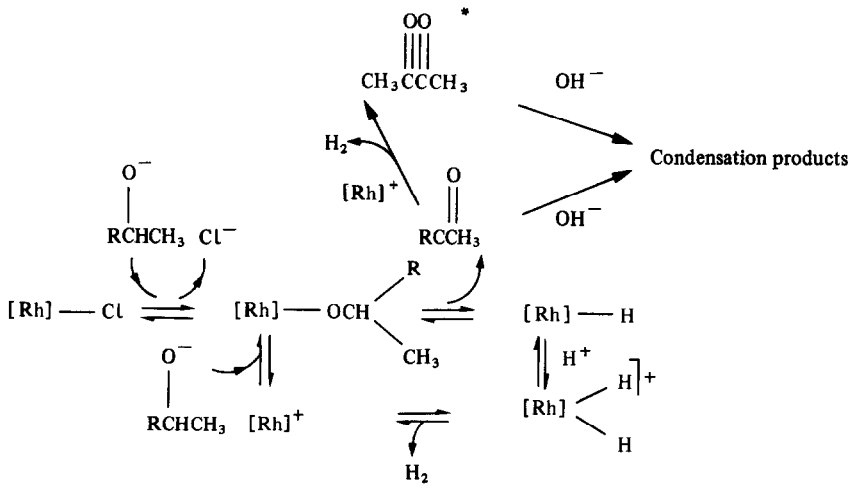
propan-2-ol	$[Rh(bipy)_2]Cl$	3.04	0.25	2	115

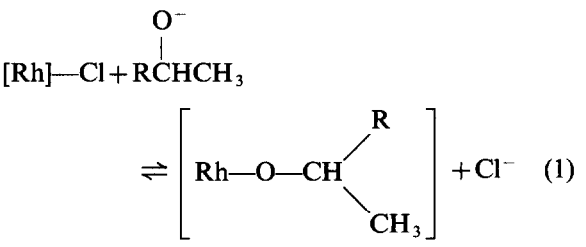
[a] Reaction was evacuated after 18, 17 or 15 h and continued for a further 5, 6 or 5 h.

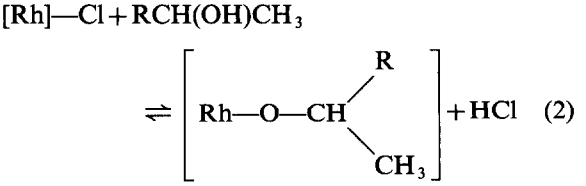


Scheme 1. Proposed mechanism for hydrogenation of secondary alcohols catalyzed by [RhCl$(PPh_3)_3$][Rh] = $[Rh(PPh_3)_2]$, R = Me or MeCH(OH). Similar mechanisms can be proposed for the other catalysts employed in this study. * R = $CH_3CH(OH)^-$.

dione* are not susceptible to decarbonylation hence poisoning of the catalyst does not occur and efficient hydrogen production is observed. Consistent with this explanation is the observation that all of the compounds efficiently dehydrogenate secondary alcohols, e.g. propan-2-ol, although less basic conditions are required for this reaction (Table 1).

In the absence of base, the activity of the catalysts drops markedly presumably because the equilibrium constants for reactions such as (1) are much higher than those for reaction (2).





* These are not detected as reaction products by g.l.c. analysis of the liquid phase, but condensation products, which are readily formed under the basic reaction conditions can be observed.

We are currently carrying out detailed experiments aimed at elucidating the mechanisms of these interesting reactions, but preliminary results suggest mechanisms of the type shown in Scheme 1.

THE SYNTHESIS OF ORGANO–IMIDO COMPLEXES OF Cr(IV) AND Fe(III)

ROBYN L. ELLIOTT, PETER J. NICHOLS and BRUCE O. WEST*

Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

(*Received* 1 *July* 1987; *accepted* 10 *July* 1987)

Abstract—The reaction of *p*-tolylazide with (5,10,15,20-tetraphenylporphyrinato) chromium(II) (Cr(TPP)) yields the high spin chromium(IV) organo–imido complex, $CH_3C_6H_4N{=}Cr(TPP)$. *N,N'*-ethylene-bis-(salicylideneiminato)iron(II), (Fe(salen)), however reacts with arylazides to produce iron(III) organo–imido-bridged compounds of general formula, $[Fe(salen)]_2NR$ showing magnetic coupling between the Fe(III) centres.

The synthesis and study of transition metal organo–imido complexes (M=NR) is of considerable current interest.[1] However, relatively few examples are yet known of compounds in which chelating ligands are attached to the metal in addition to the organo–imido group.[2–5] One synthetic route which seems to have potential application to a wide variety of metals involves reaction between arylazides and metal chelate complexes which are readily oxidizable by a two electron process to give the organo–imide with nitrogen as the second product thus,

$$(Lig)M^n + N_3R \rightarrow (Lig)M^{n+2}(NR) + N_2.$$

This type of reaction has been used with particular success in synthesizing $(Lig)_2Mo(VI)(NR)_2$ complexes from Mo(II)[3,4] and Mo(IV)[5] starting materials with Lig = dithiocarbamato or dithiophosphato ligands.

We wish to report the synthesis of the first chromium porphyrin organo–imido complex, *p*-$CH_3C_6H_4N{=}Cr(TPP)$ by reaction of the air sensitive metalloporphyrin, Cr(II)(TPP), with excess *p*-tolylazide in toluene with rigorous exclusion of moisture and air. When solutions of the reagents are mixed at room temperature, a gradual change in colour is observed over 10 min from the brown of Cr(II)(TPP) to the green–brown solution containing the product. Nitrogen is evolved during the reaction. The complex is precipitated as a green–brown solid by addition of hexane.

The molecular ion $[CH_3C_6H_4N \cdot Cr(TPP)]^{+\cdot}$ is observed as a low intensity peak in the mass spectrum of the compound together with $[Cr(TPP)]^{+\cdot}$ and $[CH_3C_6H_4NH]^{+\cdot}$, the latter peak being particularly intense. Elemental microanalyses and mass spectroscopy indicate the presence of one further molecule of toluene in the product. The magnetic moment for the complex in the solid state at 293K is 2.7 BM, consistent with a spin free d^2, Cr(IV) system. This may be compared with the diamagnetism (or at least very low paramagnetism) found for a variety of Cr(IV) oxo porphyrin[6] (O=Cr(IV)(P)) derivatives, including the isoelectronic O=Cr(TPP).

The UV/visible spectrum of the complex in toluene displays a Soret band at 423 nm with a further low intensity band at 537 nm. O=Cr(TPP) has similar bands at 431 and 544 nm.[6] Addition of tetrahydrofuran (THF) or N-methylimidazole (N-MeIm) causes shifts in the position of the Soret band and the appearance of several new bands at higher wavelengths, indicating coordination of these donor molecules to the Cr atom in the organo–imido complex thus†

THF/toluene λ_{max} = 410sh, 433, 555, 594 nm

N–MeIm/toluene λ_{max} = 417sh, 439, 558, 604 nm.

Tetrahydrofuran binds notably more strongly to the organo–imido complex than to O=Cr(TPP)

*Author to whom correspondence should be addressed.

†The determination of accurate extinction coefficients has been found to be very difficult because of the combination of low solubility and sensitivity to moisture of this complex.

since the addition of comparable amounts of THF to a toluene solution of O=Cr(TPP) causes no change in position or intensity of the absorption maxima.

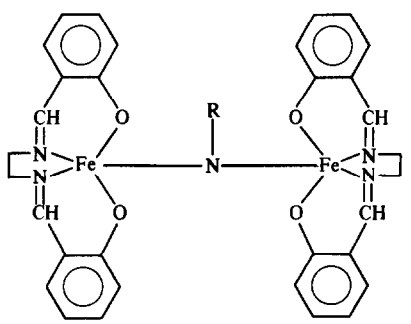
It has not been possible to determine unambiguously a value for the Cr—N(imido) stretching frequency in this complex because of the multitude of ligand vibrations in the 850–1150 cm^{-1} region where the frequency may be expected.[7]

The complex reacts with PPh_3 in toluene yielding the phosphine–imide $CH_3C_6H_4N{=}PPh_3$, this product being identified by its mass spectrum after evaporation of the reaction mixture under vacuum and extraction of the phosphine–imide together with excess PPh_3 by hexane. Cr(II)(TPP), the second product formed, was detected in the reaction mixture by its characteristic Soret absorption band at 421 nm.[6] Oxygen transfer from O=Cr(TPP) to PPh_3 has been shown to occur readily.[8]

We have also observed that the readily oxidised complex, Fe(II)(salen), undergoes smooth reactions at room temperature with a variety of arylazides.

Thus, when Fe(salen) reacted with *p*-tolylazide in dry CH_2Cl_2 under nitrogen the initial red–brown colour of the mixture lightened rapidly and nitrogen was evolved. Addition of hexane precipitated a black, microcrystalline complex whose microanalysis indicated a solvated product of formula $[Fe(salen)]_2NC_6H_4CH_3 \cdot CH_2Cl_2$. The mass spectrum of the product does not display the molecular ion of the complex but peaks due to $[Fe(salen)]^{+\cdot}$ and $[CH_3C_6H_4NH]^{+\cdot}$ were dominant once the very volatile CH_2Cl_2 had been removed. The compound has a magnetic moment $\mu_{eff} = 2.8$ BM per dimer at 293K similar to that found for the μ-oxo derivative[9] ($\mu_{eff} = 2.7$ BM). Solutions of the complex in CH_2Cl_2 rapidly turn orange in colour when exposed to air due to the formation of an Fe(III)(salen) hydrolysis product while *p*-toluidine is also recovered. The complex does not react with triphenylphosphine.

Unsolvated complexes have been isolated from toluene solution using *p*-tolyl, *p*-chloro and phenylazides. Their general properties and magnetism, each similar to those described for the CH_2Cl_2 solvated *p*-tolyl derivative, strongly indicate that they are organo–imido bridged derivatives as in (**a**). The reduced magnetic moments observed for these complexes are no doubt due to extensive spin-coupling through the organo–imido bridge as found for the complexes $[Fe(III)(salen)]_2X$, X = O[9] and S.[10] Detailed magnetic studies on several of the complexes will be reported elsewhere.



(a)

A number of homobinuclear[1,11] and trinuclear[12,13] bridged organo–imido derivatives have been reported with carbonyl or cyclopentadienyl groups attached to the metal. The present iron complexes appear to be the first examples of organo–imido bridged compounds involving simple chelating ligands.
