The platinum tetraphosphine complex [Pt(tripod)PPh_3] [tripod = $CH_3C(CH_2PPh_2)_3$] for example exhibits very different Pt–P coupling constants: 3096 Hz for the tridentate ligand but 5400 Hz for the monodentate phosphine.[1] Approximately the average of these coupling constants has been observed for $[Pt(PPh_3)_4]$.[2] This has been rationalized as follows:[1] the P—Pt—P angles involving the tripod ligand are 93–94°, i.e. essentially smaller than the tetrahedral angle. The Pt–tripod bonds will thus have a smaller *s*-character than tetrahedral Pt—P bonds, consistent with a smaller coupling constant. The Pt—PPh_3 bond will be hybridized to include more *s*-character, corresponding to a larger coupling constant.

Similar observations have been reported for $[Hg(tripod)L]^{2+/+}$, where L stands for a neutral or anionic phosphorus donor ligand.[3] We present here further evidence of this effect in mixed mercury(II) complexes with diphosphine ligands.

RESULTS AND DISCUSSION

In a solution of equimolar quantities of $[Hg(Me_2SO)_6](O_3SCF_3)_2$, dppm and dppe in dichloromethane the new asymmetric complex $[Hg(\eta^2\text{-dppe})(\eta^1\text{-dppm})]^{2+}$ (**1**) is formed in an equilibrium mixture with the symmetric species $[Hg(\eta^2\text{-dppe})_2]^{2+}$ (**2**)[4] and $[Hg(\eta^1\text{-dppm})_2]^{2+}$ (**3**).[4] The coordination sphere of mercury in complexes **1** and **3** is thought to be completed by Me_2SO. Equilibrium (1):

$$2[Hg(\eta^2\text{-dppe})(\eta^1\text{-dppm})] \rightleftharpoons [Hg(\eta^2\text{-dppe})_2]^{2+} + [Hg(\eta^1\text{-dppm})_2]^{2+} \quad (1)$$

occurs rapidly on the preparative time scale, and the equilibrium concentrations are almost statistical as estimated by the integration of the ^{31}P NMR signals.

At ambient temperature, the ^{31}P NMR signals

*dppm = $PPh_2CH_2PPh_2$, dppe = $PPh_2(CH_2)_2PPh_2$, dppp = $PPh_2(CH_2)_3PPh_2$.

†Author to whom correspondence should be addressed.

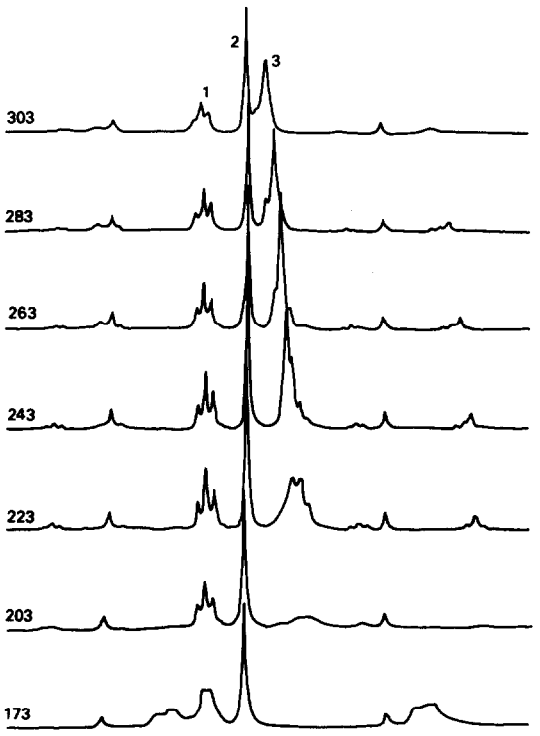

Fig. 1. $^{31}P-\{^1H\}$ NMR spectra of a solution of $[Hg(Me_2SO)_6](O_3SCF_3)_2$, dppm and dppe in a ratio of 1:1:1 in CH_2Cl_2 at different temperatures (in K): (1) dppe part of $[Hg(\eta^1\text{-dppm})(\eta^2\text{-dppe})]^{2+}$, (2) $[Hg(\eta^2\text{-dppe})_2]^{2+}$, and (3) dppm part of $[Hg(\eta^1\text{-dppm})(\eta^2\text{-dppe})]^{2+}$ and $[Hg(\eta^1\text{-dppm})_2]^{2+}$.

are broadened as a result of intermolecular ligand exchange (Fig. 1). At 263 K the ^{31}P NMR spectrum of **1** consists of two triplets attributable to coordinated dppm and dppe together with the corresponding ^{199}Hg satellites originating from the isotopomer containing ^{199}Hg atoms (abundance 16.8%). The ^{199}Hg NMR spectrum at this temperature is a triplet of triplets.

These coupling pattern are not caused by a structure $[Hg(\eta^2\text{-dppe})(\eta^2\text{-dppm})]^{2+}$ but by $[Hg(\eta^2\text{-dppe})(\eta^1\text{-dppm})]^{2+}$ involved in intramolecular exchange of the coordinated phosphorus atoms with the free phosphorus atoms of the η^1-dppm ligands occurring rapidly on the NMR time scale. Upon further cooling the dppm signals broaden, and below 173 K two broadened peaks attributable to the coordinated and the free phosphorus atoms of the η^1-dppm ligands appear, but the slow-exchange limit could not be attained.

Dean and Srivastava[5] reported very recently on the compound $[Hg(\eta^2\text{-dppe})(\eta^2\text{-dppm})]^{2+}$ which is formed from $Hg(SbF_6)_2$, dppe and dppm, but in the absence of Me_2SO. This confirms that the $Hg(\eta^2\text{-dppm})$ ring is readily opened by Me_2SO. This must be caused by the strain of the four-membered HgPCP ring since tertiary phosphines are much stronger ligands for mercury compared to oxygen donor ligands (e.g. Me_2SO). The strain in four-membered metal–dppm rings is a known fact and causes dppm to prefer the bridging bidentate or monodentate bonding mode.[6] An analogous opening of a Hg–dppm chelate ring by Me_2SO has been observed for $[Hg(\eta^2\text{-dppm})_2]^{2+}$ which exists as $[Hg(\eta^1\text{-dppm})_2]^{2+}$ when dissolved in Me_2SO.[4] The NMR parameters of **1** are summarized in Table 1. The ^{199}Hg chemical shift largely corresponds to that of other cationic Hg complexes of type $[Hg(PR_3)_3]^{2+}$.[7] On the other hand the $^{199}Hg-^{31}P$ coupling constants are rather interesting: the one bond coupling constant involving dppe (2456 Hz) is unexpectedly small. The Hg–P coupling constants of cationic mercury phosphine complexes $[Hg(PR_3)_n]^{2+}$ usually decrease with n: they are *ca* 10,000 Hz for $n = 1$,[8] *ca* 5500 Hz for $n = 2$, *ca* 3300 Hz for $n = 3$, and *ca* 2100 Hz for $n = 4$.[7] The Hg–dppe coupling constant of **2** thus more closely resembles that of a mercury tetraphosphine complex than that of a triphosphine complex.

The apparent Hg–dppm coupling at the fast-exchange limit of the end-over-end exchange is actually the mean of the one- and the three-bond mercury–phosphorus couplings. The assumption

Table 1. NMR parameters of $[Hg(LL)(LL')]^{2+}$ [a]

		LL		LL'			T
LL	LL'	δ(P)	J(Hg–P)	δ(P)	J(Hg–P)	δ(Hg)	(K)
dppm	dppe	10.2[b]	2822	32.2	2456	1835	263
dppm	dppp	17.6[c]	2338	36.2	2305	1936	300
dppe	dppp	18.2[d]	1893	16.3	2236	2083	300

[a] Chemical shifts in ppm to high frequency of 85% H_3PO_4 or aqueous $Hg(ClO_4)_2$ [2 mmol HgO (cm^3 60% $HClO_4$)$^{-1}$], coupling constants in Hz.

[b] $^2J\{[P(dppm)–P(dppe)] + {}^4J[P(dppm)–P(dppe)]\}/2 = 63$.

[c] $^2J\{[P(dppm)–P(dppp)] + {}^4J[P(dppm)–P(dppp)]\}/2 = 53$.

[d] $^2J[P(dppe)–P(dppp)] = 49$.

of a ^3J(Hg–P) of ± 70 Hz leads to a ^1J(Hg–P) of *ca* 5600–5700 Hz. This is in the region of Hg–P couplings in complexes of type $[Hg(PR_3)_2]^{2+}$. The average of the coupling constants of Hg to dppm and dppe for **2** on the other hand is in the region typically observed for $[Hg(PR_3)_3]^{2+}$ complexes. The anomalous coupling constants may be explained as those of the Pt(0)[1] or Hg(II)[3] tripod complexes mentioned above. The five-membered rings of M(η^2-dppe) complexes involve P—M—P angles of *ca* 85°. This is essentially smaller than the optimal P—Hg—P angle in **1**, and results in a diminished *s*-character of the Hg—(η^2-dppe) bonds, and therefore in a decreased coupling constant. The Hg—(η^1-dppm) bonds are hybridized to include more *s*-character and have an enlarged Hg–P coupling constant.

The complex $[Hg(\eta^2\text{-dppp})(\eta^1\text{-dppm})]^{2+}$ (**4**) is formed together with the corresponding symmetric compounds from $[Hg(Me_2SO)_6](O_3SCF_3)_2$, dppp and dppm, and behaves similarly to **1**. The NMR data show the same anomalies as **1**, and are included in Table 1.

$[Hg(\eta^2\text{-dppe})(\eta^2\text{-dppp})]^{2+}$ (**5**) is formed from $[Hg(Me_2SO)_6](O_3SCF_3)_2$, dppe and dppp in an equilibrium mixture with $[Hg(\eta^2\text{-dppe})_2]^{2+}$ and $[Hg(\eta^2\text{-dppp})_2]^{2+}$. In contrast to **1** and **4**, **5** contains four-coordinated phosphorus donor atoms. The NMR data of **5** (Table 1) are almost identical to that of $[Hg(\eta^2\text{-dppe})(\eta^2\text{-dppp})](SbF_6)_2$, which has been reported[5] since the acquisition of this data.

EXPERIMENTAL

$[Hg(Me_2SO)_6](O_3SCF_3)_2$ has been prepared as previously described,[9] and all other reagents are commercially available.

The NMR spectra were recorded in the FT mode on a multinuclear Bruker WP-80 spectrometer.

BOOK REVIEWS

Carbosilanes. Synthesis and Reactions. G. Fritz and E. Matern, Springer, Berlin, 1986. ISBN 3-540-15929-0, xii + 258 pp., 40 figs, 74 tables, DM 189.

Carbosilanes are compounds containing a molecular skeleton based on alternating carbon and silicon atoms. The present volume is an authoritative and expert in-depth review of a field which has grown up over the last 40 years.

After a brief scene-setting chapter comparing the chemistries of carbon and silicon, the book proceeds to a consideration of the synthetic routes to carbosilanes. The first route to be discovered was simple gas-phase pyrolysis of methyl silanes. Thus, pyrolysis of $SiMe_4$ yields some 45 different silicon containing products (and a range of hydrocarbons) boiling between 45 and 280°C, plus higher molecular weight silicon compounds. The simplest compounds have linear or one-ring cyclic structures, whilst many (but not all) of the polycyclic derivatives have the "adamantane" type cage, some of these being stable to above 400°C. Chlorinated carbosilanes are similarly obtained from chlorosilanes.

An alternative synthetic route to carbosilanes involves cold plasma; this permits the isolation of compounds decomposed in the thermal routes, notably linear carbosilanes. Another route involves using a copper catalyst to facilitate reaction of silicon with chloromethanes; Lewis acids such as $AlCl_3$ also catalyse rearrangement reactions of carbosilanes. The text discusses the mechanisms believed to occur in these reactions, as well as particular organometallic syntheses.

Chapter 3 treats the reactions of carbosilanes; under appropriate conditions a number of functional groups may be introduced. These include halogenation of Si—H and C—H groups, hydrogenation of Si—Hal, and alkylation with Grignard reagents and organolithium compounds. Generally speaking, it is at the silicon atoms that reaction occurs, but under the right conditions the carbon atoms can be metallated, specific reagents being available for $—CH_2—$ and $\equiv CH$ groups. Metallation with organometallic moieties such as $—Fe(CO)_2(C_5H_5)$ can also be brought about.

The final chapter contains details of all the molecular structures determined for carbosilanes, mainly, of course, by X-ray diffraction methods. Clear diagrams show all bond lengths and angles.

All references (212) are given at the end; a majority of the work cited is by Professor Fritz and his coworkers, a significant amount of it not having been published before.

This reviewer confesses to a total ignorance of carbosilanes before reading this book, but he found the work thoroughly covered, with plenty of illustrations to clarify the often-complicated structures. This is a very neatly produced contribution to keeping us abreast of the substantial area represented by silicon chemistry.

The Periodic Table of the Elements, 2nd Edition. R. J. Puddephatt and P. K. Monaghan, Oxford University Press, Oxford, 1986. ISBN 0-19-855515-6 (hbk), ISBN 0-19-855516-4 (pbk), £6.95 (pbk).

The arrangement of the chemical elements in the form known as the Periodic Table is familiar to all except those with a cursory acquaintance with chemistry. Its merits as a way of classifying the elements are illustrated by the way in which it has survived in essentially the same form from a time when many fewer elements were known and when notions of atomic structure were extremely sketchy.

This is the second edition of a book first published 14 years ago, intended for "first year students in universities and technical colleges and for senior secondary school students". Compared with the first edition, it contains about one-fifth as many pages in the text, partly accounted for by a change in typeface but also having significant additions in certain chapters.

After a brief introductory section (which points out that the book is concerned with trends in properties and comparisons between elements, rather than being a catalogue of facts) the second chapter is concerned with a brief summary of quantum theory, which in Chapter 3 is utilized to relate electronic structure to the Periodic Table. Both the traditional (I–VIII) and new IUPAC (1–18) systems of classifying groups are used.

The next three chapters (4–6) treat the main-group elements. The first of these chapters, significantly expanded from the last edition, introduces ideas like ionization energy and electron affinity, showing how these (and atomic and ionic radii) vary within a group. This chapter also outlines some basic principles of chemical bonding. Chapter 5 treats the physical and structural properties of the main-group elements, indicating the relationship between these, both within a group and across a period. Chapter 6 (again significantly expanded) looks at representative compounds (halides, oxides and hydrides) of the elements and shows how the properties of these compounds are related to the properties (i.e. metal/non-metal) of the element itself. The section on the hydrides includes a very brief discussion of the VSEPR model and of hydrogen bonding.

Chapter 7 deals with the transition elements. The chlorides are used to illustrate the property of multiple oxi-

The arrangement of the chemical elements in the form known as the Periodic Table is familiar to all except those with a cursory acquaintance with chemistry. Its merits as a way of classifying the elements are illustrated by the way in which it has survived in essentially the same form from a time when many fewer elements were known and when notions of atomic structure were extremely sketchy.

This is the second edition of a book first published 14 years ago, intended for "first year students in universities and technical colleges and for senior secondary school students". Compared with the first edition, it contains about one-fifth as many pages in the text, partly accounted for by a change in typeface but also having significant additions in certain chapters.

After a brief introductory section (which points out that the book is concerned with trends in properties and comparisons between elements, rather than being a catalogue of facts) the second chapter is concerned with a brief summary of quantum theory, which in Chapter 3 is utilized to relate electronic structure to the Periodic Table. Both the traditional (I–VIII) and new IUPAC (1–18) systems of classifying groups are used.

The next three chapters (4–6) treat the main-group elements. The first of these chapters, significantly expanded from the last edition, introduces ideas like ionization energy and electron affinity, showing how these (and atomic and ionic radii) vary within a group. This chapter also outlines some basic principles of chemical bonding. Chapter 5 treats the physical and structural properties of the main-group elements, indicating the relationship between these, both within a group and across a period. Chapter 6 (again significantly expanded) looks at representative compounds (halides, oxides and hydrides) of the elements and shows how the properties of these compounds are related to the properties (i.e. metal/non-metal) of the element itself. The section on the hydrides includes a very brief discussion of the VSEPR model and of hydrogen bonding.

Chapter 7 deals with the transition elements. The chlorides are used to illustrate the property of multiple oxi-

dation states, and also how the 4*d* and 5*d* metals tend to utilize higher oxidation states. Trends across the series in ionic and atomic radii, and in properties such as ionization energy, are illustrated, and there is a discussion of hard and soft acids and bases linking with complex formation, and of crystal-field theory. Chapter 8 is a brief (6-page) account of trends in the lanthanide and actinide series.

This book has many solid virtues and is both easy to read and extremely well illustrated. It has no pretence of being a textbook on inorganic chemistry and, indeed, refers the reader to the standard texts in the field. It is also always easy to suggest ways of expanding a short book, but there are some areas that this reviewer would look for. Although it would be covered by cognate texts, a little more account of VSEPR treatment would be welcome, as would some more account of variation in properties across periods. The authors do not state explicitly just which properties are characteristic of transition metals as distinct from other elements, and, finally, it would be nice to see the very old-fashioned table comparing the known properties of germanium with Mendeleev's predictions, if only to illustrate the power of the Periodic system in the hands of a skilled practitioner!

Organotitanium Reagents in Organic Synthesis. Manfred T. Reetz, Springer, Berlin, 1986. ISBN 3-540-15784-0, 236 pp., 23 figs, DM 168.

This volume is a timely addition to the Springer series "Reactivity and Structure Concepts in Organic Chemistry". The book is organized in eight concise chapters each with its own comprehensive references. Early chapters cover the preparation and general properties of organotitanium compounds, including a brief treatment of theoretical and spectroscopic aspects. Subsequent chapters describe the major uses of titanium in synthesis. Addition reactions of organotitanium reagents to carbonyl compounds are treated in some detail and with special regard to chemo- and stereoselectivity, and with a separate brief chapter concerning kinetics.

Other areas treated include the use of titanium species as Lewis acid mediators in reactions of enol and allyl silanes, titanium enolate chemistry, and methylenation reactions using titanium-based reagents. The book includes coverage of the literature up to early 1985 along with additional unpublished data from Prof. Reetz's own research group. The excellent organization and layout of this volume make it an enjoyable read as well as a valuable reference book, and it should prove popular and useful to all those involved in organic synthesis.

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Sn—Organotin Compounds, Part 13, Other RSn–Oxygen Compounds. Compounds with Two and Three Different Organic Groups Bonded to the Sn Atom. Springer, Berlin, 1986. xii+374 pp., DM 1456.

Organotin chemists will be delighted to see the rapid appearance of this 13th volume on organotin compounds. Like all the previous volumes, it has been compiled by Herbert and Ingeborg Schumann, and it maintains the very high standard of the series.

This volume contains all mononuclear R_3Sn–oxygen compounds with R other than methyl, ethyl, propyl and butyl, and all $R_2R'Sn$– and $RR'R''Sn$–oxygen compounds; the mononuclear restriction means that trialkyltin hydroxides are included, but bis(trialkyltin) oxides are not. The literature is covered up to the end of 1982.

For example, 8 pp. are devoted to the tribenzyltin–oxygen compounds, and cover the hydroxide, alkoxides, phenoxides, ketonates, carboxylates, peroxides, and other miscellaneous derivatives. The section on the corresponding triphenyltin–oxygen compounds is of course much larger (160 pp.). For each compound, details are given of preparations, properties, structure, reactions and applications. Much information is tabulated, and amplified in extensive footnotes. There is an empirical formula index (28 pp.) and a ligand index (59 pp.).

The printing and production are as impeccable as usual.

Doubly welcome is the promise that additional volumes describing other R_3SnO derivatives and tin–oxygen compounds with R_2Sn and RSn groups will follow in the near future.

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Sb—Organoantimony Compounds, Part 4, Compounds of Pentavalent Antimony with Three Sb—C Bonds. Springer, Berlin, 1986. 250 pp., DM 1173.

The first volume of this series covered organoantimony compounds of type R_3Sb, the second covered the compounds R_2SbX and $RSbX_2$, and the third dealt principally with the Sb(V) compounds R_5Sb.

This fourth volume describes pentavalent antimony compounds of types R_3SbX_2 and $R_3Sb{=}X$.

Most readers will be familiar with the Gmelin format. The text is now wholly in English. For each compound, the preparations are first listed, then the physical and spectroscopic properties, with figures of the molecular structure if it has been determined by diffraction

dation states, and also how the 4*d* and 5*d* metals tend to utilize higher oxidation states. Trends across the series in ionic and atomic radii, and in properties such as ionization energy, are illustrated, and there is a discussion of hard and soft acids and bases linking with complex formation, and of crystal-field theory. Chapter 8 is a brief (6-page) account of trends in the lanthanide and actinide series.

Although it would be covered by cognate texts, a little more account of VSEPR treatment would be welcome, as would some more account of variation in properties across periods. The authors do not state explicitly just which properties are characteristic of transition metals as distinct from other elements, and, finally, it would be nice to see the very old-fashioned table comparing the known properties of germanium with Mendeleev's predictions, if only to illustrate the power of the Periodic system in the hands of a skilled practitioner!

Organotitanium Reagents in Organic Synthesis. Manfred T. Reetz, Springer, Berlin, 1986. ISBN 3-540-15784-0, 236 pp., 23 figs, DM 168.

This volume is a timely addition to the Springer series "Reactivity and Structure Concepts in Organic Chemistry". The book is organized in eight concise chapters each with its own comprehensive references. Early chapters cover the preparation and general properties of organotitanium compounds, including a brief treatment of theoretical and spectroscopic aspects. Subsequent chapters describe the major uses of titanium in synthesis. Addition reactions of organotitanium reagents to carbonyl compounds are treated in some detail and with special regard to chemo- and stereoselectivity, and with a separate brief chapter concerning kinetics.

Other areas treated include the use of titanium species as Lewis acid mediators in reactions of enol and allyl silanes, titanium enolate chemistry, and methylenation reactions using titanium-based reagents. The book includes coverage of the literature up to early 1985 along with additional unpublished data from Prof. Reetz's own research group. The excellent organization and layout of this volume make it an enjoyable read as well as a valuable reference book, and it should prove popular and useful to all those involved in organic synthesis.

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Sn—Organotin Compounds, Part 13, Other RSn–Oxygen Compounds. Compounds with Two and Three Different Organic Groups Bonded to the Sn Atom. Springer, Berlin, 1986. xii+374 pp., DM 1456.

Organotin chemists will be delighted to see the rapid appearance of this 13th volume on organotin compounds. Like all the previous volumes, it has been compiled by Herbert and Ingeborg Schumann, and it maintains the very high standard of the series.

This volume contains all mononuclear R_3Sn–oxygen compounds with R other than methyl, ethyl, propyl and butyl, and all $R_2R'Sn$– and $RR'R''Sn$–oxygen compounds; the mononuclear restriction means that trialkyltin hydroxides are included, but bis(trialkyltin) oxides are not. The literature is covered up to the end of 1982.

For example, 8 pp. are devoted to the tribenzyltin–oxygen compounds, and cover the hydroxide, alkoxides, phenoxides, ketonates, carboxylates, peroxides, and other miscellaneous derivatives. The section on the corresponding triphenyltin–oxygen compounds is of course much larger (160 pp.). For each compound, details are given of preparations, properties, structure, reactions and applications. Much information is tabulated, and amplified in extensive footnotes. There is an empirical formula index (28 pp.) and a ligand index (59 pp.).

The printing and production are as impeccable as usual.

Doubly welcome is the promise that additional volumes describing other R_3SnO derivatives and tin–oxygen compounds with R_2Sn and RSn groups will follow in the near future.

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Sb—Organoantimony Compounds, Part 4, Compounds of Pentavalent Antimony with Three Sb—C Bonds. Springer, Berlin, 1986. 250 pp., DM 1173.

The first volume of this series covered organoantimony compounds of type R_3Sb, the second covered the compounds R_2SbX and $RSbX_2$, and the third dealt principally with the Sb(V) compounds R_5Sb.

This fourth volume describes pentavalent antimony compounds of types R_3SbX_2 and $R_3Sb{=}X$.

Most readers will be familiar with the Gmelin format. The text is now wholly in English. For each compound, the preparations are first listed, then the physical and spectroscopic properties, with figures of the molecular structure if it has been determined by diffraction

dation states, and also how the 4*d* and 5*d* metals tend to utilize higher oxidation states. Trends across the series in ionic and atomic radii, and in properties such as ionization energy, are illustrated, and there is a discussion of hard and soft acids and bases linking with complex formation, and of crystal-field theory. Chapter 8 is a brief (6-page) account of trends in the lanthanide and actinide series.

This book has many solid virtues and is both easy to read and extremely well illustrated. It has no pretence of being a textbook on inorganic chemistry and, indeed, refers the reader to the standard texts in the field. It is also always easy to suggest ways of expanding a short book, but there are some areas that this reviewer would look for. Although it would be covered by cognate texts, a little more account of VSEPR treatment would be welcome, as would some more account of variation in properties across periods. The authors do not state explicitly just which properties are characteristic of transition metals as distinct from other elements, and, finally, it would be nice to see the very old-fashioned table comparing the known properties of germanium with Mendeleev's predictions, if only to illustrate the power of the Periodic system in the hands of a skilled practitioner!

methods. Finally any applications of the compounds are described and references are given at the end of each section. Related compounds {e.g. the triorganoantimony dibenzoates $[R_3Sb(O_2CAr)_2]$}, or related information about a compound (e.g. the preparations of Ph_3SbO) are frequently tabulated.

For example trimethylantimony dichloride is described in 9 pp. This includes tables of the IR and Raman vibration spectra of the solid, of the reactions of Me_2SbCl_3, and of the Raman spectrum of the complex $Me_3SbCl_2 \cdot SbCl_3$, and a figure of the crystal structure of this complex. A list of 84 references completes the section.

Apparently there are now some 1200 publications and 400 patents on organoantimony compounds, more than half of which have been published within the past 10 years, and over 3000 organoantimony compounds have been described. This volume will be invaluable to the growing number of chemists who are interested in this field.

ANNOUNCEMENT

POLYHEDRON PUBLICATION AWARD

Pergamon Journals Ltd is pleased to announce the award annually of a cash prize of $1000 for the best paper published in *Polyhedron.*

The award will be made to the authors of the original research paper (not including *Polyhedron* Reports) judged to be the best on the basis of scientific originality, significance, clarity and style of presentation. The first award will be made for a paper published in Volume 6, 1987. Members of the Editorial Board will each be invited to nominate two papers for the award and the final selection will be made by an anonymous committee appointed by the Editors who themselves will not be eligible for the award.

The recipient of the first award will be notified early in 1988.

INTRODUCTION

MALCOLM H. CHISHOLM

The discovery by Cotton and coworkers in the mid 1960s that metal atoms could form quadruple bonds with one another heralded a new chapter in inorganic chemistry. Now, after more than 20 years, multiple bonds between metal atoms still provide challenges in terms of theory, spectroscopy and reactivity. In this collection of papers the reader will find articles of topical interest in the field of metal–metal multiple bonds varying from extensive reviews of an area to short contributions dealing with a very specific topic. Clearly the field is maturing. The chemistry is getting richer and more diverse and should prosper well for another two decades or more.

THE STRUCTURES OF METAL–METAL-BONDED EDGE-SHARING BIOCTAHEDRAL COMPLEXES

F. A. COTTON

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 19 *November* 1986)

The edge-sharing bioctahedron presents a broadly applicable and flexible framework within which to examine the interaction between adjacent metal (M) atoms.[1,2] The basic unit is shown in general form in Fig. 1.

The flexibility of this structure motif is due to the following factors:

(1) M may be varied in three ways: (a) atomic number (hence, size); (b) charge; and (c) number of *d*-electrons.

(2) There are at least three non-equivalent types of ligands which may be varied independently:

(a) The terminal ligands X and Z may be the same or different, anionic or neutral, and they may be connected in various ways, viz. Z to Z, X to X or Z to X.

(b) The bridging ligands Y can be varied in size, e.g. O vs S or Se, Cl vs Br or I etc. These size changes by themselves can have a major influence on the strength of the M–M interaction.

(c) The linking of Z to adjacent Z, for example if a ligand such as RCO_2^- or $R_2PCH_2PR_2$ is used, also influences the M–M distance since in this way the repulsive forces between independent Zs are reduced (a point first stressed by Shaik *et al.*[3]).

It should be noted that the highest possible symmetry for compounds of this class is D_{2h}, even if X = Y = Z. The maintenance of this symmetry does not require any special values of the various angles, e.g. X–M–X, Y–M–Y, M–Y–M, Z–M–X or Z–M–Y. It does, however, depend on the existence of two mutually perpendicular planar units, one comprised of the $X_2M(\mu\text{-}Y)_2MX_2$ set and the other of the M_2Z_4 set. There must also be another plane of symmetry perpendicularly bisecting the M ··· M line and containing the Y ligands.

There are a number of cases in which small twists about the M ··· M axis degrade the D_{2h}-symmetry. This is understandable since such a twist can increase the two Z ··· Z distances and the four X ··· Y distances, thus diminishing the repulsive energy in the molecule. An example is shown in Fig. 2. However, the twist angles are generally small (< 10°) and in considering the M–M bonding and other aspects of the electronic structure these twists are generally ignored, and calculations are performed as though D_{2h}-symmetry were fully displayed.

One further prefactory observation concerns the relationship of the various bond angles at the metal atoms to the nature and strength of the M–M interaction. If two regular octahedra are simply joined on a common edge, all angles are 90° (or 2 × 90°), including the M–Y–M angles. This situation is not, however, of any special significance in real cases, and will not be seen except by pure coincidence. In the absence of an M–M bond, numerous repulsive forces, including (and perhaps

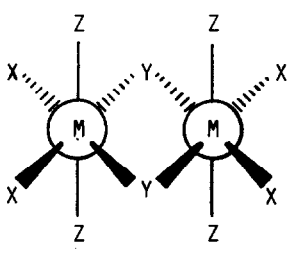

Fig. 1. Generalized, schematic representation of the edge-sharing bioctahedron.

Mo	3.84(2)	2.53	2.24	81.4	6
W	3.814(2)	2.52	2.25	81.5	7
Re	3.739(2)	2.47	2.25	81.3	8

especially) the repulsion between the two M atoms themselves, will elongate the structure so as to make the Y–M–Y angles $<90°$ and the M–Y–M angles $>90°$. This will probably indirectly cause the X–M–X angles to become $>90°$.

On the other hand, the drawing together of the metal atoms resulting from a direct M–M bond will have consequences that are the opposite of those just mentioned, i.e. Y–M–Y $> 90°$, M–Y–M $< 90°$, and probably X–M–X $< 90°$.

It is likely that even the formation of an M–M single bond will cause a net contraction of the structure; thus only contracted structures with M–M bonds or extended structures with no M–M bonds are likely to be seen. This is true for all structures presently known. The exact balancing of an attractive (i.e. M–M-bonding) force and the repulsive forces to result in the ideal structure derived from two conjoined octahedra is not to be expected in any real compound. Thus, in general, the existence of an M–M bond will be evident from the structure. Similar considerations were outlined and illustrated many years ago for confacial bioctahedral complexes.[4]

With these considerations in mind, we turn now to a tabulation of the majority of the edge-sharing bioctahedral structures known. We have intentionally excluded from this tabulation compounds with large numbers of strongly π-accepting ligands, e.g. $(OC)_4MnCl_2Mn(CO)_4$, as well as a few other compounds having odd features that place them outside of a mainstream discussion.

METAL PENTAHALIDE DIMERS

We consider these molecules separately because they lack M–M bonds. In general the higher the oxidation state of the M atoms the less likely they are to form M–M bonds, and this is especially true when the bridging atoms are as large as Cl, or larger. The four structurally characterized M_2X_{10} compounds are the chlorides of Nb (d^0), Mo (d^1), W(d^1), and Re (d^2). Their structural parameters are listed in Table 1.

It can be seen that these non-bonded M–M distances are all very long, *ca* 3.8 ± 0.1 Å, and that the stretching out of the central rhombus results in (μ-Cl)—M—(μ-Cl) angles of *ca* 80°. Another consistent characteristic of these structures is the great difference between the M—(μ-Cl) and M—Cl_t bond lengths (*ca* 0.25 Å). In the M–M-bonded structures to be considered later, we shall see very different features.

Before turning to the large group of structures with which this review is mainly concerned, we may note that even for an oxidation number of V, M–M bond formation is possible if other factors are conducive. This point is well illustrated by a condensed structure in which there are $Re_2(V)O_{10}$ units.[9] In $Nd_4Re_2O_{11}$, there are $Re_2(V)O_{10}$ fragments in which the Re–Re distance is 2.421 Å, and the assignment of a Re=Re double bond is straightforward. The presence of small bridging atoms is perhaps the major factor in allowing or even encouraging a close approach of the Re atoms. It is, however, also worth noting that this factor alone does not assure the formation of M–M bonds. In the compound $PbRe_2O_6$, there are connections to the surrounding structure that tend to draw the Re_2O_{10} unit out and the resulting Re–Re distance is 3.102(1) Å (compared to 2.77 Å calculated for idealized edge-sharing ReO_6 octahedra). Presumably no significant Re–Re bonding exists in this case.

GENERAL SURVEY OF STRUCTURES

In Table 2 all of the structural data we wish to examine and discuss here are listed. To facilitate the use of the table, note that it is organized as follows:

(1) d^1–d^1 species: (a) +3, +3; (b) +4, +4; and (c) +5, +5.

(2) d^2–d^2 species: (a) +3, +3; and (b) +4, +4.

(3) d^3–d^3 species: (a) +3, +3; and (b) +4, +4.

(3/4) d^3–d^4 species: (a) +3, +4.

(4) d^4–d^4 species: (a) +3, +3; and (b) +4, +4.

(5) d^5–d^5 species: (a) +3, +3.

In each category, complexes are listed in order of increasing atomic number, e.g. all Mo complexes

before W complexes. Each complex can then be cited by a number, such as 1(b)5, which immediately locates it in the table.

DISCUSSION

The many structures listed in Table 2, 52 in all, afford a very disparate array. No attempt will be made to discuss all of them; instead some important trends will be noted and also a few compounds that present special features will be highlighted. Before doing that, however, we must summarize the electronic structure considerations that are important in determining the M–M bond orders as a function of the number of *d*-electrons on each metal. In doing this we shall be making assertions that arise from the calculations and experiments detailed in Refs 1–3 and 28.

The M–M bonding in an edge-sharing bioctahedron can be formulated in a sort of "zero-ith order" approximation by assuming that the six σ-bonds that each metal atom forms to ligands engage the usual set of orbitals, viz. s, p_x, p_y, p_z, d_{z^2} and $d_{x^2-y^2}$ (where for the moment we use a local, conventional set of Cartesian axes). There are then three *d*-orbitals on each M atom (those conventionally designated as $d\pi$ or t_{2g} orbitals) available to form bonds between the M atoms. They are enabled by symmetry to form σ, σ^*, π, π^*, δ and δ^* combinations. Figure 3(a) shows the three bonding combinations in a schematic way and Fig. 3(b) the relative energies of all the orbitals that would be expected purely on the basis of the differing extents of overlap. From this simple picture we would expect that for complexes of the d^n–d^n type the following bond orders would arise for different values of n: $n = 1$ or 5 single (σ), $n = 2$ or 4 double ($\sigma + \pi$), and $n = 3$ triple ($\sigma + \pi + \delta$).

Even approximate MO calculations (extended Hückel or Fenske–Hall) immediately show that this simple and rigid picture is untrustworthy. Because certain M–ligand interactions can compete in importance with certain M–M interactions, especially at longer M–M distances, the pattern of orbital energies in Fig. 3(b) need not be correct. For our purpose here it will suffice to say that the major ambiguity is in the ordering of the δ- and δ^*-levels. There is reason to believe that both orderings, $\delta < \delta^*$ [as in Fig. 3(b)] and $\delta^* < \delta$, occur in different complexes. In any case, however, the δ-orbital is only weakly bonding and the δ^*-orbital only weakly antibonding, at least in most cases.

With these considerations in mind, we might expect that d^1–d^1 and d^5–d^5 complexes would have the longest M–M bonds, while d^2–d^2 and d^4–d^4 complexes, having net double bonds, would display appreciably shorter M–M distances. The d^3–d^3 systems might be expected to have fairly short bonds, but exactly how they would relate to those in the doubly-bonded systems would depend on

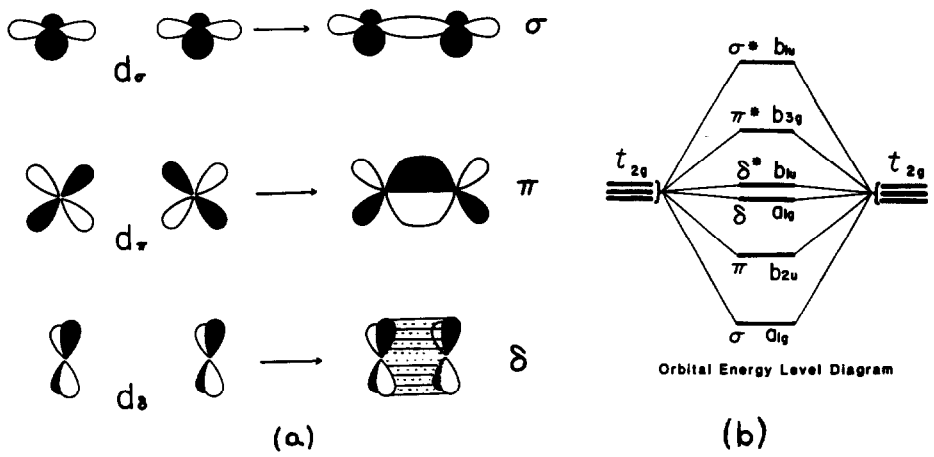

Fig. 3. (a) d–d overlaps giving rise to M–M bonding orbitals of σ, π and δ types. (b) Pattern of energy levels expected purely on the basis of relative orbital overlaps.

the ordering of the δ and δ^* levels.

All of the trends and relationships that are suggested by M–M bonding considerations are subject to major modification when the sizes, and other properties, of the ligands are changed. A particularly prominent and consistent effect is that the smaller bridging ligands promote shorter and stronger M–M bonds, other things (i.e. M charges and d^n-configurations) being equal.

(*a*) *The longest bonds*

The first compound in the table, 1(a)1, has the longest M–M *bonded* distance so far reported, namely a Zr–Zr single bond distance of 3.182(1) Å. This distance probably indicates the approximate upper limit for M–M bonds in this structural context since all other d^1–d^1 singly-bonded systems, compounds 1(b)1–1(b)5 and 1(c)1–1(c)8 have shorter ones. Only 1(b)5 is comparable, with a Ta–Ta distance of 3.165(1) Å. There are a few M–M single bonds formed by d^5–d^5 systems and no doubt more will be discovered, but we might hazard the suggestion that these should not be in any case longer than the longest d^1–d^1 single bonds because of a general contraction in atomic size as we proceed from left to right across the transition series.

(*b*) *The shortest bonds*

There are several that lie in the range 2.471–2.501 Å, namely, those in 2(b)2, 2(b)3, 2(b)4, 2(b)6, 3(a)5, 3(a)7 and 3(a)10. As is evident from their numbers, these are d^2–d^2 and d^3–d^3 systems. These complexes also all contain OR or OH groups as bridging ligands. Thus, with the electron configurations suitable for the formation of double bonds ($\sigma^2\pi^2$) or, considering the weakness of the δ overlaps, approximately double bonds ($\sigma^2\pi^2\delta^2$ or $\sigma^2\pi^2\delta^{*2}$), and with the smallest of bridging ligands, it is entirely understandable that these systems have the shortest M–M distances.

(*c*) *Effect of bridging ligand size*

We have just had occasion to cite the influence of bridging ligands on M–M distance, particularly as a consequence of their size. This is a feature of general importance in this class of compounds as the following examples, chosen from Table 2, will illustrate.

The series of Mo(V) and W(V) complexes, 1(c)1–1(c)6 all have M–M single bonds with M–M distances of about 2.70–2.78 Å. This is in contrast to the Mo_2Cl_{10} and W_2Cl_{10} molecules mentioned earlier in which there are no M—M bonds and the distances are *ca* 3.7 Å. A major factor in this contrasting behavior must be the replacement of μ-Cl groups by μ-OR groups, which are much smaller. It must be noted, however, that all of these bonded complexes also differ from the M_2Cl_{10} species in that there are some terminal OR groups replacing terminal Cl ligands. This too may favor M–M bonding because the π-donating tendency of the OR groups will serve to lessen the effective positive charge on the M atoms, thus making them more able to achieve the necessary d–d overlap for M–M bond formation.

The chloro-bridged complexes of Nb(III), e.g. 2(a)1–2(a)3 have Nb–Nb distances of *ca* 2.71 Å, while in 2(a)4, where one μ-Cl has been replaced by μ-OPr^i, the distance is reduced to 2.61 Å. Admittedly, there are also changes in the set of terminal ligands, so that this comparison is not as unambiguous as one might like. This is but one of the many instances in this field where it would be desirable

to conduct a synthetic program designed to deliver pairs or sets of molecules in which only one feature at a time is changed.

(*d*) *Influences of terminal ligands*

The strength of the M–M bond can be affected by the steric as well as the electronic properties of the terminal ligands, both the X and the Z types (Fig. 1). Shaik *et al.*[3] first called attention to the potential importance of the repulsive force between opposite pairs of Z ligands. Clearly, it is not possible to have M–Z bonds perpendicular to the central molecular plane along with M–M distances in the bonding range (i.e. < 3.2 Å) when the van der Waals' radii of the Z ligands are > 1.6 Å, which is the case for nearly all ligands. To relieve strain the M–Z bonds may bend away from perpendicularity to the central plane, but, in addition, some stretching of the M–M bond may also be caused.

In principle the way to minimize and even eliminate the Z···Z repulsion problem is to have the pairs of Z atoms tied together. There are examples among the known compounds of at least three ways to do this. The use of $R_2PCH_2PR_2$ (R = Ph or Me) is quite common. It is noteworthy, however, that the effectiveness of this approach is open to question. As will be explained under point (e) below, there is one instance in which the use of $Ph_2PCH_2PPh_2$ would appear to be critical to the formation of an M–M bond. However, we can also argue that on comparison of 2(a)1 and 2(a)2, where the diphosphine ligands chelate, with 2(a)3, where the $Me_2PCH_2PMe_2$ ligands span the adjacent axial positions, the "tying-together" does nothing to improve the M–M bonding. Thus, in 2(a)1 and 2(a)2 the Nb=Nb double bonds are 2.70 and 2.73 Å in length, while in 2(a)3 it is 2.71 Å in length. The same relationship is seen for 2(a)6 and 2(a)7 where the Ta=Ta distance in the "tied-together" case is less than 0.02 Å shorter than in the case where all Z-type positions are occupied by Cl atoms. Still another comparison that argues against the effectiveness of the $R_2PCH_2PR_2$ type ligand in enhancing M–M bonding is afforded by 3(a)1 where there are bridging $Ph_2PCH_2PPh_2$ ligands (and Mo–Mo = 2.79 Å) and 3(a)2–3(a)4, where there is no "tying together", and the Mo–Mo distances are in fact appreciably *shorter*, viz. 2.68–2.74 Å. Again, however, the comparison is marred by the fact that other features also differ and it would be safer to prepare and study some more conservatively altered pairs.

The presence of a μ_2-η^2 RCO_2^- ligand across an adjacent pair of Z positions is illustrated by 3(a)7, 3(b)1 and 3/4-2. However, the absence of any appropriate molecules that lack this feature but are otherwise closely similar means that we cannot determine whether such a carboxyl ligand is truly valuable in promoting M—M bond formation.

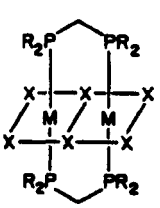
Finally, we note in 2(b)2–2(b)6 that by having an ROH and an RO ligand on each of the adjacent Z positions a "tying-together" effect arises by intramolecular hydrogen-bond formation. Indeed, in several of these molecules the hydrogen bond may well be a symmetrical one. Curiously, in 1(b)2 which is the Nb homolog of 2(b)2, no such intramolecular hydrogen bonding occurs; instead the two MeOH ligands form hydrogen bonds to neighboring molecules in the crystal.

The nature of the other terminal ligands, the X ligands in Fig. 1, may be less important than that of the Y or Z ligands, but this point remains somewhat moot on the basis of the present data. However, 4(a)1 and 4(a)2 afford evidence that such X-ligand effects can be appreciable. In going from 4(a)1 to 4(a)2 the only change in composition is the replacement of one terminal Cl ligand by an OEt group, but the Re–Re bond length increases from 2.62 to 2.67 Å. The probable reason for this increase is that the alkoxide ligand donates more strongly from its $p\pi$ orbitals to the σ^*- or π^*-orbitals of the Re_2 unit, thus weakening the Re–Re bond.

(*e*) *Comparisons in homologous series*

Because of the marked sensitivity of M–M distances to the identities and properties of the ligands (X, Y and Z), to the formal charges on the M atoms, and to the number of electrons available for M–M bonding, a meaningful search for systematic trends in M–M interaction can be successful only if we examine a series of compounds in which just one of these factors at a time is made to vary. We will summarize here the work on one suitable homologous series; it is actually the only one of sufficient extent to be really informative but no doubt other such series will be studied soon, as synthetic work makes them available.

The series in question here is comprised of complexes 2(a)3, 2(a)7, 3(a)1, 4(a)1 and 5(a)3. They are all of the type shown in the diagram below.



II

R=CH3, C6H5

X=Cl

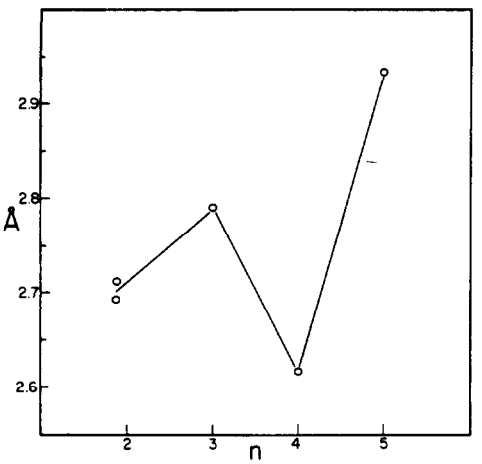


Fig. 4. M–M distances for a series of $M_2Cl_6(\mu\text{-dppm})_2$ or $M_2Cl_6(\mu\text{-dmpm})_2$ compounds covering d^n–d^n interactions form n from 2 to 5. The two points for $n = 2$ are for Nb and Ta compounds.

The details of this work will be found in Ref. 2. The purpose of the study was to employ structural data to infer the ordering of the MOs mainly responsible for M–M bonding. The particular point of uncertainty concerned the relative energies of the δ- and δ^*-levels. As already mentioned, it is not safe to assume that δ must be below δ^*, and it has been shown[2,3] that interaction of filled ligand orbitals with the M d-orbitals that contribute to the δ- and δ^*-levels can reverse this order, placing δ^* below δ.

The way in which M–M bond lengths change through a series of compounds with d^1–d^1, d^2–d^2, d^3–d^3, d^4–d^4 and d^5–d^5 M atom pairs will be different for the two possible relationships of the δ- and δ^*-orbitals. On going from d^1–d^1 to d^2–d^2 we pass from a σ^2 single bond to a $\sigma^2\pi^2$ double bond, and this should cause a marked decrease in M–M distance. Similarly, at the other end of the series, when we pass from the $\sigma^2\pi^2(\delta/\delta^*)^4$ configuration to the $\sigma^2\pi^2(\delta/\delta^*)^4\pi^{*2}$ configuration, there should be a marked increase in the M–M distance. What happens in between these end pairs, that is, between the d^2–d^2 and d^4–d^4 cases will depend on the order of filling the δ- and δ^*-orbitals. If δ is filled first, there should be a "down followed by up" pattern, whereas if δ^* is filled first there should be an "up followed by down" pattern in the M–M distances. These changes in distance should, of course, be smaller than those caused by adding the more strongly bonding or antibonding π- or π^*-electrons.

As shown in Fig. 4, the observed variation in M–M distances through the series from d^1–d^1 to d^5–d^5 is indicative of a σ, π, δ^*, δ, π^*, σ^* sequence of levels.

It should be noted that even in this study, perfect homology was not achieved for several reasons. First, the type of structure required could not be obtained in every case with either $Ph_2PCH_2PPh_2$(dppm) or $Me_2PCH_2PMe_2$(dmpm); instead it was necessary to use one of these in some cases and the other one in the remaining cases. It is not expected that changes in M–M bond length that might be caused by this would be as large as the significant variations observed, but this is a point that ought to be checked, and efforts to do so are underway. Second, the set of complexes used includes some from the second transition (4*d*) series and some from the third (5*d*) series. By examining both the niobium and tantalum compounds it was found (and can be seen in Fig. 4) that the difference is too small to influence the overall pattern of changes.

(*f*) *A puzzling anomaly*

In contradistinction to the type of regular, and understandable, behavior just discussed, there is one particularly puzzling deviation from regularity in a homologous series of complexes. As long ago as 1975 it was reported that in 4(a)3 there is no Re–Re bond, even though a $\sigma^2\pi^2\delta^2\delta^{*2}$ configuration, giving rise to a net double bond, would seem quite possible and even likely. In at least partial explanation of this, Shaik *et al.*[3] suggested that repulsive forces between the axial (Z-type in Fig. 1) Cl atoms might be sufficient to deny the system access to the bonded state. They suggested that in a similar complex where the Z positions were occupied by ligand atoms tied together, the Re=Re double bond would be seen. This prediction was later confirmed when the structures of 4(a)1 and 4(a)2 were determined. Here, the diphosphine ligands are dppms that span the adjacent pairs of Z positions.

However, further work has now shown that this apparently satisfying picture must be too simple; something of importance is omitted from it. We see this by referring to compounds 2(a)1, 2(a)2, 2(a)6, 3(a)2 and 3(a)3, to mention only the most directly pertinent ones. In each of these we have essentially the same type of ligand arrangement as in 4(a)3; indeed in 2(a)2 the composition is identical and in 2(a)6 the only difference is replacement of the chelating dppe ligands by dmpe ligands. In all of these complexes there are M–M bonds with lengths in the range 2.68–2.73 Å, formed by d^2–d^2 or d^3–d^3 M atom pairs. Thus, it appears that simply by adding two more electrons, to reach a d^4–d^4 situation, the formation of an M–M bond is abruptly disfavored.

There is at present no explanation for this discontinuous behavior. Further experimental data that

might serve to define more precisely the properties associated with the discontinuity would certainly be welcome and efforts in that direction are underway in the author's laboratory. Some pertinent synthetic targets are (dmpe)$Cl_4Re(\mu\text{-}Cl)_2ReCl_4$(dmpe), as well as the following pairs (where R = CH_3 or C_6H_5): (dRpe)$Cl_4W(\mu\text{-}Cl)_2WCl_4$(dRpe) and (dRpe)$Cl_4Tc(\mu\text{-}Cl)_2TcCl_4$(dRpe).

PROBLEMS IN THE THEORETICAL DESCRIPTION OF METAL–METAL MULTIPLE BONDS OR HOW I LEARNED TO HATE THE ELECTRON CORRELATION PROBLEM

MICHAEL B. HALL

Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 19 *November* 1986)

Abstract—The goal of this article is to present a historical perspective to theoretical calculations of metal–metal multiple bonds, to explain why calculations on these systems are so difficult and to predict the direction of future research in this area.

From the beginning, theory has played an important role in the history of the quadruple bond. The first report[1] of the structure of $K_2Re_2Cl_8 \cdot 2H_2O$ contains an explanation of the short Re–Re bond and the eclipsed Cl ligands in terms of the, now familiar, quadruple bond, $\sigma^2\pi^4\delta^2$. Although some early extended Hückel calculations were performed, 10 years passed before this problem was tackled by more accurate calculations. The first of these was a scattered-wave X-α (SW-Xα) calculation on the $Mo_2Cl_8^{4-}$ ion.[2] This calculation confirmed the $\sigma^2\pi^4\delta^2$ ordering for the orbitals in this ion. Following the initial discovery of the quadruple bond in $Re_2Cl_8^{2-}$, other second- and third-row quadruply bonded systems were prepared. In 1970 the structure of $Cr_2(O_2CCH_3)_4(H_2O)_2$ was determined (Cr–Cr = 2.362 Å) and the molecule was postulated to contain a quadruple Cr–Cr bond.[3] The first *ab initio* calculation was performed on the related $Cr_2(O_2CH)_4$ dimer and published in conjunction with the gas-phase ultraviolet photoelectron (PE) spectrum of $Cr_2(O_2CCH_3)_4$.[4] In this work the authors found that the lowest-energy single-determinant wavefunction was $\sigma^2\pi^2\pi^{*2}\sigma^{*2}$. Thus, they predicted that there was no Cr–Cr bond in this system. They suggested that this was the reason for the somewhat long bond length and they assigned all the metal ionizations to the first band in the PE spectrum.

These conclusions were the beginning of two controversies. The first centered on the nature of the Cr–Cr bonding, i.e. was it or wasn't it a quadruple bond? The second centered on the assignment of the PE spectrum, i.e. were all the Cr ionizations in the first band or was the ionization for the bonding σ-pair at a substantially higher ionization energy (IE)?

In a scientific sense the first controversy was settled rather quickly with the publication of configuration interaction (CI) calculations on $Cr_2(O_2CH)_4$ and related systems.[5,6] However, because the quadruply bonded configuration, $\sigma^2\pi^4\delta^2$, represented such a small part of the wavefunction, a semantic argument, about whether or not these systems have a quadruple bond, continued to be heard.

The second controversy was only settled recently with the publication of the PE spectra of several quadruply bonded tungsten derivatives[7] and local density functional (LDF) calculations on the IE.[8] Previously, the SW-Xα (a scattered-wave LDF approach) results[9(a)] suggested that the σ-ionization was a high IE and that the first band consisted of only the δ- and π-ionizations. Early *ab initio* results[10] suggested that the first band contained all three ionizations. The PE work on tungsten and the improved LDF calculations confirmed the conclusion of the early *ab initio* results.

A similar controversy concerning the assignment of the $Mo_2(O_2CH)_4$ PE spectrum has been resolved and the initial assignment from *ab initio* calculations[10] proved more accurate than that of the Xα-SW calculations.[9(b)] Again, more sophisticated LDF calculations agree with the *ab initio* results.[8]

Before going on with the progress of theoretical developments in this area, we will present a short discussion of the fundamentals of *ab initio* molecular electronic structure calculations as they relate to the problems in calculating the electronic structure of molecules with metal–metal bonds.

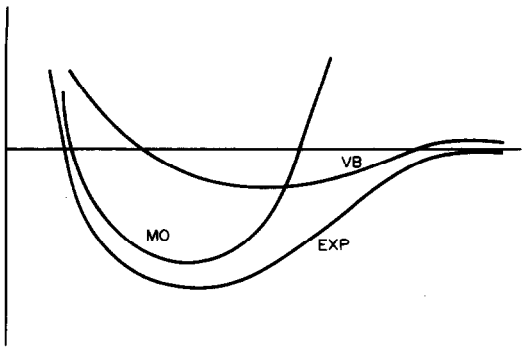

Fig. 1. Schematic potential energy curves are shown for a typical molecular orbital (MO) and valence bond (VB) wavefunction. In comparison with the "experimental" (EXP) curve, the MO wavefunction does not dissociate properly but parallels the EXP curve at short internuclear distances (R), while the VB wavefunction dissociates properly but is too repulsive at shorter R.

THEORETICAL

We will begin with a discussion of the simple diatomic H_2. The two lowest-energy molecular orbitals (MOs) of H_2 are the $1\sigma_g$ and the $1\sigma_u$. The former is the bonding MO, while the latter is the antibonding counterpart. In its ground state H_2 has two electrons in the $1\sigma_g$, i.e. $1\sigma_g^2$. The total wavefunction is the Slater determinant:

$$\Psi_{MO} = |1\sigma_g\alpha 1\sigma_g\beta|, \tag{1}$$

where α and β are the $+\frac{1}{2}$ and the $-\frac{1}{2}$ spin eigenfunction, respectively. The wavefunction must be a Slater determinant in order to obey the Pauli exclusion principle. In the usual linear combination of atomic orbitals (LCAO) approach the $1\sigma_g$ MO is expanded as a linear combination of two atomic-like orbitals, one on each H atom. If we refer to these two functions as a and b, then:

$$1\sigma_g = (a + b)N_+ \tag{2}$$

$$1\sigma_u = (a - b)N_- \tag{3}$$

where $N_\pm$ are the normalization constants.

If one uses a simple MO wavefunction like Ψ_{MO} in eqn (1) to calculate the potential energy curve for H_2, one finds that the energy begins to rise much too rapidly as the internuclear distance increases. This is shown schematically in the curve labelled MO in Fig. 1. The reason for this behavior can be seen, if we expand eqn (1) and substitute the definition of $1\sigma_g$ given in eqn (2). Expansion yields:

$$\Psi_{MO} = [1\sigma_g\alpha(1)1\sigma_g\beta(2) - 1\sigma_g\beta(1)1\sigma_g\alpha(2)]/\sqrt{2}, \tag{4}$$

where (1) and (2) refer to electron labels. We can now factor the space and spin parts

$$\Psi_{MO} = 1\sigma_g(1)1\sigma_g(2)[\alpha(1)\beta(2) - \beta(1)\alpha(2)]/\sqrt{2}, \tag{5}$$

where the latter part $(\alpha\beta - \beta\alpha)/\sqrt{2}$ is the singlet spin function. Expanding the spacial part of the wavefunction by substituting eqn (2) for $1\sigma_g$, we find that:

$$\Psi_{MO} = [a(1) + b(1)]\,[a(2) + b(2)]\,N_+^2(\alpha\beta - \beta\alpha)/\sqrt{2}. \tag{6}$$

We will discontinue writing the singlet spin function with the understanding that it always multiplies the spacial part. Multiplying out the wavefunction, we find that:

$$\Psi_{MO} = [a(1)a(2) + a(1)b(2) + b(1)a(2) + b(1)b(2)]N_+^2. \tag{7}$$

The first term represents a contribution to the wavefunction with both electrons in orbital a, i.e. on one of the H atoms. The second term represents a contribution with one electron in orbital a and the other electron in orbital b, i.e. on different H atoms. The third and fourth terms can be interpreted in a similar manner. Thus, the MO wavefunction suggests that there are equal contributions from both electrons on one H atom and from one electron on one H atom and the other electron on a different H atom. This might be a good approximation when both atoms are close together, but it is clearly incorrect as the molecule dissociates. At a large internuclear distance (R) one should have a wavefunction with one election on each atom, i.e.:

$$\Psi_{VB} = [a(1)b(2) + b(1)a(2)]N. \tag{8}$$

This wavefunction, which is correct at large R, is the simple valence bond (VB) or Heitler–London function. The potential energy curve for this simple VB wavefunction is also shown on Fig. 1. Although it dissociates properly into two neutral atoms, it is too repulsive as R gets shorter because it has no ionic contributions. On the other hand, the MO wavefunction is more accurate at short R, but dissociates improperly into a mixture of neutral and ionic atoms.

What one needs is a wavefunction that looks like an MO function at short R and a VB function at long R. One can achieve this by adding a variable amount of ionic character to the VB wavefunction [eqn (8)]. Alternatively, one can achieve the same wavefunction by doing a CI calculation using the MOs $1\sigma_g$ and $1\sigma_u$. Consider the doubly excited configuration $1\sigma_u^2$; its wavefunction:

$$\Psi'_{MO} = |1\sigma_u\alpha 1\sigma_u\beta|, \tag{9}$$

yields the following after substitution of eqn (3) and neglect of the singlet spin term:

$$\Psi'_{MO} = [a(1)a(2) - a(1)b(2) - b(1)a(2) + b(1)b(2)]N^2_-. \quad (10)$$

Notice that if one subtracts Ψ'_{MO} from Ψ_{MO} one gets Ψ_{VB}. Thus, if we form:

$$\Psi = (1 - \lambda^2)^{1/2}\Psi_{MO} - \lambda\Psi'_{MO} \quad (11)$$

we can use λ as a variational parameter to minimize the total energy at each point in the potential energy curve. As R gets large, λ will approach $1/\sqrt{2}$. Thus, the wavefunction in eqn (11) represents the simplest form for a wavefunction which is qualitatively correct over the entire potential-energy curve.

The process of adding to the simple MO wavefunction configurations which are excited with respect to the simple MO function is called CI. If one also varies the form of the MOs $1\sigma_g$ and $1\sigma_u$ as one varies λ, one has a multiconfiguration self-consistent-field (MCSCF) procedure. For this particular case of two electrons and two orbitals, the MCSCF wavefunction in eqn (11) is the same as the wavefunction obtained from other procedures such as generalized molecular orbital (GMO), generalized valence bond (GVB), and antisymmetric product of strongly-orthogonal geminals (APSG).

Although these procedures will not be equivalent for more complicated cases, their goal is the same: to correct for the deficiencies in the simple MO wavefunction by using more than one configuration to represent the wavefunction. The overall error in the MO wavefunction is usually referred to as the electron correlation error. The electrons in the MO wavefunction are uncorrelated, i.e. one electron does not know about the actual position of the other electrons, only about their average position. Thus, in the simple MO wavefunction, the electrons are equally likely to be found together on the same atom [$a(1)a(2)$ like terms] as on different atoms [$a(1)b(2)$ like terms]. When the motion of the electrons is correlated as in eqn (11) the electrons are less likely to be found together in the same atom or region of space and are more likely to be found in different atoms or regions of space.

The wavefunction in eqn (11) only represents a fraction of the total correlation energy. Because of this the potential-energy curve calculated with this wavefunction is still not exactly parallel to the experimental curve. Generally, the predicted bond distance is now too long and the dissociation energy is still too small because the wavefunction [eqn (11)] is more accurate at a large R than at small R. This discrepancy is related to the relative energy of the resonance:

$$H + H \leftrightarrow H^+ + H^-. \quad (12)$$

The simple MO model suggests both sides are of equal weight (same energy) while the simple MCSCF [eqn (11)] suggests that the left side of eqn (12) is more important. Although the simple MCSCF is basically correct, it underestimates the importance of the right side of eqn (12) because it has not calculated correctly the electron affinity of H. When additional electron correlation is added, the relative energies of the two sides of eqn (12) are calculated correctly and the potential-energy curve now parallels the experimental curve.

A correlated wavefunction like that in eqn (11) presents a problem for the calculation of the bond order (BO). The usual scheme for calculating a BO in MO theory is:

$$BO = \tfrac{1}{2}[(\text{No. of } e^- \text{ in bonding MO}) - (\text{No. of } e^- \text{ in antibonding MO})]. \quad (13)$$

Thus, for the simple MO wavefunction the BO = 1, but for the wavefunction in eqn (11):

$$BO = \tfrac{1}{2}[2(1 - \lambda^2) - 2\lambda^2] = 1 - 2\lambda^2. \quad (14)$$

As the molecule dissociates this BO approaches zero because at large R the $1\sigma_g$ and $1\sigma_u$ have an equal number of electrons. Even at the equilibrium distance the BO < 1.0. A considerably different view is apparent if we remember that, when $\lambda = 1/\sqrt{2}$, its value at $R = \infty$, the wavefunction Ψ in eqn (11) is identical to the Ψ_{VB} in eqn (8). From the valence bond viewpoint the wavefunction in eqn (8) represents a single bond, i.e. BO = 1. Thus, the same wavefunction has a BO(MO) = 0 and a BO(VB) = 1. The MO BO, as calculated by eqn (13) or (14), changes with R and reflects the strength of the bond. On the other hand the VB BO is one over the entire potential-energy curve and, thus, represents a formal BO.

RESULTS AND DISCUSSION

We can now discuss in some detail the "true" nature of the bonding in the chromium dimers. The first column in Table 1 shows the important configurations and occupation numbers from a GMO-CI calculation[11] on $Cr_2(O_2CH)_4$ at a Cr–Cr distance of 2.3 Å. The single most important configuration is the quadruple bond $\sigma^2\pi^4\delta^2$, but it only makes up about 12% of the wavefunction. The remainder of the wavefunction is made of configurations in which electrons from the bonding orbitals occupied in the $\sigma^2\pi^4\delta^2$ configuration are excited

Table 1. Comparison of quadruple-bond strength

	$Cr_2(O_2CH)_4$[a]	$Cr_2((NH)_2CH)_4$[b]
	Orbital occupations	
σ	1.47	1.73
π	2.44	3.33
δ	1.18	1.51
δ^*	0.82	0.49
π^*	1.56	0.67
σ^*	0.53	0.27
	Important configurations[c]	
$\sigma^2\pi^4\delta^2$	0.117	0.482
$\sigma^2\pi^4\delta^{2*2}$	0.054	0.085
$\sigma^2\pi^2\delta^2\pi^{*2}$	0.083	0.094
$\pi^4\delta^2\sigma^{*2}$	0.017	0.019

[a] Values for molecule at 2.3 Å.

[b] Values for molecule at 1.9 Å.

[c] Values represent the sum of the square of the coefficients corresponding to different spin components of the same configuration.

into the antibonding orbitals σ^*, π^* or δ^*. The most important configurations are those in which two electrons from a bonding orbital are excited into the corresponding antibonding one such as $\delta^2 \rightarrow \delta^{*2}$. These doubly excited configurations provide an important part of the left–right near-degenerate correlation that was described in the previous section.

This Cr–Cr quadruple bond is unusual compared to most chemical bonds at their equilibrium distance, because the contribution of the leading configuration is so small and the importance of the other configurations is so large. In "typical" molecules the leading configuration makes up more than 80% of the wavefunction at the equilibrium distance. It is only as the bond length gets longer that the importance of the leading configuration (all bonding MOs occupied) decreases and the others increase. Thus, these chromium dimers appear to be similar to a more typical bond at a long bond distance. And, one would expect the Cr–Cr bond energy to be rather small and the potential energy to be rather shallow. This theoretical result is consistent with the long and variable bond lengths found in the dichromium tetracarboxylates.

Another way of presenting the electronic structure of these dimers is shown also in Table 1 where the orbital occupations are given. These are determined from summations over all configurations in the wavefunction. Although the single most important term in the wavefunction is the quadruple bonding configuration $\sigma^2\pi^4\delta^2$, a calculation of the BO from the occupation numbers in Table 1 yields a BO of 1.1. Thus, this quadruple bond is only expected to be as strong as a "typical" single Cr–Cr bond. Naturally, this difference, between a formal (VB) BO of 4 and a much smaller calculated BO, led to some disagreement over whether these systems should be properly termed as having a quadruple bond.[6,12]

All of the dichromium tetracarboxylates have some type of axial coordination. Thus far, attempts to prevent this axial ligation have failed. The impetus for trying this was the belief that the Cr–Cr distance would shorten when the axial ligands are removed.[13] The first "supershort" Cr–Cr bond (< 1.9 Å) was found in $Cr_2(DMP)_4$ (DMP = 2,6-dimethoxyphenyl anion). In this molecule we have a much more basic bridging ligand, no axial ligands and a Cr–Cr bond length of 1.847 Å. The results of a theoretical calculation on a model for these "supershort" dimers is given in the second column of Table 1. Now, the quadruple bond configuration $\sigma^2\pi^4\delta^2$ makes up nearly 50% of the wavefunction and the calculated BO has risen to 2.6. Clearly, there has been a dramatic change in the bonding. Our theoretical work[14] on $Cr_2(O_2CH)_4$, $Cr_2(O(NH)CH)_4$ and $Cr_2((NH)_2CH)_4$ suggests that a major factor influencing the Cr–Cr bond length was the basicity of the bridging ligand. GMO-CI calculations of the potential-energy curve for $Cr_2(O_2CH)_4$ and $Cr_2((NH)_2CH)_4$ reveal minima at 2.41 and 1.93 Å, respectively. The implication of these results is that one must have ligands more basic than carboxylates to have "supershort" Cr–Cr bonds and that removal of the axial ligands from a tetracarboxylate will not result in a "supershort" Cr–Cr bond. Previous CI calculations[15] of $Cr_2(O_2CH)_4$ with and without two axially coordinated H_2O molecules also suggested that little change in the Cr–Cr bond length would result from removal of the two axial ligands.

The experimental work on the question of the relative importance of the bridging vs axial ligand in determining the Cr–Cr bond length is somewhat ambiguous. Cotton and coworkers have clearly shown that if one adds axial ligands to one of the supershort bonds the bond will lengthen.[16] In this study the parent molecule, $Cr_2[(2\text{-xylyl})NC(CH_3)O]_4$, has a Cr–Cr bond length of 1.937 Å. Adding one THF axial ligand lengthened the bond by 0.086 Å, adding a second THF axial ligand lengthened the previous one by 0.198 Å, and replacing both THF ligands in the last complex by two pyridine ligands lengthened the bond by another 0.133 Å. Clearly, the addition of axial ligands to one of the molecules with short Cr–Cr bonds will cause those bonds to lengthen.

However, will removal of axial ligands from one of the systems with a long bond cause those bonds

to shorten? The answer here is not as clear. Thus far all attempts to prepare a tetracarboxylate dimer of chromium without axial coordination have been unsuccessful. If one replaces two axial pyridine ligands by two H_2O molecules in the tetraformate or tetraacetate derivative one finds a shortening of only 0.041 and 0.007 Å, respectively.[17] This change in bond distance is much smaller than that observed for a similar ligand exchange in $Cr_2[(2\text{-xylyl})NC(CH_3)O]_4L_2$. Cotton and Wang studied the structure of a number of $Cr_2(O_2CR)_4L_2$ molecules and plotted the value of the Cr–Cr bond distance against the pK_a of the acid HO_2CR and the pK_a of L, where L was pyridine or substituted pyridine.[18] The correlation for a give class of compounds was nearly linear and different classes of compounds had parallel lines. The slope of these lines, $\Delta Cr\text{–}Cr/\Delta pK_a$, was -0.04 Å/pK_a for changes in the bridging ligand and $+0.007$ Å/pK_a for changes in the axial ligand. Thus, strengthening the basicity of the bridging ligands was much more effective in shortening the Cr–Cr bond length than weakening basicity of the axial ligands. In other words, the tetracarboxylate dimers seem to be more sensitive to the nature of the bridging ligands than the axial ligands. How much shortening will occur when one removes the axial ligands from $Cr_2(O_2CR)_4L_2$ dimers is not clear.

The ultimate experiments would be, of course, on $Cr_2(O_2CR)_4$ in the gas phase. Two experiments of this type have been performed. The electron diffraction of $Cr_2(O_2CCH_3)_4$ has been reported by Ketkar and Fink.[19] They reported a Cr–Cr bond length of 1.966 Å, but the solution of this problem was complicated because the peaks in the radial distribution for Cr–Cr and Cr–O overlapped strongly. The gas-phase ultraviolet PE spectra of a variety of dichromium species have been reported.[4,20] If one compares the low-energy region of $Cr_2(O_2CCH_3)_4$ with the same region in the PE spectra of "supershort" dimers one finds substantial differences that are best explained by assuming that the Cr–Cr bond of the tetraacetate is substantially longer than that of the "supershort" dimers. Thus, the only two gas-phase experiments appear to lead to different conclusions on the length of dichromium tetraacetate without axial ligands.

In principle one could resolve this discrepancy through more accurate calculations. To date, attempts to improve the theoretical results have been less than satisfactory.[21,22] As more complete MCSCF procedures and CI calculations have been performed, the Cr–Cr bond distance in the tetraformate model systems has gotten longer and longer. These results essentially mean that all of the previous results obtained a minimum in the potential-energy curve because of a cancellation of errors. One may argue that this cancellation is not entirely fortuitous and that those previous results are essentially correct. However, it is not very satisfying when improved calculations yield inferior results. As we mentioned in the theoretical section, calculations on small diatomics that result in bond distances which are too long are a result of the failure to properly account for the difference in the atomic IP and EA. Thus, these improved calculations may be neglecting important atomic-like electron correlation as they improve the molecular correlation (left–right near-degenerate). Goddard and coworkers[23] have suggested that this is the reason that nearly all previous calculations on the simple diatomic Cr_2 have failed to obtain the correct bond distances of 1.73 Å. These workers have empirically adjusted an atomic coulomb repulsion integral to bring theoretical ΔH for the reaction $2Cr^0 = Cr^+ + Cr^-$ into line with experiment. Using this adjusted integral they were successful in calculating the bond distance in Cr_2. Others have emphasized the change in the correlation energy of the other electrons in the system as one forms the metal–metal bond.[24] This is sometimes referred to as the differential correlation energy and played an important role in the calculation of the dissociation energy of the Mo≡Mo triple bond.[25]*

One unusual feature of theoretical work in this area that it is apparently easier to calculate the bond energy and bond distance of the heavier dimolybdenum systems than dichromium. Usually, quantum chemistry is easier on the lighter molecule (fewer electrons). However, the overlap between the 4*d* orbitals is sufficiently larger than the overlap between 3*d* orbitals that the dimolybdenum system can be calculated accurately with a more modest treatment of the electron correlation. This theoretical problem actually manifests itself in the chemistry and structure of these systems. Thus, the Mo≡Mo bond distance is essentially constant regardless of ligands, while the Cr≡Cr bond distance has the largest range of any known bond of a given order.

The chapter on Cr≡Cr bonds is not yet closed. We do not have a complete understanding of how to calculate the bond distance or dissociation energy correctly. Furthermore, we do not understand the relative importance of all the factors which determine the wide variation of Cr≡Cr bond lengths.

* Although early LDF calculations suggested a larger dissociation energy than our *ab initio* results, the most recent and sophisticated LDF calculations[26] now yield dissociation energies similar to our prediction.

Also, there has been little *ab initio* theoretical work on the excited states of systems such as these. One of the few complete studies is that by Hay[27] on $Re_2Cl_8^{2-}$. In this paper I have tried to give the reader an appreciation of the problems encountered in calculating accurate properties of the dichromium species. Future theoretical work in this area will be directed toward these remaining problems.

A THEORETICAL STUDY ON THE STRENGTH OF MULTIPLE METAL–METAL BONDS IN BINUCLEAR COMPLEXES AND TRANSITION-METAL DIMERS BY A NON-LOCAL DENSITY FUNCTIONAL METHOD

TOM ZIEGLER,* and VINCENZO TSCHINKE

Department of Chemistry, University of Calgary, Calgary, Alberta, Canada

and

AXEL BECKE

Department of Chemistry, Queens University, Kingston, Ontario, Canada

(*Received* 19 *November* 1986)

Abstract—The strength of multiple metal–metal bonds in the metal dimers M_2 (M = Cr, Mo or W) and binuclear complexes $M_2(OH)_6$ (M = Cr, Mo or W), $M_2Cl_4(PH_3)_4$ (M = V, Cr, Mn, Nb, Mo, Tc, Ta, W or Re) has been studied by a non-local density functional theory. The method employed here provides metal–metal bond energies [D(M–M)] in good accord with experiments for Cr_2 and Mo_2, and predicts that W_2 of the three dimers M_2 (M = Cr, Mo or W) has the strongest metal–metal bond with D(W–W) = 426 kJ mol^{-1} and R(W–W) = 2.03 Å. Among the binuclear complexes studied here we find the 3d elements to form relatively weak metal–metal bonds (40–100 kJ mol^{-1}), compared to the 4d and 5d elements with bonding energies ranging from 250 to 450 kJ mol^{-1}. The metal–metal bond for a homologous series is calculated to be up to 100 kJ mol^{-1} stronger for the 5d complex, than for the 4d complex. An energy decomposition of D(M–M) revealed that the σ-bond is somewhat stronger than each of the π-bonds, and one order of magnitude stronger than the δ-bond. For the same transition metal we find D(M–M) to be larger for $M_2(PH_3)_4Cl_4$ (M = Cr, Mo or W) than for $M_2(OH)_6$ (M = Cr, Mo or W), and attribute this to a stronger π-interaction in the former series. While many of the findings here are in agreement with previous HFS studies, the order of stability $D(3d–3d) \ll D(4d–4d) < D(5d–5d)$ differs from the order $D(3d–3d) \ll D(5d–5d) < D(4d–4d)$ obtained by the HFS method, and the present method provides in general more modest values for D(M–M) than the HFS scheme.

Cotton's description[1] of the metal–metal bond in terms of orbitals with local σ, π and δ axial symmetries has been immensely useful in codifying[2] the increasing number of synthesized binuclear complexes, and account for their chemical and spectroscopic properties. It is thus not surprising that much effort, both experimentally[2–4] and theoretically[5–8] have gone into expanding on Cotton's original scheme by: (a) probing the relative energies of the σ-, π- and δ-type orbitals; (b) assessing variations in the metal–metal bond lengths with changes in the metal–metal bond order; and (c) determining the metal–metal bond strength and the respective contributions from the σ-, π- and δ-bonds.

LOW-ENERGY PHOTOELECTRON SPECTROSCOPIC STUDIES ON BINUCLEAR COMPLEXES, AND THEIR THEORETICAL INTERPRETATION

One of the experimental technics with the strongest bearings on the points raised under (a) is low-energy photoelectron (PE) spectroscopy,[3] which in

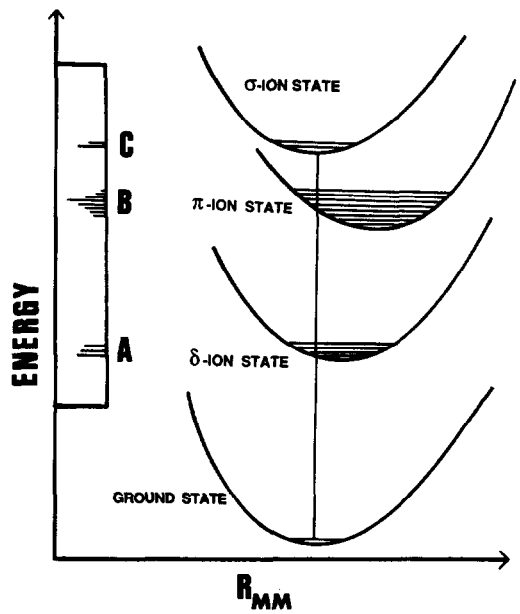

Fig. 1. Schematic representation of the energy for a quadruple bonded binuclear complex M_2L_{2n} in its ground state and first three ion states, corresponding to ionizations out of the σ, π and δ bonding orbitals, as a function of the metal–metal bond distance (R_{MM}). Schematic representation of the three first PE bands with expected shapes are given as A, B and C, respectively.

conjunction with theoretical calculations[5,6] can provide information on the relative energies of the states corresponding to ionizations of electrons out of the σ, π and δ metal–metal bonding orbitals. The triple bonded M_2L_6 (M = Mo or W, L = OR or NR_2)[3(c)] complexes (**1a**) as well as the quadruple bonded complexes $M_2(O_2CR)_4$ (M = Cr, Mo or W)[3(a)] and $M_2Cl_4(PR_3)_4$ (M = Mo or W)[3(b)] (**2** and **3**) have been particularly well studied[3] by PE spectroscopy since their volatility makes them well suited for this experimental technic.

We have previously found[5(c)] in our interpretation of the recorded PE spectra for the quadruple bonded systems, based on HFS calculations, that the first three bands corresponded to ionizations out of the σ, π and δ metal–metal bonding orbitals, respectively, with ionization out of the ligand based orbitals at somewhat higher energies, and a similar assignment has also been reached by *ab initio* calculations[6(a)] for $M_2(O_2CH)_4$ (M = Cr or Mo). It is indicated in Fig. 1, where we schematically present the energies of the three first-ion states of $[M_2(O_2CR)_4]^+$ or $[M_2Cl_4(PR_3)_4]^+$ relative to the ground state of the neutral molecules as a function of the metal–metal bond distance (R_{MM}), that the first ionization for the quadrupole bonded systems, according to our previous calculations takes place from the δ-orbital, whereas the second ionization, which, depending on the system, is 1–2 eV higher in energy, corresponds to the π-orbital. There has been some controversy[2] over the position of the ionization band due to the σ-orbital. We find[5(c)] the σ-ionization to be of higher energy than the π-ionization by 1 eV of less (Fig. 1).

All theoretical calculations to date[3(c),5(c)] indicate that the first two bands in the recorded PE spectra of the triple bonded M_2L_6 (L = OR or NR_2)[3(c)] complexes correspond to ionizations from the π- and σ-orbitals, respectively, with the σ-ionization around 1 eV higher in energy than the π-ionization.

DEPENDENCE OF R_{MM} ON THE FORMAL METAL–METAL BOND ORDER

Photoelectron spectroscopy can also in principle determine the change in R_{MM} on ionization of an

electron out of the metal–metal bonding orbitals, and thus address the point raised under (b) concerning the variation in R_{MM} as a function of the formal bond order. So far only an estimate of the change in R_{MM} from the ionization out of the δ-orbitals has been obtained experimentally.[3(e)] The influence of the δ^*-occupation on R_{MM} has further been studied[9] by X-ray diffraction methods for the series $[Re_2Cl_4(PR_3)_4]^{n+}$ ($n = 2$, 1 or 0).

We have previously calculated[5(c)] the difference in R_{MM} between the ground state and the three first-ion states of some quadruple bonded complexes. We found, perhaps not surprisingly, that an ionization out of the weakly bonding δ-orbital leads to a modest elongation of R_{MM} of around 0.04 Å, whereas the ionization out of the strongly bonding π-orbital results in a substantial elongation (~ -15 Å). What was surprising, however, was the negligible change in R_{MM}, 0.01 Å or less, accompanying the ionization from the strongly metal–metal bonding σ-orbital (Fig. 1). An analyses of this puzzling result revealed that the ionization from the σ-orbital not only reduces the bond order but also the exchange repulsion. The two factors have adverse effects on the metal–metal bond distance which cancels.[5(c)]

The different extent to which R_{MM} is influenced by ionizations out of the σ-, π- and δ-orbitals should have consequences for the shapes of the different ionization bands, with band B (Fig. 1) due to the π-ionization being rather broad, and band C due to the σ-ionization being rather narrow. This is in fact what has been observed by Bancroft *et al.*[3(a)] in the case of $W_2(O_2CCF_3)_4$. For other quadruple bonded systems[2] the width of band B seems to be comparable to the σ–π separation, resulting in overlaps of bands B and C.

STRENGTH OF THE METAL–METAL BOND IN BINUCLEAR COMPLEXES

The strength of the metal–metal bond, let alone the respective σ, π and δ contributions, has been exceedingly difficult to determine experimentally,[4] since calorimetric measurements of the metal–metal bond energy [D(M–M)] in M_2L_n complexes is hampered by an uncertainty in the M–L dissociation energy, an uncertainty that is multiplied by n in the final estimate of D(M–M).

Attempts on the other hand to estimate D(M–M) from *ab initio* calculations are faced with the formidable task of describing the correlated motion of the electrons in the metal–metal bond, and only a few attempts have so far been reported.[7] We have recently calculated D(M–M)[8] with the aid of the HFS method according to Baerends *et al.*[10(a)] for some M_2L_6 and $M_2Cl_4(Ph_3)_4$ systems with quadruple or triple bonds, and decomposed D(M–M) into its σ-, π- and δ-components. We found[8] the σ-bond to be slightly stronger than each of the π-bonds, and one order of magnitude stronger than the δ-bond. In absolute terms triple or quadruple bond strengths of 3*d* elements were calculated by the HFS method to be in the range 150–300 kJ mol^{-1}, whereas the corresponding bond energies for 4*d* and 5*d* elements were in the 400–600 kJ mol^{-1} bracket. Multiple metal–metal bonds, even for the heavier 4*d* and 5*d* elements are thus according to our HFS calculations in strength more comparable to the triple bond in P_2 than the triple bond in N_2.

RECENT ADVANCES IN DENSITY FUNCTION THEORY

Experience with the HFS (or Xα) method, accummulated over the past decade, seems to indicate that calculated bond distances and force constants as well as spectroscopic energy differences, such as ionization potentials and electronic excitation energies, are in good to fair agreement with experimental results, whereas calculated bond energies compare less satisfactorily with experiment.

The HFS method is an approximation to the density functional theory of Kohn and Sham[11(a)] in much the same way as *ab initio* Hartree–Fock theory is an approximation to many body theories including configuration interaction, since both methods completely neglect the correlation between electrons of different spins.[12] Recent advances in density functional theory,[13] which in many ways parallels the development of post-HFS methods, has lead to remedies for the lack of correlation between electrons of different spins and other shortcomings of the HFS method by including two corrections to the HFS energy expression E_{HFS}:

$$E_{BS} = E_{HFS} + E_C + E_X^{NL}. \quad (1)$$

The first correction term E_C in eqn (1) proposed by Stoll *et al.*[11(b)] represents the correlation between electrons of different spins, whereas the second correction term E_X^{NL}, according to Becke,[11(c)] represents a non-local correction to the HFS exchange energy E_X.

We shall now demonstrate that the modified HFS method, based on the energy expression of eqn (1), in the cases of Cr_2 and Mo_2 provides bond energies D(M–M) in good agreement with the accurate experimental values for D(Cr–Cr) and D(Mo–Mo).[14] Following this evaluation of the

method based on eqn (1), calculated D(M–M) and R_{MM} will be presented for the triple bonded compounds $M_2Cl_4(PH_3)_4$ (M = V, Nb, Ta, Mn, Tc or Re) and $M_2(OH)_6$ (M = Cr, Mo or V) as well as the quadruple bonded complexes $M_2Cl_4(PR_3)_4$ (M = Cr, Mo or W).

COMPUTATIONAL DETAILS

All calculations were based on the LCAO–HFS program system according to Baerends *et al.*[10(a)] or its relativistic extension due to Snijders *et al.*[15] with only minor modifications to allow for Becke's non-local exchange correction[16] as well as correlation between electrons of different spins in the formulation by Stoll,[11(b)] based on Vosko's parametrization[16] from electron gas data. Bond energies were evaluated by the generalized transition-state method[17(a)]* or its relativistic extension.[17(b)]

A triple ζ-STO basis[10(b),(c)] was used for 1*s* on H, 3*s*, 3*p* on Cl and P, as well as *ns*, *np*, *nd* and $(n+1)s$, $(n+1)p$ on the transition metals, augmented with a single 3*d* STO on P and three $(n+1)f$ STOs on the metals. Electrons in shells of lower energy were considered as core and treated by the frozen-core approximation according to the procedure Baerends *et al.*[10(a)] The total molecular electron density was fitted in each SCF iteration by an auxiliary basis[10(d)] of *s*, *p*, *d*, *f* and *g* STOs, centered on the different atoms in order to represent the Coulomb and exchange potentials accurately.[10(a)] The SCF part of the calculations, as well as the optimizations of R_{MM}, included, of the correction terms in eqn (1), only E_C, corresponding to the correlation between electrons of different spins. The wave functions generated from this type of SCF calculation were then used to calculate Becke's non-local exchange corrections (E_X^{NL}) at the optimized R_{MM}, in order to evaluate E_{BS} of eqn (1) as well as the D(M–M). Efforts[18] are under way to include D_X^{NL} in the SCF part of the calculations as well as in the geometry optimizations.

THE CALCULATED METAL–METAL BOND STRENGTH OF THE DIMERS Cr_2, Mo_2 AND W_2

The metal dimers Cr_2 and Mo_2 are among the few species with multiple metal–metal bonds for which quite accurate experimental bond energies are available,[14] and our primary aim here has been to compare those values to calculated bond energies based on eqn (1) in order to evaluate the accuracy of E_{BS}. A more extensive account of the bonding in electron-poor metal dimers with multiple metal–metal bonds involving group 4–7 transition metals is in preparation,[18] and we note that several theoretical accounts of the bonding in Cr_2 and Mo_2 have already appeared, based on *ab initio*[14] and density functional theory.[19] No calculation has, however, been reported on W_2, nor are there any experimental data available.

Table 1. Calculated bond energies [D(M–M)] (eV) and metal–metal bond distances (R_{MM}) (Å) for Cr_2, Mo_2 and W_2

	D(M–M)		R_{MM}	
M_2	Calc.	Exp.	Calc.	Exp.
Cr_2	1.75	1.56 ± 0.2	1.65	1.69
Mo_2	4.03	4.18 ± 0.2	1.95	1.93
W_2	4.41(3.54)[a]	—	2.03(2.07)[a]	—

[a]Non-relativistic results.

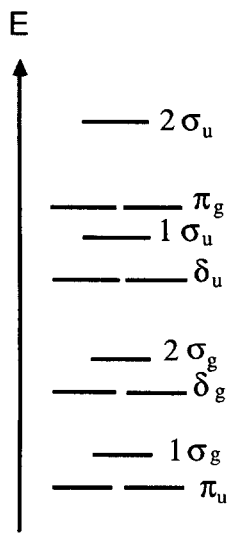

Fig. 2. Orbital-level diagram for M_2, with orbitals classified according to $D_{\infty v}$-symmetry.

The bond energies presented in Table 1 were based on spin-unrestricted calculations using $C_{\infty v}$- rather than $D_{\infty v}$-symmetry constraints, in order to allow for the polarization of electrons with different spins towards opposite metal centers. Thus, whereas the ground-state configuration for M_2 (M = Cr, Mo or W) in a single-determint description under $D_{\infty v}$-symmetry constraints is $1\sigma_g^2 2\sigma_g^2 \pi_u^4 \delta_g^4$ (see Fig. 2), a reduction in symmetry to $C_{\infty v}$ allows for the partial occupation of the anti-bonding orbitals $1\sigma_u$, $2\sigma_u$, π_g and δ_u, where equal occupation of bonding and anti-bonding orbitals (Fig. 2) corresponds to complete polarization of *d*-valence elec-

*The generalized transition state procedure is not only applicable to the HFS method but can be extended to any energy density functional such as E_{BS}, as we have done in the present work.

trons with different spins to the opposite metal centers.

The bond energies in Table 1 were calculated by evaluating the energy difference:

$$\Delta E = 2^*E(^7S) - E(M_2) \qquad (2)$$

between two metal atoms in a ^7S state corresponding to the $nd^5(n+1)s^1$ configuration and M_2. ΔE represents for Cr_2 and Mo_2 the bond energies D(Cr–Cr) and D(Mo–Mo), respectively, since Cr and Mo both have a spherical ^7S ground state. The W atom, however, has a ^{5}D ground state with the configuration $5d^46s^2$, and we have thus for W_2 subtracted the experimental energy difference (0.37 eV)[20] between the ^5D and ^7S states of W twice from ΔE in order to arrive at D(W–W) in Table 1.

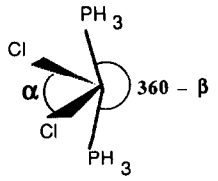
The calculated bond energies and R_{MM} for Cr_2 and Mo_2 are in good accord with experimental values, as can be seen from Table 1. We have, in contrast to other calculations based on density functional theory,[19] in the present work employed $(n+1)f$ polarization functions. There contributions on the bond energies are modest, 0.2–0.4 eV, and our results conform, among the other density functional calculations in particular, well to those of Baykara *et al.*,[19] although a slightly different energy functional was used in their work.

We predict that W_2 after the inclusion of relativistic effects (Table 1) should have a stronger metal–metal bond than Mo_2 with an R_{MM} of 2.03 Å. The bonding interaction is, even in the non-relativistic case, stronger in W_2 than in Mo_2 if the two metal atoms are referred to the same ^7S reference state.

The single-determint wave functions for Mo_2 and W_2 converged at the equilibrium distance under $C_{\infty v}$ constraints to nearly $D_{\infty v}$ symmetry with a $1\sigma_g^2 2\sigma_g^2 \pi_u^4 \delta_g^4$ configuration. The two molecules have thus, with a formal bond order of six, a hexuple metal–metal bond. For Cr_2, where bonding d–d overlaps are weaker than in Mo_2 or W_2, the converged single determinantal wave function had, at the equilibrium distance, a broken $C_{\infty v}$-symmetry with the configuration $1\sigma_g^2 2\sigma_g^2 \pi_u^4 \delta_g^{3\cdot 4} \delta_u^{\cdot 6}$, indicating substantial spin polarization in the δ-framework, and a formal bond order of less than six. We refer to Baykara *et al.*[19] for an authoratative analyses of the bonding in Cr_2 and Mo_2 at different R_{MM}.

CALCULATIONS OF D(M–M) FOR $M_2(OH)_6$ (M = Cr, Mo OR W) AND $M_2Cl_4(PH_3)_4$ (M = V, Cr, Mn, Nb, Mo, Tc, Ta, W OR Re)

The $M_2(OH)_6$ (M = Mo or W) systems were taken as models for the known alkoxy complexes $M_2(OR)_6$ (M = Mo or W), and together with $Cr_2(OH)_6$, for which the alkoxy analogues are unknown, given a staggered conformation (**1a**). All geometrical parameters, except for R_{MM} were taken from Ref. 8(a), where we previously have discussed the relative stabilities of $M_2(OH)_6$ in the staggered (**1a**) and eclipsed (**1b**) conformations. The many-electron wave function for $M_2(OH)_6$ of $D_{(3d)}$ symmetry was represented by a single Slater determinant corresponding to the $\pi^4\sigma^2$ electronic configuration.



4

The observed structures of $M_2Cl_4(PR_3)_4$ for M = Mo, W or Re are those of two deformed $MCl_2(PR_3)_2$ fragments (**4**) combined into a staggered conformation (2) with the Cl—M—Cl angle (α) close to 130° and the P—M—P angle (β) close to 165°. The structures of the model systems $M_2Cl_4(PH_3)_4$ were taken from Ref. 8(b), except for R_{MM}, which we have reoptimized for each system. The many-electron wave function for the d^3–d^3 complexes $M_2Cl_4(PH_3)_4$ (M = V, Nb or Ta) and the d^5–d^5 complexes $M_2Cl_4(PH_3)_4$ (M = Mn, Tc or Re) were represented by a single Slater determinant under $D_{(2d)}$ symmetry constraints corresponding to the $\sigma^2\pi^4$ and $\sigma^2\pi^4\delta^2\delta^{*2}$ electronic configurations, respectively. The d^4–d^4 systems $M_2Cl_4(PH_3)_4$ (M = Cr, Mo or W) were represented by a two-determint wave function as:

$$\Psi = C_1|\overset{+}{\sigma}\overset{-}{\sigma}\overset{+}{\pi_1}\overset{-}{\pi_1}\overset{+}{\pi_2}\overset{-}{\pi_2}\overset{+}{\delta}\overset{-}{\delta}| + C_2|\overset{+}{\sigma}\overset{-}{\sigma}\overset{+}{\pi_1}\overset{-}{\pi_1}\overset{+}{\pi_2}\overset{-}{\pi_2}\overset{+}{\delta^*}\overset{-}{\delta^*}| \qquad (3)$$

according to the method by Noodleman *et al.*,[21] in order to allow for spin polarization in the δ framework.

The D(M–M) given in Tables 2–5 were calculated as the energy difference between M_2L_{2n} and two ML_n fragments in a high-spin ground-state configuration.

We have in previous studies decomposed D(M–M) according to:

$$D(M\text{–}M) = -\Delta E^o - \Delta E_\sigma - \Delta E_\pi - \Delta E_\delta - \Delta E_T - \Delta E_R. \qquad (4)$$

Table 2. Optimized metal–metal bond distances, and decomposition of calculated bonding energies, for $M_2(OH)_6$ (M = Cr, Mo or W)

	R_{MM}		E (kJ mol^{-1})			
$M_2(OH)_6$	(Å)	D(M–M)	ΔE^o	ΔE_σ	ΔE_π	ΔE_R
$Cr_2(OH)_6$	1.91	31.8	644.4	−335.6	−340.6	—
$Mo_2(OH)_6$	2.22	258.2	545.6	−347.1	−456.7	—
$W_2(OH)_6$	2.30	360.1	473.4	−348.5	−419.7	−65.3[a]

[a]Contributions to bonding energy from relativistic effects are given by $-\Delta E_R$. The bonding energy is given as $D(M–M) = -\Delta E^o - \Delta E_\sigma - \Delta E_\pi - \Delta E_R$.

Table 3. Optimized metal–metal bond distances, and decomposition of calculated bonding energies, for $M_2Cl_4(PH_3)_4$ (M = Cr, Mo or W)

	R_{MM}		E (kJ mol^{-1})				
$M_2Cl_4(PH_3)_4$	(Å)	D(M–M)[a]	ΔE^o	ΔE_σ	ΔE_π	ΔE_δ	ΔE_R
$Cr_2Cl_4(PH_3)_4$	1.89	102	655	−274	−473	−10	—
$Mo_2Cl_4(PH_3)_4$	2.16	371	643	−345	−620	−49	—
$W_2Cl_4(PH_3)_4$	2.29	460	419	−316	−525	−24	−14

[a]The bonding energy is given as $D(M–M) = -\Delta E^o - \Delta E_\sigma - \Delta E_\pi - \Delta E_\delta - \Delta E_R$, where $-\Delta E_R$ is the contribution from relativistic effects to bonding energy.

Table 4. Optimized metal–metal bond distances, and decomposition of calculated bonding energies, for $M_2Cl_4(PH_3)_4$ (M = Mn, Tc or Re)

	R_{MM}		E (kJ mol^{-1})				
$M_2Cl_4(PH_3)_4$	(Å)	D(M–M)[a]	ΔE^o	ΔE_σ	ΔE_π	ΔE_δ	ΔE_R
$Mn_2Cl_4(PH_3)_4$	1.92	99	650	−291	−451	−7	—
$Tc_2Cl_4(PH_3)_4$	2.17	337	614	−355	−591	−5	—
$Re_2Cl_4(PH_3)_4$	2.29	441	427	−328	−520	−9	−11

[a]The bonding energy is given as $D(M–M) = \Delta E^o - \Delta E_\sigma - \Delta E_\pi - \Delta E_\delta - \Delta E_R$, where $-\Delta E_R$ is the contribution from relativistic effects to bonding energy.

Table 5. Optimized metal–metal bond distances, and decomposition of calculated bonding energies, for $M_2Cl_4(PH_3)_4$ (M = V, Nb or Ta)

	R_{MM}		E (kJ mol^{-1})				
$M_2Cl_4(PH_3)_4$	(Å)	D(M–M)	ΔE^o	ΔE_σ	ΔE_π	ΔE_T	ΔE_R
$V_2Cl_4(PH_3)_4$	2.04	67	521	−253	−481	146	—
$Nb_2Cl_4(PH_3)_4$	2.30	259	562	−328	−651	159	—
$Ta_2Cl_4(PH_3)_4$	2.51	297	404	−304	−562	173	−8

[a]The bonding energy is given as $D(M–M) = -\Delta E^o - \Delta E_\sigma - \Delta E_\pi - \Delta E_T - \Delta E_R$, where $-\Delta E_R$ is the contribution from relativistic effects to D(M–M) and ΔE_T twice the energy required to promote $MCl_2(PH_3)_2$ from the $b_2^1a_2^1a_1^1$ ground-state configuration to $b_2^1a_1^1b_1^1$ (see text).

Here ΔE^o is the (steric) interaction energy between two high-spin ML_n fragments of opposite spin polarization at the positions they will take up in the combined M_2L_{2n} complex. The term ΔE^o is positive and destabilizing. The terms ΔE_σ, ΔE_π and ΔE represent the stabilization of the metal–metal bond from the pairing up of electrons with opposite spin polarization on the two fragments in orbitals

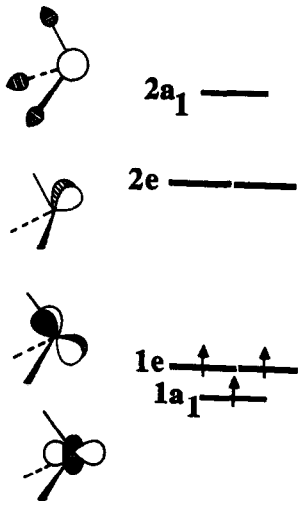


Fig. 3. Orbital-level diagram for $M(OH)_3$ of C_{3v} -symmetry.

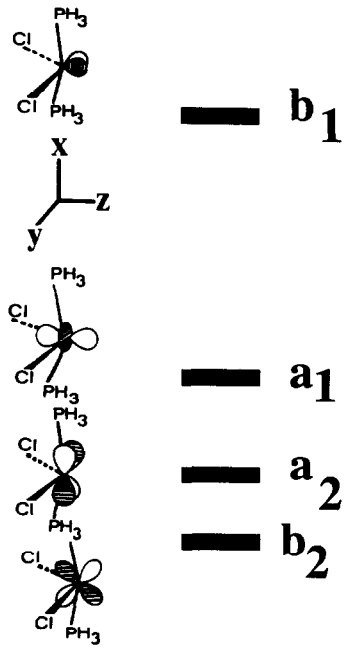

Fig. 4. Orbital-level diagram for $MCl_2(PH_3)_2$ of C_{2v}-symmetry.

with local δ, π and δ axial symmetries, as the electron density is allowed to relax to that of the first M_2L_{2n} complex. Thus, $-\Delta E_\sigma$, $-\Delta E_\pi$ and $-\Delta E_\delta$ represent the respective σ, π and δ components of D(M–M). Two $M(OH)_3$ (M = Cr, Mo or V) fragments with the $1a_1^1 1e_x^1 1e_y^1$ ground-state configurations (see Fig. 3) correlate directly with $^2\pi^4$ configuration of the $M_2(OH)_6$ complexes, and the two $MCl_2(PH_3)_2$ fragments of groups 6 and 7 metals with $1a_1^1 1a_2^1 1b_2^1 1b_1^1$ and $1a_1^1 1a_2^2 1b_2^1 1b_1^1$ configurations, respectively (see Fig. 4) correlates also directly with the respective $\sigma^2\pi^4\delta^2$ and $\delta^2\pi^4\delta^2\delta^{*2}$ ground-state configurations of the combined $M_2Cl_4(PH_3)_4$ complexes. However, two $MCl_2(PH_3)_2$ fragments of group 5 metals with the $1a_1^1 1a_2^1 1b_2^1$ configuration correlates with the excited $\sigma^2\pi^2\delta^2$ configuration of $M_2Cl_4(PH_3)_4$ rather than the ground-state configuration $\sigma^2\pi^4$. We must thus before combining them promote the two $MCl_2(PH_3)_2$ fragments to the $1a_1^1 1b_2^1 1b_1^1$ configuration correlating with the $\sigma^2\pi^4$ configuration. The energy required for this promotion is ΔE_T of eqn (4). The term $-\Delta E_E$, evaluated only[8] for complexes of 5*d* elements, constitutes the contribution to D(M–M) from relativistic effects. The decomposition of D(M–M) in eqn (4), if somewhat arbitrary, should hopefully help to pinpoint the factors responsible for the difference in the strength of the metal–metal bond of the various systems under investigation.

Our calculations here indicate that the metal–metal bond in binuclear complexes between elements of the first transition series is relatively weak (40–100 kJ mol^{-1}) in comparison to metal–metal bonds between the heavier congeners in the second and third transition series (Tables 2–5). This is understandable since 3*d* orbitals are more contracted than their 4*d* and 5*d* counterparts, with smaller *d*–*d* bonding overlaps, and consequently small bonding contributions from $-\Delta E_\sigma$, ΔE_π and $-\Delta E_\delta$ to D(M–M) (see Tables 2–5). The repulsive steric interaction ΔE^o is further relatively large for complexes of 3*d* elements, since the short metal–metal bond distance allows for substantial four-electron destabilizing interactions between the occupied core-like 3*d*, 3*p* orbitals of the two metal centers of almost the same radial extent as 3*d*. Known neutral binuclear complexes of 3*d* elements, such as $Cr_2(O_2CR)_4$, have bidentate ligands with coordination to both metal centers, and we intend to investigate to what extent this arrangement might stabilize the metal–metal bond. The order of stability D(V–V) < D(Cr–Cr) ~ D(Mn–Mn) between $M_2Cl_4(PH_3)_4$ complexes of 3*d* elements is deceiving in the sense that the interaction between two $VCl_2(PH_3)_2$ fragments with the valence configuration $1a_1^1 1b_1^1 1b_2^1$ in $M_2Cl_4(PH_3)_4$ is stronger than the corresponding interactions between two $CrCl_2(PH_3)_2$ or $MnCl_2(PH_3)_2$ complexes in their respective ground-state configurations. Thus, in our analysis it is the required promotion energy ΔE_T which gives rise to the small value for D(V–V).

We find for a pair of homologous binuclear complexes with 4*d* and 5*d* elements from the same triad, such as $Mo_2(OH)_6$ and $W_2(OH)_6$, that the complex of the 5*d* elements invariably has the stronger metal–metal bond (Tables 2–5). In going from a 4*d* complex to the 5*d* homologue one observes (Tables 2–5) a reduction in the σ, π and

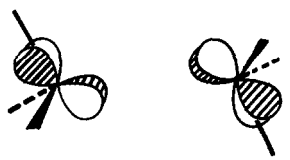
δ bonding contributions, in particular from $-\Delta E_\pi$, as well as a reduction in ΔE^o due to the four-electron destabilizing interactions between *ns*, *np* core-like orbitals on the two metal centers. Of the two reductions, both of which can be explained as due to the longer metal–metal bond distance for 5*d* elements in comparison with their lighter 4*d* congeners, the reduction in ΔE^o prevails over the reduction in the σ, π and δ bonding contributions, resulting in a stronger metal–metal bond for the 5*d* complex than its 4*d* homologue. We note again that the stability orders D(Nb–Nb) $\ll$ D(Tc–Tc) $<$ D(Mo–Mo) and D(Ta–Ta) $\ll$ D(Re–Re) $<$ D(W–W) in $M_2Cl_4(PH_3)_4$ are deceiving in that the smaller values for D(Nb–Nb) and D(Ta–Ta) are due to the promotion energies ΔE_T.

It follows from the deliberation given here that the trend in D(M–M) down a triad is set by a competition between attractive ($-\Delta E_\sigma$, $-\Delta E_\pi$ and $-\Delta E_\delta$) and repulsive (ΔE^o) interactions. The attractive interactions can be increased by shortening the metal–metal bond, but *not* without increasing the repulsive interaction ΔE^o as well. For good metal–metal bonding elements we need the *nd* orbitals to be relatively diffuse and the corresponding *ns*, *np* core-like orbitals in comparison as contracted as possible. This criterion is best met by the 5*d* elements. The elements of the first transition series have on the other hand relatively contracted 3*d* orbitals as well as 3*s*, 3*p* core orbitals of nearly the same radial extent as 3*d*. The 3*d* elements are for this reason poor metal–metal bonders. This situation might well change in such cases as Cu_2, Ag_2 and Au_2, where the metal–metal bond distance is long and due primary to the $(n+1)s$–$(n+1)s$ bonding overlaps.

There are two important differences between $M_2(OH)_6$ complexes and the $M_2Cl_4(PH_3)_4$ systems. The first is a greater contribution from relativistic effects ($-\Delta E_R$) to D(M–M) in $W_2(OH)_6$ compared to $M_2Cl_4(PH_3)_4$ (M = Ta, W or Re) as a consequence of a larger participation from $(n+1)s$ in the σ-orbital of $W_2(OH)_6$ compared to the σ-orbital of the $M_2Cl_4(PH_3)_4$ (M = Ta, W or Re) systems.[8] The second difference is a stronger π-bond in $M_2Cl_4(PH_3)_4$ compared to $M_2(OH)_6$ for metals of the same transition-metal series. In $M_2Cl_4(PH_3)_4$ the π-bond is between the two well-directed fragment orbitals $1b_1$ and $1b_2$ (Fig 4 and **6**) where in particular the lobes of the anti-bonding $1b_1$ orbital on one fragment is polarized towards $1b_2$ of the other fragment (**6**). The π-bonding overlaps in $M_2Cl_4(PH_3)_4$ were, for M = Cr, Mo or W, calculated as 0.19, 0.30 and 0.27, respectively.

In $M_2(OH)_6$, with two trigonal $M(OH)_3$ fragments at $\beta = 80°$ (**1a**) one finds on the other hand

the interaction in the π-orbital **7** to be less than optimal[8(a)] due to the tilt of the two 1*e* fragment orbitals involved. The overlaps between the 1*e* orbitals (**7**) are as a consequence relatively small, 0.08, 0.13 and 0.11 for M = Cr, Mo and W, respectively. The weaker π-interaction in $M_2(OH)_6$ is the major factor responsible for the modest strength of the metal–metal bond in $M_2OH)_6$ compared to $M_2Cl_4(Cl)_4$ of the same transition metals.



$$S = 2/3\ S_\pi - 1/3\ S_\delta$$

The present set of calculations, based on the energy expression in eqn (1), provides σ, π and δ bonding interactions as well as R_{MM} comparable to those found in previous HFS studies[8] on the same systems. We note that the σ-bond is somewhat stronger than each of the π-bonds, and for the quadruple bonded complexes one order of magnitude stronger than the δ-bond. The steric interaction energy calculated here is, on the other hand, larger than the ΔE^o values evaluated in previous HFS studies,[8] and the D(M–M) based on eqn (1) as a consequence smaller than the D(M–M) values due to the HFS method. It is a general feature of the present method, as demonstrated in recent studies on both diatomics[11(c)] and polyatomic molecules[13(c)] of main-group elements, that the bond energies based on eqn (1) are smaller and more in line with experiment than the bonding energies obtained by the HFS method. The bond energy calculated here for $Cr_2(OH)_6$ is further in reasonable agreement with the value for D(Cr–Cr) obtained in a recent *ab initio* calculation[7(b)] on the related Cr_2H_6 complex.

Acknowledgements—We would like to thank Professor E. J. Baerends and the theoretical chemistry group at the Free University in Amsterdam for providing us with a copy of their HFS program. This investigation was supported by the Natural Sciences and Engineering earch Council of Canada (NSERC).

(*Received* 19 *November* 1986)

Since the discovery of the metal–metal (M–M) quadruple bond in $Re_2Cl_8^{2-}$, the chemical literature has exploded with experimental and theoretical investigations into the nature of M–M multiple bonding.[1] As chemists, we like to think of multiple bonds most simply as derived from the overlap of atomic orbitals of σ-, π- and δ-symmetry, giving rise to multiple bonds corresponding to valence configurations such as $\sigma^2\pi^4$, $\sigma^2\pi^4\delta^2$, $\sigma^2\pi^4\delta^2\delta^{*2}$ or even $\pi^4\delta^2$. A major problem is that such descriptions, although attractive and simple, are oversimplifications when applied to the interpretation of spectroscopic data. Indeed, the quantitative description of M–M multiple bonding has provided an exceptional challenge to theoretical electronic structure methods. More recently, the problems associated with the calculation of the properties of transition-metal dimers containing heavy elements, most notably the necessity of including relativistic effects, have received greater attention. In this regard, density functional methods such as the various Xα molecular-orbital (MO) formalisms[2] hold an important position in inorganic chemistry since they provide a significantly less expensive alternative to *ab initio* methods for complex systems, they preserve an orbital description with which nontheoretical chemists are most comfortable, and they allow for the easy incorporation of relativistic effects. The Xα-SW method, in particular, has had an important role in the development of quantitative descriptions of multiple M–M bond electronic structure, a role in which it continues today, albeit subject to greater criticism than in the past. In the spirit of this Symposium-in-Print, we wish to critically assess some of the successes and failures of the Xα-SW MO method as applied to systems involving multiple bonds between transition-metal atoms. In doing so, we will draw primarily, but not exclusively, on the recent results we and others have obtained for $M_2(O_2CH)_4$ systems.

THE $\delta \rightarrow \delta^*$ TRANSITION ENERGY

For molecules with M–M quadruple bonds with an approximate valence MO configuration $\sigma^2\pi^4\delta^2$, and triple bonds of approximate valence MO configuration $\pi^4\delta^2$, the lowest-energy electronic transition is expected to be from the occupied δ-bonding orbital to the unoccupied δ-antibonding orbital: the so-called $\delta \rightarrow \delta^*$ transition. This transition is perhaps the most studied electronic phenomenon in such multiply bonded systems and a detailed review of the spectroscopy is provided by Hopkins and Gray in this symposium. The theoretical interest in the $\delta \rightarrow \delta^*$ transition energy has grown in tandem with experimental interest, particularly since the factors which influence the transition energy are not well understood from first principles. There have been major difficulties in the calculation of $\delta \rightarrow \delta^*$ transition energies using MO theory, but this is not surprising in view of the weakness of the interaction between the two orbitals of δ-symmetry. The M–M δ-orbital overlap is

*Camille and Henry Dreyfus Teacher-Scholar (1984–1989), and Fellow of the Alfred P. Sloan Foundation (1985–1987). Author to whom correspondence should be addressed.

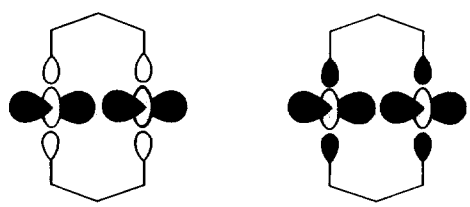
†Indiana University General Electric Fellow (1985–1986).

small enough that the two paired electrons may substantially localize, one on each metal, rather than delocalizing between the two centers as assumed in MO theory. The resulting situation is thus parallel to the breakdown in MO theory for dihydrogen at the dissociation limit, wherein the presence of low-lying electronic states of the same symmetry as the ground state renders the single configuration description of bonding inadequate. In fact, interaction of the δ-electrons is so weak that it is subject to this same problem even at the equilibrium internuclear distance! Hay has performed a detailed GVB-CI study of the state energetics of $Re_2Cl_8^{2-}$ and convincingly demonstrated that a single-configuration MO wave function is quite inadequate for describing the relative energetics of the states resulting from the δ- and δ^*-orbitals due to the severity of the correlation problem.[3] In fact, the GVB-CI treatment predicts nearly complete localization of the δ-electrons. The inadequacy of the single-configuration descriptions of the ground ("δ^2") and excited ("$\delta^1\delta^{*1}$") states has a profound effect on the calculation of the $\delta \rightarrow \delta^*$ transition energy using *any* MO method. A very simple, two Slater determinant CI description of the ground state, and singlet and triplet excited states of a typical quadruple bond leads to the conclusion that the transition is nearly completely dominated by two-electron repulsions rather than orbital energy (one-electron) terms.[4] Thus, the Xα-SW method, through Slater's transition-state formalism, usually underestimates the $\delta \rightarrow \delta^*$ transition by approximately a factor of two, but adequately calculates transitions between the other, more strongly bonding orbitals in the M–M bonding manifold (see Table 1). It is recognized[5] that the Xα exchange potential does introduce some correlation between electrons of opposite spin, and this observation prompted Noodleman and Norman to cast the Xα-SW method in a valence-bond formalism.[6] Their application of this Xα valence-bond method to the $\delta \rightarrow \delta^*$ transition in $Mo_2Cl_8^{4-}$ has resulted in a tremendous improvement in the $\delta \rightarrow \delta^*$ transition energy from 9.2×10^3 cm^{-1} (Xα-SW)[7] to $15.2 \times 10^3\,cm^{-1}$ (experimental value $18.8 \times 10^3\,cm^{-1}$).

The $\delta \rightarrow \delta^*$ transitions in systems with a bond order of 3.5, corresponding to $\sigma^2\pi^4\delta^1$ or $\sigma^2\pi^4\delta^2\delta^{*1}$ configurations are typically in the near IR region of the spectrum (*ca* $6000\,cm^{-1}$), much lower in energy than the corresponding transition in quadruply bonded complexes. MO methods have been very successful in the calculation of these transition energies,[8] despite the fact that they result from weak δ- and δ^*-interactions (Table 1). The reason for this is very clear; the removal or addition of one electron from or to the quadruply bonded configuration $\delta^2\delta^{*0}$ eliminates the low-lying excited state with the same symmetry as the ground state, and hence mitigates the extent of configuration interaction which will occur.

M–M σ-BONDING

Xα-SW calculations on $M_2(O_2CH)_4$ molecules reveal some interesting differences in M–M σ-bonding between Cr, Mo and W. The Xα-SW calculations in general yield two components to the M–M σ-bond, the $4a_{1g}$ and the $5a_{1g}$ molecular orbitals. One can envision these orbitals as the result of the interaction of a nearly pure d_{z^2} σ_g orbital of an M_2^{4+} fragment with the symmetric combination of four formate lone-pair orbitals. This interaction gives rise to the 4*a*1*g* and 5*a*1*g* orbitals which are M–O bonding and antibonding (respectively) between the torus (or "doughnut") of the σ_g-orbital and formate lone-pair orbitals, as depicted qualitatively in **I**.



I

As expected from simple perturbation theory, the amount of mixing between the M_2^{4+} σ_g and formate orbitals will depend on the relative energetics and magnitude of overlap between the σ_g and the formate levels. Weak 3*d*–3*d* bonding in Cr_2 systems results in a sizable energetic separation between the Cr–Cr σ and formate orbitals and very little metal–ligand (M–L) mixing is observed as depicted qualitatively in Fig. 1. Conversely, stronger 4*d*–4*d* and 5*d*–5*d* bonding between Mo_2 and W_2 centers (respectively) lowers the M–M σ-orbital in energy, allowing for a better energetic match, and hence greater M–L mixing occurs between metal and formate levels in Mo–Mo and W–W systems (Fig. 1). The extent of M–L mixing can be gauged by the percentage of metal contribution to the $5a_{1g}$ and $4a_{1g}$ orbitals of $M_2(O_2CH)_4$ which are 98 and 20% for M = Cr,[9] 48 and 75% for M = Mo,[7] 59 and 54% for M = W (nonrelativistic),[10] and 69 and 51% for M = W (relativistic).[10] In the case of $Cr_2(O_2CH)_4$, the $5a_{1g}$ orbital is best described as the Cr–Cr σ-bond (98% Cr), and the $4a_{1g}$ is best described as the Cr–O bonding level. However, in $Mo_2(O_2CH)_4$ and $W_2(O_2CH)_4$, stronger M–L mixing results in two orbitals with substantial M–

Table 1. A comparison of experimental and Xα-SW $\delta \rightarrow \delta^*$ transition energies in M–M multiply bonded compounds

Compound	ν_{max} ($\delta \rightarrow \delta^*$) ($\times 10^3\,cm^{-1}$)	Xα-SW ($\times 10^3\,cm^{-1}$)	Valence configuration
$Mo_2Cl_8^{4-}$	18.8	9.2	$\sigma^2\pi^4\delta^2$
$Re_2Cl_8^{2-}$	14.2	7.0	$\sigma^2\pi^4\delta^2$
$Mo_2(O_2CH)_4$	22.9	14.7	$\sigma^2\pi^4\delta^2$
$W_2(O_2CH)_4$	23.0	12.3	$\sigma^2\pi^4\delta^2$
$Tc_2Cl_8^{3-}$	5.9	6.0	$\sigma^2\pi^4\delta^2\delta^{*1}$
$[Re_2Cl_4(PH_3)_4]^+$	6.6	5.6	$\sigma^2\pi^4\delta^2\delta^{*1}$

M σ character, and it becomes difficult to label either the $4a_{1g}$ or $5a_{1g}$ orbital as the "principal" M–M σ-bond. There are clearly two MOs with substantial M–M σ character, and together they are equivalent to one strong metal–metal σ-bond. The simple description of the quadruple bond as $\sigma^2\pi^4\delta^2$ is thus rendered inadequate due to metal–ligand mixing in the orbitals of a_{1g}-symmetry for the 4*d* and 5*d* metals.

Another feature evident in the a_{1g} M–M σ-bonding orbitals is the involvement of virtual $(n + 1)s$ atomic orbitals which contribute further to the stabilization of M–M and M–L bonding. There is essentially no Cr as 4*s* atomic orbital participation to the 3*d*–3*d* σ-bond of $Cr_2(O_2CH)_4$,[9] whereas we find a significant contribution of W 6*s* atomic orbital participation to the 5*d*–5*d* σ-bond of $W_2(O_2CH)_4$.[10] The increased $(n + 1)s$ contribution to M–M σ-bonding is a combined result of decreased *nd* and $(n + 1)s$ atomic orbital energy differences, and the increased importance of relativistic effects for third-row relative to first-row transition metals. These latter effects will be examined more closely in the next section.

CONSEQUENCES OF RELATIVISTIC CORRECTIONS TO M–M σ-BONDING

One of the great advantages of the Xα-SW method is the ease with which relativistic corrections can be incorporated for heavy elements such as the third-row transition metals or the actinides. We have previously reported the major effects of including the "quasi-relativistic" corrections of Wood and Boring[11] on organouranium complexes,[12] and we are finding nearly as profound an influence of these on the valence electronic structure of metal–metal multiple bonds. Shown in Fig. 2 is a comparison of our relativistic and nonrelativistic calculations on the $W_2(O_2CH)_4$ molecule.[10] The two components of the W–W σ-bond are labeled along with the percent metal character of the predominantly M-based MOs. The relativistic corrections cause large energy shifts in the W core levels and similar shifts in valence orbitals containing significant W character, while, as expected, the primarily O-, C- and H-based MOs are scarcely affected. The changes induced in the bonding picture upon inclusion of relativistic effects are consistent with the expected influence of mass–velocity corrections on the W atomic orbitals.[13] The inner *s*-orbitals, having the highest classical velocities, are the most profoundly affected orbitals. The relativistic mass increase results in a contraction of all the *s*-orbitals with a concomitant decrease in their orbital energies. This effect is mimicked by the *p*-orbitals although the contraction and stabilization is much less pronounced than for the *s*-orbitals. The metal *d*- and *f*-electrons, which have a much smaller probability of attaining a classical velocity close to *c*, are primarily influenced by the contraction of the *s*- and *p*-orbitals. The contraction of these latter orbitals results in an expansion and

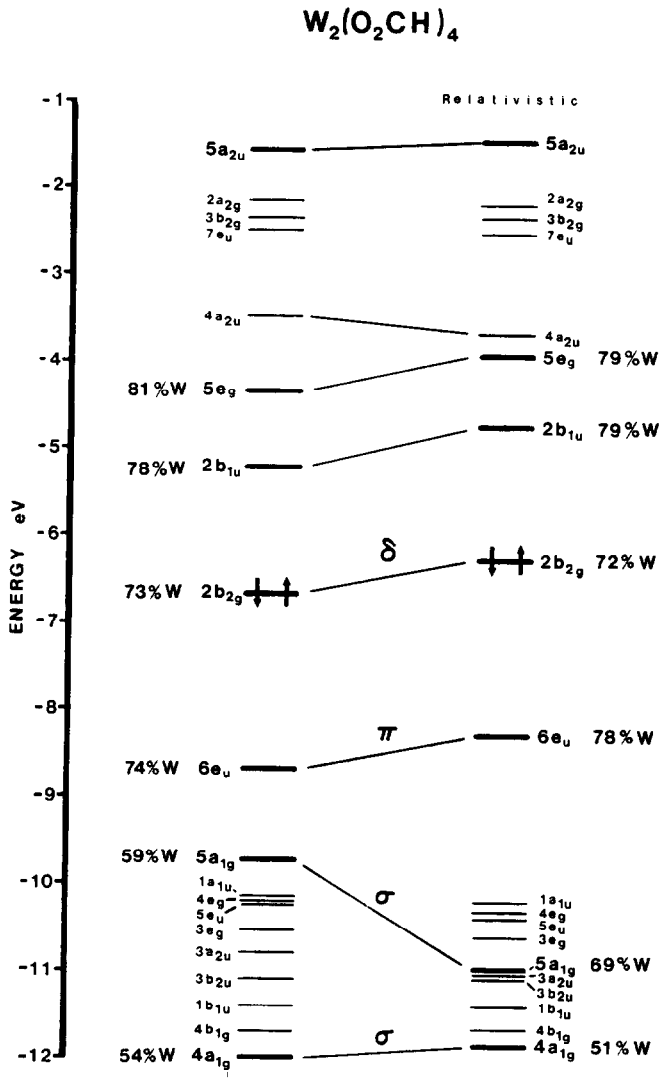

Fig. 2. Nonrelativistic and relativistic converged Xα-SW eigenvalues for $W_2(O_2CH)_4$. Primarily W-based levels are in bold face along with their percentage of W contribution. The HOMO is marked with arrows. Adapted from Ref. 10.

rise in energy of the *d*- and *f*-orbitals.

In Fig. 2 it is seen that the relativistic shifts in the orbital energies are in the expected directions. The valence levels containing significant W 5*d* character rise in energy with the exception of the $5a_{1g}$ σ-orbital; without relativistic corrections, this orbital has 17% W 6*s* and 38% W 5*d* character, and the substantial 6*s* character causes this orbital to drop in energy upon the inclusion of relativistic effects. Upon stabilization, the $5a_{1g}$ σ-orbital acquires significantly more W 6*s* character (26%) and somewhat less W 5*d* character (36%). The W 6*s* orbital contribution to this orbital represents a mixing of the 6*s*–6*s* σ-bonding orbital, normally unoccupied, with the 5*d*–5*d* σ-bonding orbital. Thus the relativistic corrections have their most profound effect on orbitals of σ-symmetry.

The importance of increased *s*-orbital participation to the M–M σ-bond needs some amplification. The *s*–*s* σ-bonding orbital was shown to be important in explaining the extremely short bond distances found for naked-metal diatomics such as Mo_2 which has a singlet ground state with a closed-shell $1\sigma_g^2 1\pi_u^4 1\delta_g^4 2\sigma_g^2$ configuration.[14,15] The $2\sigma_g$ orbital of Mo_2 represents the 5*s*–5*s* σ-bond, while the $1\sigma_g$ represents the 4*d*–4*d* σ-bond. Contour plots of the $1\sigma_g$ and $2\sigma_g$ orbitals[14] of Mo_2 are shown in comparison with the $4a_{1g}$ and $5a_{1g}$ orbitals[10] of $W_2(O_2CH)_4$ in Fig. 3. The $2\sigma_g$ orbital, representing the 5*s*–5*s* σ interaction in Mo_2 shows a striking similarity to the $5a_{1g}$ σ-orbital of $W_2(O_2CH)_4$, further emphasizing the importance of the 6*s*–6*s* contribution to the $5a_{1g}$ orbital in $W_2(O_2CH)_4$. We will show later that *s*-orbital participation is also

an important consideration in the electronic effects of axial ligation.

What effect does this valence *s* and *dσ* hybridization have on metal–metal σ-bond strength? We feel that the answer to this question is parallel to that given by Mulliken years ago when considering the effect of *s* and *pσ* hybridization in homonuclear diatomics such as N_2.[16] In the N_2 molecule (ground-state configuration $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 2\sigma_u^2 1\pi_u^4 3\sigma_g^2$) there is major *s* and *pσ* hybridization in the $2\sigma_g$, $2\sigma_u$ and $3\sigma_g$ MOs. Positive *s*-*pσ* hybridization in $2\sigma_g$ makes the MO strongly bonding, while negative *s*–*pσ* hybridization in $3\sigma_g$ makes it only weakly bonding. This "forced hybridization" is a simple consequence of the requirement of orthogonality among LCAO MOs of the same symmetry. The result of the *s*–*pσ* hybridization is a decrease in the overlap population and a resultant loss of bond strength in the $3\sigma_g$ orbital. This, of course, does not mean that N_2 has a weak σ-bond, for now these three σ MOs of N_2 are equivalent to one strong σ-bond. This situation is not at all unlike that observed for $M_2(O_2CH)_4$ compounds of second- and third-row transition metals.

THE EFFECTS OF AXIAL LIGATION ON THE M–M σ-BOND

Xα-SW calculations on a variety of $M_2(O_2CH)_4$ and $M_2(O_2CH)_4L_2$ compounds have helped to reveal both quantitative and qualitative details of the electronic effects of axial ligation.[10,17–20] We will first consider the qualitative picture of axial ligation and then discuss the effects for first vs third-row metals.

All of the calculations indicate that the interaction of the $M_2(O_2CH)_4$ moiety with an axial ligand is essentially a σ-only interaction. It is found that the M–M π, δ, δ^*, π^* and formate orbitals all have nearly identical energies in $M_2(O_2CH)_4$ and $M_2(O_2CH)_4L_2$ calculations. Even for axial ligands containing π lone-pairs, the π lone-pair orbitals are found to be essentially noninteracting with the $M_2(O_2CH)_4$ moiety. The symmetric combination of the two ligand σ lone-pair orbitals interacts with the M–M σ-bonding orbitals ($4a_{1g}$ and $5a_{1g}$); while the antisymmetric combination interacts with the M–M σ^*-orbitals, which are of a_{2u}-symmetry. The consequences of these interactions depends in part on the strength of the original M–M σ-bond and the energetic placement of the L_2 orbitals.

The important first-order M–M bond weakening upon axial ligand coordination results from axial ligand lone-pair donation into the M–M σ^*-orbital. The magnitude of the donation is reflected by the amount of M–M σ^* character found in occupied MOs and will be related to the strength of the original M–M σ-bond. In the case of $Cr_2(O_2CH)_4$ compounds,[9,17] weak $3d$–$3d$ σ-bonding results in a low-lying Cr–Cr σ^*-orbital, whereas the much stronger $5d$–$5d$ σ-bonding in $W_2(O_2CH)_4$ results in a relatively high lying W–W σ^*-orbital.[10] This criterion would suggest that for the same axial ligand (e.g. THF), the L_2 interaction should be able to introduce qualitatively more M–M σ^* character into the occupied orbitals of the Cr_2L_2 than the W_2L_2 system.

The second important interaction is between the occupied M–M σ-bonding orbital and the symmetric combination of the axial L_2 orbitals. The Xα-SW calculations[17] on $Cr_2(O_2CH)_4(H_2O)_2$ present the result that weak Cr–Cr σ-bonding places the symmetric L_2 combination lower in energy than the Cr–Cr σ-orbital. This interaction destabilizes the Cr–Cr σ-orbital by Cr–L σ-antibonding while the L-localized level is stabilized by Cr–L σ-bonding. In contrast, the much stronger W–W σ-bonding is expected to find the W–W σ-orbitals lower in energy than the symmetric L_2 combination, and interaction will stabilize the W–W σ-bond. This comparison is shown qualitatively in the interaction diagram of Fig. 4, and accounts

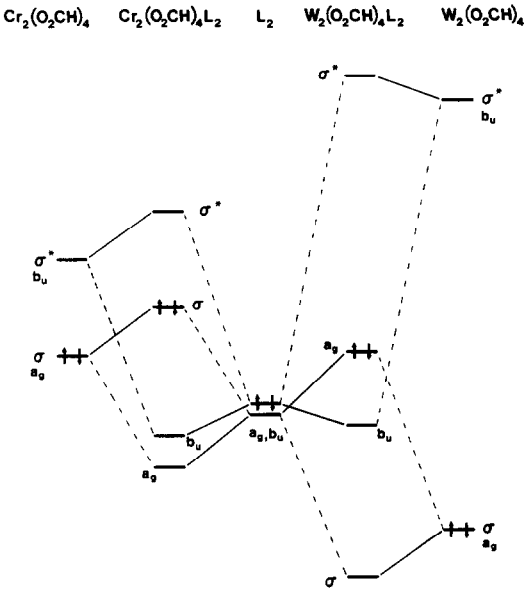

Fig. 4. Qualitative molecular-orbital diagram comparing the interaction of a neutral donor ligand L with $Cr_2(O_2CH)_4$ and $W_2(O_2CH)_4$. Only the σ interactions are depicted for clarity.

qualitatively for the extreme sensitivity and insensitivity of Cr–Cr and W–W bond lengths (respectively) in the presence of neutral axial donors.

In our recent relativistic calculations[10] on the model compound $W_2(O_2CH)_4(CH_3)_2$ we found that the interaction of the symmetric combination of L_2 orbitals with the W–W σ-bonding orbitals resulted in a significant increase in the contribution of the $6s$–$6s$ σ-bonding orbital in both W–W and W–L σ-bonding. The correlation of the MO of $W_2(O_2CH)_4(CH_3)_2$ with those of its component fragments $W_2(O_2CH)_4$ and $(CH_3)_2$ is shown in Fig. 5. One feature emphasized in Fig. 5 is that axial ligand interaction is essentially a σ-only interaction, and as expected, the M–M π, δ, δ^*, π^*, M–L and formate levels in $W_2(O_2CH)_4(CH_3)_2$ are essentially unperturbed by interaction of $W_2(O_2CH)_4$ with the axial ligands.

The symmetric combination of the $(CH_3)_2$ orbital interacts with both the $4a_{1g}$ and $5a_{1g}$ components of the W–W σ-bond. The stronger interaction is with the $5a_{1g}$ component since it is both spatially and energetically favored over the $4a_{1g}$ orbital. This interaction results in formation of the W–C σ-bonding $13a_g$ and σ-antibonding $16a_g$ MO which are occupied and unoccupied, respectively. The filled $13a_g$ orbital has 35% W character of which 63% is W $6s$. As was the case for its $5a_{1g}$ precursor, this represents a contribution of the $6s$–$6s$ σ-bonding orbital in W–CH_3 σ-bonding. The more important observation in the a_g interaction is that

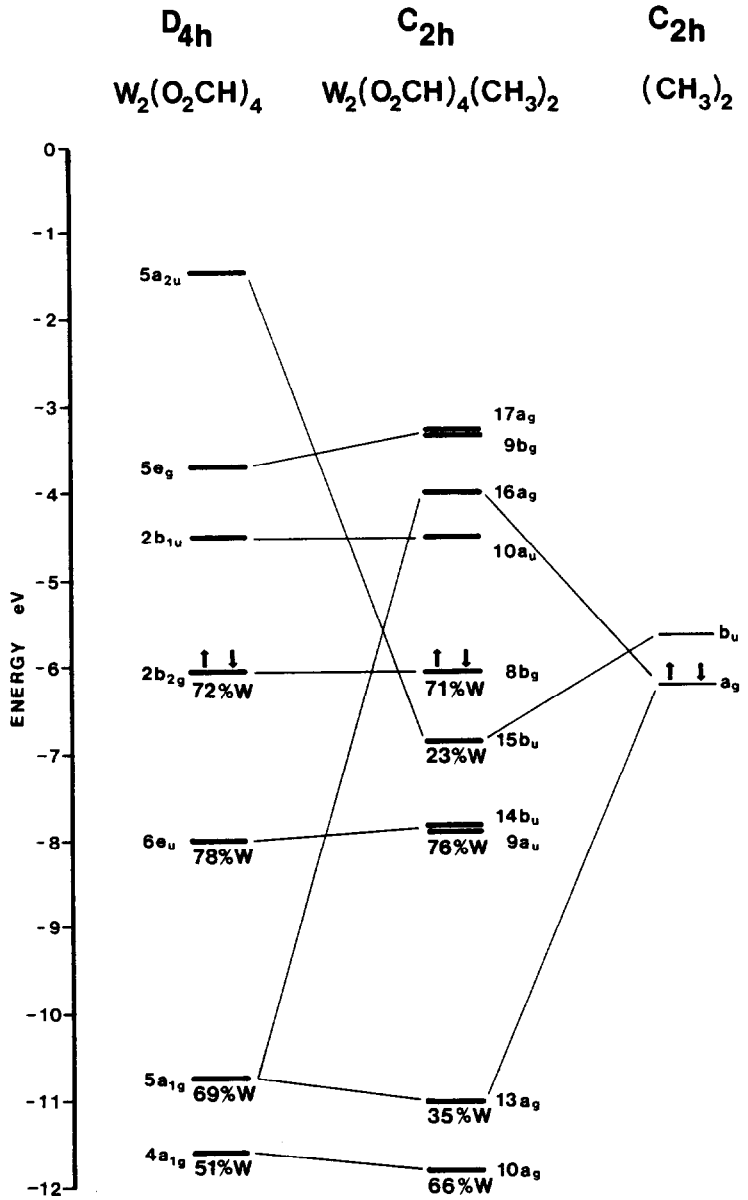

Fig. 5. Results of relativistic SCF-Xα-SW calculations on $W_2(O_2CH)_4(CH_3)_2$. This diagram shows the correlation of the orbitals of $W_2(O_2CH)_4(CH_3)_2$ to those of $W_2(O_2CH)_4$ and $(CH_3)_2$. Only those levels involved in W–W bonding or antibonding are shown. The highest occupied orbitals are depicted with arrows. Adapted from Ref. 10.

the $4a_{1g}$ MO, the principal component of the $5d$–$5d$ σ-bond, is actually stabilized by the interaction and acquires more W $5d$ character. A contour plot of the resulting $10a_g$ orbital of $W_2(O_2CH)_4(CH_3)_2$ is shown in Fig. 6, and can be compared to the $4a_{1g}$ $5d$–$5d$ σ component of $W_2(O_2CH)_4$ shown in Fig. 3.

The antisymmetric combination of the $(CH_3)_2$ orbital interacts with the $5a_{2u}$ W–W σ^*-orbital of $W_2(O_2CH)_4$, generating the W–C σ-bonding and σ-antibonding orbitals which are occupied and unoccupied, respectively (Fig. 6). The filled $15b_u$ orbital is 49% C and 23% W, of which this small amount of W character is allocated between s, p and d angular contributions. For $W_2(O_2CH)_4(CH_3)_2$, we find a rather peculiar result of strong M–M bonding in consort with strong M–L bonding in the axial position as demonstrated by the observation that experimentally both $W_2(O_2CR')_4$ and $W_2(O_2CR')_4R_2$ compounds have identical W–W bond distances.[21] Formally, the $W_2(O_2CH)_4(CH_3)_2$ molecule can be considered as having a W_2^{6+} core, and thus a d^3–d^3 triple bond of *approximate* valence MO configuration $\pi^4\delta^2$. We

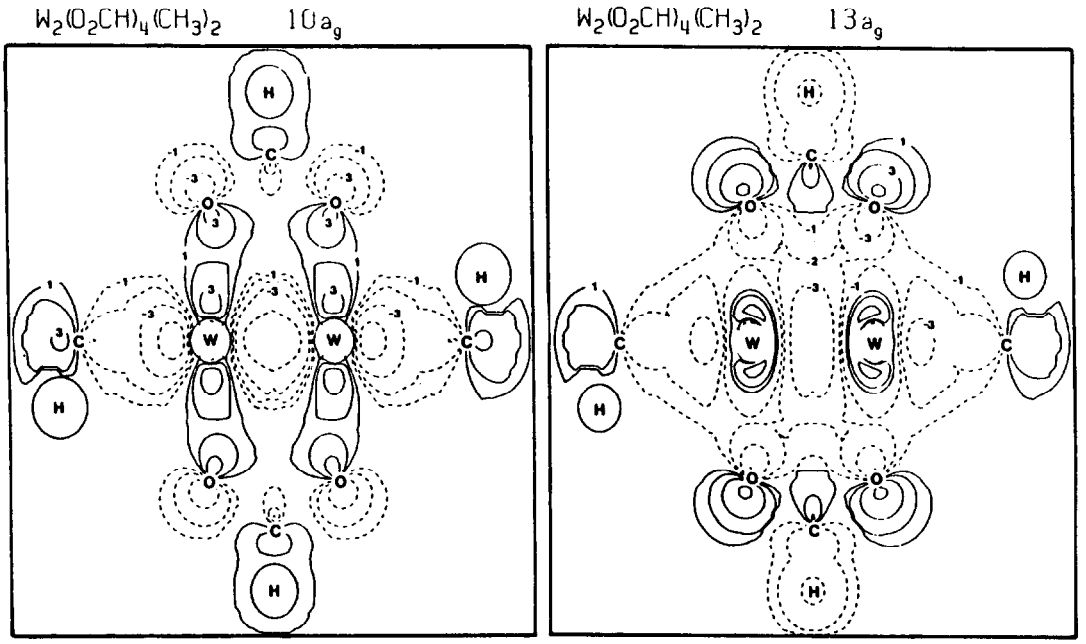

Fig. 6. Contour plots of the $10a_g$ and $13a_g$ molecular orbitals of $W_2(O_2CH)_4(CH_3)_2$. These plots are in the horizontal mirror plane containing the W atoms, two of the formate ligands, the axial C atoms, and two of the C—H bonds. Contour values are the same as those in Fig. 3(b). Adapted from Ref. 10.

emphasize that this is simply an approximation, and an aesthetically simple way to differentiate this type of d^3–d^3 dimer from one with a $\sigma^2\pi^4$ configuration. The $\pi^4\delta^2$ triple bond however suffers from a severe "σ-problem". Extensive mixing between W–W, W–CH_3 and W–O_2CH σ-bonding is so severe that we cannot asign any given orbital to any one symmetry type (i.e. M–M σ or M–L σ). There are clearly occupied MOs with substantial W–W σ character in the $\pi^4\delta^2$ triple bond as emphasized in the contour plots. Using our model of axial ligation we can readily see that the strong W–W and W–C bonding in $W_2(O_2CH)_4(CH_3)_2$ is the result of several factors. (1) Strong W–W bonding results in a very high energy W–W σ^*-orbital and little axial ligand donation into the W–W σ^*-orbital is observed. Due to the small amount of W–W σ^* character found in occupied orbitals, the W–W bond is not significantly weakened by the interaction. (2) The $4a_{1g}$ component of the $5d$–$5d$ σ-bond is scarcely affected by the axial ligation and thus remains a strong, occupied component of W–W σ-bonding in $W_2(O_2CH)_4(CH_3)_2$. (3) The major interaction of the symmetric combination of $(CH_3)_2$ orbitals is with the $5a_{1g}$ component of the W–W σ-bond, resulting in a significant contribution of the $6s$–$6s$ σ-bonding orbital in both W–W and W–C σ-bonding.

It is our belief that the participation of the s–s σ-bonding orbital is largely responsible for the electronic structural differences between first-, second- and third-row multiple M–M-bonded systems. The importance of this point needs some amplification. If the s–s σ-bonding orbital is unimportant, as it most certainly is in Cr–Cr quadruply bonded systems, the interactions of both the symmetric and antisymmetric L_2 orbitals with an M–M quadruple bond must necessarily weaken and lengthen the M–M bond. The antisymmetric combination donates into the M–M σ^*-orbital, an interaction which obviously will weaken the M–M bond. The symmetric combination will interact with the M–M σ-bond, resulting in M–L bonding and antibonding orbitals which are occupied and unoccupied, respectively. Thus, a portion of the M–M σ-bond is found in unoccupied orbitals, again weakening the M–M interaction. The importance of the s–s σ-bonding orbital in W systems, which is due in large part to the relativistic stabilization of the W $6s$ orbitals, is that it provides another mechanism by which the symmetric L_2 orbital can interact with the dimetal core. The participation of s orbitals has been found to be important in the M–M σ- and σ^*-orbitals of second-row dimers as well, although the $5s$ participation in $Mo_2(O_2CH)_4$ is not nearly so pronounced as the $6s$ participation in $W_2(O_2CH)_4$. It is our belief that this $5s$ participation accounts in part to the insensitivity of the Mo–Mo bond length in axial adducts of dimolybdenum tetracarboxylates as compared to the extreme sensi-

tivity of the corresponding Cr dimers. As an illustration we note that the W–W distances in $W_2(O_2CMe)_4$ and $W_2(O_2CMe)_4(CH_2Bu^t)_2$ are both 2.189 Å,[21] whereas a slight lengthening from 2.090 to 2.134 Å is observed for the respective Mo–analogues,[22] presumably due to the smaller degree of 5*s*–5*s* σ-participation in the Mo_2 system.

CALCULATED IONIZATION ENERGIES OF THE M–M σ-BOND

The initial assignment[23] of the low-energy photoelectron (PE) spectrum of $W_2(O_2CCF_3)_4$ has been the focus of considerable attention and, at least initially, considerable controversy.[24] Of particular note was the assignment of a very sharp band at 9.71 eV in the PE spectrum to ionization from the W–W σ-bond, an ionization less than 1 eV above that assigned to ionization from the π-bond. Recent experimental studies of Kober and Lichtenberger[25] have confirmed these assignments, which are somewhat disheartening in view of our expectations based on the relativistic Xα-SW calculations on $W_2(O_2CH)_4$. The δ–π separation of *ca* 1.8 eV is in good quantitative agreement with the predictions (2.0 eV) of the Xα-SW calculations. However, the calculations place the first σ ionization (from the $5a_{1g}$ orbital) 2.3 eV below the π-ionization. This is, in fact, a general observation in that Xα-SW calculations on M–M quadruply bonded systems *always* place the σ-orbitals well below the π-orbitals. By contrast, Ziegler's relativistic Hartree–Fock–Slater (DV-Xα) calculation[26] on $W_2(O_2CH)_4$ yields a σ–π splitting of 0.5 eV, in good agreement with the experimental results. Similarly, Xα–SW calculations[7] on $Mo_2(O_2CH)_4$ give a σ–π splitting on the order of 1.0 eV, whereas recent DV-Xα calculations[27] on the same molecule predicts the σ- and π-ionizations to be almost isoenergetic, a result also obtained using multiconfiguration *ab initio* methods.[28] It thus appears that discrete variational and scattered-wave solutions to the Xα method differ with respect to the placement of the σ-orbital in $M_2(O_2CH)_4$ compounds. We believe that the inability of the Xα-SW method to properly place the σ-orbitals is due to some of the assumptions of the overlapping-sphere formalism which is the accepted practice for such calculations. For these very short M–M bonds, the atomic spheres of the M atoms overlap substantially, and the largest errors in the description of the M–M interaction are expected to occur for those orbitals which have their maximum interatomic interactions in the overlap region. This will not be a serious problem for the δ- and π-orbitals, but could be (and apparently is) for the σ-orbitals. Sattelberger and Scioly[29] have found that the Xα-SW energies of the σ-orbitals of $W_2(O_2CH)_4$ are extremely sensitive to the choice of sphere radii, consistent with the above conjecture. The DV-Xα method, which does not employ the scattered-wave method of solution, is apparently able to more correctly model the M–M σ-interaction. It is our expectation that recognition of this apparent flaw in the Xα-SW method will lead to further examination of its causes and corrections.

CONCLUSIONS

The Xα-SW method occupies a unique role in multiple M–M bond chemistry. Beginning with Norman and Kolari's seminal work on $Mo_2Cl_8^{4-}$ and $Mo_2(O_2CH)_4$,[30] the method has been one of the most widely used quantitative electronic structural tools in this area of chemistry. The application of the method to multiple metal–metal bonds was not unjustified as the results of the calculations more often than not led to new insights about the bonding and energetics of these systems. In fact, in nearly all cases, the Xα-SW method provides results which are in excellent *qualitative* and very often (but not always) excellent *quantitative* agreement with experimental data.

It must be recognized, however, that the Xα-SW method is not a panacea for all aspects of the multiple bonding between M atoms. We have tried to present not only the successes of the method, but also areas in which it fails. Two of these are particularly notable for this Symposium: the calculation of $\delta \rightarrow \delta^*$ transition energies, and the energies of M–M σ-bonding orbitals. The former is, of course, a flaw of MO theory and there is no corrective recourse within a single-configuration description. The latter must be acknowledged as an area in which the Xα-SW method provides poor quantitative agreement with experiment. It is our hope that these discussions provide the impetus for further investigation into the source(s) of these problems.

Acknowledgments—We thank Dr A. P. Sattelberger of the Los Alamos National Laboratory, and Professor D. L. Lichtenberger of the University of Arizona for helpful discussions. (*Received* 19 *November* 1986)

Abstract—Attempts to extract estimates of the δ-bond strength of quadruply metal–metal-bonded molecules from their $\delta \rightarrow \delta^*$ electronic transitions have been hindered in the past by limited understanding of the origins of the energies and intensities of these transitions. We show that the energies of the $\delta \rightarrow \delta^*$ transitions of a wide variety of these molecules are adequately interpreted in terms of a simple zero-differential-overlap model that yields one-electron δ–δ^* splittings of 5000–10,000 cm^{-1} and two-electron exchange terms $[K(\delta, \delta^*)]$ of 5000–8000 cm^{-1}. Because of the magnitude of K, singlet–triplet $\delta \rightarrow \delta^*$ splittings are very large, and configuration interaction is important for the correct description of the ground state. The intrinsic intensity of $^1(\delta \rightarrow \delta^*)$ is estimated to be quite low. The considerable intensities observed in many cases do not correlate with δ-bond strength, but instead reflect intensity stealing from charge-transfer excited states as a result of δ,δ^*-orbital mixing with ligand orbitals. The intrinsic δ-bond stabilization is estimated to be on the order of 10 kcal mol^{-1}.

In 1964 Cotton proposed[1] the existence of a metal–metal δ-bond for $Re_2Cl_8^{2-}$ in order to account for its diamagnetism and eclipsed (D_{4h}) geometry. The d^4–d^4 electron count yields, within this molecular orbital framework, a $[\sigma^2\pi^4\delta^2]$ electronic configuration and a low-lying empty δ^* antibonding orbital, with the δ-HOMO and δ^*-LUMO being derived from metal d_{xy}-orbitals. The δ-bond completes a metal–metal quadruple bond.

A central question in the years following this discovery has concerned the strength of the δ-bond. A primary experimental probe in this regard has been the determination of the spectroscopic energies of the electronic transitions between the δ- and δ^*-orbitals. The earliest attempts along these lines were adversely affected by the primitive calculation methods that were then available,[2] and extremely inflated estimates of δ-bond strength, as well as incorrect spectroscopic assignments, resulted.

Work on three different fronts ushered in a new era in this field during 1973–75. On the theoretical side, calculations employing the then-novel SCF-Xα-SW method were published by Norman and Kolari,[3] and Mortola *et al.*[4] The postulated molecular-orbital ordering was confirmed, although the splitting of the one-electron δ- and δ^*-levels was much smaller than had previously been envisioned. Meanwhile, Cowman and Gray[5] showed that the lowest-energy visible absorption in the electronic spectrum of $Re_2Cl_8^{2-}$ ($\nu_{max} = 14{,}700\ cm^{-1}$, $\varepsilon \simeq 2500$) and related quadruply bonded compounds could be assigned to the $^1(\delta \rightarrow \delta^*)$ transition on the basis of its molecular z-polarization and pronounced vibronic structure in the metal–metal

† Contribution No. 7482 from the Arthur Amos Noyes Laboratory.

stretching mode ν_1. While the energy and intensity of this transition seemed to indicate a moderate δ interaction, the small decrease in ν_1 in the $^1(\delta\delta^*)$ excited state relative to the ground state suggested that this bond was quite weak. Finally, the method of resonance Raman spectroscopy was applied by Clark and Franks.[6] Excitation into the recently assigned $^1(\delta \rightarrow \delta^*)$ transition of $Mo_2Cl_8^{4-}$ resulted in very strong and selective resonance enhancement of ν_1, which was manifested as long overtone progressions in this mode. This result strongly indicated a metal–metal-localized transition, consistent with the single-crystal assignment.

Numerous subsequent investigations have amply supported the 1973–1975 work, while considerably expanding upon it. Unfortunately, as has been emphasized in two recent papers,[7,8] the desired correlations between $^1(\delta \rightarrow \delta^*)$ transition energies and intensities and the strength of the δ-bond have been elusive. A key example is presented by $Mo_2(O_2CCH_3)_4$ and related molybdenum carboxylates, which have among the shortest metal–metal distances of all second and third transition-series quadruply bonded dimers.[2] Although the $^1(\delta \rightarrow \delta^*)$ transition of this compound appears at relatively high energy (23,000 cm^{-1}), which seems intuitively consistent with its short bond length, it is also weak ($\varepsilon = 150$)—so weak, in fact, that the vibronically induced, x,y-polarized intensity is of comparable magnitude to the orbitally allowed, z-polarized intensity.[9]

Why is this transition simultaneously of so much higher energy and lower intensity for $Mo_2(O_2CCH_3)_4$ than for $Re_2Cl_8^{2-}$, and what, if any, inferences can be made about δ-bond strength? We attempt to answer these questions in this paper.

THE ENERGIES

We adopt a time-tested model, one originally developed for the $\pi \rightarrow \pi^*$ transition of ethylene and subsequently applied to many organic molecules.[10] We initially assume that δ-symmetry orbitals have pure metal character; mixing with ligands is ignored. The δ- and δ^*-orbitals are then derived from symmetric and antisymmetric linear combinations of face-to-face d_{xy}-orbitals on atoms A and B:

$$\phi_1 = [2(1+S)]^{-1/2}[d_{xy}(\mathrm{A}) + d_{xy}(\mathrm{B})] \equiv \delta,$$
$$\phi_2 = [2(1-S)]^{-1/2}[d_{xy}(\mathrm{A}) - d_{xy}(\mathrm{B})] \equiv \delta^*,$$

where S is the orbital overlap.

Four states, consistent with the Pauli principle, can be constructed from the δ- and δ^*-levels:

$$\Phi_1 = |\phi_1\phi_1| \equiv {}^1(\delta^2),$$
$$\Phi_2 = |\phi_2\phi_2| \equiv {}^1(\delta^{*2}),$$
$$\Phi_T = 2^{-1/2}\{|\phi_1\phi_2| - |\phi_2\phi_1|\} \equiv {}^3(\delta\delta^*),$$
$$\Phi_V = 2^{-1/2}\{|\phi_1\phi_2| + |\phi_2\phi_1|\} \equiv {}^1(\delta\delta^*).$$

We now write out the state energies, taking care to include the off-diagonal interaction between Φ_1 and Φ_2:

$$E_V = W_1 + W_2 + J_{12} + K_{12},$$
$$E_T = W_1 + W_2 + J_{12} - K_{12},$$
$$E(\Phi_1,\Phi_2): \begin{vmatrix} 2W_1 + J_{11} - \lambda & K_{12} \\ K_{12} & 2W_2 + J_{22} - \lambda \end{vmatrix} = 0.$$

The W_i are core integrals consisting of one-electron terms, J_{ii} and J_{ij} are one- and two-center coulomb repulsion integrals, and K_{12} is the exchange integral.

Invoking the zero-differential-overlap approximation, as is well established[10] for organic molecules, results in $J_{11} = J_{22} = J_{12}$. If we additionally adopt the average energy of the one-electron δ- and δ^*-levels, $\frac{1}{2}(W_1 + W_2)$, as a reference point, we eliminate the Js from the expressions and arrive at:

$$E_V = K,$$
$$E_T = -K,$$
$$E(\Phi_1,\Phi_2): \begin{vmatrix} -\Delta W - \lambda & K \\ K & \Delta W - \lambda \end{vmatrix} = 0,$$

where we have dropped the subscript on $K = K_{12}$ and set $\Delta W = W_2 - W_1$. We finally note that K is given by:

$$K = \tfrac{1}{2}[(aa\,|\,aa) - (aa\,|\,bb)],$$

where $(aa\,|\,aa)$ is the energy required to transfer a δ-electron from metal center A to metal center B at infinite A–B distance (R). The $(aa\,|\,bb)$ term is an electrostatic correction[10,11] to finite R, which is approximately given by e^2/R in the point-charge limit.

In Fig. 1 we show the internuclear-distance dependence of the δ,δ^*-manifold of states according to this simple theory. The strong dependence of ΔW on $R(\mathrm{M_2})$ (decreasing to larger R) and the weaker but much longer range $1/R$ dependence of K (increasing to larger R) have both been qualitatively indicated. It is well understood for bonding–antibonding transitions in strongly bonded dimers that K is large; using the above analysis, it is estimated to be on the order of 30,000 cm^{-1} for ethylene.[10(b)] The situation for weakly bonding cases is less well appreciated,

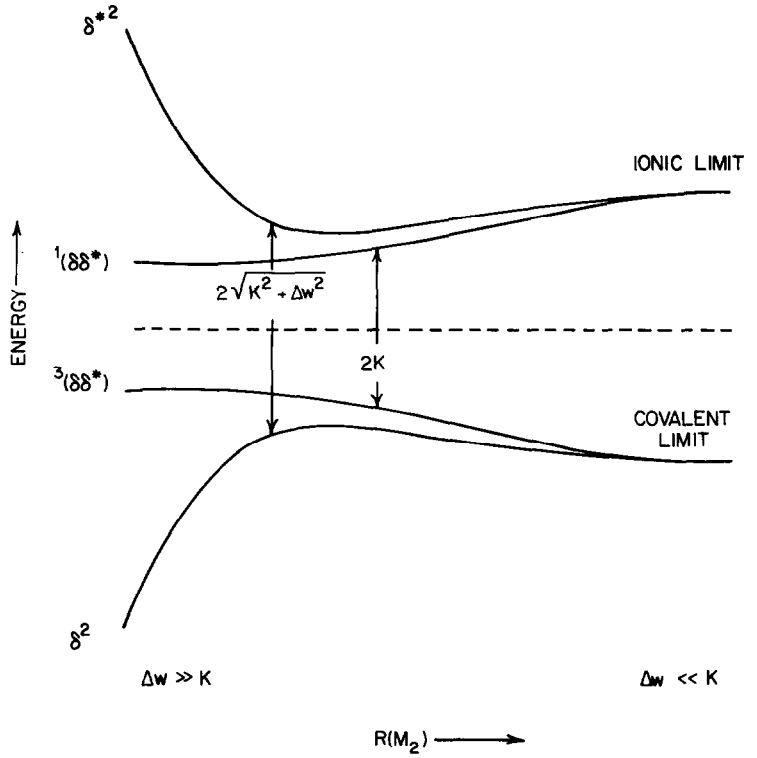

Fig. 1. Dependence of the energies of the δ,δ^*-manifold of electronic states upon metal–metal distance.

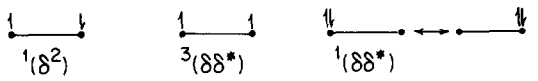
however. Even in the absence of bonding between A and B ($\Delta W = 0$), there will be a singlet "bonding–antibonding" (A-to-B charge-transfer) transition of energy $2K$; for the archetypical weakly metal–metal-interacting dimer, namely $Cu_2(O_2CCH_3)_4(OH_2)_2$, K has been estimated (neglecting ligand interactions) to be 50,000 cm^{-1}.[11] The ionic and covalent limits indicated in Fig. 1 are most easily visualized by contrasting the ionic contribution of K to the $^1(\delta\delta^*)$ state with the δ^2 and $^3(\delta\delta^*)$ states:



In order to attempt to fit this simple theory to experiment, we need at least two transition energies, but, unfortunately, only $^1(\delta \rightarrow \delta^*)$ is well established experimentally. However, there are now many examples of dimers either one-electron oxidized or reduced relative to the full quadruple bond configuration, i.e. with δ^1 or $\delta^2\delta^{*1}$ ground states. At the same theoretical level as our preceding analysis, the $^2(\delta \rightarrow \delta^*)$ transition of such molecules appears at exactly ΔW, since the contributions of the two-electron terms to the transition energy cancel each other. Numerous structural studies have shown that there is very little effect on metal–metal bond length as a result of such one-electron oxidation or reduction;[2] indeed, even two-electron oxidation or reduction does not produce large changes.[12] Since ΔW can accordingly be expected to be little affected, we propose to perform theoretical fits of the $^1(\delta \rightarrow \delta^*)$ [$^1(\delta^2)$ ground state] energies using values of ΔW derived from the $^2(\delta \rightarrow \delta^*)$ transition energies of their redox congeners.

Table 1 shows our results for the available experimental data. Also included are some comparisons with results from SCF-Xα-SW calculations. It has been observed in the past that calculations of δ–δ^* orbital energy differences for doublet ground-state molecules are in excellent agreement with observed $\delta \rightarrow \delta^*$ transition energies, and this can be traced to the good accounting of valence one-electron terms, but poor accounting of correlation energy, that this theory achieves. We note that such calculations for δ^2 ground-state molecules also give good agreement with the $^2(\delta \rightarrow \delta^*)$ transition energies of one-electron-oxidized or one-electron-reduced species, in agreement with one of our assumptions.

The derived parameters in Table 1 are values of K and predictions of $^3(\delta \rightarrow \delta^*)$ transition energies. As to the former, we observe that, despite a very large range of $^1(\delta \rightarrow \delta^*)$ transition energies, the calculated Ks are all roughly similar: ~6000–

Table 1. $\delta \rightarrow \delta^*$ Electronic transition parameters for selected quadruply bonded complexes[a]

Compound	Observed		ΔW^b (Xα)	Calculated

[a] All energies (cm^{-1}) refer to vertical transitions, thus to band maxima. Calculated values are based upon the observed $\delta \rightarrow \delta^*$ transition energies except for $Mo_2Cl_4(PMe_3)_4$, where the $X\alpha\Delta W$ values were used together with the $^1(\delta \rightarrow \delta^*)$ energy.

[b] Calculated values of ΔW are for the $[\sigma^2\pi^4\delta^2]$ electronic configuration, except as noted.

8000 cm^{-1} for second transition-series examples, and ~5000–6000 cm^{-1} for the third row. Inasmuch as these values are of comparable magnitude to the corresponding ΔWs, configuration interaction (CI) is clearly of importance in determining the ground-state energy. Nonetheless, $^1(\delta^2)$ is still a fairly good representation of the ground state. For example, the values of K and ΔW for $Re_2Cl_4(PMe_2Ph)_4^{2+}$ can be used to calculate the CI-mixed ground-state wavefunction as $0.956\Phi_1 + -0.295\Phi_2$, where Φ_1 and Φ_2 are the pure $^1(\delta^2)$ and $^1(\delta^{*2})$ state wavefunctions defined earlier. The occupation numbers (twice the squares of the coefficients) of the δ- and δ^*-orbitals are thus 1.83 and 0.17.

The 3890-cm^{-1} triplet $\delta\delta^*$ energy calculated for $Re_2Cl_4(PMe_2Ph)_4^{2+}$ is in good agreement with an *ab initio* estimate by Hay[13] of 3200 cm^{-1} for $Re_2Cl_8^{2-}$; Hay's estimate of the magnitude of CI mixing is also similar to ours. There is also experimental evidence that bears out the large singlet–triplet $\delta\delta^*$ splitting inferred by these calculations.[14,15] As our present analysis shows, this is *not* a consequence of CI, but of the large magnitude of K, as is illustrated in Fig. 2. While CI leaves the singlet–triplet $\delta\delta^*$ splitting unaffected, the effects on excitation energies are dramatic. If it were not for CI, the triplet

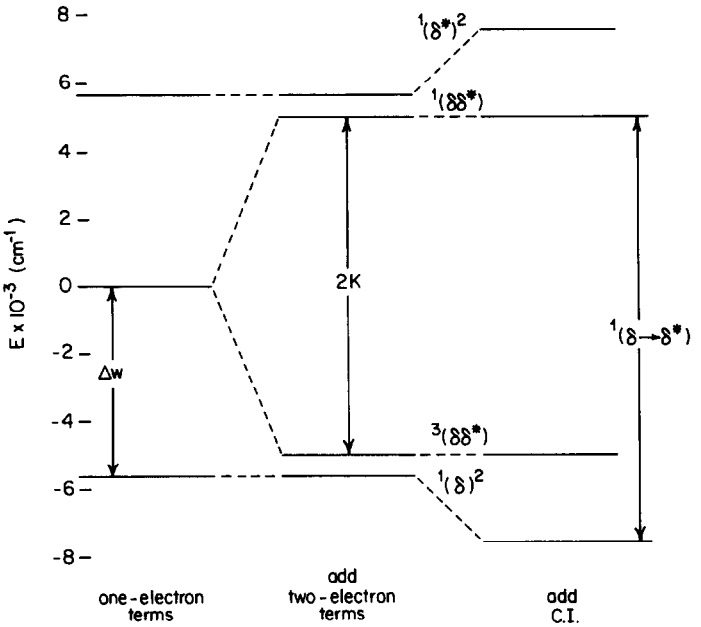

Fig. 2. Relative energies of the δ,δ^*-manifold of electronic states with and without configuration interaction. Parameters used are those for $Re_2Cl_4(PMe_2Ph)_4^{+}$ (Table 1.)

state would be close to being the ground state. But CI will make a singlet the ground state, even in the case of almost no δ interaction,[11] such as for copper acetate, despite small terms[11] neglected in our analysis that would favor a triplet ground state.

A second and completely different experimental approach to these questions can be taken. When diphosphines (e.g. $R_2PCH_2CH_2PR_2$) bridge dimers of the form β-$M_2X_4(P\text{–}P)_2$, where X is a halide, ligand-backbone strain enforces noneclipsed geometries. The torsional angle (χ) is equal to 0° for the eclipsed and 45° for the staggered ($\Delta W = 0$) geometry. A theoretical prediction of the behavior of the δ,δ^* states is very similar to that shown in Fig. 1,[15] but K is independent of rotation angle, according to the approximations defined earlier. The observed singlet "$\delta \rightarrow \delta^*$"* transition energy of the nearly staggered ($\chi = 40°$) compound β-$Mo_2Cl_4(dmpe)_2$ [dmpe = 1,2-bis(dimethylphosphino)ethane] is 12,450 cm^{-1}, which should be very near $2K$; †we thus estimate $K = 6200\,cm^{-1}$. Moreover, the rigorously eclipsed but otherwise very similar compound $Mo_2Cl_4(PMe_3)_4$ displays $^1(\delta \rightarrow \delta^*)$ at 17,090 cm^{-1}.[8] In combination with the above estimate of K, this value yields $\Delta W(\chi = 0°) = 8950\,cm^{-1}$. The agreement of these derived parameters, both with calculated one-electron δ–δ^* splittings of the model complex $Mo_2Cl_4(PH_3)_4$ obtained by the SCF-Xα-SW (8070 cm^{-1})[16(a)] and LCAO-HFS transition-state methods (8390 cm^{-1}),[16(b)] is very good.*

We now return to the anomalous case of the molybdenum carboxylates. Our analysis shows that they, and also the Re(III) carboxylates, are exceptional in having ΔW about twice as large as the other complexes. This has been previously predicted by SCF-Xα-SW calculations.[3(b),18] Of key importance is that these calculations indicate that the effect is due primarily to the interaction of δ and δ^* with carboxylate orbitals, rather than to an exceptionally large metal–metal δ-interaction; we shall return to this point shortly. There is an interesting prediction in Table 1: the large ΔW of the carboxylates results in *all* $\delta \rightarrow \delta^*$ transitions being exceptionally high-energy, including the as yet unobserved $^3(\delta \rightarrow \delta^*)$ transition.

Many attempts have been made in the past to correlate $^1(\delta \rightarrow \delta^*)$ energies with the strength of metal–metal interaction. We conclude that there is

*$^1(\delta \rightarrow \delta^*)$ is, of course, an incorrect designation in this case since the singlet ground state is nearly an equal mixture of $^1(\delta^2)$ and $^1(\delta^{*2})$. The transition actually corresponds to metal-to-metal charge transfer.

† The extinction coefficient is only 210. For rigorous D_{4d}-symmetry the transition is dipole-forbidden.

* The experimental dependence of the $^1(\delta \rightarrow \delta^*)$ energy upon torsional angle[17] is simulated very well by a calculation including the simple CI advocated here.

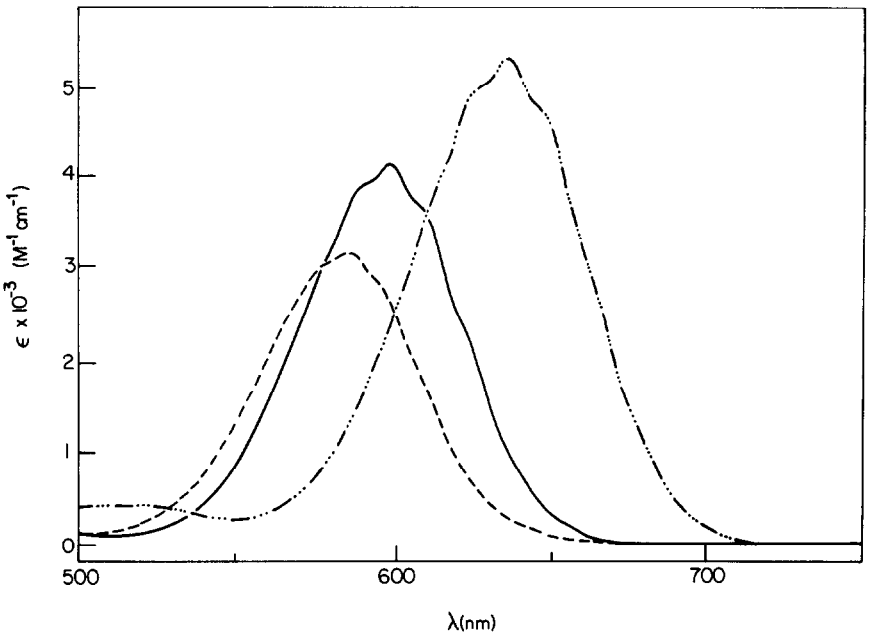

Fig. 3. Electronic absorption spectra of $Mo_2X_4(PMe_3)_4$ in 2-methylpentane solution at 300 K: X = Cl (– – – –), Br (———), or I (—···—).

a correlation of the one-electron δ–δ^* splitting with the $^1(\delta \rightarrow \delta^*)$ energy, but that it is not a simple one because two-electron terms are important. Certainly, small shifts in $^1(\delta$–$\delta^*)$ cannot be casually attributed solely to variation in metal–metal interaction, and comparisons between compounds of metals in different transition series are particularly treacherous, since two-electron integrals such as K typically decrease down a column.[19]

Having achieved some conceptual feeling for the factors involved in determining the relative energies of the δ,δ^*-manifold of states, we now turn to the question of the transition intensities.

THE INTENSITIES

In Table 2 we present selected $^1(\delta \rightarrow \delta^*)$ energy and intensity data. Groups A–C manifest a consistent trend: as the halide ligands become more reducing, the $^1(\delta \rightarrow \delta^*)$ transition both red shifts and increases in intensity.[7] Such metal–metal bond-length data as are available for these halide series fail to show a distinct correlation with the $^1(\delta \rightarrow \delta^*)$ energy or intensity. This is particularly notable for group C,[8] the spectra of which are reproduced in Fig. 3.

We suggest that the observed intensity trends are due to mixing of the "zero-order" $^1(\delta \rightarrow \delta^*)$ transition with X → M charge-transfer (CT) transitions, rather than to changes in metal–metal interactions.[8] Indeed, calculations show considerable (2–25%) halide character in the δ- and δ^*-orbitals. As the LMCT states shift to lower energy, mixing increases. That the effect on intensity should be much more dramatic than that on energy is reasonable if the inherent intensity of $\delta \rightarrow \delta^*$ is small; small amounts of mixing with intense LMCT transitions can then greatly affect intensity.

We should emphasize that a mixing mechanism involving more than nonspecific interactions with nearby LMCT states is required. First, the dominant molecular z-polarization of $\delta \rightarrow \delta^*$ requires that the interacting LMCT states also be z-polarized (LMCT states of x,y-polarization might be involved in the rather strong x,y-polarized vibronic component observed in several cases). Furthermore, effective mixing requires[20] that the two transitions have a common orbital; the LMCT must therefore be a transition of type $b_{2g}(\text{ligand}) \rightarrow b_{1u}(\delta^*)$ (D_{4h}-symmetry). Both the $M_2X_8^{n-}$ and $Mo_2X_4(PMe_3)_4$ compounds have a π(X) orbital of the appropriate symmetry, and the proposed mixing mechanism is therefore viable.

There are precedents for such an intensity-stealing mechanism among mononuclear transition-metal complexes. Well-established examples are the CoX_4^{2-} ions (X = Cl, Br or I), for which *ab initio* calculations[21(a)] strongly support LMCT mixing as the explanation for the exceptionally high[21(b)] (for a d–d transition) oscillator strength of 5.09×10^{-3} for the $^4A_2 \rightarrow {}^4T_1$ transition of $CoCl_4^{2-}$ at 14,700 cm^{-1}. The oscillator strength of this transition for CoI_4^{2-} is 8.12×10^{-3}, the increase relative to $CoCl_4^{2-}$ being consistent with a decreased

energy gap between the ligand-field and LMCT transitions; the lowest strong bands of the latter type [assigned[21(c)] to transitions to $^4T_1$ states, so that mixing is possible] occur[21(c)] at 42,600 cm^{-1} for $CoCl_4^{2-}$ and 25,000 cm^{-1} for CoI_4^{2-}.

Just what is the intrinsic or "metal–metal" intensity of $^1(\delta \rightarrow \delta^*)$? We believe that the answer is revealed by group D of Table 2. The one-electron δ–δ^* splitting for the molybdenum carboxylates was earlier indicated to be among the largest

known; this low intensity ($f < 10^{-3}$) represents the intrinsic metal–metal-induced intensity. Group D also includes examples with smaller ΔWs such as $Mo_2(SO_4)_4^{4-}$. That the δ-interaction (the magnitude of which is directly related to this low intrinsic intensity) should be so very weak, is, of course, not surprising.

Accordingly, the vast majority of the $^1(\delta \rightarrow \delta^*)$ intensity for molecules such as $Re_2Cl_8^{2-}$ is stolen from LMCT transitions. This does not mean that $^1(\delta \rightarrow \delta^*)$ is not a predominantly metal–metal-localized transition; excited distortions, as indicated by resonance Raman and low-temperature electronic spectroscopic studies, unequivocally indicate a high degree of metal–metal character. Rather, a small amount of LMCT character mixed into the transition completely dominates the intensity. It is worth considering why there is little LMCT intensity-lending for group D of Table 2. We see two major reasons. First, complexes with oxygen donor ligands should have much higher energy LMCT states than Cl^-, Br^- or I-containing compounds, according to optical electronegativities.[22]† The low $\delta \rightarrow \delta^*$ intensity for $Re_2F_8^{2-}$ (group A, Table 2) has a similar explanation. Second, the Mo_2(carboxylate)$_4$ structure imposes O–Mo–Mo angles very near 90°. As a result, z-polarized CT transitions will accidentally carry very little intensity, and CT mixing with $\delta \rightarrow \delta^*$ would therefore be an ineffective intensity-stealing mechanism, regardless of the amount of ligand character mixed into the δ- and δ^*-orbitals.

THE ENERGIES RECONSIDERED

We will now reconsider our treatment of the energies of the δ,δ^*-manifold of states. We analyzed them with a model that assumed pure d-orbitals, yet, in order to explain intensities, we found it necessary to invoke mixing with LMCT transitions. Are these approaches contradictory?

Treatments such as we have set out are fundamentally empirical, but no more so than the traditional $10Dq$ one-electron parameter, and B and C two-electron parameters of mononuclear d–d spectroscopy. That these single-center parameters are sensitive to the nature of the ligands is well known, and this, of course, is due to the ligand-field orbitals not being pure d-orbitals. While d–d spectra can be empirically analyzed in terms of crystal-field theory, it has been emphasized[24] that the derived parameters have theoretically nebulous meaning because of this mixing with ligand orbitals. It has nonetheless historically proven fruitful to analyze spectra in this way, and to correlate derived parameters with ligand properties.

Some insight into the ligand dependence of K is gained by consideration of the torsionally distorted compound β-$Mo_2Br_4(dmpe)_4$, which has $\chi = 36°$,[17(b)] similar to its chloride analogue (*vide supra*), and a $^1(\delta \rightarrow \delta^*)$ transition energy of 11,800 cm^{-1}. Taking this as the zero-δ-interaction limit, we estimate $K = 5900\,cm^{-1}$, and, from the $^1(\delta \rightarrow \delta^*)$ energy of $Mo_2Br_4(PMe_3)_4$,[8] (ΔW ($\chi = 0°$) = 9070 cm^{-1}. The differences of these parameters from those of the chloride analogues (*vide supra*) are quite small, but seem to be concentrated in a reduction of K. This results in a reduction of the energy of the $^1(\delta \rightarrow \delta^*)$ transition of about the same magnitude for both $Mo_2X_4(PMe_3)_4$ and β-$Mo_2X_4(dmpe)_2$, upon exchange of bromide for chloride, despite the large difference in transition energy for eclipsed and staggered conformers. The correlations of Cotton *et al.*[17(b)] suggest a rather constant $^1(\delta \rightarrow \delta^*)$ energy difference between chloride and bromide complexes as χ is varied, consistent with the chloride–bromide energy difference always being due to K. That two-electron integrals such as K should be smaller for bromide than for chloride complexes has precedent for mononuclear complexes, and is a manifestation of the nephelauxetic effect.[19] K for all of these complexes is undoubtedly greatly reduced from the value for a diatomic reference (M_2^{n+}) because of such ligand interactions.

What about ΔW? We have already mentioned that its anomalously large value for $Mo_2(O_2CR)_4$ reflects ligand interactions. Insight into the extent of this interaction is provided by examination of carboxylate-bridged compounds in which the metal–metal antibonding orbitals are partially occupied. The π^*- and δ^*-levels of such species are energetically close,[25] resulting in high-spin ground states of quartet $[\pi^{*2}\delta^{*1}]$ for[26(a)] $Ru_2(O_2CR)_4Cl$ ($R \simeq 2.28$ Å)[27] and triplet $[\pi^{*1}\delta^{*1}]$ for[26(b)] $Os_2(O_2CR)_4Cl_2$ ($R \simeq 2.31$ Å);[28] the bond lengths are to be compared to 2.19 and 2.24 Å, respectively,

* In our discussion of intensities, we have emphasized mixing of electronic transitions rather than of orbitals because it is likely that excited-state mixing is much larger than ground-state mixing, as a result of closer energetic proximity. Thus, an attempt to analyze these effects based solely upon ground-state wavefunctions would be incomplete.

† There appears to be a fairly low energy metal-to-ligand charge-transfer band for the $M_2(O_2CR)_4$ (M = Mo, W or Re) complexes.[23] However, this intense CT band is attributed to a transition of the wrong polarization ($\perp$ molecular z) to mix with $^1(\delta \rightarrow \delta^*)$, and there are, in fact,[3(b),18] no low-lying carboxylate orbitals of the right symmetry to yield a z-polarized $\delta \rightarrow$ carboxylate CT transition.

for[29] $M_2(O_2CC(CH_3)_3)_4Cl_2$ (M = Tc or Re). The $^2(\delta \rightarrow \delta^*)$ transitions (so termed because of the half-occupancy of δ^*) of the ruthenium and osmium compounds are centered at 9100 cm^{-1} (ε40) and 11,800 cm^{-1} (ε75), respectively.[26] These values of ΔW may additionally be compared with calculated values of 8942 cm^{-1} for $Ru_2(O_2CH)_4Cl_2^{-}$[25] and 8100 cm^{-1} for $Rh_2(O_2CH)_4(OH_2)_2$[30] (R = 2.39 Å); the π^* and δ^*-orbitals of the latter are fully occupied.

The reduction in ΔW for these compounds as antibonding orbitals are populated and R increases seems to reflect decreasing metal–metal δ-bonding interaction. It does not, however, extrapolate to zero as the bond length continues to increase, which supports an important role for metal–carboxylate interactions in maintaining large δ–δ^* separations. It is interesting that the Rh_2(II, II) value is about 6000 cm^{-1} smaller than the values for the carboxylate-bridged quadruple bond entries of Table 1. Since the direct δ interaction must be very weak indeed for the Rh_2(II,II) compound, 6000 cm^{-1} is a rough estimate of the metal–metal bonding contribution to ΔW for the Mo_2(II, II), Tc_2(III, III) and Re_2(III, III) carboxylate compounds, and it is, in fact, very similar to the values of ΔW estimated for the noncarboxylate entries of Table 1.[30]

CONCLUSIONS AND IMPLICATIONS

Our treatment of $\delta \rightarrow \delta^*$ electronic transitions leads to the conclusion that the metal–metal δ-bond is quite weak. Intrinsic metal–metal-bonding-induced one-electron δ–δ^* splittings for quadruply bonded dimers* are only about 6000–9000 cm^{-1} (corresponding to a stabilization of ~10 kcal mol^{-1}) and the intrinsic intensity for the bonding–antibonding $\delta \rightarrow \delta^*$ transition is accordingly very weak.

Interpretation of experimental data for $\delta \rightarrow \delta^*$ electronic transitions has been complicated by two previously poorly understood factors. First, there is a very large contribution of a two-electron (ionic) term to the observed transition energy. Second, mixing with ligand orbitals has profound effects upon both intensities and energies of $\delta \rightarrow \delta^*$ transitions. With regard to this latter point, it is important to note that our emphasis on sensitivity to ligands of the formally metal–metal-localized $^1(\delta \rightarrow \delta^*)$ transition is in accord with a previous discussion.[7] However, we differ with the earlier work in that we do not infer large changes in the extent of δ-bonding interactions as a function of ligand electronegativity.[8]

We finally consider the consequence of our conclusion that the $^1(\delta \rightarrow \delta^*)$ excited state has a great deal of ionic character. Excited states of this type are, in principle, subject to the phenomenon of sudden polarization, in which they can distort to the localized ionic configuration M^+M^-.[32] As we show elsewhere,[33] analyses of the vibronic structure of several examples of $^1(\delta \rightarrow \delta^*)$ transitions support the existence of such excited-state distortions. Of relevance to our present discussion of excited-state energies is that Chakravarty *et al.* recently reported[34] the preparation of $(EtO)_2Cl_2Re$-$ReCl_2(PPh_3)_2$, for which structural data suggest a considerable contribution of the polar Re(II)–Re(IV) form to the ground state of the formally quadruply bonded (eclipsed) molecule. The compound is reported to show a band at 8400 cm^{-1} (ε2800); we suggest that this band be assigned to $^1(\delta \rightarrow \delta^*)$, where electron-repulsion differences between ground and excited state have been greatly reduced, thus lowering the transition energy to near the one-electron value.

* We have emphasized analysis of ΔW based solely on the $\delta \rightarrow \delta^*$ transitions themselves. An alternate approach is to estimate δ–δ^* splittings as the difference in energy between transitions involving δ and δ^* and a third, common orbital, as in many cases the two-electron contributions should roughly cancel out. We have been able to obtain sufficiently reliable spectroscopic assignments with which to attempt this approach for only one class of compounds: the $[\sigma^2\pi^4\delta^0]$-configured $Mo_2(HPO_4)_4^{2-}$ ion and its δ^1 and δ^2 analogues $Mo_2(SO_4)_4^{3-/4-}$.[31] Assignment of the $\pi \rightarrow \delta$ and $\pi \rightarrow \delta^*$ transitions leads to estimates of ΔW of 5100, 7200 and 8500 cm^{-1} for the δ^0, δ^1 and δ^2 compounds, respectively. These estimates of ΔW are quite consistent with those of Table 1. That ΔW varies as δ is depopulated indicates a shortcoming of one of the approximations used in our earlier analysis, but the variation is not so large as to invalidate it.

OPTICAL ACTIVITY OF QUADRUPLY BONDED DIMOLYBDENUM AND DIRHENIUM COMPLEXES

ROBERT D. PEACOCK

Department of Chemistry, The University, Glasgow G12 8QQ, U.K.

(*Received* 19 *November* 1986)

Abstract—A simple metal-localized model relating the optical activity of configurationally chiral quadruply bonded complexes is presented. The predictions of the model are tested against the available data and some applications to structural and electronic assignments are discussed.

The majority of quadruply bonded dimeric metal complexes have the eclipsed ligand configuration exemplified by the structures[1] of $[Mo_2Cl_8]^{4-}$ and $[Re_2Cl_8]^{2-}$. Indeed the eclipsed geometry was one of the main reasons for the original postulation of quadruple bonds in these complexes. There is, however, an important minority of quadruply bonded complexes where due to ligand constraints or crystal packing the molecules have a staggered or partially staggered geometry about the metal–metal bond. Such molecules are necessarily chiral. Because the chromophore (in this case the Mo_2 or Re_2 unit) is chiral we call such complexes chromophorically chiral or more usually configurationally chiral. Good examples are complexes of the type β-$[Mo_2X_4(PP)_2]$, where X is halide or pseudohalide and PP represents a bidentate phosphine such as dppe or a substituted analogue; the β in the formula indicates that the phosphine is bridging the two molybdenum atoms and so engendering the twist. When the phosphine is achiral, such as dppe itself, the metal complex will be formed as a racemic mixture of the Λ and Δ forms (Fig. 1) and a solution of the complex will not show optical activity. Sometimes such racemic complexes crystallize as enantiomorphic single crystals in which all the molecules in any particular crystal are of the same hand. This happens[2] for example in β-$[Mo_2Cl_4(dmpe)_2]$.* Since the molecules are kinetically labile, however, they racemize rapidly on dissolution of the crystal and the resulting solution is optically inactive. More commonly racemic compounds crystallize as racemic crystals with equal numbers of Λ and Δ forms in the unit cell. An example[3] of this behaviour is β-$[Mo_2Cl_4(dppe)_2]$. There are a few examples of complexes containing bidentate ligands or ligands such as dmpe, which usually result in eclipsed complexes, where presumably because of packing forces the molecule is slightly twisted in the crystal. An example of this phenomenon is $[Mo_2(SCN)_4(dppm)_2]$ which has a twist of 13°.[4]

If a complex contains chiral ligands it is necessarily chiral. This ligand chirality does not always translate itself to the chromophore, however, and so produce a configurationally chiral complex. Complexes with chiral amino acids such as $[Mo_2(L\text{-leucine})_4]^{4+}$ contain[5] planar Mo_2O_2C rings and so have either zero or very small twists. The chelated (α) isomers of the $[Mo_2X_4(PP)_2]$ type complex, in which the ligand forms a five-membered chelate with each molybdenum atom, have an eclipsed geometry[6] and so are not configurationally chiral. A final example is the complex $[Mo_2Cl_4(S\text{-peap})_2]$; although the structure of this complex has not been determined its electronic spectrum is indicative of the eclipsed $Mo_2P_4Cl_4$ chromophore and it shows[7] no measurable circular dichroism (CD) under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition, indicating again a lack of configurational chirality. When chiral ligands of the type which cause the chromophore to twist are

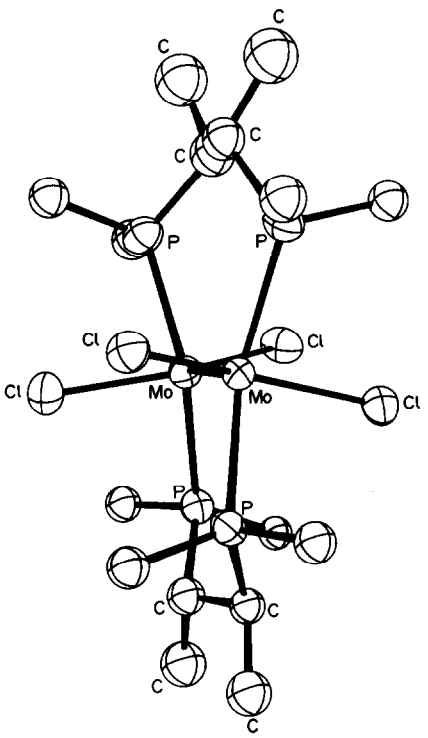

Fig. 2. Molecular structure of Λ-$[Mo_2Cl_4(S,S\text{-dppb})_2]$.

incorporated in a complex, however, we expect the conformational preference of the ligands to effect an asymmetric synthesis and produce only one of the configurational isomers. Thus conformational analysis predicts (and crystallography confirms[8]) that reaction of $[Mo_2Cl_8]^{4-}$ with *S,S*-dppb will produce solely Λ-$[Mo_2Cl_4(S,S\text{-dppb})_2]$. The structure of this molecule is shown in Fig. 2.

In this article we shall concentrate on configurationally chiral complexes for two reasons. Firstly they are expected to show much larger CD spectra under the essentially metal-localized transitions; indeed as indicated above there is usually no detectable CD under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition in eclipsed chiral complexes. Secondly it is much easier to develop a model which unambiguously relates the CD of the chromophore of a configurationally chiral complex to the geometry of the complex.

THE MODEL

The model we describe is at present a metal-localized model and so applies to those transitions which can be described without explicitly involving ligand orbitals, for example the $\delta_{xy} \rightarrow \delta^*_{xy}$ and $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transitions. It is worth issuing a caveat at the start: both the energy and intensity of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition depend quite markedly on the ligator set which implies that the ligand orbitals should not really be ignored in attempting to account for these properties. We expect the metal-localized model to be most applicable when used to compare the spectra of molecules with similar ligands and perhaps also to be better at rationalizing the signs than the magnitudes of the CD spectra. The model has a considerable merit in its simplicity but its validity has to be tested and not assumed.

The $\delta_{xy} \rightarrow \delta^*_{xy}$ transition

The transient charge distribution during the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition of a dimetal complex with eclipsed geometry is shown pictorially in Fig. 3. It can readily be seen that the movement of charge is along the metal–metal bond, i.e. that the transition is *polarized* along the metal–metal bond (*z*-polarized using the conventional co-ordinate system) and so can be excited only by light propagated perpendicular to the metal–metal bond and with electric vector directed parallel to it. This polarization has been experimentally demonstrated in a number of systems,[9] although in some cases, particularly with carboxylic acid or amino acid ligands, there is an additional intensity polarized perpendicular to the metal–metal bond (*xy* polarization) based on false origins.[10] Figure 3 is formally

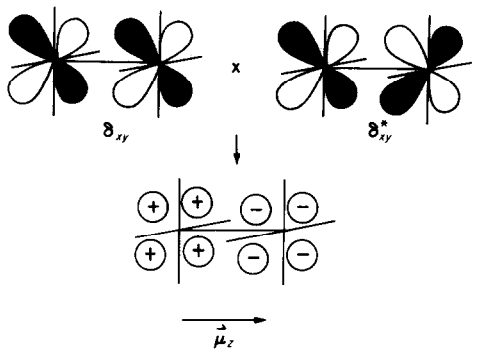

Fig. 3. Transient charge distribution for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition of an eclipsed chromophore obtained by multiplying the phases of the δ_{xy}- and δ^*_{xy}-orbitals.

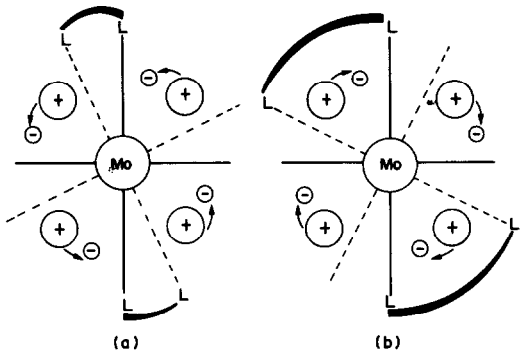

Fig. 4. Transient charge distribution for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition of a twisted $Mo_2L_4L'_4$ chromophore. (a) On rotating the near set of ligators through an angle of less than 45° in the counterclockwise (Λ) direction the transient charge distribution is that of a left-handed helix. (b) On rotating counterclockwise through an angle of greater than 45° the transition gives rise to a right-handed helical charge displacement.

equivalent to the group-theoretical statement that the produce of the symmetries of the $\delta_{xy}(b_{1g})$ and $\delta^*_{xy}(b_{2u})$ orbitals transform as $z(a_{2u})$ in D_{4h}-symmetry; the corresponding representations in D_{2h} (for the $Mo_2P_4Cl_4$ chromophore) being b_{1g} (δ_{xy}), a_u (δ^*_{xy}) and $b_{1u}(z)$.

When the molecule is configurationally chiral the symmetry of the chromophore drops to D_4 or D_2, and the product of the δ_{xy} and δ^*_{xy} orbital symmetries transform as a_2 or b_1, respectively. The transition thus becomes both electric and magnetic dipole allowed along or around the metal–metal bond and is optically active. In particular it will show the phenomenon of CD, the differential absorption of left and right circularly polarized light. This situation is shown pictorially in Fig. 4 for the Λ absolute configuration. The direction of the transient charge displacement can be obtained by following the signs from +ve to −ve (or vice versa) through the shorter spacial path. There are two situations: in both cases the charge displacement is that of a helix along and around the metal–metal bond but when the twist is between 0 and 45° the helix is left-handed, while for a twist of between 45 and 90° there is a right-handed helical charge displacement. At angles of 0, 45 and 90°, the chromophore is not chiral and the transient charge displacements are a translation, a rotation and a translation along or about the metal–metal bond, respectively.

The absolute sign of the CD associated with the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition may be deduced from the helical charge displacements of Fig. 4. We will establish the sign for the Λ absolute configuration and a twist of less than 45° [Fig. 4(a); left-handed displacement along the metal–metal bond]. The $\delta_{xy} \rightarrow \delta^*_{xy}$ transition must be excited by light propagated perpendicular to the metal–metal bond. Since any helix has the opposite helicity when viewed along or perpendicular to the helix axis, light

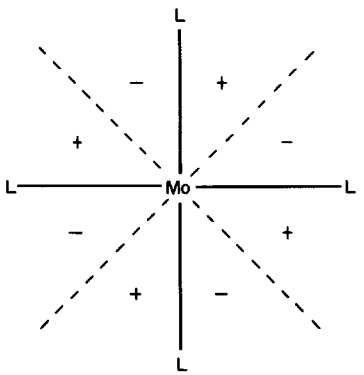

Fig. 5. Sign rule for the CD of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition. The sign of the CD is that of the sectors containing the rear set of ligating atoms.

propagated perpendicular to the metal–metal bond will see and interact with a right-handed helical charge displacement. Right circularly polarized light interacts more strongly with a right-handed helical charge displacement than does left circularly polarized light. Thus the exctinction coefficient ε_r is larger than ε_l, and the differential extinction coefficient $\Delta\varepsilon$ ($\varepsilon_l - \varepsilon_r$) is negative for the geometry depicted in Fig. 4(a). The sign of the CD changes every 45° and a sign rule can be constructed (Fig. 5) in which the sign of the CD is related to the sense and magnitude of the twist angle.

The variation of the magnitude of the CD with twist angle can be made at least semi-quantitative. The rotational strength of a transition (the area under the CD band) is proportional to the product of the electric and magnetic dipole transition moments:

$$R = \mu \times m.$$

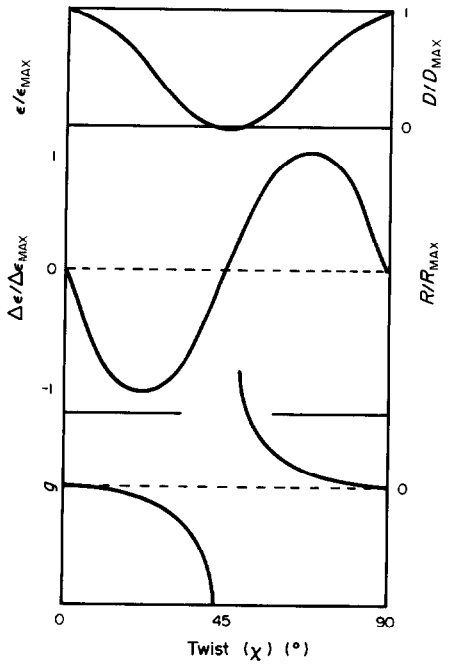

Fig. 6. Variation of dipole strength (D) (and ε), rotational strength (R) (and $\Delta\varepsilon$) and g value with twist angle χ (for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition of a complex with the Λ absolute configuration).

The electric dipole transition moment is proportional to the angular overlap of the d_{xy} orbitals and is a maximum for the eclipsed configuration; it therefore is proportional to cos 2χ, where χ is the angle of twist about the metal–metal bond. Similarly the magnetic dipole transition moment is proportional to sin 2χ. Thus:

$$R = R_{\mathrm{MAX}} \cos 2\chi \sin 2\chi.$$

The dipole strength (the area under the absorption band) and the g value ($g = 2R/D$ or $\Delta\varepsilon/\varepsilon$) can be written as functions of χ in a similar way:

$$D = D_{\mathrm{MAX}} \cos^2 2\chi,$$

$$g = g_{\mathrm{MAX}} \tan 2\chi.$$

These relations are summarized in Fig. 6.

The $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition

In many complexes there is a transition to slightly higher energy of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition which has a low extinction coefficient but a very large g value. This identifies it as a magnetic dipole transition and the current assignment is to the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ excitation. The transient charge distribution during this transition is shown in Fig. 7 for the eclipsed

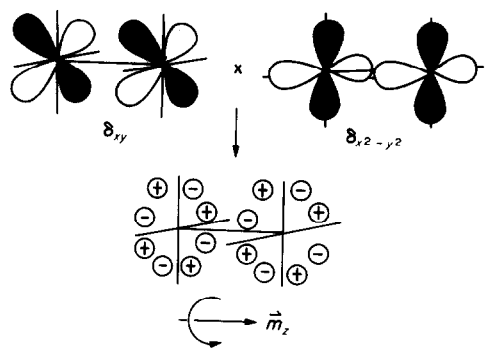

Fig. 7. Transient charge distribution for the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition of an eclipsed chromophore obtained by multiplying the phases of the δ_{xy}- and $\delta_{x^2-y^2}$-orbitals.

geometry and can be seen to involve a rotation of charge around the metal–metal bond ($A_{1g} \rightarrow A_{2g}$ in D_{4h}, $A_{1g} \rightarrow B_{1g}$ in D_{2h}). Twisting the molecule about the metal–metal bond makes the transition electric as well as magnetic dipole allowed. The same analysis as described above for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition gives[11] a sign rule with the same form but with opposite signs to those of Fig. 6. Thus the CD of the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition is predicted to have opposite sign to that of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition. The $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition is also expected to have a much larger g value than that of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition because the former is magnetic dipole allowed in the parent achiral symmetry.

How well does the model work?

The main predictions of our model are:

(1) The absolute sign of the CD of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition is related to the absolute configuration of the molecule and the twist angle as indicated in Fig. 5.

(2) The way in which the magnitudes of the CD and g value of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition is shown in Fig. 6. As mentioned above we expect the variation of the g value, being the ratio of the magnetic to electric dipole transition moment, to be more accurately described by the metal-localized model than either the absorption intensity or CD. In particular we predict that the g value should be very small for small twists away from 0 or 90°, should vary rather slowly in the 20–30° region but should be large for small deviations from 45°.

(3) The $\delta_{xy} \rightarrow \delta^*_{xy}$ and the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition should have CD of opposite sign.

(4) The g value of the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition should be much larger than that of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition in the same complex.

So far only two configurationally chiral dimolyb-

denum complexes have had their structures determined[8] by X-ray crystallography: Λ-[Mo_2Cl_4(*S,S*-dppb)$_2$] and Λ-[Mo_2Br_4(*S,S*-dppb)$_2$]. The structure of the former is shown in Fig. 2. It is worth noting that the absolute configuration (Λ) is correctly predicted by conformational analysis of the six-membered $Mo_2P_2C_2$ ring and that a scale model suggests that the twist angle should be in the 20–30° region, agreeing well with the experimental value of 24°. The bromide complex has a similar structure with a very slightly smaller twist angle of 22°. Our model predicts that both complexes should have −ve CD under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition and +ve CD under the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition. The spectra are illustrated in Fig. 8 and show that this is so. The *g* values for the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition (7.3 and 8.5 × 10^{-2} for the chloride and bromide complexes) are approximately an order of magnitude larger than those for the corresponding $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions and indeed are among the largest *g* values measured for any solution CD spectra. The effect of changing the *S,S*-dppb ligand to *R*-dppp is to produce a complex with Δ absolute configuration, Δ-[Mo_2Cl_4(*R*-dppp)$_2$]. The CD spectra of this complex and of Λ-[Mo_2Cl_4(*S,S*-dppb)$_2$] are shown in Fig. 9, and are seen to be essentially enantiomeric apart from a small wavelength shift due to slightly different twist angles.

The model is equally applicable to quadruply bonded dirhenium complexes. The CD of [Re_2Cl_4(*S,S*-dppb)$_2$]$^{2+}$ produced[12] by *in situ* oxidation of neutral triply bonded [Re_2Cl_4(*S,S*-dppb)$_2$] is shown in Fig. 10. The sign of the CD associated with the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition (at 930 nm, absent in the triply bonded species) is the same as that of Λ-[Mo_2Cl_4(*S,S*-dppb)$_2$] and has a comparable *g* value. This suggests very strongly that the complex (given the Λ configuration dictated by the *S,S*-dppb ligands) has a twist in the region of 20–30°. The fact that the metal-localized model appears to fit rhenium complexes is important because calculations suggest that the δ_{xy} and δ^*_{xy} orbitals in quadruply bonded dirhenium complexes have more ligand character than the analagous dimolybdenum complexes.

Those predictions of our model which it has been possible to test show good agreement with experiment. The one interesting prediction it has not yet been possible to explore is the behaviour of the *g* value when the twist angle is close to 45°. Figure 6 shows that both the dipole and rotational strength tend to zero at 45°. The *g* value for a pure metal-localized transition with only *z*-polarised intensity behaves as a tangent function and tends to infinity as *R* and *D* tend to zero. What happens

to the g value of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition in a real molecule at angles close to 45° remains to be seen. In the final section we give an indication of the possible uses which CD spectra have in structural assignments and in the detection and assignment of electronic transitions in the spectra of quadruply bonded complexes.

Structural and electronic assignments

The octant nature of the sign rule connecting the CD of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition to the twist about the metal–metal bond makes the assignment of absolute configuration and/or magnitude of the twist angle from CD spectra ambiguous. Examples of this ambiguity are illustrated by the complexes β-$[Mo_2Cl_4(S\text{-chairphos})_2]$ and β-$[Mo_2Cl_4(S,S\text{-skewphos})_2]$. The ligands have three carbon atoms in the backbone chain and so the complexes contain seven-membered $Mo_2P_2C_3$ rings. Both complexes show negative CD under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition thus implying either Λ (0–45°) or Δ (45–90°) twists (spectroscopic data for all the complexes discussed in the review are collected in Table 1). Another structural tool available is the experimental correlation between magnitude of the twist angle and energy of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition due to Campbell *et al.*[13] This too is ambiguous, however, since twists of χ and $(90 - \chi)$ will result in the same energy of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition. For the two seven-membered ring complexes, therefore, we can predict absolute configurations (twist) of either Λ (18°) or Δ (72°) for β-$[Mo_2Cl_4(S\text{-chairphos})_2]$ and Λ (22°) or Δ (68°) for β-$[Mo_2Cl_4(S,S\text{-skewphos})_2]$. Conformational analysis suggests the larger angle and Δ-configuration in both cases but a recent structural determination[14] on β-$[Mo_2Cl_4(dppp)_2]$, which has an unsubstituted three carbon backbone, shows that this complex has a twist of 22°. Our experience with the six-membered ring complexes shows that backbone substitution drastically alters the twist angle [β-$[Mo_2Cl_4(dppe)_2]$ has a twist of 60° while β-$[Mo_2Cl_4(S,S\text{-dppb})_2]$ has one of 24°] and so we feel that despite the structural results for β-$[Mo_2Cl_4(dppp)_2]$ the twist angles in the methyl-substituted complexes must remain ambiguous at present.

We are on much safer ground if we use CD spectra to decide whether a complex is or is not twisted about the Mo–Mo bond. The chelated complexes α-$[Mo_2Cl_4(S\text{-chairphos})_2]$ and α-$[Mo_2Cl_4(R\text{-dppp})_2]$ show no measurable c.d. under either the $\delta_{xy} \rightarrow \delta^*_{xy}$ or $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transitions. The amino acid complex $[Mo_2(\text{L-leucine})_4]^{4+}$ has a twist in the crystal of 1.4° and again has no measurable c.d. in the solid-state spectrum under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition (interestingly it does have a weak but measurable CD in solution perhaps indicating a larger twist). The implication is, therefore, that if the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition has a reasonably large CD the complex must be configurationally chiral. We shall give one example. Until recently $[Mo_2(en)_4]^{4+}$ was the only example[15] of a dimolybdenum complex with saturated amine ligands. The crystal structure has not been determined and it was not known if the 1,2-diaminoethane ligands are chelating or bridging. The analogous complex $[Mo_2(R\text{-pn})_4]^{4+}$ has been synthesized[16] and its absorption and CD spectra are shown in Fig. 11. The CD spectrum shows clearly that we have a configurationally chiral chromophore; the g value for the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition in particular being the largest for any dimolybdenum complex we have measured. There seems no doubt that $[Mo_2(R\text{-pn})_4]^{4+}$, and by extension $[Mo_2(en)_4]^{4+}$, has a twisted chromophore and so most probably contains bridging diamine ligands.

CD spectra are also useful for assigning and identifying electronic transitions. We have already mentioned the assignment of the magnetic dipole $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition based on the magnitude of its g value and there seems little doubt that the absorption found around 21,000 cm^{-1} in complexes containing the $Mo_2P_4Cl_4$ chromophore is due to the $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ excitation. As well as this transition and the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition we can clearly identify five more transitions in the c.d. spectrum of Λ-[Mo Cl (*S,S*-dppb)] in the energy region below 350 nm. These are assigned fully in reference 8b. Briefly the very weak feature at 570 nm, which can

ELECTRONIC ABSORPTION SPECTRA OF M_2L_6 COMPOUNDS CONTAINING METAL–METAL TRIPLE BONDS OF $\sigma^2\pi^4$ CONFIGURATION

M. H. CHISHOLM,* D. L. CLARK, E. M. KOBER† and W. G. VAN DER SLUYS

Department of Chemistry, Indiana University, Bloomington, IN 47401, U.S.A.

(*Received* 19 *November* 1986)

Abstract—The electronic absorption spectra of compounds containing metal–metal triple bonds of $\sigma^2\pi^4$ valence electronic configuration are presented and discussed. The lowest-energy transition of M_2L_6 compounds (M = Mo or W, L = CH_2Bu^t or OBu^t) is expected to be the dipole-allowed $\pi \rightarrow \pi^*$ ($e_u \rightarrow e_g$) transition. This appears to be the case for $M_2(CH_2Bu^t)_6$ and $M_2(OBu^t)_6$ compounds, in which the lowest energy absorption bands occur between 26,000 and 28,000 cm^{-1} ($\varepsilon = 1.1 \times 10^3$–$1.8 \times 10^3\ M^{-1}\,cm^{-1}$). For $M_2(NMe_2)_6$ compounds, the lowest energy absorption is not the $\pi \rightarrow \pi^*$ transition but is assigned instead to a LMCT transition originating from nitrogen lone-pair orbitals, $N_{1p} \rightarrow \pi^*$, observed at 30,800 cm^{-1} ($\varepsilon = 1.4 \times 10^4$–$1.9 \times 10^4\ M^{-1}\,cm^{-1}$). The $\pi \rightarrow \pi^*$ transition is not observed in these compounds, but is presumably masked by the more intense LMCT. These assignments are derived from Xα-SW calculations performed and described by other authors (Bursten *et al.*, *J. Am. Chem. Soc.* 1980, **102**, 4579).

The rapid growth in the synthetic and structural chemistry of dinuclear transition-metal complexes containing strong metal–metal bonds has provided a wealth of information concerning the nature of metal–metal bonding interactions. The study of strong metal–metal bonding interactions initially focused on the family of quadruple bonds of valence configuration $\sigma^2\pi^4\delta^2$ where the combination of sophisticated calculations, electronic absorption, emission, and photoelectron spectroscopic studies have provided a fairly detailed understanding of this class of multiple bond.[1] More recently, active research programs involving the study of metal–metal triple bonds have developed in several major research groups. Again, sophisticated molecular-orbital calculations coupled with photoelectron spectroscopy have demonstrated that triple bonds between metal atoms may contain a variety of valence electronic structures ranging from $\sigma^2\pi^4$ or $\sigma^2\pi^4\delta^2\delta^{*2}$ to the recently discovered $\pi^4\delta^2$ configuration.[2] Although the latter two configurations have been the subject of much recent attention, we note that there has been no study of the electronic absorption spectra of a homologous series of the $\sigma^2\pi^4$ triple bonds. We report here a comparison of the electronic absorption spectra of M_2L_6 compounds (M = Mo or W; L = CH_2Bu^t, NMe_2 or OBu^t) which have the $\sigma^2\pi^4$ valence M–M electronic configuration, and offer a tentative assignment for the lowest-energy transitions.

RESULTS AND DISCUSSIONS

The $\sigma^2\pi^4$ M≡M bond

The simplest of complexes containing the $\sigma^2\pi^4$ M≡M bonding configuration are the unbridged, "ethane-like" d^3–d^3 dinuclear compounds of molybdenum and tungsten of formula M_2L_6 (L = R,[3] NR_2,[3] OR[3] or SAr[4]) depicted in **I**. The qualitative view that the valence electronic structure is composed of one σ- and two π-components has been

confirmed by photoelectron spectroscopy[2,5] and a variety of molecular-orbital calculations employing the Xα-SW,[2(a),(b)] Hartree–Fock–Slater,[6] Hartree–Fock,[7] generalized molecular orbital,[8] and extended Hückel[9] methods. The Xα-SW calculations have been performed on $Mo_2(OH)_6$, $Mo_2(NH_2)_6$, $Mo_2(NMe_2)_6$ and $Mo_2(CH_3)_6$, and the projected Xα formalism applied to determine accurate orbital populations and atomic charges for these systems.[2(b)] The latter calculations were shown to be in favorable agreement with the results of photoelectron spectroscopy, and these results are summarized in the form of a qualitative energy level diagram shown in Fig. 1. The lowest unoccupied molecular orbital (LUMO) in each compound was calculated to be a Mo–Mo π*-orbital of e_g-symmetry in the D_{3d} point group.[2(b)] The highest occupied molecular orbital (HOMO) was calculated to be a Mo–Mo π-bonding orbital of e_u-symmetry for L = CH_3 and OH, yet for L = NH_2 and NMe_2 the calculated HOMO was predicted to be a nitrogen lone-pair orbital of either a_{2g}- or a_{1u}-symmetry. These calculations have found support from photoelectron spectroscopic studies.[2(b),5] For L = OR, there is a clear separation in energy between the $\sigma^2\pi^4$ M≡M bonding orbitals and the orbitals of the M–L σ-bonds, and this shows up very nicely in the He(I) and He(II) photoelectron spectra of these compounds. For L = R, extensive mixing is observed between M–M and M–L bonding orbitals which complicates the simple description of the valence electronic structure as $\sigma^2\pi^4$.

Electronic absorption spectra of M_2L_6 compounds

A summary of electronic absorption data and tentative band assignments for a representative series of M_2L_6 compounds (M = Mo or W; L = CH_2Bu^t, NMe_2 or OBu^t) are given in Table 1. A series of electronic absorption spectra comparing homologous Mo and W compounds for L = CH_2Bu^t, NMe_2 and OBu^t are shown in Figs 2–4. For each ligand set, the lowest-energy transition occurs in the UV and tails into the visible region of the spectrum, accounting for the characteristic yellow to red colors of the M_2L_6 compounds.

The ground state of the M_2L_6 systems is $^1A_{1g}$, and symmetry-allowed transitions are to excited states of A_{2u}- and E_u-symmetry in the D_{3d} point group. Thus the M≡M $\pi \rightarrow \pi^*$ ($e_u \rightarrow e_g$) transition is orbitally-allowed and expected to be the lowest-energy transition for compounds where L = CH_2Bu^t or OBu^t. For these compounds, the lowest-energy transitions are observed as relatively weak (ε = 1200–1700 $M^{-1}cm^{-1}$) bands centered between 25,000–27,000 cm^{-1}. These absorptions are tentatively assigned to the dipole-allowed $\pi \rightarrow \pi^*$ ($^1A_{1g} \rightarrow {}^1E_u$) transitions in these molecules. The relatively weak intensity of these transitions presumably arises from a mixing of M–M π and δ character in the π- and π*-orbitals under D_{3d}-symmetry. The PXα results indicate that this δ–π mixing in the occupied π-orbitals is only appreciable in magnitude for L = alkyl.[2(b)] Fenske–Hall calculations performed in our laboratory yield the same result, but, more important, they reveal that the magnitude of δ–π mixing in the π*-orbitals is severe,[10] and we feel that this will have important consequences to the intensity of the $\pi \rightarrow \pi^*$ transition in these compounds. Absorption intensity is expected to increase as the square of the overlap between ground and excited states, and in this regard we note that the intrinsically weak, yet fully-allowed $\delta \rightarrow \delta^*$ transition in quadruply bonded dimers has been rationalized by use of the weak coupling model.[11] A shoulder on the $\pi \rightarrow \pi^*$ transition is observed for $W_2(OBu^t)_6$ but not for $W_2(CH_2Bu^t)_6$ and we propose that this arises from the dipole-allowed, spin-forbidden triplet component $^3(\pi \rightarrow \pi^*)$ of the $\pi \rightarrow \pi^*$ transition. For heavy atoms such as tungsten, the effects of spin–orbit coupling become significant and can contribute to the intensity of forbidden transitions.[12] A slight mixing of triplet character into the ground state, or a mixing of singlet character into the triplet state, will contribute to the intensity of singlet–triplet transitions. The lack of a $^3(\pi \rightarrow \pi^*)$ component for $W_2(CH_2Bu^t)_6$ may be the result of the increased mixing of M–M and M–C bonding orbitals, resulting in a

lower percent metal character in the M–M π-orbitals compared to those of $W_2(OBu^t)_6$.[2(b)]

By contrast, for $M_2(NMe_2)_6$ compounds the lowest-energy transition is expected to be a ligand-to-metal charge transfer transition (LMCT) arising from a nitrogen lone-pair excitation to the M≡M π^*-orbital ($^1A_{1g} \rightarrow {}^1E_u$) ($a_{1u} \rightarrow e_g$) which is in good agreement with the observed absorption energy (30,800 cm^{-1}), and intensity [$\varepsilon = 1.4 \times 10^4$ M^{-1} cm^{-1} (M = Mo) and intensity [$\varepsilon = 1.4 \times 10^4 M^{-1} cm^{-1}$; M = Mo]. Interestingly enough, the LMCT in $W_2(NMe_2)_6$ is found at higher energy ($3.55 \times 10^4 cm^{-1}$) than the corresponding transition in $Mo_2(NMe_2)_6$. This shift uncovers a shoulder at *ca.* 360 nm ($2.78 \times 10^4 cm^{-1}$, $\varepsilon = 1.0 \times 10^3 cm^{-1} M^{-1}$) which is most likely the $\pi \rightarrow \pi^*$ transition. Presumably in $Mo_2(NMe_2)_6$ the $\pi \rightarrow \pi^*$ transition is masked by or hidden beneath the LMCT.

When comparing the spectra of $M_2(CH_2Bu^t)_6$

compounds, transitions are observed for the molybdenum compound which are not observed for the tungsten counterpart. The origin of these absorption features, which occur at higher energy than the $\pi \rightarrow \pi^*$ transitions are admittedly much more speculative. However, the Xα-SW calculations and photoelectron spectroscopic studies indicate that M–C σ-bonding orbitals of a_{2u}- and e_u-symmetry are located energetically just below the M≡M π-bonding orbitals.[2(b)] Transitions from these M–C σ bonding orbitals into the empty M≡M π^*-orbitals are dipole-allowed under D_{3d}-symmetry. Furthermore, from photoelectron spectroscopy it is known that the metal–metal bonding orbitals for tungsten compounds lie higher in energy than those of molybdenum counterparts, yet the metal–carbon orbitals remain at about the same energy.[13] We summarize the effect of changing the metal from molybdenum to tungsten in the form of a qualitative energy level diagram in Fig. 5. Orbitals with large amounts of metal character will be raised in energy for tungsten relative to molybdenum, whereas orbitals with large amounts of carbon character will be relatively unaffected. Thus, while the π to π^* separation remains relatively unchanged, the separation of M–C σ- and M≡M π^*-orbitals is greatly changed. We feel that this diagram qualitatively accounts for the observation of M–C $\sigma \rightarrow$ M≡M π^* transitions at lower energy for molybdenum relative to tungsten.

Concluding remarks

We have presented a summary of the electronic absorption spectra for the prototypical compounds containing metal–metal triple bonds of valence M–M configuration $\sigma^2\pi^4$, namely the M_2L_6 compounds of molybdenum and tungsten. For, M = Mo, W; L = CH_2Bu^t OBu^t and L = NMe_2; M = W the lowest-energy absorptions can reasonably be assigned to the $\pi \rightarrow \pi^*$ transition whereas for M = Mo; L = NMe_2 the lowest-energy absorption is most likely LMCT. The overall understanding of these metal–metal triple bonds from both a theoretical and experimental basis seems quite satisfactory. Calculations using the Xα-SW method have proved useful in the interpretation of both the electronic absorption spectra and the photoelectron spectra. It should be recognized that the valence molecular orbital description of $\sigma^2\pi^4$ is only an approximation, and that this description is dependent on the ligands L, and that the degree of M–M and M–L mixing increases in the order OBu^t to NMe_2 to CH_2Bu^t.

EXPERIMENTAL

Compounds were prepared using standard Schlenk and glove-box techniques as described elsewhere* and were purified by either sublimation

SOME RECENT DEVELOPMENTS IN THE CHEMISTRY OF MULTIPLY BONDED DIMETAL COMPLEXES THAT CONTAIN THE INTRAMOLECULAR BRIDGING PHOSPHINE LIGANDS $R_2P(CH_2)_nPR_2$

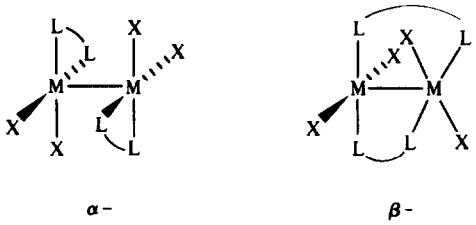
ANDREW C. PRICE and RICHARD A. WALTON*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 19 *November* 1986)

Abstract—Recent synthetic and structural studies on multiply bonded complexes of stoichiometry $M_2X_4[\mu\text{-}R_2P(CH_2)_nPR_2]_2$ (M = Mo, W or Re; X = Cl, Br or I; R = Me, Et or Ph; $n = 1$ or 2), the ditungsten(III) hydride $W_2(\mu\text{-H})(\mu\text{-Cl})Cl_4(\mu\text{-dppm})_2$ (dppm = $Ph_2PCH_2PPh_2$), $Re_2Cl_4(\mu\text{-dmpm})_3$ (dmpm = $Me_2PCH_2PMe_2$), and $M_2(\mu\text{-Cl})_2Cl_4(\mu\text{-}R_2PCH_2PR_2)_2$ (R = Me or Ph) are surveyed. The first examples of multiply bonded complexes that contain the $Ph_2PCH{=}CHPPh_2$ ligand (abbreviated dppee) are described, viz. the α- and β-isomers of $M_2X_4(dppee)_2$ (M = Mo or Re, X = Cl or Br). The reactions of $Re_2X_4(dppm)_2$ (X = Cl or Br) with RNC, RCN and CO ligands that yield complexes in which a metal–metal multiple bond is preserved are reviewed.

Bidentate phosphine ligands of type $R_2P(CH_2)_nPR_2$ can not only chelate or bind in a monodentate fashion to a single metal center but, in the case of $n = 1$ or 2, they can also bridge dimetal units to give quite stable five- or six-membered rings. Such species can have an important and extensive chemistry, e.g. the $Ph_2PCH_2PPh_2$ (dppm) complexes of the platinum metals.[1] A few years ago it was discovered[2–10] that multiply bonded dimolybdenum(II), ditungsten(II) and dirhenium(II) complexes could be isolated in which such phosphines either chelate to the individual metal centers within the dinuclear unit or form intramolecular bridges between them. In the case of the $Ph_2PCH_2CH_2PPh_2$ ligand (dppe), there are instances where both structural forms have been isolated. These compounds, which are designated α- (for chelating) and β- (for bridging), respectively, have been shown to display a rich chemistry, many aspects of which have been summarized in a text[11] and in two very recent review articles.[12,13] The present article addresses some of the recent developments in this field with a particular emphasis upon the reactions of these systems with the π-acceptor CO and RNC ligands.



L–L = $Ph_2P(CH_2)_nPPh_2$, X = halide

A. RECENT SYNTHETIC AND STRUCTURAL STUDIES ON MIXED HALIDE–BIDENTATE PHOSPHINE COMPLEXES

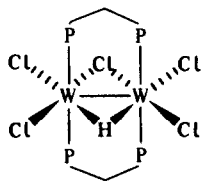
Multiply bonded complexes of type $M_2X_4(LL)_2$ [X = halide, LL = $R_2P(CH_2)_nPR_2$] are limited to cases where M = Mo, W or Re. Only work carried out or reported during the last 2 years or so will be summarized here; surveys of earlier studies can be found elsewhere (see Refs 11–13). The quadruply-bonded dimolybdenum(II) complexes $Mo_2X_4(dppm)_2$ (X = Br or I) can be prepared in high yield from $Mo_2Cl_4(dppm)_2$ via simple halide-exchange reactions (using NaX in acetone).[14] Alter-

*Author to whom correspondence should be addressed.

native routes to the iodide complex have recently been devised that involve the decarbonylation of $Mo_2I_4(CO)_8$ in toluene in the presence of dppm, and the reaction of $Mo_2(O_2CCH_3)_4$ with Me_3SiI in toluene with two equivalents of dppm.[15] These synthetic procedures[14,15] have led to two independent crystallographic studies of $Mo_2I_4(dppm)_2$ with a view to comparing its structure with those reported for $Mo_2Cl_4(dppm)_2$[4] and $Mo_2Br_4(dppm)_2$[16] and thereby providing a structural comparison of a homologous series of multiply bonded dinuclear complexes of the type $M_2X_4(LL)_2$ (X = Cl, Br or I). Crystals of $Mo_2I_4(dppm)_2$ grown from toluene were found[15] to contain the molecule in the expected fully eclipsed rotational geometry [the Mo–Mo distance is 2.139(1) Å] with a *trans* bridging arrangement of dppm ligands as is the case for its chloride and bromide analogues.[4,16] However, crystals of this complex which were grown from CH_2Cl_2–CH_3OH are different.[17] There are two independent sets of molecules in the unit cell both of which possess a structure in which the dppm ligands are present in an intramolecular bridging mode with a transoid disposition to one another. One molecule, which resides on a crystallographic inversion center, has the usual eclipsed rotational geometry, while the two symmetry-related molecules in general positions have an Mo–Mo distance of 2.152(2) Å and a twist angle [i.e. average torsional angle (χ)] of 17(2) Å.[17] This is one of the first instances where two quite different rotational geometries are present in the solid state for a molecule of this general type, *a result which indicates that crystal packing forces can play an important role in determining the exact rotational geometry*. While there is crystallographic and chemical evidence that these crystals contain small amounts of chloride and that the true composition may actually be $Mo_2I_{4-x}Cl_x(dppm)_2$, with $x \sim 0.2$, this does not appear to influence the structure in any significant way. Interestingly, the β-form of $Mo_2I_4(dppe)_2$ has recently been prepared and structually characterized and found[18] to possess a structure in which independent molecules in the unit cell have different rotational geometries.

The dimolybdenum(II) complex $Mo_2Cl_4(dmpm)_2$ (dmpm = $Me_2PCH_2PMe_2$) has been prepared by the reactions of dmpm with a mixture of $Mo_2(O_2CCH_3)_4$ and Me_3SiCl in toluene and with a suspension of $K_4Mo_2Cl_8$ in methanol.[19] The latter of these two procedures has also been used to prepare β-$Mo_2Cl_4(depe)_2$ (depe = $Et_2PCH_2CH_2PEt_2$).[20] Crystals of $Mo_2Cl_4(dmpm)_2$ have been shown to possess the usual phosphine-bridge eclipsed structure with an Mo–Mo distance of 2.1253(4) Å. The structure and properties of this complex resemble quite closely those of $Mo_2Cl_4(dppm)_2$.[14] Of special note is the accessibility of several redox processes for $Mo_2Cl_4(dmpm)_2$. Thus, solutions in 0.1 M n-Bu_4NPF_6–CH_2Cl_2 display a reversible process ($i_{p,a}/i_{p,c} \sim 1$) at +0.49 V vs Ag–AgCl, which corresponds to a one-electron oxidation of the bulk complex. An irreversible oxidation is seen at $E_{p,a} = +1.25$ V vs Ag–AgCl, and an irreversible reduction is observed near the solvent limit with $E_{p,c} = -1.75$ V vs Ag–AgCl. The crystal structure determination of β-$Mo_2Cl_4(depe)_2$ has confirmed its staggered rotational geometry [$\chi = 42.7(2)°$].[20] A comparison of this structural data with that for the other quadruply bonded dimolybdenum(II) mixed halide–bidentate phosphine complexes of this type has revealed an inverse linear relationship between the Mo–Mo bond length and cos 2χ (correlation coefficient of 0.9547). From this, the complete loss of the δ-component to the quadruple bond (corresponding to a fully staggered geometry) is seen to lead to an increase of 0.097 Å in the bond length.[20] Further refinements in this correlation can be expected as more structural data are forthcoming.

In the case of ditungsten(II) complexes that contain $R_2P(CH_2)_nPR_2$ ligands, earlier studies have reported $W_2Cl_4(dmpe)_2$ and $W_2Cl_4(dppe)_2$ (dmpe = $Me_2PCH_2CH_2PMe_2$).[5,11,13] These quadruply bonded species are prepared by the reactions of dmpe and dppe with $W_2Cl_4(P\text{-}n\text{-}Bu_3)_4$.[5] When such reactions are carried out between dppm and $W_2Cl_4(P\text{-}n\text{-}Bu_3)_4$ in toluene, the μ-hydrido ditungsten(III) complex $W_2(\mu\text{-}H)(\mu\text{-}Cl)Cl_4(dppm)_2$ (**1**)



1

is formed.[21] An alternative and more logical synthetic method utilizes the reaction between $W_2(mhp)_4$ (mhp = anion of 2-hydroxy-6-methylpyridine), Me_3SiCl, and dppm in methanol. The W–W distance in **1** is 2.483(1) Å. While the location of the hydride ligand is not apparent from the X-ray crystal structure analysis, its presence has, nonetheless, been confirmed by spectroscopic means. Furthermore, the structural details of this molecule resemble closely those of $W_2(\mu\text{-}H)(\mu\text{-}Cl)Cl_4(4\text{-}Etpy)_4$.[22]

A most useful development in the area of dirhenium(II) chemistry has been the discovery that the

bis-carboxylate complexes $Re_2(O_2CCH_3)_2X_4 \cdot 2L$ (X = Cl, Br or I; L = H_2O or γ-picoline) react with dppm in hot ethanol to give $Re_2X_4(dppm)_2$.[23] When dppe is used in place of dppm, these reactions afford β-$Re_2X_4(dppe)_2$ (X = Cl, Br or I). In the case of X = Cl or Br, the paramagnetic mixed-valent intermediates $Re_2(O_2CCH_3)X_4(dppm)_2$ have been isolated.[23] The reactions of lithium acetate with mixtures of $Re_2(O_2CCH_3)_2X_4 \cdot 2L$ and dppm or with $Re_2(O_2CCH_3)X_4(dppm)_2$ in methanol afford the species $Re_2(O_2CCH_3)_2X_2(dppm)_2$ in good yield.[23] These same complexes can be obtained by a redox reaction in which $Re_2(O_2CCH_3)_4X_2$ is reacted with dppm in refluxing ethanol.[23] The full characterization of these complexes is currently in progress.

The X-ray crystal structure of $Re_2Cl_4(dppm)_2$ has confirmed that this complex has a staggered rotational geometry.[24] The conformation of the two fused metallocyclic rings can be considered to be derived from the twist-boat conformation of the cyclohexane-like ring. For an Re(II)–Re(II) compound in which there is a $\sigma^2\pi^4\delta^2\delta^{*2}$ triple bond that imposes no electronic barrier to rotation, the observed staggered arrangement appears to correspond to an energy minimum. This is easy to visualize in a qualitative sense because a twist about the metal–metal axis relieves repulsive steric interactions. Attempts to prepare $Re_2Cl_4(dmpm)_2$ have led to an unexpected result. The reaction of dmpm with $(n\text{-}Bu_4N)_2Re_2Cl_8$ in methanol or with $Re_2Cl_4(P\text{-}n\text{-}Pr_3)_4$ in ethanol–toluene affords the novel complex $Re_2Cl_4(dmpm)_3$[25] that contains three intramolecular phosphine bridging ligands. The ^1H NMR spectrum of this species displays six broad singlets of approximate equal intensity in accord with six pairs of inequivalent methyl groups. The structure of $Re_2Cl_4(dmpm)_3$ as revealed by X-ray crystallography is shown in Fig. 1.

When the phosphine complexes $Re_2Cl_4(PMe_3)_2(LL)$ [LL = dppm or $Ph_2PNHPPh_2$ (dppa)][26] are reacted with dppe or arphos ($Ph_2PCH_2CH_2AsPh_2$) in hot *n*-butanol, the PMe_3 ligands are displaced to give the mixed-ligand species $Re_2Cl_4(LL)(LL')$ (LL = dppm or dppa, LL' = dppe or arphos).[27] The crystal structure of $Re_2Cl_4(dppm)(dppe)$ has been determined (Fig. 2) and the complex shown[27] to possess a staggered rotational geometry with an Re–Re distance of 2.237(1) Å; this value is intermediate between that of $Re_2Cl_4(dppm)_2$[24] and β-$Re_2Cl_4(dppe)_2$.[9] This structure can also be compared with that of the recently characterized complex β-$Re_2Cl_4(depe)_2$ for which the Re–Re distance is 2.211(1) Å.[20] The reported method for the synthesis of this complex produced it in a 20% yield. In order to utilize this material as a reactant with other ligands, an improved synthetic route has recently been developed.[28] By using $Re_2Cl_4(P\text{-}n\text{-}Pr_3)_4$ in place of $(n\text{-}Bu_4N)_2Re_2Cl_8$ and refluxing this with depe in a mixture of toluene and ethanol, the yield of β-$Re_2Cl_4(depe)_2$ increases to 70%. The bromide derivative has also been synthesized in an analogous manner but proceeds in much lower yield (< 10%) since α-$Re_2Br_4(depe)_2$ is the major product.

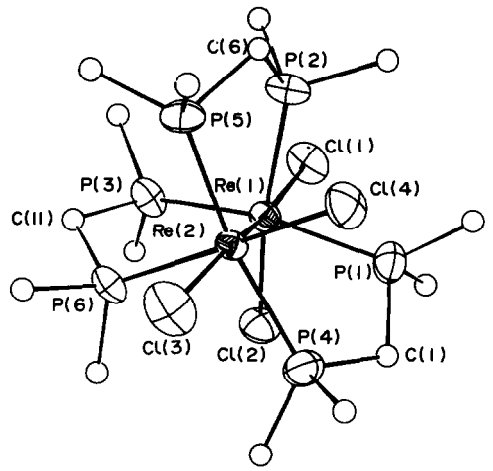


Fig. 1. ORTEP representation of the structure of $Re_2Cl_4(dmpm)_3$.[25] Carbon atoms are represented as circles of arbitrary radius. Other atoms are given as their 35% probability ellipsoids.

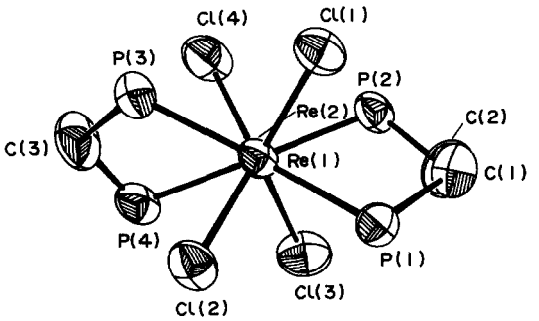

Fig. 2. The ORTEP structure of $Re_2Cl_4(dppm)(dppe)$ as viewed down the Re–Re axis.[27] One rhenium atom has been obscured by the other. Phenyl rings have been omitted for clarity and atoms are given as their 50% probability ellipsoids.

The first studies have now been carried out on multiply bonded dimetal complexes that contain phosphine ligands of the types $R_2PCH{=}CHPR_2$ and $R_2PC{\equiv}CPR_2$. In the case of the ligand *cis*-$Ph_2PCH{=}CHPPh_2$ (abbreviated *cis*-dppee),* it reacts in refluxing alcohol solvents to give α-$Mo_2Cl_4(dppee)_2$ or β-$Mo_2Cl_4(dppee)_2$; the β-

*Sometimes abbreviated ebdp, dppen or Pf=Pf.

isomer is favored by higher reaction temperatures.[29] Solutions of α-$Mo_2Cl_4(dppee)_2$ in CH_2Cl_2 isomerize slowly to the β-isomer at room temperature. Both isomers of the analogous dirhenium(II) complex have also been isolated using reactions (1) and (2):

$$[Re_2X_8]^{2-} + dppee \xrightarrow[\text{reflux}]{\text{MeOH–HCl or EtOH}} \alpha\text{-}Re_2X_4(dppee)_2 \quad (X = Cl \text{ or } Br) \qquad (1)$$

$$Re_2Cl_6(P\text{-}n\text{-}Bu_3)_2 + dppee \xrightarrow[\text{reflux}]{\text{EtOH}} \alpha\text{-}Re_2X_4(dppee)_2$$

$$Re_2X_4(PR_3)_4 + dppee \xrightarrow[\text{reflux}]{\text{benzene}^{\wedge}} \beta\text{-}Re_2X_4(dppee)_2 \quad (X = Cl \text{ or } Br;\ R = Et \text{ or } n\text{-}Pr) \qquad (2)$$

The X-ray crystal structure of β-$Re_2Cl_4(dppee)_2$ has shown that this molecule has a staggered geometry in which the disposition of the pairs of *trans* P–Re–P units is intermediate between that found previously in complexes of type $Re_2Cl_4(PR_3)_4$ and in $Re_2Cl_4(dppe)_2$. This represents the first structure of its kind for a dppee-bridged complex. Although the crystal structure of α-$Re_2X_4(dppee)_2$ has not yet been determined, it is very likely analogous to the structures of α-$Re_2Cl_4(dmpe)_2$[24] and α-$Re_2Cl_4(dppp)_2$ [dppp = $Ph_2P(CH_2)_3PPh_2$][10] both of which possess eclipsed structures with chelating bidentate phosphine ligands. The latter complexes are prepared from the reactions between $(n\text{-}Bu_4N)_2Re_2Cl_8$ and the appropriate phosphine ligand.

Both $Ph_2PC{\equiv}CPPh_2$ and *trans*-$Ph_2PCH{=}CHPPh_2$ (*trans*-dppee) react with $(n\text{-}Bu_4N)_2Re_2Cl_8$ in MeOH–HCl to give "dimer of dimers" species $[(n\text{-}Bu_4N)Re_2Cl_7(LL)_{0.5}]_2$ in which quadruply bonded $[Re_2Cl_7]$ units are linked by intermolecular phosphine bridges. The reaction chemistry of these molecules is currently under investigation.

By using the ligand *S,S*-dppb (*S,S*-$Ph_2PCHMeCHMePPh_2$), the novel chiral complex $Re_2Cl_4(S,S\text{-}dppb)_2$[30] has been synthesized and probably has a similar structure to β-$Re_2Cl_4(dppe)_2$,[9] namely a staggered geometry with a twist between the two $ReCl_2P_2$ units. Oxidation of $Re_2Cl_4(S,S\text{-}dppb)_2$ with $NOPF_6$ in acetonitrile solution yields the mono- and dications $[Re_2Cl_4(S,S\text{-}dppb)_2]^{n+}$ ($n = 1$ or 2).[30] Circular-dichroism experiments indicate that the dication, which contains a Re_2^{6+} core, and therefore a quadruple bond, has a twist angle of less than 45°. This is the first example of a twisted dirhenium complex with a formal quadruple Re–Re bond, and $Re_2Cl_4(S,S\text{-}dppb)_2$ and $[Re_2Cl_4(S,S\text{-}dppb)_2]^{2+}$ are the first configurationally chiral dirhenium complexes reported. They resemble the related dimolybdenum(II) complex $Mo_2Cl_4(S,S\text{-}dppb)_2$ that was studied previously.[31]

Some important studies have been carried out on edge shared bioctahedral complexes of the type $M_2(\mu\text{-}Cl)_2Cl_4(LL)_2$. Following upon the earlier isolation and structural characterization of $Re_2(\mu\text{-}Cl)_2Cl_4(\mu\text{-}dppm)_2$,[32] the redox chemistry of this complex has recently been explored.[33,34] Reduction with cobaltocene yields the monoanion $[(\eta\text{-}C_5H_5)_2Co][Re_2Cl_6(dppm)_2]$ while oxidation using $NOPF_6$ yields the cation $[Re_2Cl_6(dppm)_2]PF_6$. Hydrolysis of the PF_6^- anion in the latter complex gives rise to $[Re_2Cl_6(dppm)_2]\text{-}H_2PO_4 \cdot H_3PO_4 \cdot 4H_2O$ which has been structurally characterized.[33,34] The Re–Re bond length of 2.682 Å (compared with that of 2.616 Å in the neutral precursor) is in accord with a bond order of 1.5 and the $\sigma^2\pi^2\delta^{*2}\delta^1$ electronic configuration. Although $[(\eta\text{-}C_5H_5)_2Co][Re_2Cl_6(dppm)_2]$ has not yet been structurally characterized, its electronic configuration is believed to be $\sigma^2\pi^2\delta^{*2}\delta^2\pi^{*1}$, which is also representative of a metal–metal bond order of 1.5.

Of relevance to the studies on $Re_2Cl_6(dppm)_2$ has been the recent isolation and full structural characterization of the stoichiometrically homologous compounds $Nb_2Cl_6(dmpm)_2$,[35] $Ta_2Cl_6(dmpm)_2$,[36] $Mo_2Cl_6(dppm)_2$,[36] and $Ru_2Cl_6(dmpm)_2$.[36] The structural features for this series of five complexes are very similar and the variations in M–M bond lengths through the d^2–d^2(Nb, Ta), d^3–d^3 (Mo), d^4–d^4(Re) and d^5–d^5(Ru) series of metal atom pairs is consistent with the following electronic configurations: $\sigma^2\pi^2$, $\sigma^2\pi^2\delta^{*2}$, $\sigma^2\pi^2\delta^{*2}\delta^2$ and $\sigma^2\pi^2\delta^{*2}\delta^2\pi^{*2}$.[36] The ditungsten(III) analogue $W_2Cl_6(dppm)_2$ has recently been prepared by the reaction of $W_2Cl_6(THF)_4$ with dppm,[37] but it has not yet been structurally characterized although its monohydrido derivative $W_2(\mu\text{-}H)(\mu\text{-}Cl)Cl_4(\mu\text{-}dppm)_2$ has.[21]

B. PHOSPHINE-BRIDGED DIMETAL COMPLEXES THAT CONTAIN ISOCYANIDE, NITRILE AND CARBONYL LIGANDS

Multiply bonded dimetal complexes that contain monodentate phosphines react with the π-acceptor ligands CO, NO and the alkyl and aryl isocyanides to form mononuclear cleavage products.[38] Recent examples include the carbonylation of $[Re_2Cl_4(PMe_2Ph)_4]^{n+}$ (n = 0, 1 or 2) to give the carbonyl derivatives $ReCl(CO)_3(PMe_2Ph)_2$, $ReCl(CO)_2(PMe_2Ph)_3$ and $ReCl_3(CO)(PMe_2Ph)_3$[39] and the mixed isocyanide–phosphine salts of stoichiometry $[Re(CNR)_4(PR'_3)_2]PF_6$ and $[Re(CNR)_4(PEtPh_2Cl_2]PF_6$ (R = t-Bu or cyclohexyl, R' = Et or n-Pr) from the reactions of $Re_2Cl_4(PR_3)_4$ and $Re_2Cl_6(PEtPh_2)_2$, respectively, with isocyanides.[40] While these cleavage reactions are of considerable synthetic value, relatively little information regarding the mechanisms involved has been gathered since these reactions are quite facile and are difficult to control.

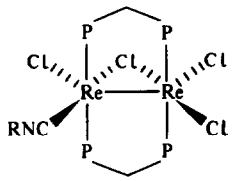
By resorting to the phosphine-bridged complexes $Re_2X_4[R_2P(CH_2)_nPR_2]_2$ (X = halogen, R = alkyl or aryl, n = 1 or 2) we have found that cleavage by carbonyls, isocyanides and nitriles is prevented, presumably due to the very stable Re–Re–P(CH$_2$)$_n$P rings that are formed,* and we have developed the chemistry of these particular class of multiply bonded complexes extensively.

B(i) *Isocyanide derivatives*

$Re_2Cl_4(dppm)_2$ reacts readily with one equivalent of an isocyanide, RNC (R = Me, t-Bu or xylyl), to form the mono-isocyanide adducts $Re_2Cl_4(dppm)_2(CNR)$ in high yield.[41] The ^{1}H NMR spectrum of the t-butyl derivative is in accord with the complex possessing an A-frame type structure (**2**), and an X-ray crystal structure analysis[42] has indeed confirmed this. However, refinement of the structure was frustrated by a disorder problem which involves the Cl and t-BuNC ligands *trans* to the bridging Cl ligand. Nevertheless, an Re–Re distance of 2.30(1) Å is indicative of a multiple bond which is slightly longer than that in the parent complex.[24] A qualitative treatment of the bonding in this complex, a member of a rare class of $M_2(\mu\text{-}L)L_8$ species possessing the A-frame type structure, predicts a slightly weakened triple bond.[42] An especially interesting property of these compounds is the fact that two ν(C≡N) modes at frequencies characteristic of a terminally coordinated RNC ligand are observed in the IR spectra of Nujol mulls, CH_2Cl_2 and benzene solutions. These findings indicate that the complexes exist as a mixture of isomers but only one of which forms suitable crystals for a crystallographic determination. These isomers interconvert rapidly on the NMR time scale.

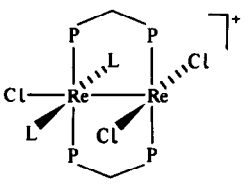
The bromide derivatives of these isocyanides, viz. $Re_2Br_4(dppm)_2(CNR)$, have also been prepared[42] and show very similar properties to their chloride analogues. Oxidation of these complexes using $NOPF_6$ forms $[Re_2X_4(dppm)_2(CNR)]PF_6$ (X = Cl or Br)[42] which show one ν(C≡N) mode in their IR spectra, indicating that only a single isomer is now present in each case.

The treatment of $Re_2Cl_4(dppm)_2$ with two equivalents of t-BuNC in acetone in the presence of PF_6^- gives yellow and green isomers of stoichiometry $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_2]PF_6$.[41,43] A comparison of their IR, ^{1}H NMR and ^{31}P–{^{1}H} NMR spectra show that these isomers are structurally very different. Based upon the similarities between the electrochemical redox properties, electronic absorption spectra and NMR spectral properties of these two complexes and related bis-nitrile and mixed isocyanide–nitrile species (*vide infra*) they are suggested to have structures **3a** and **3b**. A novel complex which contains a μ-iminyl ligand

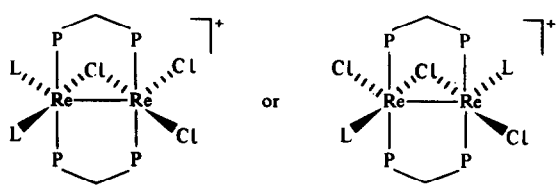


2

R = t-Bu



3a



3b

L = t-BuNC

*Both kinetic and thermodynamic factors presumably contribute to the stability of these rings.

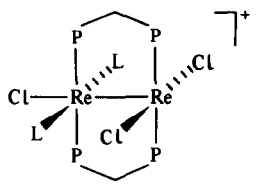
$[Re_2Cl_3(dppm)_2(\mu\text{-}C{=}NH\text{-}t\text{-}Bu)(CN\text{-}t\text{-}Bu)_2]PF_6$ has been isolated as a by-product in the synthesis of the green isomer and has been structurally characterized.[43,44] This blue, paramagnetic complex exhibits a well-defined X-band ESR spectrum which may be explained by the fact that the μ-C=NH-*t*-Bu ligand (which symmetrically bridges the two rhenium atoms) is bound as an iminyl moiety with a net -1 charge, giving rise to a Re_2^{5+} core that contains one unpaired electron.

When $Re_2Cl_4(dppm)_2$ is reacted with 3 equivalents of *t*-BuNC in the presence of KPF_6 the green tris-isocyanide complex $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_3]PF_6$ is produced.[43] This salt and its xylylNC derivative can also be prepared via an alternative route using a mixed isocyanide–nitrile containing species [see Section B(iii)]. While the stoichiometries of these two complexes are identical, their electrochemical redox properties are very different. This suggests that they may be structural isomers. Reduction of the monocation $[Re_2Cl_3(dppm)_2(CNxylyl)_3]PF_6$ with cobaltocene yields the neutral paramagnetic complex $Re_2Cl_3(dppm)_2(CNxylyl)_3$ containing (formally speaking at least) the rare Re_2^{3+} core, while oxidation with $NOPF_6$ gives the paramagnetic dication $[Re_2Cl_3(dppm)_2(CNxylyl)_3](PF_6)_2$ possessing a Re_2^{5+} core. The related *t*-BuNC derivative $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_3]PF_6$ does not possess any reversible redox chemistry.

A study has recently been carried out which details the reactions of $Mo_2X_4(dppm)_2$ (X = Cl, Br or I) with isocyanide ligands.[14] With one equivalent of RNC (R = *i*-Pr or *t*-Bu) in the presence of $TlPF_6$ (in THF) or KPF_6 (in acetone), the complexes $[Mo_2X_3(dppm)_2(CNR)]PF_6$ are formed. These are the first examples of multiply bonded Mo_2^{4+} complexes that contain coordinated π-acceptor RNC ligands. Reactions with an excess of RNC lead to seven-coordinate mononuclear $[MoX(dppm)(CNR)_4]^+$ and thence to other mononuclear isocyanide-containing species.[14]

B(ii) *Nitrile derivatives*

Nitriles (RCN) also react very readily with $Re_2Cl_4(dppm)_2$ in the presence of KPF_6 to yield the stable, ionic, bis-nitrile complexes $[Re_2Cl_3(dppm)_2(NCR)_2]PF_6$ (R = Me, Et, Ph or 4-PhC_6H_4).[45] These reactions proceed via the intermediacy of rather unstable neutral 1:1 adducts. The 1:2 benzonitrile derivative has been structurally characterized and has both nitrile ligands coordinated to the same rhenium atom (**4**). The Re–Re bond length of 2.270 Å is greater than that generally



4

L = R'CN

observed in neutral triply bonded dirhenium compounds, and may be explained by the fact that there is a contraction of the Re–Re σ and π bonding orbitals due to the increased positive charge on the molecule, and also the presence of an axially coordinated chloride ligand. The molecule is staggered with a P–Re–Re–P torsion angle of 22°. The bis-nitrile salts react cleanly with $NOPF_6$ to generate the paramagnetic ESR-active dications $[Re_2Cl_3(dppm)_2(NCR)_2](PF_6)_2$[34] which possess the Re_2^{5+} core and a $\sigma^2\pi^4\delta^2\delta^{*1}$ ground-state electronic configuration.

B(iii) *Mixed isocyanide–nitrile derivatives*

Treatment of the monoisocyanides $Re_2Cl_4(dppm)_2(CNR)$ (R = *t*-Bu or xylyl) with an excess of nitrile R'CN (R' = Me, Et or Ph) and KPF_6 affords the mixed isocyanide–nitrile salts $[Re_2Cl_3(dppm)_2(CNR)(NCR')]PF_6$.[43] These have very similar electrochemistry, electronic absorption and NMR spectral properties to those of the bis-nitrile salts discussed in Section B(ii). Even though no structural information is available at the present time, we believe that these complexes have a structure similar to the aforementioned bis-nitrile salts (**4**) and the green isomer $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_2]PF_6$ (**3a**), i.e. the isocyanide and nitrile ligands are coordinated to the same rhenium atom. These mixed-ligand salts have been oxidized chemically with $NOPF_6$ to yield the paramagnetic dications $[Re_2Cl_3(dppm)_2(CNR)(NCR')](PF_6)_2$ which show[43] complex ESR spectra comparable to those of the bis-nitrile species.[34]

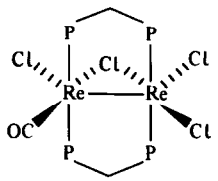
As mentioned in Section B(i), the tris-isocyanide complex $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_3]PF_6$ is synthesized readily from $Re_2Cl_4(dppm)_2$ and three equivalents of *t*-BuNC. An alternative synthesis is provided through the reaction between $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)(NCEt)]PF_6$ and *t*-BuNC, i.e. substitution of a nitrile by an isocyanide along with the addition of another isocyanide. There is no evidence for the formation of the intermediate $[Re_2Cl_3(dppm)_2(CN\text{-}t\text{-}Bu)_2]PF_6$ which would be expected to occur if a simple

displacement of a nitrile by an isocyanide were the first step in the reaction. Related to this is the reaction between $[Re_2Cl_3(dppm)_2(CNxylyl)(NCPh)]PF_6$ and 2.5 equivalents of xylylNC to give the tris-xylyl isocyanide salt $[Re_2Cl_3(dppm)_2(CNxylyl)_3]PF_6$.[43]

The reactions of $Re_2Cl_4(dppm)_2$ with isocyanide and nitrile ligands which have been discussed in Sections B(i)–(iii) are summarized in Scheme 1.

B(iv) *Carbonyl derivatives*

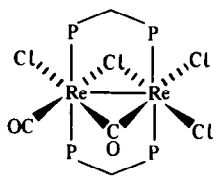
The isoelectronic nature of CO and isocyanides has prompted a thorough investigation of the reactions between $Re_2X_4(dppm)_2$ (X = Cl or Br) and CO.[46,47] The red monocarbonyls $Re_2X_4(dppm)_2(CO)$ are formed readily when CO is bubbled through a dichloromethane solution of the starting complex for 5 min. Two $\nu(C{\equiv}O)$ modes are observed in the IR spectra (Nujol mull and solution) and these vary in their relative intensities depending on the solvent used. This information, along with NMR spectral data which clearly indicates that a fluxional process is occuring in solution, suggests that isomers are present as is the case for the monoisocyanide species $Re_2X_4(dppm)_2(CNR)$.[41,42] A mechanism which is entirely in accord with the ^1H, ^{13}C and ^{31}P NMR spectral data has been proposed.[46,47] An X-ray crystal structure determination of the chloride derivative on crystals grown from a mixture of CH_2Cl_2 and benzene (5) reveals the characteristic A-frame-like



5

structure in which the CO ligand is *trans* to the bridging chloride. The observed Re–Re distance of 2.338 Å is consistent with a triple bond, but an accurate appraisal of the electronic configuration of this species is not yet at hand. However, a qualitative treatment of the bonding[42] in these types of molecules is consistent with the presence of a slightly weakened triple bond.

If CO is bubbled into a CH_2Cl_2 solution of $Re_2Cl_4(dppm)_2$ [or $Re_2Cl_4(dppm)_2(CO)$] for 3 h, the green dicarbonyl $Re_2Cl_4(dppm)_2(CO)_2$ is formed in which one CO ligand bridges the Re–Re bond and the other remains terminal.[46] This dicarbonyl has been characterized by X-ray crystallography, but due to a disorder problem it is impossible to say if the two CO ligands are *cis* or *trans* to each other with respect to the Re–Re axis. However, in light of the reactions of this dicarbonyl with isocyanides and nitriles (*vide infra*), we suggest that the CO ligands are *cis* to one another and reside on the same side of the molecule as in **6**. The Re–Re bond distance of 2.584 Å is far longer than bonds observed in triply bonded complexes with a Re_2^{4+} core. Accordingly, this dicarbonyl can be viewed[46] as containing a Re_2^{6+} core by regarding the bridging CO as divalent, and hence giving rise to a $\sigma^2\pi^2\delta^{*2}\delta^2$ configuration, i.e. a double bond.

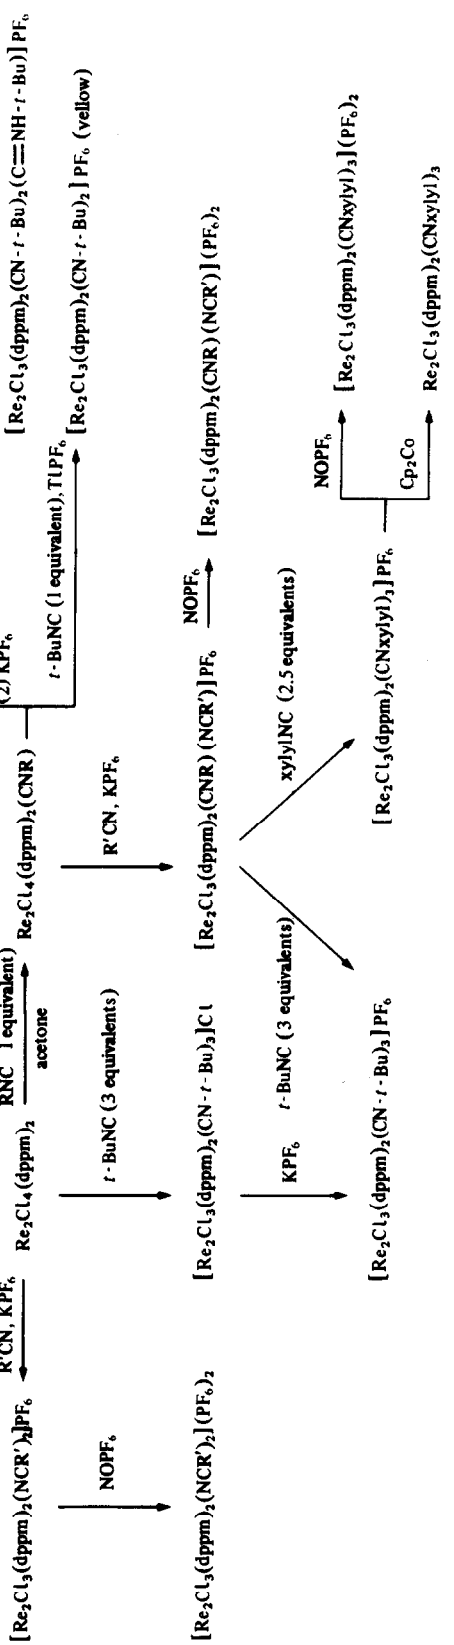


6

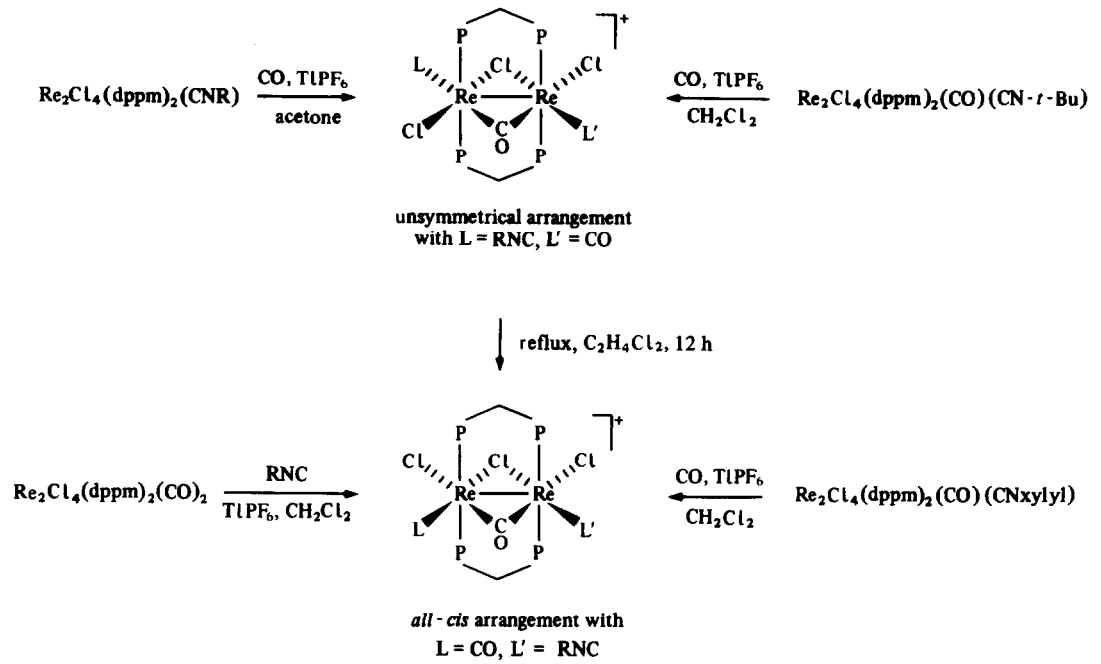
B(v) *Mixed carbonyl–isocyanide derivatives*

The monocarbonyl $Re_2Cl_4(dppm)_2(CO)$ reacts with 1 equivalent of an isocyanide to form the neutral complexes of stoichiometry $Re_2Cl_4(dppm)_2(CO)(CNR)$ (R = *i*-Pr, *t*-Bu, xylyl or mesityl).[47] A comparison of their IR spectral properties shows that the alkyl isocyanide derivatives have both π-acceptor ligands terminally bound, but the CO ligand in the aryl isocyanide derivatives bridges the Re–Re bond while the isocyanide remains terminal. Their electrochemical properties and hence their electronic configurations are very different. An X-ray crystal structure of $Re_2Cl_4(dppm)_2(CO)(CNxylyl)$[47] has shown that the CO and xylylNC ligands are *cis* to one another and the Re–Re bond distance of 2.581 Å, which is very close to that of the dicarbonyl $Re_2Cl_4(dppm)_2(CO)_2$,[46] is consistent with an Re–Re double bond. A twinning problem with the crystals of the alkyl isocyanide derivatives have so far prevented us from obtaining any structural data on these unique complexes.

The dicarbonyl reacts with isocyanides in the presence of $TlPF_6$ to give the salts $[Re_2Cl_3(dppm)_2(CO)_2(CNR)]PF_6$ (R = *i*-Pr, *t*-Bu or xylyl).[48,49] No structural information is available on these salts but we suspect that all three chlorides lie on the same side of the molecule, since an X-ray crystal structure on the reduced isopropyl isocyanide complex $Re_2Cl_3(dppm)_2(CO)_2(CN\text{-}i\text{-}Pr)$[49] (*vide infra*) shows this *all-cis* arrangement of ligands. These dicarbonyl–monoisocyanide complexes may be prepared by using two other synthetic procedures, viz. either by stirring the monoisocyanide



Scheme 1. Reactions of $Re_2Cl_4(dppm)_2$ with isocyanides and nitriles.



Scheme 2. Synthesis and isomerization of $[Re_2Cl_3(dppm)_2(CO)_2(CNR)]PF_6$ (R = *t*-Bu or xylyl).

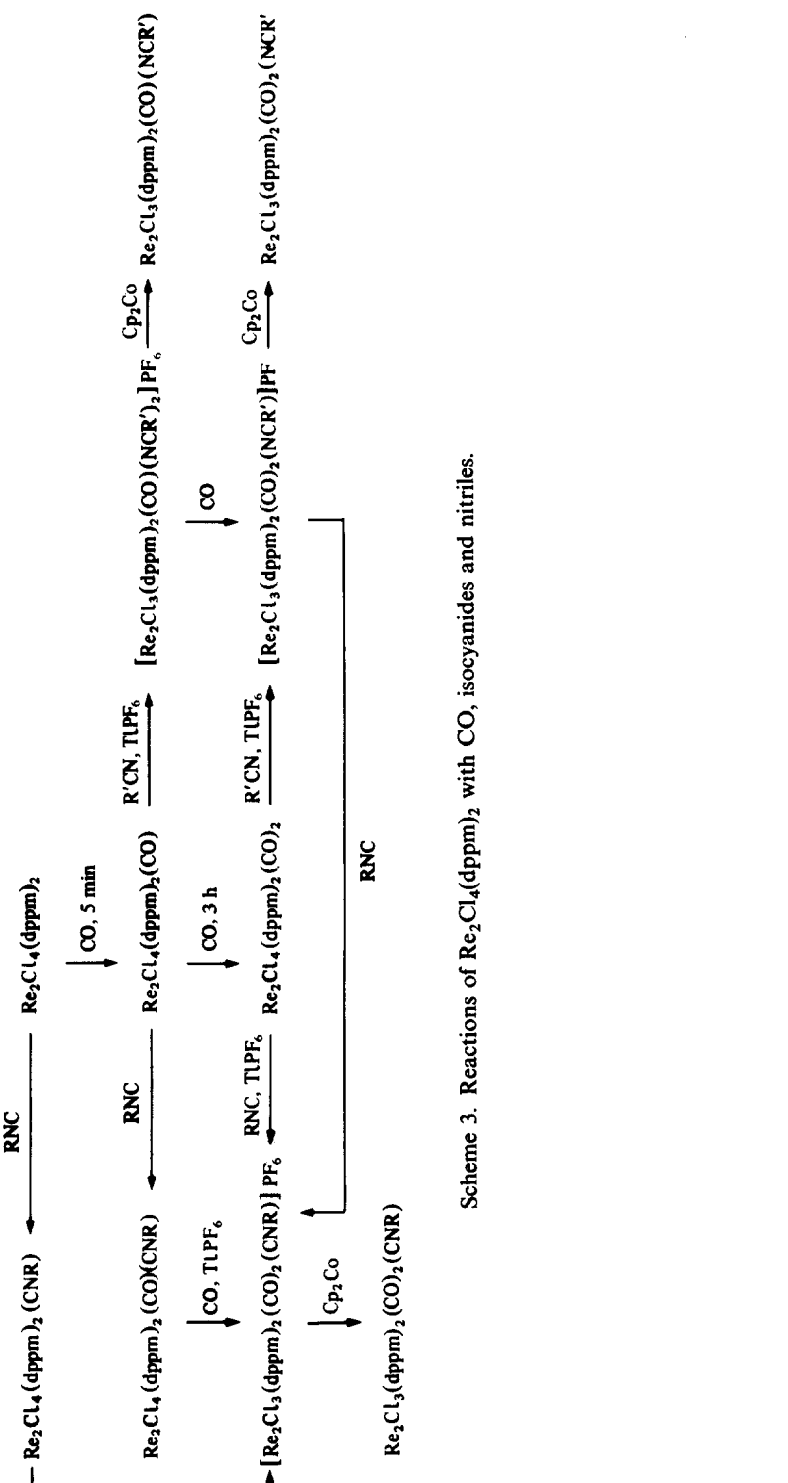
$Re_2Cl_4(dppm)_2(CNR)$ or the mixed carbonyl–isocyanide $Re_2Cl_4(dppm)_2(CO)(CNR)$ under an atmosphere of CO in the presence of $TlPF_6$.[49] However, depending on the isocyanide used (*t*-BuNC or xylyl), isomers are formed. The isomer derived from $Re_2Cl_4(dppm)_2(CNR)$ (R = *t*-Bu or xylyl) and $Re_2Cl_4(dppm)_2(CO)(CN\text{-}t\text{-}Bu)$ possesses an unsymmetric arrangement of ligands in the equatorial plane as confirmed by an X-ray crystal structure of $[Re_2Cl_3(dppm)_2(CO)_2(CN\text{-}t\text{-}Bu)]PF_6$ (prepared from the reaction of $Re_2Cl_4(dppm)_2(CN\text{-}t\text{-}Bu)$ with CO–$TlPF_6$). These results are summarized in Scheme 2. However, isomerization to the *all-cis* derivatives occurs upon heating $C_2H_4Cl_2$ solutions of these species over a period of 12 h. This thermal conversion, which leads to some decomposition, must involve bond breaking and reforming. We conclude, therefore, that the *all-cis* configuration is the thermodynamically stable form.

Reduction of these mixed carbonyl–isocyanide salts to the neutral, paramagnetic species $Re_2Cl_3(dppm)_2(CO)_2(CNR)$,[48,49] has been achieved either chemically using cobaltocene, or electrochemically in $n\text{-}Bu_4NPF_6$–CH_2Cl_2 solutions. The X-ray crystal structure of $Re_2Cl_3(dppm)_2(CO)_2(CN\text{-}i\text{-}Pr)$,[49] derived from the dicarbonyl, shows the *all-cis* arrangement of chloride ligands. An Re–Re distance of 2.718 Å is in accord with the complex possessing a $\sigma^2\pi^2\delta^{*2}\delta^2\pi^{*1}$ electronic configuration; this gives rise to a bond order of 1.5 if we regard the bridging CO as divalent, i.e. an Re_2^{5+} core complex.

B(vi) *Mixed carbonyl–nitrile derivatives*

Salts of stoichiometry $[Re_2Cl_3(dppm)_2(CO)(NCR')_2]F_6$[47] and $[Re_2Cl_3(dppm)_2(CO)_2(NCR')]PF_6$[48] (R' = Me, Et or Ph) may be prepared by reacting the mono or dicarbonyls, respectively, with an excess of nitrile in the presence of $TlPF_6$. An X-ray crystal structure of $[Re_2Cl_3(dppm)_2(CO)_2(NCEt)]PF_6$[48] shows the now familiar *all-cis* arrangement of ligands. The Re–Re bond length of 2.586 Å is almost identical with the value of 2.584 Å found in $Re_2Cl_4(dppm)_2(CO)_2$[46] and 2.581 Å in $Re_2Cl_4(dppm)_2(CO)(CNxylyl)$.[47] While the salts $[Re_2Cl_3(dppm)_2(CO)(NCR')_2]PF_6$ have not yet been subject to any crystallographic characterization, their ^1H and $^{31}P\text{-}\{^1H\}$ NMR spectral properties[47] suggest strongly that these complexes must also possess the *all-cis* arrangement of ligands. Although the dicarbonyl complexes can be reduced by cobaltocene to give the fairly air-stable neutral species $Re_2Cl_3(dppm)_2(CO)_2(NCR')$,[48] the bis-nitrile salts are more difficult to reduce and yield the highly air-sensitive $Re_2Cl_3(dppm)_2(CO)(NCR')_2$.[50] This is in accord with the notion that two π-acceptors (in this case CO) are more effective than one at stabilizing low oxidation states.

As discussed in Section B(iii), nitrile ligands have been found to undergo substitution by isocyanides. We have discovered that $[Re_2Cl_3(dppm)_2(CO)_2(NCEt)]PF_6$ reacts with RNC to yield $[Re_2Cl_3(dppm)_2(CO)_2(CNR)]PF_6$[48,50] and free



Scheme 3. Reactions of $Re_2Cl_4(dppm)_2$ with CO, isocyanides and nitriles.

nitrile, and $[Re_2Cl_3(dppm)_2(CO)(NCR')_2]PF_6$(R' = Me or Et) reacts with CO to form $[Re_2Cl_3(dppm)_2(CO)_2(NCR')]PF_6$.[50] The latter complex does not react further with CO, although we are still investigating the possibility of synthesizing the tricarbonyl $[Re_2Cl_3(dppm)_2(CO)_3]PF_6$ and a mixed carbonyl–isocyanide–nitrile $[Re_2Cl_3(dppm)_2(CO)(CNR)(NCR')]PF_6$ by this means.

Scheme 3 summarizes the reactions of $Re_2Cl_4(dppm)_2$ with isocyanides, nitriles and CO.

(*Received* 19 *November* 1986)

Abstract—Reduction of the quadruply-bridged (2Cl, 2H) tantalum(IV) dimer, $Ta_2Cl_6(PMe_3)_4H_2$ (**2**) with sodium amalgam in glyme or THF at 0°C provides deep green $Ta_2Cl_4(PMe_3)_4H_2$ (**3**) in 70% yield. Dimer **3** has a D_{2d} $Ta_2Cl_4(PMe_3)_4$ substructure which closely resembles that of the quadruply metal–metal-bonded dimer $W_2Cl_4(PMe_3)_4$. The hydride ligands of **3** are located on a diagonal plane, bridging the two tantalum atoms and the Ta–Ta separation is 2.545(1) Å. **3** reacts cleanly with Cl_2, HCl and H_2 in diethyl ether to provide the quadruply-bridged dimers **2**, $Ta_2Cl_5(PMe_3)_4H_3$ (**4**), and $Ta_2Cl_4(PMe_3)_4H_4$ (**5**), respectively, in high yield. Dimer **5** can also be prepared in high yield via thermolysis of the tantalum(IV) hydride $TaCl_2H_2(PMe_3)_4$ (**6**) in refluxing methylcyclohexane. The X-ray structure of **5** shows that the $(\mu\text{-H})_4$ group is staggered by 45° with respect to the eclipsed pyramidal $TaCl_2(PMe_3)_2$ end groups. The molecular symmetry of **5** is D_{2d} and the Ta–Ta separation is 2.511(2)Å. Multiple-scattering Xα calculations on the model compounds $Ta_2Cl_4(PH_3)_4H_2$ and $Ta_2Cl_4(PH_3)_4$ are used to elucidate the ground-state electronic structures of **3** and **5**, and to probe the question of $(\mu\text{-H})_x$ rotation about the metal–metal bonds in these complexes. Crystal data (at 160°C) are as follows: for **3**, monoclinic space group $C2/c$, $a = 18.371(5)$ Å, $b = 9.520(3)$ Å, $c = 18.942(6)$ Å, $\beta = 125.36(2)°$, $V = 2701.8$ Å^3, $Z = 4$, $d_{calc.} = 1.991$ g cm^{-3}; for **5**, tetragonal space group $P4/nbm$, $a = b = 12.579(2)$ Å, $c = 10.205(2)$ Å, $V = 1614.7$ Å^3, $Z = 2$, $d_{calc.} = 1.670$ g cm^{-3}.

The great propensity with which molybdenum and tungsten form metal–metal-bonded dinuclear complexes[2] might lead one to expect the same of their group 5 neighbors, niobium and tantalum. Operating under this assumption, we set out, several years ago, to prepare a number of low-valent ditantalum complexes. Our choice of target molecules was influenced by a report[3] on the syntheses of $W_2Cl_6(PMe_3)_4$ and $W_2Cl_4(PMe_3)_4$. These dimers were obtained by sodium amalgam reduction of polymeric tungsten(IV) chloride in THF, in the presence of trimethylphosphine (PMe_3), and we reasoned that their tantalum(III) and tantalum(II) analogues could be prepared in a similar fashion. This logic held up in the case of $Ta_2Cl_6(PMe_3)_4$ (**1**). Reduction of tantalum(V) chloride with sodium amalgam (2 equivalents) in toluene–PMe_3 provides burgundy red **1** in good yield.[4] The latter adopts

*Metal–metal bonded complexes of the early transition metals—XI. For Part X, see Ref. 1.

†Dow Britton Fellow (1983–1984).

‡Author to whom correspondence should be addressed.

an edge-sharing bioctahedral geometry with axial phosphines on one metal center and equatorial phosphines on the second, and it contains a formal Ta–Ta double bond, represented by a $\sigma^2\pi^2$ ground-state electronic configuration. The synthesis of $Ta_2Cl_4(PMe_3)_4$, a molecule which should contain an unbridged Ta–Ta triple bond ($\sigma^2\pi^4$), has not been achieved. Treatment of **1** with a variety of powerful reducing agents (e.g. NaNp and Na–K) failed to effect its conversion to the desired product. This disappointing result was offset by our observation that the Ta=Ta bond in **1** could be hydrogenated under mild conditions (25°C, 1 atm H_2).[5] The hydrogenation product, viz. $Ta_2Cl_6(PMe_3)_4H_2$ (**2**) is a quadruply-bridged (2Cl, 2H) dimer with pyramidal $TaCl_2(PMe_3)_2$ end groups. Subsequently, we discovered that **2** could be reduced to $Ta_2Cl_4(PMe_3)_4H_2$ (**3**), a doubly hydrogen-bridged tantalum(III) dimer, which may be viewed as the hydrogenation product of the elusive $Ta_2Cl_4(PMe_3)_4$. In this paper, we describe: (1) the synthesis, physicochemical properties and X-ray structure of **3**; (2) the reactions of **3** with Cl_2, HCl and H_2; (3) the X-ray structure of the hydrogenation product, $Ta_2Cl_4(PMe_3)_4H_4$, a molecule with four bridging hydrides; and (4) the electronic structures of **3** and $Ta_2Cl_4(PMe_3)_4H_4$. Preliminary reports of certain aspects of this work have been published.[6,7]

RESULTS

Synthesis and characterization of 3

Reduction of **2** with 2 equivalents of sodium amalgam in ethylene glycol dimethyl ether (glyme) or THF [eqn (1)]:

$$\underset{\mathbf{2}}{Ta_2Cl_6(PMe_3)_4H_2} + 2Na\text{–}Hg \xrightarrow[4\,h,\,0°C]{THF} \underset{\mathbf{3}}{Ta_2Cl_4(PMe_3)_4H_2} + 2NaCl \quad (1)$$

at 0°C provides deep green solutions containing **3**. The latter is isolated as a dark green powder after filtration, solvent removal, extraction of the solid residue with diethyl ether, filtration, and evaporation of the filtrate. These operations provide a spectroscopically pure product in *ca* 70% yield. If only 1 equivalent of sodium amalgam is used, an approximately 1:1 mixture of **2** and **3** is obtained. There is no spectroscopic evidence (NMR or ESR) for the presumed intermediate in the reduction, $Ta_2Cl_5(PMe_3)_4H_2$.

Dimer **3** is very air-sensitive in the solid state, decomposing within seconds after exposure to laboratory air. It is soluble in ethereal and aromatic solvents, and slightly soluble in hexane. **3** decomposes rapidly in chloroform, methylene chloride and acetonitrile. Well-defined products were not obtained from these reactions. The dimeric formulation was established by an osmometric molecular weight measurement in benzene (Calc: 810; Found: 813). Attempts to obtain electron impact or chemical ionization mass spectra were unsuccessful. PMe_3 was the only gas-phase species observed.

The presence, number and location of the hydride ligands were established by NMR and IR techniques. The room-temperature 360-MHz proton NMR spectrum of **3** is shown in Fig. 1. The binomial quintet ($^2J_{PH}$ = 13.4 Hz) at δ 8.52 (area 2) is assigned to a pair of chemically and magnetically equivalent bridging hydride ligands. The resonance at δ 1.52 (area 36) is due to the methyl hydrogens of virtually coupled pseudo-*trans* PMe_3 ligands. The ^{31}P–$\{^1H\}$ NMR spectrum consists of a single resonance at δ + 1.3 which splits into a 1:2:1 triplet ($^2J_{PH}$ = 13.4 Hz) upon selective ^1H-decoupling of the proton NMR resonance at δ 1.52. No significant changes were observed in either the ^1H or ^{31}P NMR spectra on cooling toluene-d_8 solutions of **3** to −90°C.

The location of the hydride ligands in bridging positions is supported by the IR spectra (KBr disc) of $Ta_2Cl_4(PMe_3)_4H_2$ and $Ta_2Cl_4(PMe_3)_4D_2$. The former shows a band of moderate intensity at 1232 cm^{-1} which shifts to 860 cm^{-1} in the spectrum of the deuteride (ν_H/ν_D = 1.43). We assign these bands as the Ta–H(D)–Ta vibrations.

With the preceding data in hand, we initially assumed that **3** was an edge-sharing bioctahedral complex with C_{2h}-symmetry. Such a structure is reminiscent of those found[8,9] for $H_2W_2(CO)_8^{2-}$ and $H_2Re_2(CO)_8$ but it was rejected on steric grounds. In **1**, which has axial phosphines on one metal center and equatorial phosphines on the second, there is clear structural evidence for axial crowding, i.e. the axial ligands are bent back and the $TaCl_2(PMe_3)_2$ end groups twist away from each other.[4] Placing four phosphines in axial positions and (presumably) shortening the metal–metal bond (**1** → **3**) will certainly exacerbate the axial crowding problem. Space-filling molecular models show this quite clearly. The rejection of the C_{2h} structure, the only static model which satisfies the spectroscopic data, raised the obvious question and we turned to X-ray crystallography for the answer.

Solid state structure of 3

In the crystalline state, the compound is composed of discrete molecules of **3**. Final atomic coordinates and isotropic thermal parameters are

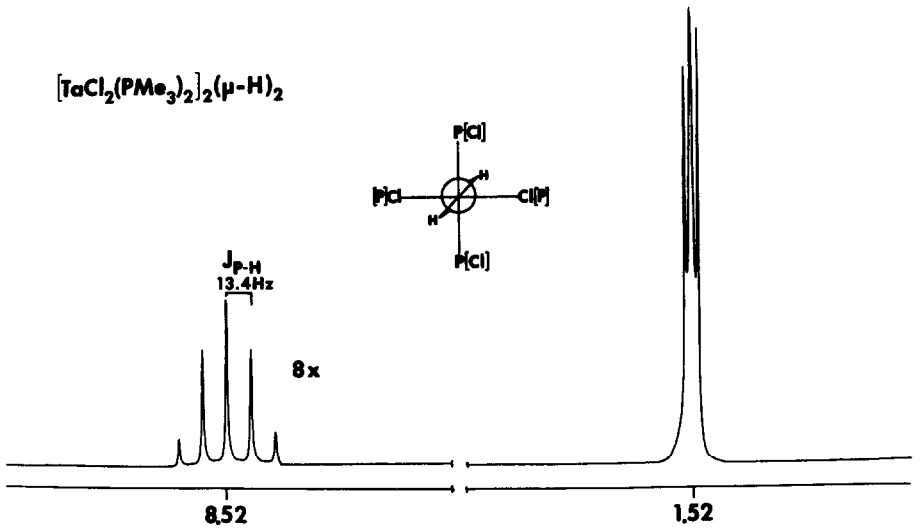

Fig. 1. 360-MHz ^{1}H NMR spectrum of $Ta_2Cl_4(PMe_3)_4H_2$. In this and the following proton NMR spectra, end-on Newman projections are included and the atoms in brackets ([ ]) are associated with the back tantalum.

[a]Fractional coordinates are $\times 10^4$ for nonhydrogen atoms and $\times 10^3$ for hydrogen atoms. B_{iso} values are $\times 10$. Isotropic values for those atoms refined anisotropically were calculated using the formula given in: W. C. Hamilton, *Acta Cryst.* 1959, **12**, 609. Parameters marked with an asterisk (*) were not varied.

listed in Table 1. Interatomic distances and angles are provided in Table 2. An ORTEP drawing of **3**, indicating the atom-numbering scheme, is shown in Fig. 2. A two-fold axis, passing through Ta(1) and Ta(2) is required by the space group.

The structure of **3**, excluding the bridging hydrides (*vide infra*), resembles those of the quadruply metal–metal-bonded group 6 dimers $Mo_2Cl_4(PMe_3)_4$ and $W_2Cl_4(PMe_3)_4$.[10] The latter also have eclipsed pyramidal $MCl_2(PMe_3)_2$ end groups and staggered PMe_3 ligands. In **3**, the Ta–Ta–Cl and Ta–Ta–P angles average 115.7[3] and 102.0[1]°, respectively.* Corresponding values in $W_2Cl_4(PMe_3)_4$ are 111.65[9] and 101.14[4]°. The Ta–Cl and Ta–P bond lengths average 2.416[2] and 2.596[4] Å, respectively. These bond distances are comparable to those found for the axial ligands in **1**. The Ta=Ta bond length of 2.545(1) Å is, by a wide margin, the shortest metal–metal double bond yet observed in diniobium or ditantalum chemistry, and it compares favorably with the W=W bond length of 2.530(2) Å found in the isoelectronic tungsten(IV) dimer $W_2S_2(S_2CNEt_2)_4$.[11]

The next feature of **3** to consider is the bridge region. There are two conceivable locations for the hydride ligands, i.e. they are either eclipsed or staggered with respect to the terminal ligands. Our prejudice for the D_2 structure (Fig. 2) is clear but it requires some justification. A careful search of the final difference Fourier map revealed only one peak ($\sim 0.8e$ Å^{-3}) which might reasonably be assigned as H_b. It was located on the diagonal plane 1.97 Å from Ta(1) and 1.86 Å from Ta(2), and the Ta–H_b–Ta angle was 83.1°. The shortest intramolecular contact was H_b–P(5) at 2.54 Å. When the position of H_b was rotated 45° into the eclipsed C_{2v}-conformation, this contact distance shortened to 2.02 Å. These observations favor the D_2 structure but there

*The number in brackets is equal to $[\Sigma_m \Delta_i^2/m(m-1)]^{1/2}$, where Δ_i is the deviation of the ith value in a set of m such values from the arithmetic mean.

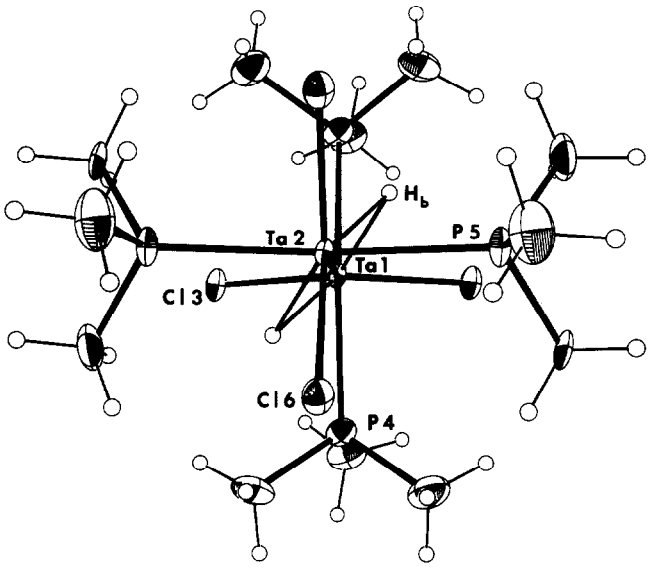

Fig. 2. ORTEP drawing of $Ta_2Cl_4(PMe_3)_4H_2$. Each nonhydrogen atom is represented by a thermal vibration ellipsoid enclosing 50% of its electron density. A crystallographic C_2-axis runs through Ta(1) and Ta(2).

are some complications. These can be summarized as follows. (1) Because of experimental difficulties (see Experimental), the X-ray data were not corrected for absorption [$\mu = 86.32\,cm^{-1}$, (Mo-K_α)]. (2) As a consequence of (1), the final difference map was not as "clean" as one would like. Several peaks of comparable or greater density than H_b were observed near the tantalum (1.5–2.1e Å^{-3}), phosphorus (<0.8e Å^{-3}) and chlorine (<0.8e Å^{-3}) atoms. (3) There are no significant distortions in the $Ta_2Cl_4(PMe_3)_4$ portion of the molecule (Table 2 and supplementary data†) which might be used as corroborating evidence for the location of H_b. In fact, given the number of possible hydride sites, one must accept the possibility that the bridging hydrides are disordered in the solid state. In view of these reservations, H_b was not included in the final stages of refinement.

A static D_2 structure cannot account for the proton NMR spectrum shown in Fig. 1 unless the two P–H coupling constants are accidentally degenerate. An alternative explanation for the apparent magnetic equivalence of $H_b(1)$ and $H_b(2)$, and the one which we favor, is rapid rotation of the bridging ligands about the Ta–Ta axis in solution. We will return to this point later on in the paper.

Reactivity of **3**

3 is very susceptible to binuclear oxidative-addition reactions. Here we describe three representative examples.

(1) Ether solutions of **3** react readily with chlorine at −20°C [eqn (2)]:

$$\underset{\mathbf{3}}{Ta_2Cl_4(PMe_3)_4H_2} + Cl_2 \xrightarrow[1\,h,\,-20°C]{OEt_2} \underset{\mathbf{2}}{Ta_2Cl_6(PMe_3)_4H_2} \quad (2)$$

and deposit a sparingly soluble green powder in 70% yield. The latter has been identified as **2** by comparison of its ^1H NMR spectrum [Fig. 3(a)] with that of an authentic sample[5] prepared by the original route (*vide supra*). As an aside, we note that there are two isomers of **2** (one with C_s-symmetry and one with D_2-symmetry) depending on the disposition of the bridging ligands. In our studies, only the C_s isomer has been detected and it does not rearrange to the D_2 isomer thermally or photochemically.

†Tables of anisotropic thermal parameters and observed and calculated structure factors for **3** and **5**, plus hydrogen atom positions and tortion angles for **3** are available from the Executive Editor, Queen Mary College, London, or the Indiana University Molecular Structure Center, upon request.

Table 2. Selected bond distances (Å) and angles (°) for $Ta_2Cl_4(PMe_3)_4H_2$

A	B	Distance	A	B	C	Angle
Ta(1)	Ta(2)	2.545(1)	Ta(2)	Ta(1)	Cl(3)	116.0(1)

			Ta(1)	P(4)	C(8)	112.3(5)
			Ta(1)	P(4)	C(9)	117.8(5)
			C(7)	P(4)	C(8)	103.6(7)
			C(7)	P(4)	C(9)	102.3(7)
			C(8)	P(4)	C(9)	102.9(7)
			Ta(2)	P(5)	C(10)	115.3(5)
			Ta(2)	P(5)	C(11)	113.1(5)
			Ta(2)	P(5)	C(12)	115.9(5)
			C(10)	P(5)	C(11)	102.2(8)
			C(10)	P(5)	C(12)	104.0(7)
			C(11)	P(5)	C(12)	104.8(9)

(2) Ether solutions of **3** also react readily with hydrogen chloride at −20°C [eqn (3)]:

$$\underset{\mathbf{3}}{Ta_2Cl_4(PMe_3)_4H_2} + HCl \xrightarrow[1\,h,\,-20°C]{OEt_2} \underset{\mathbf{4}}{Ta_2Cl_5(PMe_3)_4H_3}. \quad (3)$$

A yellow-green solid (**4**) was isolated by concentration of the suspension and cooling to −40°C (70% yield). Elemental analyses and a molecular-weight measurement suggested that **4** was $Ta_2Cl_5(PMe_3)_4H_3$. If HCl adds to **3** in the same fashion as Cl_2, we expect a dimer with C_2-symmetry. The proton and $^{31}P-\{^1H\}$ NMR spectra are in accord with this expectation. In the former [Fig. 3(b)], we observe two complex hydride multiplets, one at δ 9.68 (area 1) and the other at δ 7.69 (area 2), and two phosphine doublets (each of area 18) at δ 1.60 and 1.29. The chemically equivalent PMe_3 ligands in the C_2 structure are magnetically nonequivalent (an AA′XX′ spin system), and this is consistent with what we observe in the $^{31}P-\{^1H\}$ NMR spectrum (see Experimental).

(3) Ether solutions of **3** react slowly with hydrogen (40 psi) at 25°C [eqn (4)]:

$$\underset{\mathbf{3}}{Ta_2Cl_4(PMe_3)_4H_2} + H_2 \xrightarrow[12\,h,\,25°C]{OEt_2} \underset{\mathbf{5}}{Ta_2Cl_4(PMe_3)_4H_4}. \quad (4)$$

A yellow-green solid (**5**) was isolated from the reaction suspension by concentration and cooling to −40°C (85% yield). Elemental analyses and a molecular-weight measurement indicated that **5** was $Ta_2Cl_4(PMe_3)_4H_4$.* Addition of H_2 across the metal–metal bond of **3** should provide a dimer with D_{2d}-symmetry. The room-temperature ^1H NMR spectrum of **5** [Fig. 3(c)] supports this prediction. A single hydride multiplet is observed at δ 8.79 (area 4) together with one phosphine methyl resonance at δ 1.47 (area 36). Because the hydride resonance is not a simple first-order pattern, we propose that the hydride ligands in **5** are static, i.e. they do not rotate about the Ta–Ta axis. There was no change in the appearance of the hydride resonance up to +100°C in toluene-d_8. Higher temperatures led to decomposition. The $^{31}P-\{^1H\}$ NMR spectrum of **5** (C_6D_6, 25°C) shows a singlet at δ −1.8. Selective ^1H-decoupling of the phosphine methyl resonance broadened this peak, but we were unable to resolve any fine structure. Because the spin system is complex (AA′A″A‴XX′X″X‴), this result is not particularly surprising. Below, we provide definitive proof for the proposed structure of **5**, but first we would like to describe an alternate, and more convenient, synthesis of **5**.

Synthesis of **5** *from* $TaCl_2H_2(PMe_3)_4$

The deep red tantalum(IV) hydride complex, $TaCl_2H_2(PMe_3)_4$ (**6**) can be synthesized, in high yield (≥75%) via reduction of $TaCl_5$ with sodium

*This dimer has been prepared independently by Fellmann[12(b)] and Schrock from monomeric $Ta(CHCMe_3)(H)Cl_2(PMe_3)_3$ and molecular hydrogen.

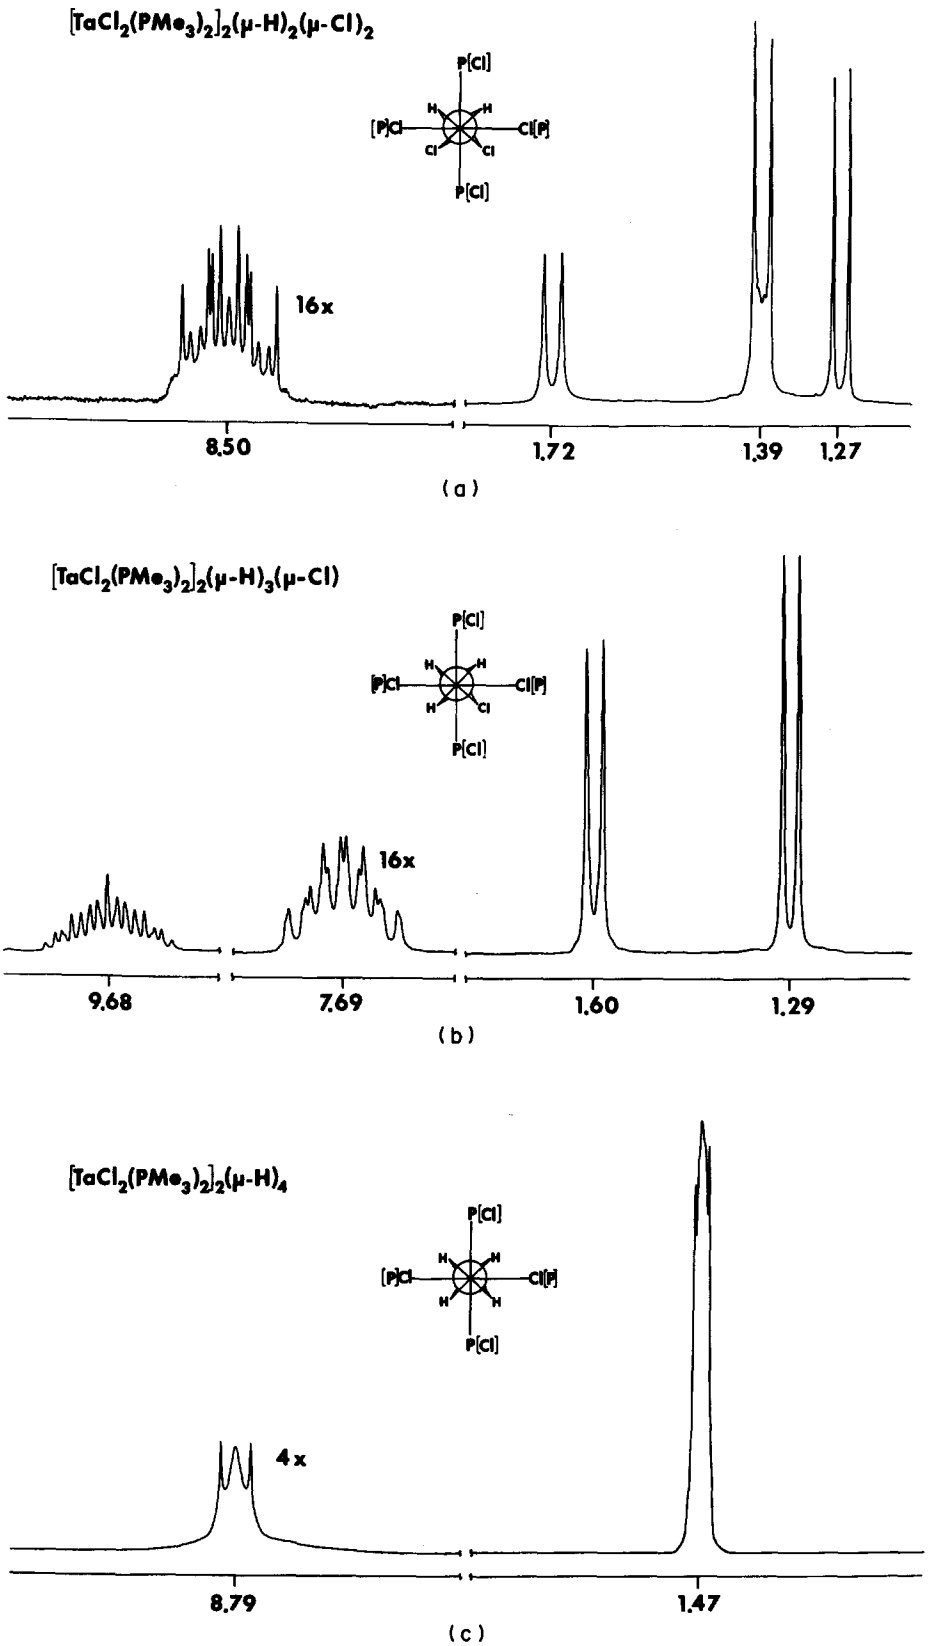

Fig. 3. 360-MHz ^{1}H NMR spectra of: (a) $Ta_2Cl_6(PMe_3)_4H_2$, (b) $Ta_2Cl_5(PMe_3)_4H_3$, and (c) $Ta_2Cl_4(PMe_3)_4H_4$.

amalgam (3 equivalents) in ether and subsequent treatment with molecular hydrogen.[13] The reduc-reduction step generates the tantalum(II) monomer, *trans*-$TaCl_2(PMe_3)_4$, which then oxidatively adds hydrogen to give the paramagnetic dihydride. The latter, as well as its 1,2-bis(dimethylphosphino)-ethane analog, $TaCl_2H_2(dmpe)_2$, have been fully characterized by solution and solid-state ESR, magnetic-susceptibility measurements, and X-ray crystallography.[13,14] As we commented earlier,[13] the isolation of **6** was quite unexpected. We thought that it would decompose to **5** and free phosphine as fast as it was formed. This prejudice was based on a popular misconception that paramagnetic early transition metal hydrides were simply too unstable to permit isolation.[15] **6** does decompose to **5** in solution at 25°C, but the reaction is very slow because the liberated trimethylphosphine inhibits further decomposition of the monomer [eqn (5)]:

$$2\underset{\mathbf{6}}{TaCl_2H_2(PMe_3)_4} \xrightarrow[25°C]{C_6H_6} \underset{\mathbf{5}}{Ta_2Cl_4(PMe_3)_4H_4} + 4PMe_3. \quad (5)$$

In an open system at higher temperatures, however, **6** decomposes readily to **5**. Refluxing methylcyclohexane (b.p. 101°C) is quite suitable for this purpose. This route is a considerable improvement over the original four-step ($TaCl_5 \rightarrow 1 \rightarrow 3 \rightarrow 5$) procedure and provides **5** in *ca* 65% yield based on tantalum pentachloride.

Solid state structure of 5

In the crystalline state, the compound is composed of discrete molecules of **5**. Final atomic coordinates and isotropic thermal parameters are listed in Table 3. Interatomic distances and angles are provided in Table 4. The molecular geometry and atom-numbering scheme are shown in Fig. 4. The pseudo-square planes of chloro and PMe_3 ligands are in the eclipsed conformation, the phosphine ligands are staggered among themselves, and the bridging H_4 group is staggered by 45° with respect to the end groups. The molecular symmetry, D_{2d}, is a *requirement* of the tetragonal space group $P4/nbm$ ($Z = 2$).

The Ta–Ta–Cl and Ta–Ta–P bond angles in **5** are 121.6(1) and 110.3(1)°, respectively. Both are more obtuse than their counterparts in **3** and the increases of 5–8° are almost certainly a reflection of the decrease in the metal–metal separation going from **3** [Ta = Ta, 2.545(1) Å] to **5** [Ta–Ta, 2.511(2) Å]. In the bridge region, the Ta–H_b distance is 1.81(21) Å and the Ta–H_b–Ta angle is 88(4)°. The only other structurally characterized $(\mu\text{-H})_4$ dimer is $Re_2H_8(PEt_2Ph)_4$.[16] Here the metal–metal separation is 2.538(4) Å, the Re–H_b distance is 1.878(7) Å, and the Re–H_b–Re angle is 85.0(3)° (neutron diffraction data).

[a]See footnote to Table 1.

Electronic structure calculations

Why is it that the briding hydrides in **5** do not rotate about the metal–metal bond axis? Why do the bridging hydrides in **3** rotate rapidly about the metal–metal bond axis? In order to answer these questions, we calculated the ground-state electronic structures of the model compounds $Ta_2Cl_4(PH_3)_4H_4$ and $Ta_2Cl_4(PH_3)_4H_2$ using the multiple-scattering Xα method.[17]* For each of these models, the calculation of Xα eigenvalues was first carried out nonrelativistically. Relativistic corrections[18] were then added, and the calculations were reconverged. Additional information on the calculations is provided in Experimental.

$Ta_2Cl_4(PH_3)_4H_4$

The results of the calculations are displayed in Fig. 5, which shows both the nonrelativistic levels and those obtained after approximate relativistic corrections were applied. The energies of the relativistic levels and the atomic contributions to them are presented in Table 5. The levels fall naturally into a number of small groups; these will be discussed in turn.

*The programs we used were written by M. Cook, Harvard University, and B. E. Bursten and G. G. Stanley, Texas A&M University. We are grateful to Professor Bruce Bursten (Ohio State University) for a copy of the programs.

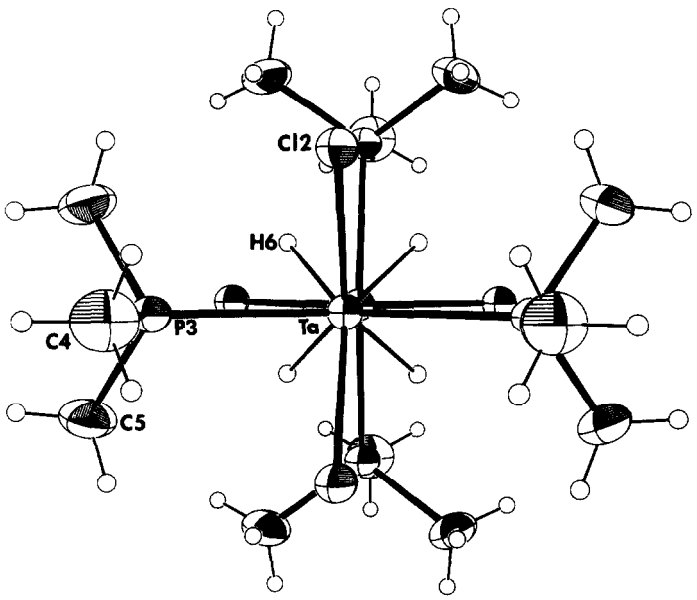

Fig. 4. ORTEP drawing of $Ta_2Cl_4(PMe_3)_4H_4$. Each nonhydrogen atom is represented by a thermal vibration ellipsoid enclosing 50% of its electron density. D_{2d}-symmetry is a space group requirement (see text).

First, we examine the highest occupied molecular orbital (HOMO) and the low-lying virtual orbitals. As seen from the breakdown in Table 5, both the HOMO ($8a_1$) and the lowest unoccupied molecular orbital (LUMO) ($3a_2$) are metal localized with modest contributions from the chloro and phosphorus ligands. A cross-section of the HOMO is shown in Fig. 6. The Ta–Ta interaction is a bonding one, arising from overlap of the $5d_{z^3}$ orbitals. There is also evidence of Ta–P bonding and Ta–Cl antibonding here. The bridging hydrogens make a negligible contribution to this level, which is clearly a Ta–Ta σ-bond. The LUMO (not pictured here) is essentially the δ^*-orbital, i.e. the out-of-phase combination of the $5d_{xy}$ orbitals on the tantalum centers. The HOMO–LUMO gap is 1.26 eV. Other virtual orbitals of note are the $7b_2$ and the $10e$. These are the Ta–Ta σ^*- and π^*-levels, respectively.

Lying below the HOMO are four groups of levels (see Fig. 5): (1) the Ta–P σ-bonding orbitals ($9e$, $7a_1$, $6b_2$; -6.5 to -7.8 eV); (2) the chlorine lone pair orbitals ($3b_1$, $8e$, $2a_2$, $7e$, $5b_2$, $6a_1$; -8.1 to -8.7 eV); (3) the Ta–Cl σ-bonding orbitals ($6e$, $5a_1$, $4b_2$; -9.0 to -9.7 eV); (4) the P–H σ-bonding orbitals ($5e$, $1a_2$, $4e$, $1b_1$, $3b_2$, $4a_1$; -11.8 to -12.0 eV). Both the ordering and the energies of these levels are in accordance with an earlier MS-Xα calculation on $W_2Cl_4(PH_3)_4$.[19]

The four remaining occupied levels in Fig. 5 and Table 5 are those which describe the σ-, π and δ-

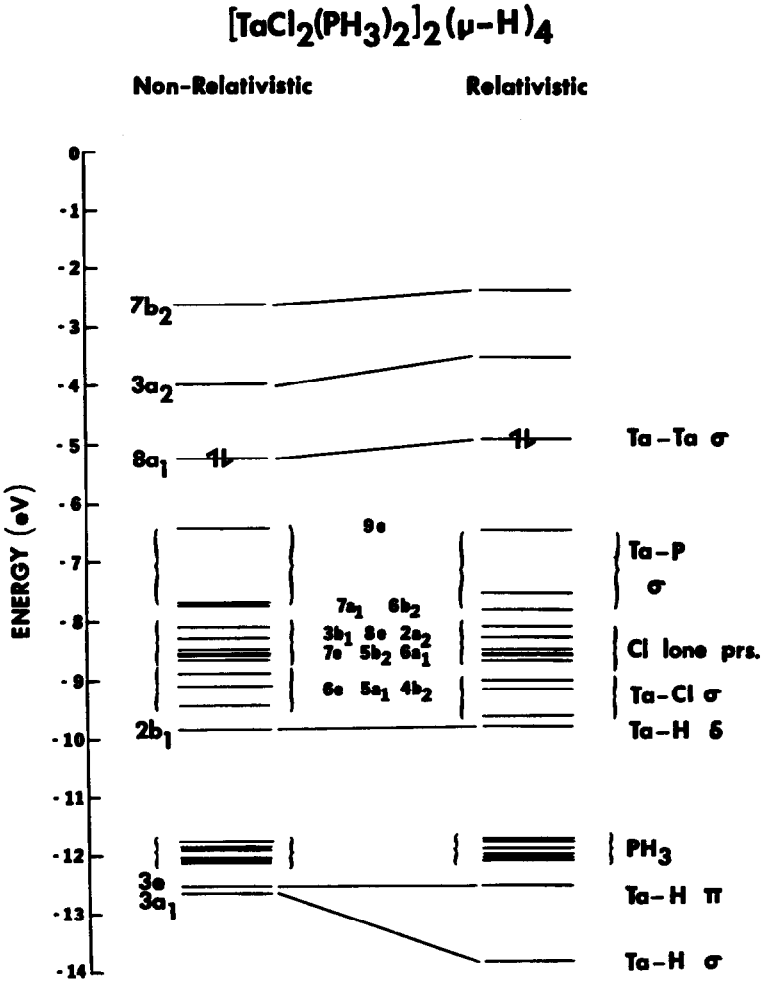

Fig. 5. Summary of the nonrelativistic and relativistic eigenvalues for the model complex $Ta_2Cl_4(PH_3)_4H_4$.

type interactions between the tantalum atoms and the four bridging hydride ligands. The lowest-lying of these is the $\sigma(3a_1, -13.9\,eV)$ and a cross-section of this level is shown in Fig. 7. The interaction here is between the in-phase combination of all four hydrogen 1*s* orbitals, and a pair of tantalum hybrid orbitals (62% 6*s*, 23% $6p_z$ and 14% $5d_{z^2}$). The substantial tantalum 6*s* character in this level is responsible for its marked stabilization. Note also that this is the only level which drops dramatically in energy when relativistic corrections are introduced into the calculations (see Fig. 5). This extra stabilization of the $3a_1$ level is a direct consequence of its high tantalum *s* + *p* character.[20]

At somewhat higher energy are the degenerate π-type levels (3*e*, −12.5 eV), one of which is shown in Fig. 8. Here we have another strong, stabilizing interaction. This one is primarily between the tantalum $5d_{\pm 1}$ orbitals (note the lobular structure about each Ta) and an antisymmetric combination of hydrogen 1*s* orbitals. Finally, at −9.8 eV, we find the $2b_1$ or δ-type level. In-phase overlap of the tantalum $5d_{xy}$ orbitals with the bridging ligand orbitals is the genesis of this level. A cross-section of the $2b_1$ level shows the δ-symmetry quite clearly (Fig. 9).

Now that we have a good picture of the M–M and M–H–M interactions in $Ta_2Cl_4(PH_3)_4H_4$, we are in a position to address the question of $(\mu\text{-H})_4$ rotation in **5**. The σ- and π-interactions are cylindrically symmetric with respect to the Ta–Ta axis and do not engender a conformational preference for the bridging hydride ligands. The same cannot be said for the TaH_4Ta δ-interaction. This bridge bonding component will stabilize the staggered hydride conformation relative to the eclipsed hydride conformation.* Unfortunately, ground-state calculations of the type reported here

*Similar conclusions have been reached in the case of $Re_2H_8(PH_3)_4$, a model for $Re_2H_8(PEt_2Ph)_4$.[16,21]

[a]Chlorine 3*s*, phosphorus 3*s*, and core levels have been omitted. The HOMO is $8a_1$. H1 and H2 refer to the out-of-plane and in-plane PH_3 hydrogens, respectively (see text). H3 refers to the bridge hydrogens.

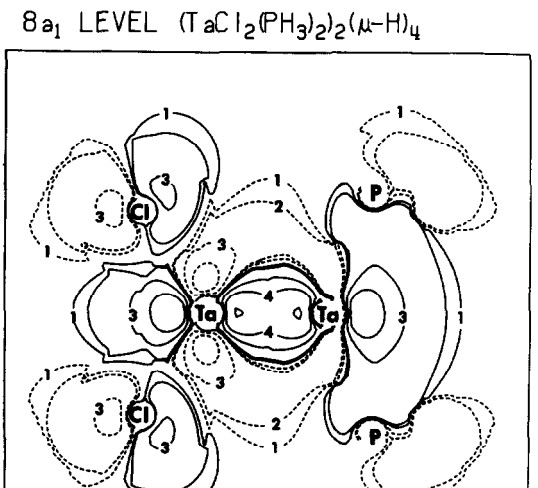

Fig. 6. Cross-section of the $8a_1$ level (HOMO) of $Ta_2Cl_4(PH_3)_4H_4$. For this and all other diagrams, solid lines represent positive wave function values and dashed lines represent negative values. The number 1 represents 0.005 electrons bohr^{-3}, and each succeeding number represents a factor of two increase in electron density, except for 7, which stands for 0.22 electron bohr^{-3}.

do not provide any information on the energetics of $(\mu\text{-H})_4$ rotation about the metal–metal bond. All we can say is that our inability to effect an averaging of spin couplings in **5** from 25 to 100°C is consistent with the presence of a substantial δ-interaction which effectively "locks" the hydride ligands into the staggered conformation. Hoffmann and co-workers[21] have calculated (using extended Hückel methods) a 35 kcal mol^{-1} barrier to $(\mu\text{-H})_4$ rotation in $Re_2H_8(PH_3)_4$, a model for structurally characterized $Re_2H_8(PEt_2Ph)_4$[16] whose $(\mu\text{-H})_4$ group is also staggered by 45° with respect to its eclipsed pyramidal $ReH_2(PEt_2Ph)_2$ end groups. We do not expect a significant difference between $(\mu\text{-H})_4$ rotation barriers in the rhenium(IV) and tantalum(IV) dimers because the orbitals which are depopulated (Re → Ta) are essentially pure M–M σ^*- and δ^*-orbitals and are therefore unaffected by $(\mu\text{-H})_4$ rotation. Note that a barrier greater than *ca* 20 kcal mol^{-1} is all that is required to account for our failure to observe an averaging of spin couplings at +100°C.

$Ta_2Cl_4(PH_3)_4H_2$

The overall electronic structure of this D_2 model compound is quite similar to that of the quadruply

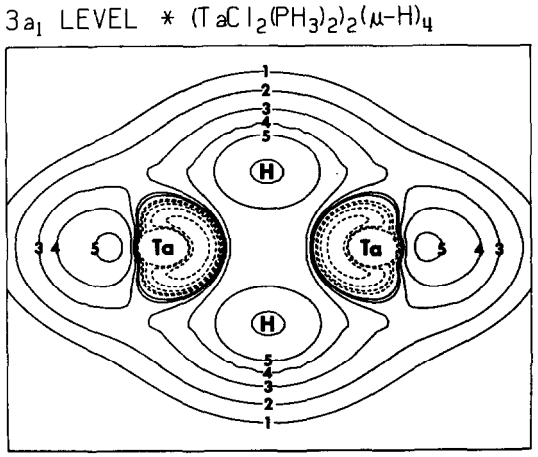

Fig. 7. Cross-section of the $3a_1$ level (Ta–H σ-interaction) of $Ta_2Cl_4(PH_3)_4H_4$.

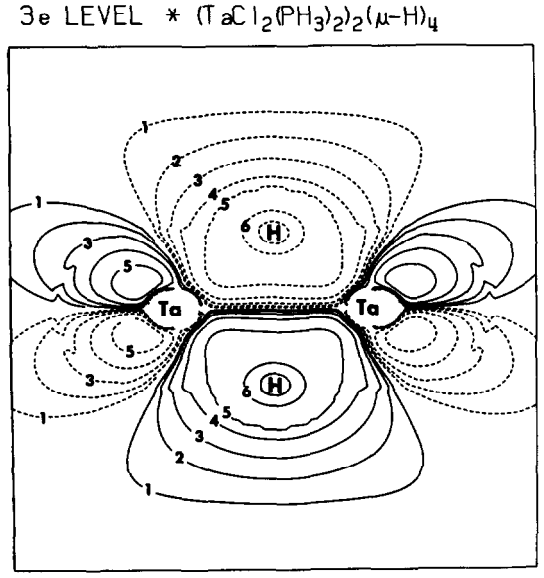

Fig. 8. Cross-section of one component of the $3e$ level (Ta–H π-interaction) of $Ta_2Cl_4(PH_3)_4H_4$.

hydrogen-bridged D_{2d} dimer described above and *we will not discuss it in detail. Rather, the focus* here will be specific changes brought about by removal of two bridging hydrides.

The relativistic energy eigenvalues obtained for $Ta_2Cl_4(PH_3)_4H_2$ are listed in Table 6. Figure 10 is a correlation diagram showing schematically how the Ta–H–Ta interactions change in going from $Ta_2Cl_4(PH_3)_4H_4$ to $Ta_2Cl_4(PH_3)_4H_2$. The σ-interaction remains strong. A cross-section of the $5a$ level of the $(\mu\text{-H})_2$ dimer is very similar to the $3a_1$ level of $Ta_2Cl_4(PH_3)_4H_4$. The most striking change can be seen in the splitting of the π-levels. In the $(\mu\text{-H})_4$ dimer, we have two equivalent TaH_2Ta π-interactions. Removal of a pair of *trans* hydrides

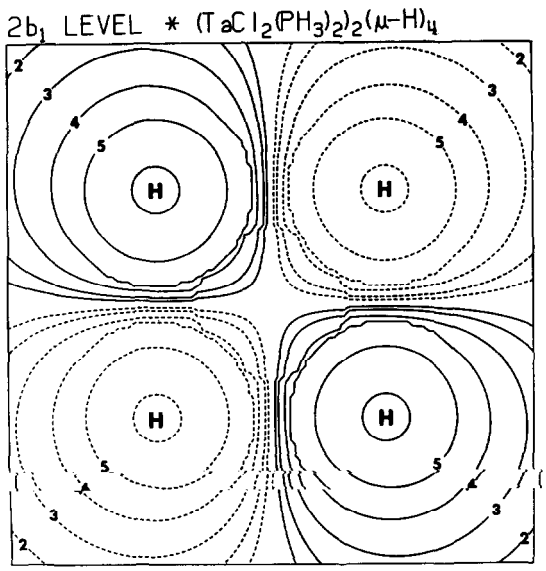

Fig. 9. Cross-section of the $2b_1$ level (Ta–H δ-interaction) of $Ta_2Cl_4(PH_3)_4H_4$, through the four bridging hydride ligands.

from the bridge leaves us with only one and a pair of tantalum $5d_{\pm 1}$ orbitals which overlap to form a weak metal–metal π-bond. The Ta–Ta π-bonding level [$9b_3$ (Fig. 11)] is the HOMO of $Ta_2Cl_4(PH_3)_4H_2$, lying slightly above the Ta–Ta σ-bonding $10a$ level. Finally, we note that the bridge hydrogens of $Ta_2Cl_4(PH_3)_4H_2$ no longer possess a representation of δ-symmetry and, consequently, there is no TaH_2Ta δ-interaction. The δ-level ($2b_1$) of $Ta_2Cl_4(PH_3)_4H_4$ becomes the LUMO ($9b_1$) of $Ta_2Cl_4(PH_3)_4H_2$ and loses all of its hydride character. It is now the (virtual) metal–metal δ-bonding level. The loss of a δ-interaction involving the bridge hydrogens removes the electronic barrier to hydride rotation which was indicated for the $(\mu\text{-H})_4$ dimers (*vide supra*). As a consequence, we expect the barrier for $(\mu\text{-H})_2$ rotation about the Ta–Ta axis of **3** to be lower in energy than the barrier for *$(\mu\text{-H})_4$ rotation about the Ta–Ta axis of* **5**. The proton NMR spectrum of $Ta_2Cl_4(PMe_3)_4H_2$ (Fig. 1) and our inability to effect hydride magnetic nonequivalence in the temperature range -90 to $+25$°C are consistent with this hypothesis and indicate that the barriers differ by at least 10 kcal·mol^{-1}.

DISCUSSION

The preparation of metal–metal-bonded *niobium(III) and tantalum(III) dimers by sodium* amalgam reduction of higher-valent halides or their complexes has ample precedent. The synthesis of

[a]See footnote to Table 5. The HOMO is $9b_3$.

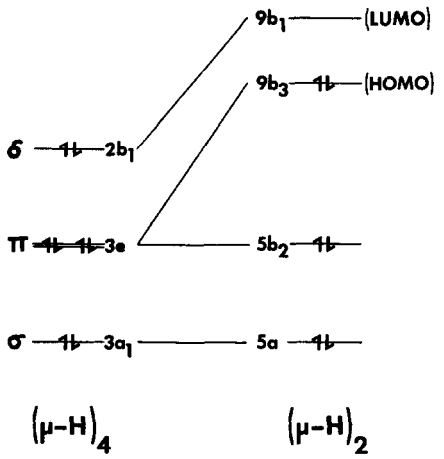

Fig. 10. Schematic correlation diagram uniting the Ta–H interactions in the $(\mu\text{-H})_4$ and $(\mu\text{-H})_2$ dimers.

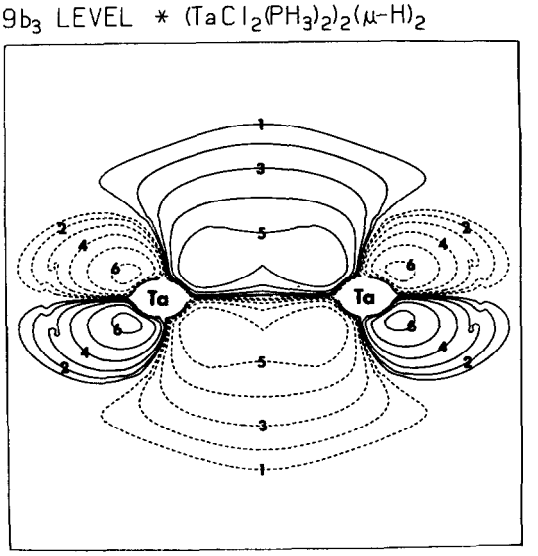

Fig. 11. Cross-section of the $9b_3$ level (HOMO) of $Ta_2Cl_4(PH_3)_4H_2$.

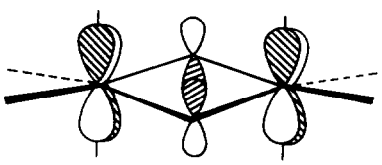
$Ta_2Cl_6(PMe_3)_4$ from $TaCl_5$ was mentioned in the Introduction, but the approach is due to Maas and McCarley.[22] In 1973, these authors prepared a series of $Nb_2X_6(THT)_3$ complexes (X = Cl, Br or I;

THT = tetrahydrothiophene) by Na–Hg reduction of $NbX_4(THT)_2$ in benzene. The synthesis of **3** reported here is novel only in the sense that precursor **2** is a well-defined, metal–metal-bonded tantalum(IV) dimer. The structure of **3**, on the other hand, is unprecedented in niobium(III) or tantalum(III) dimer chemistry. The chloro-bridged species, **1** and $Ta_2Cl_6(dmpe)_2$,[23] adopt edge-sharing bioctahedral geometries while the $M_2X_6(SR_2)_3$ dimers prefer confacial bioctahedral structures.[24]

We can understand the structure of **3** in terms of the following hypothetical transformation. Replacement of the bridging halogens in **1** with smaller hydride ligands must shorten the Ta–Ta separation because effective Ta–H bonding requires that the metals be brought into closer proximity to each other. This, in turn, forces the terminal ligands into pyramidal arrangements to relieve axial–axial interactions. In addition, replacement of the chlorides destroys the δ-interaction shown below, which locks **1** into the edge-sharing geometry. Recall that the hydride ligands in **3** do not possess a representation with δ-symmetry and, therefore, are not constrained to a specific location about the Ta–Ta axis.



Dimer **3** is the only metal–metal multiply bonded system which reacts readily and cleanly with Cl_2, HCl *and* H_2.* These substrates add across the Ta=Ta bond, decreasing the bond order from two to one, and there are none of the gross structural rearrangements which usually accompany oxidative-addition reactions in metal–metal-bonded complexes.[26] Our observation that only the C_s isomer of **2** is formed in the chlorination reaction also suggests that the addition of X_2 to **3** is a concerted process.

The X-ray structure of dimer **5** confirms that H_2 addition is across the Ta–Ta bond of **3** and also shows the combined effect of four strong Ta–H–Ta interactions on the Ta–Ta separation. The Ta–Ta bond length in **5** is *ca* 0.03 Å shorter than found in **3**, where we have no δ-interaction and only one π-type TaH_2Ta interaction.

The electronic structure calculations on $Ta_2Cl_4(PH_3)_4H_4$ and $Ta_2Cl_4(PH_3)_4H_2$ complement our structural and spectroscopic studies on **3** and **5**. We now have some appreciation of the electronic factors which influence hydride rotation in these systems, and the calculations support the assignments of Ta–Ta bond orders in **3** and **5**. The MS-Xα results can also be used to interpret the optical spectra of **3** and **5**, but this is another story and one which we will relate in a future paper in this series.

The synthesis of **3** and **5** naturally call for a comment on the possible existence of $Ta_2Cl_4(PMe_3)_4$, since the $(\mu\text{-H})_2$ and $(\mu\text{-H})_4$ complexes are the sequential hydrogenation products of this tantalum(II) dimer. *A priori*, we have no reason to believe that $Ta_2Cl_4(PMe_3)_4$ should not exist and efforts to prepare it, or an analogue, continue in our laboratory at Los Alamos. Neither reduction of **1** nor thermolysis of *trans*-$TaCl_2(PMe_3)_4$[27]† have yielded this dimer, but there are other possibilities which merit investigation, e.g. thermally induced reductive elimination of H_2 from **3**, and these are being pursued.

We would be remiss not to mention the recent success of the Cotton group[28] in preparing and structurally characterizing the face-sharing bioctahedral tantalum(II) dimer, $[Ta_2Cl_6(\mu\text{-THT})_3]^2$. The isolation of this material, which contains a formal metal–metal triple bond [Ta–Ta 2.626(1) Å], provides further impetus in the search for molecules containing unbridged Ta–Ta triple bonds.

EXPERIMENTAL

Reagents

Tantalum pentachloride was purchased from Pressure Chemical and sublimed under high vacuum to remove nonvolatile impurities. $Ta_2Cl_6(PMe_3)_4H_2$, $Ta_2Cl_6(PMe_3)_4D_2$ and $TaCl_2H_2(PMe_3)_4$ were prepared and purified by literature procedures.[5,13] Hydrogen (Air products, 99.995%) and deuterium (Linde, 99.5%) were used as received. Chlorine and hydrogen chloride (both from Matheson) were dried by passage through concentrated sulfuric acid.

THF, ether and glyme were dried and freed from dissolved molecular oxygen by distillation under argon from a solution of the solvent, benzophenone, and sodium or potassium. *n*-Hexane was purified

*The Mo–Mo bond of $[CpMo(CO)_2]_2$ will add HI and I_2 thermally but not H_2.[25]

†Thermolysis of *trans*-$TaCl_2(PMe_3)_4$ in refluxing cyclohexane leads to disproportionation and hydride abstraction from the solvent.[27(b)]

by stirring over saturated $KMnO_4$ in 10% sulfuric acid (2 × 6 h). It was then sequentially washed with water, saturated aqueous Na_2CO_3 and water, dried over $MgSO_4$, filtered and distilled under argon from sodium–potassium alloy.

Physical and analytical measurements

Elemental analyses and molecular-weight measurements were performed by Galbraith Laboratories, Knoxville, TN.

IR spectral measurements were made on a Perkin–Elmer Model 1330 spectrometer. Samples were run as KBr discs. NMR spectra were run on Bruker WM-360 and JEOL FX90Q spectrometers. ^{31}P spectra were recorded at 36.20 or 145.80 MHz, and ^1H spectra at 360.1 MHz. Benzene-d_6 was used as a lock solvent for most spectra. Phosphorus chemical shifts (δ) are reported relative to external 85% aqueous H_3PO_4. Negative chemical shifts are assigned to resonances at lower frequency (higher field) than the reference.

General synthetic procedures

Manipulations of air-sensitive reagents and solutions and the workup of reaction products were usually performed within the confines of a helium-filled Vacuum Atmospheres Dri-Lab (HE-43). The latter is equipped with a high capacity Dri-Train (MO-40V), and a Dri-Cold Freezer maintained at −40°C.

$Ta_2Cl_4(PMe_3)_4H_2$ (3)

Inside the drybox, $Ta_2Cl_6(PMe_3)_4H_2$ (3.0 g, 3.41 mmol) was added to 150 cm^3 of THF in a two-neck, 250-cm^3 Morton flask, equipped with a mechanical stirrer and N_2-gas inlet. Sodium amalgam (2.5 cm^3 of 0.5% amalgam, 7.35 mmol of Na) and mercury (8 cm^3) were added and the flask was removed from the drybox. The flask was connected to a source of argon, cooled to 0°C in an ice–salt bath, and the reaction mixture was stirred *vigorously* for 4–5 h. The yellow-green suspension turned dark green during this period. The flask was returned to the drybox, the contents were filtered through *ca* 1 inch of Celite on a 60 cm^3 medium porosity sintered glass frit, and the flask was rinsed with 50 cm^3 of fresh THF. The combined filtrate was stripped to dryness and the solid residue was extracted with diethyl ether (4 × 50 cm^3). After filtration, the combined extracts were stripped to dryness, providing **3** as a dark green powder. Yield 2.01 g (73%).

An analytical sample was obtained by recrystallization from a concentrated ether solution at −40°C.

Calc. for $Ta_2Cl_4(PMe_3)_4H_2$ ($C_{12}H_{38}Cl_4P_4Ta_2$): C, 17.8; H, 4.7; Cl, 17.5%; M_r, 810. Found: C, 17.8; H, 4.7; Cl, 17.8%; M_r, 813.

IR (cm^{-1}): 1232 (m, $\nu_{Ta-H-Ta}$).

^1H NMR (ppm, C_6D_6): 8.52 (quin, 2, J_{PH} = 13.4 Hz, H_b), 1.52 [t, 36, J_{PH} = 3.8 Hz, $P(CH_3)_3$].

^{31}P NMR (ppm, C_6D_6, selective $\{^1H\}$ at 1.52): +1.3 (t, J_{PH} = 13.4 Hz)

The deuteride, $Ta_2Cl_4(PMe_3)_4D_2$, was prepared from $Ta_2Cl_6(PMe_3)_4D_2$ in a similar fashion. IR (cm^{-1}): 860 ($\nu_{Ta-D-Ta}$).

$Ta_2Cl_6(PMe_3)_4H_2$ (2) *from* 3

A 0.25 g (0.31 mmol) sample of **3** was dissolved in 30 cm^2 of ether in a 100-cm^3 Schlenk flask equipped with a N_2-gas inlet, pressure-equalizing dropping funnel and a magnetic stir bar. The solution was cooled to −20°C in a dry ice–acetone bath and 30 cm^3 of a 0.01 M Cl_2–ether solution was added dropwise over the course of 0.5 h. A light green powder precipitated during the addition. The suspension was stirred for an additional 0.5 h at −20°C. Approximately half the ether was removed *in vacuo* and the solid was collected by filtration, washed with hexane (2 × 10 cm^3) and dried. Yield 0.91 g (70%). The spectroscopic properties (NMR and IR) of this material were identical to those reported for **2**.[5] The filtrate was stripped to dryness and checked by NMR. **2** and a trace of unreacted **3** were the only materials detected.

$Ta_2Cl_5(PMe_3)_4H_3$ (4)

A 0.60-g (0.74-mmol) sample of **3** was dissolved in 40 cm of ether in a 100-cm^3 Schlenk flask, equipped as noted above. The solution was cooled to −20°C and 30 cm^3 of a 0.025 M HCl–ether solution was added dropwise over the course of 0.5 h. A light green solid precipitated during the addition. When the latter was complete, the reaction mixture was stirred for an additional 0.5 h at −20°C. Half of the ether was then removed *in vacuo* and the suspension was cooled to −40°C for several hours. The product was filtered, washed with hexane (2 × 10 cm^3) and dried *in vacuo*. Yield 0.45 g (72%). An analytical sample was obtained by recrystallization from ether at −40°C.

Calc. for $Ta_2Cl_5(PMe_3)_4H_3$($C_{12}H_{39}Cl_5P_4Ta_2$): C, 17.0; H, 4.6; Cl, 20.9%; M_r, 846.5. Found: C, 16.9; H, 4.6; Cl, 21.0%; M_r, 853.

IR(cm^{-1}): 1260 (m, $\nu_{Ta-H-Ta}$).

^1H NMR (ppm, C_6D_6): 9.68 (complex m, 1, H_b), 7.69 (complex m, 2, H_b'), 1.60 [d, 18, J_{PH} = 9.3 Hz,

$P(CH_3)_3]$, 1.29 [d, 18, $J_{PH} = 8.8$ Hz, $P'(CH_3)_3]$.

^{31}P NMR (ppm, C_6D_6, $\{^1H\}$): +8.45 [m, 1, $P(CH_3)_3$, $J_{AX} + J_{AX'} = 28.7$ Hz], −13.34 [m, 1, $P'(CH_3)_3$, $J_{AX} + J_{AX'} = 28.7$ Hz].

$Ta_2Cl_4(PMe_3)_4H_4$ (5)

Method A. A 1.00-g sample of **3** was dissolved in 50 cm^3 of ether in a 90-cm^3 Fischer–Porter pressure vessel. The latter was sealed, removed from the drybox, and connected to a source of hydrogen and vacuum. The bomb was evacuated and back-filled with H_2 (40 psi). After 12 h, the bomb was vented, returned to the drybox and half the ether was removed *in vacuo*. The light green suspension was cooled to −40°C for several hours. The product was filtered off, washed with hexane (2 × 10 cm^3) and dried *in vacuo*. Yield 0.85 g (85%). An analytical sample was obtained by recrystallization from ether at −40°C.

Calc. for $Ta_2Cl_4(PMe_3)_4H_4(C_{12}H_{40}Cl_4P_4Ta_2)$: C, 17.8; H, 5.0; Cl, 17.5%; M_r, 812. Found: C, 17.6; H, 5.0; Cl, 17.4%; M_r, 799.

IR (cm^{-1}): 1225 (m, $\nu_{Ta-H-Ta}$).

^1H NMR (ppm, C_6D_6): 8.79 (m, 4, H_b), 1.47 [t, 36, $J_{HP} = 4$ Hz, $P(CH_3)_3]$.

^{31}P NMR (ppm, C_6D_6, $\{^1H\}$): −1.8 (s).

Method B. A freshly recrystallized sample of **6** (2.0 g, 2.6 mmol) was transferred to a 100-cm^3 Schlenk flask containing *ca* 40 cm^3 of methylcyclohexane. The flask was fitted with a reflux condenser and the red suspension was heated at reflux (101°C) for 2 h under a slow argon flush. Over the course of the thermolysis, the color of the suspension turned pale green. The suspension was then cooled to −40°C for several hours, filtered, and the product was washed with hexane (2 × 5 cm^3) and dried *in vacuo*. Yield 1.3 g (89%). The purity of **5** synthesized by this route should be checked by proton NMR. If any **3** is detected, the entire yield is placed in a 90 cm^3 Fischer–Porter pressure vessel together with 20 cm^3 of ether and the vessel is pressurized (40 psi) with H_2 for several hours. The pure product is then isolated by removal of the solvent in vacuo.

X-ray structure determinations

General procedures were the same as those described previously.[29]

$Ta_2Cl_4(PMe_3)_4H_2$. Crystals of **3** were grown by slow cooling of concentrated glyme solutions. The bulk sample consisted of well-formed green-black crystals of various sizes. Attempts to use the smaller crystals for data collection were unsuccessful; omega scans were in excess of 2°. Several of the larger crystals were then fractured and examined. In most cases twinning occurred, yielding cells with equivalent *a*- and *c*-axes, and considerable peak splitting. After numerous attempts, an irregularly-shaped fragment of maximum dimension 0.06 mm was obtained which was not twinned, and data were collected using it. The sample manipulation and mounting were performed in a nitrogen-filled glove bag and the sample was transferred to the goniostat (under N_2) and cooled to −160°C for characterization and data collection (see supplementary data).

The structure was solved by a combination of direct methods, Patterson techniques, and difference Fourier techniques, and refined by full-matrix least squares. All nonhydrogen atoms were located, and their positional and thermal parameters (anisotropic) refined. The molecule lies on a crystallographic two-fold axis and no disorder is apparent in the nonhydrogen positions. Hydrogen atoms, excluding the bridging hydride, were located in a difference Fourier synthesis and refined isotropically. Several of the hydrogen thermal parameters are rather large, and the distances and angles involving the methyl hydrogens indicate they are poorly located.

A final difference Fourier indicated several peaks of density between 0.8 and 2.1e Å^{-3}. While one of these peaks was located in the bridge region, there was sufficient doubt as to preclude its inclusion in the refinement.

$Ta_2Cl_4(PMe_3)_4H_4$. Crystals of **5** were grown by slow cooling of concentrated THF solutions. Inside a nitrogen-filled glove bag, a green block was mounted on a glass fiber, and then transferred to the goniostat where it was cooled to −165°C. The structure was solved by Patterson and Fourier techniques, and refined by full-matrix least squares. The data were corrected for the effects of absorption. All nonhydrogen atoms were located and their positional and anisotropic thermal parameters refined. A difference Fourier synthesis, phased on the nonhydrogen atom parameters, revealed peaks which could be assigned as the hydrogens. When all of these were included in the refinement, two of the methyl group hydrogens failed to converge. For this reason, *all* methyl hydrogens were placed in fixed positions and only the bridging hydrogen was refined. A final difference Fourier map was essentially featureless, the largest peaks being *ca* 0.6e Å^{-3}, located near the tantalum and chlorine atoms. Crystal data are given in Table 7.

Calculations

The multiple-scattering Xα method was applied to the model compounds $Ta_2Cl_4(PH_3)_4H_2$ and $Ta_2Cl_4(PH_3)_4H_4$. Values of α were taken from

Schwartz,[30] except for hydrogen ($\alpha = 0.77725$)[31] and tantalum, whose α value was extrapolated from Schwartz as 0.69319.[32] For inter- and outer-sphere regions, values of α were calculated as valence-electron weighted averages of the atomic α values.

The starting molecular potentials were a superposition of the Herman–Skillman atomic potentials[33] of the neutral atoms. Atomic spheres were allowed to overlap in accordance with the scheme of Norman.[34] The final radii were chosen as 89% of the atomic number radii. In each calculation, the outer sphere was chosen to be tangent to the outermost atomic sphere.

Coordinates were calculated using the crystallographic data for the individual trimethyl phosphine species. The bond distances and bond angles used for $Ta_2Cl_4(PH_3)_4H_4$ were: Ta–Ta, 2.511 Å; Ta–Cl, 2.461 Å; Ta–P, 2.604 Å; Ta–H, 1.81 Å; Ta–Ta–P, 110.3°; Ta–Ta–Cl, 121.6°; Ta–H–Ta, 88°; P–H, 1.415 Å; Ta–P–H, 110.3°. The geometry was idealized to D_{2d}-symmetry. The corresponding data for the $(\mu\text{-H})_2$ dimer were: Ta–Ta, 2.545 Å; Ta–Cl, 2.416 Å; Ta–P, 2.596 Å; Ta–H, 1.85 Å; Ta–Ta–P, 102°; Ta–Ta–Cl, 116°; Ta–H–Ta, 87°. The PH_3 data were the same as given above and the geometry was idealized to D_2-symmetry.

The molecules were each placed in a coordinate system with its origin at the midpoint of the Ta–Ta bond, the Z-axis colinear with the Ta–Ta bond and the XZ and YZ planes each chosen to include four terminal ligand atoms. Each PH_3 ligand was oriented about the Ta–P bond such that each distal hydrogen atom was in the XZ or YZ plane.

Partial waves up to $l = 0, 2, 2, 3$ and 4 were used for H, P, Cl, Ta and outer sphere, respectively.

For each molecule the calculation of the Xα eigenvalues was first carried out nonrelativistically, until consecutive values of the SCF potential differed by less than 0.001 Ry. Relativistic corrections, viz. Darwin and mass–velocity terms for both core and valence metal orbitals,[21] were then added and the calculation was reconverged.

Acknowledgments—We are grateful to the National Science Foundation for support of this research and to Wrubel Computer Center, Indiana University, for a generous gift of computing time. AJS and APS would like to thank Professor B. E. Bursten (Ohio State) for helpful discussions on the MS-Xα method.

REACTIONS OF THE METAL–METAL TRIPLE BOND IN $Cp_2Mo_2(CO)_4$ AND RELATED COMPLEXES

M. DAVID CURTIS

Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109, U.S.A.

(*Received* 19 *November* 1986)

Abstract—The reactions of the M≡M triple bonds in compounds of type $Cp_2M_2(CO)_4$ (M = Cr, Mo or W) are reviewed. These reactions are grouped under the headings of synthesis and structures of $Cp_2M_2(CO)_4$-type compounds, nucleophilic additions to the M≡M bonds, reactions with 1,3-dipoles, oxidative reactions with nonmetals, and cluster-building reactions. Literature coverage is until the end of 1985 with 102 references.

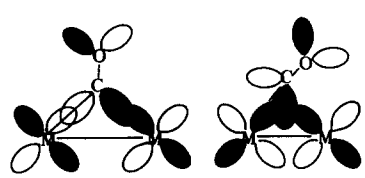
Our discovery of a simple, high-yield synthesis of the triply-bonded compound $Cp_2Mo_2(CO)_4$ (**1**) and our subsequent demonstration of the diverse chemistry associated with the Mo≡Mo triple bond has stimulated the use of this and related compounds in many new areas. In the 5 years since we first reviewed[1] the chemistry of **1**, the molecule has continued to attract interest and is now a standard, more reactive alternative to $Cp_2Mo_2(CO)_6$ as a starting material in CpMo chemistry.

Most of the new chemistry has been reported for (**1**) or $Cp^*_2Mo_2(CO)_4$ (**2**) ($Cp^* = C_5Me_5$). $Cp_2Cr_2(CO)_4$ shows a disappointing lack of reactivity associated with the Cr≡Cr triple bond, per se, and $Cp_2W_2(CO)_4$ seems to parallel its Mo congener in much of its chemistry. This article reviews work which has been published since the last review[1] as well as unpublished work from the author's laboratory. In order to present a comprehensive picture, some overlap with the previous article occurs here. The literature coverage extends to the end of 1985.

SYNTHESIS AND STRUCTURES OF $Cp_2Mo_2(CO)_4$-TYPE COMPOUNDS

The structure of **1** was shown to have a linear Cp–Mo–Mo–Cp skeleton and four semi-bridging carbonyls.[2] The semi-bridging carbonyls are linear, as opposed to the nonlinear M–CO structure usually associated with semi-bridging carbonyls. It was proposed that these two classes of semi-bridging carbonyls represented donor (linear) and acceptor (nonlinear) interactions.[3,4]

An EHMO calculation for **1** indicated the linear, semi-bridging COs were election acceptors, although no rationale for the bent vs linear classification was proposed.[5] Hall and coworkers[6] have recently reported a PES study of $Cp_2M_2(CO)_4$ (M = Cr, Mo or W) and also have addressed the question of linear vs bent semi-bridging carbonyl groups with Fenske–Hall MO calculations.[6] They find that the geometry of the bridging CO is determined by the nature of the HOMO associated with the metal–metal interaction. If the HOMO is a π^*-orbital (as is usually the case for M–M single bonds between late transition metals), the M–C–O group is bent (**A**), whereas if the HOMO is an M–M π-bond, the M–C–O group is nearly linear (**B**). The calculations show a nest of tightly spaced M–M orbitals of σ-, δ-, δ^*-, π_{xz}- and π_{yz}-symmetry, and are consistent with the observed PES.



A **B**

The mechanism of the formation of **1** from the thermolysis of a solution of $Cp_2Mo_2(CO)_6$ has been shown[7] to involve loss of CO *without* M–M bond homolysis as originally proposed.[8] The presumed intermediate, $Cp_2Mo_2(CO)_5$, has been observed in a matrix.[9]

The structure of **2** has been determined and shown to have a bent Cp*–Mo–Mo–Cp* axis (ω = 168°).[10] The Mo≡Mo bond length [2.488(3) Å] is somewhat longer than the 2.448(1) Å observed for **1**.[2]

The compound originally reported[11] as (indenyl)$_2$Mo$_2$(CO)$_6$ has been shown by X-ray crystallography to be the triply-bonded tetracarbonyl In$_2$Mo$_2$(CO)$_4$ (**3**).[12] The overall structure closely resembles that of **2** in that only two of the four COs are semi-bridging and the InMoMoIn axis is nonlinear (Fig. 1). The Mo≡Mo distance is 2.500(1) Å. The triply-bonded tetracarbonyl reacts readily with CO at room temperature to give authentic In$_2$Mo$_2$(CO)$_6$.[12] The latter is also obtained from ferricenium ion oxidation of InMo(CO)$_3^-$ [eqn (1)].[12(b),(c)] Thermolysis of the purified hexacarbonyl dimer gives the highest yields of triply-bonded **3** [eqn (2)]:

$$2\mathrm{InMo(CO)_3^-} + 2\mathrm{Cp_2Fe^+} \longrightarrow \mathrm{In_2Mo_2(CO)_6} \qquad (1)$$

In = η^5-indenyl

$$\mathrm{In_2Mo_2(CO)_6} \xrightarrow[-2\mathrm{CO}]{110-140^\circ\mathrm{C}} \mathrm{In_2Mo_2(CO)_4} \qquad (2)$$

(3)

To date, no "indenyl effect" on the reactivity of **3** *vis-à-vis* **1** has been observed, probably because the unsaturation inherent in the Mo≡Mo triple bond overides any such effect.[12(c)]

Oxidation of the TpMo(CO)$_3^-$ anion with Cp$_2$Fe$^+$ gives the *mono*nuclear, 17e radical TpMo(CO)$_3$ (**4**) (Tp = hydridotrispyrazolylborato) [eqn (3)].[13] Refluxing acetonitrile solutions of (**4**) gives the triply-bonded dimer **5** [eqn (4)]:

$$\mathrm{TpMo(CO)_3^-} + \mathrm{Cp_2Fe^+} \longrightarrow \underset{\mathbf{4}}{\mathrm{Cp_2Fe}} + \mathrm{TpMo(CO)_3} \qquad (3)$$

$$2\mathrm{TpMo(CO)_3} \xrightarrow[\Delta]{} \underset{\mathbf{5}}{\mathrm{Tp(CO)_2Mo{\equiv}Mo(CO)_2Tp}} \qquad (4)$$

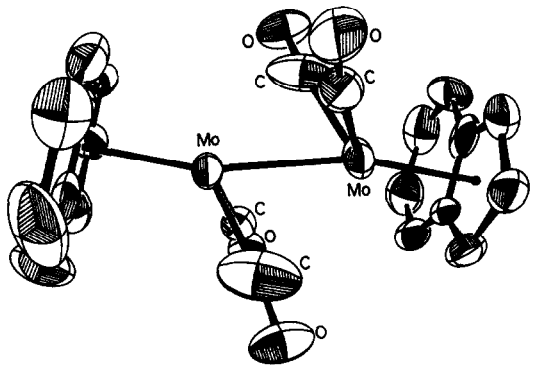


Fig. 1. ORTEP plot of (indenyl)$_2$Mo$_2$(CO)$_4$(Mo≡Mo).

The Tp–Mo–Mo–Tp axis in **5** is also nonlinear and only two of the four carbonyl groups are semi-bridging. The Mo≡Mo distance is 2.507(1) Å. The coordination about each Mo is quasi-octahedral if the metal–metal bond is considered to occupy one coordination site.

The chemistry associated with the Mo≡Mo bond in **5** is rather disappointing. No reaction was observed with acetylenes, Ph_2CN_2, CH_2N_2, S_8, propylene sulfide, P(OMe)$_3$ or H_2. Even CO does not react with **5** at atmospheric pressure. Prolonged reaction of **5** with CO (172 atm, 35°C) gave Mo(CO)$_6$ as the only carbonyl-containing product. In its reactions with Br_2 or I_2, **5** resembles **2** in that CO transfer occurs and RMo(CO)$_3$X (R = Tp or Cp*) are the only carbonyl products isolated.

A mixed Mo≡W triply-bonded compound may be prepared by refluxing a diglyme solution of Cp$_2$Mo$_2$(CO)$_6$ and Cp$_2$W$_2$(CO)$_6$ according to eqn (5).[14] The use of diglyme as solvent also gives an improved synthesis of compound **1**.[14] A mixed Tp–Cp dimer could not be prepared either by heating a solution of TpMo(CO)$_3$ and Cp$_2$Mo$_2$(CO)$_6$ or by mixing TpMo(CO)$_3^-$ with CpMo(CO)$_3$BF$_4$.[13(b)] In the former case, only **1** and unreacted TpMo(CO)$_3$ were recovered, while the latter reaction gave TpMo(CO)$_3$ and Cp$_2$Mo$_2$(CO)$_6$ by an electron-transfer process.

$$\mathrm{Cp_2Mo_2(CO)_6} + \mathrm{Cp_2W_2(CO)_6} \xrightarrow[\Delta]{-\mathrm{CO}} \mathrm{Cp_2M_2(CO)_4} + \mathrm{Cp_2MoW(CO)_4} \qquad (5)$$

M = Mo or W

The $R_2M_2(CO)_4$ compounds described in this section all display the same basic structure. However, the details of their reactivity seem to be influenced enormously by subtle changes in the steric and electronic properties of the groups R. We turn now to a survey of the chemistry associated with the metal–metal multiple bonds. Where warranted, the chemistry of some of the more interesting compounds prepared from **1** and its homologs will also be described.

NUCLEOPHILIC ADDITIONS TO THE M≡M BONDS

Molecular-orbital basis for reactivity

In molecular-orbital parlance, a molecule interacting with a nucleophile must possess a relatively low energy acceptor orbital. Both the Fenske–Hall[6] and EHMO[5,15] calculations on Cp$_2$Mo$_2$(CO)$_4$ show the π^*_{yz} MO to be the LUMO when the Cp rings are centered on the Mo–Mo axis. The π^*_{xz}

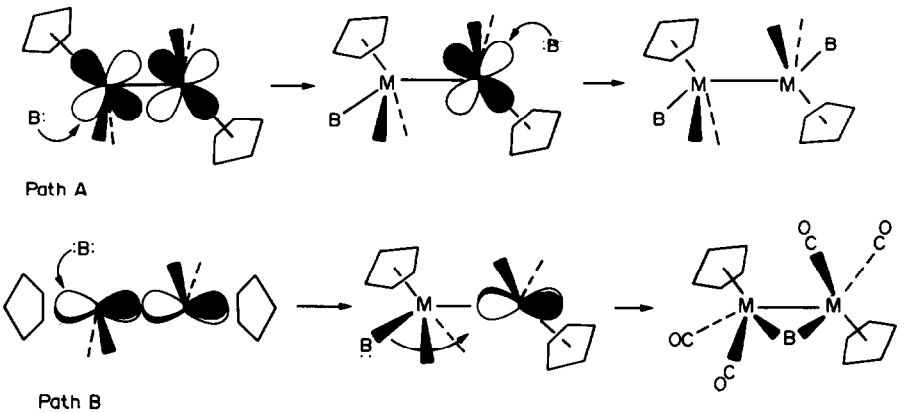
orbital lies at slightly higher energy. When the rings are tilted off the Mo–Mo axis as shown in Fig. 2, the energy of the π^*_{xz} orbital drops and it becomes the LUMO.

An inspection of the structures of the products of a variety of nucleophilic additions suggests that the regioselectivity of nucleophilic addition may be controlled by either π^*_{xz} or π^*_{yz}. The energy barrier to bending the CpMoMoCp axis is apparently quite low,[5] so that either path A or path B (Scheme 1) may be followed, depending on subtle electronic and steric requirements of the reactants. Path A seems to be followed by bulkier nucleophiles, e.g. phosphines and phosphites,[8,14] whereas bridging ligands, e.g. cyanide ion,[3] alkynes and diazoalkanes, seem to prefer path B (see below). Isomerization of the products has been noted in some instances (see below), so that the observed geometries of the isolated products may not correspond to those of initial, kinetic products, however.

In any event, simple electron counting suggests that an M=M double bond should result if the *net* result of a reaction is the addition of two electrons to the dimetal unit, an M–M single bond results from adding 4 electrons net, while donation of six electrons disrupts the metal–metal bonding.

Reactions with sulfur-containing reagents

Molybdenum is the chief constituent of many hydrotreating catalysts, especially those used for hydrosulfurization (HDS).[16] The reactions of the Mo≡Mo bond with sulfur-containing molecules has therefore been of interest. Alper and coworkers



Scheme 1.

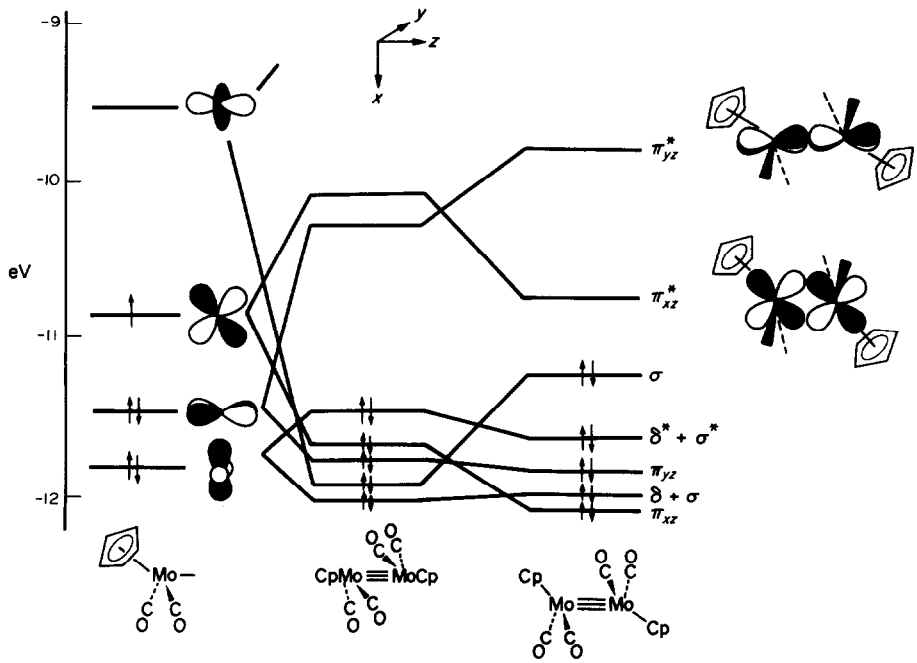


Fig. 2. MO energy levels of $Cp_2Mo_2(CO)_4$ as a function of the Cp–Mo–Mo angle (ω).

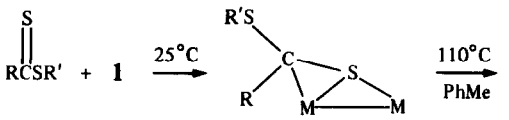
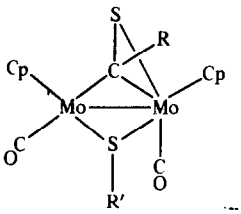
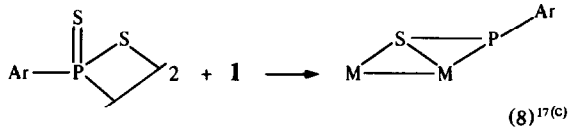
have shown that organosulfur compounds bind to the dimetal framework of **1** to give unusual structures [eqns (6)–(8)] [M = $Mo(CO)_2Cp$]:

(6)[17]



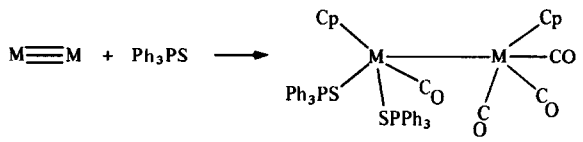


(7)[18]



(8)[17(c)]

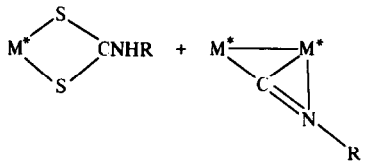
With Ph_3PS, **1** gives an unusual 1,1-disubstituted product [eqn (9)] rather than the usual 1,2-product shown in path A of Scheme 1.[19]



(9)

Isothiocyanates react with $(C_5Me_5)_2Mo_2(CO)_4$ (**2**) according to eqn (10). With a 10-fold excess of RNCS, only the dithiocarbamate was isolated. With a 1:1 ratio of RNCS and **2**, the μ,η^2-isocyanide was produced with a conversion of 6%.[20] Similar isonitrile complexes are produced directly in high yield from the reaction of RNC with **1**.[21]

2

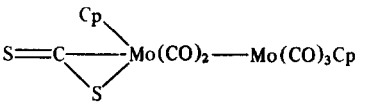


(10)

M* = $Mo(CO)_2Cp^*$

Refluxing a CS_2 solution of **1** gave the CS_2 adduct in *ca* 20% yield [eqn (11)]:[22]

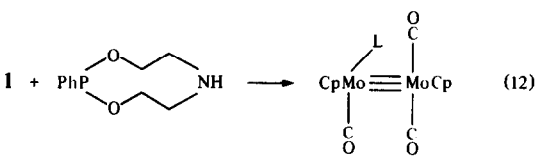
1



(11)

Reactions with phosphorus-containing nucleophiles

Most simple phosphines or phosphites react with **1** to give the disubstituted dimers corresponding to path A of Scheme 1. The cyclic phosphite (**6**) reacts with **1** with CO *substitution* and retention of the Mo≡Mo triple bond [Mo–Mo distance in **7** = 2.506(1) Å] [eqn (12), L = **6**].[23]

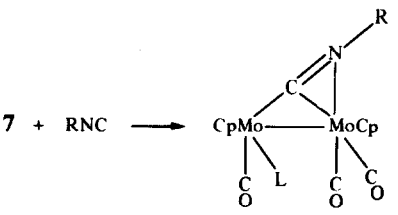


(12)

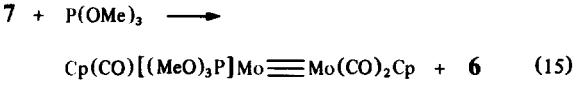
6 **7**

Compound **7** reacts with CO and isonitriles in the same manner that the parent **1** reacts [eqns (13) and (14)], but with $P(OMe)_3$, the ligand **6** is displaced [eqn (15)].[23] There is no ready explanation for the unusual behavior of phosphite **6**.

(13)



(14)

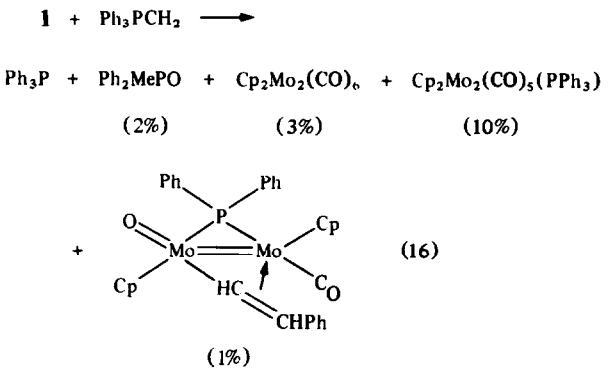


(15)

The reactions of M≡M with ylides are of considerable interest since such reactions could lead to new routes to alkylidene complexes. Unfortunately, these reactions are exceedingly messy and interesting products cannot be obtained in high yield.*

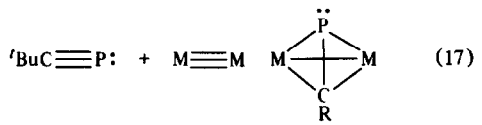
* Reactions of **1** with Me_3PCH_2 or $Me_2P(CH_2)_2^-$ gave very complex mixtures.[24]

The products, **8** and Ph_3P, show that extensive fragmentation of the ligand occurs.[25] The Mo=Mo distance in **8** is 2.885(1) Å.



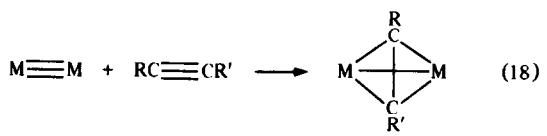
8

The phosphaalkyne $^tBuC{\equiv}P$ reacts with **1** to give an adduct with the same tetrahedrane type structure obtained from **1** and alkynes:[26]



Reactions with alkynes and alkenes

At room temperature, **1** reacts rapidly with all but the most hindered alkynes to give tetrahedrane-type adducts [eqn (18)].[8,27–29] These adducts typically have the following bond lengths (Å): Mo–Mo, 2.98; Mo–C, 2.18; and C–C, 1.33. The ^{13}C chemical shifts of the acetylenic carbons of a variety of adducts of type **9** are collected in Table 1. The values range from δ 29 for a silyl-substituted carbon to *ca* 140 for stannyl substitution. Large differences between two differently substituted carbons in the same coordinated acetylene are evident, viz. 100.7 and 29.3 for $HCCSiMe_3$, and 117 and 40 for $MeCCSiMe_3$. The usual range for C- or H-substitution is 60–90 ppm.



9

These alkyne adducts show interesting reactivity. At higher temperatures (>100°C), they lose CO and react with additional alkynes to form new

Table 1. ^{13}C NMR chemical shifts of acetylene and acetylide dimolybdenum complexes

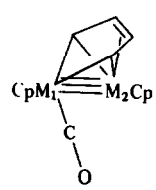
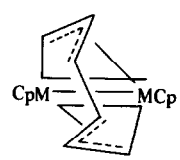
[c] Acetylide structure **23**.

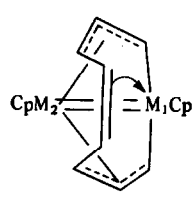
ligands derived from sequential coupling of two–four alkyne ligands.[28,30–33] The structural types so produced are indicated by **10–13** shown below:



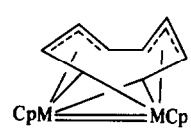
10



11



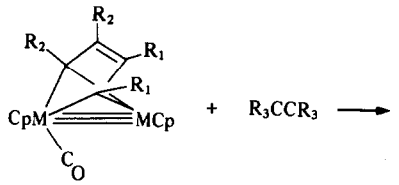
12

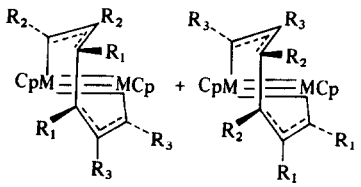


13

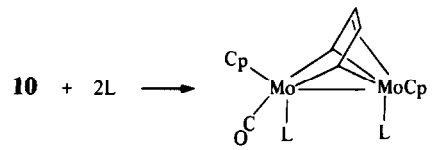
When terminal alkynes (RCCH) are employed, the C_4-ring in **10** shows predominate head-to-tail coupling of the two alkynes. The isomers of **11–13** which are formed by the reaction of alkynes with **10** show that the new alkynes which are incorporated may enter at either Mo–C bond in the MoC_4 ring [eqn (19)]. Structures of type **12** are also formed by one electron reduction of the mononuclear, $CpMo(RCCR)_2(NCMe)^+$ complexes.[34]

In addition to the main products shown above, smaller quantities of compounds of type **14** and **15** may be isolated from the reaction mixtures. These compounds are probably formed by the reaction of the triply-bonded precursors **10** and **11** with CO as has been demonstrated in one instance [eqns (20) and (21)]:[32]





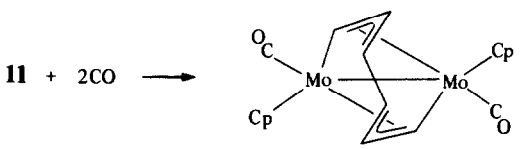
(19)



(20)

L = CO or RNC

14



(21)

15

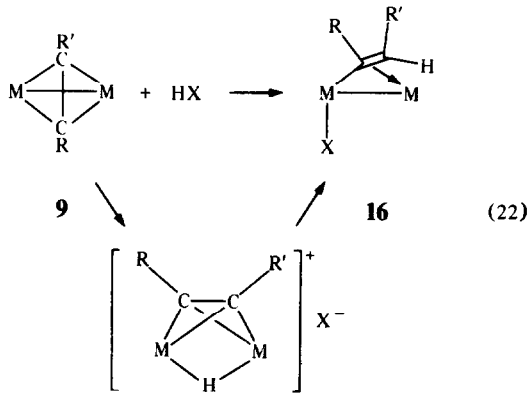
The details of the structures of these alkyne adducts show some interesting features. The terminal carbons of the C_4-fragment in **10** are symmetrically bonded to both metals [*d*-(Cr–C) = 2.025(7) Å avg.] and thus appear to be bridging alkylidene carbons. Their ^{13}C NMR resonance ($\delta \sim 210$ ppm) is consistent with this description.[35] The middle carbons of the M_1C_4 fragment are η^2-bonded to the M_2 metal [$d(M_2–C) = 2.23$ Å]. The M_1C_4 ring system itself appears to be delocalized[36] with equal C–C bond lengths (≈ 1.42 Å avg.).

Structure types **12** and **13** are isomeric. In **12**, both termini (C_t) of the C_8-ligand are very tightly bonded to one metal [$d(M_1–C_t) = 2.08$ Å, $d(M_2–C_t) = 2.23$ Å]. The $M_1–C_t$ distance approaches that expected for Mo=C double bonds,[37] while the $M_2–C_t$ distance is in the range found for Mo—C single bonds. M_2 is η^3-bonded to opposite ends of the C_8-fragment while M_1 is also η^2-bonded to the two central carbons.

In **13**, the two terminal carbons bridge the two metals in a nearly symmetrical manner (the M_2C_2 rhombus has essentially C_2-symmetry with two opposite M–C bonds of length 2.18 Å and another opposite set of two M–C bonds of length 2.14 Å) (cf. structure **10**). The next three carbons from each end of the C_8-chain are η^3-bonded to one metal each and the two halves are joined by a C—C single bond. This description of the bonding differs from that originally proposed.[30,31]

In both isomers, **12** and **13**, the electron count demands a Mo=Mo double bond to achieve an 18-electron count at each Mo.[1] The Mo=Mo distances[31,34] range from 2.595(1) to 2.635(1) Å. This distance compares with *ca* 3.0 Å for bridged M—M single bonds and 2.448(1) Å for the Mo≡Mo bond in **1**.

The mono-alkyne adducts (**9**) are readily protonated by strong acids to produce the μ,η^1,η^2-vinyl complexes **16**.[29,38] The stereochemistry of the protonated product suggested that the proton was delivered to the alkyne moiety via the metal in an intermediate, e.g. **17**. The tungsten analogue of **17** was subsequently observed as a product of the protonation of the carbyne complex $Cp(CO)_2W{\equiv}CR$.[39]

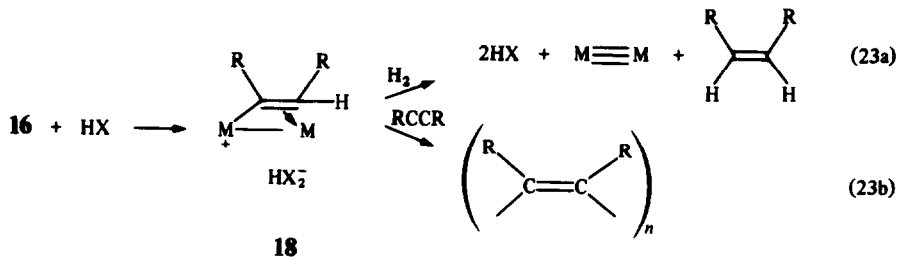


(22)

17

Excess acid protonates the trifluoroacetate group ("X" in **16**) giving coordinatively unsaturated intermediate **18** which is fluxional on the NMR scale. The coordination unsaturation of **18** allows for the oxidative addition of H_2 and subsequent stoichiometric hydrogenation of the alkyne. Under catalytic conditions with a large excess of alkyne, the excess alkyne inhibits the oxidative addition of hydrogen and the alkyne is polymerized instead [eqn (23b)].[29]

Methoxyallene reacts with **1** to give the adduct **19** [eqn (24)]. Fluoroboric acid reacts with **19** to give MeOH and the cation **20**. Cation **20** is also obtained from the reaction of the adduct of methyl propargyl ether (**9**: R = H, R′ = CH_2OMe) with HBF_4 [eqn (25)].[40] Figure 3 is a PLUTO drawing of **20**. This perspective shows that **20** may be regarded as a cationic μ-η^1,η^1,η^3-allenyl complex in which the C_3-fragment is π-bonded to Mo1 and



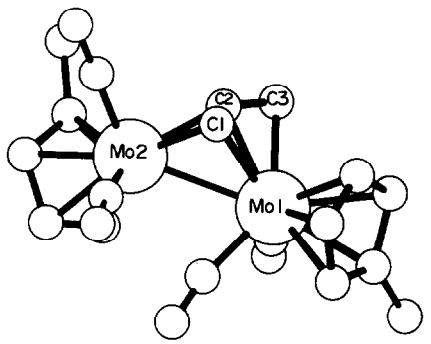


Fig. 3. PLUTO drawing of the cation, $Cp_2Mo_2(CO)_4(\mu\text{-}C_3H_3)^+$ (**20**).

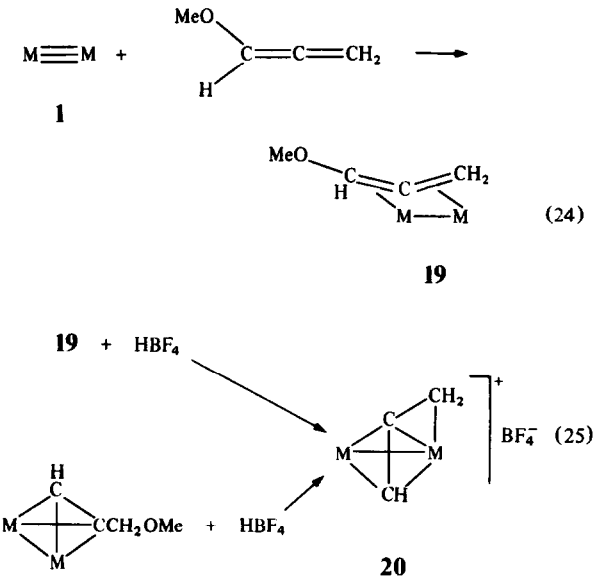
two C—H bonds of the π-allyl group have been replaced with two Mo2–C σ-bonds.



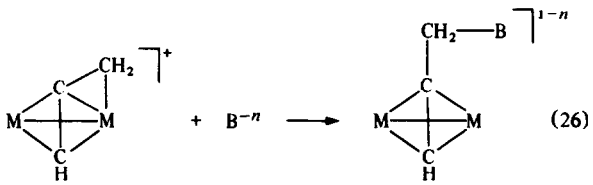
9 (R = H, R′ = CH_2OMe)

Complex **20** is fluxional on the ^1H NMR time scale ($\Delta G^{\pm}$ = 16.9 kcal mol^{-1} at 338 K). At −60°C, the spectrum is consistent with the solid-state structure (two types of Cp groups): δ 6.76 (d, J = 1.7 Hz, =CH), 5.33 (d, J = 1.7, —CH_2), 5.05 (s, —CH_2). At 75°C, the Cp groups are equivalent but the signals due to the C_3H_3 fragment do not vary with temperature. The dynamic process shown in Scheme 2 interconverts enantiomers of **20** via the symmetrically bridged intermediate in which the plane of the C_3H_3 fragment is perpendicular to the Mo–Mo bond. This process resembles the higher energy fluxional processes[27,28] in the acetylene adducts (**9**) and μ-vinyl complexes (**16**).[29,38]

The ^{13}C NMR shifts of the C_3-fragments in **20** and its precursor complexes **19** and **9** (R = H, R′ = CH_2OMe) show interesting trends. We label the MeO-bearing carbon Cα in the precursors. Upon loss of MeO^- to form **20**, Cα of **19** but Cγ of **9** become C1 of **20**. These relationships and the chemical shifts of corresponding carbons are shown below (see Fig. 3 for numbering scheme of **20**):

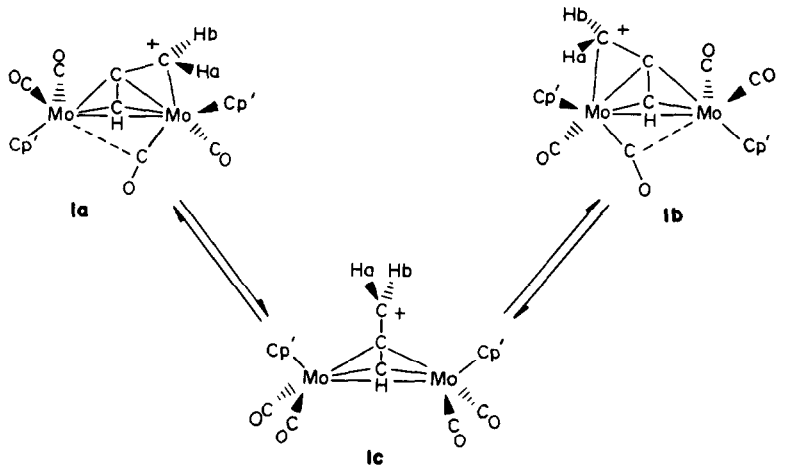
19	**20**	**9** (R = H, R′ = CH_2OMe)
38 (Cγ) →	76 (C3) ←	76 (Cα)
176 (Cβ) →	118 C2) ←	56 (Cβ)
101 (Cα) →	81 (C1) ←	86 (Cγ)

Insofar as these chemical-shift changes reflect charge redistribution, it is seen that the electronic structure of the C_3-fragment in **20** resembles more closely that of the acetylene adduct **9** than the allene adduct **19**. In particular, the deshielding of Cγ in **19** suggests that positive charge is transferred from Cα to Cγ in the transformation **19** → **20**. This conclusion is borne out by the reactivity of **20** toward nucleophiles [eqn (26)].[40] Even hindered bases, e.g. $^iPr_2NLi$, attack the terminal carbon, C3, to yield alkyne complexes **21**. We have been unsuccessful in attempts to remove a proton from **20**.



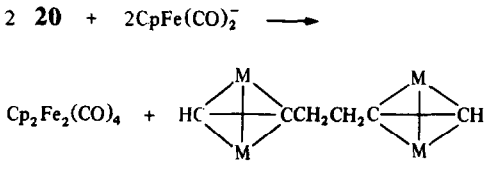
20 **21**

B = Py, $^iPr_2N^-$, MeO^-, CN^- or R_3P



Scheme 2.

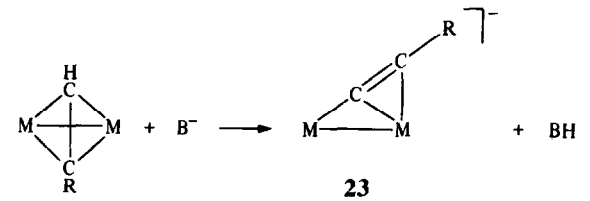
Metal carbonyl anions react [eqn(27)] with **20** in a redox manner to give the bis-adduct (**22**)[40] of 1,5-hexadiyne, previously prepared from **1** and the free diyne.[30] The reduction of **20** to give **22** is also accomplished with Na amalgam. Figure 4 is a PLUTO drawing of the structure of **22**.



(27)

22

Complexes (**9**) of terminal alkynes react with strong bases, preferably $^{i}Pr_2NLi$ or $NaNH_2$, to produce μ-η^1,η^2-acetylide complexes (**23**) [eqn (28)].[41] The molecular structure of **23** (R = CH_2-OMe) is shown in Fig. 5. The counter ion in this crystal is Na(15-crown-5)$^+$. The Na^+ ion is also chelated by the methoxy oxygen and to one carbonyl oxygen in the solid state. Similar coordination of alkali cations to carbonyl groups has been observed previously.[42] These μ-η^1,η^2-acetylide complexes exhibit the same "windshield wiper" fluxional motion previously established for the



R = Ph or CH_2OMe (28)

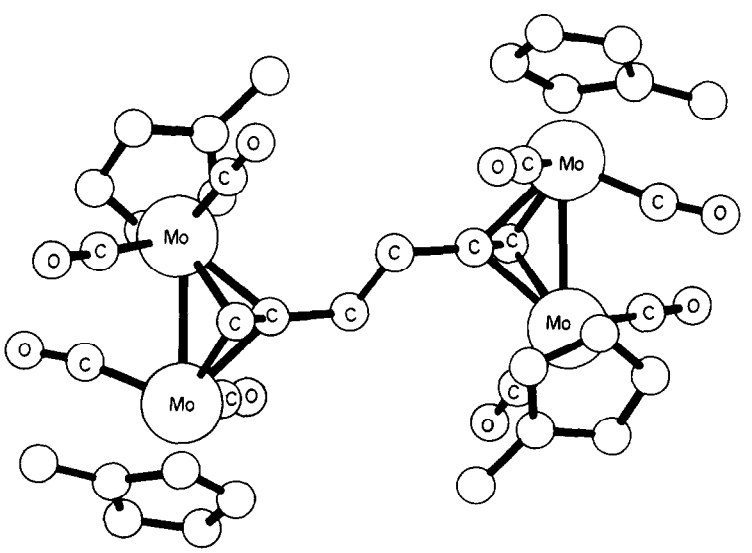


Fig. 4. PLUTO drawing of the 1,5-hexadiyne adduct (**22**) of $Cp_2Mo_2(CO)_4$.

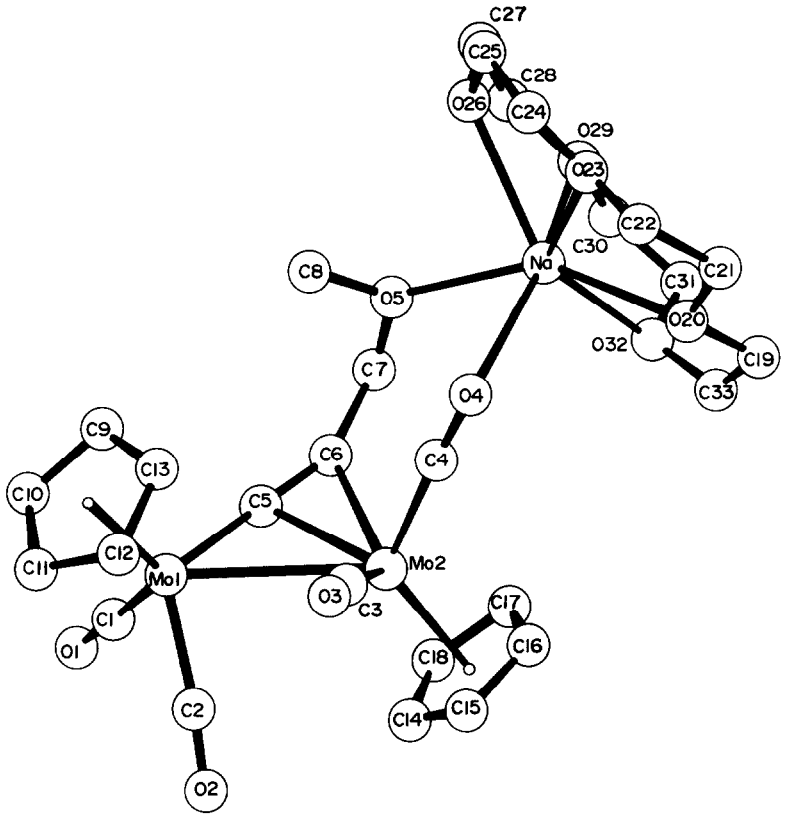

Fig. 5. ORTEP plot of Na(15-crown-5) $Cp_2Mo_2(CO)_4$ (μ-$CCCH_2OMe$) (**23**) showing the coordination of Na^+ to the methoxy and carbonyl oxygens of the anion.

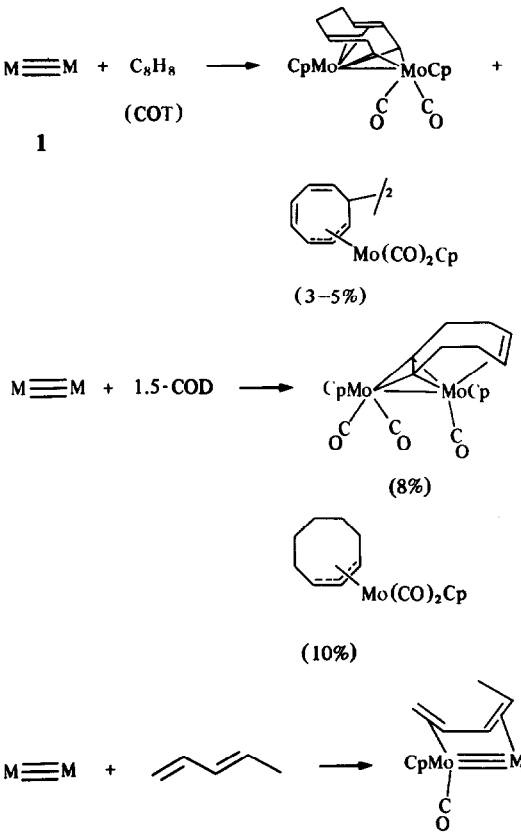
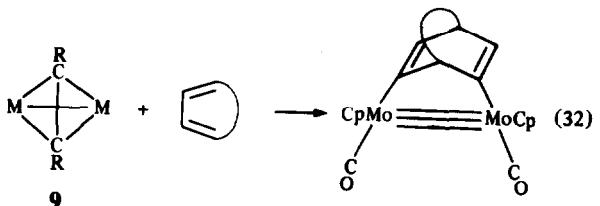
cyanide adduct[3] of **1** and for other μ-η^1,η^2-acetylide adducts.[43,44]

The Mo1–C5 distance in **23** (Fig. 5) is 2.03(1) Å, a distance approaching those observed for Mo=C double bonds.[41] The Mo2–C5 and Mo2–C6 distances [2.285(6) and 2.318(6) Å, respectively] are not unusual for Mo bound to π-systems. The ^{13}C NMR chemical shifts of the acetylide carbons show a remarkable downfield shift in comparison to those in the parent complex **9** (cf. Table 1). The resonances due to C5 and C6 occur at δ 186 and 102, respectively.[41] The former resonance lies toward the downfield side of the range of chemical shifts observed for bridging methylene groups.[35] Thus, both the Mo1–C5 distance and the ^{13}C NMR chemical shift suggest considerable "carbene" character for the terminal carbon of the acetylide bridge in **23**.

The early papers on the reactivity of the Mo≡Mo triple bond reported that **1** does not react with alkenes.[8,27] It was later shown that more severe conditions (1–21 days, 110–130°C) gave complex mixtures from which low yields of structurally interesting compounds could be isolated [eqns (29)–(31)].[45,46]



The alkyne adducts (**9**) react with cyclic, conjugated dienes to give products with ligands derived from formal Diels–Adler condensation of the diene with the coordinated alkyne [eqn(32)].[47] The Mo≡Mo bond length in **24** is 2.504(1)Å. All of these rather complex reactions involving alkenes undoubtedly occur with prior loss of CO from **1** or **9**.[32]

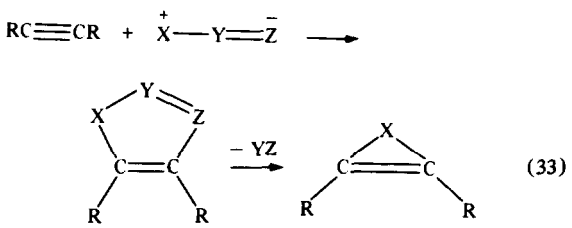


9 **24**

The reactions described in the section amply demonstrate that the easily prepared alkyne adducts of the Mo≡Mo triple bond form the basis for an extensive chemistry of hydrocarbon conversions on a bimetallic center. Even in those reactions which require higher temperatures and proceed with loss of CO, the strength of the Mo≡Mo triple bond serves to maintain the integrity of the dinuclear unit and suppress the formation of mononuclear products.

REACTIONS WITH 1,3-DIPOLES

The reactions of carbon–carbon multiple bonds with 1,3-dipolar reagents have been studied extensively.[48] For example, alkynes normally react with the 1,3-dipole to give the cycloadduct **25**. This adduct may expel the small molecule Y≡Z to give a three-membered ring (**26**) [eqn(33)].



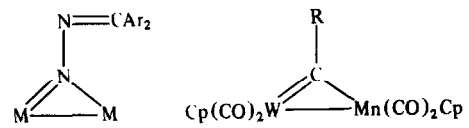
25 **26**

It is therefore of interest to determine how metal–metal multiple bonds interact with 1,3-dipolar reagents. What are the similarities and differences in behavior of metal–metal multiple bonds *vis-à-vis* their well-studied organic counterparts? The answers to such questions lead to increased understanding of factors governing chemical reactivity and, at the same time, provide the synthetic chemist with new routes to molecules of interest in related areas.

Reactions with diazolkanes

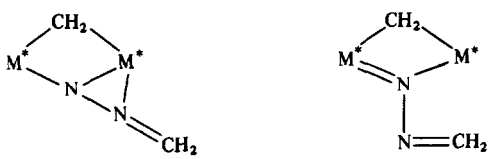
Diazoalkanes ($R_2C{=}N_2$) are prototypal 1,3-dipoles. In addition to the interest attached to the bonding of the diazoalkane ligand itself to a dimetal fragment, loss of N_2 from the adduct may give metal alkylidene complexes. The latter compounds are still of interest in connection with CO reduction chemistry.[35]

The coordination chemistry of diazoalkanes with M≡M (**1**) and related complexes has been both rewarding and frustrating in its complexity. No less than *seven* different reaction paths of diazoalkanes with M≡M have been well characterized. These are summarized in Scheme 3. The reaction of **1** with diaryldiazomethanes was the first reaction of this type to be reported and the product was shown to have the unusual bonding mode depicted in **27** (M = $Mo(CO)_2Cp$).[49,50] This structure is isolobal and isoelectronic with the bridging alkylidyne (**28**).[51]



27 **28**

The parent diazomethane ($CH_2{=}N_2$) reacts with **1**, but no stable complex could be isolated—N_2 is evolved and polymethylene is formed.[1] However, CH_2N_2 reacts with the pentamethylcyclopentadienyl analog of **1**, hereinafter denoted by M*≡M* [M* = $Mo(CO)_2(C_5Me_5)$], with loss of N_2 to give an adduct with either structure **29** or **30**.[52,53]

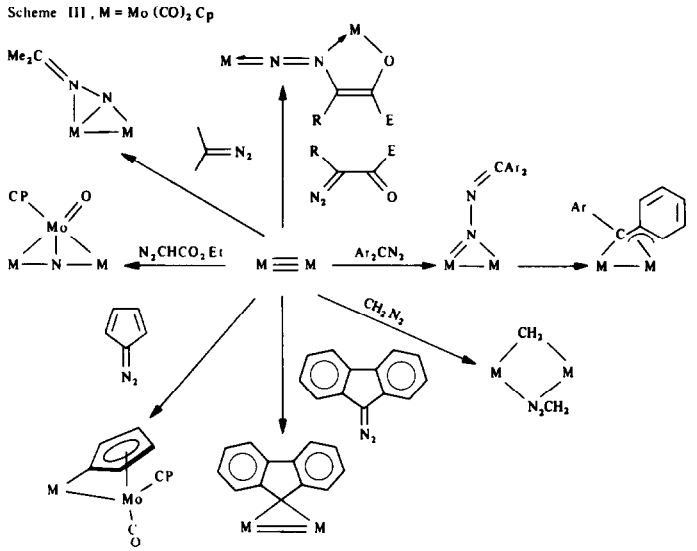


29 **30**

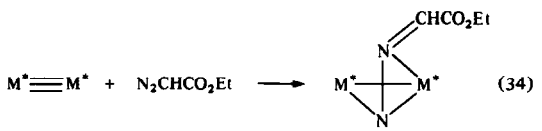
Diazopropane ($Me_2C{=}N_2$) reacts with either M≡M or M*≡M* to give an adduct in which the terminal nitrogen is bonded to both Mo atoms, and the central nitrogen also bonded to one of the Mo atoms.[54,55] In solution, a second isomer of $M_2(N_2CMe_2)$ is present as shown by the NMR spectrum.[50,54]

Ethyl diazoacetate reacts cleanly with M*≡M* to give adduct **31** which has the same coordination mode as the Me_2CN_2 adducts [eqn(34)].[50] An ORTEP plot of the structure of **31** is shown in Fig. 6. The major difference between the structure types **31** and **27** is that in **27** the terminal N donates a

Scheme III, M = Mo(CO)$_2$Cp



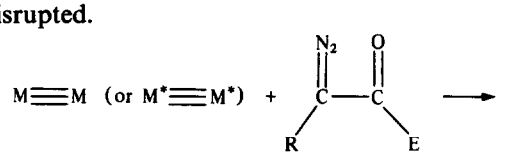
total of four electrons to the dimetal fragment, whereas in **31** the terminal N donates two electrons and the central N donates two also. In spite of their seemingly disparate structures, the bond distances and angles in the N_2C portion of the molecules **27** and **31** are virtually identical.



(34)

31

Reaction (34) is surprising because previous work had shown potential donor groups adjacent to the diazo group become coordinated to the metal in these diazoalkane adducts. Thus α-ketodiazoalkanes[56] and diethyl diazomalonate[50,54] react with M≡M or M*≡M* to give products containing a chelate ring which incorporates the keto or carboxyl oxygen [eqn(35)]. In these adducts, the α-keto or α-carboxyl diazoalkane reacts as a six-electron donor so the M≡M bond is completely disrupted.



(35)

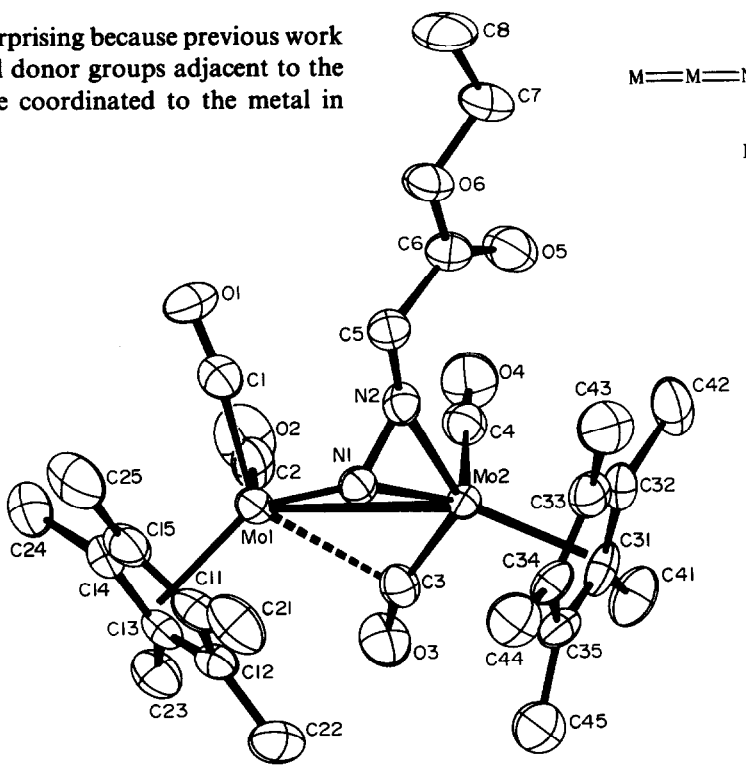


Fig. 6. ORTEP plot of $Cp^*_2Mo_2(CO)_4(N_2CHCO_2Et)$ (**31**).

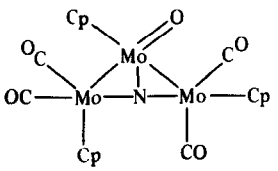
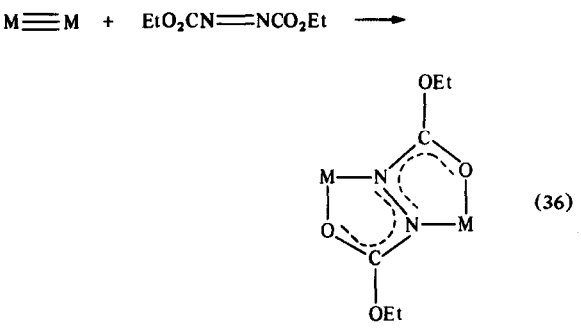
Ethyl diazoacetate reacts with M≡M (**1**) at temperatures from −78°C to +110°C to give extremely complex mixtures.[54,57] Feasey *et al.* isolated cluster **32** in 5% yield from such a mixture.[57]



32

The reaction of **1** with the dienophile, diethyl azidodicarboxylate, gives a product (**33**) with a structure related to those depicted in eqn (35).[58] The molecular structure of **33** is shown in Fig. 7.



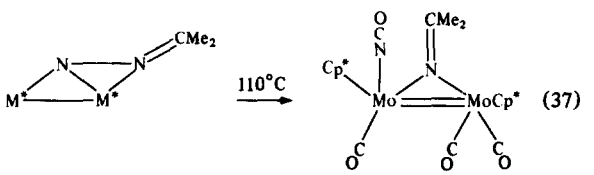
(36)

33

Reactions of diazoalkane adducts

By analogy with the organic chemistry of 1,3-dipolar cycloadducts depicted in eqn (33), it was of interest to investigate the tendency of the diazoalkane adducts of **1** and related compounds to lose N_2 and form dimetallacyclopropenes, i.e. μ-alkylidene complexes.

Herrmann *et al.* found that the adduct of 2-diazopropane and M*≡M* underwent a rearrangement in which the N–N bond was broken, one nitrogen then inserting into an Mo–CO bond to form an isocyanate, and the Me_2CN fragment forming a μ-imido group [eqn (37)].[53]



(37)

34

Me_2CN_2 or $C_5H_4N_2$ react with the triply-bonded tungsten complex, $Cp^*_2W_2(CO)_4$, at *ca* −20°C to give the μ-imido isocyanate W complexes analogous to **34**.[59]

The doubly-bonded complex **34**, and its W analog, add one equivalent of CO to form singly-bonded **35**.[53,59] In order for each metal to maintain the 18-electron count during this transformation,

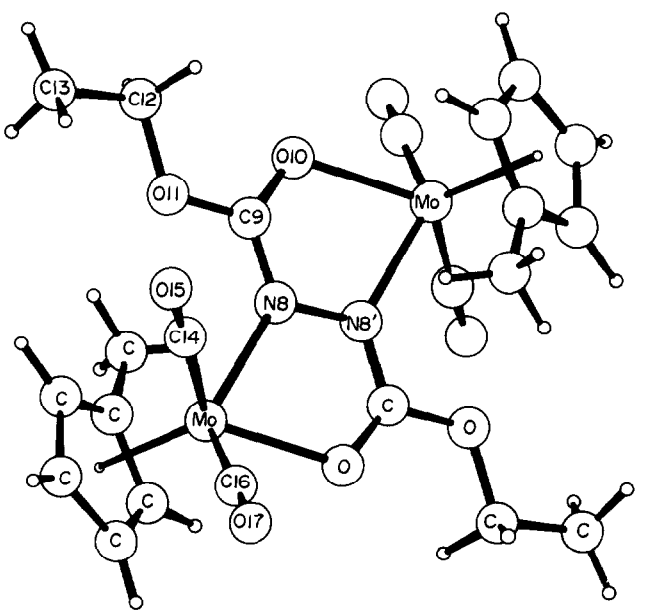


Fig. 7. ORTEP drawing of adduct (**33**) of diethyl azidodicarboxylate and $Cp_2Mo_2(CO)_4$.

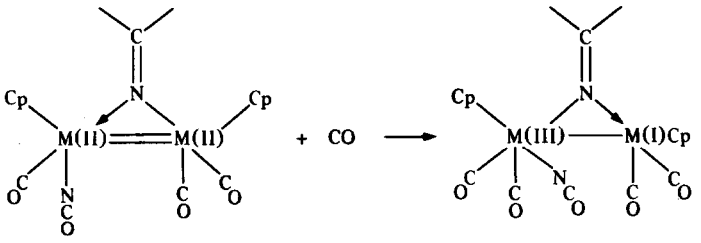
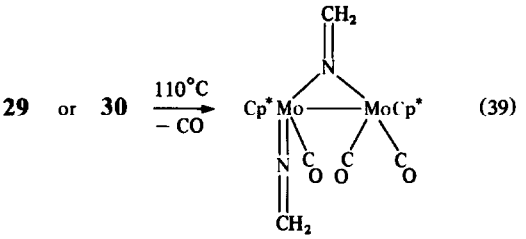
an internal redox disproportionation must occur as illustrated in eqn (38).

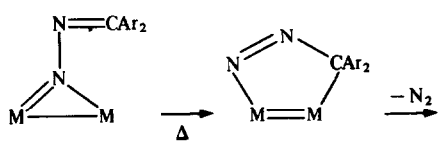


34 35

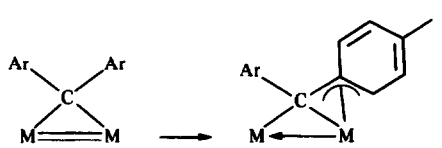
The adduct with structure **29** or **30** also undergoes an isomerization upon heating, but in this case the nitrogen inserts into the methylene bridge and two methyleneimido ligands are formed [eqn (39)].[53]



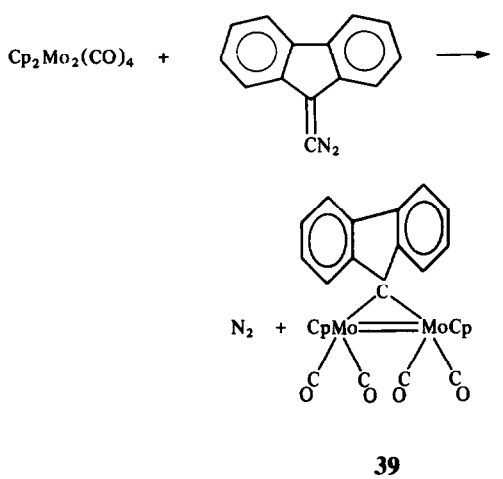
To date, the only diazoalkane adducts which cleanly lose N_2 and form μ-alkylidene complexes were the first to be discovered, viz. the diaryldiazomethane adducts (**27**).[49,50] Heating **27** (Ar = phenyl or *p*-tolyl) to 60°C causes an *intra*molecular loss of dinitrogen. The resulting μ-diarylalkylidenes were shown to have the structure depicted in **36** in which one aryl group has become coordinated to one Mo.[49,50] The intramolecular loss of N_2 from **27** is believed to occur through the 1,3-dipolar cycloadduct (**37**). This view is supported by the fact that the complexes $M_2^*(\mu\text{-}N_2CAr_2)$ do not lose N_2 cleanly, presumably because attainment of the transition state **37** is blocked by steric interactions between the bulky Cp* groups and the aryl groups.[50] Conversely, 9-diazofluorene reacts with **1** with loss of N_2 even below room temperature, presumably because the steric congestion in intermediate **38** is less than that in **37** as shown below. The product is the μ-fluorenylidene complex **39** which now has a Mo=Mo bond [2.798(1) Å] since the aryl groups are tied together and cannot bend over and coordinate to a metal as does the aryl group in **36**. The reactions of the μ-alkylidenes **36** and **39** with small molecules, e.g. CO, H_2, isocyanides and alkynes, are the subject of several reports.[60–62]



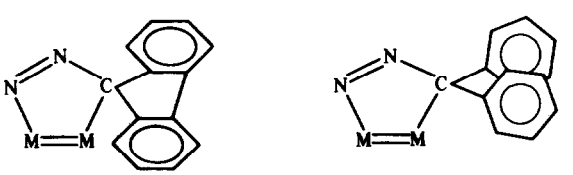
27 37



36

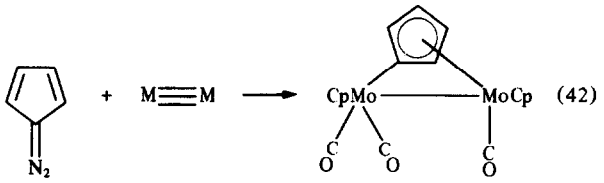


39



38 37

An uncrowded transition state similar to **38** also explains the facile loss of N_2 and subsequent formation of **40** when diazocyclopentadiene reacts with **1** [eqn (42)].[63]

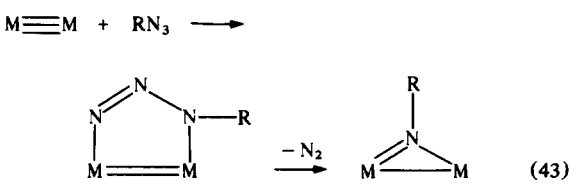


(42)

40

Reactions with other 1,3-*dipoles*

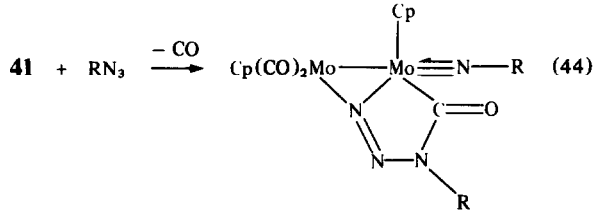
Organoazides are isoelectronic with diazoalkanes. Hence, the interaction of an organoazide with the M≡M triple bond could lead to a dimetallatriazene (the cyclic 1,3-adduct) which would be expected to lose N_2 and form a nitrene complex [eqn (43)].



(43)

41

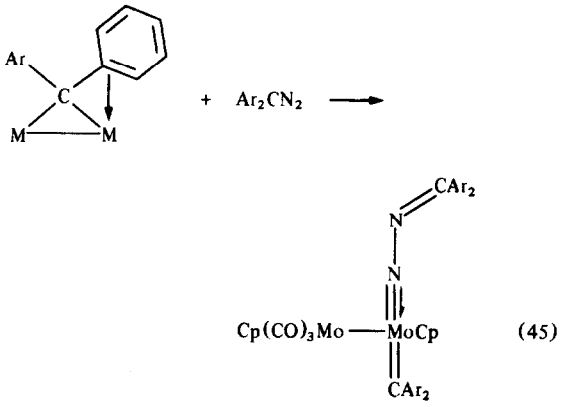
In fact, the reaction of aryl or alkyl azides with **1** follows a different course.[54,64] The *initial* product is probably the nitrene adduct (**41**). However, this initial product reacts with additional azide nearly as fast as it is formed to give the final complex (**42**).



(44)

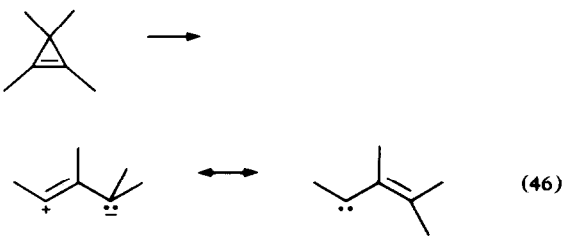
42

The final product contains a terminal nitrene triply bonded to Mo [Mo≡N = 1.75(1) Å] and a bridging chelate ring formed by attack of the second azide on a coordinated carbonyl. The transformation of a bridging nitrene to a terminal nitrene upon reaction with excess azide has its exact parallel in the transformation of an alkylidene from bridging to terminal upon reaction with excess diazoalkene [eqn (45)].[61] The major difference is that the carbon of the diazoalkane is not sufficiently nucleophilic to attack a coordinated carbonyl as does the N in eqn (44).

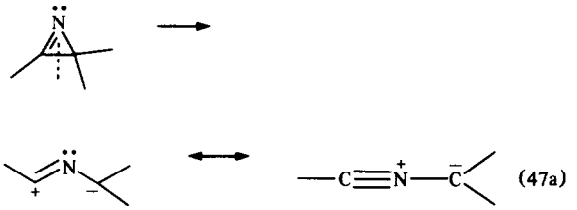


(45)

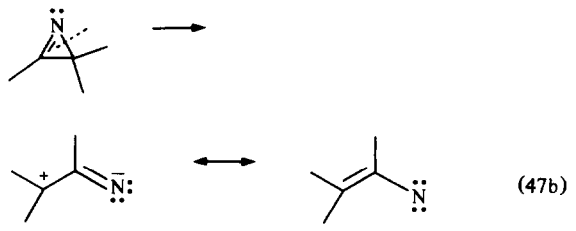
Cyclopropenes and azirines may be regarded as "masked" 1,3-dipoles.[48] The cyclopropene is a masked vinylcarbene [eqn (46)] and the azirine a masked nitrile ylide [eqn (47a)] or a masked vinyl nitrene [eqn (47b)].



(46)

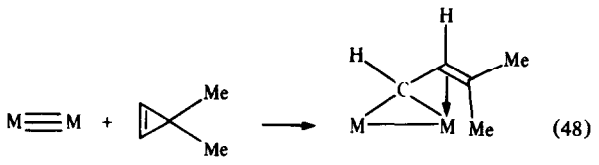


(47a)

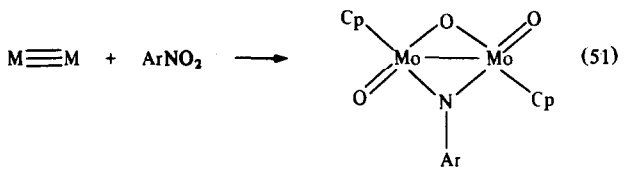


(47b)

In fact, **1** reacts with 1,1-dimethylcyclopropene to give the bridged, vinyl alkylidene (**43**).[65] The pattern of Mo–C (bridge) distances in **43** are very similar to those in **36** as might be expected. Thus, cyclopropene adds to the Mo≡Mo triple bond as if it were a vinyl carbene [cf. eqn (46)].

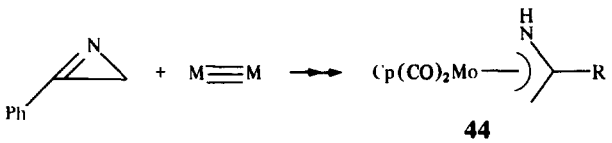


43 (48)



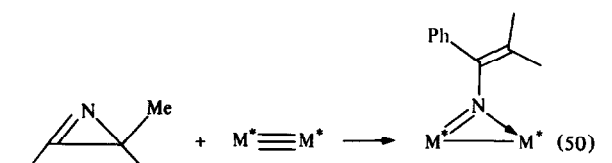
46 (51)

We have found that the Mo≡Mo triple bond is very reactive towards azirines. Compound **1** reacts with 2-phenyl-1-azirine to form a red, thermally labile complex which decomposes above 0°C to a green mixture of products.[66] Green and coworkers have isolated the azaallyl complex **44** by column chromatography from this mixture.[67] The extra proton on the azaallyl ligand presumably comes from the column packing.



44 (49)

The phenylazirine also reacts with M*≡M* to give a labile adduct. However, 2-phenyl-3,3-dimethyl-1-azirine with M*≡M* gives a thermally stable product believed to have structure **45** on the basis of its NMR spectra (an X-ray structure determination is planned).[66] It thus appears that the azirine ring is behaving as a masked vinyl nitrene in reactions with Mo≡Mo triple bonds.

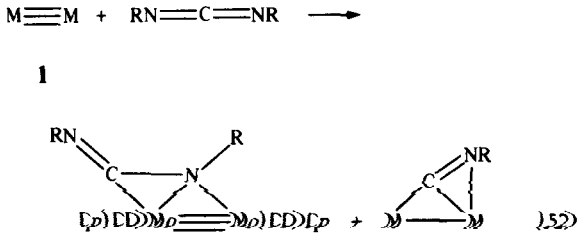


45 (50)

Alper *et al.*[68] have found that nitro arenes ($ArNO_2$) react with **1** or the W-analog to give the complex shown in eqn (51). Although $ArNO_2$ may be classified as a 1,3-dipole,[48] it is doubtful that this property is required for reaction (51) since aryl nitroso compounds (ArNO) react with **1** to give the same products.[68]

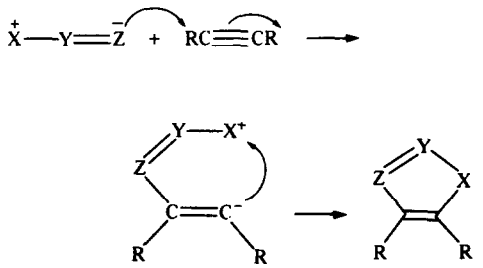
The Mo–Mo single bond distance in **46** is only 2.65 Å, a distance which is shorter than the formal Mo=Mo double bonds in compounds **34** and **39** discussed above. In compounds in which the Mo is in a high formal oxidation state, e.g. in **46**, extensive π-bonding with the bridging ligands undoubtedly serves to contract the Mo–Mo bond distance.

Compound **1** reacts slowly with excess carbodiimides in refluxing toluene to give the products shown in eqn (52).[69] The high temperature and slow rate of reaction again suggest that the reaction is proceeding by prior loss of CO from **1** followed by coordination of the carbodiimide. The Mo≡Mo triple bond in **47** reacts with CO to give a saturated derivative $[Cp_2Mo_2(CO)_5(RNCNR)]$.[69]



47 (52)

Although many interesting structures are formed by the interaction of 1,3-dipolar reagents with the M≡M triple bonds in **1** and related compounds, only in the decomposition of the adducts of Ar_2CN_2 with **1** [eqn (40)] is there any persuasive evidence that 1,3-dipolar cycloadducts are formed. The lack of cycloadduct formation is in keeping with the different behavior of these M≡M triple bonds *vis-à-vis* C≡C triple bonds. Attack of the nucleophilic end of the 1,3-dipole on a C≡C bond generates a nucleophilic site on the contiguous carbon. Ring closure then occurs when this nucleophilic carbon reacts with the electrophilic end of the dipolar reagent [eqn (53)].



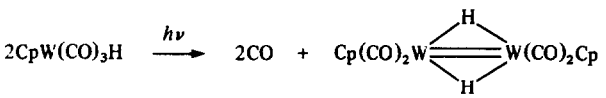
(53)

In contrast, attack by a nucleophile on one end of the M≡M triple bond in **1** generates a 16-electron, *electrophilic* site on the remote metal [eqn(54)] due to collapse of electrons into non-bonding levels which are not available to carbon (see electron-counting arguments in Ref. 1). Thus, there is no charge development which directs ring closure to a 1,3-dipolar cycloadduct. Instead, the preferred reaction path seems to be first coordination of the most nucleophilic portion of the dipolar reagent, followed by rearrangements and/or coordination of other donor functions on the dipolar reagent to eventually "saturate" the M≡M triple bond according to the scheme in eqn (54) (B′ represents any second donor function, i.e. B and B′ may be in the same molecule or on different molecules).

(54)

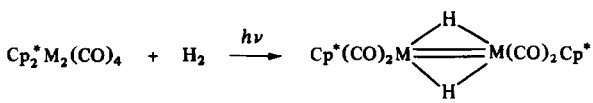
OXIDATIVE REACTIONS WITH NON-METALS

In our initial explorations of the chemical behavior of compound **1**, we were disappointed in its lack of reactivity toward molecular H_2. However, it was demonstrated recently that photolysis of $CpW(CO)_3H$ gives the μ-dihydride [eqn(55)].[70] Compound **48** is unstable in solution, presumably dissociating to H_2 and $Cp_2W_2(CO)_4$. The C_5Me_5 derivatives are stable, however, and may be prepared by the direct reaction of the M*≡M* bonded compounds with H_2 under UV photolysis.



48

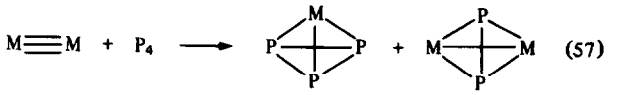
(55)



M = Mo or W

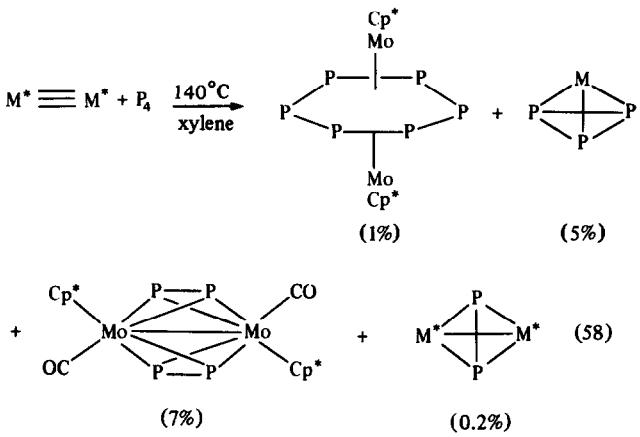
(56)

The multiply-bonded Mo dimers show high reactivity toward other non-metals, e.g. P, As, S, Se etc. With white phosphorus, **1** forms tetrahedrane clusters [eqn(57)].[71]



M = $CpMo(CO)_2$

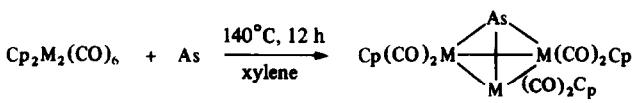
Under more forcing conditions, the derivatives react to give a mixture of structurally novel complexes in low yield [eqn(58)].[72] Included in the products is a triple-decker complex with a P_6-ring sandwiched between two Cp*Mo moieties. The Mo–Mo distance in this complex is 2.647(1) Å and the Mo–P avg. distance is *ca* 2.54 Å. There is some evidence for a ring current associated with the P_6-ring: the Me groups of the Cp* ligands resonate at δ 0.47 instead of their more usual value of *ca* 2.



(1%) (5%) (7%) (0.2%)

(58)

Arsenic and its derivatives also react with **1** [or its precursors, $Cp_2Mo_2(CO)_6$ or $CpMo(CO)_3H$] at elevated temperatures to give novel Mo–As clusters [eqns (59),[73] (60),[74] (61),[75] (62)[76] and (63)[77]].

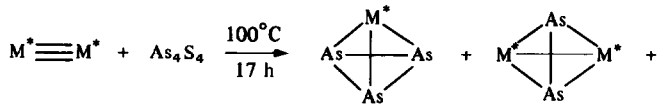


M = Mo, 65%
M = W, 40% **49**

(59)

The structure of **49** is similar to that of the isoelectronic cation, $Cp_3Mo_3(CO)_6S^+$ (see below) except that in **49** the $CpMo(CO)_2$ units are twisted relative to one another in such a way that the cluster has no symmetry, whereas the sulfur cation cluster has approximate C_3-symmetry in the solid state.[78]

Reactions (61)–(63) do not use the triply-bonded dimers as starting material, but the reactions are conducted under conditions where **1** (or **2**) forms rapidly. In any event, the products are so closely



(12%) (4%)

50 **51**

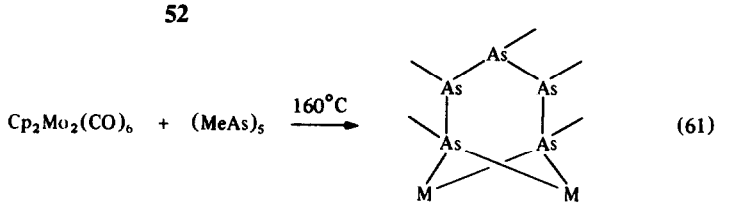
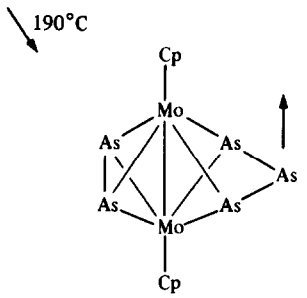
52

(60)

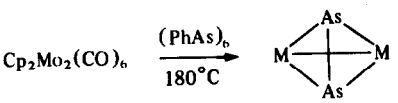


(61)



(62)

53



(63)

54

related to those obtained from **1** or **2** that they are included here for completeness.

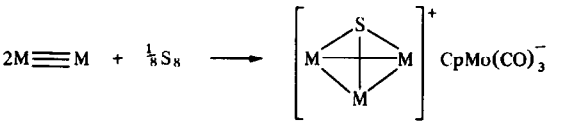
Compound **53** was described originally by the authors as having a Mo=Mo double bond. However, if the ligands are considered to be μ-As_2^{4-} and μ-As_3^{4-}, then the formal oxidation state of Mo is $+5(d^1)$ so the maximum Mo–Mo bond order is one. The Mo–Mo distance [2.75 Å] is consistent with an Mo–Mo single bond bridged by three or four groups.* Complex **53** is quite unusual nevertheless. The five As atoms are essentially coplanar and the Mo–Mo bond is perpendicular to the As plane. The As atoms are segregated into two groups, As_2 and As_3, and an odd electron is apparently localized on the central As of the μ,η^2-As_3 ligand.[76] Reaction 61 is very similar to the reaction of M≡M with disulfides (RSSR).[8]

The series, M_nAs_{4-n} ($n = 1$–3), is represented by compounds **50**, **51** or **54**, and **49**. The $n = 0$ (As_4) is known in the gas phase, but there is no convincing evidence for the existence of the $n = 4$ member, i.e. M_4.[8,14] The As–As distance in **54** is 2.31 Å, commensurate with an As=As double bond. Complexes **51** and **54** may then be regarded as adducts of

* Mo–Mo distances in a variety of Mo–S dimers and clusters show a strong correlation with the number of sulfide bridges: μ-S, Mo–Mo ≃ 2.9–3.0 Å; 2μ-S, Mo–Mo = 2.75–2.8 Å; 3 or 4μ-S, Mo–Mo = 2.65–2.7 Å.[79]

M≡M with the alkyne analogue As≡As. Synergic bonding reduces the As–As bond order from 3 to 2 in the same manner that the C–C bond order is reduced in the alkyne adducts.

The M≡M triple bond is also quite reactive with the chalcogens. The reaction of **1** with excess sulfur produces red, insoluble polysulfides[78] ($[CpMoS_x]_n$) identical to those obtained from the reaction of $Cp_2Mo_2(CO)_6$ with excess sulfur. However, if the stoichiometry is carefully controlled and $\frac{1}{8}S_8$ (solution in CH_2Cl_2, CS_2 or toluene) is added to the solution of **1** a surprising disproportionation of two dimers into a trimer and a monomer is observed [eqn (64)].

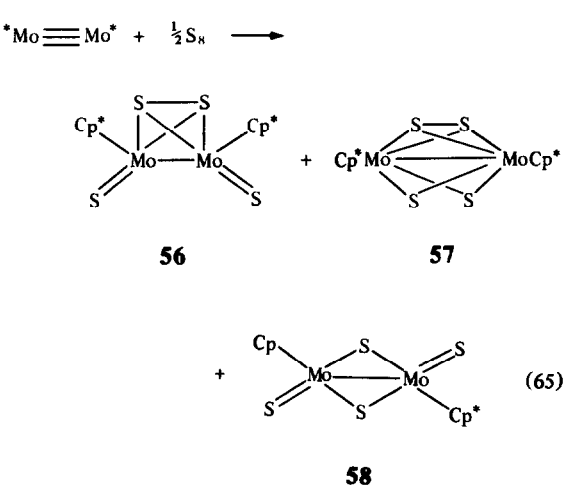


55

(64)

Yields of the cation **55** of 50–70% have been realized. The $CpMo(CO)_3^-$ anion is easily replaced with halide either by adding RX and washing the $CpMo(CO)_3R$ (R = H or Me) away from the salt (**55**·X) with petroleum ether.

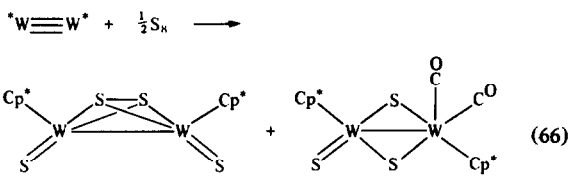
The more soluble (and more hindered) Cp* complexes of Cr, Mo and W react with excess sulfur to give discrete tetrasulfide complexes which display an interesting series of isomeric forms.[80] These isomers may have different formal oxidation states due to the formation of S–S bonds in the ligands [eqn (65)]. Prolonged refluxing of the reaction mixture converts **57** into **56**. Under UV photolysis, **58** is converted into **57** which in turn is converted to **56**. Photolysis of **56** regenerates **58** so that a photo-steady-state mixture of all three isomers results.[81]



56 **57** **58**

(65)

The reaction of $Cp_2^*W_2(CO)_4$ with sulfur proceeds as in eqn (66). Compound **60** reacts with excess sulfur to form **59**.[80] Similar sulfur compounds to those shown in eqns (65) and (66) may be obtained from either the single-bonded dimers, $Cp_2M_2(CO)_6$, or the hydrides, $CpM(CO)_3H$.[82]



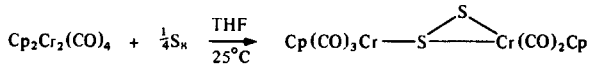
59 **60**

(66)

The Cr≡Cr triple bond in $Cp_2Cr_2(CO)_4$ is reported to react with sulfur as shown in eqns (67) and (68).[83] In our laboratory, we have been unable to obtain the disulfide **62** according to eqn (68); only **61** was isolated.

61 (100%)

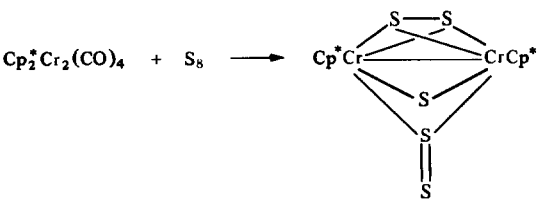
(67)



62 (90%)

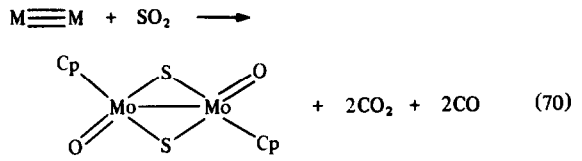
(68)

The more hindered Cp* complex reacts with excess sulfur to give a 22% yield of the pentasulfide shown in eqn (69).[84(a)] The Cr–Cr distance is 2.489(2) Å, and the Cr–S distances range from 2.24 to 2.35 Å. The S—S and S=S distances are 2.15 and 2.10 Å, respectively.



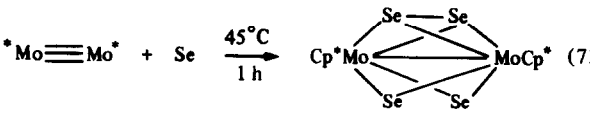
(69)

Compound **1** reacts with SO_2 according to eqn (70).[85]



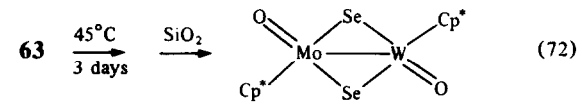
(70)

Results for the heavier chalcogens is limited to the reaction of **2** with Se.[84(b)] A short reaction time gives a 10% conversion to the tetraselenide (**63**); most of the Mo is recovered as unchanged starting material. When a toluene solution of **63** was stirred at 45°C for 3 days, a 45% yield of **64** was obtained following chromatography on silica gel. The source of the oxygen is unknown. The tungsten compound gave the Se analog of **60** [eqn(73)].



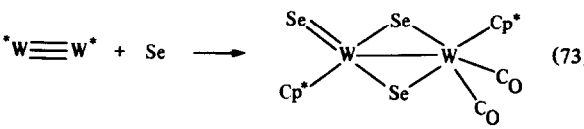
(71)

63



(72)

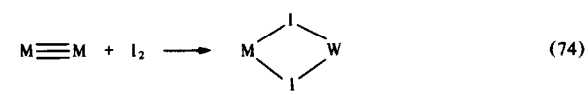
64



(73)

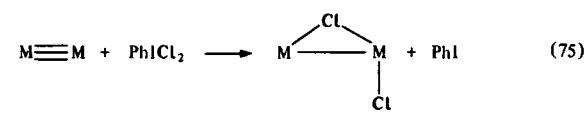
10%

The M≡M triple bond in **1** reacts readily with halogens to give dinuclear adducts.[86] With I_2, the structure is the μ-diiodide (**65**) but the dichloride is suggested to have the unsymmetrical structure (**66**) on the basis of Cl-XPS and NMR data.



(74)

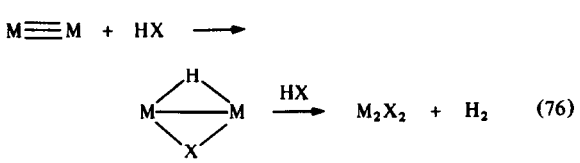
1 **65**



(75)

66

Hydrogen halides, HCl and HI, react with **1** to give the oxidative addition products **67** (X = Cl or I). These hydrohalide adducts react with excess HX to give their respective dihalides (**65** or **66**) and H_2.[86]



(76)

67

In the oxidative reactions of the type discussed above it makes little difference if the starting complex is saturated $Cp_2M_2(CO)_6$ or $CpM(CO)_3H$, or the unsaturated, multiply-bonded derivatives $Cp_2M_2(CO)_4$, if: (a) elevated temperatures, or (b) a large excess of the non-metal is used in the reaction. The utility of the unsaturation in the M≡M bond is best realized when the reactions are carried out under mild conditions with stoichiometric quantities of reagents. Then the enhanced reactivity of the metal–metal multiple bond is advantageous and allows for the isolation of thermally labile or kinetically controlled products, e.g. **55**, **67** etc.

CLUSTER-BUILDING REACTIONS

One of the most useful properties of carbon–carbon multiple bonds is their ability to polymerize and oligomerize into larger structures which maintain the basic skeleton of the monomers. An analogous oligomerization of metal–metal multiply bonded complexes gives metal clusters. To date, the *simple* olimerization of M≡M bonds as depicted in eqn (77) has not been observed.[14,*] Nevertheless, the M≡M triple bond in **1** has served as a convenient synthon in the construction of trinuclear and tetranuclear clusters containing the M_2 unit.

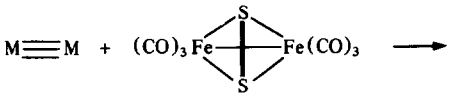
(77)

In our first paper on the reactivity of **1**, we noted that $(R_3P)_2Pt^{(0)}$ could be added to the M≡M bond to give M_2Pt triangulo clusters.[8] Unfortunately, the instability of these clusters has precluded an X-ray structure determination. Several clusters of types MX_3, M_2X_2 and M_3X are produced in the oxidative reactions of M≡M with non-metals (see above). However, the most useful cluster-building

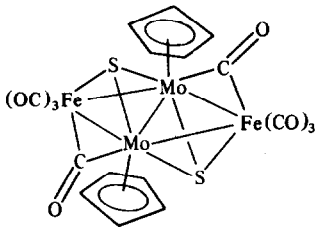
*Oligomerization of metal–metal multiply bonded species upon loss of ligand[87(a)] or through the formation of ligand bridges[87(b),(c)] has been realized.

reactions of M≡M are those which give ligand-bridged, bimetallic clusters.

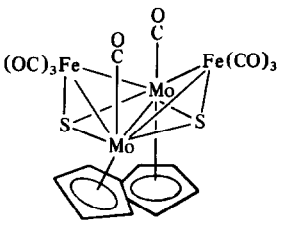
Thus, **1** reacts with the disulfide linkage in **68** to give the isomeric clusters **69** and **70**.[88,89] Both **69** and **70** are 62-electron clusters and have five metal–metal bonds in accordance with various electron-counting schemes.[90] They differ primarily in the disposition of the sulfide ligands—in the planar isomer (**69**), the sulfide ligands are on opposite sides of the Mo_2Fe_2 plane (the molecule is centrosymmetric) whereas in **70** the sulfurs are cisoid and the metals are in the more common butterfly geometry. The chromium derivative, $Cp_2Cr_2(CO)_4$, reacts with **68** to give the Cr butterfly analogous to **70**.[91] These $Mo_2Fe_2S_2$ clusters and related $Mo_2Co_2S_3$ clusters[92] are effective catalysts for CO methanation and thiophene HDS when supported on Al_2O_3.[93]



1 **68**



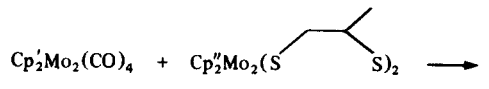
69



(78)

70

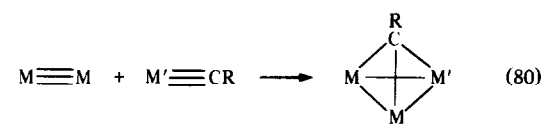
The triple bond in **1** also displaces propene from $Cp_2Mo_2(SCH_2CH(Me)S)_2$ [eqn. (79)] or H_2 from $Cp_2Mo_2(\mu\text{-}SH)_2(\mu\text{-}S)_2$ (**71**) to give the Mo_4S_4 cubane, **72**.[88] This route to these cubanes is the most convenient and allows one to control the substitution on the Cp rings almost at will. The reaction of **71** with $Cp_2W_2(CO)_4$ failed to give the $Cp_4Mo_2W_2S_4$ cubane.[94] The $Cp_4Mo_4S_4$ cubanes are very readily oxidized to mono- or dications, the structures of which have been determined.[95] The PES of the Mo_4S_4 cubanes,[95] their cyclic voltametry, their structural parameters, and an EHMO calculation[94] are all consonant with an electron configuration of $a_1^2e^4t_2^6$ for the six cluster framework electron pairs as originally suggested by Trinh-Toan *et al.*[96]



$$Cp'_2Mo_2(CO)_4 + Cp''_2Mo_2(SC_3H_6S)_2 \longrightarrow Cp'_2Cp''_2Mo_4S_4 + 4CO + 2C_3H_8 \quad (79)$$

72

A beautiful illustration of the utility of the isolobal principle is the addition of a metal carbyne to the M≡M bond to give trimetalla-tetrahedrane structures as shown in eqn (80) [cf. eqn (18)].[97]

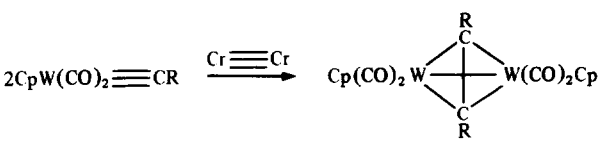


(80)

1 **73**

M = $Cp(CO)_2Mo$, M′ = $Cp(CO)_2W$

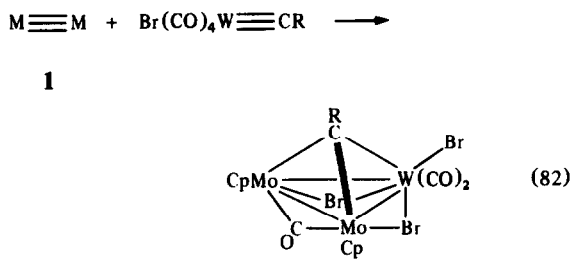
Cluster **73** is obtained in quantitative yield when M = Mo and M′ = W. The reaction of the W carbyne with $Cp_2Cr_2(CO)_4$ led to the dimerization of the carbyne [eqn (81)]. It was found that the Cr≡Cr complex *catalyzes* the dimerization of the carbyne.[97]



(81)

Green *et al.*[97] found that a complex mixture resulted when **1** was allowed to react with $Br(CO)_4W{\equiv}CR$ in ether. A 22% yield of the trimetallic cluster **73** [M = M′ = $Mo(CO)_2Cp$], was obtained by chromatography of the mixture over Florisil. Cotton and Schwotzer isolated a 20% yield of cluster **74** from the nearly identical reaction (THF solvent, followed by chromatography over silica gel).[98] Either the solvent exerts a strong influence on the course of this reaction, or the reaction mixture reacts further on the chromato-

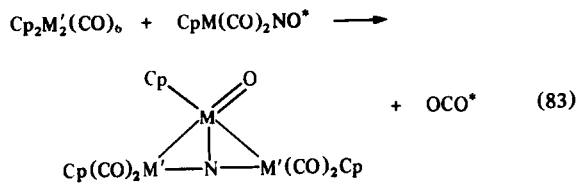
graphy column to give products which depend on the column packing.



(82)

74

The nitrosyl complexes, $Cp(CO)_2M{\equiv}NO$ (M = Mo or W) react with $Cp_2M'_2(CO)_6$ (M′ = Mo or W) to give trimetallic nitrido clusters (**75**) in a reaction that is superficially related to the reactions of the carbynes above.[99] However, the conditions (200°C, sealed tube, 1 h), low yields, and the demonstrated cleavage of the N–O bond suggest the mechanism of formation of the clusters **75** is not a straightforward addition of the M≡NO bond to the M≡M bond.

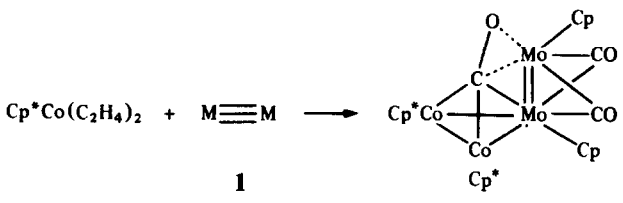


(83)

75

M and M′ = Mo or W

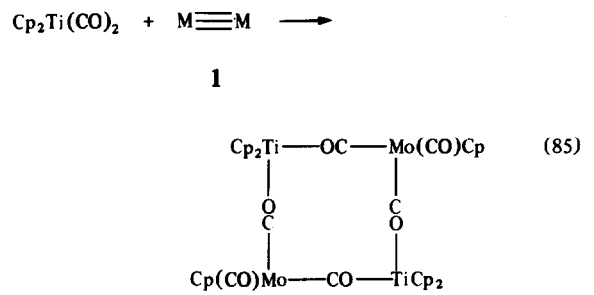
Attempts to insert the M≡M unit into preformed clusters by thermal reactions have been largely unsuccessful.[1] However, **1** does react with Cp*Co $(C_2H_4)_2$ under UV photolysis to give the novel cluster **76** in 20% yield.[100]



76

(84)

Finally, $Cp_2Ti(CO)_2$ reacts with **1** as shown in eqn (85). The carbonyl groups are transferred from Ti to Mo and the Ti is formally oxidized from Ti(II) to Ti(III). Lewis bases (B) cleave the dimeric structure to give $Cp_2Ti(B)OC(CO)_2MoCp$.[101]



(85)

CONCLUSION

The compounds $Cp_2M_2(CO)_4$ (M = Mo or W) and related substituted-Cp derivatives have proven to be extremely versatile reagents for the elaboration of more complex molecules containing the Cp_2M_2 units. The M≡M units may be thought of as dimetal fragments which have been stripped of two ligands (four electrons) and are thus extremely electrophilic. Consequently, reactions with nucleophiles often occur under very mild conditions so that thermally labile products may be isolated and new bonding modes revealed.

At higher temperatures (>100°C), or under UV photolysis, CO is lost from the M≡M unit and more complex modes of reactivity are often observed. Even here, however, the presence of the metal–metal triple bond may be instrumental in directing the reaction to give dinuclear products. It is well known,[7,8] that the Mo–Mo or W–W *single* bonds in $Cp_2M_2(CO)_6$ complexes are extensively dissociated at elevated temperatures, and these single-bonded dimers often form mononuclear products as a result. In contrast, there is no evidence at all that the triply-bonded dimers dissociate into mononuclear fragments either thermally or under UV photolysis.[102]

The Cr≡Cr triple bond in $Cp_2Cr_2(CO)_4$ and related complexes has hot been as useful a starting material as its Mo and W congeners. Intractable mixtures are often produced.

Finally, a word about the concept of an "inorganic functional group" is appropriate. The term "functional group", as derived from organic chemistry, connotes more than a reactive grouping of atoms in a larger molecule. The term also suggests that a particular grouping of atoms will react in certain specified ways when exposed to certain conditions and/or reagents.

Are the Mo≡Mo and W≡W triple bonds in $Cp_2M_2(CO)_4$ "inorganic functional groups"? They are certainly reactive and some generalizations

concerning their reactivity can be made. However, as the reactions of M≡M with diazoalkanes so amply demonstrate, the course of the reactions of M≡M may be greatly altered by subtle changes in the reagents, the substitution on the Cp ring etc. Under such circumstances, the utility of the functional group *concept* is clearly limited.

The utility of the M≡M *compounds* is not restricted by our limited ability to predict the exact course of the reactions, however. The rational syntheses of the clusters **69–73**, or the metallacyclopropene (**39**) clearly show that the reactivity of the M≡M unit can be extrapolated successfully to new areas. In any event, it is clear that the availability of compounds with metal–metal multiple bonding opens a new dimension to the synthetic chemist, and that the exploration of metal–metal multiple bond reactivity will continue to be an exciting area of research.

Abstract—$W_2(OR)_6L_n$ compounds [R = Bu^t, $n = 0$; R = Pr^i or Np (Np = neopentyl), L = py (py = pyridine) or $HNMe_2$, $n = 2$] react with alkynes (R′C≡CR′) under mild conditions (hexane solutions, room temperature or below) to yield a variety of products depending upon the nature of the alkoxide, the alkyne and the mole ratio of the reactants. The products include alkylidyne complexes, $L_n(RO)_3W{\equiv}CR'$ ($n = 1$ or 0) (Schrock *et al.*, *Organometallics* 1985, **4**, 74), alkyne adducts, $W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)$, alkylidyne-capped tritungsten complexes, $W_3(\mu_3\text{-}CR')(OR)_9$, and $W_2(OR)_6(L)(\mu\text{-}C_4R'_4)$ or $W_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds. Evidence for equilibria involving alkyne adducts and alkylidyne species is found for certain combinations of R and R′. (1) The alkylidyne complexes $(Bu^tO)_3W{\equiv}CMe$ and $(py)_2(Pr^iO)_3W{\equiv}CNMe_2$ react with CO (1 atm, 22°C, in hexane) to yield alkyne adducts $W_2(OBu^t)_6(\mu\text{-}C_2Me_2)(CO)$ and $W_2[(OPr^i)_6(CO)_2(\eta^2\text{-}C_2(NMe_2)_2]$, respectively. (2) The alkylidyne complexes $[(Pr^iO)_2(HNMe_2)(R'C{\equiv})W(\mu\text{-}OPr^i)]_2$ react with alkynes R′C≡CR′ (>2 equiv, hexane, 22°C) to give $W_2(OPr^i)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds (R′ = Me or Et). (3) The alkyne adducts $W_2(ONp)_6(py)_n(\mu\text{-}C_2R'_2)$ (R′ = Et or Ph, $n = 1$; R′ = Me, $n = 2$) react with $W_2(ONp)_6(py)_2$ in a 1:2 mole ratio at 22°C in hexane to yield $W_3(\mu_3\text{-}CR')(ONp)_9$ compounds. In related reactions involving 1,2-bishydrocarbyltetraalkoxides, $W_2(CH_2R'')_2(OR)_4$, and alkynes (R′C≡CR′) (2 equiv), alkyne adducts of formula $W_2(CH_2R'')_2(\eta^2\text{-}C_2R'_2)_2(OPr^i)_4$ and $W_2(CH_3)_2(\mu\text{-}C_2R'_2)(OBu^t)_4(py)$, alkylidyne-bridged complexes $HW_2(\mu\text{-}CR'')(\mu\text{-}C_4R'_4)(OPr^i)_4$ and products of W≡W and C≡C metathesis have been isolated for various combinations of R, R′ and R″.

The reactivity of multiple bonds between metal atoms represents a new chapter in inorganic chemistry. The classic text[1] on inorganic reaction mechanisms makes no mention of this topic, not surprisingly since the discovery of multiple bonds between metal atoms by Cotton and his coworkers came only in the mid-to-late 1960s.[2] The original emphasis was on determining the electronic structure of the bonds that held metal atoms so close together. There too was the ensuing flourish of activity directed toward determining the propensity for metal atoms to form such compounds and even this has not yet been unequivocally established.[3]

The reactivity of M–M multiple bonds was not given specific attention until the mid-to-late 1970s. One of us speculated about the general patterns of reactivity for triple bonds between molybdenum and tungsten atoms and noted that the different modes of reactivity of the M≡M bond in compounds of formula $M_2(OR)_6$ and $Cp_2M_2(CO)_4$ could be traced to their different electronic configurations and their different sets of attendant ligands.[4] These two factors make the chemistry of M–M triple bonds (M = Mo or W) much more varied than that of C–C triple bonds. The latter always have $\sigma^2\pi^4$ MO configurations and are only somewhat perturbed by substituent effects. By contrast M–M triple bonds may have one of a variety of valence MO configurations, $\sigma^2\pi^4$, $\pi^4\delta^2$, $\sigma^2\pi^4\delta^2\delta^{*2}$

*Author to whom correspondence should be addressed.

and $\sigma^2\pi^2\delta^2$, and are greatly influenced by the supporting ligands.

Over the past 10 years the reactivity of the M≡M bonds in $M_2(OR)_6$ and $Cp_2M_2(CO)_4$ compounds has been extensively and systematically studied. Several reviews dealing with various aspects of the chemistry of these compounds are to be found in the literature.[4–8] In this article we describe results from our laboratory, together with those reported by Professors Schrock and Cotton and their coworkers, dealing with reactions between W–W triple bonds and C–C triple bonds. The supporting ligands on tungsten are alkoxides or alkoxide–alkyl combinations. Comparisons with the reactivity observed for $Mo_2(OR)_6$ and $Cp_2M_2(CO)_4$ compounds are only briefly described.

METATHESIS-LIKE SCISSION OF C–C AND W–W TRIPLE BONDS

Schrock and co-workers[9] first noted the remarkable scission of C–C and W–W triple bonds and the formation of alkoxy-supported alkylidyne complexes [eqn (1)]:

$$W_2(OBu^t)_6 + R'C{\equiv}CR' \xrightarrow[\text{hexane}]{22^\circ C} 2(Bu^tO)_3W{\equiv}CR' \qquad (1)$$

R′ = Me, Et or Pr

Subsequent work[10] showed that this type of reaction could be used for the synthesis of a large group of compounds which were tolerant of a variety of organic functionalities (R′). The simple cleavage of C≡C bonds for symmetrically substituted alkynes was limited by steric factors and reactions employing PhC≡CPh and $Bu^tC{\equiv}CBu^t$ did not yield $(Bu^tO)_3W{\equiv}CR'$ compounds, though other routes could be found for their synthesis. The major thrust of this work was directed toward the utility of the tris-tert-butoxy tungsten alkylidyne complexes as alkyne-metathesis catalysts.[11]

In later work, Cotton and coworkers[12] studied reactions involving PhC≡CPh and EtC≡CEt at somewhat elevated temperatures (60–80°C) and with differing mole ratios of alkyne to $W_2(OBu^t)_6$, but with this ratio always being less than 1. Under these conditions some cleavage of the C≡C bond was observed although alkoxide group scrambling and ligand breakdown also occurs.

Crystalline products that have been structurally characterized from the Cotton reactions include $(Bu^tO)_3W{\equiv}CPh$[12(c)] (**I**), $W_2(OBu^t)_4(\mu\text{-}CPh)_2$,[12(a)] $W_2(OBu^t)_4(\mu\text{-}C_2Ph_2)_2$[12(a)] and $[W_3(OBu^t)_5(\mu\text{-}O)(\mu\text{-}CEt)O]_2$.[12(b)] In our laboratory we have also examined the crystal and molecular structures of $[(Bu^tO)_3W{\equiv}CX]_2$ (**II**) (X = Me[13] or NMe_2[14]), and $(py)_2(Pr^iO)_3W{\equiv}CNMe_2$[15] (**III**). The benzylidyne compound (**I**) is monomeric, while for X = Me and NMe_2 there is loose association to the dimeric structure shown in **II** below. The pyridine adduct (**III**) contains a pseudo octahedral tungsten atom. In each structural type the W≡C bond distance is *ca* 1.76 Å and is little perturbed by groups trans to itself. The terminal alkoxide ligands have fairly short W–O distances (*ca* 1.88–1.90 Å) while bonds *trans* to the W≡C bond in **II** and **III** are extremely long, e.g. W–O = 2.484(4) Å in **II** (X = Me) and W–N = 2.457(12) Å in **III**.

ALKYNE ADDUCTS

Reactions between $W_2(OBu^t)_6$ or $W_2(OR)_6(py)_2$ and alkynes (1 equiv) in hydrocarbon solvents in the presence of excess pyridine have allowed the isolation of an extensive series of alkyne adducts of formula $W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)$.[7,16] For R = Bu^t[16(a)] and Pr^i[16(a)] only ethyne adducts (R′ = H) can be isolated, whilst for the less sterically demanding neopentoxide ligands R′ may be H,[16(b)] Me,[16(a)] Et[16(b)] or Ph.[16(b)] However, attempts to prepare adducts where R′ = Bu^t or $SiMe_3$ failed even for R = Np.[16(b)] Three structural types have been observed in the solid state for these compounds and these are depicted in **IV–VI** below.

Table 1. Selected bond distances (Å) for $W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)$ compounds (n = 1 or 2)

Compound	Structure type	M–M	C–C	M–C(av)	Reference

VI

In each there is a cross-wise or perpendicular alkyne bridge supported by either one or two alkoxide bridges. As a trend one can see that as the combined steric bulk of R and R′ increases so: (i) the number of pyridine ligands decreases, and (ii) the structures having only one alkoxide bridge are favored. It is also interesting to note that the W–W and μ-(C–C) distances are around 2.60 and 1.40 Å, respectively, with the longest W–W and C–C distances being found for $W_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$. Pertinent structural data are summarized in Table 1.

In solution a number of these compounds are fluxional at room temperature and all are labile toward pyridine dissociation. One must therefore recognize that in solution other structural types are energetically accessible at ambient temperatures and one can only speculate about their structural forms. At low temperatures, however, in toluene-d_8, the ^{1}H NMR data are entirely consistent with expectations based on the observed solid-state structures. Only in the case of the compound $W_2(ONp)_6(py)_2(\mu\text{-}C_2H_2)$ is there evidence[16(b)] for the presence of another structural type in solution and, in this instance, an equilibrium mixture involving the bis-alkoxide-bridged structure (IV) and the mono-alkoxide-bridged structure (V) can reliably be established.

A point of interest arises from a consideration of the spectra of $W_2(\mu\text{-}{}^*C_2H_2)$-containing compounds (*C represents 92 mol % ^{13}C). The ^{1}H and ^{13}C spectra associated with the μ-C_2H_2 moiety are each part of a AA′XX′ spectrum with additional satellites arising from coupling to ^{183}W (I = 1/2, 14.5% natural abundance). The magnitude of $^1J_{^{13}C-^{13}C}$ is very small, falling in the range 11–19 Hz.[7,16(a),17] For related $Mo_2(\mu\text{-}C_2H_2)$-containing compounds, $^1J_{^{13}C-^{13}C}$ values of 23–29 Hz[7,17] are found while in the carbonyl-containing compounds $Cp_2Mo_2(CO)_4(\mu\text{-}C_2H_2)$ and $Co_2(CO)_6(\mu\text{-}C_2H_2)$, $^1J_{^{13}C-^{13}C} = 43$[17] and 56[18]* Hz, respectively (see Table 2). For these alkyne adducts there exists an approximate linear inverse correlation between the magnitude of $^1J_{^{13}C-^{13}C}$ and the C–C bond distance.[17] The smallest value of $J_{^{13}C-^{13}C}$ is seen for the compound $W_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$ which also has the longest W–W and C–C distance. In solution this compound exists in equilibrium with $(Bu^tO)_3W{\equiv}CH$,[16(a)] as we describe later, and it appears that the magnitude of $J_{^{13}C-^{13}C}$ provides an indication of the likelihood for C–C and M–M cleavage to give alkylidyne species. For a comparison we note that the values of $^1J_{^{13}C-^{13}C}$ in ethyne, ethylene and ethane are 171.5, 67.2 and 34.6 Hz,[19] respectively, with C–C distances of *ca* 1.21, 1.34 and 1.54 Å.[20] Only in small organic rings have such small values of $^1J_{^{13}C-^{13}C}$ been seen; $^1J_{^{13}C-^{13}C}$ = 9.4 Hz[21] and d_{C-C} = 1.48 Å[22] recently reported for the central C_4 tetrahedral unit in $C_4Bu^t_4$ is particularly worthy of mention. On the basis of W–W, C–C and W–C bond distances and $^1J_{^{13}C-^{13}C}$ coupling constants, we formulate these $W_2(\mu\text{-}C_2H_2)$-containing compounds as ditungstatetrahedranes. The presence of a W–W single bond allows one to formally ascribe oxidation states +5 to each tungsten atom. In other words, the addition of an alkyne across the W≡W bond leads to a

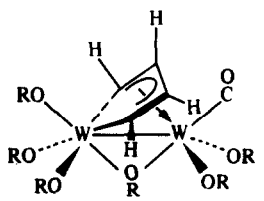
W_2^{6+} to W_2^{10+} transformation. Along the same line of reasoning by counting an alkylidyne as a 3-ligand, the metathesis-like reaction (1) may be viewed as an oxidative cleavage of the W≡W bond: $W_2^{6+} \rightarrow 2W^{6+}$.

C–C COUPLING REACTIONS

In all cases where $W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)$ compounds are isolable and in some instances where such compounds are not (see later) the addition of more alkyne leads to products of C–C coupling, specifically $W_2(OR)_6(L)(\mu\text{-}C_4R'_4)$ and/or $W_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$.[23] These reactions parallel those originally discovered by Rothwell[24] in these laboratories for $Mo_2(OR)_6$ compounds in their reactions with alkynes. The isolation of $M_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds was possible only for M = W, though related molybdenum analogues are probably involved in the catalytic cyclotrimerization of alkynes by $Mo_2(OR)_6$ compounds. By contrast, $W_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds (R = Pr^i; R′ = H,[23] Me[23] or Et:[25] R = Np, R′ = H[23] or Me[23]) do not readily eliminate benzenes, and therefore $W_2(OR)_6$ compounds are not catalytically active in the cyclotrimerization of alkynes. This difference in the chemistry of $M_2(OR)_6$ compounds reflects the general truism: reductive elimination is easier from Mo_2 centers than W_2 centers while oxidative addition occurs in the inverse order. This is a reflection of thermodynamic factors and not the mechanism or mechanisms involved.

Addition of ethyne (2 equiv) to $W_2(OBu^t)_6$ in the absence of py leads to $W_2(OBu^t)_6(\mu\text{-}C_4H_4)$[23] which, though rather thermally unstable, can be isolated as a carbonyl adduct, $W_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$,[23] in a crystalline state and has been shown to adopt the structure depicted by **VII** below.



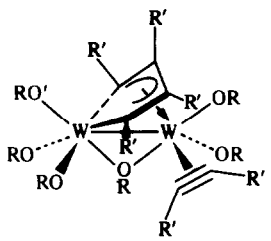
R = Bu^t

VII

Presumably $W_2(OBu^t)_6(\mu\text{-}C_2H_2)$ is a reactive intermediate in the formation of **VII** but such a compound has not been detected. If only 1 equiv of C_2H_2 is added to a solution of $W_2(OBu^t)_6$, **VII** and unreacted $W_2(OBu^t)_6$ are all that are detectable by NMR spectroscopy.[23] Ethyne polymerization to shiny grey metallic $(C_2H_2)_n$ is always competitive with formation of isolable tungsten-containing compounds. It is worth noting that an unstable compound $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$ was detected in analogous reactions employing $Mo_2(OBu^t)_6$ and we have confirmed this claim by Schrock and coworkers[26] in our measurement of $^1J_{^{13}C-^{13}C}$ for the central $Mo_2(\mu\text{-}C_2H_2)$ moiety (see Table 2).

* The original values were obtained using a 60-MHz NMR. The compound was synthesized and analyzed in our labs using a 360-MHz NMR. The values were found to correlate well with the originally reported values; however, for the sake of consistency, our values are entered in Table 2.

The molecular structure found for $W_2(OR)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds is shown diagramatically in **VIII** below.



VIII

In both **VII** and **VIII** the coordination about one tungsten atom approximates to octahedral whilst the other tungsten may be viewed as trigonal bipyramidal with the μ-C_4 ligand being π-bonded to one of the equatorial sites. The W–W distances are long, in the range 2.85–2.88 Å, representing single bonds between the metal atoms. The M–M bond can be viewed as a dative bond formed by electron pair donation from the π-C_4-bonded tungsten atom to the six-coordinate W(6+) center. Of course, this is only a simplistic picture.

ALKYLIDYNE-CAPPED TRITUNGSTEN COMPOUNDS

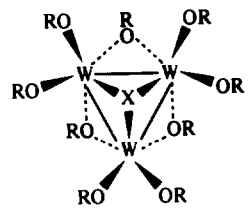
The first member of the $W_3(\mu_3\text{-}CR')(OR)_9$ series to be discovered was for R′ = Me and R = Pr^i.[27] This was obtained from the reaction between $W_2(OPr^i)_6(py)_2$ and MeC≡CMe in a hydrocarbon solvent at room temperature. The tritungsten compound was found together with $W_2(OPr^i)_6(\mu\text{-}C_4Me_4)(\eta^2\text{-}C_2Me_2)$ and some unreacted $W_2(OPr^i)_6(py)_2$. Evidently competitive reactions were occurring and the desired compound $W_2(OPr^i)_6(py)_n(\mu\text{-}C_2Me_2)$ was in some way too reactive to be isolated.

A logical comproportionation route to the above compound, suggested by analogy with reactions of Stone and his coworkers[28] and previous results in this lab involving the formation of oxo-capped tritungsten compounds,[29] proved successful as shown in eqn (2):

$$W_2(OPr^i)_6(py)_2 + (Bu^tO)_3W{\equiv}CMe \xrightarrow[\text{hexane–}Pr^iOH]{22^\circ C} W_3(\mu_3\text{-}CMe)(OPr^i)_9. \quad (2)$$

Extensions of this type of reaction have allowed the synthesis of $W_3(\mu\text{-}CR')(OR)_9$ compounds (R′ = Me,[27] R = Pr^i, R′ = Me[16(b)] or Et,[16(b)] R = Np). In most cases it is important that the added alcohol not be in excess to prevent an initial reaction leading to $W(OR)_6$ and alkane. Consequently, addition of ROH is subsequent to the mixing fo the inorganic compounds and is kept to a minimum (3 equiv). Steric factors are apparently important and prevent any comproportionation involving $W_2(OBu^t)_6$ and $(Bu^tO)_3W{\equiv}CR'$ compounds.

The compound where R′ = Me and R = Pr^i has been characterized by a full X-ray study.[27] ^1H and ^{13}C NMR data for all compounds are consistent with the maintenance of the capped, tris-RO-bridged structure depicted by **IX** below. In solution, bridge-terminal RO group exchange is slow on the NMR time-scale.



X = CR′

IX

EQUILIBRIA INVOLVING ALKYNE ADDUCTS AND ALKYLIDYNE COMPLEXES

During the course of our characterization of $W_2(OBu^t)_6(py)(\mu\text{-}{}^*C_2H_2)$[16(a)] we discovered in the ^{13}C and ^1H NMR spectra a persistent impurity which could only reasonably be formulated as the methylidyne complex $(Bu^tO)_3W{\equiv}{}^*CH$. When the ^{13}C NMR spectra were recorded on samples prepared from mixtures of the separately labeled compounds $W_2(OBu^t)_6(py)(\mu\text{-}{}^*C_2H_2)$ and $W_2(OBu^t)_6(py)(\mu\text{-}C_2D_2)$, the appearance of a new signal in the ^{13}C NMR spectra was present and assignable to a $W_2(\mu\text{-}H{}^*CCD)$ moiety. When the analogous experiment was carried out for each of the compounds $W_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$[16(a)] and $W_2(ONp)_6(py)_2(\mu\text{-}C_2H_2)$[16(b)] in their labeled forms, no new signal assignable to a $W_2(\mu\text{-}H{}^*CCD)$ moiety was present. It should also be mentioned that no C–H/C–D scrambling was observed in any of the above experiments.

A plausible interpretation of the above was that the μ-ethyne and methylidyne complexes were, in the case of the Bu^tO ligated system, in equilibrium:

$W_2(\mu\text{-}C_2H_2) \rightleftharpoons 2W{\equiv}CH$. If this were the case then at room temperature the position of equilibrium favored the ethyne adduct by *ca* 5:1. The temperature dependence of the equilibrium constant could not reliably be established since the samples were thermally unstable, decomposing over a period of hours at room temperature and within minutes at +60°C. One could not be sure that at any given temperature the sample was at equilibrium and all spectra were recorded by rapidly cooling the sample to −40°C. The frustrating situation then arises in as much as the labelling study does not prove the existence of the equilibrium, it is merely a plausible explanation. However, since that time a number of other chemical reactions and spectroscopic characterizations lead us to the general conclusion that alkyne adducts of formula $W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)$ and alkylidyne species $(RO)_3W{\equiv}CR'$ are commonly in equilibrium with one another and that the position of equilibrium is dependent on the nature of R and R'. Bulky R and R' combinations favor the alkylidyne species and of the two groups the position of equilibrium is most sensitive to R. We summarize here the basis for our conclusion.

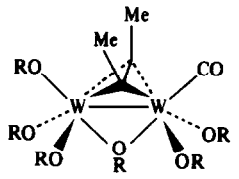
(1) The spectroscopic characterization of the compounds formed in the reaction between $W_2(OCMe_2Et)_6$ and $*C_2H_2$ (1 equiv) in benzene-d_6 in the presence of pyridine indicate a $W_2(\mu\text{-}*C_2H_2)$: $W{\equiv}*CH$ ratio of *ca* 1:5[30] which is roughly the inverse of that found for R = CMe_3.

(2) The compounds $W_2(ONp)_6(py)_n(\mu\text{-}C_2R'_2)$ (R' = Me, $n = 2$; R' = Et or Ph, $n = 1$) act as alkylidyne sources in their reactions with $W_2(ONp)_6(py)_2$ according to eqn (3):[16(b),31]

$$W_2(ONp)_6(py)_n(\mu\text{-}C_2R'_2) + 2W_2(ONp)_6(py)_2 \xrightarrow[\text{hexane}]{22°C} 2W_3(\mu_3\text{-}CR')(ONp)_9 + (n+4)py. \quad (3)$$

A direct preparation of $W_3(\mu_3\text{-}CR')(ONp)_9$ involves the reaction between $W_2(ONp)_6(py)_2$ and $R'C{\equiv}CR'$ in a mole ratio of 3:1.[16(b),31]

(3) The addition of CO (1 atm) to a pale yellow solution of $(Bu^tO)_3W{\equiv}CMe$ causes the solution to turn blue with the formation of $W_2(OBu^t)_6(\mu\text{-}C_2Me_2)(CO)$.[31] The latter compound is stereochemically rigid on the NMR time-scale and has a strongly bond CO ligand [ν(CO) = 1918 cm^{-1}]. The data are consistent with the maintenance of the structure found in the solid state depicted by X below for which W–W = 2.633(1) Å and C–C (μ-C_2Me_2) = 1.36(1) Å.



R = Bu^t

X

Our interpretation of (3) is that CO reacts with $W_2(OBu^t)_6(\mu\text{-}C_2Me_2)$, which is a reactive species in equilibrium with the more stable alkylidyne species $(Bu^tO)_3W{\equiv}CMe$. In a similar way, $(py)_2(Pr^iO)_3W{\equiv}CNMe_2$ reacts with CO (1 atm, 22°C) in toluene to yield $W_2(OPr^i)_6(CO)_2(\eta^2\text{-}C_2(NMe_2)_2)$.[15] It is apparent that the π-acceptor properties of the CO ligand drain electron density away from the metal and this displaces an equilibrium between $W_2(\mu\text{-}C_2R'_2)$ and $W{\equiv}CR$ species toward the alkyne adduct. But it should be emphasized that not all $(RO)_3W{\equiv}CR'$ compounds react in the same manner and a competing reaction involving alkylidyne carbon–carbonyl carbon coupling can occur.[15,32]

(4) Addition of alkynes ($R'C{\equiv}CR'$) to $[(Pr^iO)_2(HNMe_2)(R'C{\equiv})W(\mu\text{-}OPr^i)]_2$,[25] which has a structure closely related to that shown in **III** involving μ-OPr^i ligands *trans* to the $W{\equiv}CR'$ moiety, leads to formation of $W_2(OPr^i)_6(\mu\text{-}C_4R'_4)(\eta^2\text{-}C_2R'_2)$ compounds (**VIII**) (R = Me or Et).[25] The reaction is rapid in hydrocarbon solvents at room temperature. When $*C_2H_2$ is added to $[(Pr^iO)_2(HNMe_2)(EtC{\equiv})W(\mu\text{-}OPr^i)]_2$, $W_2(\mu\text{-}C_2{*}C_2H_2Et_2)$ ligands are formed that have the *CH and CEt groups scrambled over all possible sites as determined by ^{13}C NMR spectroscopy. Fractional crystallization of the products derived from the analogous reaction employing ethyne which was not labeled gave the specific isomeric form shown in Fig. 1.[30] This implies that alkyne metathesis is more rapid than μ-C_4R_4 formation; the latter, however, shuts off the former reaction.

(5) Addition of 2.5 equiv of Quin (Quin = quinuclidine) to a toluene-d_8 solution of $W_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$, which shows two resonances in the ^1H NMR assignable to a bridging ethyne compound and a methylidyne compound, cleanly converts[30] both species to the $(Quin)(Bu^tO)_3W{\equiv}CH$ compound.[10] Conversely, addition of CO (1 equiv) to an equilibrium mixture of $W_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$ and its methylidyne counterpart in toluene-d_8 leads to the formation of $W_2(OBu^t)_6(\mu\text{-}C_2H_2)(CO)$, an analogue of **X**. Thus, for an equilibrium mixture, $W_2(\mu\text{-}C_2R_2) \rightleftharpoons 2W{\equiv}CR$, supported by alkoxide ligands,

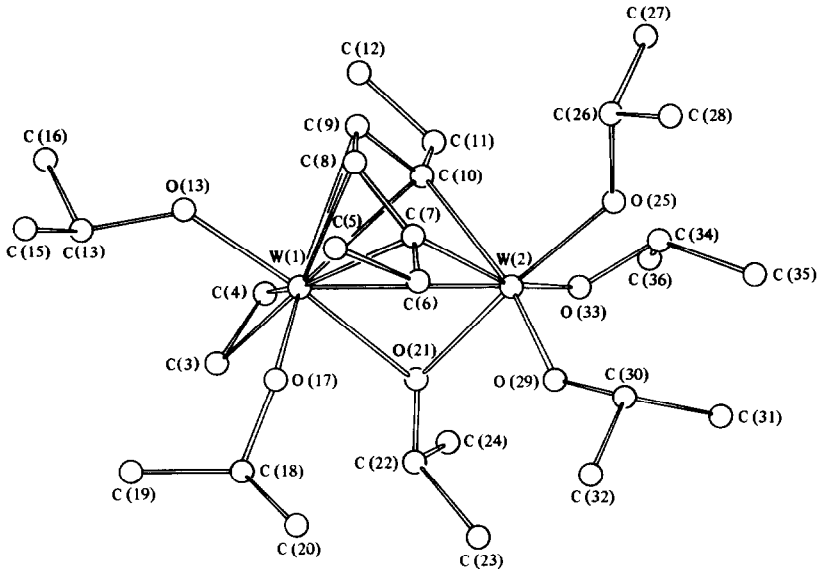


Fig. 1. A ball-and-stick drawing of the $W_2(OPr^i)_6(\mu\text{-}C_4H_2Et_2)(\eta^2\text{-}C_2H_2)$ molecule. Pertinent bond distances (Å) are: W(1)–W(2) = 2.8741(16), W(2)–C(7), W(2)–C(10) = 2.151(16), 2.167(15); W(1)–C(7), W(1)–C(8), W(1)–C(9), W(1)–C(10) = 2.417(16), 2.389(15), 2.407(16), 2.411(16); W(1)–C(3), W(1)–C(4) = 2.110(17), 2.072(16). The W–O distances fall within the range of W–OR distances (terminal and μ_2) reported in Ref. 6.

addition of neutral donor ligands may displace the equilibrium to either the left or the right. The strong σ-donor quinuclidene stabilizes the W(6+) W≡CR species while the π-acceptor CO traps the $W_2(\mu\text{-}C_2R_2)$ species by competing with the alkyne for π-electron density.

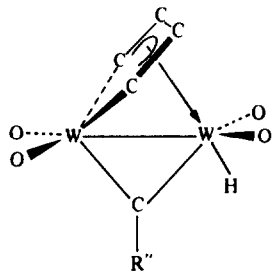
REACTIONS BETWEEN 1,2-DIALKYLTETRAALKOXIDES OF DITUNGSTEN AND ALKYNES

Alcoholysis reactions involving 1,2-$W_2(CH_2R'')_2(NMe_2)_4$ compounds[33] have allowed the preparation and isolation of stable compounds of formula 1,2-$W_2(CH_2R'')_2(OR)_4$ (R = Bu^t, R'' = H: R = Pr^i; R'' = Ph, $SiMe_3$ or Bu^t) together with other combinations for R and R'' where CH_2R'' contains no accessible β-hydrogen atoms.[34] These compounds display a variety of reactions with alkynes.[29(b),35] For the sake of brevity we shall focus only on those tungsten compounds specified above and their reactions with MeC≡CMe and EtC≡CEt.

The $W_2(CH_2R'')_2(OPr^i)_4$ compounds react with MeC≡CMe (2 equiv) in hydrocarbon solvents according to eqn (4):

$$W_2(CH_2R'')_2(OPr^i)_4 + 2MeC{\equiv}CMe \rightarrow HW_2(\mu\text{-}CR'')(\mu\text{-}C_4Me_4)(OPr^i)_4 + R''CH_3. \quad (4)$$

The structures of these alkylidyne bridged ditungsten compounds are depicted by **XI** below. The hydride ligand, which was not located by X-ray

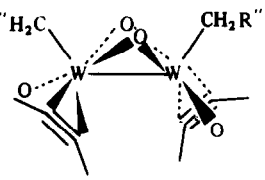


XI

diffraction[35] in the study of the benzylidyne compound $HW_2(\mu\text{-}CPh)(\mu\text{-}C_4Me_4)(OPr^i)_4$, was detected by NMR spectroscopy. The magnitude of J_{W-H} (125 Hz) and more importantly the integral intensity of the satellites relative to the central hydride resonances indicate a terminal W–H moiety. Also, the chemical shift for the hydride at +20.4 ppm is nearly 10 ppm downfield of $W_2(\mu\text{-H})$ signals commonly found with alkoxide-supported, hydrido-bridged W_2 and W_4 species.[36] The actual location of the terminal H ligand was established from NOE difference spectroscopy based on reciprocal NOEs of the hydride with the ortho-hydrogen atoms of the benzylidyne ligand and the adjacent OPr^i methine hydrogens.[29(b)]

The relative rate of reaction (4) is dependent on the steric bulk of R'' following the order R'' = Bu^t -> $SiMe_3$ > Ph and, for R'' = $SiMe_3$ and Ph, inter-

mediates of formula $W_2(CH_2R'')_2(\eta^2\text{-}C_2Me_2)_2(OPr^i)_4$ have been fully characterized. These compounds adopt a common structure based on **XII** and this has been determined crystallographically for R″ = Ph.[35]



XII

Each tungsten atom is in a square based pyramidal environment with the CH_2R'' ligand in the apical position. The $\eta^2\text{-}C_2Me_2$ ligand can be viewed as a 2- ligand, a metallacyclopropene, and the W–W distance [2.668(1) Å] is representative of a single bond. On the NMR time-scale rotation about the $W\text{–}C_2$ alkyne vector can be monitored, and based on coalescence temperatures, the activation energy was calculated to be 9.9(2) kcal mol^{-1}.

The rate of conversion of **XII** to **XI** in benzene-d_6 [eqn (5)]:

$$W_2(CH_2R'')_2(\eta^2\text{-}C_2Me_2)_2(OPr^i)_4 \xrightarrow{k} HW_2(\mu\text{-}CR'')(\mu\text{-}C_4Me_4)(OPr^i)_4 + R''CH_3 \quad (5)$$

has been followed by NMR spectroscopy as a function of temperature for R″ = Ph and $SiMe_3$.

The reactions obey first-order kinetics beyond four half-lives over the temperature ranges studied, and cross-over experiments employing $W_2(CD_2C_6D_5)_2(\eta^2\text{-}C_2Me_2)_2(OPr^i)_4$ (**XIII**) indicated an intramolecular reaction: no scrambling of H/D was observed in the formation of toluene and toluene-d_8 in eqn (5). Activation parameters were determined to be $\Delta H\dagger = 24 \pm 1$ kcal mol^{-1} and $\Delta S\dagger = -9 \pm 2$ eu for R″ = Ph, and $\Delta H\dagger = 21 \pm$ kcal mol^{-1} and $\Delta S\dagger = -9 \pm 2$ eu for R″ = $SiMe_3$. A comparison of rate constants (k) for **XII** (R″ = Ph) and **XIII** revealed a small primary kinetic isotope ($k_H/k_D = 1.4$ at 60°C).[29(b)]

Interpretation of these data must be speculative at this point since a number of individual reaction steps must occur in eqn (5), and the specific order of C–C coupling to generate the $\mu\text{-}C_4Me_4$ ligand and $C\text{–}H_\alpha$ activation leading to elimination of CH_3R'' remains to be established. The latter presumably involves a 1,2-alkyl shift forming a 1,1-$W_2(CH_2R'')_2$ reactive intermediate prior to $C\text{–}H_\alpha$ activation. Such a shift is observed in a related reaction between 1,2-$W_2Me_2(OBu^t)_4(py)_2$ and MeC≡CMe, forming the thermally unstable compound 1,1-$W_2Me_2(\mu\text{-}C_2Me_2)(OBu^t)_4py$.[29(b)] The solid-state structure of this alkyne-bridged 1,1-dialkyl compound is shown in Fig. 2.

Reactions involving EtC≡CEt and $W_2(CH_2R'')_2(OPr^i)_4$ compounds are more complex and an analogue of **XI** with R′ = Et has not been well characterized. However, the bis-alkyne adducts analogous to **XII** have been fully characterized for R″ = Pr and $SiMe_3$, and are more thermally stable toward $R''CH_3$ elimination than their dimethylacetylene analogues. In the case of R″ = Bu^t, a competing reaction leading to propylidyne formation is extremely rapid [eqn (6)]:

$$W_2(CH_2Bu^t)_2(OPr^i)_4 + EtC{\equiv}CEt \xrightarrow[\text{hexane}]{22°C} [W({\equiv}CEt)(OPr^i)_2(CH_2Bu^t)]_2 \quad (6)$$

and no intermediates have been detected thus far.[29(b)]

The molecular structure of the propylidyne complex is shown in Fig. 3 and reveals that each tungsten atom is in a trigonal bipyramidal environment. The structure is a derivative of **II** in which a pair of terminal OR ligands, one on each tungsten atom, is replaced by a pair of CH_2Bu^t ligands. It is worth noting here that when 1 equiv of alkyne is used in reaction (4), only bis-alkyne compounds (**XII**) or their derivatives (**XI**) and unreacted $W_2(CH_2R'')_2(OPr^i)_4$ are isolated. Evidently in the reaction between EtC≡CEt and $W_2(CH_2Bu^t)_2(OPr^i)_4$, the C≡C and W≡W bond metathesis reaction is faster than any possible C–C coupling or C–H activation reactions.

RELATED REACTIONS INVOLVING C≡C AND W≡W BONDS

Alkynes are known to add to $Cp_2M_2(CO)_4$ compounds to give 1:1 alkyne adducts.[37(a)] No alkylidyne formation has been reported but at elevated temperatures where CO dissociation becomes favored other C–C coupling reactions have been documented: $M_2(\mu\text{-}C_2R_2) \rightarrow M_2(\mu\text{-}C_4R_4) \rightarrow M_2(\mu\text{-}C_8R_8)$.[37(b)]

Though neither $W_2(CH_2SiMe_3)_6$ nor $W_2(NMe_2)_6$ appear to react with alkynes,[9] at least under the conditions employed for the alkoxides, the mixed chlorodimethylamide $W_2Cl_2(NMe_2)_4$ is reactive and a number of alkyne adducts supported by pyridine ligands have been isolated having formula $W_2Cl_x(NMe_2)_{6-x}(\mu\text{-}C_2RR')(py_2)$ ($x = 2$, 3 or 4; R and R′ are one of H, Me or Ph).[38] Phosphine adducts have also been isolated for some of the above, and the conversion of $W_2Cl_3(NMe_2)_3(\mu\text{-}C_2H_2)L_2$ to $W_2Cl_3(NMe_2)_2(\mu\text{-}N(CH_2)CH_3)$

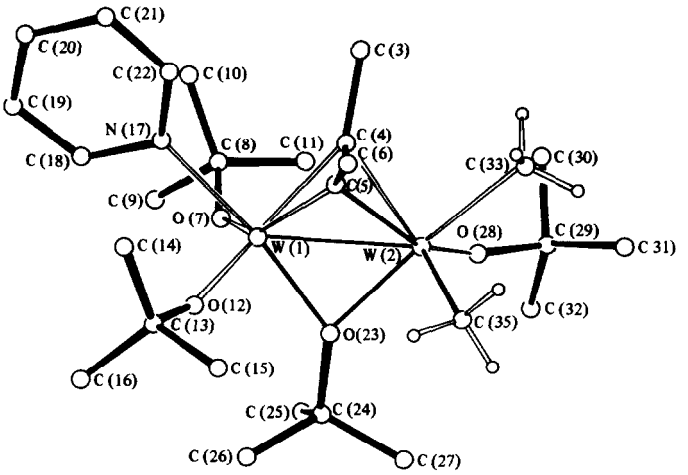


Fig. 2. A ball-and-stick drawing of the 1,1-$W_2Me_2(\mu\text{-}C_2Me_2)(OBu^t)_4(py)$ molecule. Pertinent bond distances (Å) and angles (°) averaged where appropriate: W(1)–W(2) = 2.6223(12); C(4)–C(5) = 1.412(19); W(2)–C(33) = 2.233(16); W(2)–C(35) = 2.162(16); W–O(23) = 2.05(3); W(2)–O(28) = 1.873(11); W(1)–O(terminal) = 1.91(3); W(1)–N(17) = 2.216(12); C–C–C(alkyne) = 133(3); W(2)–O(28)–C(29) = 158.7(11); W(1)–O–C(terminal) = 150(5).

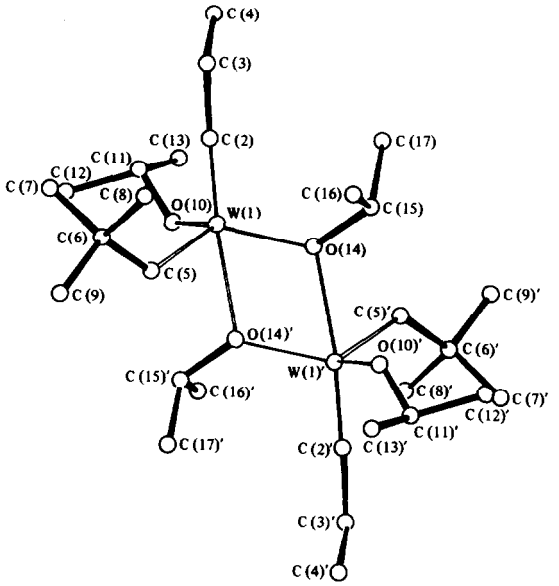

Fig. 3. A ball-and-stick drawing of the $[W(\equiv CEt)(CH_2Bu^t)(OPr^i)_2]_2$ molecule. Pertinent bond distances (Å) and angles (°): W(1)–C(2) = 1.765(7); W(1)–C(5) = 2.105(7); W(1)–O(14) = 1.961(5); W(1)–O(14)′ = 2,365(5); W(1)–O(10) = 1.882(5), W(1)–W(1)′ = 3.514(1); W(1)–O(10)–C(1) = 134.6.

$(\mu\text{-}CHCH_2)L_2$ has been studied for L = PMe_3 and PMe_2Ph.[38(a)] No cleavage of the C–C bond has yet been noted in these studies.

CONCLUSIONS

The reactions between alkynes and $W_2(OR)_6$ compounds highlight the fascinating chemistry surrounding the W≡W bond supported by alkoxide ligands. The latter provide ancillary ligands (spectator ligands) which can tune the reactivity of the W≡W moiety in terms of both its electronic properties and its steric accessibility. This allows one to enter a realm of reactivity not accessible from mononuclear chemistry, though some of the compounds described here, notably the $(RO)_3W{\equiv}CR'$ compounds, can be made from other routes.[39] Many of the detailed reaction pathways at the ditungsten center remain to be established. These matters are of continuing interest to us in our efforts to unravel the chemistry of triple bonds between molybdenum and tungsten atoms supported by alkoxide ligands.

THE SYNTHESIS AND PROPERTIES OF COMPLEXES CONTAINING HETERONUCLEAR QUADRUPLE BONDS

ROBERT H. MORRIS

Department of Chemistry and the Scarborough Campus, University of Toronto, 80 St George St., Toronto, Ontario, Canada M5S 1A1

Abstract—The complexes $CrMo(O_2CMe)_4$, $CrMo(mhp)_4$, $MoW(mhp)_4$ (mhp = 2-hydroxy-6-methylpyridine anion), $MoW(O_2CCMe_3)_4$, $MoWCl_4(PMe_3)_4$, $MoWCl_4(PMePh_2)_4$ and $Cl_2(PMe_3)_2MoWCl_2(PMePh_2)_2$ are the only ones known to contain heteronuclear quadruple bonds. The synthesis and properties of these complexes are reviewed and compared to analogous complexes containing homonuclear quadruple bonds. The complexes containing bridged Mo–W bonds appear to have enhanced stability relative to their homonuclear congeners whereas complexes containing bridged Cr–Mo bonds or unbridged Mo–W bonds have properties close to the average of their corresponding homonuclears.

Some of the strongest metal–metal bonds found in coordination complexes are the heteronuclear quadruple bonds formed between Mo and W.[1,2] Cotton's group reported that the compound $MoW(mhp)_4$ (mhp = 2-hydroxy-6-methylpyridine anion) has a higher force constant for its quadruple bond and a formally shorter bond than its homonuclear analogues, $Mo_2(mhp)_4$ and $W_2(mhp)_4$.[1,2] Katovic *et al.* in McCarley's laboratory synthesized the pivalate-bridged dimer $MoW(O_2CCMe_3)_4$[3,4] and were surprised to find that it has a shorter bond than the corresponding complex $Mo_2(O_2CMe)_4$.[5] The electronegativity difference between W and Mo is small ($\Delta\chi < 0.1$) and thus the excess bond energy and bond shortening as originally defined by Pauling might not have been expected to be as large as had been observed in these intriguing compounds.

The two other well-characterized compounds known to contain mixed-metal quadruple bonds which are spanned by bridging ligands are $CrMo(O_2CCMe_3)_4$[6,7] and $CrMo(mhp)_4$.[1] The former was the first example of a heteronuclear quadruple bond to be reported; the Cr–Mo spacing appeared to be at the distance predicted by a sum of quadruple-bond covalent radii for Cr and Mo.[7] However other physical properties (Table 1) of the hydroxymethylpyridine-bridged dimers were not at the average of the properties of the Cr_2 and Mo_2 congeners but instead fell closer to the Mo_2 values.[1] The complexes $Cr_2(mhp)_4$ and $Mo_2(mhp)_4$ are examples of complexes containing "supershort" quadruple bonds.[1]

The recent syntheses of some unbridged complexes $MoWCl_4(PR_3)_4$ by Rudy Luck in my lab[8,9] (PR_3 = $PMePh_2$, PMe_2Ph or PMe_3) and independently by Carlin and McCarley[10] ($PR_3 = PMe_3$) have provided valuable information on the properties of the first unbridged Mo–W bonds. The study of these complexes should in principle allow the evaluation of the contribution of bridging ligands to the apparently deviant properties of these heteronuclear dimers. It should be noted that the crystal-structure determinations reported to date for all of these heteronuclears have the problem of disorder of the two metal atoms M and M′ since the two ends of the molecules are so similar; usually a site occupancy of 0.5 for each of M and M′ is observed.[2,4,7] We have recently overcome this problem by making the unbridged complex $Cl_2(PMePh_2)_2WMoCl_2(PMe_3)_2$ where the two centers are quite different[8] (see below).

SYNTHETIC ROUTES TO HETERONUCLEAR QUADRUPLE BONDS

Compounds containing the strong Mo–Mo bond are quite stable relative to their Cr_2 and W_2 congeners. Thus synthetic routes to CrMo and MoW compounds must either avoid the formation of Mo_2 or must include a separation step which can distinguish between these very similar compounds. Successful methods are described in Table 2. No preparation for complexes containing a Cr–W bond has been discovered. It should be noted that

Table 1. A comparison of properties of complexes containing homonuclear and heteronuclear quadruple bonds

Property	Ligands	CrCr	CrMo	MoMo	MoW	WW

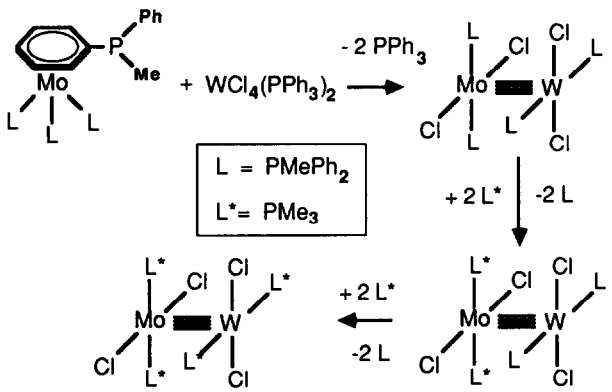
Ligands	CrMo	MoW
$(OAc)_4$	Add $Mo(CO)_6$ in HOAc–AcOAc–CH_2Cl_2 to excess $Cr_2(OAc)_4(H_2O)_2$ in HOAc–AcOAc at 118°C CrMo ~ 30%, some Mo_2 and $Cr(OAc)_3$ Purification by sublimation[7]	—
$(O_2CCMe_3)_4$	—	$16HO_2CCMe_3 + Mo(CO)_6 + 3W(CO)_6$ (reflux o-$Cl_2C_6H_4$) MoW 70% of product, Mo_2 30% Selective oxidation with I_2 gives MoW^+ which is then reduced with Zn[3]
$(mhp)_4$	$4Hmhp + Cr(CO)_6 + Mo(CO)_6$ (reflux diglyme–heptane) CrMo ⩽ 1%, equal amounts of Cr_2 and Mo_2[2] Or $CrMo(OAc)_4$ + excess Na(mhp) in ethanol[13]	$4Hmhp + 1.5Mo(CO)_6 + W(CO)_6$ (reflux diglyme–heptane) MoW > 50%, Mo_2 ~ 20%, W_2 ~ 0% Selective oxidation gives MoW^+ which is then reduced with Zn[2]
$Cl_4(PMePh_2)_4$	—	Mo(η^6-PhPMePh)$(PMePh_2)_3 + 3WCl_4(PPh_3)_2$ in C_6H_6 at 22°C MoW > 60%, Mo_2 ⩽ 5%, W_2 0%[8]
$Cl_4(PMe_3)_4$	—	$MoW(O_2CCMe_3)_4$ + excess PMe_3 + excess Me_3SiCl[10] or $MoWCl_4(PMePh_2)_4$ + excess PMe_3 in C_6H_6 at 60°C for 3 h[9]

only a few complexes are known to contain CrW bonds (single in these cases).[11,12]

The method of choice for the synthesis of bridged Cr–Mo bonds is that of Garner and Senior.[6] The mechanistic pathway to $CrMo(O_2CMe)_4$ formation is postulated to involve the attack of reactive $Cr(O_2CMe)_2$ on a low oxidation state (0, I or II) carbonyl complex of Mo to initiate metal–metal bond formation. The carbonyl ligands are lost as a result of the high temperatures of the reaction (>100°C). The Cr reagent is present in excess to avoid the formation of Mo–Mo compounds. The acetate bridges can be replaced by other bridging ligands [trifluoroacetate[7] and mhp[13] (Table 2)] but not by chloride ions.[7] The reaction with Cl^-/HCl results in the cleavage of the Cr–Mo bond.[7]

Complexes containing Mo–W bonds bridged by pivalate or mhp are prepared by reacting a mixture of the hexacarbonyls with the acid form of the ligands at high temperature (>100°C) as in Table 2. Usually a mixture of Mo_2 and MoW dimers are obtained. Under the acidic conditions of the pivalic acid reaction, $W_2(O_2CCMe_3)_4$ would not be stable,[14,15] and thus it is not found in the reaction mixture. Ditungsten complexes are readily oxidized as indicated by their negative oxidation potentials (Table 1). Because of the similar molecular dimensions and structures of the Mo_2 and MoW dimers it is not possible to separate the mixtures by crystallization or chromatography. Instead the MoW complexes can be selectively oxidized with iodine to give $[MoW(O_2CCMe_3)_4]I$[3] or $MoW(mhp)_4I_3$.[2] This is possible because of the more negative potential, $E_{1/2}(ox)$, of the MoW complexes [~ −0.2 V (Table 1)]. These insoluble compounds are then readily separated from the corresponding Mo_2 complexes. The oxidized complexes can then be reduced by Zn to give pure samples of $MoW(O_2CCMe_3)_4$ or $MoW(mhp)_4$.

Complexes of the type $MoWCl_4(PR_3)_4$ which contain unbridged Mo–W bonds can be made either by reacting molybdenum(0) complexes containing η^6-arylphosphine ligands with tungsten(IV) complexes (see below) or by substitution reactions on complexes which already contain Mo–W bonds. Examples are listed in Table 2. McCarley has unpublished work involving the removal of the bridging ligands from $MoW(O_2CCMe_3)_4$ by use of $SiMe_3Cl$ and PMe_3 to give $MoWCl_4(PMe_3)_4$.[10] Trimethylsilylchloride is a mild and selective reagent for similar reactions with homonuclear complexes.[16,17] The Mo–W distance[10] (see Table 1) and the ^{31}P NMR spectrum[8,10] of $MoWCl_4(PMe_3)_4$ have been reported. Preparative routes



Scheme 1. Preparation and substitution reactions of $MoWCl_4(PMePh_2)_4$.

to $MoWCl_4(PMePh_2)_4$ and its derivatives have been developed in the author's laboratory and are discussed in more detail in the next section.

PREPARATION AND REACTIONS OF $MoWCl_4(PMePh_2)_4$

A particularly direct synthetic route to the green complex $MoWCl_4(PMePh_2)_4$ and its derivatives is outlined in Scheme 1. The preparation of $MoWCl_4(PMePh_2)_4$ differs from the other preparations listed in Table 2 in two respects.

The first difference is the redox reaction involved. In our case molybdenum in the zero oxidation state as $Mo(\eta^6\text{-PhPMePh})(PMePh_2)_3$ ($E_{1/2}(ox) = -0.44$ V)[9] is used to reduce the tungsten(IV) complex $WCl_4(PPh_3)_2$, whereas, in the other methods of M–M′ formation, the acidic ligands are involved in the oxidation of the zero-valent metal carbonyls. Despite its seemingly exotic structure, the complex $Mo(\eta^6\text{-PhPMePh})(PMePh_2)_3$ is a useful starting material as it can be synthesized in one step in 75% yield from commercially available materials (Mo_2Cl_{10}–$PMePh_2$–Mg–THF).[18]

The other main difference is the course of the reaction. The preparations of the bridged Mo–W complexes invariably yield mixtures containing significant amounts ($\geq 20\%$) of the stable Mo_2 complex. These reactions which occur at elevated temperatures may be under thermodynamic control so that the factors favoring the formation of Mo–W would be the ratio of Mo to W employed in the preparation and the slightly greater bond strength of the heteronuclear. By contrast the formation of $MoWCl_4(PMePh_2)_4$ takes place rapidly at 22°C in quite a regiospecific reaction, and thus could be under kinetic control. The fact that $Mo(\eta^6\text{-PhPMePh})(PMePh_2)_3$ gives a much cleaner reaction with $WCl_4(PPh_3)_2$ than does $Mo(N_2)_2(PMePh_2)_4$[8] suggests that precoordination of the η^6-phosphine phosphorus atom to the W is the favoured pathway. Roberts and Geoffroy have classified this type of heternuclear bond formation as a "bridge-assisted" reaction and have reviewed many examples.[12] We have demonstrated elsewhere that a variety of η^6-phosphine complexes of molybdenum(0) can be used as phosphine-like ligands in complexes of rhodium(I),[19] molybdenum(0)[20] and group VI carbonyls.[21] The phosphine ligands in $WCl_4(PPh_3)_2$ are known to be rapidly substituted by a variety of phosphines, and therefore coordination of the η^6-phosphine complex is quite feasible.

The use of η^6-phosphine complexes of molybdenum(0) for the formation of other heteronuclear quadruple bonds may be limited in scope. The reaction of $WCl_4(PPh_3)_2$ with $Mo(\eta^6\text{-PhPMe}_2)P\text{-Me}_2Ph)_3$ does yield $MoWCl_4(PMe_2Ph)_4$[8] but its reaction with $Mo(\eta^6\text{-PhPMePh})(PPh_2CH_2CH_2PPh_2)(PMePh_2)$ does not give a mixed-ligand Mo–W complex as might be expected. In addition, reactions of $Mo(\eta^6\text{-PhPMePh})(PMePh_2)_3$ with other metal chlorides such as $NbCl_4(THF)_2$, $[Nb\text{-}Cl_3(THF)_2]_2(\mu\text{-}N_2)$, $CrCl_3$ and $ReCl_5$ do not yield identifiable products.

Other heteronuclear dimers can be prepared by substitution of the phosphine ligands of complex $MoWCl_4(PMePh_2)_4$ with smaller phosphine ligands. Scheme 1 outlines the substitution reactions involving PMe_3. At 22°C only the phosphines on Mo are replaced to give blue-green $Cl_2(PMe_3)_2Mo\text{-}WCl_2(PMePh_2)_2$. The selectivity of this reaction probably stems from the fact that the Mo–P bonds are weaker than the W–P bonds. As Scheme 1 indicates all of the $PMePh_2$ ligands are displaced by PMe_3 ligands at 60°C and blue-green $Mo\text{-}WCl_4(PMe_3)_4$ can be isolated although the yield of pure material is low ($\sim 10\%$) because the complex partly decomposes during work-up when the free $PMePh_2$ is distilled away. Substitution of $MoWCl_4(PMePh_2)_4$ by excess $PPh_2CH_2CH_2PPh_2$ also yields heteronuclear products which are currently being characterized. Isocyanide ligands on the other hand cleave the Mo–W bond to give mononuclear isocyanide complexes; Walton's group has demonstrated the generality of reactions involving the cleavage of quadruple bonds by isocyanides.[22] Attempts to replace the chloride ligands in our complexes by methyl groups have not succeeded.

PROPERTIES OF COMPLEXES CONTAINING UNBRIDGED Mo–W BONDS

The complexes which have had their structures determined by single-crystal X-ray diffraction are $MoWCl_4(PMePh_2)_4$,[9] $Cl_2(PMe_3)_2MoWCl_2(PMePh_2)_2$[8,9] and $MoWCl_4(PMe_3)_4$.[9,10] Figure 1 shows

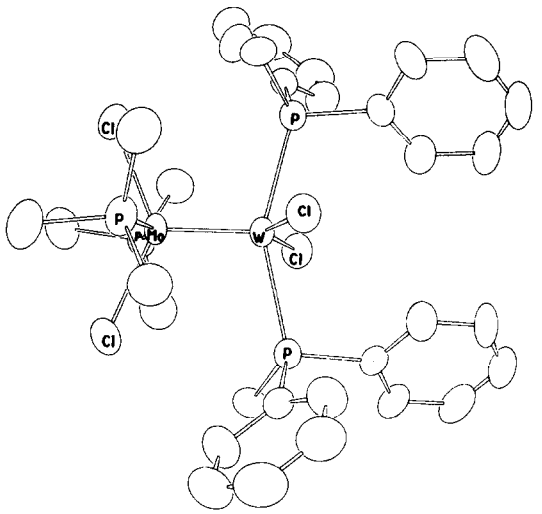


Fig. 1. ORTEP view of the complex $Cl_2(PMe_3)_2Mo$-$WCl_2(PMePh_2)_2$.

an ORTEP view of the second complex. All of the complexes have similar geometries with two pseudo-square-planar MCl_2P_2 fragments eclipsed with respect to one another and separated by a short metal–metal distance of ~2.207(1) Å (Table 3). As is usual for $M_2X_4L_4$ complexes the halide ligands are next to phosphine ligands across the metal–metal bond to minimize steric interactions. Another feature in common with homonuclear $M_2X_4L_4$ complexes[23] is the bending away from the M≡M′ bond of the Cl–M—Cl vectors (angle ~133–141°) and the P–M–P vectors (angle ~153–158°). No intermolecular ligand–metal interactions *trans* to the quadruple bond are possible for these molecules.

The structure determined for $Cl_2(PMe_3)_2Mo$-$WCl_2(PMePh_2)_2$ is significant as it is the only heteronuclear M≡M′ complex which is not disordered with respect to the placement of the metal ions. In this case the two metals are "labelled" with different phosphine ligands and so the two ends of the molecule are quite different. The metal–ligand distances are thus accurately determined in this case: d(Mo–P) = 2.532(2), d(W–P) = 2.539(2), d(Mo–Cl) = 2.424(2), d(W–Cl) = 2.378(2) Å. These are similar to values observed for homonuclear congeners $M_2Cl_4(PMe_3)_4$.[23] The metal–phosphorus distances are the longest ones known for complexes of Mo or W with pseudo-*trans* PMe_3 ligands perhaps indicating a labilization of these ligands by the *cis*-M≡M bond. Phosphine ligands in these complexes can indeed be substituted as indicated in Scheme 1.

Approximate covalent—radii for unbridged quadruple bonds can be derived from the structures of the homonuclear complexes $M_2Cl_4(PMe_3)_4$ (M = Mo or W):[23] r≡(Mo) = 1.065 Å, r≡(W) = 1.131 Å. Therefore the observed Mo–W distances [~2.207(1) Å] for our heteronuclear complexes which are listed in Table 3 are just slightly longer than the sum of these radii [2.196(1) Å] and there is no evidence for extra shortening of the bond with respect to bond distances of the homonuclear complexes. This contrasts with the structural features of bridged MoW complexes (Table 1). The covalent bond radii for bridged quadruple bonds with small or no axial interactions range from 0.92 to ~1.0 Å for Cr,[13] 1.03–1.05 Å for Mo, and 1.08–1.09 Å for W (Table 1), so that the Mo–W distances in $MoW(O_2CCMe_3)_4$ [2.080(1) Å] and MoW $(mhp)_4$ [2.091(1) Å] fall short of the sum of these radii (2.11–2.14 Å). Clearly the bridging ligands in these complexes must be responsible for the unexpectedly large shortening. The reported Cr–Mo distance in $CrMo(O_2CMe)_4$ of 2.050(1) Å is not shorter but appears closer to the sum of the covalent radii; the reason for this is not clear.

The ^{31}P NMR spectra of the complexes $MoWCl_4(PR_3)_4$ are diagnostic of their solution structures. Two equivalent phosphine ligands on Mo couple to two equivalent ligands on W to give an overall spectrum consisting of two sets of triplets with $^3J(^{31}P–^{31}P)$ couplings (Table 3). The resonance for phosphines on W has characteristic satellite triplets corresponding to a coupling $^1J(^{31}P–^{183}W)$ of the $Mo^{183}W$ isotopomer. A $^2J(^{31}P–^{183}W)$ coupling of 43 Hz was resolved for the $Mo^{183}W$ isotopomer of $MoWCl_4(PMePh_2)_4$.[8]

Some other spectroscopic and electrochemical properties of the heteronuclears are listed in Tables 1 and 3. In general these properties are intermediate between those of the corresponding homonuclear complexes. The $\delta^2 \rightarrow \delta\delta^*$ transitions of the complexes $MoWCl_4(PR_3)_4$ (PR_3 = PMe_3 or $PMePh_2$)[8,9] fall between the energies of the Mo_2 and W_2 congeners[23] but closer to the W_2 values (Tables 1 and 3). Replacing $PMePh_2$ ligands by the more basic and smaller PMe_3 ligands shifts this transition to higher energy for the homonuclears $Mo_2Cl_4(PR_3)_4$ (Table 1) and the heteronuclear series (Table 3). This shift is paralleled by a decrease in the energies of both reversible redox couples $MoW^+ \leftrightarrow MoW$ [$E_{1/2}$(ox)] and $MoW \leftrightarrow MoW^-$ [$E_{1/2}$(red)], which indicates that the complexes with more PMe_3 ligands are more electron-rich. The redox products (MoW^+ and MoW^-) which should have the electron configurations $\sigma^2\pi^4\delta$ and $\sigma^2\pi^4\delta^2\delta^*$, respectively, have not yet been isolated. The $E_{1/2}$(ox) value for $MoWCl_4(PMe_3)_4$ falls between the values for related homonuclears with PBu_3 ligands (Table 1).[24]

[a] r(WW).
[b] r(MoMo).

$MoWCl_4(PMe_3)_4$ has been determined by photoelectron spectroscopy to be 6.11 eV.[25] This value is approximately the average of the homonuclear energies (Table 1). Similarly the π and σ ionization energies at 7.35 and 7.67 eV, respectively, are close to the averages of energies assigned to the Mo_2 and W_2 congeners.[25] These data were useful in demonstrating that the σ and π ionization energies tend to overlap for Mo_2 quadruply bonded compounds[25,26] and were useful in explaining discrepancies in earlier assignments of the σ(M–M) ionization peaks of Mo_2[26–28] and W_2[28–30] PES spectra. The stretching frequency ν(MoW) has not been located[8] so that a comparison of bond force constant with those of the homonuclears (Table 1) is not possible.

A COMPARISON OF PROPERTIES AND REACTIONS OF COMPLEXES CONTAINING HETERONUCLEAR vs HOMONUCLEAR QUADRUPLE BONDS

The question of interest is whether the M–M′ fragment has enhanced stability above that expected from the average of the properties of the homonuclear congeners M–M and M′–M′.

The evidence is sketchy for CrMo complexes since only two complexes are known and both contain bridging ligands (Table 1). However it appears that the heteronuclear bond strength is close to the average of those of the homonuclears in this case. A thermochemical study has allowed the estimation of the quadruple bond dissociation energy for the complexes $Cr_2(O_2CMe)_4$, $CrMo(O_2CMe)_4$ and $Mo_2(O_2CMe)_4$.[31] The energy for Cr–Mo (249 kJ mol^{-1}) was found to be slightly less than the average of the energies of the homonuclears. Note however that these estimates may be consistently low[32] since spectral[33] and computational[34] determinations give values in the range 500–700 kJ mol^{-1} for Mo–Mo compounds. The Cr–Mo distance in $CrMo(O_2CMe)_4$ is at or above the sum of the covalent radii derived from the homonuclear species as discussed above. The force constants for the mhp complexes listed in Table 1 were based on preliminary assignments of complex vibrational spectra.[1,35] A more extensive low-temperature electronic absorption and emission study of $Cr_2(hmp)_4$ indicated that the ground-state vibration ν(Cr–Cr) is 340 cm^{-1} [36] so that the force constant is much lower than had been initially thought (1.77 vs 4.73 mdyne $Å^{-1}$). Thus the determination of the Cr–Mo force constant may also need more work. The δ ionization energies for both $CrMo(O_2CMe)_4$[37] and CrMo-$(mhp)_4$[1] are closer to those of the analogous Mo_2 compounds (Table 1).

The homonuclears Cr_2 and Mo_2 are the greatly favored products when mixtures of the metal carbonyls are refluxed with the ligands in attempts to synthesize the mixed-metal compounds (see Table 2); however it is not known whether this is a kinetic or a thermodynamic effect. The Cr–Mo bond of $CrMo(O_2CMe)_4$ is disrupted when treated with aqueous HCl whereas the Mo–Mo bond of $Mo_2(O_2CMe)_4$ remains intact when it is converted to $Mo_2Cl_8^{4-}$ in a similar reaction.[7] However this CrMo complex can be converted to $CrMo(mhp)_4$ (Table 2) under basic conditions.[13] Thus there is no evidence for enhanced stability of the Cr–Mo bond.

The available data for complexes containing bridged Mo–W bonds suggest that such bonds do have enhanced stability. The bonds are shorter than the sum of the covalent radii of the metals as discussed above. The Mo–W force constant of $MoW(mhp)_4$ is actually higher than those of both homonuclears (Table 1)[1] although the validity of force constants of bonds with bridging groups is questionable. Certainly the mixed-metal products $MoW(mhp)_4$ and $MoW(O_2CCMe_3)_4$ do predominate when the metal carbonyls are heated with the acid forms of their respective ligands (Table 2). The MoW fragment usually does remain intact during reactions. The reaction of HCl with the pivalate complex yields the anion $MoWCl_8H^{3-}$ which contains a formal triple bond.[4,38] The pivalate ligands of $MoW(O_2CCMe_3)_4$ can be replaced by phosphine and chloride ligands by use of trimethylsilylchloride in the presence of excess phosphine ligands (Table 2). It has been reported that in the presence of Me_3SiCl and reduced amounts of PMe_3, the tetramer $Mo_2W_2Cl_8(PMe_3)_4$ forms by a reaction that can be viewed as the cycloaddition reaction of the two Mo–W units.[10] A similar cycloaddition of Mo–Mo units to produce the rectangular cluster $Mo_4Cl_8(PEt_3)_4$ has been reported.[39] The details of the structure of this complex are yet to be published. Such a complex could also be pictured as an intermediate in the (unknown) metathesis reaction of Mo–W bonds to Mo–Mo- and W–W-bonded species. The metathesis of the Mo–Mo and W–W bonds in $M_2(\eta^5\text{-}C_5H_5)_2(CO)_4$ to give the heteronuclear $MoW(\eta^5\text{-}C_5H_5)_2(CO)_4$ has been reported.[40]

The complexes $MoWCl_4(PR_3)_4$ containing unbridged Mo–W bonds appear to have properties at the average of those of the homonuclear complexes. The bond lengths are close to the sum of the covalent radii derived from the homonuclear species. The properties listed in Tables 1 and 3 fall close to the average and slightly nearer to the properties of the W_2 complexes. The Mo–W bond remains

intact in substitution reactions with PMe_3 and $PPh_2CH_2CH_2PPh_2$ but fragments with isocyanide ligands.[8,9] When heated the complexes do not metathesize to homonuclear species.[8]

CONCLUSIONS

The limited data available to date indicate that the Cr≡Mo bond bridged by acetate or mhp does not have extra stabilization with respect to homonuclear congeners and its energy is near or slightly less than the average of the Cr_2 and Mo_2 bond energies. The enhanced stability noted for the bridged Mo≡W complexes may be due to the favorable geometry of the sterically unhindered bridging ligands that allows the metal–metal bond to achieve optimum overlap. The small amount of information available on the unbridged Mo≡W complexes of the type $MoWCl_4(PR_3)_4$ suggests that this heteronuclear bond has properties which are close to the average of the homonuclear properties. More experiments and calculations are needed to verify these interesting observations. Further research into the synthesis of new complexes containing heteronuclear bonds, both bridged and unbridged, could involve pairwise combinations of Tc, Re, Mo, W, Nb and Ta where high quadruple-bond energies are expected.

POLYHEDRON REPORT NUMBER 20

THE ORGANOMETALLIC CHEMISTRY OF THE LANTHANIDE ELEMENTS IN LOW OXIDATION STATES

WILLIAM J. EVANS

Department of Chemistry, University of California, Irvine, Irvine, CA 92717, U.S.A.

CONTENTS

I. INTRODUCTION

In the three decades following the discovery of ferrocene,[1] organometallic chemistry was investigated extensively and became a major field of chemical research. During this period, research efforts were focused primarily on the transition metals and the organometallic chemistry of the lanthanide elements received comparatively little attention. This situation is understandable when one considers

how the chemistry of the lanthanides was viewed during the time in which organometallic chemistry was being developed.

The early studies on organolanthanide complexes suggested that their chemistry was limited. For example, the first well-documented reports in this area, which concerned the simple cyclopentadienyl complexes $(C_5H_5)_3Ln$,[2] showed that these compounds were rather ionic and suggested that organolanthanide complexes would merely be trivalent versions of alkali and alkaline earth metal organometallic species.

In general, all of the lanthanide elements traditionally were thought to have a very similar chemistry, in contrast to the diverse chemistry observed for a row of transition elements. Furthermore, most lanthanide chemistry centered on a single oxidation state, the trivalent state. Of the few lanthanide elements which had readily accessible non-trivalent oxidation states, Ce^{4+}, Sm^{2+}, Eu^{2+} and Yb^{2+}, none had both the +4 and the +2 oxidation state readily available on the same metal. Hence, the diversity of oxidation states found with transition metals was not present in the lanthanide series and the two-electron processes common in transition-metal chemistry, such as oxidative addition and reductive elimination, were not possible at a single lanthanide metal center. In addition, many reagents of interest to organometallic chemists, e.g. CO, unsaturated hydrocarbons, hydrogen, phosphines, isocyanides, nitrogen etc., were not thought to have a substantial chemistry with these ionic metal complexes. Finally, many reaction pathways important in organometallic synthesis and catalysis were not thought to be available to these elements. All of these factors suggested that lanthanide chemistry would not be as interesting as transition-metal chemistry.

In addition to the problem of an anticipated limited chemistry, the organolanthanide complexes were experimentally more difficult than many transition-metal systems. Almost all organolanthanides are extremely air- and moisture-sensitive and even the metal trihalide starting materials are hydrolytically unstable. Purification and isolation of organolanthanide compounds is difficult because the complexes decompose on chromatographic supports, generally cannot be sublimed in high yield, and frequently undergo ionic redistribution reactions giving mixtures during crystallization attempts. Moreover, the paramagnetism of many of the metals precluded characterization by NMR spectroscopy, the organometallic chemist's most common method of analysis.

Despite the limitations and difficulties described above, it was realized that the lanthanides had the potential for some unique chemistry distinct from anything possible with main-group or transition metals.[3] The basis for this contention was that the lanthanide elements have a special combination of physical properties, including size, type of valence orbital, ionization potential, electron affinity etc., which is not duplicated anywhere else in the periodic table. Hence, a lanthanide element, if placed in the proper oxidation state and coordination environment, could display an unusual chemistry.

In the past few years, the status of organolanthanide chemistry has changed dramatically. The goal of demonstrating a unique organometallic chemistry with these metals has been realized in terms of unusual compounds, unprecedented structures, and spectacular reactivity.[4-7] Increasing numbers of investigators are turning their attention to 4*f*-element chemistry and it is currently one of the most rapidly developing areas of organometallic chemistry.

The most extensively developed area of organolanthanide chemistry has involved trivalent complexes and a substantial body of experimental data is now available. Principles regarding structure and reactivity are emerging for trivalent species as outlined in a recent review[5] and in Section II.

This Report focuses on the organometallic chemistry of the lanthanides in oxidation states less than +3. This area is at that exciting stage of development in which many unusual structures and reactions have been observed, but the general principles governing this chemistry have yet to be determined. The field is in that frontier stage of exploration in which each new piece of data has the potential of providing key insights into general principles.

Low oxidation state organolanthanide chemistry is described in parts of other reviews of organolanthanide chemistry,[4,5,7-10] but only one of these concentrates solely on this topic.[7] In that review, the emphasis was on applications of divalent ytterbium and samarium chemistry to organic synthesis. This review will concentrate on the synthesis and reactivity of divalent and zero-valent organometallic systems and will start with a background section describing basic principles of the chemistry of these elements and their trivalent complexes.

II. TRADITIONAL PRINCIPLES OF ORGANOLANTHANIDE CHEMISTRY

II.1. *Properties of the elements*

The main factor which distinguishes the lanthanide elements from other metallic elements is that their valence orbitals are the 4*f* orbitals. The main factor which differentiates the 4*f* orbitals from valence orbitals of other metallic elements is their relatively limited radial extension. Calculations on lanthanide ions, which have [Xe]$4f^n$ electron configurations, suggest that the 4*f* orbitals do not extend significantly beyond the filled $5s^25p^6$ orbitals of the xenon inert gas core.[11] Consequently, a trivalent lanthanide ion looks like a closed-shell inert-gas electron cloud with a tripositive charge, a situation which has a major effect on the chemical and physical properties of these metals and their complexes.

One effect of the small radial extension of the lanthanides' valence orbitals is that the metals' orbital interactions with ligands are smaller than those in transition-metal complexes. This is the traditional explanation of why the chemistry tends to be much more ionic.[12] Electrostatic factors appear to be more important in determining the stability, structure and chemistry of lanthanide complexes than orbital generalizations. Consistent with this, the physical properties arising from a given $4f^n$ configuration for a lanthanide ion, e.g. the optical spectrum and the magnetic moment, are relatively similar regardless of the nature of the attached ligand.[12-13]

Another consequence of the limited radial extension of the 4*f* orbitals is that the chemistry of the trivalent lanthanide ions can be similar in many systems regardless of the $4f^n$ configuration.[12] Hence, a single symbol, Ln, often has been used in the past to describe the chemistry of all the elements in the series. For example, one similarity in the chemistry of the lanthanide metals is that for each element the +3 oxidation state is the most stable. Another example is the similarity in structure and reactivity of the $(C_5H_5)_3Ln(thf)$ complexes[2,15,16] (except for the single radioactive system, Ln = Pm). This contrasts sharply with the large variation in structure and stability of transition-metal $(C_5H_5)_2M$ complexes as M is varied across a row of the periodic table.[17]

Some differences in the chemistry of the individual lanthanides are observed due to the variations in the radial size of the metals. Radial size diminishes gradually from La^{3+} (1.061 Å) to Lu^{3+} (0.848 Å) as the series is crossed.[18] The other basis for differences in chemistry between the metals arises with the four elements for which non-trivalent oxidation states are accessible under normal reaction conditions: Ce^{4+} ($4f^0$), Eu^{2+} ($4f^7$), Yb^{2+} ($4f^{14}$), and Sm^{2+} ($4f^6$). Differences in trivalent chemistry arise for these elements primarily under strongly oxidizing or reducing conditions. Differences in lower oxidation state chemistry will be discussed in Section III.

Two other important general features of the lanthanide metals are their size and electronegativity. Compared to transition metals the lanthanides are quite large. High coordination numbers of 8–12 are common in lanthanide complexes.[12] The lanthanides are also rather electropositive compared to transition metals[19] and are quite oxophilic.

II.2. *Stability principles for trivalent species*

Given these physical properties, two generalizations on organolanthanide stability traditionally have been followed in order to obtain isolable organolanthanide complexes. First, electrostatic interactions must be optimized by using stable organic anions to balance the charge of the metal cation. Second, additional stability often can be gained by choosing large, bulky anions which can completely occupy the coordination sphere of the metal and sterically block decomposition pathways. The polyhapto anions $C_5H_5^-$ and $C_8H_8^{2-}$ meet both of these requirements and, not coincidentally, they are the most prevalent ligands in organolanthanide chemistry. The reason the smaller metals later in the lanthanide series, Lu, Yb and Er, have been investigated most extensively is that their small size makes steric saturation of the metal coordination sphere less difficult and hence provides more tractable complexes.

Since the electrostatic charge balance requirement for stability must always be met in organolanthanide complexes, the determining factor in stability/reactivity is often steric. Recent results in trivalent organolanthanide chemistry suggest emerging patterns of structure and reactivity which depend on the relative sizes of the ligands vs the metals.[5] Quantitative assessment of this steric saturation is also under development.[20]

Several basic generalizations appear to apply to trivalent organolanthanides based on the data currently available.[5] High reactivity and limited stability are associated with free coordination sites, i.e. steric unsaturation, and with terminal, as opposed to bridging, ligands. High reactivity/limited stability can be caused by insufficient ligand bulk around the metal (steric unsaturation) or by excessive ligand bulk (steric oversaturation) when it leads to structures with open coordination positions and terminal ligands. Examples of these ideas follow. Since trivalent Y displays chemistry much like that of the late lanthanide ions of similar size [Ho(III) and Er(III)],[21-24] examples from Y chemistry will also be included.

The importance of terminal ligands and open coordination positions to organolanthanide reactivity can be readily seen from hydrogenolysis studies [reactions (1)–(4)]. For example, the bridged species $[(C_5H_5)_2Ln(\mu\text{-}CH_3)]_2$ (Ln = Y, Er, Yb or Lu) react slowly with H_2 in arene solvents in which they are fully bridged [reaction (1)]:[23,25]

$$(C_5H_5)_2Ln\begin{matrix}\diagup CH_3 \diagdown \\ \diagdown CH_3 \diagup\end{matrix}Ln(C_5H_5)_2 + H_2 \overset{\text{toluene}}{\rightarrow} \text{very slow.} \quad (1)$$

In contrast, the *tert*-butyl complexes, $(C_5H_5)_2Ln(CMe_3)$ (thf), which do not form bridged dimers, react rapidly with hydrogen in toluene to form the hydride dimers $[(C_5H_5)_2Ln(\mu\text{-}H)(thf)]_2$ [reaction (2)].[22]

$$2(C_5H_5)_2Ln(CMe_3)(thf) + 2H_2 \underset{\text{rapid}}{\overset{\text{toluene}}{\rightarrow}} [(C_5H_5)_2Ln(\mu\text{-}H)(thf)]_2 + 2HCMe_3. \quad (2)$$

This demonstrates the higher reactivity available to terminal ligands.[23]

In thf however, the *tert*-butyl complexes $(C_5H_5)_2Ln(CMe_3)$ (thf) are unreactive to hydrogen [reaction (3)]:[26]

$$(C_5H_5)_2Ln(CMe_3)(thf) + H_2 \overset{\text{thf}}{\rightarrow} \text{no reaction.} \quad (3)$$

The difference in reactivity in toluene vs thf presumably arises because in toluene some dissociation of thf occurs to give a free coordination position, whereas in thf the metal center is constantly solvated. Hence, even with the small reagent hydrogen and the large lanthanide metals, an open coordination position is needed for high reactivity.

These steric effects are subtle, however.[26] For example, hydrogenolysis in thf is possible when the alkyl group is methyl rather than *tert*-butyl [reaction (4)]:

$$2(C_5H_5)_2Ln(CH_3)(thf) + 2H_2 \overset{\text{thf}}{\rightarrow} [(C_5H_5)_2Ln(\mu\text{-}H)(thf)]_2 + 2CH_4. \quad (4)$$

Hence, $(C_5H_5)_2Ln(CH_3)$ (thf) reacts readily with H_2 in thf when Ln = Y or Er. Based on crystal structures of $(C_5H_5)_2Lu(CMe_3)$ (thf)[27] and $(C_5H_5)_2Yb(CH_3)$ (thf),[26] one can estimate that the main difference between a methyl and a *tert*-butyl $(C_5H_5)_2LnR(thf)$ complex for a given Ln is that the *tert*-butyl complex has a Ln—C bond approximately 0.1 Å longer than the Ln—C bond in the methyl complex. The longer distance presumably occurs because the *tert*-butyl complex is sterically too crowded to form a shorter "normal" Ln—C bond.[26,28] Since the *shorter* Ln—C methyl bond is the Ln—C unit which is more reactive to hydrogen, the difference in reactivity appears to be steric.

Although hydrogenolysis of $(C_5H_5)_2Ln(CH_3)$ (thf) is facile in thf for Ln = Er and Y, for Ln = Yb and Lu the reactivity is very low.[26] This presumably occurs because of the increased steric crowding in the coordination environment around these smaller metals. Hence, a change in metallic radius of just 0.03 Å can significantly affect reactivity.

Steric factors can affect structure as well as reactivity, a fact which is well illustrated by the many examples of dicyclopentadienyl lanthanide halide complexes characterized by X-ray diffraction. These complexes exist as symmetrically bridged dimers, $[(C_5H_4R)_2Ln(\mu\text{-}Cl)]_2$, when Ln is one of the smaller metals Sm–Lu and Y, and when the cyclopentadienyl ligand is C_5H_5 or $CH_3C_5H_4$.[29-31] Such complexes are generally considered sterically saturated. For the larger

lanthanides earlier in the series, La, Ce, Pr and Nd, $[(C_5H_5)_2Ln(\mu\text{-}Cl)]_2$ complexes are reported to be unstable with respect to ligand redistribution to the sterically more saturated $(C_5H_5)_3Ln$ species.[9,30] These early lanthanide $[(C_5H_5)_2Ln(\mu\text{-}Cl)]_2$ complexes are sterically unsaturated and therefore less stable. To obtain an isolable bis(cyclopentadienyl) lanthanide halide complex of a large early lanthanide metal, the steric bulk of the ligand set must be increased. This can be done with a substituted cyclopentadienyl ligand, as demonstrated in the structure $\{[(Me_3Si)_2C_5H_3]_2Pr(\mu\text{-}Cl)\}_2$,[32] or by adding an "extra" ligand to the coordination sphere, as found in $[(C_5H_5)_2Nd(thf)(\mu\text{-}Cl)]_2$.[33]

When sterically bulky ligands such as C_5Me_5 are used with the small metals late in the series, complexes such as $[(C_5Me_5)_2Ln(\mu\text{-}Cl)]_2$ are too sterically crowded to form. These sterically oversaturated systems distort from a symmetrical structure to accommodate the ligand–metal size imbalance. For Ln = Y, a monobridged structure, $[(C_5Me_5)_2Y(\mu\text{-}Cl)YCl(C_5Me_5)_2]$, is observed.[34] For the methyl and hydride Lu derivatives $[(C_5Me_5)_2LuZ]_n$ (Z = H or CH_3; n = 1 or 2), an equilibrium is reported to exist between a monobridged structure, $(C_5Me_5)_2Lu(\mu\text{-}Z)LuZ(C_5Me_5)_2$ and the monomer $(C_5Me_5)_2LuZ$.[6,35]

The three classes of organolanthanide complexes, i.e. sterically saturated, sterically unsaturated, and sterically oversaturated compounds, display different types of reactivity due to the differences in terminal vs bridging groups and the relative availability of open coordination positions. This point is illustrated well by the metalation reactivity of organolanthanide hydrides with ethers, hydrocarbons and pyridine. The sterically saturated hydrides $[(C_5H_4R)Ln(\mu\text{-}H)(thf)]_2$ (R = H or CH_3; Ln = Er, Y or Lu) are stable to ethers, metalate only rather acidic hydrocarbons such as terminal alkynes, and do 1,2-LnH addition rather than metalation when reacted with pyridine.[23] In contrast, the sterically oversaturated $[(C_5Me_5)_2LuH]_n$ complex decomposes ethers, metalates pyridine to form a $(C_5Me_5)_2Lu(\eta^2\text{-}NC_5H_4)$ complex, and is such a powerful metalation reagent that not only benzene and Me_4Si are metalated, but even CH_4.[36,37] The sterically unsaturated $[(C_5Me_5)_2Sm(\mu\text{-}H)]_2$[38] has intermediate reactivity—it decomposes ether and metalates pyridine, but metalates arenes only slowly.[39]

Given that all of this reactivity involves the same, nominally ionic, Ln—H bond, it is clear that steric factors influence trivalent organolanthanide chemistry to a great extent. Obviously, the thermodynamic differences in bond strengths and the differences in the charge: radius ratio from one metal to another will also affect the chemistry. However, in many cases these factors are likely to be sufficiently similar that it is the steric parameters which will govern the observed variations in reactivity.

III. DIVALENT ORGANOLANTHANIDE CHEMISTRY

Divalent organolanthanide complexes are the most fully characterized and investigated of the available low oxidation state lanthanide organometallics. Consequently, this is the first class of low-valent species which will be presented in detail. This section is organized into three parts: a brief description of divalent-metal properties, a discussion of synthesis and structure organized according to ligand, and a discussion of reactivity.

III.1. *Background*

Although divalent lanthanide ions for almost all of the elements in the series have been generated by irradiating trivalent ions doped into CaF_2,[40–42] only three elements have divalent states which are chemically accessible in organometallic systems under normal conditions: Eu, Yb and Sm. It is only for these elements that X-ray crystallographic structures of divalent organolanthanide complexes are available. A report of a Ce(II) complex formed by K reduction is in the literature,[43,44] but this result remains to be structurally confirmed.

The aqueous reduction potentials for the Ln^{3+}–Ln^{2+} couple are reported to be −0.35 V for Eu, −1.1 V for Yb and −1.5 V for Sm (vs NHE)[45,46] indicating that Eu^{2+} should be the most stable and Sm^{2+} the most reactive in terms of reducing power. As described in Section II, complexes of the smaller Yb^{2+} ion could be the most stable in terms of steric saturation of the metal coordination sphere and Sm^{2+} could be the most reactive in this regard.

Sm(II) is most desirable not only in terms of high reactivity, but also when NMR characterization

is considered. Sm provides the only Ln(II)–Ln(III) system in which both oxidation states have complexes which are NMR-accessible.[47] Despite room-temperature magnetic moments of 3.4–3.8 μ_B for Sm(II) and 1.3–1.9 μ_B for Sm(III), ^{1}H NMR resonances are reasonably sharp and are found within $\pm$10 ppm of the normal 0–10-ppm region where diamagnetic resonances are located. This is not true for Eu(II), Eu(III) or Yb(III), which have room temperature magnetic moments in the ranges 7.4–8.0, 3.4–4.2 and 4.2–4.9 μ_B, respectively.[48,49] Of course, diamagnetic Yb(II) provides NMR-observable complexes.

Divalent organolanthanide complexes differ in appearance from trivalent species in that their colors are more intense and these colors vary as the ligand set is changed. For trivalent species, the colors arise from Laporte-forbidden $4f \rightarrow 4f$ transitions.[12,13] Due to the limited radial extension of the $4f$ orbitals, crystal field splitting is very small and hence the colors vary little as the ligand set is changed. Another consequence of the limited radial extension is that little vibronic coupling occurs to relax the Laporte-forbidden nature of the transitions. Hence, the colors of the complexes are pale. In contrast, the colors of the divalent lanthanide ions are attributed to Laporte-allowed $4f \rightarrow 5d$ transitions.[14,40] The energies of these transitions change as the ligand set varies. The variation in color with ligand environment is greatest with Sm(II) and Yb(II). Organometallic Sm(II) compounds can be green or purple and Yb(II) species can be yellow, red, blue, green or purple. Eu(II) organometallics, on the other hand, are almost always yellow, orange or red.

III.2. *Synthesis and structure*

III.2(a) *Cyclooctatetraenyl complexes.* The first divalent organolanthanide complexes were prepared by taking advantage of the fact that Eu and Yb dissolve in liquid ammonia to form highly reducing solutions of $[Ln(NH_3)_x^{2+}]$ $[e^-(NH_3)_4]_2$.[50] The cyclooctatetraenyl species, EuC_8H_8 and YbC_8H_8, were obtained by adding 1,3,5,7-cyclooctatetraene to solutions of Eu and Yb in liquid ammonia [reaction (5)]:

$$Ln + 1,3,5,7\text{-}C_8H_8 \xrightarrow{NH_3(l)} LnC_8H_8. \tag{5}$$

The compounds precipitate from the ammonia solution and are insoluble in hydrocarbons and ethers. Soluble adducts are formed in pyridine and dimethylformamide, but have never been fully characterized. C_8H_8Yb can also be prepared by metal vapor methods from zero-valent Yb and 1,3,5,7-C_8H_8.[51] Reduction of [K(glyme)] $[Ce(C_8H_8)_2]$ in glyme with excess K is reported to form $[K(glyme)]_2[Ce(C_8H_8)_2]$, the only organocerium(II) complex in the literature.[43] Neither structural characterization nor reaction chemistry have been reported for any of the divalent cyclooctatetraenyl species.

III.2(b) *Complexes containing unsubstituted cyclopentadienyl ligands.* Divalent cyclopentadienyl complexes were also originally obtained from liquid-ammonia reactions. For Eu, an NH_3 solvate is initially formed [reaction (6)]:

$$Eu + 3C_5H_6 \xrightarrow{NH_3(l)} (C_5H_5)_2Eu(NH_3) + C_5H_8 \tag{6}$$

which can be desolvated by heating to 120–200°C *in vacuo*.[15] This complex is not soluble in hydrocarbons and common ethers, but dissolves in liquid ammonia and dimethylformamide.

For Yb, which has a less stable divalent oxidation state, the reaction analogous to 6 is more complex. The trivalent complex $(C_5H_5)_3Yb(NH_3)$ is obtained in the reaction despite the reducing conditions and sublimation gives trivalent products as well as $(C_5H_5)_2Yb$.[15,52,53] This exemplifies in part the general trend in divalent lanthanide chemistry that Eu(II) complexes are least difficult to obtain in pure form, Yb(II) chemistry is more complex, and Sm(II) chemistry is the most difficult.

A variety of ammonia-free synthetic routes to $(C_5H_5)_2Yb$ are known. One type of reaction involves reduction of $[(C_5H_5)_2YbCl]_2$ with Na,[53] Yb[53] or *tert*-butyllithium[26,27] [reactions (7)–(9) the $(C_5H_5)_2Yb$ product in these and the following reactions is generally isolated as an ether adduct]:

$$[(C_5H_5)_2YbCl]_2 + 2Na \rightarrow 2(C_5H_5)_2Yb + 2NaCl, \tag{7}$$

$$3[(C_5H_5)_2YbCl]_2 + 2Yb \rightarrow 6(C_5H_5)_2Yb + 2YbCl_3, \quad (8)$$

$$[(C_5H_5)_2YbCl]_2 + 2LiCMe_3 \rightarrow 2(C_5H_5)_2Yb + HCMe_3 + H_2C{=}CMe_2 + 2LiCl. \quad (9)$$

Reduction of $(C_5H_5)_3Yb$ with Na[53] or Yb[54,55] also gives $(C_5H_5)_2Yb$ [reactions (10) and (11)]:

$$(C_5H_5)_3Yb + Na \rightarrow (C_5H_5)_2Yb + NaC_5H_5, \quad (10)$$

$$2(C_5H_5)_3Yb + Yb \rightarrow 3(C_5H_5)_2Yb. \quad (11)$$

$(C_5H_5)_2Yb(thf)$ can be obtained by decomposition of $[(C_5H_5)_2Yb(\mu\text{-}H)(thf)]_2$ and $\{[(C_5H_5)_2Yb(\mu\text{-}H)]_3(\mu_3\text{-}H)\}\{Li(thf)_4\}$ although this is not a preparatively desirable synthesis.[26]

Recently, syntheses have been reported which start from Yb metal, which is a more convenient starting material than the $YbCl_3$ reagent needed for reactions (7)–(11). For example, $(C_5H_5)_2Yb$ can be prepared from the reaction of C_5H_5Tl with excess Yb metal,[54] a reaction which is reported to have $(C_5H_5)_3Yb$ as an intermediate [reaction (12)]:

$$6C_5H_5Tl + 3Yb \rightarrow 6Tl + 2(C_5H_5)_3Yb + Yb \rightarrow 3(C_5H_5)_2Yb + 6Tl. \quad (12)$$

Yb metal, which has been activated with $HgCl_2$ to form an amalgam, is also reported to be successful [reaction (13)]:[55]

$$(C_5H_5)_2Hg + Yb \rightarrow Hg + (C_5H_5)_2Yb. \quad (13)$$

$YbI_2(thf)_x$ prepared from Yb metal and ICH_2CH_2I in thf also can be used as a precursor to $(C_5H_5)_2Yb$ [reaction (14)]:[56]

$$YbI_2 + 2C_5H_5Na \rightarrow (C_5H_5)_2Yb + 2NaI. \quad (14)$$

The acid–base reaction of cyclopentadiene with $(C_6F_5)_2Yb$ and $(C_6F_5)_2Eu$, both obtainable from the elemental metal [see Section III.2(g.)], have also been used to form $(C_5H_5)_2Yb(MeOCH_2CH_2OMe)$ and $(C_5H_5)_2Eu(thf)$.[57]

$(C_5H_5)_2Sm(thf)$ was first prepared from $(C_5H_5)_3Sm$ by reduction with $KC_{10}H_8$ [cf. reaction (10)].[58] A more recent synthesis employs the divalent precursor $SmI_2(thf)_x$, in a reaction analogous to reaction (14).[56] A reported synthesis[59] of $(C_5H_5)_2Sm(thf)_2$ from $Hg(C_5H_5)_2$ and Sm according to reaction (13) has been subsequently shown to give only $(C_5H_5)_3Sm(thf)$.[60] Unfortunately, since $(C_5H_5)_2Sm(thf)$ is insoluble in common solvents, the chemistry of this organometallic complex of the most reactive divalent lanthanide metal was not explored. A subsequent study of the $(C_5H_5)_3Sm$–K system in the presence of benzophenone indicates that extraction of the insoluble product with dimethoxyethane (dme) gives a soluble material characterized by elemental analysis as divalent $KSm(C_5H_5)_3$.[60]

Recently, a bis(cyclopentadienyl) Yb complex was characterized by X-ray diffraction as a dme adduct, $(C_5H_5)_2Yb(MeOCH_2CH_2OMe)$.[61] The structure (Fig. 1) is typical of a bent metallocene with two additional ligands. A summary of structural data on all of the crystallographically characterized divalent organolanthanide complexes discussed in this review is presented in Table 1.

III.2(c) *Complexes containing monosubstituted cyclopentadienyl ligands.* Although the first divalent organolanthanide complexes were prepared in 1965,[15] no structural data on any low-valent organolanthanides were reported until 1980. The first X-ray structure determination of a divalent organolanthanide complex involved the methyl-substituted derivative $(CH_3C_5H_4)_2Yb(thf)$.[25] This complex can be synthesized by alkali metal reduction of $[(CH_3C_5H_4)_2YbCl]_2$ [cf. reaction (7)], by transmetalation with $TlC_5H_4CH_3$[54] [cf. reaction (12)], by reaction of $CH_3C_5H_5$ with $Yb(C{\equiv}CC_6H_5)_2$[57] and by thermolysis, photolysis or hydrogenolysis of $[(CH_3C_5H_4)_2YbCH_3]_2$ [(15)–(17)]:[25]

[a] $[(C_5Me_5)_2Yb(\mu\text{-}C{\equiv}CPh)_2]_2Yb$, in which the unique ytterbium is divalent [coordination number 4, Yb—C = 2.52(1) Å][92] is not included in this table.
[b] For $(C_5R_5)_2LnL_2$ complexes.
[c] These distances are for the bridging MeC_5H_4 ligands which are coordinated to ytterbium atoms on each side.
[d] The toluene is not coordinated to the metal.
[e] Not reported.[f]
[f] Unpublished results cited in Ref. 92.

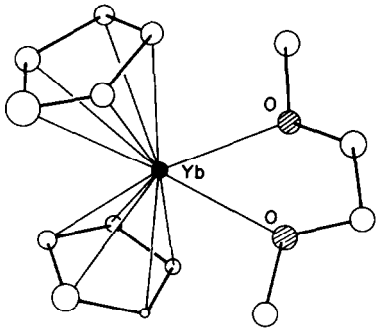

Fig. 1. Structure of $(C_5H_5)_2Yb(CH_3OCH_2CH_2OCH_3)$. White circles are carbon atoms.

$$[(CH_3C_5H_4)_2YbCH_3]_2 \xrightarrow[80°C]{\text{pentane–}Et_2O} 2(CH_3C_5H_4)_2Yb, \tag{15}$$

$$[(CH_3C_5H_4)_2YbCH_3]_2 \xrightarrow[\text{toluene, } 5°C]{h\nu} 2(CH_3C_5H_4)_2Yb, \tag{16}$$

$$[(CH_3C_5H_4)_2YbCH_3]_2 + 2H_2 \xrightarrow[50°C]{\text{toluene}} 2[(CH_3C_5H_4)_2YbH] \rightarrow 2(CH_3C_5H_4)_2Yb. \tag{17}$$

These latter three reactions are significant in divalent organolanthanide chemistry in that they demonstrate that access to the reactive Yb(II) oxidation state is possible without using strongly reducing conditions (e.g. alkali metal present). These reactions may provide the basis for interesting catalytic cycles involving the Yb(III)–Yb(II) couple.

The actual crystals used in the X-ray study of $(CH_3C_5H_4)_2Yb(thf)$[25] were prepared in an attempt to derivatize an Yb–3-hexyne cocondensation product[62] [reaction (18) (see Section IV)]:

$$YbC_6H_{10} + 2CH_3C_5H_5 \xrightarrow{thf} (CH_3C_5H_4)_2Yb(thf). \tag{18}$$

As shown in Fig. 2, $(CH_3C_5H_4)_2Yb(thf)$ is polymeric in the solid state forming a chain structure in which the monomeric $(\mu\text{-}CH_3C_5H_4)(CH_3C_5H_4)Yb(thf)$ units are linked by bridging methylcyclopentadienyl groups.[25] Apparently, a monomeric $(CH_3C_5H_4)_2Yb(thf)$ unit is sterically unsaturated and polymerizes to increase steric saturation in the solid state. Isopiestic molecular-weight studies indicate that in thf, $(CH_3C_5H_4)_2Yb(thf)$ also increases its coordination number and exists as a disolvate in solution.

The trimethylsilyl-substituted cyclopentadienyl complex $(Me_3SiC_5H_4)_2Yb(thf)_2$ was prepared from $[(Me_3SiC_5H_4)_2YbCl]_2$ according to reaction (7) using Na(Hg) as the reductant in thf.[63] The thf of solvation can be displaced by $Me_2NCH_2CH_2NMe_2$ (tmeda) to form $(Me_3SiC_5H_4)_2Yb$ (tmeda) and the solvent-free $(Me_3SiC_5H_4)_2Yb$ can be obtained by sublimation at 308°C. In contrast to the polymeric nature of $(CH_3C_5H_4)_2Yb(thf)$, $(Me_3SiC_5H_4)_2Yb(thf)_2$ crystallizes as a monomer with a bent metallocene structure analogous to that of $(C_5H_5)_2Yb(dme)$ in Fig. 1.

The divalent methylcyclopentadienyl Sm complex $(CH_3C_5H_4)_2Sm$ can be made from $[(CH_3C_5H_4)_2SmCl]_2$ by reduction, but, like the unsubstituted analog, it is insoluble in common solvents.[64]

The indenyl complexes $(C_9H_7)_2Yb(thf)_2$ and $(C_9H_7)_2Eu(thf)$ have been prepared from indene and $Yb(C_6F_5)_2$ and $Eu(C_6F_5)_2$ [Section III.2(g.)], respectively.[57]

III.2(d) *Solvated pentamethylcyclopentadienyl complexes.* The pentamethylcyclopentadienyl ligand, C_5Me_5, has proven to be of great importance in organometallic chemistry. As demonstrated by Bercaw and co-workers with Ti and Zr complexes[65,66] and as subsequently shown by Marks *et al.* for actinide complexes,[67,68] the C_5Me_5 ligand provides solubility and crystallinity to systems difficult to fully characterize using simple unsubstituted C_5H_5 ligands. Utilization of this ligand in divalent organolanthanide chemistry has had similarly spectacular results.

Bis(pentamethylcyclopentadienyl) complexes of all three readily accessible divalent lanthanides are known. $(C_5Me_5)_2Eu(thf)$ was prepared from trivalent $EuCl_3$ and three equivalents of NaC_5Me_5

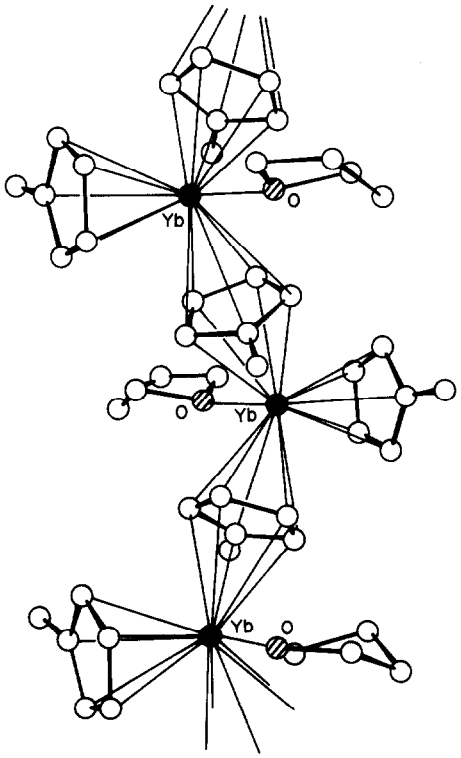

Fig. 2. Structure of $[(CH_3C_5H_4)(thf)Yb(\mu\text{-}CH_3C_5H_4)]_n$. Three units of the continuous chain are shown. White circles are carbon atoms.

in a reaction in which NaC_5Me_5 functions as a reducing agent [reaction (19)]:[69]

$$EuCl_3 + 3NaC_5Me \xrightarrow[\text{reflux}]{\text{thf}} (C_5Me_5)_2Eu(thf). \tag{19}$$

This is not an efficient use of the NaC_5Me_5 reagent, but the simple reaction of two equivalents of NaC_5Me_5 with $EuCl_2$ fails to generate the desired product. Reaction (19) is quite sensitive to specific conditions: using LiC_5Me_5 instead of NaC_5Me_5 or toluene instead of thf fails to give $(C_5Me_5)_2Eu(thf)$. Depending on crystallization conditions, the europium complex can be isolated as the mono-thf solvate or as $(C_5Me_5)_2Eu(thf)(OEt_2)$.

$(C_5Me_5)_2Yb(thf)$ can be prepared from YbI_2 by the route of reaction (14), but the success of the reaction depends on the specific reagents used. $YbBr_2(thf)_2$–KC_5Me_5–ethers[70] and $YbCl_2(thf)_x$–NaC_5Me_5–thf[69] are productive combinations whereas $YbCl_2$–NaC_5Me_5–Et_2O and $YbCl_2$–LiC_5Me_5–thf are not.[69] In addition to the mono-thf solvate, $(C_5Me_5)_2Yb(OEt_2)$,[69] $(C_5Me_5)_2Yb(thf)\cdot\frac{1}{2}CH_3C_6H_5$,[69] $(C_5Me_5)_2Yb(thf)_2$,[70] and $(C_5Me_5)_2Yb(CH_3OCH_2CH_2OCH_3)$[70] have been isolated by varying the conditions of crystallization. In a variation of reaction (7), bis(pentamethylcyclopentadienyl) complexes of Yb can also be prepared by reduction of the trivalent KCl adducts $(C_5Me_5)_2YbCl_2K(solvent)_x$ in CH_3CN or $CH_3OCH_2CH_2OCH_3$ [reaction (20)]:[71]

$$(C_5Me_5)_2YbCl_2K(solvent)_x + Na(Hg) \rightarrow (C_5Me_5)_2Yb(solvent)_y. \tag{20}$$

This reaction was found to be solvent-dependent with thf being a less desirable solvent than dme. Reaction (20) is an inferior synthesis in general for $(C_5Me_5)_2Yb(solvent)$ complexes when compared to reaction (14). $(C_5Me_5)_2Yb(dme)$ can also be prepared by reduction of trivalent $(C_5Me_5)_2Yb(dme)(PF_6)$ with KH or $LiCH_2CMe_3$ [cf. reactions (17) and (9), respectively].[70] $(C_5Me_5)_2Yb(NC_5H_5)_2$ has been obtained by displacing Et_2O from $(C_5Me_5)_2Yb(OEt_2)$ with pyridine.[72] The mono-thf and bis-pyridine adducts have both been structurally characterized as typical bent metallocene structures (cf. Fig. 1).

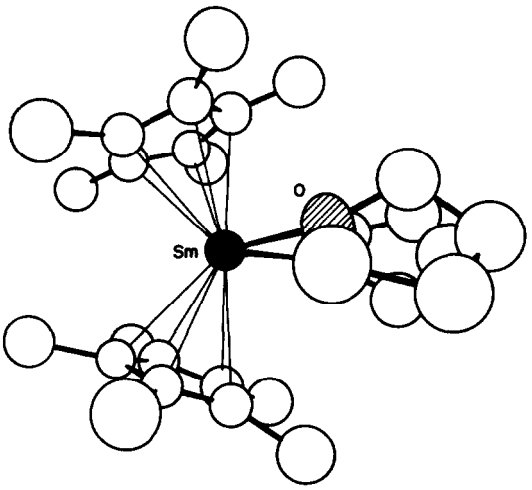

Fig. 3. Side view of the structure of $(C_5Me_5)_2Sm(thf)_2$. The two thf molecules overlap such that only one oxygen atom can be seen from this perspective.

C_5Me_5H reacts with liquid-ammonia solutions of Eu and Yb at low temperature over a 24–36-h period to form bis(pentamethylcyclopentadienyl) products.[73] Crystallization of these products from thf gives $(C_5Me_5)_2Eu(thf)$ and $(C_5Me_5)_2Yb(thf)(NH_3)$. The latter complex has been characterized by X-ray crystallography.[73]

Mono (pentamethylcyclopentadienyl) Yb complexes such as $(C_5Me_5)YbI$ and $[(C_5Me_5)YbI_2]^-$ are thought to be intermediates in the YbI_2–$C_5Me_5^-$ and YbI_2–$(C_5Me_5)_2Yb$ reaction mixtures, but no details on these species were reported.[70,71] Interestingly, YbI_2 has not been mentioned in the literature as a precursor to $(C_5Me_5)_2Yb(solvent)_x$.

The greatest impact of the C_5Me_5 ligand on divalent organolanthanide chemistry has been with Sm. The initially synthesized Sm(II) organometallics, $[(C_5H_5)_2Sm(thf)]_n$ and $[(CH_3C_5H_4)_2Sm(thf)]_n$, are insoluble in common solvents, possibly because with the larger radial size of the metal, more extensive oligomerization/polymerization occurs in the solid state than in the analogous Yb case (cf. Fig. 2). A consequence of this insolubility was that the organometallic chemistry of Sm(II), the most reactive of the divalent lanthanides, could not be investigated with the $(C_5H_4R)_2Sm(thf)$ systems. With the C_5Me_5 ligand, Sm(II) complexes are soluble and a rich and varied chemistry has developed as a consequence.

The initial synthesis of $(C_5Me_5)_2Sm(thf)_2$ was achieved via metal vapor methods [reaction (21) (cf. Section IV)]:[47,74]

$$2Sm + 2C_5Me_5H \xrightarrow{thf} 2[(C_5Me_5)SmH(thf)_2] \rightarrow (C_5Me_5)_2Sm(thf)_2. \quad (21)$$

The bracketed intermediate Sm(II) hydride was not isolated in a pure form. The metal vapor method was also used to synthesize $(C_5Me_4Et)_2Sm(thf)_2$.[74] This species is similar to $(C_5Me_5)_2Sm(thf)_2$ in most respects except that $(C_5Me_4Et)_2Sm(thf)_2$ is more soluble. Like other bis(cyclopentadienyl) bis(ligand) divalent lanthanide complexes (e.g. Fig. 1), the structure of $(C_5Me_5)_2Sm(thf)_2$ has canted cyclopentadienyl rings and the oxygen atoms of the solvating thf molecules lie in a plane which bisects the (ring centroid)–metal–(ring centroid) angle (Fig. 3).

$(C_5Me_5)_2Sm(THF)_2$ subsequently was prepared by solution methods according to reaction (14) using $SmI_2(thf)_x$ and two equivalents of KC_5Me_5.[75] This is a much more convenient synthesis and readily allows the preparation of multigram quantities of this interesting complex. The SmI_2–KC_5Me_5 system contains several species including a mono(pentamethylcyclopentadienyl) complex, $[(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2$, which can be best isolated by reacting $SmI_2(thf)_x$ with one equivalent of KC_5Me_5 [reaction 2)]:[75]

$$2SmI_2(thf)_x + 2KC_5Me_5 \rightarrow [(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2. \quad (22)$$

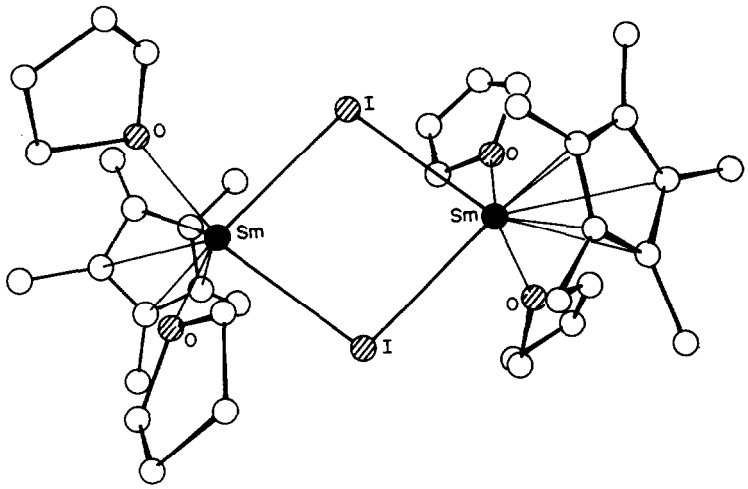

Fig. 4. Structure of $[(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2$.

Crystallographic characterization of this complex reveals an iodide-bridged structure as shown in Fig. 4.

III.3(e) *Unsolvated pentamethylcyclopentadienyl complexes.* Almost all lanthanide complexes containing two cyclopentadienyl rings have one to three additional ligands in the coordination sphere of the metal. This is consistent with the large size of these metals and their tendency toward steric saturation in stable complexes. For many years, no structurally characterized simple bis(cyclopentadienyl) system analogous to ferrocene was known. Instead, stable bis(ring) *f*-element sandwich complexes were known only when the larger cyclooctatetraenyl rings were present as in $U(C_8H_8)_2$[76] and $[Ln(C_8H_8)_2]^-$.[77] Although compounds of formula $(C_5H_5)_2Eu$[15] $(C_5H_5)_2Yb$[15,52,53] and $(Me_3SiC_5H_4)_2Yb$[63] could be obtained by high-temperature sublimation, no structural data were available on these systems. Based on the low ether solubility of $(C_5H_5)_2Eu$[15] and the polymeric 10-coordinate structure found for $[(CH_3C_5H_4)_2Yb(thf)]_n$ (Fig. 2),[25] it seemed likely that these unsolvated complexes might be oligomeric in the solid state.

The potential for isolating a monomeric unsolvated divalent bis(cyclopentadienyl) lanthanide complex seemed greater with C_5Me_5 ligands. The first such complex was made by metal vapor methods as a byproduct in the synthesis of $(C_5Me_5)_2Sm(thf)_2$ [reaction (23)]:[47,74]

$$Sm + \text{excess } C_5Me_5H \rightarrow (C_5Me_5)_2Sm. \tag{23}$$

This product was recovered in low yield from the alkane soluble fraction of the metal vapor reaction mixture. Unsolvated $(C_5Me_4Et)_2Sm$ was obtained in a similar manner.[74]

Following the development of a high-yield solution synthesis of $(C_5Me_5)_2Sm(thf)_2$,[75] this species was examined as a precursor to $(C_5Me_5)_2Sm$. Direct desolvation was the obvious synthetic route, but data in the literature did not suggest this would be successful. For example, $[(C_5H_5)_2Sm(thf)]_n$ was reported to decompose on heating[58] and attempts to desolvate $(C_5Me_5)_2Yb(thf)_2$ at 90°C gave only $(C_5Me_5)_2Yb(thf)$.[70] Surprisingly, desolvation of $(C_5Me_5)_2Sm(thf)_2$ is rather facile and occurs at 75°C [reaction (24)]:[78]

$$(C_5Me_5)_2Sm(thf)_2 \xrightarrow[\text{vacuum}]{75^\circ C} (C_5Me_5)_2Sm + 2thf. \tag{24}$$

The desolvated product is soluble in arenes and can be sublimed to give X-ray quality crystals.

The surprising structure of $(C_5Me_5)_2Sm$ is shown in Fig. 5.[78,79] The molecule crystallizes as a monomer with a (ring centroid)–metal–(ring centroid) angle of 140.1°, rather than the 180° angle anticipated for a parallel-ring structure analogous to that found for ferrocene[80] and decamethylferrocene, $(C_5Me_5)_2Fe$.[81] The (ring centroid)–metal–(ring centroid) angle in $(C_5Me_5)_2Sm$ is only slightly larger than the 136.7° angle found in $(C_5Me_5)_2Sm(thf)_2$ (Fig. 3). It is as though

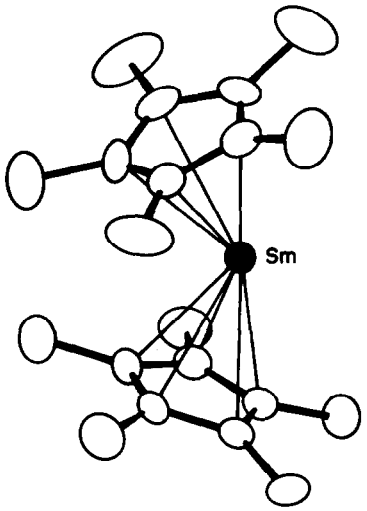

Fig. 5. Structure of $(C_5Me_5)_2Sm$.

removal of the two thf ligands had no effect on this structural feature.

For a predominantly ionic complex governed by electrostatic factors, a parallel-ring structure would be optimal for $(C_5Me_5)_2Sm$ since the anionic ligands would be as far apart as possible. Based on steric considerations a parallel-ring ferrocene-like structure would also be favored over the bent metallocene arrangement. A molecular orbital analysis also suggests that the parallel-ring structure is most stable, although it predicted that distortions would not be energetically costly.[82]

The possibility that the bent structure was due to intermolecular interaction was carefully examined.[78] One methyl group of each $(C_5Me_5)_2Sm$ unit points toward a Sm atom of another unit, but the distances are too long for a substantial interaction (Sm—C, 3.22 Å; Sm—H, 2.75 Å). Moreover, this interaction comes from the side of the bent metallocene unit, not through the sterically most accessible, open, "front" part of the $(C_5Me_5)_2Sm$ unit. Attempts to obtain the gas-phase electron diffraction structure of $(C_5Me_5)_2Sm$ were unsuccessful due to the limited thermal stability of this complex.[83]

To determine if the $4f^6$-electron configuration of Sm^{2+} affected the structure, the structure of the $4f^7$-system $(C_5Me_5)_2Eu$ was also determined.[79] $(C_5Me_5)_2Eu$ is isostructural with $(C_5Me_5)_2Sm$ although the desolvation of $(C_5Me_5)_2Eu(thf)$ was found to be significantly more difficult (multiple desolvation/sublimation reactions were necessary to get the solvate-free species).

The facile synthesis and unusual structure of $(C_5Me_5)_2Sm$ suggest that the principles of divalent organolanthanide chemistry may differ substantially from those of the trivalent species discussed in Section II. A reaction such as reaction (24), in which an oxygen donor adduct is removed to form an isolable sterically much less saturated species (eight-coordinate → six-coordinate), does not follow the expected reactivity patterns for ionic, electropositive oxophilic trivalent lanthanides. The observed structures of $(C_5Me_5)_2Sm$ and $(C_5Me_5)_2Eu$ follow neither the traditional electrostatic nor steric principles.

The best current explanation for the bent structures is the polarization argument used to explain why some heavy alkaline earth metal dihalides, MX_2, are bent rather than linear in the gas phase.[18,84,85] In a parallel-ring $(C_5Me_5)_2Ln$ structure analogous to a linear MX_2 structure, polarization of the cation by one C_5Me_5 anion could diminish the electrostatic interaction between the cation and the second C_5Me_5 anion directly opposite. A bent structure may optimize the polarization of a large cation by two anions and may give better total electrostatic bonding for the two rings. This argument provides an electrostatic rationale for the bent structures of $(C_5Me_5)_2Sm$ and $(C_5Me_5)_2Eu$ without involving 4*f*-orbital participation and without invoking high-energy 5*d* and 6*s* orbitals (via a stereochemically active lone pair argument).[86] If these polarization effects are generally valid for divalent organolanthanides, this may be an important differentiating factor between divalent and trivalent lanthanide chemistry.

III.2(f) *Alkynide complexes.* Several divalent organolanthanide complexes involving alkynyl ligands, —C≡CR, have been reported in the literature. Transmetalation with Hg reagents has been

used to obtain $Yb(C{\equiv}CC_6H_5)_2$ and $Eu(C{\equiv}CC_6H_5)_2(thf)_{0.25}$ [reaction (25)]:[87]

$$Yb + Hg(C{\equiv}CC_6H_5)_2 \rightarrow Yb(C{\equiv}CC_6H_5)_2 + Hg. \tag{25}$$

$Yb(C{\equiv}CCMe_3)_2$ has been prepared in solution by the same method but was not isolated. Divalent Yb alkynides can also be obtained from $Yb(C_6F_5)_2(thf)_4$ (see next section) by an acid–base reaction:[87]

$$Yb(C_6F_5)_2(thf)_4 + 2HC{\equiv}CC_6H_5 \rightarrow Yb(C{\equiv}CC_6H_5)_2 + 2C_6F_5H. \tag{26}$$

Attempts to repeat reaction (26) with $HC{\equiv}CCMe_3$ gave an explosive product.[87] The reaction of methylcyclopentadiene with $Yb(C_6F_5)_2(thf)_4$ similarly gives an explosive material.[57] On the basis of ebulliometric measurements, $Yb(C{\equiv}CC_6H_5)_2$ is associated into a trimer or tetramer in boiling thf.[87]

Eu in liquid ammonia is reported to react with propyne to form a divalent complex [reaction (27)]:

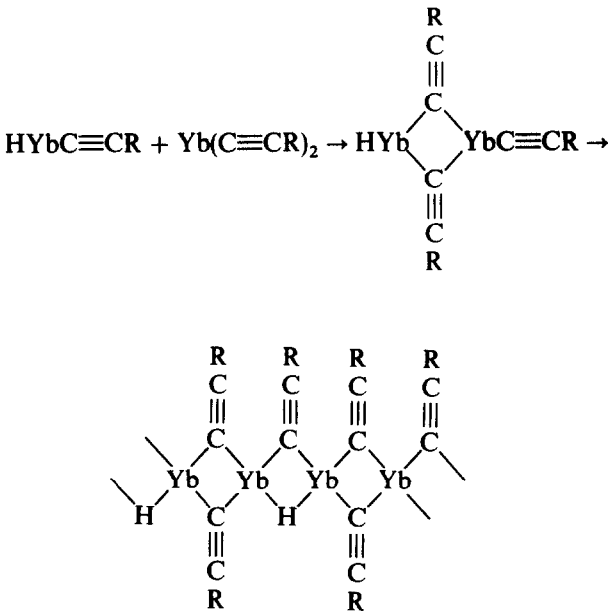
$$Eu + \text{excess } HC{\equiv}CCH_3 \xrightarrow{NH_3(l)} Eu(C{\equiv}CCH_3)_2, \tag{27}$$

but the analogous Yb reaction does not give a pure product presumably due to contamination by $Yb(NH_2)_2$.[88] Structural information has not yet been obtainable on these alkynide products.

Divalent alkynides can also be made from terminal alkynes by metal vapor methods. Hence, reaction of Yb metal with 1-hexyne forms complexes of general formula $[HYb_2(C{\equiv}CC_4H_9)_3]_n$.[89] Isopiestic molecular-weight studies indicated that this species is highly associated in solution and no X-ray quality single crystals of this oligomer were obtainable. Based on the structures of $[(C_5H_5)_2Er(\mu\text{-}C{\equiv}CCMe_3)]_2$[90] and $[(CH_3C_5H_4)_2Sm(\mu\text{-}C{\equiv}CCMe_3)]_2$,[91] oligomerization via alkynide bridges is quite possible. A possible route to the observed product is given in reactions (28)–(30) (R = C_4H_9):

$$Yb + HC{\equiv}CR \rightarrow HYbC{\equiv}CR, \tag{28}$$

$$HYbC{\equiv}CR + HC{\equiv}CR \rightarrow Yb(C{\equiv}CR)_2 + H_2, \tag{29}$$

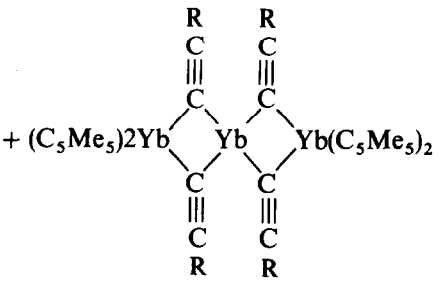


Reaction (28) is a basic oxidative addition of a C—H bond. Reaction (29), a hydride-based

metalation, is well precedented in organolanthanide and organoyttrium hydride chemistry.[23,87] The oligomerization shown in reaction (30) is expected based on the steric unsaturation of the mono- and bimetallic precursors (cf. Fig. 2).

Using the C_5Me_5 ligand, structures of the type shown above have been confirmed crystallographically. The complexes $(C_5Me_5)_2Ln(OEt_2)$ (Ln = Yb or Eu) react with $HC{\equiv}CC_6H_5$ to give mixed-valent and divalent alkynide-bridged species [reactions (31) and (32), R = C_6H_5]:[92]

$$+ (C_5Me_5)_2Yb(OEt_2) + 4HC{\equiv}CR \rightarrow 2C_5Me_5H + H_2$$



(31)

$$2(C_5Me_5)_2Eu(OEt_2) + 2HC{\equiv}CR \xrightarrow{thf} 2C_5Me_5H + [(C_5Me_5)(thf)_2Eu(\mu\text{-}C{\equiv}CR)]_2. \quad (32)$$

In both reactions the terminal alkyne gives up a proton to C_5Me_5,[93] but with the more strongly reducing Yb system some oxidation of the metal occurs. Magnetic studies show no exchange in the mixed-valent trimetallic Yb system. The Eu dimer has a structure analogous to that of $[(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2$[75] shown in Fig. 4.

III.2(g) *Alkyl and aryl complexes.* Reactions of alkyl and aryl iodides with Eu, Yb and Sm metal have been reported to form divalent alkyl and aryl lanthanide halide complexes.[94] These are complex systems, however, and a variety of both trivalent and divalent products may be present including RLnI, LnI_2,[71] $RLnI_2$ etc. The reaction mixtures behave like Grignard reagents. No structural data has been obtainable on these systems.

Subsequent studies of the RX–Ln system using Yb and C_5Me_5I in the presence of LiI led to the identification of the trivalent complexes $(C_5Me_5)YbI_3Li(Et_2O)_2$ and $(C_5Me_5)_2YbI_2Li(Et_2O)_2$ as well as YbI_2.[70,71] The complexity of RX–Ln systems in general is demonstrated well by this case. For example, $(C_5Me_5)YbI_3Li(Et_2O)_2$ is obtained in 30% yield in 15 h but subsequently is converted to $(C_5Me_5)_2YbI_2Li(Et_2O)_2$, which is obtained in 30% yield in 24–48 h. In addition, no organometallic products are isolated in the absence of LiI. The LiI-free reaction of ytterbium metal and C_5Me_5I gives only $C_{10}Me_{10}$, YbI_3 and YbI_2.[71]

Divalent lanthanide aryl complexes can be obtained using fluorinated aryl mercury reagents [reaction (33)]:[95,96]

$$(C_6F_5)_2Hg + Yb \xrightarrow{thf} (C_6F_5)_2Yb(thf)_4 + Hg. \quad (33)$$

$(C_6F_5)_2Yb(thf)_4$ is not very stable thermally and $(2,3,5,6\text{-}F_4C_6H)_2Yb$, prepared in the same way, is less stable. $(2,3,4,5\text{-}C_6F_4H)_2Hg$ reacts with Yb but gives a product too unstable to isolate. Neither $(C_6H_5)_2Hg$ nor $(C_6Cl_5)_2Hg$ are reported to react with Yb. Recently, however, NMR and hydrolytic data have been cited to suggest that $(C_6H_5)_2Hg$–Yb does form $Yb(C_6H_5)_2(thf)_n$.[97] Sm reactions with $(C_6F_5)_2Hg$ and $(C_6F_4H)_2Hg$ are more complex and a mixture of products is formed. The course of reactions such as reaction (33) have been followed by quenching with acid and identifying the products.[98]

Transmetalation as shown in reaction (33) also reportedly can be used to make divalent derivatives of ferrocene,[99] $C_5H_5Mn(CO)_3$,[99] and carboranes.[100] Hence, $(C_5H_5FeC_5H_4)_2Yb$, $[(CO)_3MnC_5H_4]_2Yb$ and $(\eta^1\text{-}C_2B_{10}R)_2Yb$ (R = CH_3 or C_6H_5) are obtained from the reaction of Yb with $Hg(C_5H_4FeC_5H_5)_2$, $Hg[C_5H_4Mn(CO)_3]_2$ and $Hg(C_2B_{10}R)_2$, respectively. $(C_5H_4I)Fe(C_5H_5)$ and $(C_5H_4I)Mn(CO)_3$ are reported to react with Yb metal to form $C_5H_5FeC_5H_4YbI$ and $(CO)_3MnC_5H_4YbI$, respectively.[99] Reaction of $LiC_2B_{10}C_6H_5$ with LnI_2 (Ln = Eu, Yb or Sm) is said to form $[\eta^1\text{-}C_2B_{10}(C_6H_5)]LnI$. Metalation of $C_2B_{10}C_6H_5$ with

"CH_3YbI" forms similar products.[101] Transmetalation of Eu, Sm and Yb with $Hg[C_6H_5Cr(CO)_3]_2$ is reported to form divalent complexes, $[(CO)_3CrC_6H_5]_2Ln(thf)_n$.[97] Lowered ν_{CO} absorptions in the IR spectra suggest Ln—O—C coordination. The only ^1H NMR resonance cited for the phenyl protons was δ 5.645, $J(^{171}Yb-^1H) = 80$ Hz. This is unusual since coupling to ^{171}Yb, which has a natural abundance of only 14.3%, has not been observed previously for divalent Yb organometallic species.

The formation of a divalent methyl complex $(C_5Me_5)Yb(CH_3)_2Li$ by displacement of $C_5Me_5^-$ in $(C_5Me_5)_2Yb$ by CH_3^- has been mentioned in the literature but no details of this reaction were revealed [reaction (34)]:[70]

$$(C_5Me_5)_2Yb + 2CH_3Li \rightarrow (C_5Me_5)Yb(CH_3)_2Li + LiC_5Me_5. \quad (34)$$

An additional class of divalent lanthanide complexes which have some metal hydrocarbon interactions involves the bis(trimethylsilyl) amido ligand, $—N[Si(CH_3)_3]_2$. Although these complexes do not possess formal metal carbon σ-bonds, the conformations of the $(Me_3Si)_2N$ groups are such that long-distance metal–CH interactions are observed. Reaction of EuI_2 or YbI_2 with $NaN(SiMe_3)_2$ gives either $Ln[N(SiMe_3)_2]_2(R_2O)_x$ or $NaLn[N(SiMe_3)_2]_3$, depending on the ether solvent used and the manner of recrystallization.[102] Crystal structures of $NaLn[N(SiMe_3)_2]_3$ (Ln = Eu or Yb) and $Yb[N(SiMe_3)_2]_2(Me_2PCH_2CH_2PMe_2)$ (obtained by displacing the R_2O of solvation with the diphosphine) show that some of the methyl groups are oriented to bring the carbon atoms within 2.86–3.04 Å of Yb and 2.97–3.14 Å of Eu. Similarly, $Yb[N(SiMe_3)_2(AlMe_3)]_2$ has six methyl groups within 2.756(2)–3.202(3) Å of Yb(II).[103]

III.3 *Reactivity*

Although the reactivity of divalent organolanthanide complexes is only beginning to be explored, some general types of reactivity are discernible. An attempt to organize these reactions into general classes is made in the following subsections. The first three subsections deal with reactions which might be expected for complexes which are one-electron reducing agents and which contain electropositive lanthanide metal centers. In each of these cases, the metal gets oxidized and forms a sterically saturated complex containing a new bond or bonds to the most electronegative ligands available in the system. Subsequent sections deal with less traditional lanthanide reactivity patterns and ultimately to unprecedented types of reactivity. Applications of divalent lanthanide chemistry to organic chemistry will not be discussed here since they recently have been comprehensively reviewed elsewhere.[7]

III.3(a) *Oxidation reactions involving halide, pseudohalide and aryl ligands.* Bis(cyclopentadienyl) Yb and Sm complexes react with a variety of alkyl halides to form dicyclopentadienyl halide complexes. Many systems have been observed to have this reactivity including: (a) $(CH_3C_5H_4)_2Yb(thf)$ and $(CH_3C_5H_4)_2Sm(thf)$ with CH_3I, Me_3CCl and $H_2C{=}CHCH_2Br$,[104] (b) $(C_5Me_5)_2Yb(dme)$ with CH_2Cl_2,[70,105] (c) $(C_5Me_5)_2Sm(thf)_2$ with Me_3CCl and ICH_2CH_2I,[106] and (d) $(C_5Me_5)_2Yb(OEt_2)$ with n-C_4H_9Cl and $C_6H_5CH_2Cl$.[107] The trivalent halide complexes $(C_5R_5)_2LnX(solvent)$ are generally the main products of these reactions. $(C_5Me_5)_2SmCl(thf)$ and $(C_5Me_5)_2SmI(thf)$ have been made preparatively by route (c) above and have been crystallographically characterized.[106] The $(C_5Me_5)_2Yb(OEt_2)$–$C_6H_5CH_2Cl$ system has been studied in detail and found to give a variety of products in the presence of a slight excess of RX [reaction (35)]:[107]

$$(C_5Me_5)_2Yb(OEt_2) + 1.52C_6H_5CH_2Cl \rightarrow 0.48(C_5Me_5)_2YCl + 0.52(C_5Me_5)YbCl_2 + Et_2O + 0.52C_5(CH_3)_5(CH_2C_6H_5) + 0.5(C_6H_5CH_2)_2. \quad (35)$$

The reactivity of $(C_5H_5)_2Yb$ in thf or dme with metal halides and pseudohalides has also been studied. Reactions of the divalent ytterbium species with HgX_2, TlX, AgX_2 and CuX salts where

X = O_2CMe, $O_2CC_6F_5$, $O_2CC_5H_4N$, Cl, Br, I, C_6F_5, C≡CPh, $CH(OCMe)_2$ or $CH(OCPh)_2$ have been examined [reactions (36) and (37)]:[108]

$$(C_5H_5)_2Yb(solvent) + MX \rightarrow (C_5H_5)_2YbX(solvent) + M(M = Tl\,or\,Cu), \quad (36)$$

$$2(C_5H_5)_2Yb(solvent) + MX_2 \rightarrow 2(C_5H_5)_2YbX(solvent) + M\,(M = Hg\,or\,Ag). \quad (37)$$

The crystal structure of the $O_2CC_6F_5$ reaction product has been determined to be the dimer $(C_5H_5)_2Yb(O—C(C_6F_5)—O)_2Yb(C_5H_5)_2$. Similarly, $(CH_3C_5H_4)_2Sm(thf)$ can be oxidized with HgI_2 or I_2 to give $(CH_3C_5H_4)_2SmI(thf)$.[104] A toluene suspension of $YbCl_3$ can be used as an oxidant to transform $(C_5Me_5)_2Yb(thf)$ into $(C_5Me_5)_2YbCl(thf)$.[105] $(C_5Me_5)_2Yb(dme)$ can be oxidized by the ferricinium ion [reaction (38)]:[70]

$$(C_5Me_5)_2Yb(dme) + [(C_5H_5)_2Fe][PF_6] \rightarrow (C_5Me_5)_2Yb(dme)(PF_6) + (C_5H_5)_2Fe. \quad (38)$$

$(C_5Me_5)_2Sm(thf)_2$ reacts with $Hg(C_6H_5)_2$ to provide a halide-free synthesis of a trivalent phenyl complex [reaction (39)]:[74]

$$2(C_5Me_5)_2Sm(thf)_2 + Hg(C_6H_5)_2 \rightarrow 2(C_5Me_5)_2Sm(C_6H_5)(thf) + Hg. \quad (39)$$

Oxidation of the mono(pentamethylcyclopentadienyl) anion $[C_5Me_5YbI_2]^-$ by C_5Me_5I is also reported to occur [reaction (40)]:[70]

$$(C_5Me_5)YbI_2Li + C_5Me_5I \rightarrow (C_5Me_5)YbI_3Li + C_5Me_5. \quad (40)$$

The aryl complexes[95] $(C_6F_5)_2Yb(thf)_4$ and $(p\text{-}HC_6F_4)Yb(thf)_4$ generated *in situ* in thf, react with the transition-metal halides $Rh(CO)Cl(PPh_3)_2$, $NiCl_2(bipy)$ (bipy = 2,2′-bipyridine), $NiCl_2(PPh_3)_2$ and $PtCl_2(bipy)$ to form complexes in which the halide ligands have been replaced by fluorinated aryl groups, i.e. $RRh(CO)(PPh_3)_2$, $R_2Ni(bipy)$ (R = C_6F_5 or $p\text{-}HC_6F_4$), $(C_6F_5)_2Ni(PPh_3)_2$ and $(C_6F_5)_2Pt(bipy)$.[96] $YbCl_2$ is the presumed byproduct. The $(C_6F_5)_2Yb(thf)_4$ complex also transfers C_6F_5 to Ph_3SnCl to form $Ph_3SnC_6F_5$. At low temperature I_2 reacts with $(C_6F_5)_2Yb(thf)_4$ to form C_6F_5I. With $HgCl_2$, some oxidation of $(C_6F_5)_2Yb(thf)_4$ occurs giving Hg metal as well as $(C_6F_5)_2Hg$. $(C_6F_5)_2YbCl$ or $YbCl_3$ were possible byproducts.[96] The decomposition of the divalent Yb fluoro-aryl complexes with CO_2[96] and the decomposition of the divalent Yb alkynides with H_2O have also been studied.[87]

III.3(b) *Oxygen abstraction reactions.* $(C_5Me_5)_2Sm(thf)_2$ reacts with a variety of oxygen-containing substrates including $CH_3CH_2\overline{CHCH_2O}$, NO, N_2O and C_5H_5NO to form the trivalent oxide complex $[(C_5Me_5)_2Sm]_2(\mu—O)$ (Fig. 6).[109] The epoxide system [reaction (41)]:

$$(C_5Me_5)_2Sm(thf)_2 + CH_3CH_2\underset{\diagdown\,\diagup}{\overset{O}{CH}}CH_2 \rightarrow (C_5Me_5)_2Sm—O—Sm(C_5Me_5)_2 + CH_3CH_2CH{=}CH_2 \quad (41)$$

and the pyridine *N*-oxide reaction give the oxide product in approximately 50% yield. The other reactions are much more complicated and give mixtures of many products of which the oxide is just one component. The oxide complex is structurally interesting in that the Sm—O—Sm unit is crystallographically linear.

III.3(c) *Reduction of transition-metal carbonyl complexes.* Divalent Yb and Sm organometallics are strong enough reducing agents to react with many transition-metal carbonyl complexes to form anions.[110] Although the simple unsubstituted cyclopentadienyl complexes like $(C_5H_5)_2Yb$ will react with transition-metal carbonyls,[111] reactions with C_5Me_5 derivatives give products which are easier to characterize. The reactivity of $(C_5Me_5)_2Yb(OEt_2)$ has been extensively studied in this regard.[112–115]

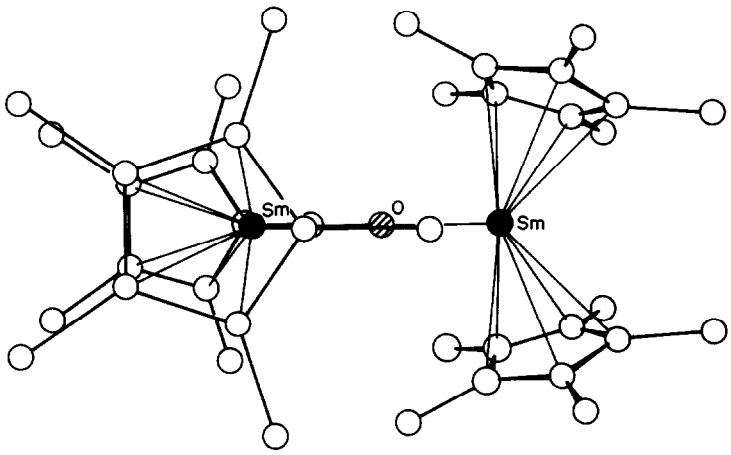


Fig. 6. Structure of $[(C_5Me_5)_2Sm]_2(\mu\text{-}O)$.

Reaction (42):

$$2(C_5Me_5)_2Yb(OEt_2) + Co_2(CO)_8 \xrightarrow{thf} (C_5Me_5)_2(thf)Yb(\mu\text{—}OC)Co(CO)_3 \qquad (42)$$

shows a simple reduction sequence in which the metal–metal bond in $Co_2(CO)_8$ is cleaved to generate the anion $[Co(CO)_4]^-$.[112] The product exists as a tight ion pair in which an isocarbonyl linkage, Yb—O—C—Co, is present. This reactivity is typical in that the divalent lanthanide gets oxidized and gets an additional electronegative ligand. The $Mn_2(CO)_{10}$ system is similar in that trivalent Yb and $Mn(CO)_5^-$ anions are formed. However, the structure of the product is complex and contains dimers, $[(C_5Me_5)_2Yb]$ $[(\mu\text{—}OC)Mn(CO)_3(\mu\text{—}CO)]_2$ $[Yb(C_5Me^5)_2]$, as well as a polymeric chain, $\{[(C_5Me_5)_2Yb]$ $[(\mu\text{-}OC)_3Mn(CO)_2]\}_n$.[113]

$Fe(CO)_5$ reacts with $(C_5Me_5)_2Yb(OEt_2)$ to form an analog of $Na_2Fe(CO)_4$ [reaction (43)]:[114]

$$2(C_5Me_5)_2Yb(OEt_2) + Fe(CO)_5 \rightarrow (CO)_3Fe[(\mu\text{-}CO)Yb(C_5Me_5)_2(thf)]_2. \qquad (43)$$

However, when the trinuclear transition-metal carbonyl $Fe_3(CO)_{12}$ was reacted with $(C_5Me_5)_2Yb(OEt_2)$, an iron–iron bond was broken, a carbonyl ligand was lost, and an $Fe_3(CO)_{11}^{2-}$ unit was formed which was attached to two $[(C_5Me_5)_2Yb]^+$ moieties via four isocarbonyl linkages [reaction (44)]:[114]

$$2(C_5Me_5)_2Yb(OEt_2) + Fe_3(CO)_{12} \rightarrow$$

$$(C_5Me_5)_2Yb\begin{matrix} O\text{–}C \\ \\ O\text{–}C \end{matrix}\begin{matrix} Fe(CO)_3 \\ C\text{–}O \\ Fe\text{–}CO \\ C\text{–}O \\ Fe(CO)_3 \end{matrix}Yb(C_5Me_5)_2 + CO. \qquad (44)$$

Reductive formation of tight ion pairs containing isocarbonyl connections has also been reported for $(C_5Me_5)_2Yb(OEt_2)$ with $(C_5H_5)_2Fe_2(CO)_4$, $(C_5H_5)_2Mo_2(CO)_6$ and $(C_5H_5)Co(CO)_2$.[115]

$(C_5Me_5)_2Sm(thf)_2$ reduces $Co_2(CO)_8$ to form a $(C_5Me_5)_2SmCo(CO)_4$ complex, but the structure of the compound is unknown because a refinable solution to the X-ray data was not readily obtainable. Interestingly, when $SmI_2(thf)_x$ reduces $Co_2(CO)_8$, a $Co(CO)_4^-$ product is obtained which *does not* have isocarbonyl connections. The product of this reaction, $[SmI_2(thf)_5]$ $[Co(CO)_4]$, has discrete $[SmI_2(thf)_5]^+$ and $Co(CO)_4^-$ units.[116]

III.3(d) *Substitution reactions.* As described in Section III.2(d), the solvating ether ligands in $(C_5Me_5)_2YbL_x$ and $(C_5Me_5)_2EuL_x$ ($x = 1$ or 2) can be readily substituted with other ethers.[69]

Hence, depending on crystallization conditions, complexes with L_x = thf, $(thf)_2$, Et_2O, (thf) (Et_2O) or dme can readily be obtained. These complexes have not been formed by deliberate substitution reactions, but rather by specific crystallization procedures.[69] Therefore, a definitive pattern of substitution reactivity has yet to be reported. The direct substitution of Et_2O from $(C_5Me_5)_2Yb(OEt_2)$ by pyridine in toluene has been studied however [reaction (45)]:[72]

$$(C_5Me_5)_2Yb(OEt_2) + 4C_5H_5N \rightarrow (C_5Me_5)_2Yb(NC_5H_5)_2 + 2NC_5H_5 + Et_2O. \quad (45)$$

Given the lability of the solvating ligands in solution, this type of substitution reactivity is expected.

Displacement of C_5Me_5 ligands from $(C_5Me_5)_2LnL_x$ complexes has also been reported. SmI_2 reacts with $(C_5Me_5)_2Sm(thf)_2$ in a ligand redistribution reaction to form a structurally characterized dimer [reaction (46) (Fig. 4)]:[75]

$$(C_5Me_5)_2Sm(thf)_2 + SmI_2 \rightarrow [(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2. \quad (46)$$

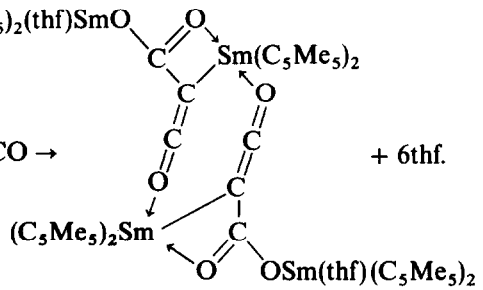
Displacement of C_5Me_5 from an unspecified solvate of $(C_5Me_5)_2Yb$ by LiI [reaction (47)]:

$$(C_5Me_5)_2Yb + 2LiI \rightarrow (C_5Me_5)YbI_2Li + LiC_5Me_5 \quad (47)$$

and MeLi [reaction (34)] has been reported to give $(C_5Me_5)YbI_2Li$ and $(C_5Me_5)YbMe_2Li$, respectively.[70] If the Yb in these products is not solvated and is therefore formally five-coordinate, this would be an unusual reaction. When Li and I are replaced by K and Br in reaction (47), the reverse reaction is preferred.[70]

III.3(e) CO *reduction.* The reduction of CO by $(C_5Me_5)_2Sm(thf)_2$[47,117] provides an excellent example of the unique reactivity available through this divalent lanthanide oxidation state. $(C_5Me_5)_2Sm(thf)_2$ reacts under a variety of conditions with CO to give complex mixtures of products. Under 90 psi of CO in THF, a crystalline product separates which was crystallographically characterizable [reaction (48)]:

$$4(C_5Me_5)_2Sm(thf)_2 + 6CO \rightarrow \text{[structure]} + 6thf. \quad (48)$$



The remarkable dimeric product contains four Sm(III) centers and the equivalent of six CO molecules. Hence, in reaction (48) six CO units have been reduced by four electrons and the reductive homologation has formed two ketenecarboxylate units.

The most interesting feature in the formation of the ketenecarboxylate complex is that complete cleavage of one CO triple bond must have occurred to give the central, oxygen-free carbon of the C=C—C skeleton. Although CO cleavage is thought to occur in heterogeneous Fischer–Tropsch systems,[118] this rarely occurs in homogeneous systems. Complete CO cleavage is not observed in the extensive studies of CO reduction by molecular early transition-metal,[65,119] actinide[120] and lanthanide[121] hydride systems.

Although metal hydride reduction of CO has been heavily investigated, hydrogen-free reduction of CO using one-electron reducing agents as in reaction (48) has received much less attention. The closest related system is the two-electron reduction of two CO molecules by alkali metals which is reported to form an insoluble alkyne diolate [reaction 49)]:[122]

$$2K + 2CO \rightarrow 2[KOC{\equiv}COK]. \quad (49)$$

The relationship between reactions (48) and (49) can be seen by comparing KOCCOK with the

atom connectivity on the right hand (or left hand) side of the ketenecarboxylate dimer, $SmO\overset{O}{\overset{\|}{C}}CCOSm$. Both the K and Sm systems contain MOCCOM units involving two-electron reduction of two CO molecules. The samarium system, a two-electron–three-CO system, has an extra CO formally "inserted" between a C and O bond. The insolubility of the KOC≡COK product may be responsible for the lack of further homologation in this system compared to the Sm system. Hence, $(C_5Me_5)_2Sm(thf)_2$, although strongly reducing like the alkali metals, is differentiated from those reducing agents by its solubility. The C_5Me_5 ligands provide solubility to the reducing agent as well as to intermediate reduction products and allow $(C_5Me_5)_2Sm(thf)_2$ to accomplish chemistry different from that of the alkali metal.

The reactivity of $(C_5Me_5)_2Sm(thf)_2$ with CO can also be compared with that of $(C_5Me_5)_2Ti$. Both organometallic reagents are soluble, strongly reducing complexes of oxophilic metals. As shown in reaction (50):

$$(C_5Me_5)_2Ti + 2CO \rightarrow (C_5Me_5)_2Ti(CO)_2, \tag{50}$$

decamethyltitanocene forms a carbonyl[123] complex rather than reducing the CO. Since the 4*f* valence orbitals of Sm(II) are not as suitable for carbonyl complex formation as those of Ti(II), this is less likely for Sm and reduction occurs.

Considering the comparisons above and the fact that neither $(C_5Me_5)_2Yb$[70,92] nor $(C_5Me_5)_2Eu(thf)$ react with CO, $(C_5Me_5)_2Sm(thf)_2$ appears to be a unique reducing agent in the periodic table. The combination of strong reducing power, oxophilicity, solubility and lack of *d* valence orbitals is not duplicated by any other reducing agent presently available.

$(C_5Me_5)_2Sm(thf)_2$ is not the only Sm(II) reagent which reacts with CO, however. Both $(C_5Me_5)_2Sm$ and $[(C_5Me_5)(thf)_2Sm(\mu\text{-}I)]_2$ reduce CO.[117,124] Again, mixtures of complex products are obtained. The reaction of $(C_5Me_5)_2Sm$ with CO provides X-ray quality crystals but the molecule is so complex that a solution to the X-ray data has not been found.

III.3(f) *Reduction of internal alkynes and azobenzene.* $(C_5Me_5)_2Sm(thf)_2$ reacts with $C_6H_5C{\equiv}CC_6H_5$ instantaneously to form a black product characterized by elemental analysis as $[(C_5Me_5)_2Sm]_2C_2(C_6H_5)_2$.[38] A possible formation pathway and structure are shown in reaction (51):

$$(C_5Me_5)_2Sm(thf)_2 + C_6H_5C{\equiv}CC_6H_5 \rightarrow [(C_5Me_5)_2Sm](C_6H_5)C{=}\dot{C}(C_6H_5) + 2\,thf$$

$$\xrightarrow{(C_5Me_5)_2Sm(thf)_2}$$

$$(C_5Me_5)_2Sm\diagdown \quad \diagup C_6H_5 \qquad\qquad (51)$$

$$\quad\quad C{=}C \qquad + 4thf.$$

$$C_6H_5\diagup \quad \diagdown Sm(C_5Me_5)_2$$

This reaction has some precedent in reactions of alkali metals with arylalkynes, except that in the heterogeneous alkali metal systems, polymerization or dimerization of the radical generally occurs.[125] The more soluble $(C_5Me_5)_2Sm(thf)_2$ may more readily trap the radical to give the bimetallic product. Once again the solubility of $(C_5Me_5)_2Sm(thf)_2$ may be responsible for chemistry different from that of the alkali metals.

$[(C_5Me_5)_2Sm]_2C_2(C_6H_5)_2$ is unusual in several respects.[38] Room-temperature magnetic-susceptibility measurements indicate that it contains Sm(III) centers. Given this oxidation state, the black color of this complex is abnormal since virtually all Sm(III) complexes are pale orange, yellow or red. Also unexpected is the fact that the complex reacts with excess thf to regenerate $(C_5Me_5)_2Sm(thf)_2$ and $C_6H_5C{\equiv}CC_6H_5$. Given the strongly reducing nature of Sm(II), this Sm(III) to Sm(II) conversion under mild conditions was unanticipated. The structure shown in reaction (51) is unproven but is consistent with spectroscopic data, hydrolysis to *trans*-stilbene, and the structure of the azobenzene complex described below.

$(C_5Me_5)_2Sm(thf)_2$ reacts with $C_6H_5N{=}NC_6H_5$ to form an intensely colored product which also has unusual properties [reaction (52)]:[126]

$$2(C_5Me_5)_2Sm(thf)_2 + C_6H_5N{=}NC_6H_5 \rightarrow \begin{array}{l}(C_5Me_5)_2Sm \quad\quad C_6H_5\\ \quad\quad\quad\quad\quad\quad N{=}N\\ C_6H_5 \quad\quad\quad\quad\quad Sm(C_5Me_5)_2\end{array} + 4thf. \qquad (52)$$

The complex has an overall structure like that proposed for $[(C_5Me_5)_2Sm]_2C_2(C_6H_5)_2$ and, given the N for C change, could be viewed as an azobenzene base adduct of $(C_5Me_5)_2Sm(II)$. However, room-temperature magnetic-susceptibility measurements indicate that the metal is in the trivalent oxidation state and the Sm—N distances, 2.40(1) and 2.41(1) Å, are consistent with single σ-bonds. This suggests the presence of a $[(C_6H_5)NN(C_6H_5)]^{2-}$ dianion. However, the 1.25(1) Å NN distance is the same as the N=N double-bond distances in a variety of azobenzene structures. As shown in Fig. 7, the molecule is distorted in that the N—C (phenyl) distances are stretched from a normal 1.42 Å to 1.56–1.61 Å. In addition, the Sm atoms are displaced asymmetrically such that both come within 2.29–2.34 Å of the *ortho* hydrogens of a single phenyl ring in a bonafide agostic[127] Sm–H interaction. The ability of Sm(II) to structurally distort azobenzene in this way is remarkable.

Attempts to get $(C_5Me_5)_2Yb(OEt_2)$ to react with $C_6H_5C{\equiv}CC_6H_5$ in analogy to reaction (51) were unsuccessful.[92]

In the presence of hydrogen, $(C_5Me_5)_2Sm(thf)_2$ reacts with alkynes such as $C_6H_5C{\equiv}CC_6H_5$ and $CH_3CH_2C{\equiv}CCH_2CH_3$ to form systems which are active hydrogenation catalysts.[38] Formation of an enediyl-like structure [cf. reaction (51)] followed by hydrogenolysis of the Sm—C bond, a well-established reaction[22,23] may give the SmH unit which could be the active catalyst [reactions (53)–(55), $(Cp^5{=}C_5Me_5)$]:

$$2Cp^5_2Sm(thf)_2 + RC{\equiv}CR \rightarrow \begin{array}{l}Cp^5_2Sm \quad\quad R\\ \quad\quad C{=}C\\ R \quad\quad\quad SmCp^5_2\end{array} \xrightarrow{H_2} 2[Cp^5_2SmH], \qquad (53)$$

$$[Cp^5_2SmH] + RC{\equiv}CR \rightarrow \begin{array}{l}Cp^5_2Sm \quad\quad H\\ \quad\quad C{=}C\\ R \quad\quad\quad R\end{array} \xrightarrow{H_2} [Cp^5_2SmH] + \begin{array}{l}H \quad\quad H\\ \quad\quad C{=}C\\ R \quad\quad\quad R\end{array} \qquad (54)$$

$$[Cp^5_2SmH] + RHC{=}CHR \rightarrow Cp^5_2SmCHRCH_2R \xrightarrow{H_2} [Cp^5_2SmH] + RCH_2CH_2R. \qquad (55)$$

This scheme is supported by the isolation of the structurally characterized dimer $[(C_5Me_5)_2$

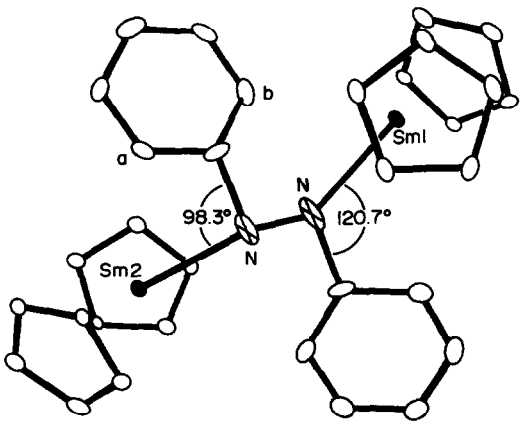


Fig. 7. Structure of $[(C_5Me_5)_2Sm]_2N_2(C_6H_5)_2$. Sm2 is 2.36 Å from the hydrogen atom on phenyl carbon atom a. Sm1 is 2.32 Å from the hydrogen atom on phenyl carbon atom b.

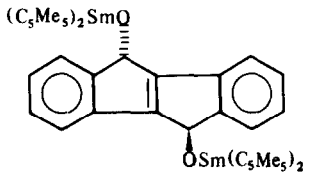
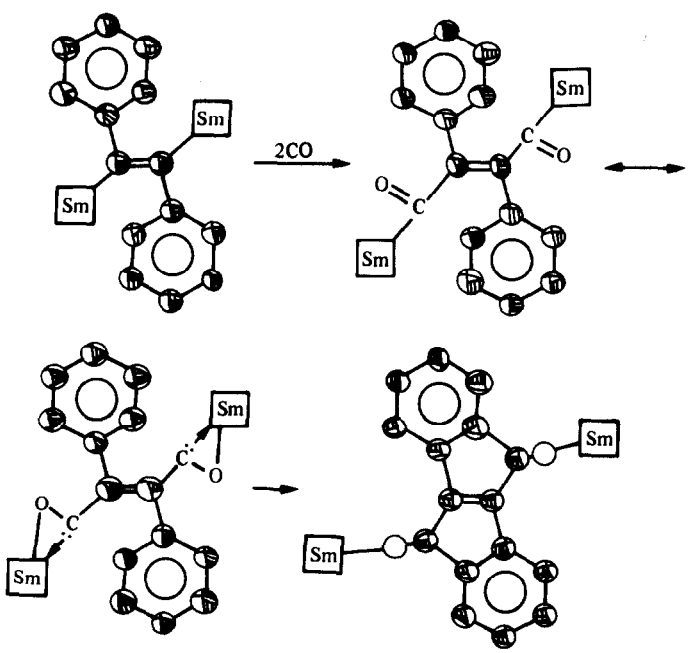
$Sm(\mu\text{-}H)]_2$ from a stoichiometric reaction like reaction (53).[38] In addition, the *cis* addition and hydrogenolysis sequence [reactions (54) and (55)] has been demonstrated for other lanthanide and yttrium hydrides.[23] A subsequent mechanistic study of lanthanide-based hydrogenation catalysis reconfirms the above result.[128]

III.3(g) *Productive* CH *and* CO *activation via* Sm(II). The reaction of the $(C_5Me_5)_2Sm(thf)_2$–$C_6H_5C{\equiv}CC_6H_5$ reaction product with CO has led to a remarkably facile stereospecific synthesis of a tetracyclic hydrocarbon [reaction (56)]:[129]

$$2(C_5Me_5)_2Sm(thf)_2 + C_6H_5C{\equiv}CC_6H_5 \xrightarrow{-4\,thf} [(C_5Me_5)_2Sm]_2C_2(C_6H_5)_2 \xrightarrow{2CO} \text{(56)}$$



Based on the proposed structure of the product of the $(C_5Me_5)_2Sm(thf)_2$–$C_6H_5C{\equiv}CC_6H_5$ reaction [see reaction (51)] and earlier studies of CO insertion into lanthanide–carbon σ-bonds,[130] the scheme shown below was proposed to explain this synthesis [$(C_5Me_5)_2Sm$ is shown as Sm in a box].



Activation of CO by insertion into the Sm—C bonds could give two dihaptoacyl units with considerable Sm–O interaction and carbene character on the acyl carbon atoms. Insertion of these carbene-like centers into *ortho* C—H bonds would give the two five-membered rings. The proximity of the *ortho* C—H bonds to the samarium-containing moiety in the agostic hydrogen structure of $[(C_5Me_5)_2Sm]_2N_2(C_6H_5)_2$ [reaction (52)] gives support for this possible mode of CH activation. If this synthesis is generally applicable, it would be a valuable way to make polycyclic hydrocarbons in a stereospecific manner from simple starting materials, namely alkynes and CO.

III.3(h) *Reactions with alkenes and dienes.* Attempts to make ethene or butadiene complexes of $(C_5Me_5)_2Yb(thf)$ failed,[70] a result which was not surprising in view of the traditional picture of lanthanides as oxophilic hard acids which have little affinity for unsaturated hydrocarbons. However, $(C_5Me_5)_2Sm(thf)_2$ was found to polymerize ethene.[47,131] Further studies of the catalytic

activity of $(C_5Me_5)_2Yb(OEt_2)$ and $(C_5Me_5)_2Eu(OEt_2)$ in ethene polymerization reactions have shown that these complexes do have low activity.[131]

$(C_5Me_5)_2Sm(thf)_2$ also interacts with other alkenes. It readily isomerizes *cis*-stilbene to the *trans* isomer.[132] It reacts with cyclohexene in a complex reaction which gives a product which on the basis of preliminary X-ray data contains a short 3.03-Å Sm—Sm distance.[133] It reacts readily with cyclohexadienes and with cyclopentadiene. In the latter case, $(C_5Me_5)_2SmC_5H_5$ is formed.[133] In addition, $(C_5Me_5)_2Sm(thf)_2$ in the presence of hydrogen and alkenes leads to a catalytic hydrogenation system [see reactions (53)–(55)].[134]

III.4. *Principles of structure and reactivity for divalent organolanthanides*

Since only 13 divalent organolanthanide complexes have been structurally characterized (Table 1), any firm structural conclusions may be premature at this point. However, 10 of the structures do follow traditional principles of organolanthanide chemistry. The $(C_5R_5)_2Ln(solvent)_x$ systems have typical "bent metallocene plus x ligand" structures in the cases in which the steric bulk of the ligand set is sufficient to confer steric saturation on the complex. When this is not the case, e.g. with $(CH_3C_5H_4)_2Yb(thf)$ (Fig. 2),[25] oligomerization occurs to increase the steric saturation around the metal. Similarly, the monocyclopentadienyl systems such as $[(C_5Me_5)Sm(thf)_2(\mu\text{-}I]_2$ (Fig. 4)[75] and $[(C_5Me_5)Eu(thf)_2(\mu\text{-}C{\equiv}CC_6H_5)]_2$[92] form bridged structures to gain a higher coordination number.

Although the majority of divalent organolanthanide structures follow traditional principles, the remarkable $(C_5Me_5)_2Ln$ complexes ((Ln = Sm or Eu)[78,79] do not. The bent, sterically unsaturated structures are unexpected on the basis of both electrostatic and steric arguments and this structure occurs regardless of the 4*f*-electron configuration or reduction potential of the metal [a differentiating factor in reactivity (see below)].

The unusual geometry of the $(C_5Me_5)_2Ln$ complexes may signal the existence of an entire series of unanticipated structural possibilities for divalent organolanthanides. These complexes strongly indicate that the traditional principles of trivalent organolanthanide chemistry will not carry over directly to divalent systems. One of the exciting questions currently being explored in this area is how generally available are such sterically unsaturated divalent species.

Like the structural features discussed above, the reactivity of divalent complexes follows traditional organolanthanide principles in many cases. For example, there are numerous examples in Sections III.3(a)–(c) in which the metal gets oxidized and forms a sterically saturated trivalent complex which contains a new ligand involving the most electronegative of the donor atoms available in the system. As expected, reactivity parallels reduction potential, with Sm(II) more reactive than Yb(II) which is more reactive than Eu(II). The substitution reactions in Section III.3(d) are also expected considering the lability of solvating species and the tendency toward ligand redistribution reactions found for trivalent species.

Most of the unusual chemical reactivity observed for divalent organolanthanides is found with Sm(II) species. In many cases, what distinguishes Sm(II) from Yb(II) and Eu(II) is its greater reducing power. This opens up avenues of reactivity to Sm(II) which are unavailable to the other divalent lanthanide systems. Prime examples are the reductions of CO and $C_6H_5C{\equiv}CC_6H_5$ which succeed for Sm(II) and fail for Yb(II). Sm(II) has proven to be a unique one-electron reductant due to its special combination of physical properties. Hence, the Sm(II)-based reductive homologation of CO to $O_2C{-}C{=}C{=}O$ is a non-traditional unprecedented CO reduction. However, the reaction follows traditional organolanthanide principles in that sterically saturated oxygen-bound products are formed. Likewise the unusual distortions rendered to $C_6H_5N{=}NC_6H_5$ in the reaction with $(C_5Me_5)_2Sm(thf)_2$ can be traditionally explained given the formation of a highly reduced organic species. An electropositive lanthanide with a strong tendency to achieve a high coordination number will coordinate to whatever electron rich species are available. Hence, in the azobenzene complex the short Sm—N distance and agostic Sm—H interactions occur. The productive CH and CO activations discussed in III.3(g) are seen to follow traditional principles of organolanthanide–CO chemistry given the unusual features of $[(C_5Me_5)_2Sm]_2C_2(C_6H_5)_2$.

There is, however, an observed Sm(II) chemistry which does not follow traditional organolanthanide principles. The facile desolvation of $(C_5Me_5)_2Sm(thf)_2$ to form the sterically unsaturated $(C_5Me_5)_2Sm$ was unexpected. The difference in the desolvation tendencies of $(C_5Me_5)_2Sm(thf)_2$

and $(C_5Me_5)_2Eu(thf)$ is also unusual given the adjacent position of Sm and Eu in the periodic table. The facile reversal of the $(C_5Me_5)_2Sm(thf)_2$ reduction of $C_6H_5C{\equiv}CC_6H_5$ by thf, i.e. the formation of Sm(II) from Sm(III) under very mild conditions, was unanticipated. The unusual reactivity of $(C_5Me_5)_2Sm$ with cyclohexene is another example of non-traditional chemistry. These results, like the unusual structure of the $(C_5Me_5)_2Ln$ complexes, suggest there may be a major part of divalent organolanthanide reactivity which will not follow the traditional principles of the trivalent metals.

IV. ZERO OXIDATION STATE CHEMISTRY: THE CHEMISTRY OF THE METALS

In the mid-1970s, when only a limited amount of trivalent organolanthanide chemistry was known and almost no divalent organolanthanide chemistry was explored, there was an impetus to do rather speculative, highly exploratory synthetic studies in oxidation states other than +3 or +2.[135] The goal was to demonstrate a broader chemistry for the lanthanides than had previously been observed. It was anticipated that by taking a non-traditional approach to lanthanide chemistry, new areas in the field would be opened up and a greater potential for these elements in all oxidation states would be demonstrated.

An intriguing non-trivalent lanthanide oxidation state suitable for non-traditional exploration and available to all of the metals was the formally zero oxidation state of the metals. Although some reactivity was accessible from the bulk metal (see Section IV.3), a much more reactive form of the metal was available in the vapor phase. The metal vapor technique, in which a metal is vaporized from a resistively-heated tungsten container under high vacuum and is cocondensed with a potential ligand at −125 to −196°C, had proven useful in the synthesis of a variety of unusual low-valent transition-metal complexes.[136-140] This method provided the opportunity to study zero-valent lanthanide chemistry and also had the potential to generate zero-valent lanthanide complexes.

IV.1. *Background*

The stability of zero oxidation state complexes of transition metals depends in large part on the transfer of the excess electron density on the metal center back to the ligands via back bonding. Given the limited radial extension of the 4*f* orbitals, the possibility of stabilizing a zero-valent lanthanide complex by backbonding of the 4*f* electron density seemed remote. However, the atomic spectra of the lanthanides show that *in low oxidation states*, the 5*d* orbitals are close in energy to the 4*f* levels and that a variety of mixed 4*f*–5*d*–6*s* electron configurations are low in energy.[13,141] Hence, it is possible that the valence electrons of a low-valent lanthanide metal would possess 5*d* as well as 4*f* character. This electronic situation would be unique among metals and might provide the basis not only for new lanthanide chemistry but also for new types of metal-centered chemistry in general. As an example, zero-valent Er in a neutral complex could have single-electron approximation configurations such as $4f^{13}5d^1$, $4f^{12}5d^2$ and $4f^{11}5d^26s^1$ as well as the $4f^{12}6s^2$ configuration of the elemental metal. The chemistry of an uncharged $5d^1$ or $5d^2$ metal would certainly be unusual.

IV.2. *Lanthanide metal vapor reactivity*

IV.2(a) *Reactions with* CO. One of the early studies of zero-valent lanthanide metal vapor chemistry involved the matrix isolation reaction of the metals with CO.[142] Based on IR data, a variety of metal carbonyl complexes, $Ln(CO)_n$ (n = 1–6), were postulated. This was not a preparative-scale experiment, however, and the postulated complexes were not stable except at very low temperature. Hence, unambiguous confirmation of the formula and structure of these complexes could not be obtained.

IV.2(b) *Reactions with substituted alkynes and alkenes.* One major focus of the study of zero oxidation state lanthanide chemistry on a preparative scale involved reactions with unsaturated hydrocarbons.[3,143,144] Although alkenes and alkynes were not known as ligands or reactants with the trivalent lanthanides at that time, it was important to explore the potential of the zero-valent lanthanide metals to interact with such substrates given the importance of unsaturated hydrocarbon reactions in organometallic chemistry.

These exploratory studies demonstrated that the lanthanide metals have an extensive chemistry with unsaturated hydrocarbons and generated some of the most unusual organolanthanide species currently known. The lanthanide metal vapor reactions (57)–(61):

$$Ln + H_2C{=}CH{-}CH{=}CH_2 \rightarrow Ln(C_4H_6)_3 \quad (Nd, Sm \text{ or } Er), \quad (57)^{135}$$

$$Ln + H_2C{=}C(CH_3){-}C(CH_3){=}CH_2 \rightarrow Ln(C_6H_{10})_2 \quad (La, Nd, Sm \text{ or } Er), \quad (58)^{135}$$

$$Ln + CH_3CH = CH_2 \rightarrow Ln(C_3H_6)_3 \quad (Er), \quad (59)^{145}$$

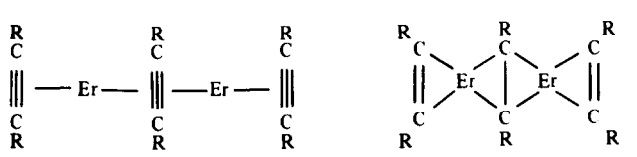
$$Ln + CH_3CH_2C{\equiv}CCH_2CH_3 \rightarrow Ln_2(C_6H_{10})_3 \quad (Nd \text{ or } Er), \quad (60)^{62}$$

$$\rightarrow Ln(C_6H_{10}) \quad (Sm \text{ or } Yb) \quad (61)^{62}$$

illustrate the main features of this chemistry. In each case, the metal was vaporized at temperatures ranging from 500–1600°C depending on the specific lanthanide involved and cocondensed with the unsaturated hydrocarbon at −196°C. The product was isolated on a preparative scale in an inert-atmosphere glove box and the product formula was determined by complete elemental analysis. Yields varied depending on the specific metal–ligand combination, but as much as 2–3 g of isolated product were obtained in some of the systems.[3,144]

The metal vapor reaction products differed from traditional organolanthanide complexes in many ways. First, the observed stoichiometries had low ligand: metal ratios. For example, the Yb– and Sm–3-hexyne products [reactions (60) and (61)] had formal ligand: metal ratios of 1:1, whereas most organolanthanides are commonly 9- or 10-coordinate. Second, the stoichiometries varied in an unusual manner depending on the ligand and metal. For example, 2,3-dimethyl substitution of the butadiene ligand changed the ligand: metal ratio from 3:1 [reaction (57)] to 2:1 [reaction 58)]. In the 3-hexyne system, changing from Nd and Er to Yb and Sm changed the ratio from 1.5:1 [reaction (60)] to 1:1 [reaction (61)]. Traditionally, the stoichiometries of organolanthanide complexes are invariant to minor substitutional changes on the ligand and are similar for each lanthanide in the series. Third, in contrast to traditional organolanthanides, which have pale colors (see Section III.1), the metal vapor products were intensely colored materials which displayed strong charge transfer absorptions in the near IR and visible regions. Fourth, the room-temperature magnetic moments for these complexes were often outside the range of "free-ion" values previously reported for organolanthanide compounds. Consistent with this, the NMR spectra of the La, Sm and Lu products were broad and uninformative whereas these metals, when trivalent, provide sharp interpretable spectra. The lanthanum butadiene product displayed an EPR absorption (La^{3+} is $4f^0$). Finally, the solution behavior of these complexes was unusual. For example, the 3-hexyne product $[ErC_9H_{15}]_n$ was dimeric in arenes, i.e. $n = 2$ [e.g. $Er_2(C_6H_{10})_3$], but in concentrated solution or in thf it was highly associated with $n > 10$. This is just the opposite of the trend found for traditional organolanthanides which are more highly associated in arenes than in thf.[21,30] Unfortunately, because these metal vaporization products oligomerized rather than crystallized in concentrated solution, these species were not structurally characterized by X-ray diffraction.

Analysis of possible zero-valent reaction pathways suggested three conceivable structural types for these products and initiated further experimental studies to verify them.[144] For the Er–3-hexyne product, $(ErC_9H_{15})_n$, one possibility was a π-complex as shown in **A** below:

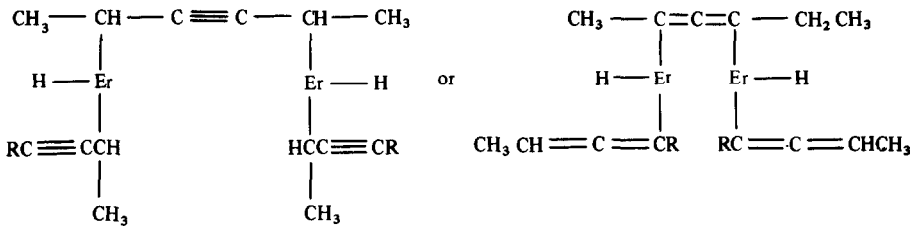


A **A'**

This structure has an alternate cyclometallopropene form (**A'**) which may be more reasonable for

these complexes considering the electropositive nature of the lanthanides. No π-complexes of lanthanides have yet been observed. However, η^2-coordination of C=N double bonds to trivalent Er and Y centers has been structurally characterized in formimidoyl complexes[145,146] and numerous examples of unsaturated hydrocarbons participating in lanthanide reactions are now known.[5,6,23,128,133]

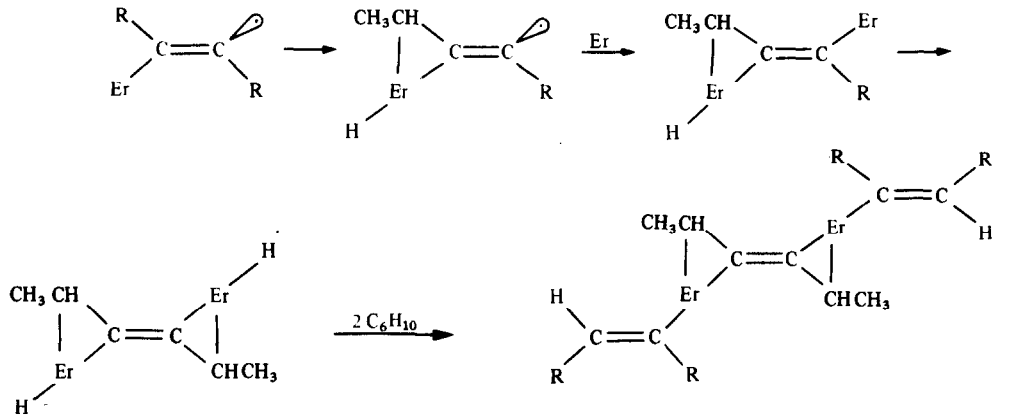
Alternatively, the lanthanide may not interact with the unsaturated bond at all, but instead could insert into C—H bonds by oxidative addition as in **B**:



B

This type of C—H activation reaction subsequently was demonstrated in lanthanide metal vapor reactions with terminal alkynes[89] and C_5Me_5H.[47]

A third possibility for the reaction of a lanthanide metal with an alkyne is radical formation (structure **C**) as has been postulated for the Al–HC≡CH system based on matrix EPR spectroscopy.[147] If the monovalent Er in the initially formed radical oxidatively inserts into a C—H



C

linkage and the resulting Er—H adds to excess 3-hexyne in the matrix, the radical-forming reaction can be rationalized to form a product with the exact formula determined experimentally (in contrast to structure **B** which is low in hydrogen). Subsequent studies of the reduction of $C_6H_5C{\equiv}CC_6H_5$[38] and $C_6H_5N{=}NC_6H_5$[126] by $(C_5Me_5)_2Sm(thf)_2$ [see reactions (51) and (52)] support this reaction pathway. Interestingly, the diphenylethyne and azobenzene products are intensely colored like the metal vapor reaction products. Structure **C** fits the available data best, but remains to be structurally established.

IV.2(c) *Reactions with unsubstituted alkenes and cyclopropane.* Since the reactions leading to structures **B** and **C** in the previous section required that substituents attached to the multiply-bonded carbon contain hydrogen for C—H activation, it was of interest to investigate metal vapor reactions involving smaller unsaturated hydrocarbons which lacked these potentially reactive sites. Accordingly, the reactions of ethene and 1,2-propadiene were surveyed with Sm, Yb and Er. The reactivity of two other small hydrocarbons, propene and cyclopropane, was also studied for comparison. These studies indicated an even wider range of reactivity was possible for the lanthanides.[148]

In contrast to the reactions discussed in the previous section, lanthanide metal vapor reactions with these smaller hydrocarbons did not provide soluble products (with the exception of the erbium product, $Er(C_3H_6)_3$ [reaction (59)]). Information on reaction pathways was obtained primarily by analyzing the products of hydrolysis of the metal vapor reaction product.

In ethene reactions, these data indicated that simple stable π-complexes (type A in the previous section) were not predominant products and that σ-bonded linkages, such as  (type A' in the previous section) or $LnCH_2CH_2Ln$ were more likely.[148] The data suggested that alkene insertion and polymerization were occurring as in organolithium chemistry.[149] Lanthanide-based alkene polymerization[150] has been heavily studied subsequently.[151,152] Hydrolytic formation of CH_4 and homologated three-carbon products from the ethene reaction products suggested that the lanthanides had the capacity to break and reform C—C bonds. The presence of Ln—H moieties was also indicated and was consistent with activation of C—H bonds by oxidative addition.

The major reactivity patterns observed in ethene reactions were also found in reactions of lanthanide metal vapor with 1,2-propadiene, propene and cyclopropane, although the larger hydrocarbons gave less complex reaction products.[147] With 1,2-propadiene as the substrate, oxidative addition of CH and the formation of  appeared to be the major routes of reaction. Propene reacted with lanthanide metal vapor primarily by CH oxidative addition to form insoluble allyl hydride complexes. With Er, however, $[Er(C_3H_6)_3]_n$, was obtained. Hydrolysis products also included propyne which indicated that extensive dehydrogenation of propene occurred in this system.

In the cyclopropane–Er system, oxidative addition of C—H to form cyclopropyl Er hydride groups as well as ring cleavage and dehydrogenation reactions were inferred from the hydrolytic data. The fact that the relatively inert C—H bonds in cyclopropane could be activated by a lanthanide metal testifies to the high reactivity found in these systems.[148]

IV.2(d) *Reactions with readily reducible or acidic hydrocarbons.* The metal vapor reactions described in this section involve substrates which are readily convertible to stable organic anions. As described in Section III.2(a), YbC_8H_8 can be prepared by reacting Yb metal vapor with 1,3,5,7-C_8H_8.[51] When this reaction is carried out with lanthanide metals which do not have a readily accessible divalent state, for example, La, Ce, Nd or Er, a different type of product is obtained. Extraction with thf gives trivalent species consisting of a tight ion pair of $[(C_8H_8)Ln(thf)_2]^+$ and $[(C_8H_8)_2Ln]^-$.[51] Hence, complete oxidation of the metal can occur under these conditions with the proper reducible substrate.

When hydrocarbon substrates containing acidic hydrogen are used, oxidative addition of CH readily occurs. As described in Section III.2(f), ytterbium reacts with 1-hexyne to form alkynide hydride complexes $[HYb_2(C{\equiv}CC_4H_9)_3]_n$.[89] With Sm, trivalent alkynide hydride complexes are formed and may involve some dimetalated as well as monometalated alkynide ligands. The Er reaction also forms trivalent alkynide hydrides and is even more complex than the Sm system.[89] The complexity of these systems increases as the stability of the divalent oxidation state decreases.

The reactions of Sm metal vapor with C_5Me_5H and C_5Me_4EtH also give C—H oxidative addition products [see Sections III.2(d) and (e)].[47,74] For C_5Me_5H, a thf workup gives an unstable divalent hydride, $[(C_5Me_5)SmH(thf)_2]$, which transforms to $(C_5Me_5)_2Sm(thf)_2$.[47] Again, oxidative addition of C—H explains this result. When a thf-free workup of the Sm—C_5Me_5H reaction mixture was carried out, an interesting alkane-soluble product was isolated which contained nitrogen by elemental analysis. Addition of toluene to this product liberated N_2 gas and left $(C_5Me_5)_2Sm$. Unfortunately, definitive identification of the nitrogen complex was not possible.[74]

In a similar reaction to those above, Yb metal vapor reacts with C_5H_6 to form $(C_5H_5)_2Yb$.[153]

IV.2(e) *Catalytic activity of metal vapor products.* In the course of characterizing the lanthanide metal vapor 3-hexyne products, it was discovered that these complexes had the capacity to initiate catalytic hydrogenation of alkynes to alkenes and alkanes.[62] A variety of lanthanide metal vapor products have been found to generate catalytic hydrogenation systems. Not only the 3-hexyne

reaction products, but also the products of lanthanide metal cocondensations with 1-hexyne, 2,3-dimethylbutadiene, $(CH_3)_3SiC{\equiv}CSi(CH_3)_3$ and $P(C_6H_5)_3$ are able to do this.[154] Using 3-hexyne as a substrate, these catalytic systems generally give high yields of *cis*-3-hexene, many with >95% stereospecificity.

Although catalytic hydrogenation of alkynes can be accomplished in many other ways, this catalytic system was significant because it was the first time an *f*-element complex had been observed to catalytically activate hydrogen in homogeneous solution.[62] The result had additional importance because the metal hydride complexes presumably involved in the catalyses provided the first evidence for the existence of discrete molecular lanthanide hydrides. The existence of lanthanide hydride complexes subsequently was demonstrated crystallographically[22] and fully characterized lanthanide hydrides were shown to have catalytic activity in hydrogenation reactions.[38] High levels of catalytic hydrogenation activity have subsequently been observed under optimized conditions.[128]

IV.3. *Bulk metal, metal amalgam, and activated metal reactions*

Lanthanide metals in the form of powders, filings or ingots have been used in a variety of systems as reagents. In some cases, the metal is "activated" by addition of Hg or $HgCl_2$ to form an amalgam. When ytterbium is used, divalent products are often obtained and many of these reactions have been discussed in Section III.2. These include oxidation reactions using alkyl and cyclopentadienyl halide reagents, transmetalation reactions with cyclopentadienyl, aryl, alkynyl, carboranyl, transition-metal, mercury and thallium reagents, and reductions of $(C_5H_5)_2YbCl$ and $(C_5H_5)_3Yb$ with Yb. The latter two reductions and some of the transmetalations can give clean reactions, whereas the RX reactions are generally complex. Extension of these reactions to samarium tends to give more complex results due to the formation of Sm(III) products. As is observed in metal vapor reactions with terminal alkynes, the complexity of these oxidations often increases with decreasing stability of the divalent oxidation state.

Lanthanide elements which do not have a readily accessible divalent oxidation state also participate in oxidations of the type described above to give trivalent products. The reactions of Ce and La with alkyl and aryl iodides[94] and Pr, Nd, Gd and Ho with triphenylmethylchloride, benzyl chloride and phenyl bromide[155] have been studied. Mixtures of colored products corresponding to R_aLnX_{3-a} are thought to be present. In a related approach the reactions of La, Tm and Yb with C- and B-mercuriocarboranes have been investigated.[100] Tris(cyclopentadienyl) complexes of Ce, Nd, Gd and Er have been prepared from the metals and thallous cyclopentadienides.[54]

A variety of lanthanide metals have been reacted with transition-metal reagents including $Hg[Co(CO)_4]_2$,[156] $Mn(CO)_5Br$,[157] $C_3H_5Fe(CO)_3I$,[157] $C_5H_5Cr(CO)_3HgCl$[157] and $[(C_5H_5)Mo(CO)_3]_2$.[157,158] These are complex reactions and only recently has a product been crystallographically characterized. The reaction of "lanthanum amalgam" with $[(C_5H_5)Mo(CO)_3]_2$ forms $(thf)_5La[(\mu\text{-}OC)Mo(CO)_2(C_5H_5)]_3 \cdot (thf)$.[158]

Reduction of $PrCl_3$ with K in thf gives an activated reduced form of praseodymium which has an organometallic chemistry. Treatment of the reduced praseodymium with 1,5-cyclooctadiene at room temperature gives products from which 1,3,5,7-cyclooctatetraene can be isolated upon oxidation.[159] The exact oxidation state of the lanthanide was not determined. The C_8H_{12} to $C_8H_8^{2-}$ conversion which apparently occurs led to the development of a high-temperature K-based preparation of 1,3,5,7-C_8H_8 from 1,5-C_8H_{12}.[160]

IV.4. *General principles governing zero-valent lanthanide chemistry*

Since little structural evidence is available on most of the products reported in Section IV, this area of low-valent lanthanide chemistry cannot be analyzed as precisely as was done for trivalent and divalent systems in Sections II.2 and III.4, respectively. The identity of many of the products discussed in Section IV remains unknown. Given what we now know about the reactivity/stability of sterically unsaturated trivalent organolanthanides (Section II.2), and strongly reducing divalent lanthanides (Section III.3) it is not surprising that the zero-valent lanthanide systems would be difficult to fully characterize. However, the goal of much of this chemistry, namely to broaden

organolanthanide chemistry in general, has been achieved.

These studies demonstrated several key aspects about the capacity of the lanthanides to participate in organometallic chemistry. The lanthanides were clearly shown to interact with the unsaturated hydrocarbons, a class of ligands previously uncommon in lanthanide chemistry. The lanthanides were shown to have the potential to effect a variety of interesting transformations on hydrocarbon substrates including C—H activation by oxidative addition, two-electron reduction of unsaturated C—C bonds, C—C cleavage, oligomerization, dehydrogenation, homologation and catalytic hydrogenation. The metal vapor reactions generated products which could catalytically activate hydrogen and which could probably generate molecular lanthanide hydride complexes.

The metal vapor syntheses in particular generated a variety of unusual organolanthanide complexes and "defined a set of conditions under which a variety of remarkable hydrocarbon activation reactions take place in the presence of the lanthanide metals".[148] These studies demonstrated the potential of the lanthanide metals and indicated areas where further development should take place in the field. As stated previously "the challenge in this area is to control this reactivity so that it can be used selectively"[148] and this is being done.

V. CONCLUSIONS

The organometallic chemistry of the lanthanide metals in low oxidation states has grown enormously since the isolated reports of the first complexes of this type appeared in the 1960s. The greatest development has occurred in the past few years and the rate of growth shows no signs of diminishing. The field is still too young to have a definable scope and potential at the present time, although recent results are starting to provide a basis for developing general principles.

The utility of the elemental metals in organolanthanide chemistry has been clearly shown in terms of demonstrating reactivity and the potential of lanthanides in general. The value of zero-valent lanthanide chemistry in forming isolable complexes has yet to be realized.

Although only three of the lanthanide elements have accessible divalent oxidation states, it is clear that divalent chemistry will be an important component of the organolanthanide field. The strong reducing capacity of Sm(II) will continue to distinguish it not only as a special lanthanide, but also as a special reducing reagent in chemistry in general. Clearly, low oxidation state lanthanide complexes have much to offer the field of organometallic chemistry.

Acknowledgements—The research results from my laboratory described in this Report were achievable through the support of the National Science Foundation, the donors of the Petroleum Research Fund administered by the American Chemical Society, and the Division of Basic Energy Sciences of the Department of Energy. I am grateful to those agencies, to the Camille and Henry Dreyfus Foundation for a Teacher–Scholar Grant, and to the Alfred P. Sloan Foundation for a Research Fellowship. I am also grateful to all of the students who participated in my research program.

SYNTHESIS AND CHARACTERIZATION OF DICHLORODICARBONYLRUTHENIUM(II) COMPLEXES OF OXYGEN, SULPHUR AND NITROGEN DONOR LIGANDS

A. O. BAGHLAF,* M. ISHAQ and A. K. A. RASHED

King Abdulaziz University, College of Science Department of Chemistry, P.O. Box 9028, Jeddah 21413, Kingdom of Saudi Arabia

(*Received* 7 *April* 1986; *accepted after revision* 27 *June* 1986)

Abstract—Complexes of dichlorodicarbonylruthenium(II) of formula $[RuCl_2(CO)_2L_2]$ (L = tetramethylthiourea, monomethylthiourea, dimethylthiourea, pyridine 2-thiol, piperidine or pyridine) and $[RuCl_2(CO)_2L']$ (L' = 1,2-diaminoethane or tetramethylurea), have been prepared. The complexes were characterized by their IR, NMR and elemental analyses.

Dihalodicarbonylruthenium(II) compounds were first reported by Manchot and Konig[1] in 1924. Wilkinson[2,3] first reported compounds of type $[RuCl_2(CO)_2L_2]$ (L = PPh_3 or $AsPh_3$). Colton and Farthing[4] and later Cleare and Griffith[5] have reported that refluxing $RuCl_3 \cdot xH_2O$ with formic acid produced $[RuCl_2(CO)_2]_n$ almost quantitatively. Since then halocarbonylruthenium(II) $\{[RuX_2(CO)_2]_n\}$ has proved to be a very useful precursor for the synthesis of a variety of complexes.[6] Here we report the synthesis of dichlorodicarbonylruthenium(II) complexes of type $[RuCl_2(CO)_2L_2]$ [L = tetramethylthiourea (TMTU), monomethylthiourea (MMTU), dimethylthiourea (DMTU) or pyridine 2-thiol (PYT)]. These ligands are monodentate and it has been suggested on the basis of IR spectroscopic data that coordination of these ligands to the metal is through the S atom.[7] In the case of $[RuCl_2(CO)_2(PIP)_2]$, (PIP = piperidine), $[RuCl_2(CO)_2(PY)_2]$ (PY = pyridine) and $[RuCl_2(CO)_2(en)]$, (en = 1,2-diaminoethane), the coordination to the metal is through the N atom. All the complexes were insoluble in common organic solvents such as benzene, petroleum ether and carbon tetrachloride, but are soluble or slightly soluble in chloroform, ethanol, acetonitrile and tetrahydrofuran (THF). All the complexes were stable, yellow or pale yellow solids except for complex **3**, which was a waxy solid, and all can be handled in air for a short time.

EXPERIMENTAL

The salt "$RuCl_3 \cdot xH_2O$" and substituted urea, thioureas and amines were purchased from Fluka Inc. and were used without further purification.

IR spectra were measured (KBr pellets) using a Zeiss Model IMR-16 spectrophotometer. Proton magnetic resonance spectra were recorded on a Varian EM 390–90-MHz NMR spectrometer.

Elemental analyses were carried out by the microanalysis laboratory of King Abdulaziz University, Jeddah.

$[RuCl_2(CO)_2]_n$ was prepared as reported.[4]

Preparation of $[RuCl_2(CO)_2(TMTU)_2]$

A typical reaction is described.

To a solution of $[RuCl_2(CO)_2]_n$ (0.5 g, 2.2 mmol) dissolved in THF (30 cm^3) was added tetramethylthiourea (0.6 g, 4.5 mmol). The mixture was refluxed for 1 h. During this period some orange yellow crystals separated out. The contents were then cooled and the addition of petroleum ether separated out the orange yellow crystals of the product $\{[RuCl_2(CO)_2 \cdot (TMTU)_2]\}$ almost quantitatively. This was washed twice with petroleum ether, and dried *in vacuo*. Yield 1.08 g (98%). M.p. 243°C.

*Author to whom correspondence should be addressed.

All the complexes shown in Table 1 were prepared by the same general method from $[RuCl_2(CO)_2]_n$ and a monodentate ligand in a 1:2 mole ratio and a bidentate ligand in a 1:1 mole ratio, respectively. The preparation of complex **8** using a different method has been reported.[9]

RESULTS AND DISCUSSION

The reaction of $[RuCl_2(CO)_2]_n$ with TMTU or other monodentate ligands in a 1:2 mole ratio gives stable yellow crystalline solids.

IR spectra of all the complexes were determined as KBr pellets and the low value of the terminal metal–carbonyl (M–CO) stretching frequencies observed in all the complexes (Table 1) may be attributed to a flow of electron density from the ligand to the metal causing a decrease in the M.⊳CO stretching frequencies. The presence of only two strong CO bands indicates that the two CO groups are *cis*.[8]

The ambidentate nature of substituted thiourea and its mode of coordination with transition metals has been a subject of controversy. Schafer and Curran[7] have suggested for TMTU complexes that an increase in the frequency to 1504 cm^{-1} (which they claim is mainly due to the N.C.N antisymmetrical stretching vibration) and a decrease to 1126 cm^{-1} (which is mainly due to C=S band) means that ligand–metal coordination is through the S atom. Therefore complexes **2**, **4** and **5** also show a lower C=S value ($\sim$10–20 cm^{-1}) compared to the free ligands. A similar behaviour has been noticed in the case of the pyridine 2-thiol complex (**6**). We have shown earlier a similar trend for these ligands with molybdenum carbonyl[10] and uranyl[11] complexes.

The low N.H stretching frequencies of PIP (acting as a monodentate ligand) in complex **7** and en (a bidentate ligand) in complex **9** suggest that these ligands are coordinated to the metal through N atoms.

The NMR spectrum (Table 2) of the dichlorodicarbonylruthenium(II)–TMTU amplex in $CDCl_3$ shows only a single peak at δ 3.3 for the four methyl groups. If bonding of the ligand to the metal occurred through an N atom rather than an S atom then the methyl protons of the complexed dimethylamino group should have a chemical shift different from that of the methyl protons of the uncomplexed dimethylamino group. On the other hand, the NMR spectrum of the dichlorodicarbonylruthenium(II)–TMU complex in $CDCl_3$ shows a low-field chemical shift and splitting of the methyl protons of the complexed dimethylamino group, showing that they are not equivalent. However, the IR spectrum of this complex shows a decrease of $\sim$100 cm^{-1} in ν(C=O) compared to the free ligand. This may be attributed to the fact that the ligand is coordinated to the metal through both an O atom and an N atom.

The NMR spectra of complexes **7** and **8** are given in Table 2.

The low-field shift is indicative of a strong

TWO NEW VANADYL(IV) COMPLEXES CONTAINING BIURET

ENRIQUE J. BARAN,* SUSANA B. ETCHEVERRY and DIANA S. M. HAIEK

Departamento de Química, Facultad de Ciencias Exactas, Universidad Nacional de La Plata, 1900-La Plata, Argentina

(*Received* 17 *June* 1986; *accepted* 24 *July* 1986)

Abstract—Two new biuret/vanadyl(IV) complexes, a normal bis(biuret) oxygen-bonded $VO(biur)_2Cl_2 \cdot 3H_2O$ and a polymeric one, with bridging-bidentate sulfato groups, $VO(biur)SO_4 \cdot 3H_2O$, have been prepared. They were characterized by their IR and electronic spectra and by TG and DTA measurements. One water molecule is strongly bonded to the cation in both compounds.

Vanadium is an essential trace element in both plants and animals[1–3] with numerous physiological effects. There is ample evidence that in living organisms, vanadium exists primarily as the vanadyl(IV), VO^{2+}, cation complexed with proteins and other cellular components.

In order to obtain a deeper insight into some basic aspects of the inorganic biochemistry of vanadium, we have begun the study of different model systems, containing this metal, which are relevant for a better understanding of its biochemical properties and effects.[4–6]

In this context we have now investigated the interaction of the VO^{2+} cation with biuret, which constitutes a good simple model for studies of the coordination properties of amide bonds (cf. for example, Ref. 7). Two new VO^{2+} complexes, $VO(biur)_2Cl_2 \cdot 3H_2O$ and $VO(biur)SO_4 \cdot 3H_2O$, containing the neutral biuret as ligand, were obtained and thoroughly characterized during these studies.

EXPERIMENTAL

Preparation of $VO(biur)_2Cl_2 \cdot 3H_2O$

A solution of vanadyl chloride was prepared by reacting 0.455 g (2.5 mmol) of V_2O_5 with 5 cm^3 of concentrated HCl in the presence of a few drops of ethanol on a water bath until all the pentoxide dissolved giving a clear blue solution.[8] After a dilution of 30 cm^3 of water, another solution containing 1.031 g (10 mmol) of biuret dissolved in 80 cm^3 of ethanol was slowly added. The resulting mixture was left to evaporate slowly at room temperature until a greenish-blue precipitate was obtained. The fine crystalline mass was filtered, washed with small portions of absolute ethanol and dried in a vacuum desiccator over P_4O_{10}. *Analysis*: Found: V, 13.0; N, 21.0%; C, 11.9; H, 3.9%. Calc. for $VO(C_2H_5O_2N_3)_2Cl_2 \cdot 3H_2O$: V, 12.8; N, 21.1; C, 12.1; H, 4.0%.

Preparation of $VO(biur)SO_4 \cdot 3H_2O$

1.256 g (5 mmol) of $VOSO_4 \cdot 5H_2O$ were dissolved in a solution of 35 cm^3 ethanol + 5 cm^3 water. To this solution, 1.031 g (10 mmol) of biuret, dissolved in 80 cm^3 of ethanol, was added dropwise. A fine crystalline clear-blue powder precipitated after a few minutes. It was filtered and handled in the same way as above. *Analysis*: Found: V, 15.8; N, 13.4; C, 7.8; H, 3.3%. Calc. for $VO(C_2H_5O_2N_3)SO_4 \cdot 3H_2O$: V, 15.9; N, 13.1; C, 7.5; H, 3.4%.

Physicochemical measurements

The electronic spectra of the solid samples were recorded with the reflectance attachment of a Shimadzu UV-600 spectrophotometer, using MgO as a standard. The IR spectra were obtained with a Perkin–Elmer 580 B instrument employing the KBr pellet technique. The thermal behavior was investigated on a Rigaku thermoanalyzer (type YLDG/CN 8002 L2) using a chromel–alumel thermoelement and working under a flowing N_2 stream, at a heating rate of 10°C min^{-1}. Al_2O_3 was used as a DTA standard; sample weight ranged between 25–30 mg.

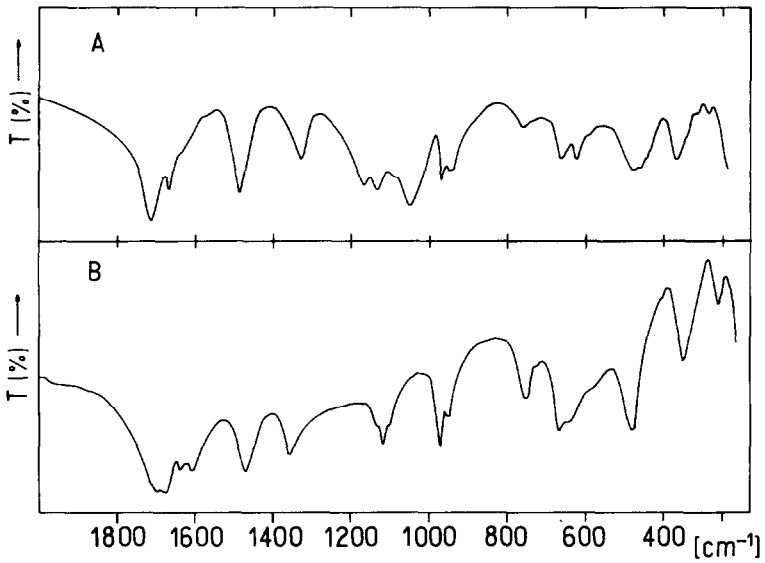

Fig. 1. IR spectra of $VO(biur)SO_4 \cdot 3H_2O$ (A) and $VO(biur)_2Cl_2 \cdot 3H_2O$ (B).

RESULTS AND DISCUSSION

It is known that biuret ($NH_2CONHCONH_2$) can form two types of chelate rings,[7,9,10] coordinated to the metal ions through both carbonyl oxygens or to the two, single deprotonated, NH_2 groups.

The stoichiometry found for the two new vanadyl(IV) complexes indicated the formation of C=O coordinated complexes but two different environments, which depend on the starting vanadyl salt, are found. In the case of the sulfate, this anion is incorporated as a bidentate ligand and a polymeric complex (see below) is probably generated. Starting with the chloride, a normal bis(biuret) cationic complex is obtained.

The IR spectra of both complexes in the range 2000–250 cm^{-1} (Fig. 1) and their assignment shown in Table 1, support the above suppositions. The spectrum of $VO(biur)_2Cl_2 \cdot 3H_2O$ is similar to that of $Cu(biur)_2Cl_2$[11,12] in which the C=O coordination is supported by a structural[13] as well as by a complete normal coordinate analysis.[11]

The $VO(biur)SO_4 \cdot 3H_2O$ spectrum is more complex, due to the presence of the coordinated SO_4-ligand. The spectral features and band positions of these SO_4^{2-} vibrations indicate the presence of bridging bidentate sulfato groups,[12,14,15] which strongly suggest the presence of a polymeric complex, an assumption which is also supported by the rapid precipitation of this species after mixing the biuret and the vanadyl sulfate solutions.

The symmetric stretching and bending vibrations (ν_1 and ν_2) of the sulfate groups apparently are too weak in intensity to be detected or they may be overlapped by stronger bands lying in the same spectral range. Also the antisymmetric bending (ν_4) is clearly overlapped by a $\rho(NH_2)$ biuret vibration.

The characteristic V=O stretching vibration lies in the same range for both complexes, although it shows a small shift to higher wavenumbers and also a somewhat higher intensity in the case of the chloro-compound. The V—O stretching mode which originated in the interaction of the cation with the carbonyl oxygens should lie in the lower frequency region of the spectra. We have tentatively assigned this mode to the band found around 350 cm^{-1}, although in the bis(biuret) copper(II) dichloride and in the nickel(II) analog it was found below 300 cm^{-1}.[11] Notwithstanding, in vanadyl(IV) acetate a band lying at 442 cm^{-1} was assigned to this stretching mode.[16]

The electronic reflectance spectra of both compounds are very similar as can be seen from Fig. 2. They show a very strong and broad band and a well-defined shoulder on its higher energy side. The first band is found at 760 nm (13,757 cm^{-1}) in the bis(biuret) complex and at 750 nm (13,333 cm^{-1}) in the sulfato complex. The shoulder is located at 635 nm (15,748 cm^{-1}) in the first case and at ~600 nm (16,666 cm^{-1}) in the second one.

According to the well known Ballhausen and Gray energy level diagram[17] the main peak can be assigned to the $^2E \leftarrow {}^2B_2$ and the shoulder to the $^2B_1 \leftarrow {}^2B_2$ transitions, respectively. The value for the crystal field splitting parameter $10Dq$ is given directly by the last transition. The observed values are in good agreement with those obtained for other vanadyl complexes with a similar VO^{2+} environment.[18] The small differences in color arise from the relative displacements of the shoulders and from the different form and extension of the 'window' located between the shoulder and the

beginning of the strong charge-transfer band, located at higher energies, and not seen in Fig. 2.

The thermal analysis gives more information about the characteristics of the coordination sphere of both complexes.

The thermogram of $VO(biur)SO_4 \cdot 3H_2O$ shows four well-defined endothermic DTA signals, the first of which appears in a doublet form. This doublet (96° and 111°C) corresponds to the loss of two water molecules and the release of the third one occurs at 192°C. After this loss the thermogravimetric curve shows a continuous but irregular weight decrease, related to the other two endothermic peaks. One of them, located at 258°C, is associated with the release of the organic ligand. The last one, at 420°C, corresponds to the generation of SO_3. Further heating, up to 700°C, gives neither mass changes nor thermal effects. From these results, the thermal degradation can be formulated as follows:

$$VO(biur)SO_4 \cdot 3H_2O \rightarrow VO(biur)SO_4 \cdot H_2O + 2H_2O \quad (1)$$

$$VO(biur)SO_4 \cdot H_2O \rightarrow VO(biur)SO_4 + H_2O \quad (2)$$

$$VO(biur)SO_4 \rightarrow VOSO_4 + biur \quad (3)$$

$$VOSO_4 \rightarrow VO_2 + SO_3. \quad (4)$$

The theoretical total weight loss [addition of equa-

tions (1)–(4)] gives 74.06% which correlates with the value of 73.8% found experimentally.

In the case of $VO(biur)_2Cl_2 \cdot 3H_2O$ the release of the first two water molecules is associated with a strong and well-defined endothermic DTA peak centered at 141°C, whereas the release of the third one corresponds to a second endothermic peak, located at 200°C. After the loss of water a continuous weight decrease is observed. Between 220° and 500°C, the observed weight change corresponds to the release of the two biuret molecules. In this range two not well-defined and weak endothermic DTA signals at 260° and 378°C are observed. At 500°C a clear inflexion is observed in the TG curve, and a further weight loss begins and continues slowly until the maximum temperature (700°C) is reached. In this case, the formation of $VOCl_2$ as an intermediate can be expected, but pure $VOCl_2$ decomposes into VOCl and $VOCl_3$ at temperatures above 380°C.[19] The total conversion of the complex to VOCl requires a weight loss of 74.27% in good agreement with the experimentally found values, which always lie around 75%.

Therefore, the degradation of $VO(biur)_2Cl_2 \cdot 3H_2O$ can be formulated as follows:

$$VO(biur)_2Cl_2 \cdot 3H_2O \rightarrow VO(biur)_2Cl_2 \cdot H_2O + 2H_2O \quad (5)$$

$$VO(biur)_2Cl_2 \cdot H_2O \rightarrow VO(biur)_2Cl_2 + H_2O \quad (6)$$

$$VO(biur)_2Cl_2 \rightarrow VOCl_2 + 2biur \quad (7)$$

$$2VOCl_2 \rightarrow VOCl(s) + VOCl_3(g). \quad (8)$$

The most important result obtained from the thermal analysis is the clear evidence of the presence of one strongly bonded water molecule in both complexes. This molecule is probably coordinated directly to the vanadium atom in the *trans* position to the vanadyl oxygen.

The formation of these complexes is another example of the particularly high stability of vanadyl complexes with oxygen donors[21] and suggests a preferential interaction of the VO^{2+} cation with C=O oxygens in the presence of amide groups in biological environments.

Acknowledgements—This research was supported by CONICET (Programa QUINOR) and CIC-Provincia de Buenos Aires. It is also a part of a special program devoted to the chemistry and biochemistry of vanadium, which is sponsored by the Foundation 'Volkswagenwerk' (Hannover, F.R.G.).

SYNTHESIS OF TERNARY COPPER(II) COMPLEXES OF PHENANTHROLINES AND L-DOPA AND RELATED LIGANDS

NEELA A. EMANUEL and PABITRA K. BHATTACHARYA*

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda 390 002, India

(*Received* 22 *November* 1985; *accepted after revision* 13 *May* 1986)

Abstract—The series of ternary complexes of type [CuAL] where A = 1,10-phenanthroline or 5-nitro-1,10-phenanthroline and L = catechol, 2,3-dihydroxynaphthalene, dopamine, phenylalanine, tyrosine or L-dopa have been synthesized and characterized by spectral and magnetic moment studies.

Tyrosine and L-3,4-dihydroxyphenylalanine (L-dopa) are compounds of biochemical importance in the neurotransmission process.[1] Dopa is also used as a drug and is administered orally in the treatment of Parkinson's disease. However, during the passage through the intestine or liver, dopa is converted into dopamine.

It was shown[1] that coordination of L-dopa with a metal ion from the aminocarboxylate end reduces the decarboxylation caused by pyridoxal and a greater portion of L-dopa is transported to the brain.

L-dopa is also interesting because of its ambidentate nature,[2–8] coordinating with Cu(II) from the amino-acid end at low pH and from the catechol end at higher pH. However, it has been shown[8] that in mixed ligand complexes [Cu 2,2′-dipyridyl dopa], the chelation of dopa is from amino-acid end up to higher pH ($\sim$ 7.0). The chelate is similar to that in phenylalanine, tyrosine or tryptophan.

The solution study of these complexes [Cu dipy aminoacid with side groups] shows that the formation constant of the mixed ligand complex is much higher than expected. This has been attributed[9] to hydrophobic interaction of the side group in the axial direction of the metal ion in the ternary complexes.

Following from our study of ternary complexes in solution involving 1,10-phenanthroline or 5-nitro-1,10-phenanthroline[10] and aminoacids with aromatic side chains, this paper presents an account of the isolation of two series of ternary complexes of Cu(II) containing 5-nitro-1,10-phenanthroline or 1,10-phenanthroline (A) and one of the following secondary ligands (L): phenylalanine, tyrosine, L-dopa, catechol, 2,3-dihydroxynaphthalene and dopamine. The structures of the complexes have been characterized by IR spectral, electronic spectral and magnetic studies.

EXPERIMENTAL

Preparation of [Cu A aminoacid] complexes

An aqueous solution of copper acetate (8 mmol) in 20 cm^3 distilled water was added to 20 cm^3 of ethanolic solution of 1,10-phenanthroline or 5-nitro-1,10-phenanthroline (8 mmol). A blue solid was formed immediately. As the mixture was stirred magnetically the appropriate amount of aminoacid (10 mmol) in 10 cm^3 0.1 M hydrochloric acid was slowly added, followed by 1 M ammonium hydroxide solution until a clear blue solution was obtained. The solution was warmed and stirred for a further 45 min, heated until its volume was reduced by approximately half and then a 0.1 M solution of sodium tetraphenylborate was added. The solid immediately separated out and was filtered, washed with small portions of cold water followed by ethanol and then dried *in vacuo*.

Preparation of [CuA $O^- - O^-$] complexes

An aqueous solution of catechol, 2,3,-dihydroxynaphthalene or dopamine (10 mmol) in 20 cm^3 distilled water was slowly added to an ethanolic solution of 1,10-phenanthroline or 5-nitro-1,10-phenanthroline (8 mmol). This ligand mixture was then slowly added to an aqueous solution of copper

acetate (8 mmol) in 20 cm^3 distilled water followed by 1 M ammonium hydroxide solution in order to raise the pH to 6.0, where upon the complex was formed immediately. This was filtered, washed with distilled water followed by ethanol and then dried *in vacuo*.

Copper(II) was estimated gravimetrically. Percentages of nitrogen, carbon and hydrogen were estimated on Coleman Analyzer Models 29 and 33, respectively. TLC analysis were done on a silica gel G (Sichem) plates using ethanol as solvent.

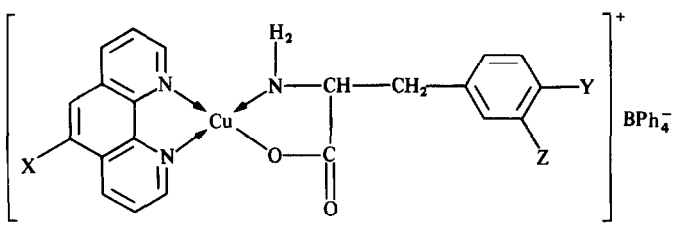
IR spectra were recorded on a Perkin–Elmer Model 638 spectrometer. KBr and Nujol mulls were employed. Electronic spectra were run at a concentration of 10^{-2} mol dm^{-3} in freshly prepared aqueous dioxan (1 : 1, v/v) solvent. A Carl Zeiss specord UV–vis spectrometer with 1-cm quartz cells was used for these measurements.

Magnetic susceptibilities were determined at room temperature only by Gouy's method using a Mettler balance and electromagnet working at a constant current strength of 3 A in all cases. The balance was calibrated with $Hg[Co(NCS)_4]$.

RESULTS AND DISCUSSION

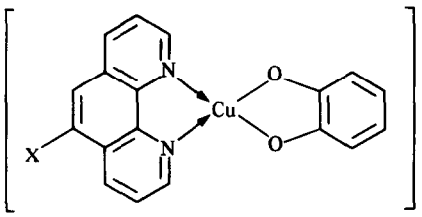
TLC of all the complexes, using ethanol as solvent, show a single spot confirming their purity. The elemental analysis of the ternary complexes isolated in the present study are given in Table 1 along with the values of their magnetic moments. The analysis is consistent with the structure suggested. As proposed earlier on the basis of solution studies, L-dopa is found to be coordinating from aminocarboxylate end. Hence [CuA L-dopa] has one positive charge and one $(Bph_4)^-$ is present as a counter ion. In the case of the ternary complex involving dopamine, the complex was immediately formed when metal and two ligands were added and the pH was raised to 6.0. Dopamine coordinates from two phenolic groups, and amino group remains protonated. Hence the ligand contains effectively one negative charge. The complex ion is left with one positive charge and hence one counter ion (acetate ion) is found to be present.

The complex exhibits slightly lower magnetic moment than expected for one unpaired electron.

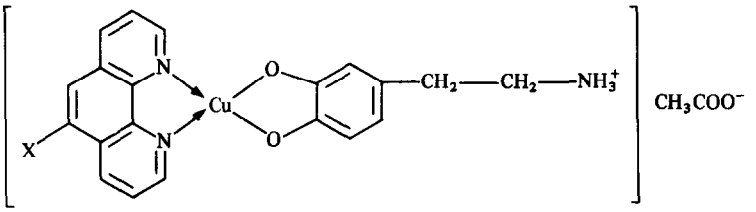


X = H or NO_2, Y = H or OH, Z = H or OH

[CuA (aminoacid)]



X = H or NO_2
[CuA(catechol)]



X = H or NO_2
[CuA(dopamine)] acetate

IR spectral studies

The ternary complexes exhibit IR absorptions typical of coordinated ligands (phen: 1625, 1575, 1420, 840, 700 cm^{-1} and 5-nitro-1,10-phen: 1625, 1515, 1420, 840, 720 cm^{-1}). Furthermore in the case of aminoacid complexes remarkable similarities are observed among these ternary complexes in the absorption regions due to the amino and the carboxyl groups, which are found to occur at (a) 3450–3200 cm^{-1}, 1640–1600 cm^{-1}, 1420–1380 cm^{-1} and 600–610 cm^{-1} and (b) 1640–1600 cm^{-1} and 490–460 cm^{-1}, respectively.[11–14]

The mode of coordination of the ambidentate ligands L-dopa, tyrosine and dopamine can be inferred from the IR spectral data of these metal complexes. The uncoordinated unionised phenolic O—H stretching band occurs at 3500 cm^{-1} in the [CuA L-dopa] complex indicating that it is coordinating from the aminoacid end.

In the cases of catechol or 2,3-dihydroxynaphthalene, the coordination is from phenolic groups and hence no unionised phenolic stretching frequencies of phenolic groups (ν_{OH} = 3550–3450 cm^{-1}) are observed. In the case of the dopamine ternary complexes, there are no un-ionised phenolic stretching frequencies of phenolic groups and moreover there are uncoordinated protonated amino stretching frequencies (ν_{NH} = 3450–3400 cm^{-1}) present indicating that the coordination is from phenolic group and amino group is remaining protonated.

Electronic spectral studies

The electronic spectra of these ternary Cu(II) complexes in solution and in the solid state exhibit broad absorption bands in the visible region due to the overlap of three possible transitions $d_{x^2-y^2} \rightarrow d_{xy}$, $d_{x^2-y^2} \rightarrow d_{xz}$, $d_{x^2-y^2} \rightarrow d_{yz}$. The electronic spectra of complexes involving tyrosine and L-dopa are similar to those containing phenylalanine, showing that coordination is from the aminoacid site of all the aminoacids.

The ternary complexes of [CuAL] where L = catechol, 2,3-dihydroxynaphthalene or dopamine exhibit intense broad charge-transfer bands in the visible region (~500 nm), with its tail overlapping the *d–d* absorption bands.

BROMO- AND CHLORO-SELENATE(II) COMPOUNDS

J. B. MILNE

Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa Campus, Ottawa, Canada, K1N 9B4

(*Received* 6 *July* 1986; *accepted* 4 *August* 1986)

Abstract—Addition of R_4NX (R = Et, *n*-Pr, *n*-Bu) to solutions of SeX_2 (X = Cl, Br) in acetonitrile results in the formation of tri- and tetra-haloselenate(II) complexes (SeX_3^- and SeX_4^{2-}). Raman spectroscopic characterization of these solutions and solids, R_4NSeX_3 and $(R_4N)_2SeX_4$, which may be crystallized from them, are reported. R_4NSeCl_3 compounds are shown to be relatively unstable; they are readily destroyed by laser light,

$$2R_4NSeCl_3 = (R_4N)_2SeCl_6 + Se(0)$$

and especially sensitive to hydrolysis,

$$2SeCl_3^- + H_2O = SeOCl_3^- + 2HCl + Cl^- + Se(0).$$

The Raman spectra of solutions of SeX_3^- and SeX_4^{2-} are consistent with T-shaped and square planar structures, respectively.

Compounds of selenium in the +2 oxidation state are relatively uncommon. A few reports of selenium dihalides have been made. Their existence in the gas phase at elevated temperatures has been known for a long time[1] and recent Raman work has confirmed the existence of $SeCl_2$ in the vapour phase over $SeCl_4$ at 350°C.[2] Selenium difluoride has been studied by matrix isolation.[3] The existence of $SeCl_2$ and $SeBr_2$ in non-aqueous media has been demonstrated[4–6] and the presence of $SeCl_2$ in equilibrium with Se_2Cl_2 and other Se(IV) species in solutions of elemenetal selenium and SeO_2 in aqueous HCl has been established.[7] Several chloro-, bromo- and cyano-complex anions of Se(II) have been described.[8] These three-coordinate complexes dimerize in the solid state in a manner similar to that of the oxotrihaloselenate(IV) anions[9,10] and, since this indicates that the coordination shell of Se(II) is not completely filled in these compounds, it seemed likely that tetrahaloselenate(II) complexes might be prepared. Indeed since this work was started $(Ph_4P)_2SeBr_4$ has been prepared and its crystal structure reported.[11] The oxotetrachloro- and oxotetra-bromoselenate(IV) compounds have both been synthesized.[12,13] Moreover, there is a remarkable similarity between the spectra reported for $SeCl_3^-$ in acetonitrile and that for solid Et_4NSeCl_3 with the reported spectra for the $SeOCl_3^-$ and $(Et_4N)_2SeCl_6$,[14,15] respectively. In view of these similarities and in order to extend our understanding of Se(II) chemistry, a study of chloro- and bromo-selenate(II) compounds was carried out.

EXPERIMENTAL

Materials

Acetonitrile (MeCN) and nitromethane($MeNO_2$) were purified by refluxing over P_4O_{10} for 1 h and distilling (b.p. 81–82°C and 100–101°C, respectively). Selenium (Baker AR) was ground before use. Bromine (Baker AR) was distilled (b.p. 59–60°C) before use. Chlorine (Matheson) was used directly. All quaternary ammonium halides (Aldrich) were dried at 100°C under high vacuum and analysed before use. Selenium tetrabromide and tetrachloride were prepared by standard methods.[16,17]

Preparations

All compounds and solutions were handled under dry conditions. The haloselenate(II) compounds were prepared from a stoichiometric solution of quaternary ammonium halide, selenium tetrahalide and selenium in acetonitrile.

$$2R_4NX + Se(0) + SeX_4 = 2R_4NSeX_3 \quad (1)$$

$$4R_4NX + Se(0) + SeX_4 = 2(R_4N)_2SeX_4 \quad (2)$$

In general ~ 0.4 M, or less, solutions of Se(II) complex were soluble at room temperature and reasonable recoveries could be achieved by cooling in dry ice to the point of crystallization followed by rapid filtration. For instance, 663 mg Et_4NCl, 79 mg Se(0) and 221 mg $SeCl_4$ were combined in 7.4 g MeCN. Sufficient time and mixing were allowed to permit complete dissolution of the elemental selenium and the solution was then cooled and filtered. In the case of the chloro-compounds there appeared to be initial formation of hexachloroselenate(IV) which was insoluble, then slow reaction to give the desired product. Found: Se, 24.8; Cl, 33.4. Calc. for $(Et_4N)SeCl_3$: Se, 25.0; Cl. 33.7%. Found: Cl, 29.3. Calc. for $(Et_4N)_2SeCl_4$: Cl, 29.5%. Found: Cl, 24.1. Calc. for $(Bu_4N)SeCl_3$: Cl, 24.9%. Found: Cl, 20.0. Calc. for $(Bu_4N)_2SeCl_4$: Cl, 20.1%. Found: Br, 53.2. Calc. for $(Et_4N)SeBr_3$: Br, 53.4%. Found: Br, 48.8. Calc. for $(Et_4N)_2SeBr_4$: Br, 48.5%. Found: Br, 47.2. Calc. for $(n\text{-}Pr_4N)SeBr_3$: Br, 47.5%. The trichloro-complexes were orange in colour, the tetrachloro-, yellow while the bromo-complexes were red-orange. All products were very moisture sensitive, turning opaque red on exposure to water. The tetra-*n*-butyl ammonium compounds were very difficult to crystallize and could only be isolated by pumping to dryness. $(Et_4N)_2SeCl_6$ was prepared as described previously.[14]

Melting points

$(Et_4N)_2SeCl_6$ dec. p. 220–225°C; Et_4NSeCl_3 dec. p. 50–51°C; $(Et_4N)_2SeCl_4$ dec. p. 174–182°C.

Raman spectroscopy

Raman spectra were taken with a Jobin–Yvon grating monochromator in conjunction with PAR photon counting. All spectra were excited with a Spectra Physics Model 160 Kr ion laser. The spectra of the solids were excited at low power levels (40 mW at 647.1 nm for Et_4NSeCl_3). In general the Raman lines due to the R_4N^+ ions were very weak or not observed.

RESULTS AND DISCUSSION

The previous preparations of trihaloselenate(II) complexes in acetonitrile were done by redox reactions of selenocyanate with sulphur chloride or bromine[8] or by reaction of tetraphenylphosphonium bromide with the decomposition products of $SeOBr_2$ or $SeBr_4$ in acetonitrile. The recent demonstration of the existence of high concentrations of SeX_2 (X = Cl, Br) in 1 : 1 Se/X_2 mole ratio mixtures in acetonitrile[6] suggested that direct addition of quaternary ammonium halides to such solutions would yield haloselenate(II) complexes.

Chloroselenates

Addition of Et_4NCl to a nitromethane or acetonitrile solution of $SeCl_2$ results in the disappearance of the characteristic strong peak of $SeCl_2$ at 412 cm^{-1}[6] and the appearance of the spectrum shown in Fig. 1(A), which corresponds to 1 : 1 $Et_4NCl/SeCl_2$ stoichiometry. Further addition of Et_4NCl results in a weakening of the band at 346 cm^{-1} and a broadening and strengthening of the band at 261 cm^{-1}, indicating the formation of another species [Fig. 1(C)]. The changes are accounted for by the formation of the $SeCl_3^-$ and $SeCl_4^{2-}$ anions according to,

$$SeCl_2 + Cl^- = SeCl_3^- \quad (3)$$

$$SeCl_3^- + Cl^- = SeCl_4^{2-}. \quad (4)$$

The spectrum of the 2 : 1 $Et_4NCl/SeCl_2$ mole ratio solution has a small peak at 347 cm^{-1} indicating that some $SeCl_3^-$ ion is still present. This peak persists in solution up to 5 : 1 $Et_4NCl/SeCl_2$ where $SeCl_4^{2-}$ dissociation is finally repressed. Cooling of 1 : 1 and 2 : 1 $Et_4NCl/SeCl_2$ mixtures yielded orange and yellow crystals respectively, which analysed correctly for Et_4NSeCl_3 and $(Et_4N)_2SeCl_4$. The spectrum of the $SeCl_3^-$ ion in solution reported by Wynne and Golen shows a band at 231 cm^{-1}, which is not observed in this work. This band is probably due to the presence of $SeOCl_3^-$ ion. Addition of water to, or exposure to moisture of, solutions of $SeCl_3^-$ ion resulted in a darkening of the solutions accompanied by a growth of bands in the Raman spectrum at 950 and 231 cm^{-1}. The growth of these bands and the colour change may be accounted for by the reactions,

$$3Et_4NSeCl_3 + H_2O = Se_2Cl_2 + Et_4NSeOCl_3 + 2Et_4NCl + 2HCl \quad (5)$$

$$2Et_4NSeCl_3 + H_2 = Se(0) + Et_4NSeOCl_3 + Et_4NCl + 2HCl. \quad (6)$$

The bands at 231 and 950 cm^{-1} are due to the $SeOCl_3^-$ ion, which has a Raman spectrum similar to that reported[8] for $SeCl_3^-$. However, the absence of peaks at 139 and 291 cm^{-1} as well as the constant size of the weak Et_4N^+ cation band at 410 cm^{-1}, which is nearly coincident with an Se_2Cl_2 band, and the solvent band at 370 cm^{-1}, which is coincident with the strongest Se_2Cl_2 Raman band,[6] indicates

that Se_2Cl_2 is not formed. Moreover, Se_2Cl_2 undergoes disproportionation in the presence of Cl^- ion. An attempt was made to prepare chloro-anions of Se_2Cl_2 in acetonitrile. Addition of Et_4NCl to a solution of Se_2Cl_2 (1 : 1 mole ratio) resulted in an immediate darkening of the solution and precipitation of elemental selenium and a Raman spetrum of the supernatant showed bands for the $SeCl_3^-$ anion

$$Se_2Cl_2 + Cl^- = Se(0) + SeCl_3^-. \qquad (7)$$

Thus reaction (6) is favoured in the hydrolysis of the $SeCl_3^-$ ion. It should further be noted that although the Cl^- to Se(IV) stoichiometric ratio for the products of reaction (6) is high, the $SeOCl_4^{2-}$ anion is not observed in significant concentration because the Se(IV) concentration is low.[12]

The spectra of solid Et_4NSeCl_3 and $(Et_4N)_2SeCl_4$ are shown in Fig. 1 and listed in Table 1. While the tetrachloroselenate(II) was stable to 647.1 nm laser irradiation at 50 mW power, the trichloroselenate(II) decomposed rapidly as shown by the change in colour from orange to black. This change was accompanied by a change in the Raman spectrum from that of Et_4NSeCl_3 to that of $(Et_4N)_2SeCl_6$. Apparently a disproportionation occurs according to

$$2Et_4NSeCl_3 = (Et_4N)_2SeCl_6 + Se(0). \qquad (8)$$

The characteristic Se(0) band at 240 cm^{-1}[18] is masked by the strong E_g stretch of the $SeCl_6^{2-}$ ion at 241 cm^{-1}.[14] The Raman spectrum of the decomposition product is identical with that observed by Wynne and Golen[8] for their solid Et_4NSeCl_3. But their spectrum cannot be the result of laser decomposition, since their product was yel-

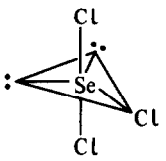
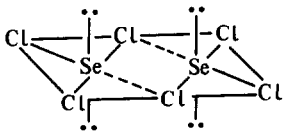
low in colour and had a high decomposition point (243–244°C) not unlike that of $(Et_4N)_2SeCl_6$ (220–225°C) but very different from that of Et_4NSeCl_3 (50–51°C). The nature of their product, which analysed correctly for Et_4NSeCl_3, is unknown.

The solution spectra for the anions are listed in Table 1. The observed spectrum of the $SeCl_3^-$ anion is consistent with that expected for the stretching modes of an anion with shape based upon a trigonal bipyramid with two Cl axial and one Cl equatorial[14,15]



The spectrum is similar to that of the $SeOCl_3^-$ ion, where the SeCl stretching modes are the strongest observed. The $SeCl_3$ skeleton shape is predicted to be the same (T-shaped) by VSEPR theory for both ions and the substitution of an oxygen for a lone pair in the equatorial position has only a small effect on the SeCl stretching modes. There is an increase in the mean of the SeCl stretching frequencies on going from $SeOCl_3^-$ to $SeCl_3^-$, which parallels the change in SeCl stretching frequencies and force constants observed for $SeOCl_2$ and $SeCl_2$.[6]

The Raman spectrum of $SeCl_3^-$ in solution is distinctly different from that in solid Et_4NSeCl_3, which supports the proposal that $SeCl_3^-$ is dimerized in the solid.[5]



There, is however, a similarity between the spectrum of the $SeCl_4^{2-}$ ion in solid and solution. VSEPR theory predicts that the $SeCl_4^{2-}$ anion will have D_{4h} symmetry ($\Gamma(D_{4h}) = A_{1g}+A_{2u}+B_{1g}+B_{2g}+B_{2u}+2E_u$) and the spectra are consistent with this. Three strong peaks are observed in the Raman spectrum of solid $(Et_4N)_2SeCl_4$, two in the SeCl stretching region, 265 and 235 cm^{-1} and one in the deformation region, 150 cm^{-1}. Of these, the peak at 265 cm^{-1} is strongly polarized ($\rho \sim 0.2$) and may be assigned to the A_{1g} stretching mode. The remaining two peaks are the B_{2g} stretching and B_{1g} deformation modes. There is a weak peak at 310 cm^{-1}, which is not a cation band and is unlikely to be due to any impurity in view of the analysis and the high crystallinity of the product. This may be the forbidden E_u stretching band, which appears due to a distortion from exact D_{4h} symmetry. Such a distortion has been observed in the case of the $SeBr_4^{2-}$ ion in $(Ph_4P)_2SeBr_4$.[11]

Bromoselenates

The strong characteristic peaks of $SeBr_2$ in CH_3CN at 290 and 266 cm^{-1}[16] decrease in intensity on addition of Et_4NBr to the solution and are replaced by strong peaks at 258 and 159 cm^{-1}. The spectrum of a 1 : 1 $SeBr_2/Et_4NBr$ solution is shown in Fig. 2 and the frequencies are listed in Table 2. The spectrum is very similar to that reported for Et_4NSeBr_3 in nitromethane[8] except for the presence of a small peak at 285 cm^{-1} no doubt due to the presence of a small amount of $SeBr_2$ as a result of incomplete formation of the $SeBr_3^-$ ion at these concentrations ($C_{Se(IV)} = 0.09$ M). Further addition of Et_4Br up to 1 : 6 mole ratio $SeBr_2/Et_4NBr$ with the same $C_{Se(IV)}$ results in a progressive increase in the intensity of the peak near 160 cm^{-1} and a decrease in that at 258 cm^{-1} (Fig. 2). These changes are due to further complexation according to

$$SeBr_3^- + Br^- = SeBr_4^{2-}. \qquad (9)$$

[c] *n*-Pr_4N^+ and Et_4N^+.
[d] Et_4N^+.

Cooling of 1 : 1 and 1 : 2 $SeBr_2/Et_4NBr$ solutions results in crystallization of the corresponding tribromo- and tetrabromo-salts, Et_4NSeBr_3 and $(Et_4N)_2SeBr_4$. The Raman spectra of these compounds are shown in Fig. 2 and listed in Table 2. The spectrum of Et_4NSeBr_3 corresponds well with that reported for $(Ph_4P)SeBr_3$,[11] which is known to contain the dimeric anion with Br bridging similar to that of $Se_2Cl_6^{2-}$ above. The solution spectrum of tribromo-selenate(II) ion differs significantly from that of the solid. In solution the monomeric solvated $SeBr_3^-$ ion is present.[8] The Raman spectrum of this ion parallels closely that of the $SeOBr_3^-$ ion, ignoring the SeO stretching and deformation modes, as expected where the '$SeBr_3$' skeletons in both anions are T-shaped.

Only one band is observed in the solution spectrum of the $SeBr_4^{2-}$ ion. This band at 162 cm^{-1} is strongly polarized and lies very close to the A_{1g} band observed for solid $(Ph_4P)_2SeBr_4$.[11] However, the Raman spectrum of solid $(Et_4N)_2SeBr_4$ is more complex than that reported for $(Ph_4P)_2SeBr_4$[11] and the strongest peak is 31 cm^{-1} higher than that observed for the latter compound. The spectrum suggests that some anion–anion interaction may occur in the compound with the smaller cation and further work will be necessary to confirm this.

Abstract—The crystal structures of three copper(II) complexes with phenoxyisobutyric acid (PIBAH) and *p*-chlorophenoxyisobutyric acid (PCIBAH) have been determined by X-ray diffraction. Tetra-μ-[2-methyl-2-(4-chlorophenoxy)-propanoato-*O*,*O*′]-bis[2-aminopyrimidine)copper(II)], $[Cu_2(PCIBA)_4(2\text{-aminopyrimidine})_2]_2$ (**1**) is a centrosymmetric tetracarboxylate bridged dimer [Cu···Cu, 2.689(2) Å] with the nitrogens of the 2-aminopyrimidine molecules occupying the axial positions [Cu—N, 2.198(7) Å]. Tetraaquacopper(II) tri-μ-[2-methyl-2-phenoxypropanoato-*O*,*O*′]-bis[(2-methyl-2- phenoxypropanoato(copper(II)], $[Cu(H_2O)_4]^{2+}$ $\{[Cu_2(PIBA)_5]^-\}_2$, (**2**), is a disordered precursor of the stable structure (**3**), $[Cu(H_2O)_5]^{2+}$ $\{[Cu_2(PIBA)_5]^-\}\cdot 4H_2O$, consisting of centrosymmetric square planar $[Cu(H_2O)_4]^{2+}$ cations and tris(carboxylate)-bridged dimer anions [Cu···Cu, 2.85(1) Å] (**2**). The fourth position of each square planar dimer 'end' is occupied by a carboxylate oxygen of a PIBA molecule which also provides the ether oxygen capping each axial dimer site [Cu—O, 2.15(4), 2.19(5) Å]. This completes a five-membered chelate ring. A symmetrical array of eight hydrogen bonds link the four waters of the $[Cu(H_2O)_4]^{2+}$ cation to the carboxyl oxygens of both the capping PIBA ligands of the two dimeric anions. Structure (**3**) has essentially identical $[Cu_2(PIBA)_5]^-$ dimer anions [Cu···Cu, 2.929(1) Å] and hydrogen-bonding interactions with the tetraaquacopper(II) cations. However, water molecules partially occupy the octahedral sites of these cations [Cu—O, 2.46(1) Å], as well as a number of lattice sites in the crystal.

*Part XXII. The structure of silver(I) (2-carbamoyl)phenoxyacetate.

†Author to whom correspondence should be addressed.

Phenoxyisobutyric acid (PIBAH) has been shown to form unusual complexes with divalent metal ions. With zinc, a novel polymeric complex $[Zn_5(PIBA)_{10}(H_2O)_2]_n$ is formed, having three independent complex centres, two octahedral and one trigonal bipyramidal.[2] Reaction of copper(II) carbonate with PIBAH in aqueous ethanol gave several polymorphs. An early formed green triclinic form (**2**) showed the unusual stoichiometry $\{[Cu_5(PIBA)_{10}(H_2O)_4]\}$, while digestion of the reaction mixture for longer periods gave stable dark green monoclinic crystals. Single crystal preliminaries indicated that a disorder problem decreased with the digestion period, giving finally complex (**3**) with an analysis consistent with the formula $[Cu_5(PIBA)_{10}(H_2O)_9]$.

When *p*-chlorophenoxyisobutyric acid (clofibric acid or PCIBAH) was used instead of PIBAH, a green microcrystalline complex was formed which, on digestion with 2-aminopyrimidine, gave the dark green adduct $[Cu_2(PCIBA)_4(2\text{-aminopyrimidine})_2]$ (**1**). The structures of all three complexes were determined to help clarify the anomalous behaviour of these acids towards copper(II).

EXPERIMENTAL

Preparation

The complexes were prepared as previously described by reacting PIBAH or PCIBAH respectively with excess copper(II) carbonate in boiling aqueous ethanol. Digestion of copper(II) *p*-chlorophenoxyisobutyrate with 2-aminopyrimidine in ethanol gave (**1**) as dark green needles. Complex (**3**) was obtained as the final product in the crystallization of copper(II) phenoxyisobutyrate after a minimum of 2 h digestion on a steam bath.

X-ray data collection, structure solution and refinement

Data for compounds (**1**)–(**3**) were collected at 293 K on a Nicolet R3m four-circle diffractometer using monochromated Mo-K_α radiation. 4662, 5699 and 4211 unique reflections were collected up to $2\theta_{max} = 50$, 42 and 40° respectively, from crystals measuring $0.40 \times 0.24 \times 0.05$ mm (**1**), $0.46 \times 0.10 \times 0.08$ mm (**2**) and $0.36 \times 0.32 \times 0.18$ mm (**3**). Of these, 2935, 1922 and 3211 respectively, with $I > 2.5\sigma(I)$ were considered observed and used in structure analysis. Data were processed using the learnt profile fitting procedure of Diamond[4] and used without corrections for absorption or extinction. The structure of (**1**) was solved by direct methods[5] and refined by blocked matrix least-squares with unit weights to $R(= \Sigma \|F_o - F_c\| / \Sigma |F_o|) = 0.082$ with anisotropic temperature factors for only the atoms of the coordination sphere and the two chlorines. A number of hydrogens were located in a difference-Fourier synthesis and included in the refinement at fixed positions with their isotropic U values fixed at 0.05 Å^2. The high residual is attributed to considerable thermal motion in evidence in certain of the ring atoms and the attached chlorines, possibly due to disorder in these systems. With (**2**) and (**3**), sharpened Patterson syntheses gave the positions of three copper atoms, one at (0, 0, ½) (**2**) or (0, 0, 0) (**3**) the other two at general positions, separated by ~ 2.8 Å. The latter distance, although long compared with typical values for tetracarboxylate bridged copper(II) dimers, e.g. 2.69 Å for (**1**) and a range of 2.56–2.89 Å for 43 dimers,[6] suggested dimeric species. Subsequent weighted difference-Fourier syntheses gave for (**2**) well-defined coordination polyhedra for both a square planar $[Cu(H_2O)_4]^{2+}$ monomer about (0, 0, ½) and a dimer. However, atoms of the phenoxyisobutyrate ligands of (**2**) were

‡ Reduced cell: $a = 10.94(1)$, $b = 13.47(1)$, $c = 19.67(°)$ Å, $\alpha = 82.21(4)$, $\beta = 80.82(4)$, $\gamma = 70.93(4)°$.

not located with any degree of accuracy, indicative of considerable disorder throughout the structure. Because of the size of the molecule, resolution of the problem in space group $P\bar{1}$ was not attempted and the results are therefore presented in the discussion for the structure at $R = 0.17$, with only the copper atoms being refined anisotropically.

Unlike (**2**), the ring disorder problem was not found in (**3**) and blocked matrix least-squares refinement with anisotropic thermal parameters for the coppers, the oxygens of the PIBA ligands and the coordinated waters, was used. In addition, a number of disordered lattice water molecules, consistent with the formula derived from chemical analyses and density measurements were included in the refinement with the appropriate site occupancy. This gave a final $R = 0.088$ and $Rw = 0.098$. A value of $w = 3.51$ $(\sigma^2 F_o + 1.23 \times 10^{-3} F_o^2)$ was obtained. No hydrogens were located or added to the refinement. For all analyses, neutral atom scattering factors were used, corrected where appropriate for the effects of anomalous dispersion.[7] Bond distances and angles about the coordination polyhedra for (**1**), (**2**) and (**3**) are listed in Table 1. Atomic coordinates, anisotropic thermal parameters, hydrogen atom coordinates (**1**), and observed and calculated structure factors have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

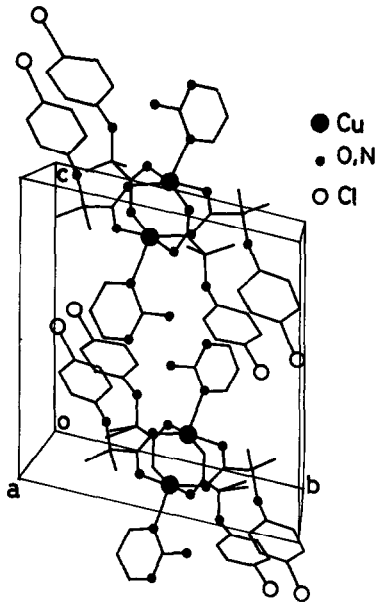

Fig. 2. Packing of (**1**) in the unit cell.

DISCUSSION

$[Cu_2(PCIBA)_4(2\text{-}aminopyrimidine)_2]$ (**1**)

Compound (**1**) forms discrete centrosymmetric tetracarboxylate bridged dimers (Fig. 1), analogous to the 2-aminopyrimidine adduct of copper(II) 4-fluorophenoxyacetate, $[Cu_2(4\text{-FPA})_4(2\text{-aminopyrimidine})_2]$.[8] The bond distances and angles about the dimer cage (mean Cu—O, Cu—N and Cu···Cu) are similar [1.968(7), 2.198(7), 2.689(2) Å (**1**) and 1.977(3), 2.176(3), 2.710(1) Å respectively]. Bonding of the pyrimidine molecules is also via one of the hetero nitrogens while the 2-amino groups provide stabilization to the structure through intradimer hydrogen bonding associations with carboxyl oxygens of one of the coordinated ligands [N(21)···O(11)B, 2.85 Å]. This structure contrasts with that for the 2-aminopyrimidine adduct of copper(II) 2-chlorophenoxyacetate, $[Cu_2(2\text{-CPA})_4(2\text{-aminopyrimidine})]_n$ which forms polymer chains through the *meta*-related hetero nitrogens of the pyrimidine ring.[9] With (**1**), there are no interdimer associations involved in the packing of the molecules in the unit cell (Fig. 2). However, the packing does appear to influence the conformations

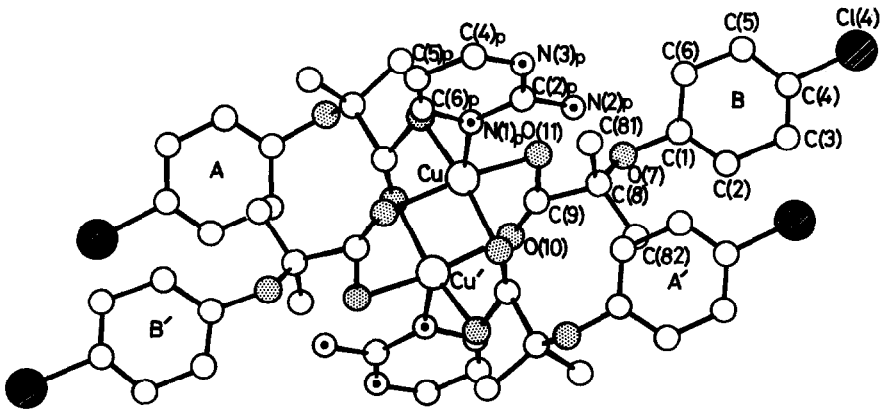

Fig. 1. Molecular configuration and atom naming scheme for (**1**).

assumed by the ligands which tend to orientate so as to acheive parallelism in the phenoxy groups. This is consistent with observations for other copper(II) phenoxyalkanoate dimers. The comparative torsion angles for ligands A and B in (**1**) [C(2)—C(1)—O(7)—C(8): −84.8, +98.8°; C(1)—O(7)—C(8)—C(9): +80.3, +179.9°; O(7)—C(8)—C(9)—O(10): +10.7, −172.8°] indicate that B is extended while A is twisted. The ligands consequently assume gross conformations with the ether oxygen and one of the carboxyl oxygens synplanar but with significantly different

O(ether)···O(carboxyl) distances [2.719 Å; 2.536 Å]. These values compare with 2.723 Å found for the acid itself.[10]

$[Cu_5(PIBA)_{10}(H_2O)_4]$ (2) *and* $[Cu_5(PIBA)_{10}(H_2O)_9]$ (3)

Although the structure of (2) was not well refined ($R = 0.17$), disorder appears to be confined to the peripheral regions of the complex while the core, consisting of the three copper(II) polyhedra, is quite well defined and allows a meaningful comparison with (3). The net formula of both (2) and (3) [the cell contents in complex (2)] comprises two $[Cu_2(PIBA)_5]^-$ anionic dimers and a square planar $[Cu(H_2O)_4]^{2+}$ cation, lying at a centre of inversion [(0, 0, $\frac{1}{2}$) (2) and (0, 0, 0) (3)]. The Cu—Ow distances in the monomers are 1.92, 1.92(4) Å (2) and 1.92, 1.96(1) Å (3). The occurrence of a discrete square planar tetraaquacopper(II) species is very unusual since the aquated ion more readily gives a rhombic distorted octahedral $[Cu(H_2O)_6]^{2+}$ cation, such as found in Tutton's salts,[11,12] $[Cu^{II}(H_2O)_6SO_4 \cdot M^I_2SO_4]$ and where $M^I = K^+$, Rb^+ or Cs^+. In this isomorphous series, the Cu—O distances in the centrosymmetric 'square' plane range from 1.943(2), 2.069(2) Å in $[Cu(H_2O)_6SO_4 \cdot K_2SO_4]$[13] to 1.966(5), 2.004(4) Å in $[Cu(H_2O)_6SO_4 \cdot Cs_2SO_4]$ neutron).[14] The situation is approached in (3) with a water molecule [Ow(4)] partially occupying the tetragonal sites of the distorted octahedron [Cu—O, 2.46(1) Å]. Some distortion is also apparent in the Cu—O (equatorial) distances compared to those in (2). This axial water forms only a very weak bond to copper since the Cu—O (axial) distance in the Tutton's salts is typically 2.26(1) Å.[13]

The $[Cu_2(PIBA)_5]^-$ dimers in both complexes represent the first examples of tris-carboxylate bridged copper(II) dimeric species, instead of the usual tetra-carboxylate bridging mode. However, the usual dimer core is essentially retained with the fourth position on each square planar 'end' occupied by a carboxylate oxygen of a non-bridging phenoxyisobutyrate ligand, giving mean Cu—O (equatorial) distances of 1.98(4) Å (2) and 1.96(1) Å (3). These same two non-bridging ligands also provide ether oxygens to cap the axial positions of the dimer [Cu—O, 2.15(4), 2.19(5) Å (2) and 2.201, 2.220(9) Å] (Figs 3 and 4) forming five-membered chelate rings. These axial Cu—O bonds are close to colinear in (2) [O(7)A—Cu(2)···Cu(3), 174.3(9)°; O(7)B—Cu(3)···Cu(2), 172.8(8)°]; and for ligand B in (3) [171.3(2)°] but deviate for ligand A, [160.9(2)°]. This is accompanied by a shortening of the Cu—O(11)A distance to 1.917(9) Å. In addition, the carboxylato-*O,O'* bridges are twisted in some of the ligands (Fig. 5), presumably because of the steric imposition of the bulky PIBA ligands.

All bond distances are in agreement with those

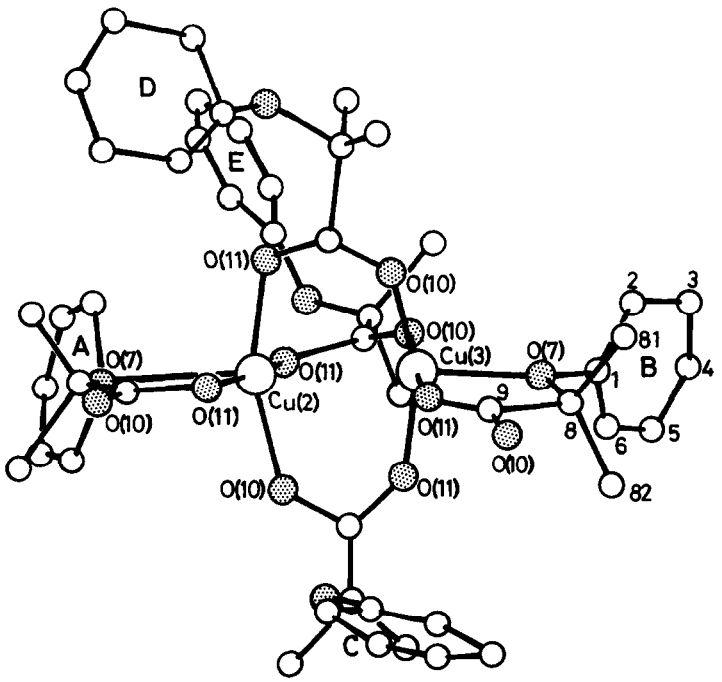

Fig. 3. Molecular configuration of the anionic dimer unit in the structure of (2).

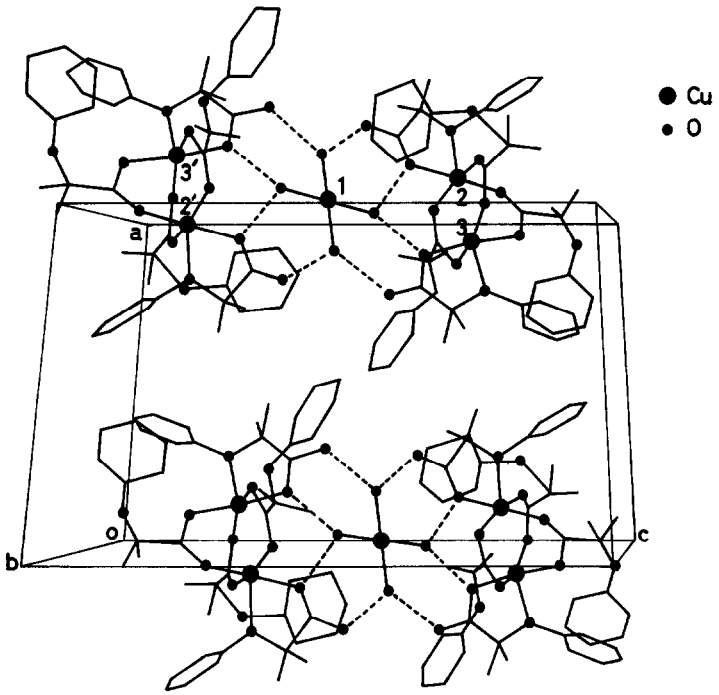

Fig. 4. Packing of (**2**) in the unit cell.

of the conventional copper(II) dimers[6] although the Cu···Cu separation for (**2**) [2.85(1) Å] approaches, or for (**3**) [2.929(1) Å] exceeds the maximum known {2.89 Å in $[Cu_2(CF_3COO)_4(quin)_2]$.[15] The occupancy of the axial positions of the dimer by ether oxygens is consistent with the usual formation in monomeric tetragonally distorted octahedral copper(II) phenoxyacetates of bis-chelate species having ether oxygens at the tetragonally elongated sites.[3] However, these Cu—O distances in (**2**) and (**3**) are considerably shorter than those in the copper(II) monomers which are typically 2.47 Å $[Cu(4\text{-fluorophenoxyacetato})_2(H_2O)_2]$.[8]

In both (**2**) and (**3**), the two complex anions are linked to the waters of the $[Cu(H_2O)_4]^{2+}$ cation by a symmetrical network of eight hydrogen bonds with the carboxyl oxygens of the terminal PIBA ligands (A and B) (Fig. 4). Both the coordinated and uncoordinated oxygens [O(11) and O(10), respectively] are involved [Ow(1)···O(10)A, 2.72 Å (**2**) 2.62 Å (**3**); ···O(10)B, 2.53 Å (**2**), 2.58 Å (**3**); Ow(2)···O(11) A. 2.58 Å (**2**), 2.61 Å (**3**);

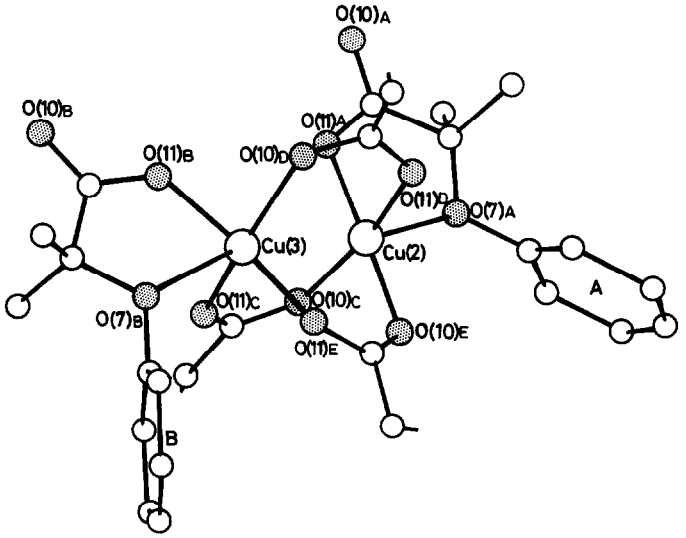

Fig. 5. Molecular configuration of the anionic dimer in (**3**).

···O(11)B, 2.63 Å (**2**), 2.65 Å (**3**)], resulting in discrete $[Cu_5(PIBA)_{10}(H_2O)_4]$ units centred about crystallographic inversion centres in their respective cells. No inter-unit associations are found. The ligands show considerable conformational variation, but as for the majority of the phenoxyalkanoic acids and their ligands found in metal complexes, the O(ether)···O(carboxyl) interactive distances are relatively constants [2.59–2.77 Å (**2**); 2.55–2.77 Å (**3**)]. The shorter distances are found in the ligands A and B of both complexes [2.59, 2.63 Å (**2**) and 2.55, 2.58 Å (**3**)] and are a consequence of the chelate ring formation in each. Comparable O···O distances are found for the analogous chelate rings in the tetragonally distorted monomeric copper(II) phenoxyalkanoate complexes.[8] With the bridging ligands the O···O distances are closer to that of the parent acid PIBAH (2.71 Å).[10]

Lattice stability in the case of (**3**) appears to be derived to some degree from the incorporation of additional water molecules in the lattice. The majority of these waters have only partial site occupancy and are either inter-associated or form hydrogen-bonding interactions with the waters of the $[Cu(H_2O)_4]^{2+}$ complex or with the carboxylate oxygens of the dimers. Of greater importance is the stability achieved through the hydrogen bonding between the $[Cu(H_2O)_4]^{2+}$ cations and the $[Cu_5(PIBA)_{10}]^-$ dimer anions. This is emphasized by the presence of the well-defined complex core even in the disordered triclinic crystals of (**2**), which may be considered as a disordered precursor of the stable monoclinic form (**3**). It might be reasonable to postulate that a more stable form than (**3**) was possible via full site occupancy by the lattice waters, without change in the unit cell. However, there is no evidence that any product other than (**3**) is formed even when prolonged digestion and crystallization conditions are employed.

THE SYNTHESIS, STRUCTURE AND SPECTROSCOPIC PROPERTIES OF THE DI- AND TRI-NUCLEAR Ni(II) THIOLATE COMPLEXES

JOHN R. NICHOLSON, GEORGE CHRISTOU,* JOHN C. HUFFMAN and KIRSTEN FOLTING

Department of Chemistry and the Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 15 *May* 1986; *accepted* 4 *August* 1986)

Abstract—The anions $[Ni_2(edt)_3]^{2-}$ (edt = ethane-1,2-dithiolate) and $[Ni_3(edt)_4]^{2-}$ have been prepared by the reaction of $Na_2(edt)$ with $NiCl_2 \cdot 6H_2O$ and, with subsequent work-up, isolated as their $[PPh_4]^+$ salts. For the first time, the structure of di- and tri-nuclear Ni(II) thiolates with identical ligands can be compared. The complex $[PPh_4]_2[Ni_2(edt)_3]$ (**1**) crystallizes in the triclinic space group $P\bar{1}$ with unit cell parameters (at −152°C) $a = 12.861(7)$, $b = 21.057(14)$, $c = 10.324(5)$ Å, $\alpha = 96.03(3)°$, $\beta = 109.88(3)°$, $\gamma = 76.82(3)°$, and $Z = 2$, while $[PPh_4]_2[Ni_3(edt)_4]$ (**2**) crystallizes in the monoclinic space group $P2_1/c$ with (at −60°C) $a = 13.713(3)$, $b = 13.255(3)$, $c = 15.754(5)$ Å, $\beta = 96.53(2)°$ and $Z = 2$. The structures were solved by direct methods and Fourier techniques from 4576 and 2671 diffractometer data, respectively, and refined to respective R values of 0.0552 and 0.0649. In the anion of **1**, one of the ligands provides two terminal thiolate-groups, and the other two each provide one terminal and one μ-thiolate-group such that each Ni(II) has an approximately square planar coordination geometry. The central NiS_2Ni unit is not planar, being folded along the vector joining the two bridging sulphur atoms. The anion of **2** is best considered as chelation of two identical $[Ni(edt)_2]^{2-}$ units to a third, central Ni(II) atom. The anion has a crystallographically observed centre of symmetry, with the central nickel atom thus lying in a perfect plane formed by its four coordinated sulphur atoms. The outer two nickel atoms are approximately square planar and the $Ni(NiS_4)_2$ core exists in a chair conformation. Both of the anions described have short Ni···Ni distances [2.9414(22) in (**1**) and 2.8301(13) Å in (**2**)]. The structures and the spectroscopic properties achieved for these complexes are described and discussed herein.

Our interest in the thiolate chemistry of nickel was stimulated by reports that in several reduced and oxidized hydrogenases the primary coordination sphere of nickel contains several sulphur atoms[1,2] and by the paucity of well-characterized compounds of this type in the literature which might be considered useful structural analogues. Although nickel is found in its +3 oxidation level in the resting state of the hydrogenases,[1,2] the +2 level is involved in the catalytic cycle. Hence the synthesis and characterization of some nickel(II) thiolates was considered to be of importance as a necessary first step in a modelling approach.

Prior to this work being undertaken, a few structurally characterized homoleptic nickel(II) thiolates had been reported[3–9] but none with edt. In our investigation of this area the bidentate ligand ethane-1,2-dithiolate was employed because this ligand has recently found much utility in the thiolate chemistry of the first row transition metals[10,11,13–16] and has been shown to stabilize some of these metals in what is regarded as high oxidation levels.[11,13,16]

Herein, we report the preparation, spectroscopic, and structural characterization of the two title complexes, $[PPh_4]_2[Ni_2(edt)_3]$ and $[PPh_4]_2[Ni_3(edt)_4]$, which contribute to the structural diversity already established for existing nickel thiolates[3–9,12] and allow for the first time direct structural comparison

of di- and tri-nuclear Ni(II) thiolates with identical ligands.

EXPERIMENTAL

All manipulations were performed using standard inert-atmosphere techniques. Acetonitrile was distilled from CaH_2 under a dinitrogen atmosphere and ethanol was dried over molecular sieves and degassed before use. Ethane-1,2-dithiol was used as received.

Proton NMR spectra were measured for concentrated solutions in $(CD_3)_2SO$ at 300 and 360 MHz on Varian XL-300 and Nicolet NT-360 instruments. Electronic spectra were obtained in CH_3CN or DMF solution on a 8450A Hewlett Packard UV–Vis spectrophotometer interfaced with a Hewlett Packard 7470A Plotter. IR spectra were recorded, with Nujol mulls between CsI plates, in the range 4000–200 cm^{-1} on a Perkin–Elmer 283 spectrometer. Electrochemical measurements were performed in the cyclic voltammetric mode with an IBM model EEC 25 voltammetric analyser in conjunction with a glassy carbon working electrode, a platinum-wire auxiliary electrode, and an SCE reference electrode. The supporting electrolyte was 0.1 M tetra-*n*-butylammonium perchlorate (TBAP), and concentrations of electroactive species were in the *c.* 5 mM range. Measurements were performed in MeCN solution, and potentials are quoted vs the normal hydrogen electrode (NHE) with ferrocene as an internal standard ($E_{1/2}$ = 0.400 V vs NHE).

Preparation of $[PPh_4]_2[Ni_2(SCH_2CH_2S)_3]$

Sodium metal (0.77 g, 34.0 mmol) was dissolved in EtOH (60 cm^3) and ethane-1,2-dithiol (1.40 cm^3, 17 mmol) added followed by solid $NiCl_2 \cdot 6H_2O$ (2.0 g, 8.4 mmol). Stirring at room temperature resulted in the formation of a white precipitate (NaCl) in a dark green solution within 0.5 h. The solution was filtered into a Schlenk tube containing PPh_4Br (7.4 g, 18 mmol). Intensely green coloured microcrystals of the product began precipitating almost immediately and after storage at room temperature for 24 h this product was collected by filtration, washed with two portions of an $EtOH/Et_2O$ mixture (10 cm^3, 1 : 1 composition) and dried *in vacuo*. The crude yield obtained was 2.8 g (52% with respect to nickel). After several days a further 0.55 g of product was isolated from the filtrate as very large chunky crystals which are intensely green coloured. The crude material is analytically and spectroscopically pure and crystals of a suitable size and quality for X-ray diffraction can be obtained from a slightly more dilute solution. Found: C, 60.7; H, 4.6; S, 18.5. $C_{54}H_{52}Ni_2P_2S_6$ requires C, 60.4; H, 4.9; S, 17.9%.

The crude product can be recrystallized by extracting with hot MeCN followed by slow cooling to room temperature, though this significantly reduces the overall yield (32%).

Employing a Ni : edt^{2-} ratio of 2 : 3 and following the procedure described above leads to the isolation of the same product in lower yield (1.7 g, 32%, crude product). Recrystallization from hot MeCN affords rhomb-shaped crystals which appear red-brown to transmitted light. [Found: C, 59.9; H. 5.0; S, 18.7%.) [Note: Although crystals of $[PPh_4]_2[Ni_2(edt)_3]$ obtained from reactions employing 2 : 1 and 3 : 2 ligand to metal ratios consistently lead to crystals which have different colours, their fully refined X-ray crystal structures are identical.

Preparation of $[PPh_4]_2[Ni_3(SCH_2CH_2S)_4]$

Sodium metal (0.58 g, 25 mmol) was dissolved in EtOH (60 cm^3) and ethane-1,2-dithiol (1.06 cm^3, 12.6 mmol) added followed by solid $NiCl_2 \cdot 6H_2O$ (1.50 g, 6.3 mmol). After *c.* 0.5 h the white precipitate (NaCl) was separated by filtration and PPh_4Br (5.55 g, 13.0 mmol) was added to the dark green filtrate to incipient crystallisation. The Schlenk tube was allowed to stand at room temperature for 36 h before the product was collected by filtration. The product was washed with two portions of an $EtOH/Et_2O$ mixture (8 cm^3, 1 : 1 composition) and dried *in vacuo*. The identity of this product was established as $[PPh_4]_2[Ni_2(edt)_3]$ (1.0 g, 29.6% yield). The filtrate from this product was then exposed to the atmosphere for 24 h by removing the septum cap and leaving the flask undisturbed. A mixture of black crystalline material and white solid was precipitated from solution. Anaerobic conditions were re-established and the mixture was collected by filtration and then extracted with either hot EtOH or hot MeCN. Brown crystals were obtained from the EtOH solution upon standing at room temperature for one week and from the MeCN solution upon storage in a freezer (*c.* −20°C) for three weeks. Crystals from the latter recrystallization were of a suitable quality for X-ray diffraction studies. The non-optimized yield of recrystallized material was 0.3 g (12% with respect to nickel). Found: C, 54.4; H, 4.7; S, 21.6. $C_{65}H_{56}Ni_3P_2S_8$ requires C, 55.0; H, 4.6; S, 21.0%.

Crystal structure determination

and computational procedures employed by the Molecular Structure Center are available elsewhere.[17] For **1** a systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited no symmetry or extinctions. The choice of the centrosymmetric space group $P\bar{1}$ was confirmed by the subsequent solution and refinement of the structure. For **2** a similar search located a set of diffraction maxima with monoclinic symmetry and systematic absences corresponding to space group $P2_1/n$. The structures were solved by a combination of direct methods and Fourier techniques and refined by full-matrix least-squares.

All non-hydrogen atoms of $[PPh_4]_2[Ni_2(edt)_3]$ (**1**) were readily located and the hydrogen atoms were located after initial refinement. However, there is a slight disorder problem in the anion at atoms C(12) and C(13). During refinement the hydrogen atoms moved to positions which gave unreasonable distances. A check of the root mean square displacements of the anisotropic atoms showed that the ellipsoids for C(12) and C(13) were quite elongated (.16.24.39) compared to the rest of the atoms. In the subsequent cycles of refinement the C(12) and C(13) atoms were kept isotropic and the hydrogen atoms associated with them were fixed. The structure refinement was completed using full-matrix least-squares with anisotropic thermal parameters on all non-hydrogen atoms (except C(12) and C(13)) and all hydrogen atoms were refined with isotropic thermal parameters (except H(9) to H(12)). The final difference map was essentially featureless except for a few peaks of c. 1e Å^{-3} in the vicinity of C(12) and C(13).

In the refinement of $[PPh_4]_2[Ni_3(edt)_4]$, non-

hydrogen atoms were assigned anisotropic thermal parameters whilst hydrogens were allowed to vary isotropically. A final difference Fourier was essentially featureless, with the largest peak being 0.50 e $Å^{-3}$.

Final values of atomic positional and thermal coefficients and lists of F_o/F_c values have been deposited as Supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure of the anions of $[PPh_4]_2[Ni_2(edt)_3]$ (**1**) and $[PPh_4]_2[Ni_3(edt)_4]$ (**2**) are shown in Figs 1 and 2, respectively. In the anion of **1**, one of the ligands provides two terminal thiolate groups, and the other two each provide one terminal and one μ-thiolate group such that each Ni(II) has an approximately square planar coordination geometry. The central NiS_2Ni unit is not planar, being folded along the vector joining the two bridging sulphur atoms. The anion of **2** is best considered as chelation of two identical $[Ni(edt)_2]^{2-}$ units to a third, central Ni(II) atom. The anion has a crystallographically observed centre of symmetry, with the central nickel atom thus lying in a perfect plane formed by its four coordinated sulphur atoms.

In order to describe the detailed structure of these anions a consideration of the Ni—S bond lengths given in Table 2 is necessary. It can be seen that a simple classification of these bond lengths into 'terminal' and 'bridging' is not entirely adequate. Those Ni—S bonds which form part of a Ni—S—C—C—S—Ni five-membered chelate ring are, on average, significantly shorter than those Ni—S bonds which are not within this chelate, and yet the former group contains ostensibly bridging *and* terminal ligation. Therefore, the $[Ni_2(edt)_3]^{2-}$

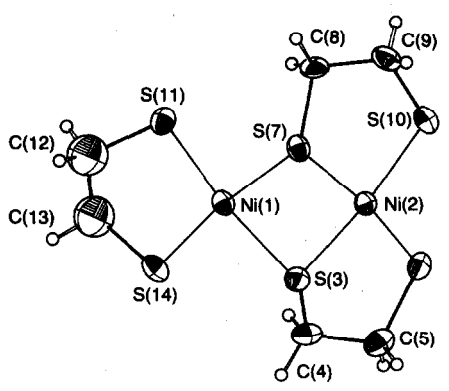

Fig. 1. Structure of $[Ni_2(edt)_3]^{2-}$ (in **1**) showing the atom-labelling scheme.

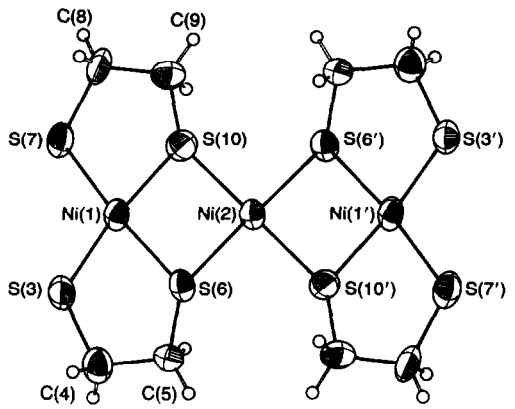

Fig. 2. Structure of $[Ni_3(edt)_4]^{2-}$ (in **2**) showing the atom-labelling scheme.

anion may best be thought of as arising from the chelation of a $[Ni(edt)_2]^{2-}$ monomeric unit to a Ni(edt) fragment with a folding of the two square planes thus formed along the common S···S edge. Similarly, $[Ni_3(edt)_4]^{2-}$ may be viewed as the chelation of a central Ni(II) atom by two $[Ni(edt)_2]^{2-}$ units in such a way as to generate a chair-like configuration of the Ni_3S_8 core. This Ni_3S_8 fragment closely conforms to C_{2h} symmetry, there being a mirror plane passing through the three nickel atoms and the mid-points of the sulphur atoms and a C_2 axis perpendicular to this. Inclusion of the methylene groups in the anion lowers the symmetry from C_{2h} to the crystallographically observed C_i-1. There are precedents for the kind of description given above, viz., the trimeric complexes $[Ni_3(S_2\text{-}o\text{-xyl})_4]^{2-}$ [4] and $[Ni(Ni(NH_2CH_2CH_2S)_2)_2]^{2+}$.[5] The former comprises the chelation of a central $[Ni(S_2\text{-}o\text{-xyl})_2]^{2-}$ unit to two $Ni(S_2\text{-}o\text{-xyl})$ fragments whilst the latter is analogous to $[Ni_3(edt)_4]^{2-}$.

Grouping the Ni—S bonds in the manner described above, i.e. within and without a chelate ring, gives the following average distances: $[Ni_2(edt)_3]^{2-}$, 2.181(14) and 2.216(13) Å; $[Ni_3(edt)_4]^{2-}$, 2.183(8) and 2.217(9) Å; $[Ni_3(S_2\text{-}o\text{-xyl})_4]^{2-}$,[4] 2.192(10) and 2.226(5) Å; $[Ni(Ni(NH_2CH_2CH_2S)_2)_2]^{2+}$,[5] 2.155(1) and 2.212 Å. With the exception of the two Ni—S bond distances within the Ni—S—C—C—N—Ni chelate ring of the latter being slightly shorter than the corresponding distances in the edt and S_2-*o*-xyl complexes, there are no significant differences between the four complexes with respect to their Ni—S bond lengths. The Ni—S bond lengths in the $[Ni_2(SEt)_6]^{2-}$ anion are comparable to those lying outside a chelate ring in the four complexes above [Ni—S_b = 2.220(6), Ni—S_t = 2.208(8) Å].[12]

There are several notable differences between the $[Ni_2(edt)_3]^{2-}$ and $[Ni_2(SEt)_6]^{2-}$ [12] anions.

[a] This is the only S—Ni—S angle that occurs *inside* a chelate ring in either (1) or (2).

$[Ni_2(SEt)_6]^{2-}$ is centrosymmetric and is formed by edge sharing of two planar units to generate an Ni_2S_2 *planar* rhomb.[12] In $[Ni_2(edt)_3]^{2-}$ there is no centre of symmetry and the Ni(1,2)S(3,7) core is not planar, there being a folding along the S(3)···S(7) vector. There is a dihedral angle of 119.07° at the intersection of the two NiS_4 planes. This has the effect of bringing the two Ni atoms closer together than in $[Ni_2(SEt)_6]^{2-}$ [2.9414(22) vs 3.355(2) Å] and to make the Ni—S—Ni bond angle in the bridge more acute [83.83(9) and 84.50(8) ° vs 98.2(1)°]. In $[Ni_2(edt)_3]^{2-}$, Ni(1) lies in the least squares plane formed by S(3,7,11,14) (maximum deviation, S(7) 0.085 Å) and Ni(2) is perpendicularly displaced by −0.08 Å from the least squares plane S(3,6,7,10) (maximum deviation, S(3,7) 0.048 Å).

The central nickel atom Ni(2) and the four attached sulphur atoms are required by the crystallographic centre of symmetry, located at Ni(2), to be exactly planar in $[Ni_3(edt)_4]^{2-}$. There is a deviation, though, from perfect square planarity of these sulphur atoms as evidenced by the S(6)—Ni(2)—S(10) angle of 99.59(9)°. Each of the two outer nickel atoms is perpendicularly displaced from its S(3,6,7,10) and S(3′,6′,7′,10′) least squares plane by 0.0874 Å in the direction opposite to the side of the central nickel atom Ni(2). In $Ni(Ni(NH_2CH_2CH_2S)_2)_2^{2+}$ the two outer nickel atoms are similarly displaced, by 0.12 Å.[5] Ni(2) is 1.556 Å from the least squares plane formed by S(3,6,7,10) (maximum deviation by S(10), 0.00979 Å).

In order to try and rationalize the degree of folding along the S···S vector and the Ni···Ni distances observed in this and other, similar complexes, Table 3 was compiled. This gives a selec-

tion of distances and bond angles in some thiolate-bridged nickel complexes. The most notable feature is a variation in Ni···Ni distances of more than 0.6 Å. There appear to be a number of factors which might be responsible for the specific metal–metal distances found. These include, (i) direct, net positive, Ni···Ni interaction, (ii) the stereochemistry at the bridging sulphur atom (any chelate constraints will be manifested in this), (iii) the total charge provided by the ligand set, (iv) the S···S separation of the bridging sulphur atoms, and (v) ligand–ligand steric interactions. Crystal packing may or may not be an important additional factor. It is quite clear that no one factor dominates over all of the others and it would appear that they are capable of assuming different relative importances.

The nickel–nickel separation in $[Ni_2(edt)_3]^{2-}$ and $[Ni_3(edt)_4]^{2-}$ is certainly short enough to permit some kind of a net weak positive interaction, though its nature is not clear. Dahl has proposed that this is due to overlap of the filled $3d_z^2$ orbitals on Ni.[5] Similarly, the bridging S···S separation is *c* 0.4 Å shorter than would be expected for a non-bonding interaction, but there is nothing to suggest that it is optimal in these two complexes. Chelate constraints alone cannot be responsible for the resulting Ni···Ni distances, because a difference of 0.6 Å exists between the two dimers[12,20] which both have unconstrained $C_2H_5S^-$ as bridging ligands.

From a consideration of the two trimeric complexes $[Ni_3(edt)_4]^{2-}$ and $Ni(Ni(NH_2CH_2CH_2S)_2)_2^{2+}$ we can make some interesting observations. The similarities between them indicate that of those factors (i)–(v) listed, (iii) should be the one most responsible for the difference in observed Ni···Ni distance. As noted earlier in this section, the Ni—S bonds found within the Ni—S—C—C—N—Ni chelate rings are the shortest (2.155 Å) Ni—SR bonds of any in the complexes under discussion. A reason for this might be that the aminoethanethiolate effectively provides two neutral and two negatively charged ligands for the outer nickel atoms, whereas the edt provides four negatively charged ligands. This results in a larger net positive charge in the nickel in the former which consequently leads to shorter Ni—S distances. As a result, the Ni···Ni separation is decreased. Indeed, of the compounds listed in Table 3, $Ni(Ni(NH_2CH_2CH_2S)_2)_2^{2+}$ has the shortest Ni···Ni distance and is the only one to have a neutral donor atom in its nickel coordination sphere. Pursuing this idea a little further, it could be argued that the trithiocarbonate ligands in $[Ni(CS_3C_2H_5)(SC_2H_5)]_2$[20] and $[Ni(CS_3CH_2Ph)(SCH_2Ph)]_2$[19] have only a uninegative charge which allows the Ni—S bonds in the bridge to shorten (to 2.186 and 2.189 Å) with respect to those average distances found in the compounds having purely thiolate coordination. This then leads to the shorter Ni···Ni distances found in these two complexes. Having said this, however, the effect of total charge provided by the ligand set cannot explain the difference in Ni···Ni separation observed for the $[Ni_2(edt)_3]^{2-}$ and $[Ni_3(edt)_4]^{2-}$ anions. In these two anions, the mean of four Ni—S_b bond distances are identical. The shorter Ni···Ni separation in the trimer is a net result of more acute Ni—S—Ni and dihedral angles and larger S···S separation. All three changes are con-

sistent with a shortening of the Ni···Ni separation, given no variation in Ni—S_b lengths, but it is impossible to categorize them as cause or consequence.

The data in Table 3 do show that, without exception, a shortening of the Ni···Ni distance results in a more acute Ni—S—Ni angles in the bridge and a more acute dihedral angle. The S—Ni—S bond angles within the bridging unit tend to lie in the range 79–84° for the complexes listed in Table 5. Exceptions to this are one of the angles in the $[Ni_3(edt)_4]^{2-}$ anion which is exceptionally large (99.59(9)°) and the angle in $[Ni_2(SB_z)_2(S_2CSCH_2C_6H_5)_2]$ (98.3°).[19] [The data provided[4] for the $[Ni_3(S_2\text{-}o\text{-}xyl)_4]^{2-}$ anion do not permit a definitive comparison.]

^{1}H NMR, IR, UV–VIS AND ELECTROCHEMICAL STUDIES

^{1}H NMR spectroscopy proved to be a very effective analytical tool in this work. Integration of the ligand methylene protons vs those of the PPh_4^+ cation accurately determines the ligand to cation ratio. Also, the spectrum of $[PPh_4]_2[Ni_3(edt)_4]$ is quite distinctly different from and more complex than, that of $[PPh_4]_2[Ni_2(edt)_3]$ in the methylene proton chemical shift region. In the $[Ni_2(edt)_3]^{2-}$ anion, the proton resonances appear as two multiplets having an approximate relative intensity of 1 : 5 centred at 1.72 and 1.95 ppm respectively. The room temperature spectrum of the $[Ni_3(edt)_4]^{2-}$ complex appears to be much more complicated than one would expect from the solid state structure. The methylene proton resonances are found between 1.65 and 2.70 ppm. Within this region there are two reasonably well-resolved multiplets each having six lines centered at 1.7 and 2.65 ppm; the remaining features are relatively broad. It is conceivable that fluxional processes are in effect in the DMSO solvent; this might involve breaking the weaker Ni—S bonds or the existence of different isomers in solution. For both compounds the PPh_4^+ proton resonances are centered around 8.0 ppm as expected.

On the basis of their IR spectra, recorded between 4000 and 200 cm^{-1}, compounds **1** and **2** are essentially indistinguishable.

The UV–Vis spectra were recorded for **1** and **2** on solutions prepared and maintained under an inert atmosphere. **1** dissolves to give a green coloured solution in MeCN and **2** gives a red/brown coloured solution in MeCN and in DMF. Within *c.* 2 h a solution of **2** in MeCN will turn cloudy. The spectrum of **1** has $\lambda_{max}(\varepsilon_m)$ at 468 nm (3,459) and 624 nm (954) which agree reasonably well with the data reported previously for this complex anion.[10] The spectrum of **2** was recorded for both MeCN and DMF solutions and λ_{max} were found at 297(sh) nm (15,561), 325(sh) (13,225), 424 (3818) and 538 (2806) in MeCN and at 432 nm (6775), 542 (4944), and 720 (1576) in DMF. These spectra show a slight shift in band position in CH_3CN vs DMF and both clearly differ from the values reported[10] for putative $[NEt_4]_2[Ni_3(edt)_4]$ in CH_3CN [392 nm (2200) and 468 (1280)]. Unfortunately, neither **1** nor **2** displayed electrochemically reversible behaviour when studied by cyclic voltammetry. **1** gave three oxidation peaks, at $E_{p,a} = -0.32$, -0.03 and $+0.73$ V vs NHE and **2** gave two oxidation peaks, at $E_{p,a} = -0.06$ and $+0.73$ V.

In conclusion, use of the edt^{2-} ligand has allowed nickel(II) thiolate complexes of differing nuclearity to be prepared. Structural characteristics of di- and tri-nuclear products can be compared for the first time under identical ligation. Unfortunately, use of the edt^{2-} ligand does not result in easier accessibility of the nickel(III) oxidation level, as judged by our electrochemical results are least, a situation we had hoped might result given the stabilization by this ligand of manganese(III)[13,16] and cobalt(III).[11] However, the continuing desire for nickel(III) species with sulphur ligation to model the nickel(III) sites of hydrogenases demands further effort in this area, perhaps with mixed ligation around the metal center.

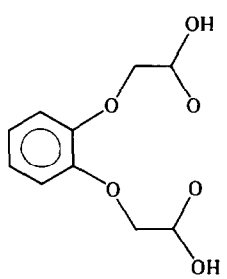
(*Received* 8 *April* 1986; *accepted* 8 *August* 1986)

Abstract—The divalent calcium, manganese, zinc, cobalt, magnesium and nickel complexes of benzene-1,2-dioxydiacetic acid ($BDDAH_2$) have been prepared and their structures determined by X-ray diffraction. Complexes $[Ca(BDDA)(H_2O)_2]_n \cdot nH_2O$ and $[Mn(BDDA)(H_2O)_2]_n \cdot nH_2O$ are isomorphous and isostructural. There is a pentagonal bipyramidal seven-coordination about each metal, involving four oxygens of the BDDA ligand, two axial waters and a fifth bridging carboxyl oxygen giving a polymer structure. In contrast, $[Zn(BDDA)(H_2O)_3] \cdot 3.5H_2O$ (and the cobalt and magnesium isomorphs) is discretely monomeric with the bridging position of the Ca/Mn structure replaced by a water. The nickel complex with formula $[Ni(BDDAH)_2(H_2O)_4] \cdot H_2O$ is monomeric and six-coordinate, bonded through only one carboxyl group of each of two *trans*-related BDDAH ligands.

Benzene-1,2-dioxydiacetic acid ($BDDAH_2$) [*O,O'*-catecholdiacetic acid, $CDAH_2$] is a multidentate chelating reagent, analogous to EDTA. However, stability constants for the metal complexes with



$BDDAH_2$ are substantially smaller than for the corresponding EDTA complexes.[1]

It is possible to modify the basic molecule to produce other acidic complexones with varying selectivities towards cations.[2] An unusual property of $BDDAH_2$ is its ability to form a crystalline precipitate with potassium ion, but not with lithium, sodium, caesium or ammonium ions.[3] The higher precipitimetric selectivity of $BDDAH_2$ towards K^+ compared to $NaBPh_4$ is probably due to the more compatible size of the potassium ion and a more favourable mode of coordination (or electrostatic interaction). The crystal structure of the K complex has an adducted species with formula $[K(BDDAH)(BDDAH_2)]$, with a pentagonal antiprismatic 'coordination' about the metal, one of the known stereochemistries by which K achieves solid state stabilization.[3] This is also seen in the related closed-chain polyether systems; e.g. di-benzo-18-crown-6 or 2,3,11,12-(bis-1,2-acenaptho)-18-crown-6, the latter giving with K^+ a regular 'hexagonal' interaction.[4]

$BDDAH_2$ has also been used to complex trivalent lanthanum as a model for a lanthanide shift ^1H and ^{13}C NMR study[5] since it forms both 1:1 and 1:2 complexes. Earlier, thermodynamic data indicated that the ligand was tetradentate and approximately planar,[6] in contrast with the skew conformation proposed for the ligands on the basis of the NMR solution spectra. The crystal structure of the complex $Na[La(BDDA)_2(H_2O)_2] \cdot 4H_2O$ showed an *s*-

*Author to whom correspondence should be addressed.

capped square antiprismatic deca-coordinate stereochemistry about La with two essentially planar BDDA ligands.[7]

A study of the structural systematics of divalent metal complexes of the phenoxyalkanoic acids,[8,9] which include the commercial herbicides 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 4-chloro-2-methylphenoxyacetic acid (MCPA), has been extended to include the complexes of certain difunctional acids. These have been prepared and characterized using X-ray diffraction. The acids include 4-carboxyphenoxyacetic acid ($PCPAH_2$), 2-carboxyphenoxyacetic acid ($OCPAH_2$) and benzene-1,2-dioxydiacetic acid. The manganese complex $[Mn(PCPA)_2(H_2O)_4]_n$ is a polymer bridged through both carboxyl groups in *cis*-related octahedral coordination sites, in contrast to the isomorphous Ni and Co complexes which have the formula $[M(PCPAH)_2(H_2O)_4]$ and are discretely monomeric octahedral with *trans*-related unidentate phenoxyacetate ligands.[9] The two copper(II)–$OCPAH_2$ complex polymorphs, $[Cu(OCPA)(H_2O)]_n$, (A) and $[Cu(OCPAH)_2(H_2O)_2]$, (B)[10] also differ markedly. Complex (A) is a step-polymer based on square pyramidal repeating units with tridentate OCPA occupying positions in the complex square plane while in (B), Cu is square planar with *trans*-related OCPA ligands, each having its carboxy group monoprotonated.

The divalent metal complexes of $BDDAH_2$ were prepared and characterized using elemental analysis, infrared spectroscopy and where applicable, X-ray diffraction. Structural results are reported for:

(1) $[Ca(BDDA)(H_2O)_2]_n \cdot nH_2O$

(2) $[Mn(BDDA)(H_2O)_2]_n \cdot nH_2O$

(3) $[Zn(BDDA)(H_2O)_3] \cdot 3.5H_2O$

(4) $[Ni(BDDAH)_2(H_2O)_4] \cdot H_2O$

Complexes (1) and (2) are isostructural and isomorphous. Isomorphism also exists between (3) and $[Co(BDDA)(H_2O)_3] \cdot 3.5H_2O$, (**3a**) and $[Mg(BDDA)(H_2O)_3] \cdot 3.5H_2O$ (**3b**).

EXPERIMENTAL

Preparation of complexes

All complexes were prepared using a previously described method[9] which involved mixing at 80°C, aqueous solutions of the ammonium salt of $BDDAH_2$ and an equimolar quantity of the appropriate metal acetate. An alternative procedure,[8] digesting at *c.* 80°C an aqueous ethanolic solution of $BDDAH_2$ with an excess of the metal carbonate, followed by removal of the unreacted excess by filtration, was also used. Crystals were obtained as colourless prisms [except (**4**) (pale green) and (**3a**) (red)] after partial room temperature evaporation of the filtrate. Because of insufficient sample, no carbon and hydrogen analyses were obtained for **3(a)** and **3(b)**. IR spectra were recorded on Perkin Elmer model 457 or Jasco IR-810 spectrometers using Nujol mulls on KBr discs. Single crystal X-ray preliminaries were completed on an Enraf-Nonius Weissenberg goniometer using nickel filtered Cu-K_α radiation. Unique intensity data sets were collected on a Nicolet R3m four-circle diffractometer at 20°C using graphite crystal monochromated Mo-K_α radiation and were corrected for Lorentz and polarization effects but not for absorption.

Structure solution and refinement

Details of unit cell parameters, data acquisition and structure solution for compounds (**1**)–(**4**) are given in Table 1. Data were recorded using a Nicolet R3m diffractometer and Mo-K_α radiation ($\lambda = 0.7107$ Å); structures were solved and refined via the heavy atom method using the SHELXTL[11] structure solution package on the Nicolet R3m. All structures were refined by blocked-matrix least-squares with anisotropic temperature factors on all non-hydrogen atoms. Three water molecules in the zinc structure (**3**) were found to have only partial site occupancy and were subsequently refined at half weights. This is consistent with its elemental analysis [Found: C, 29.6; H, 5.15. Calc. for $C_{10}H_{21}O_{12.5}Zn$, $\{[Zn(BDDA)(H_2O)_3] \cdot 3.5H_2O\}$: C, 29.5; H, 5.20%]. Neutral atom scattering factors and the f′, f″ terms for anomalous dispersion were taken from Ref. 12. Cell data and details of the structure analyses are given in Table 1 while bond distances and angles about the coordination polyhedra for the four complexes are listed in Table 2.

Tables of atomic coordinates, anisotropic thermal parameters, intraligand bond distances and angles, hydrogen atom coordinates, observed and calculated structure factors and IR spectra have been deposited with the Editor as supplementary material; copies are available on request from the Editor or the Authors. Atomic coordinations have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

[c] $w = (\sigma^2 F_o + A F_o^2)^{-1}$.

Mn (**2**) have been determined. Single crystal X-ray diffraction methods have confirmed that complexes (**1**) and (**2**) are isomorphous and isostructural. Isomorphism has been observed for a number of Mn and Mg phenoxyacetates, but (**1**) represents the first reported example of a Ca phenoxyacetate. Moreover, Ca is not known to behave in a similar manner to the other two metals. Because the BDDA ligand is essentially planar, as observed in the La complex[7] and the K complex adduct,[3] its donor sites are fixed relative to the metal ion. Therefore the ligand would be expected to exert a strong influence on the stereochemistry assumed by the metal ion. The structures of (**1**) and (**2**) are therefore based upon pentagonal bipyramidal repeating units (Fig. 1), which form into one-dimensional polymer structures. The pentagonal plane comprises four oxygens from the BDDA ligand, with the bonds to the ether oxygens elongated relative to those of the carboxyl oxygen [mean M—O(ether); 2.541(4) Å (**1**); 2.441(9) Å (**2**); mean—O(carboxyl); 2.322(4) Å (**2**)]. The fifth position is occupied by a bridging oxygen [2.451(3) Å (**1**); 2.271(8) Å (**2**) while in the axial positions are two water ligands [mean M—Ow, 2.366(3) Å (**1**); 2.248(8) Å (**2**).] Complex systems involving Ca(II) and Mn(II) with analogous tetra-oxygen donor ligands, the neutral noncyclic ionophores

TPBDD,* TPCDD† and TPDOD,‡ [13] show similar bond weakening towards the ether oxygen, although the metals do not have pentagonal bipyramidal stereochemistries in these complexes.

Both the pentagonal bipyramidal stereochemistry and the observed Ca—O bond distances in (**1**) are quite normal for calcium carboxylates, even when the acid ligand has less rigidity than BDDA. A strong tendency also exists for Ca to participate in α-chelation (more so than for other divalent metals).[14] Calcium di-DL-glycerate dihydrate[15] is very similar to (**1**), having two bidentate glycerate ligands and a bridging carboxyl—O in the pentagonal plane while the two waters occupy the axial positions of the bipyramid [mean Ca—O, 2.381 Å]. In calcium malonate dihydrate,[16] the structure is also polymeric but with the two waters in the pentagonal plane [mean Ca—O, 2.528 Å (X-ray) and 2.430 Å (neutron)]. Other variations are found in anhydrous calcium hydrazinecarboxylate[17]

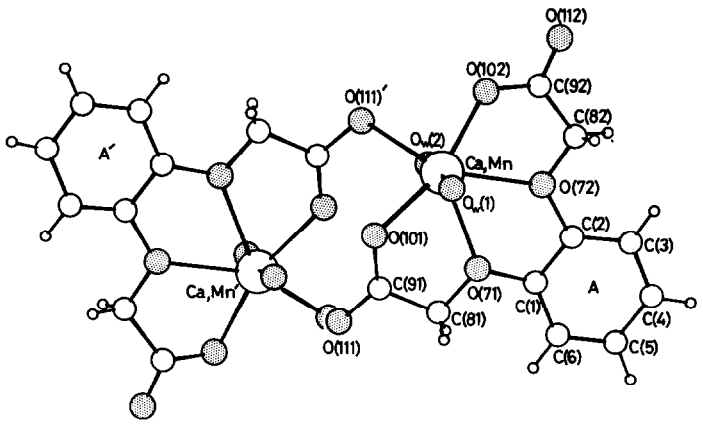

Fig. 1. $[Ca(BDDA)(H_2O)_2]_n \cdot nH_2O$ (**1**) and $[Mn(BDDA)(H_2O)_2]_n \cdot nH_2O$ (**2**).

$[CaO_5N_2$; mean Ca—O, 2.35 Å] and calcium hydrazinecarboxylate monohydrate[18] which is similar in most respects to the anhydrous complex but has a monocapped trigonal bipyramidal stereochemistry $[CaO_6N_2$; mean Ca—O, 2.44 Å]. However, the Mn complex has no precedent among the phenoxyalkanoates which tend to form polymer structures based on octahedral metal centres. Mn—O bond distances are considered normal for manganese carboxylates.

The comparative Ca—O(ether) and Ca—O (amide) distances for $[Ca(TPBDD)_2 \cdot Br_2]$ and $[Ca(TPDOD)_2 \cdot Cl_2]$ are 2.487, 2.327 Å (mean) and 2.462, 2.365 Å respectively while those for Mn—O in the complexes $[Mn(TPBDD)_2 \cdot MnBr_4]$ and $[Mn(TPCDD)_2 \cdot MnBr_4]$ are 2.380, 2.168 and 2.370, 2.185 Å respectively.[13] Mean distances for La—O bonds in $Na[La(BDDA)_2(H_2O)_2] \cdot 4H_2O$[7] (2.689, 2.504 Å), where the lanthanum stereochemistry approximates to an *s*-capped square antiprism and the equivalent values in $[K(BDDAH)(BDDAH_2)]$ (2.89, 2.75 Å) (irregular pentagonal antiprismatic stereochemistry), show similar bond length differences.

The $[M(BDDA)(H_2O)_2]$ repeating units in (**1**) and (**2**) are centrosymmetrically related in step-stack polymer chains which form down the *b* direction in their respective unit cells (Fig. 2). The lattice water [Ow(3)] is involved in hydrogen bonding interactions with the bridging carboxyl oxygen [O(111)]; 2.853 Å (**2**)] and with both coordinated waters [···Ow(1): 2.874 Å (**1**); 2.844 Å (**2**). ···Ow(2): 2.820 Å (**1**); 2.955 Å (**2**)]. Other significant intermolecular hydrogen bonding contacts are: Ow(1)···O(112), 2.683 Å (**1**); 2.696 Å (**2**) and Ow(1)···O(111), 3.023 Å (**1**); 2.952 Å (**2**). The most significant difference between the two polymorphs involve the long contacts between the metal and an *n* glide related carboxylate oxygen [O(101)]* which is considerably shorter in (**1**) (Ca—O, 2.863 Å) than in (**2**) (Mn—O, 3.132 Å). This may be due to a greater tendency for Ca cf. Mn to expand its coordination polyhedron, although the Ca—O distance is not intepreted as a formal bond.

Series B complexes

The complexes of BDDA with zinc(II) (**3**), cobalt(II) (**3a**) and magnesium(II) (**3b**) have been confirmed as isomorphous and isostructural on the basis of single crystal X-ray diffraction preliminaries and IR spectra. Elemental analysis and the X-ray determination for (**3**) is consistent with a

* Symmetry operation $(\frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}-z)$.

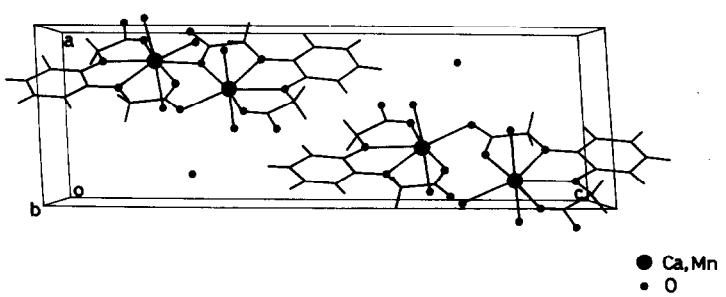

Fig. 2. Packing of (**1**) or (**2**) in the unit cell viewed perpendicular to *ac*.

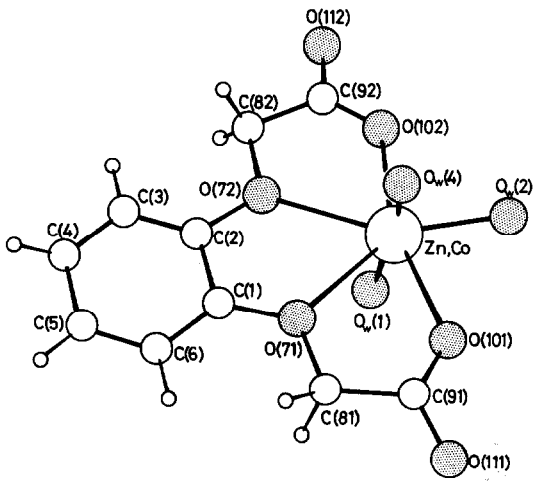

Fig. 3. $[Zn(BDDA)(H_2O)_3]\cdot 3.5H_2O$ (**3**).

formula $[Zn(BDDA)(H_2O)_3]\cdot 3.5H_2O$, with partial occupancy for the lattice water molecules [Ow(6), Ow(7)A, Ow(7)B], which may have significant lability in the solid state. The slight variations in the water absorption bands of the IR spectra for complexes (**3**) and (**3a**) are also probably a consequence of this lability.

In contrast to the Series A complexes, complex (**3**) is discretely monomeric (Fig. 3). However, the stereochemistry about zinc is similarly pentagonal bipyramidal. The planar BDDA ligand is quadridentate with the bonds to zinc similarly elongated towards the ether oxygens [Zn—O, 2.475(7) Å] compared to the carboxyl oxygens [Zn—O, 2.149(7) Å]. The remaining three meridional positions of the pentagonal bipyramid are occupied by waters [mean Zn—Ow, 2.061(7) Å]. This metal stereochemistry has no precedent among the zinc phenoxyalkanoates nor among zinc carboxylates generally, although there are examples with seven-coordination. However, the phenoxyalkanoates have previously shown only four, five and six-coordination, with tetrahedral trigonal bipyramidal, octahedral and skew trapezoidal stereochemistries.[8,19] Pentagonal bipyramidal coordination has been found for the isomorphous diaquanitratopurpuratozinc(II) and cobalt(II) dihydrates.[20] The ligand in this complex is similar to BDDA but with a tridentate O,N,O donor array (Zn—N, 2.229; Zn—O, 2.112, 2.114 Å) which, with an asymmetric bidentate nitrate group (Zn—O, 2.266, 2.511 Å) complete the coordination positions about the square plane. The axial positions are occupied by water molecules (Zn—O, 2.014, 2.138 Å). The stability constants for the zinc, cobalt and magnesium complexes [log K_1, 2.0 (**3**), 1.1 (**3a**) and < 1.5(**3b**)[1]] are also consistent with the isostructurality observed.

Packing of the complex molecules in the unit cell involves the lattice waters in interactive associations with carboxyl oxygens, coordinated waters and with other lattice waters in a complex network (Fig. 4).

These intermolecular O···O contacts are as follows: Ow(1)···O(5), 2.75 Å. Ow(2)···O(111), 2.67 Å. Ow(3)···Ow(6), 2.66, 2.80 Å. Ow(4)···Ow(7), 2.76 Å; ···Ow(8), 2.76 Å; ···O(102), 2.93 Å. Ow(5)···Ow(6), 2.68 Å; ···Ow(8), 2.81 Å; ···O(111), 2.90 Å. Ow(6)···Ow(7), 2.64 Å, Ow(7)···Ow(7)′, 2.77 Å; ···Ow(8), 2.90 Å; ···O(112), 2.83 Å. Ow(8)···Ow(8)′, 2.58 Å; ···O(112), 2.82 Å.

Series C complexes

To date, only nickel(II) forms a complex with $BDDAH_2$ with the formula $[Ni(BDDAH)_2(H_2O)_4]\cdot H_2O$ (**4**). This form, in which the second carboxyl group is protonated, is the product of either the neutral salt method (via the ammonium salt from aqueous solution) or by the carbonate method (from aqueous ethanol). The latter method,

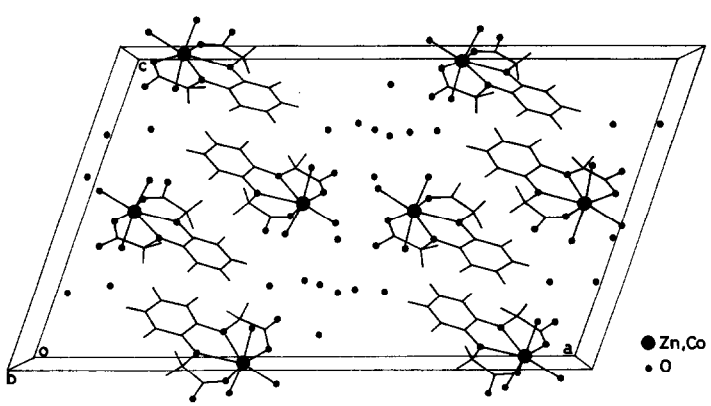

Fig. 4. Packing of (**3**) in the unit cell viewed perpendicular to *bc*.

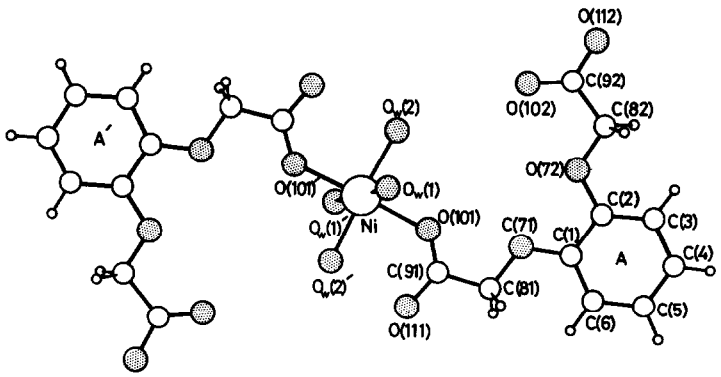

Fig. 5. $[Ni(BDDAH)_2(H_2O)_4]\cdot H_2O$ (**4**).

in which some free unreacted carboxylic acid is often present in the crystallizing mixture, often results in formation of acid adducts of complexes of the phenoxyalkanoates.[21] Although this is not the case in the present instance, the pH may be sufficiently low to protonate the first carboxylate group after which the conventional octahedral nickel complex proceeds to form from solution. The pK_{a1} and pK_{a2} values for the two carboxyl protons are 2.40 and 3.45 respectively for $BDDAH_2$.[1] A similar effect is observed with the complexes $[Ni(PCPAH)_2(H_2O)_2]$[9] and $[Cu(OCPAH)_2(H_2O)_4]$.[10] Complex (**4**) is centrosymmetric six-coordinate with the nickel at the centre of an almost regular octahedron comprising four waters [Ni—Ow, 2.047, 2.092(7) Å] and two carboxylate oxygens from unidentate BDDAH ligands [Ni—O, 2.064(10) Å] (Fig. 5). Unlike previous Series A or B complexes, the ether oxygens are not involved in coordination to the metal. Despite being unidentate, the BDDAH ligand is essentially planar, a conformational state probably maintained by the presence of hydrogen bonding interactions between the uncoordinated carboxyl oxygen [O(102)] and a coordinated water [Ow(1); O···O, 2.765 Å], between O(111) and the second coordinated water [Ow(1); O···O, 2.718 Å] and in addition, a very short contact (2.528 Å) between the protonated carboxyl oxygen [O(112)] and an adjacent carboxyl oxygen [O(111)'] (Fig. 6). This is analogous to the formation of inter-complex cyclic hydrogen bonding contacts found in $[Ni(PCPAH)_2(H_2O)_4]$[9] (2.59 Å) and in $[Cu(OCPAH)_2(H_2O)_2]$ (2.92 Å).[10]

The lattice water [Ow(3)], which lies on a crystallographic two-fold axis is also associated at considerably longer range with the protonated carboxyl oxygen [O(112)] (3.109 Å), the uncoordinated carboxyl oxygen [O(111)] (3.478 Å) and with the coordinated water molecule Ow(2) [3.197 Å].

The BDDA ligand

The important structure parameters of the BDDA ligands in each of the complexes (**1**)–(**4**) are listed in Supp. Table 5. The essentially planar conformation of the ligand in all complexes, as well as in the K^{+3} and La^{3+7} complexes is consistent with the contention that energetically this conformation is preferred for the oxyacetic acid side-chain in the free monofunctional phenoxyalkanoic

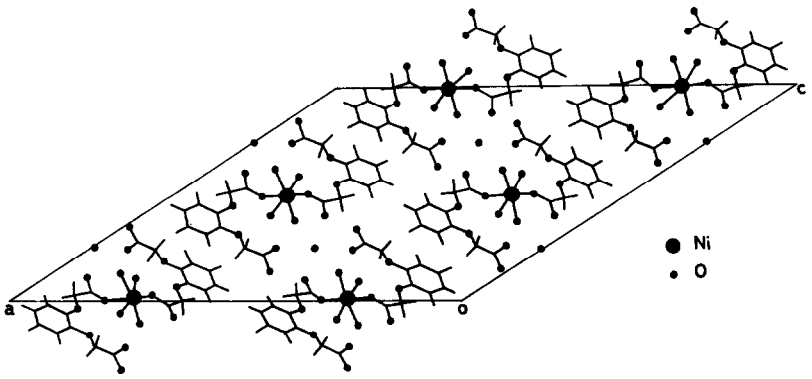

Fig. 6. Packing of (**4**) in the unit cell viewed perpendicular to *ac*.

acids.[22] In addition, other significant structural features generally shared with both the free acids and their metal complexes are

(1) The *exo*-C(1) and C(2) angles are considerably distorted compared with the expected trigonal value, being enlarged away from C(6) and C(3) respectively [mean C(2)—C(1)—O(71)/C(1)—C(2)—O(72), 115(1)°; C(6)—C(1)—O(71)/C(3)—C(2)—O(7), 125(1)°]. These values compare with means of 115° and 125° for equivalent angles in a series of 22 phenoxyalkanoic acids.[22] This indicates that little distortion results from the insertion of the metal ion in the ionosphore cavity during complexation.

(2) In these acids, the side-chain conformation with the carbonyl oxygen [O(10)] synplanar with respect to the ether oxygen [O(7)] is always found. This conformation is also found without exception for C—C—C=O among the α,β-saturated acids.[23] For the phenoxy acids, this results in a relatively constant O···O interactive distance [acid series mean (19 examples), 2.711 Å].[24] Furthermore, this interactive distance is retained on complexation, irrespective of the mode, i.e. unidentate, bidentate, bidentate-chelate. The observation is also true for the complex series (**1**)–(**4**) [mean O···O, 2.60(1) Å], the BDDA complexes of K^+ (2.62 Å),[3] La^{3+} (2.62 Å)[8] and the diacetamide complexes (2.56 Å).[13] The comparable O(71)···O(72) distance [series mean, 2.55 Å, cf. 2.57 Å (K^+); 2.60 Å (La^{3+}); 2.60 Å (diacetamide)] also shows little variation. From this observation for the known phenoxyalkanoate complexes, it is considered that the O···O non-bonded interactions (comparable in length to quite strong OH···O hydrogen bonding interactions) is instrumental in conferring planarity on these side-chains. This does not apply to the analogous (phenylthio)acetic acid complexes[24] in which there is no regularity in the S···O distance, nor any tendency for the thioacetate side-chain to remain planar. This is tenable on the basis of weaker S···O vs O···O interactions.

(3) The significant differences associated with the C—C—O ('carbonyl') and the C—C—O ('hydroxyl') angles, a phenomenon known for carboxylic acids generally [typically 123°, 113° respectively[23] and 125°, 112(1)° for the protonated ligand (**4**)]. Although this was expected to disappear on complexation, it is actually retained in most cases giving their distinctive angular features. This allows labelling of the oxygen either as 'carbonyl' or 'hydroxyl'. Thus in complexes (**1**)–(**4**), complexation of the metal involves the 'carbonyl' oxygen rather than the 'hydroxyl', with retention of the side-chain conformation expected to be found in the free acid.

CONCLUSION

It could be concluded that the free acid $BDDAH_2$ would be essentially planar in the solid state and that the *synplanar* conformation [as for the protonated oxoacetic acid side-chain in complex (**4**)] would be found in both residues in the diprotic acid. Complexation results in little change to the structural features of the BDDA ligand, with the divalent Ca, Mn, Mg, Zn and Co ions providing a compatible fit into the molecular pore-space. In fact, it would appear that ionic radius is not an important determinative factor in predicting the stability of the metal complex. A correlation of stability constants with ionic radii for this series 'shows some anomalous relationships'.[1] The cadmium complex of BDDA ($\log K_1$, 3.8; $r = 0.97$ Å) represents the first example of a Cd chelate in which the stability constant is larger than that of the corresponding Cu complex (3.3; 0.73 Å). With the exception of Cu (high) and Co (low) (1.1; 0.74 Å), the values of the stability constants increase steadily from Mg through Zn and Mn (2.8; 0.82 Å) to Cd, then decrease through Ca (3.1; 0.99 Å) to Ba (2.0; 1.35 Å). Suzuki *et al.* indicate that the unusual order is probably due to the structure of the BDDA ligand. This study confirms that Series A types (Ca, Mn) and Series B types (Zn, Co, Mg) are respectively isostructural and that both structure types are based on the pentagonal bipyramidal stereochemistry, it would appear that the ligand imposes a greater influence on the metal stereochemistry than vice versa. The structures of the Cd and Cu complexes are similar (from IR spectra) despite their different stoichiometries $[Cd(BDDA)(H_2O)_3]$;* $Cu(BDDA)(H_2O)_5$]† and are probably based on the pentagonal plane, although Cu^{II} shows little tendency to give this stereochemistry. More often the stereochemistry ranges from tetragonally distorted octahedral six-coordinate through trigonal bipyramidal or square pyramidal five-coordinate [polymorph A, $Cu(OCPA)(H_2O)$[10]], to square planar four-coordinate [polymorph B, $Cu(OCPAH)_2(H_2O)_4$[10]]. It is also suggested that structurally, Series A and Series B complexes are very similar, the stability constants being marginally enhanced with the formation of

* $[Cd(BDDA)(H_2O)_3]$; Found: C, 30.8; H, 3.62. Calc. for $C_{10}H_{14}CdO_9$; C, 30.7; H, 3.59%.

† $[Cu(BDDA)(H_2O)_5]$; Found: C, 31.7; H, 4.72. Calc. for $C_{10}H_{18}CuO_{11}$: C, 31.8; H, 4.77%.

the polymer structure. Morphologically, both forms are also similar. Consequently, it may be possible to form both modifications with all metal ions under suitable conditions. Nickel(II) usually assumes octahedral $[ML_2(H_2O)_4]$ coordination. It does this with BDDA only when the ligand is monoprotonated and unidentate.

Abstract—The crystal structures of diaquabis[(benzylthio)acetato]zinc(II), $[Zn(BTA)_2(H_2O)_2]$ (**1**), *catena*-[diaqua-tetra[(benzylthio)acetato)]-bis[cadmium(II)], $[Cd_2(BTA)_4H_2O)_2]_n$ (**2**), *catena*-{tetra-μ-[2-methyl-3-(phenylthio)propionato-*O,O'*]-bis[copper(II)]}, $[Cu_2(MPTP)_4]_n$ (**3**) and tetra-μ-[2-methyl-2-(phenylthio)propionato-*O,O'*]-bis[ethanol copper(II)], $[Cu_2(PTIBA)_4(EtOH)_2]$ (**4**) have been determined using X-ray diffraction techniques. Complex (**1**) is monomeric with distorted octahedral stereochemistry and lies on a two-fold rotational axis. The MO_6 coordination involves four oxygens from two slightly asymmetric bidentate BTA carboxyl groups [Zn—O, 2.138(3), 2.28(3) Å] and two *cis*-related waters [Zn—Ow, 1.996(3) Å]. The cadmium complex (**2**) is best described in terms of a polymer with the repeating unit consisting of two different centres, one seven, the other six-coordinate. With the first, the distorted MO_6S coordination sphere has four oxygens from two asymmetric bidentate carboxylate groups (ligands B and C) [Cd—O, 2.36, 2.56(1) Å; 2.26, 2.67(1) Å], an oxygen and a sulphur from a bidentate chelate ligand (A) [Cd—O, 2.36(1) Å; Cd—S, 2.773(4) Å] and an oxygen from a bridging carboxyl group (ligand D) [Cd—O, 2.28(1) Å]. Ligands C and D also bridge two Cd centres through

* Part VI, Ref. 1.

† Authors to whom correspondence should be addressed.

sulphurs [Cd—S, 2.739, 2.723(4) Å]. The second carboxyl oxygen of ligand A also forms a bridge to the second Cd [(Cd—O, 2.30(1) Å], while the distorted octahedral MO_4S_2 stereochemistry is completed by two waters [Cd—O, 2.25(1), 2.49(1) Å] and a sulphur from ligand D [Cd—S, 2.723(4) Å] giving a polymer structure. Complexes (**3**) and (**4**) are centrosymmetric tetra-carboxylate bridged dimers [for (**3**) Cu···Cu, 2.586(3) Å; mean Cu—O(equatorial), 1.957(11) Å; for the two independent dimers in (**4**), Cu···Cu, 2.596(1), 2.616(1) Å; Cu—O (equatorial), 1.952(4), 1.968(4) Å mean]. The axial positions of the dimer in (**3**) are occupied by carboxyl oxygens of adjacent dimers [Cu—O, 2.280(9) Å] forming a polymer structure. In contrast, these positions in (**4**) are occupied by ethanol molecules with Cu—O, 2.222(3) and 2.177(4) Å respectively for the two independent dimers.

In the course of this current investigation into metal (phenylthio)alkanoic acid interactions, some unusual and unexpected coordination systems have emerged. In the hope of finding some unusual examples, this work has now been extended to include complexes of (benzylthio)acetic acid (BTAH), (phenylsulphinyl)acetic acid (PSAH), 2-methyl-3-(phenylthio)propionic acid (MPTPH) and 2-methyl-2-(phenylthio)propionic acid (PTIBAH). Copper complexes with the first two ligands bis[(benzylthio) - acetato] - bis(pyridine)copper(II) and diaquabis[(phenylsulphinyl)acetato]-bis-pyridine)copper(II) have already been reported.[1] The object of this study is to determine what effect additional carbon atoms in the aliphatic acid side-chain have on Zn(II) and Cd(II) complexes with BTAH, $[Zn(BTA)_2(H_2]_2]$ (**1**) and $[Cd_2(BTA)_4(H_2O)_2]_n$ (**2**) which together with the Cu(II) complexes $[Cu_2(MPTP)_4]_n$ (**3**) and $[Cu_2(PTIBA)_4(EtOH)_2]$ (**4**) are reported here.

EXPERIMENTAL

Preparations

Complexes (**1**), (**2**), (**3**) and (**4**) were prepared by reacting aqueous ethanolic solutions of BTAH, MPTPH or PTIBAH with a suspension of excess metal carbonate (in aqueous ethanol) and digesting for *c.* 1 h at 70–90°C. After removal of the excess carbonate by filtration, standing at room temperature resulted in deposition of crystals which were recrystallised from absolute ethanol as colourless prisms [(**1**) and (**2**)] and dark green needles [(**3**) and (**4**)]. The acid PTIBAH was prepared by the Gilman and Wilder[2] modification of the Galimberti and Defranceschi procedure[3] by reacting thiophenol (0.1 mol) in 100 cm^3 of ethanol with NaOH (0.44 mol) and chloroform (0.11 mol) under reflux for 4 h. After acidification, the acid was obtained in 34% yield as colourless crystals (m.p. 67°C) after recrystallisation from petroleum ether. The crystals of complex (**4**) were found to lose crystallinity rapidly in air, presumably due to loss of ethanol solvate. Consequently, data collection was carried out with the specimen sealed in a glass capillary under an atmosphere of ethanol.

Crystal data, X-ray data collection and structure refinement

Table 1 lists information about unit cell parameters, data acquisition and structure solution for compounds (**1**), (**2**), (**3**) and (**4**). Data were processed using a profile fitting procedure.[4] Structures were solved by the heavy atom method and refined using the SHELX-76 set of programs.[5] Refinement was by blocked-matrix least-squares, with all heavy atoms anisotropic for (**1**) and (**4**) but with only those for Cd and S in (**2**) and Cu, S and O in (**3**) anisotropic. Hydrogens were located from difference Fourier syntheses and included in the respective refinements at fixed positions with their isotropic *U*s set invariant at 0.05 Å.[2]

Data for (**2**) were corrected for absorption. Neutral atom scattering factors were used with the metal and sulphur being corrected for anomalous dispersion.[6] Final atomic parameters, lists of hydrogen atom coordinates, anisotropic thermal parameters intraligand bond distances and angles and observed and calculated structure factors are available from the Editor or the authors.* Bond distances and angles about the coordination spheres for complexes (**1**)–(**4**) are given in Table 2.

DISCUSSION

(**1**) $[Zn(BTA)_2(H_2O)_2]$

The structure of (**1**) consists of very distorted octahedral six-coordinate monomers (Fig. 1), with

*Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

two-fold rotational symmetry coincident with crystallographic symmetry. In this respect, (1) is similar to zinc acetate dihydrate,[7] zinc salicylate dihydrate,[8] zinc phenoxyacetate dihydrate,[9] zinc(phenylthio)acetate dihydrate[10] and zinc (2-formyl-6-methoxyphenoxy)acetate dihydrate.[11] The carboxyl oxygens of the two (benzylthio)acetate ligands in (1) form asymmetric bidentate links to Zn [2.139(3), 2.227(3) Å, O—Zn—O, 58.8(1)°] with two waters [Zn—Ow, 1.996(3) Å] completing the coordination sphere. The degree of asymmetry in (1) is intermediate between symmetric zinc acetate dihydrate (2.17, 2.17 Å), and zinc (phenylthio(acetate dihydrate[10] (2.18, 2.20 Å) and zinc salicylate dihydrate[8] (2.03, 2.52 Å). Examples such as zinc phenoxyacetate dihydrate[9] (2.12, 2.34 Å) and zinc 2-ethoxybenzoate dihydrate[12] (2.05, 2.31 Å) are also intermediate. The substituted benzoate complexes[8,12] were considered tetrahedral but on the basis of repulsion energy calculations,[13] complexes of the type [M(bidentate)$_2$(unidentate)$_2$], with small normalized ligand 'bite', distortion of the six-coordinate *trans*-related octahedral structure occurs, giving a skew-trapezoidal bipyramidal structure. Thus these examples, together with (1), are best described on this basis, with the extreme case being the undistorted octahedral species in $[Zn(2,4\text{-}D)_2(H_2O)_4\cdot Zn(2,4\text{-}D)_2(H_2O)_2]$[14] (2,4-D = 2,4-dichlorophenoxyacetate) and in zinc 2-chlorophenoxyacetate tetrahydrate,[11] where the carboxylate ligands are unidentate.

The (benzylthio)acetate ligand in (1) is significantly distorted [torsion angle about the S(7)—C(8) vector c. 90°], in common with the phen-

ylthio ligand in the Zn and Cd complexes[10] but contrasting with (phenylthio)acetic acid (PTAH)[10] and the Ba and K complexes of PTA[15] (torsion angles *c.* 180°). This is the case even when the thioether-S is not coordinated to the metal as with the Zn,[11] Ba, K[15] and Cu complexes[1] but not the Cd examples, $[Cd_2(PTA)_4(H_2O)]_n$[10] and $[Cd_2(BTA)_4(H_2O)_2]_n$ [example (2), this work]. The non-bonding S···O(carboxylate) distance of 3.03 Å is maintained while the only significant intermolecular contact is a relatively short hydrogen bonding contact (2.67 Å) between the carboxyl oxygen O(10) and a coordinated water (Fig. 2).

(2) $[Cd_2(BTA)_4(H_2O)_2]_n$

Complex (2) is a polymer in which the repeating unit comprises two independent Cd centres, one seven-coordinate, the other six (Fig. 3). The first, Cd(1) has an irregular MO_6S coordination, with two asymmetric bidentate carboxylate groups from ligands B and C [Cd—O: 2.36, 2.56(1) Å; 2.26, 2.67(1) Å respectively], together with a bidentate O, S chelated ligand A (Cd—O(11), 2.36(1) Å; Cd—S, 2.773(4) Å]. The seventh coordination position is occupied by a bridging oxygen [O(10)D^b, 2.28(1) Å] $(1-x, 1-y, 1-z)$. Ligands C and D also provide two O—S bridges between the two Cd centres [Cd(2)—S(7)C, 2.739(4) Å; Cd(2)—S(7)D, 2.723(4) Å] while O(11)C also bridges two centres

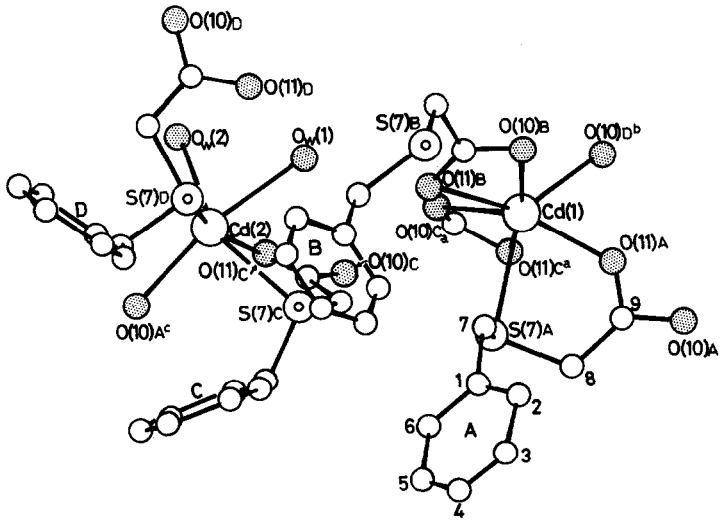

Fig. 3. Molecular configuration and atom naming scheme for (2).

[Cd(2)—O(11)C, 2.61(1) Å]. The second Cd has very distorted octahedral $MO_2Ow_2S_2$ six-coordination, with *cis*-angles varying from 75.3° [Ow(1)—Cd—S(7)C] to 116.9° [O(10)A—Cd—Ow(2)] while the minimum *trans* angle is 150.3° [S(7)C—Cd—Ow(2)]. The two *cis*-related waters are also bound to Cd(2) by unequal bonds [2.25(1), 2.49(1) Å]. Longer Cd—O distances are also found in the structure, but Cd(1)—O(11)D (2.83 Å) and Cd(2)—O(11)A (2.88) Å are not considered as formal bonds.

Although $Cd_2(PTA)_4(H_2O)]_n$[10] is also a polymeric dimer with two independent but different Cd centres, it is quite unlike (**2**) both in the nature of the coordination about each Cd centre and in the bridging mode. In addition, the analogous phenoxyacetate complexes $[Cd(PA)_2(H_2O)_2]$ (PA = phenoxyacetate)[9] and $[Cd(2\text{-}CPA)_2(H_2O)_3]\cdot 2H_2O$ (2-CPA = 2-chlorophenoxyacetate)[11] are different in all respects. Both are monomeric, $[Cd(PA)_2(H_2O)_2]$ being isomorphous with the zinc analogue[9] but with no asymmetry in the Cd—O(carboxyl) distances [2.363, 2.365 Å].[16] $[Cd(2\text{-}CPA)_2(H_2O)_3]\cdot 2H_2O$ is seven-coordinate, with asymmetric bidentate carboxylates [Cd—O, 2.26, 2.49(2) Å] and three waters [Cd—O, 2.27, 2.27, 2.34(2) Å], one on a two-fold axis.[11] At this stage of the work, no general rules for Cd complexes can be formulated as a consistent pattern has yet to emerge.

The packing of the polymer chains of (**2**) in the unit cell (Fig. 4) involves few inter-dimer associations, via the two waters attached to Cd(2): Ow(1)···O(11)B, (2.74 Å); Ow(1)···O(11)B, (2.82 Å); Ow(1)···O(10)D, 2.72 Å and Ow(2)···O(10)D, (2.69 Å).

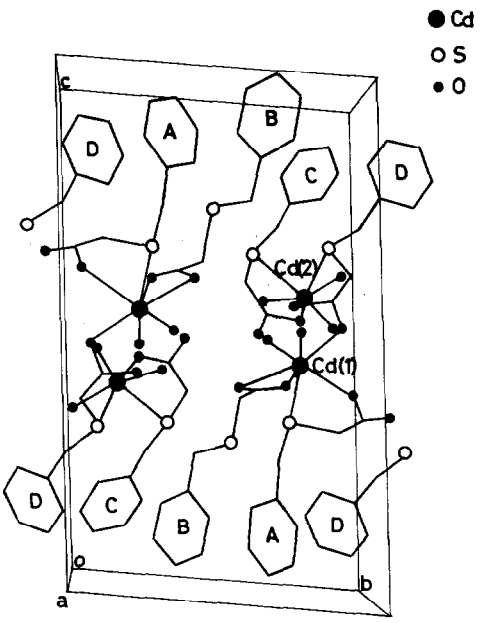

Fig. 4. Packing of (**2**) in the unit cell.

(3) $[Cu_2(MPTP)_4]_n$ *and* (4) $[Cu_2(PTIBA)_4(EtOH)_2]$

The structures of both (**3**) and (**4**) are based on centrosymmetric tetracarboxylate bridged dimers of the copper acetate hydrate type $[Cu_2(Ac)_4(H_2O)_2]$.[17] However, in the anhydrous complex (**3**), the axial water molecules of the copper acetate monomer are replaced by carboxyl oxygens of adjacent dimer units (Fig. 5). This extends the structure into a two-dimensional step polymer which extends down the *b* direction of the unit cell (Fig. 6). In this respect it is similar to other anhydrous examples such as copper(II) propionate,[18] copper(II) butyrate[19] and copper(II) 2-chlorophenoxyacetate.[20] In all these complexes, the structural features of the respective tetracarboxylate cages are generally comparable: Cu—Cu, mean Cu—O (equatorial) and Cu—O (axial) distances are 2.568(3), 1.975(9), 2.280(9) Å (**3**); 2.578(4), 1.94(1), 2.28(1) Å (propionate); 2.565, 1.982, 2.245 Å (butyrate); 2.583(2), 1.965(5), 2.169(5) Å (2-chlorophenoxyacetate). It has been previously noted[20] that these examples exhibit some of the shortest known Cu—Cu separations among the 55 known dimeric copper(II) carboxylates which range up to 2.886 Å $[Cu_2(CF_3COO)_4(quinoline)_2]$.[21] In the only three known copper(II) (phenylthio)carboxylate dimers $[Cu_2(PTA)_4(py)_2]$[22] [PTA = (phenylthio)acetate], $[Cu_2(DCMPTA)_4(acetone)_2]$[23] [(DCMPTA) = (2,4-dichloro-5-methyl-phenylthio)acetate and $[Cu_2(DCMPTA)_4$

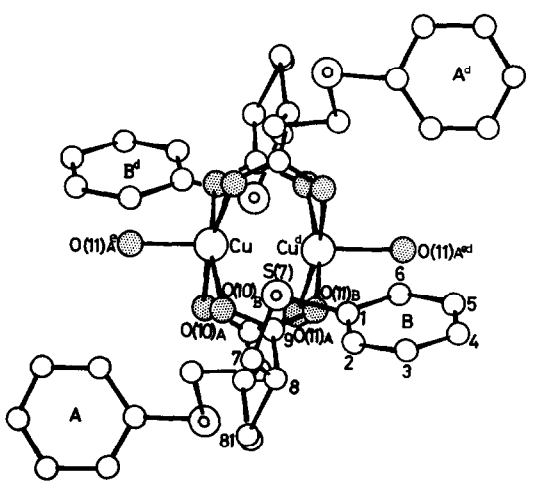

Fig. 5. Molecular configuration and atom naming scheme for (**3**).

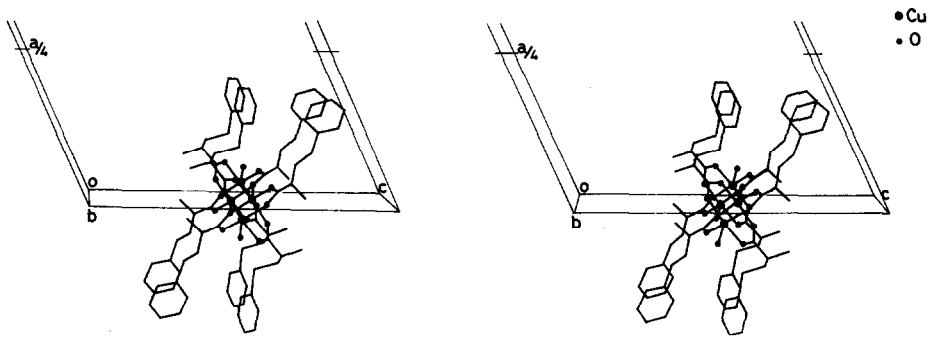

Fig. 6. Stereoview of the packing of part of the unit cell for (3), showing the polymer structure.

$(H_2O)_2]\cdot 2$ acetone[24] the comparative distances are 2.685(1), 1.984(4), 2.151(4) Å (Cu—N); 2.646(1), 1.961(4), 2.206(3) Å; 2.639(5), 1.99(2), 2.13(2) Å respectively. Furthermore the polymer motif of (3) contrasts with the more stereotypical distorted octahedral stereochemistries for the pyridine adducts of copper(II) (benzylthio)acetate and (phenylsulfinyl)acetate.[1]

Structure (4), is also different from that of (3), being discretely dimeric but having two independent, but similar centrosymmetric dimers (A and B) in the asymmetric unit. These lie at inversion centres in the unit cell (Fig. 7). The Cu—Cu and mean Cu—O (equatorial) distances [2.596(1) 1.952(4) Å (A) and 2.616(1), 1.968(4) Å (B) respectively] are within what is considered a normal range for copper(II) dimers.[25] In the axial sites of the dimers are found ethanol molecules [Cu—O, 2.177(4) Å (A); 2.222(3) Å (B)]. This is a reasonably common phenomenon among copper(II) dimers, but (4) represents the first occurrence for either the copper(phenylthio)alkanoates or the (phenoxy)alkanoates. However, the only known example of a dimer with acetone molecules in the axial sites is

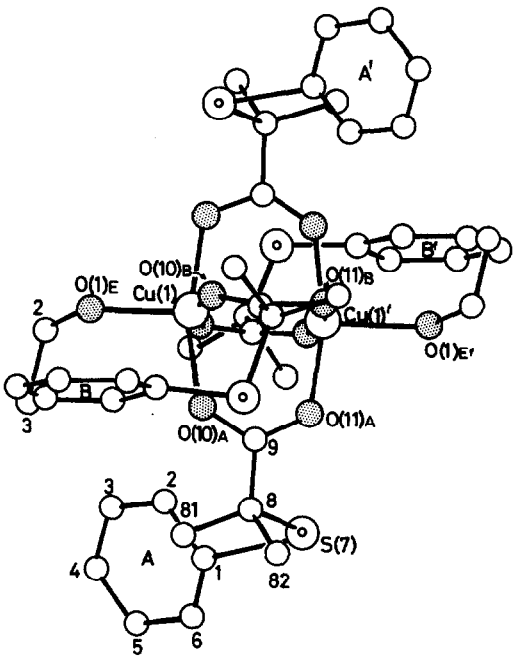

Fig. 7. Molecular configuration and atom naming scheme for (4).

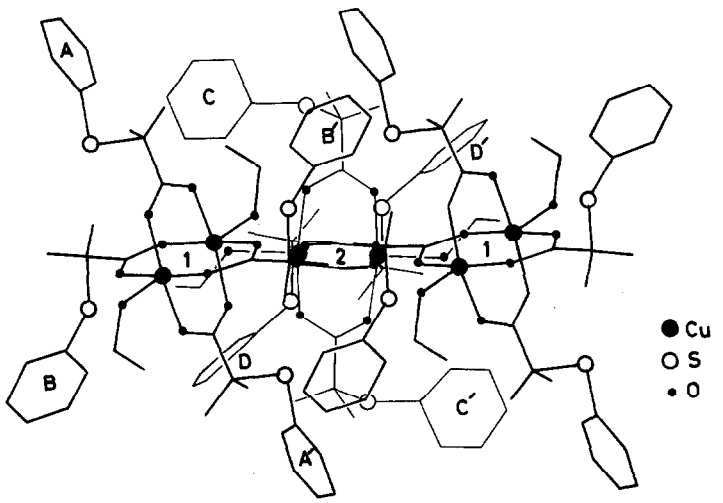

Fig. 8. Packing of (4)

one of the current series, $[Cu_2(DCMPTA)_4(acetone)_2]$.[23] In this example, the acetone molecules were strongly coordinated [Cu—O, 2.206(3) Å], presumably due to the greater steric freedom allowed by the longer (phenylthio)acetate side-chains of the acid.

With (**4**), few inter-dimer associations are found, the most significant being a hydrogen bond between the ethanol molecules, O(1)E···O(1)F, 2.880 Å. This links the two independent dimer units, stabilizing the packing in the unit cell (Fig. 8).

The (phenylthio)alkanoate ligands

The thioacetate (**1**,**2**), 3-thiopropionate (**3**) and thiobutyrate (**4**) side-chains in the four reported complexes vary markedly in formation. This is consistent with previous observations.[1,10,15,16] The introduction of an additional methylene group into the chain (BTAH) or up to two α-methyl groups into the acid (MPTPH or PTIBAH) adds to the conformational possibilities imposed by the coordination and packing modes for the complexes. Previously, conformation has not been a predictable quantity for this series, unlike the observations for the analogous metal phenoxyalkanoates. The much weaker non-bonding S···O cf. O···O interactions are considered the mean causative factor in this respect. For this series, the S···O distances are 3.03 Å (**1**); 2.83, 3.00, 3.12, 3.33 Å (**2**); > 4.0, 3.78 Å (**3**) and 3.11, 3.14, 3.20, 3.33 Å (**4**).

Furthermore, only in the Cd complex (**2**) does the thioether-S enter into coordination with the metal {as is also the case with $[Cd_2(PTA)_4(H_2O)]_n$[10]}. This parallels the lesser affinity of the ether-O of the phenoxyalkanoates towards metals compared to the carboxylate oxygen. With the Cd examples, bonding probably is the result of the greater tendency for Cd to expand its coordination sphere to give irregular stereochemistries through polymerization compared with copper(II) which is more predictable in its coordination in giving monomeric, dimeric or polymeric forms. Even in the zinc complex of (phenylthio)isobutyric acid, $[Zn_2(PTIBA)_4]_n$,[26] which involves a tris-carboxylate bridged dimer with tetrahedral zinc centres, forming a chain polymer through the fourth carboxylate group, only one very weak Zn—S interaction if found (Zn—S, 2.98 Å).

TROPOLONATO COMPLEXES OF OSMIUM, IRIDIUM, PLATINUM, MOLYBDENUM AND TUNGSTEN, AND THE X-RAY CRYSTAL STRUCTURE OF MoO_2trop_2

WILLIAM P. GRIFFITH,* CAROL A. PUMPHREY and ANDRZEJ C. SKAPSKI*

Chemical Crystallography and Inorganic Chemistry Laboratories, Imperial College, London SW7 2AY, U.K.

(*Received* 16 *June* 1986; *accepted* 12 *August* 1986)

Abstract—The new tropolonato (trop) complexes $Os(trop)_3$, $Ir(trop)_3$, $[Pt(trop)(PPh_3)_2]BPh_4$, $OsO_2(trop)_2$, $MoO_2(trop)_2$ and $W_2O_5(trop)_2$ are reported. The vibrational, ^1H and ^{13}C NMR spectra of the complexes have been measured and the X-ray crystal structure of MoO_2trop_2 has been determined. The crystals are monoclinic with $a = 15.485(3)$, $b = 13.583(3)$, $c = 14.211(3)$ Å, $\beta = 117.74(1)°$, space group $C2/c$, $Z = 8$; and the structure has been refined to $R = 0.033$.

We have reported the preparation and characterisation of catecholato (cat) complexes of osmium[1,2] and, more recently, of catecholato complexes of other second and third row elements.[3] The tropolonato ligand $(C_7H_5O_2)^-$ is the seven-membered ring analogue of the benzenoid catecholato ligand $(C_6H_4O_2)^{2-}$; like the latter[4] it is a good chelating ligand for transition metals, lanthanides and actinides.[5,6] Tropolonato complexes of all the first-row transition elements have been isolated[6,7] but there are very few such complexes known of the second and third row elements, and no structural or spectroscopic data on such species. We present here the results of a study of complexes of this ligand with the platinum group metals and with molybdenum and tungsten, complementing our earlier work on catecholato complexes of these metals.

Tropolonato complexes of the platinum metals

The complexes $Rh(trop)_3$[5] and $Pd(trop)_2$[6] are well-characterised; the published preparation of $Ru(trop)_3$[7] involves complex separational procedures. The only reported iridium complex seems to be $Ir(trop)(\pi\text{-}C_3H_7)_2$.[8]

We find that $Os(trop)_3$ can be made by reaction of $[OsCl_6]^{3-}$ with tropolone under basic conditions, and $OsO_2(trop)_2$ can, like its catecholato analogue, be made from *trans*-$K_2[OsO_2(OH)_4]$ and the ligands. Despite many attempts we failed to prepare the unknown $Pt(trop)_2$, but $[Pt(trop)(PPh_3)_2]^+$ was made by an adaptation of the procedure used[9] to make $Pt(cat)(PPh_3)_2$.

Oxo-molybdenum and oxo-tungsten tropolonato complexes

Although there are many oxo-molybdenum and oxo-tungsten complexes with catecholato ligands[3,4,10,11] the only tropolonato complexes of these metals to have been reported are $MoO(trop)_2Cl$[5] and $W(trop)(\pi\text{-}C_3H_7)(CO)_2Cl$.[12]

We find that reaction of ammonium molybdate with tropolone gives yellow crystals of $MoO_2(trop)_2$, the structure of which is discussed below, but similar reaction of tungstates gives a white complex which analyses as $W_2O_5(trop)_2$.

Physico-chemical studies on the complexes

X-ray crystal structure of $MoO_2(trop)_2$. Although there is a number of X-ray crystal structure determinations on *tris*-[13] and *tetrakis*-[14] tropolonato complexes, none has been reported on complexes also containing an oxo ligand. We therefore grew crystals of $MoO_2(trop)_2$ and carried out an X-ray study (see experimental section); attempts to obtain single crystals of $W_2O_5(trop)_2$ were not successful.

* Authors to whom correspondence should be addressed.

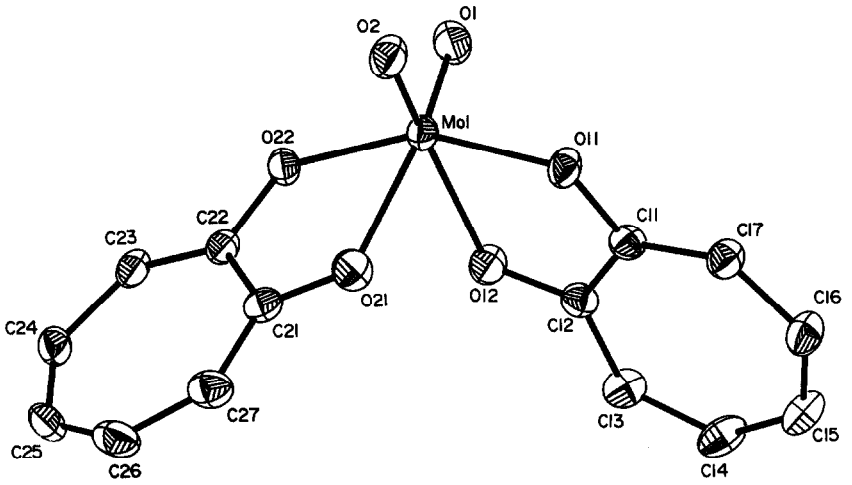

Fig. 1. Molecular structure of $MoO_2(trop)_2$. Thermal vibration ellipsoids are scaled to enclose 50% probability.

Figure 1 shows the molecular structure, and the more important bond lengths and bond angles are given in Tables 1 and 2, respectively. The molecule has approximate C_2 symmetry, and coordination about the molybdenum atom is distorted octahedral with *cis* oxo ligands [mean Mo—O 1.694 Å, O(1)—Mo—O(2) angle 103.4(2)°]. The two Mo—O distances *trans* to these oxo ligands are significantly longer (mean 2.178 Å) than the other two Mo—O distances (mean 2.012 Å); a similar *trans*-weakening effect has been noted in *cis*-$K_2[MoO_2(cat)_2 \cdot 2H_2O$[15] [mean Mo—O(cat) distance *trans* to oxo ligand 2.15(2) Å, mean Mo—O(cat) distance *cis* to oxo ligands 2.05(2) Å].

Within each coordinated tropolonato ligand the two C—O distances are significantly different (mean of 1.322 and 1.279 Å), consistent with the short and the long adjacent Mo—O distances respectively. This 'knock-on' effect persists in the ring systems though becoming slightly less clear-cut further from the Mo—O bonds. The longest bond length in the ring is between the carbon atoms bonded to the two oxygen atoms in each ligand.

IR and Raman spectra. The IR and Raman spectra[16] of tropolone have been measured and assigned, and also the IR spectra of a number of *bis* and *tris* tropolonato complexes[17] and those of normal and ^{18}O-substituted $Cu(trop)_2$.[18] The spectra of tropolonato complexes above 750 cm^{-1} are similar to those of the ligand; there is a small shift

to lower wavenumber of the ν(C—C) stretches near 1615 and 1555 cm^{-1}, and a slight shift to higher wavenumber and considerable increase in intensity of the ν(C═O) mode at 1330 cm^{-1} on co-ordination.[17,18]

We observe these features in the spectra of our complexes and note only the ν(C═O) band in Table 3. In addition to bands arising from the tropolonato ligand there are strong bands in the infrared at 931 and 900 cm^{-1} for $MoO_2(trop)_2$; these bands, observed also in the Raman, are assigned to the symmetric and asymmetric $\nu^s(MoO_2)$ and

Table 3. Spectroscopic data for tropolonato complexes

[a] Frequencies in cm^{-1}; Raman bands in parentheses.
[b] All δ values are quoted relative to tetramethylsilane on its low-field side.
[c] In ^2H_2O.
[d] Obscured by phenyl resonances.
[e] In d_6-DMSO; other spectra in C^2HCl_3.

$\nu^{as}(MoO_2)$ modes, respectively. The greater intensity of the 931 cm^{-1} band in the Raman suggests it to be the symmetric stretch; similar bands are observed in *cis*-$K_2[MoO_2(cat)_2]$[3] and in other *cis* molybdenum(VI) dioxo species.[19] The IR spectrum of $W_2O_5(trop)_2$ is similar to that for $(NH_4)_2[Mo_2O_5(cat)_2]$;[3] the two bands at 940 and 902 cm^{-1} are likely to arise from the *cis*-WO_2 moiety, while the band at 740 cm^{-1} may be due to a W—O—W asymmetric stretch. A similar band at 733 cm^{-1} is observed in $(NH_4)_2[Mo_2O_5(cat)_2]$;[3] the anion in the latter contains a bridging oxo ligand and also one oxygen atom from each catecholato ligand has a bridging role.[20] It is possible that $W_2O_5(trop)_2$ has a similar structure.

The strong IR band at 845 cm^{-1} in $OsO_2(trop)_2$ has no Raman counterpart and is likely to be $\nu^{as}(OsO_2)$ of a centrosymmetric *trans* O=Os=O 'osmyl' grouping; likewise the strong Raman band at 884 cm^{-1}, not found in the IR, is likely to be the symmetric $\nu^{s}(OsO_2)$, as in other osmyl complexes.[19]

^1H and ^{13}C NMR spectra. The ^1H NMR spectrum of tropolone in C^2HCl_3 shows a complex multiplet from δ 6.87 to 7.55 ppm, with sodium tropolonate in ^2H_2O giving an even broader multiplet, and the diamagnetic complexes show a slight downfield shift. There are few data in the literature on ^1H spectra of tropolonato complexes, but broad multiplets near δ 7.0 ppm have been noted for M(trop)(π-$C_3H_7)_2$[8] and Rh(trop)(diene) complexes.[21]

No ^{13}C NMR data on tropolonato complexes have been published. The ^{13}C NMR (proton-decoupled) spectra of liquid tropolone shows four resonances,[22] close to those found by us for the solution of the ligand. The peak of lowest intensity we tentatively assign to C(n5), the unique carbon atom; the other three are resonances time-averaged by hydroxylic proton exchange, and arise from C(n1, n2), C(n3, n7) and C(n4, n6). The resonance at δ 172.4 ppm is the one most affected by coordination, shifting to higher field in the complexes and in sodium tropolonate, and so may arise from C(n1, n2), the atoms bound to oxygen. This shift could be a consequence of the increased ring current induced in the C_7 ring by coordination; it is interesting to note that two resonances are observed near 175 ppm for $MoO_2(trop)_2$ since, as discussed in the X-ray section above, the chemical environments of C(11, 22) and C(12, 21) are somewhat different.

Mass spectra. We have measured the mass spectra of M(trop)$_3$ (M = Os, Ru, Ir, Rh). These behave in a similar fashion to Cr(trop)$_3$ and Fe(trop)$_3$:[23] the complexes show the molecular ion $[M(trop)_3]^+$ which fragments exclusively by loss of a ligand radical to give $[M(trop)_2]^+$. No peak was found for $[M]^+$ however, although weak peaks were observed for Cr(trop)$_3$ and Fe(trop)$_3$.[23] This may reflect the stability of the trivalent state for the metals studied here, and is indeed analogous to the situation observed for the mass spectra of M(acac)$_3$ (M = Os, Ir, Rh).[24]

EXPERIMENTAL

Tris *tropolonato complexes*

Tris (*tropolonato*)*osmium*(*III*), Os(trop)$_3$. The general method used was similar to that described for the preparation of Os(acac)$_3$.[25]

Silver powder (1.1 g, 0.01 mol) in water (50 cm^3) with 36% hydrochloric acid (10 cm^3), was degassed with nitrogen for 30 min. Solid $Na_2[OsCl_6]\cdot 2H_2O$ (4.5 g, 0.01 mol) was added, and the reddish solution was stirred under nitrogen overnight. To the resulting pale yellow-green solution, potassium bicarbonate (0.6 g, 6 mmol) was added, followed by addition of tropolone (3.67 g, 0.03 mol). The solution was boiled for 15 min. Further potassium bicarbonate (0.4 g, 4 mmol) was then added to the resulting very dark solution which was then heated gently for 2 h. After cooling, it was extracted twice with chloroform, and the chloroform solution washed twice with 2% aqueous sodium hydroxide solution. The resulting red chloroform solution was reduced on the rotary evaporator and the red-brown solid recrystallised from ethanol.

Found: C, 45.4; H, 3.0; $C_{21}H_{15}O_6Os$ requires: C, 45.6; H, 2.7%.

Tris (*tropolonato*)*iridium*(*III*), Ir(trop)$_3$. Sodium acetate trihydrate (0.19 g, 2 mmol) was dissolved in water (10 cm^3). Hydrated iridium trichloride (0.12 g, 0.3 mmol) was added and the solution warmed to give a dark green solution. Tropolone (0.25 g, 2 mmol) was added, with stirring. As the solid tropolone dissolved, the solution became brick red in colour. It was warmed and strirred for a few hours. After cooling, the oily precipitate was filtered off and washed with water, ethanol, and diethyl ether. The resulting red powder was dried over concentrated sulphuric acid.

Found: C, 45.0; H, 2.9; $C_{21}H_{15}IrO_6$ requires: C, 45.4; H, 2.7%, Yield = 40%.

Tris(*tropolonato*)*rhodium*(*III*) *and ruthenium*(*III*), M(trop)$_3$. The literature method was used for Rh(trop)$_3$.[5] The preparation of Ru(trop)$_3$ was attempted by adapting the method used for Ir(trop)$_3$ (above) and Rh(trop)$_3$.[5] It was successful only once and could not be repeated.

Found: C, 54.0; H, 3.6; $C_{21}H_{15}O_6Ru$ requires: C, 54.3; H, 3.3%.

Substituted tropolonato complexes

Bis(*tropolonato*) trans-*dioxo-osmium*(*VI*), $OsO_2(trop)_2$. Potassium osmate, *trans*-$K_2[OsO_2(OH)_4]$ (0.37 g, 1 mmol) was dissolved in water (30 cm^3) by stirring. Tropolone (0.25 g, 2 mmol) in ethanol (5 cm^3) was added, and immediately a mustard coloured precipitate came down. It was filtered off after standing for 30 min, washed with water, ethanol, and diethyl ether, and dried under vacuum.

Found: C, 36.7; H, 2.3; $C_{14}H_{10}O_6Os$ requires: C, 36.2; H, 2.2%; Yield = 90%.

Bis(*tropolonato*) cis - *dioxomolybdenum*(*VI*), $MoO_2(trop)_2$. Tropolone (0.25 g, 2 mmol), in ethanol (5 cm^3) was added to a solution of ammonium molybdate (0.19 g, 1 mmol) in water (10 cm^3). A light yellow precipitate immediately formed. After standing for 30 min it was filtered off, washed with water, ethanol, and diethyl ether. It was dried under vacuum.

Found: C, 44.9; H, 2.7; $C_{14}H_{10}MoO_6$ requires: C, 45.4; H, 2.7%; Yield = 70%.

Bis(*tropolonato*) - μ - *oxo* - bis (cis - *dioxotungsten*(*VI*)), $W_2O_5(trop)_2$. Tropolone (0.25 g, 2 mmol) in ethanol (5 cm^3) was added to a solution of sodium tungstate (0.29 g, 1 mmol) in water (10 cm^3). A pale yellow colour was seen immediately on mixing. After standing for 2 h, the resulting pale yellow solid was filtered off, washed with water and ethanol, and diethyl ether, and dried under vacuum. (The solid may be obtained more quickly by precipitation with ethanol, after mixing the two reactant solutions.)

Found: C, 24.7; H, 1.7; $C_{14}H_{10}O_9W_2$ requires: C, 24.4; H, 1.5%; Yield = 60%.

Mono (*tropolonato*) bis (*triphenylphosphine*) *platinum*(*II*) *tetraphenylboronate* $[Pt(PPh_3)_2(trop)](BPh_4)$. This complex was prepared using the method described for $Pt(PPh_3)_2(cat)$,[9] i.e. via the intermediates $Pt(PPh_3)_4$ and $Pt(PPh_3)_2(O_2)$. All manipulations were carried out under nitrogen, and all solvents were degassed before use. Tropolone (0.06 g, 0.5 mmol) in ethanol (5 cm^3) was added slowly, with stirring, to a solution of $Pt(PPh_3)_2(O_2)$ (0.6 g, 1 mmol) in toluene (10 cm^3) kept in an ice/water bath. The solution became yellow and was left to stir for 1 h. Sodium tetraphenylboronate (0.17 g, 0.05 mmol) in ethanol (8 cm^3) was added to the clear yellow solution, and the pale yellow precipitate which formed immediately was filtered off, washed with ethanol and diethyl ether and left to dry under nitrogen. The solid was stable in air.

Sodium tropolonate was prepared as described by Sasada and Nitta.[26]

IR spectra were measured on a Perkin-Elmer 683 instrument as liquid paraffin mulls between CsI plates, and Raman spectra on a Spex Ramalog 5 instrument as spinning disks on KBr, using a Coherent Radiation Model 52 krypton-ion laser. ^1H NMR spectra were measured on a Perkin-Elmer R32 90 MHz instrument and ^{13}C spectra on a 67.9 MHz Jeol FX 90Q Fourier transform spectrometer at 22.51 MHz. Mass spectra were measured on a VG-Micromass 7070E-HS.

Crystallographic studies

A prismatic crystal of $MoO_2(trop_2)$ of approximate dimensions $0.11 \times 0.075 \times 0.056$ mm was used for intensity data collection. Measurements were carried out on a Nicolet R3m/Eclipse S140 diffractometer system with graphite-monochromated Cu-K_α radiation. Unit-cell dimensions were determined by least-squares refinement of the angular settings of 21 automatically centred reflections.

Crystal data. $C_{14}H_{10}O_6Mo$, $M = 346.3$, monoclinic, $a = 15.485(3)$, $b = 13.583(3)$, $c = 14.211(3)$ Å, $\beta = 117.74(1)^\circ$, $U = 2645.5$ Å^3 (at 20°C), space group $C2/c$, $Z = 8$, $D_c = 1.74$ g cm^{-3}, $F(000) = 1472$, μ(Cu-K_α) = 85.1 cm^{-1}.

Integrated intensities in one quadrant were measured using the ω scan technique. Two reflections (022 and 220) were monitored every 50 measurements, and showed no significant variation in their intensities. A total of 1789 unique reflections were measured (to $\theta = 57^\circ$), of which 360 were judged to be 'unobserved' [$I < 3\sigma(I)$]. The data were scaled using the reference reflections and were corrected for Lorentz and polarisation effects. At a later stage of refinement an analytical absorption correction was applied.[27] All calculations and drawings were made using the SHELXTL program system,[27] and the atomic scattering factors and anomalous dispersion corrections were taken from ref. 28.

The coordinates of the molybdenum atom were derived from an initial Patterson synthesis and the positions of all the other atoms were found from subsequent difference Fourier syntheses. Least-squares refinement was by the block cascade method, typical of the SHELXTL system. All non-hydrogen atoms are refined with anisotropic temperature parameters, while the positions of the hydrogen atoms were tied to those of the parent carbon atoms. A weighting scheme was applied so that $\omega = 1/[\sigma(F_o)^2 + 0.00005F_o^2]$ for the last cycle. R reduced to 0.033, and $R_w = (\Sigma w|\Delta F|^2/\Sigma w|F_o|^2)^{1/2}$ was 0.030. The final difference Fourier synthesis was featureless, with a highest remaining peak of

0.3 e/Å^2 in the immediate vicinity of the metal atom.*

(*Received* 22 *July* 1986; *accepted* 15 *August* 1986)

Abstract—Homo- and heterodinuclear complexes of composition $[M_2L_2](ClO_4)_2 \cdot 4H_2O$, $[CuML_2](ClO_4)_2 \cdot nH_2O$ (M = Ni, Co or Mn; L = L^1 or L^2) and $[CuML^2Cl_2] \cdot 2H_2O$ (M = Ni or Co) have been synthesized with the dinucleating ligands 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde (HL^1) and 1,3-diacetyl-2-hydroxy-5-methylbenzene (HL^2). These compounds have been characterized and their chemical reactivities investigated. The electrochemical behaviour of $[M_2L_2^2](ClO_4)_2 \cdot 4H_2O$ and $[CuML_2^2](ClO_4)_2 \cdot nH_2O$ complexes have been examined in acetonitrile and dimethyl sulfoxide using Hg and Pt electrodes. The cyclic voltammograms obtained with a Hg electrode show quasi-reversible electron transfers for both metal centres that often get complicated due to decomplexation of metal ions and adsorption phenomena. On a Pt electrode irreversible electron transfers occur at more negative potentials.

Recent studies on dinuclear metal complexes in which the two metal centres are held in close proximity have addressed ligand environment, redox behaviour, magnetic exchange interactions and spectroscopic properties.[1–12] Considerable interest has also been focussed on synthesis and biomimetic reactions of model systems[13–21] related to copper enzymes.[22–25] For obvious reasons, dinucleating ligands are often used as the building blocks for designing such molecules. While the use of symmetric dinucleating ligands almost invariably lead to the formation of homodinuclear species [see, however, Ref. 6(b) for an exception], heterodinuclear complexes, on the other hand, are generally obtained from ligands containing two non-equivalent co-ordination sites. Frequently, one metal is in an N_2O_2 co-ordination site and the other occupies an O_4 site. Synthesis of heterodinuclear complexes from symmetric dinucleating ligands, therefore, remains to be an important task. We have previously reported chemistry and electrochemical behaviour of phenoxo-bridged acyclic and macrocyclic dicopper(II) complexes.[26–30] Herein we report the synthesis, characterization and electrochemistry of homo- and heterodinuclear complexes of copper(II), nickel(II), cobalt(II) and manganese(II) from 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde [HL^1 (**1a**)] and 1,3-diacetyl-2-hydroxy-5-methylbenzene [HL^2 (**1b**)].

EXPERIMENTAL

Materials

All reagents and solvents were purchased from commercial sources and used as such unless otherwise described. Methanol, ethanol and acetone were dried according to standard methods.[31] HL^1 and HL^2 were prepared as reported earlier.[27] Dried and purified nitrogen gas was used for the preparation of compounds containing cobalt(II) and manganese(II).

Preparation of the complexes

$ML_2 \cdot H_2O$ (M = Cu, Ni, Co *or* Mn; L = L^1 *or* L^2). The copper(II) complexes were obtained as described earlier.[26] The following method was used for the preparation of other complexes. The ligand (4 mmol) was dissolved in ethanol (100 cm^3) and treated with an aqueous solution (400 cm^3) of NaOH (4 mmol). To this was added with stirring an aqueous solution of hydrated metal chloride (2 mmol). The mixture was heated on a steam bath for *ca* 1 h. The compound separated was collected by filtration, washed several times with water, and dried over $CaCl_2$ *in vacuo*. The compound was then dissolved in required amount of chloroform, filtered, concentrated to half of its volume, and allowed to crystallize by adding an equal volume of petroleum ether (b.p. 40–60°C).

$[M_2L_2](ClO_4)_2 \cdot 4H_2O$ (M = Ni, Co *or* Mn; L = L^1 *or* L^2). The preparation of dicopper(II) complexes, $[Cu_2L_2](ClO_4)_2 \cdot 2H_2O$ was reported earlier.[26] Other homodinuclear complexes were obtained according to the method given below. To a boiling suspension of the mononuclear complex, $ML_2 \cdot H_2O$ (1 mmol) in dry ethanol (25 cm^3) corresponding metal perchlorate hexahydrate (1.2 mmol) was added. In a short period, most of the material went into solution and a colour change took place. The mixture was refluxed for *ca* 0.5 h. It was then centrifuged to remove a small amount of slimy residue that tends to pass through filtering glass frit. The centrifugate was concentrated to about 5 cm^3 and kept in a desiccator over $CaCl_2$ for several hours. The crystals that deposited during this period were collected by filtration, washed with a dry ethanol–chloroform (1 : 10) mixture, and dried over $CaCl_2$.

$[CuML_2](ClO_4)_2 \cdot nH_2O$ (M = Ni, Co *or* Mn; L = L^1 *or* L^2). $CuL_2 \cdot H_2O$ (1 mmol) was suspended in dry ethanol (20 cm^3) and solid $M(ClO_4)_2 \cdot 6H_2O$ (1.3 mmol) was added. The mixture was heated under reflux for 1 h. The clear solution that resulted was filtered hot and the filtrate on concentration gave crystals of the desired complex, which were collected and treated as above.

$[CuML^2_2Cl_2] \cdot 2H_2O$ (M = Ni *or* Co). These compounds were prepared in the same way as described above using $MCl_2 \cdot 6H_2O$ instead of the perchlorate salts.

Analytical data for a few representative complexes are given in Table 1.

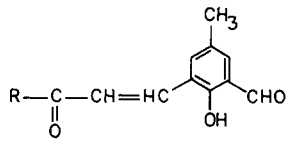
were recorded on a Perkin–Elmer model 783 IR spectrophotometer in the range 4000–200 cm^{-1} using KBr discs. Electronic spectra were obtained either with a Cary 17d or a Pye–Unicam SP8-150 spectrophotometer with 1-cm quartz cells for solution studies and as Nujol mulls on filter paper for solids. X-ray powder diffraction measurements were carried out on a Philips PW1051 diffractometer using Cu-K_α radiation. Magnetic measurements were made with a PAR model 155 vibrating sample magnetometer at room temperature employing $Hg[Co(SCN)_4]$ as a calibrant. Diamagnetic corrections were made by using Pascal's constants. The electrochemical measurements were made with a previously described[32] apparatus. All potentials refer to an aqueous saturated calomel electrode (s.c.e.). The temperature was controlled at 20 ± 0.1°C. Cyclic voltammograms were recorded using both Pt and Hg working electrodes. The solvents used were dimethyl sulfoxide (dmso) and acetonitrile (MeCN) (Burdick & Jackson u.v. grade). Tetraethyl ammonium perchlorate (Carlo Erba) dried in a vacuum oven was used as the supporting electrolyte. Nitrogen gas (99.99%) was employed to remove dissolved oxygen from the solutions.

RESULTS AND DISCUSSION

Synthesis and reactivities of the complexes

We previously reported[26] that $CuL_2 \cdot H_2O$ complexes are readily formed when copper(II) acetate is reacted with HL. This method, however, is not applicable for the preparation of other mononuclear complexes. $ML_2 \cdot H_2O$ (M = Ni, Co or Mn; $L = L^1$ or L^2) compounds are obtained by reacting one equivalent of the metal salt with two equivalents of the ligand and two equivalents of sodium hydroxide in an ethanol–water medium. Water should be present in large proportion in order to obtained the desired complex. In the case of nickel(II), when the reaction was carried out in ethanol alone, a green insoluble compound of apparent composition NiL_2 was obtained. This compound appears to have a tetrahedral configuration and does not react further to produce dinuclear species. $ML_2 \cdot H_2O$ complexes react smoothly with corresponding metal perchlorates in dry methanol or ethanol to form homodinuclear complexes, $M_2L_2(ClO_4)_2 \cdot 4H_2O$ (M = Ni, Co or Mn; $L = L^1$ or L^2). The heterodinuclear complexes $[CuML_2](ClO_4)_2 \cdot nH_2O$ (M = Ni, Co or Mn; $L = L^1$ or L^2) and $[CuML_2^2Cl_2] \cdot 2H_2O$ are also similarly obtained when a suspension of $CuL_2 \cdot H_2O$ in ethanol is treated with appropriate metal salts. Conversely, if $ML_2 \cdot H_2O$ is reacted with $Cu(ClO_4)_2 \cdot 6H_2O$, the product is always $[Cu_2L_2](ClO_4)_2 \cdot 2H_2O$. This reaction demonstrates that copper(II) has much greater affinity for O_4 co-ordination sites than the other metals. Attempts to prepare heterodinuclear complexes other than copper were unsuccessful. For example, reactions involving $NiL_2 \cdot H_2O$ and $Co(ClO_4)_2 \cdot 6H_2O$ or $CoL_2 \cdot H_2O$ and $Ni(ClO_4)_2 \cdot 6H_2O$ caused scrambling of metal ions in the heterodinuclear species ($2NiCoL_2^{2+} \rightarrow Ni_2L_2^{2+} + Co_2L_2^{2+}$), and the product isolated was a mixture of homodinuclear species. It should be noted that the dinuclear complexes are stable in solution only when the solvent is perfectly dry; moisture in the solvent causes hydrolytic cleavage of the phenoxo bridge and liberates a metal ion. In the case of $[CuML_2](ClO_4)_2 \cdot 2H_2O$ complexes, bridge splitting occur invariably at the M^{2+} site, showing again that the Cu—O linkages have greater bond strengths. The dinuclear complexes of HL^1 are more susceptible to hydrolysis than those of HL^2.

An interesting aspect of the dinuclear metal complexes of the ligand HL^1 is that one of the formyl groups is more susceptible to nucleophilic attack. For example, $[Cu_2L_2^1](ClO_4)_2 \cdot 2H_2O$ complex generated *in situ* undergoes aldol type condensation with a number of ketones containing α-methyl and methylene groups. Working up of the reaction product followed by removal of the metal ion leads to the isolation of 2-hydroxy-3-formyl-5-methyl-1-benzal ketone (**2**) in fairly high yield. By contrast,



(2)

no such reaction takes place with the mononuclear complex, $CuL_2^1 \cdot H_2O$. The free ligand, HL^1, on the other hand, undergoes self- and polycondensation reactions in the presence of a base producing non-characterized resinous products. The mechanism of the regioselective aldol condensation of $[Cu_2L_2^1](ClO_4)_2 \cdot 2H_2O$ has been investigated in detail,[33] and the reaction has been used to synthesize various derivatives of **2**.

Characterization of the complexes

The IR spectral features of the homo- and heterodinuclear complexes are similar. They are characterized by a broad band centred at about 3450 cm^{-1} due to the constituent water molecules, two strong bands at about 1650 and 1630 cm^{-1} due to

the metal bound carbonyl (C=O) stretchings, and another strong band at *ca* 1530 cm^{-1} due to metal-bonded phenolic ν(C···O) vibration. The ν(C=C) vibration appears at about 1610 cm^{-1}, often in the form of a shoulder. The most important feature, that the two ν(C=O) vibrations are about 20 cm^{-1} apart, implies that the two metal atoms are not equally strongly bound by the carbonyl groups.

The X-ray powder data for $[CuNiL_2^2](ClO_4)_2 \cdot 2H_2O$, $[CuCoL_2^2](ClO_4)_2 \cdot 2H_2O$ and $[Ni_2L_2^2](ClO_4)_2 \cdot 4H_2O$ are compared in Table 2. It may be noted that these complexes have similar *d*-spacings and intensities, indicating that they have related crystal structures.

The room-temperature magnetic moments (Table 3) of $ML_2 \cdot H_2O$ complexes (M = Ni, Co or Mn) are consistent with high-spin octahedral or square pyramidal stereochemistries, and do not support square planar or tetrahedral arrangements. Similar steric configurations are expected for the homodinuclear complexes, although the observed moments per metal ion for these compounds are

Table 3. Electronic spectral data and magnetic moments for the mono- and dinuclear complexes

less than the corresponding mononuclear species, indicating magnetic exchange interactions between two metal ions. In the case of heterodinuclear complexes also the observed moments are less than the expected spin-only values (Cu–Ni, 3.73 BM; Cu–Co, 4.24 BM; Cu–Mn, 6.17 BM) in the absence of such magnetic interactions. However, we presently could not investigate the magnetic properties in detail.

The electronic spectral data of the compounds are given in Table 3. The spectral features of $NiL_2 \cdot H_2O$ and $CoL_2 \cdot H_2O$ complexes provide evidences in favour of a square pyramidal environment[34,35] around the metal ions. $MnL_2 \cdot H_2O$ species lack absorption peaks in the visible range presumably because the weak *d–d* bands are submerged in the tail of the charge transfer band appearing at about 25,000 cm^{-1}.

Concerning the dinuclear complexes $[CuML_2Cl_2] \cdot 2H_2O$, both the metal atoms are likely to have a square pyramidal environment. Their spectral characteristics (Table 3) show a resemblance to $ML_2 \cdot H_2O$ species and are reminiscent of the chloro-bridged dinuclear macrocyclic complexes[35] obtained by condensing HL^1 with 1,3-diaminopropane. Similar to the macrocyclic systems, the chlorine atoms are also believed to be apically bound to the metal atoms. Less clear, however, is the steric environment around metal ions in the dinuclear complexes containing perchlorate ions. In these compounds it is possible to interpret the bands due to nickel(II) and cobalt(II) ions in terms of a pseudo-octahedral symmetry. However, considering the facts that $ML_2 \cdot H_2O$ complexes have C_{4v}-symmetry, and $[CuML_2](ClO_4)_2 \cdot 2H_2O$ and $[Ni_2L_2](ClO_4)_2 \cdot 4H_2O$ complexes are isostructural, it seems more likely that the two metal atoms in both homo- and heterodinuclear species have two different coordination environments. In $[M_2L_2](ClO_4)_2 \cdot 4H_2O$ complexes, one of the metals is probably having a square pyramidal arrangement and in the other two water molecules are axially bound. Similarly in $[CuML_2](ClO_4)_2 \cdot 4H_2O$ complexes, the metal ion M(II) appears to be hexacoordinated.

Electrochemistry

As mentioned earlier the dinuclear complexes of the ligand HL^2 are more stable with respect to solvolytic decomposition; consequently, their electrochemical behaviour was investigated. Cyclic voltammetric studies were made with MeCN and dmso solutions of the complexes using Hg and Pt electrodes.

The typical electrochemical responses for the compounds $[CuML_2^2](ClO_4)_2 \cdot nH_2O$ (**I–III**) and $[M_2L_2^2](ClO_4)_2 \cdot 4H_2O$ (**IV–VI**) are those shown in Fig. 1, which refer to the voltammograms of $[CuCoL_2^2](ClO_4) \cdot 2H_2O$ (**II**) in MeCN (a) and dmso (b), respectively, at an Hg electrode. In MeCN [Fig. 1(a)], the observed electrochemical features of **II** can be explained as follows. The cathodic–anodic peak system, *A/H*, is due to Cu(II) → Cu(I) electron transfer followed by re-oxidation in the reverse scan. The peak, *B*, which is irreproducible in height, is due to adsorption electrode-poisoning phenomena that made it necessary to clean the electrode mechanically after each cycle. The peak, *C*, is due to the subsequent reduction of the copper site [Cu(I) → Cu(0)], as indicated by the appearance of the characteristic stripping peak, *I*, in the reverse scan. The peak system *D/G* is due to the reduction of the second metal centre, Co(II) → Co(I). Finally, the peak system *E/F* is due to ligand-based electron transfer.

Analysis of the metal-centred responses with scan rates reveals that the first cathodic process, Cu(II) → Cu(I) is a quasi-reversible charge transfer followed by a chemical reaction. When the scan rate (v) was varied from 20 mV s^{-1} to 5 V s^{-1}, the following features hold:[36] (i) the anodic to cathodic peak ratio, $i_{p(H)}/i_{p(A)}$, increases from 0.56 to 0.8, (ii) the difference between the peak potentials ($\Delta E_p = E_H - E_A$) increases from 90 to 220 mV, (III) the ratio between the peak current of the cathodic sweep and the square root of the scan rate, $i_{p(A)}/v^{1/2}$, tends to increase, in agreement with the adsorption phenomenon. It is likely that the chemical complication following the electron transfer involves decomplexation of the electrogenerated copper(I) centre giving rise to free Cu^+ ions, as evidenced by the appearance of a reoxidation peak at about +1 V on scan reversal using a Pt electrode (see below). The Co(II) → Co(I) electron transfer appears to be a quasi-reversible process on the basis of the increase of ΔE_p with scan rate (from 65 to 130 mV). However, the study of the relevant electrode kinetics could not be made due to the presence of the pre-peak *C*.

In dmso, the electrochemical response from **II** is more simplified [Fig. 1(b)]. Here, the peak systems present are: *A/H* [Cu(II) → Cu(I)], *D/G* [co(II) → Co(I)], and *E/F* (ligand-based). Moreover, these responses are better reproducible because of the absence of adsorption phenomena; $i_{p(A)}/v^{1/2}$ remains substantially unchanged with the variation in scan rate. However, in this case also the ratio $i_{p(H)}/i_{p(A)}$ remains less than unity, indicating that the species $[Cu(I)Co(II)L^2]^+$ is not a stable product. As regards the Co(II) → Co(I) electron transfer, which can be better tested here with scan rate than in MeCN,

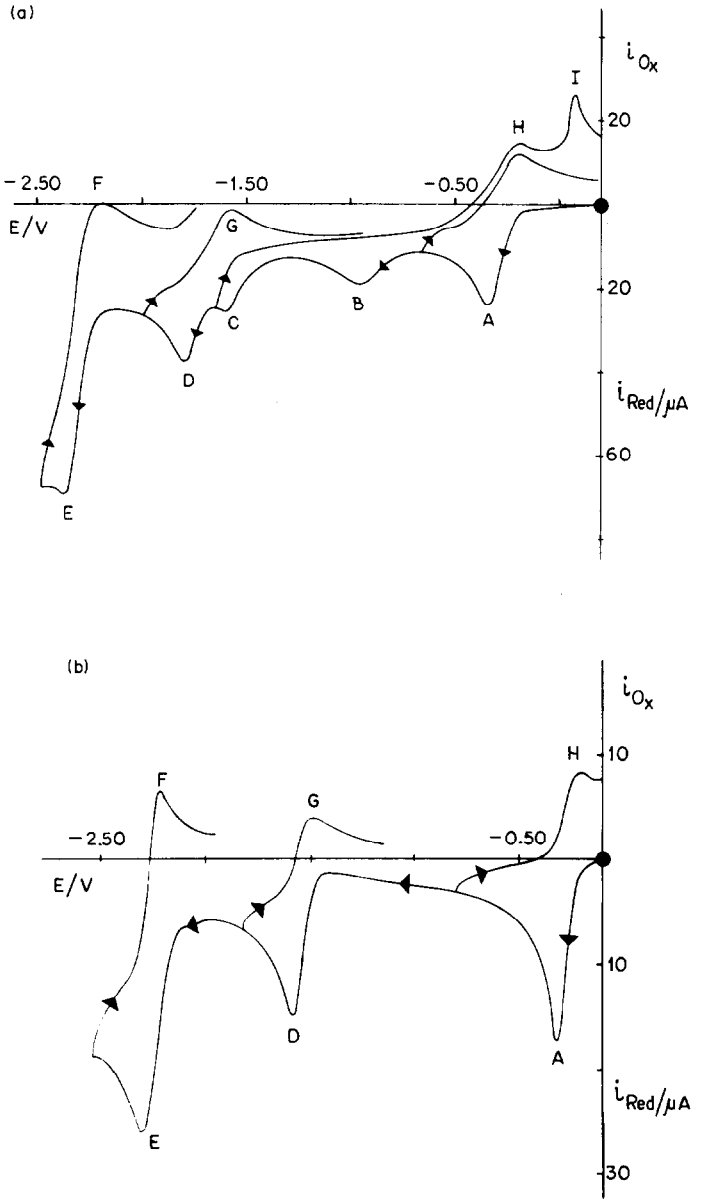

Fig. 1. (a) Cyclic voltammogram of $[CuCoL_2^2](ClO_4)_2 \cdot 2H_2O$ (**II**) in MeCN on an Hg electrode at a scan rate of 200 mV s^{-1}. Concentration of **II** = 1.3×10^{-3} mol dm^{-3}; concentration of supporting electrolyte, $[Et_4N](ClO_4)$ = 0.1 mol dm^{-3}. (b) Cyclic voltammogram of **II** in dmso on an Hg electrode at a scan rate of 200 mV S^{-1}. **II** = 1.3×10^{-3} mol dm^{-3}; $[Et_4N](ClO_4)$ = 0.1 mol dm^{-3}.

appears to have the same characteristic as the Cu(II) → Cu(I) reduction, i.e. a quasi-reversible process followed by a chemical reaction (in the scan rate range 20 mV s^{-1} to 5 V s^{-1}, the $i_{p(G)}/i_{p(D)}$ ratio increases from 0.4 to 0.8, ΔE_p increases from 70 to 150 mV, and the ratio $i_{p(D)}/v^{1/2}$ remains constant). These data indicate that the reduction of cobalt(II) to cobalt(I) leads to its decomplexation.

At a Pt electrode the voltammetric behaviour of the heterodinuclear complexes are quite different in both solvents, in particular for the cathodic reduction of the copper moiety. It appears as a totally irreversible process at a significantly more negative potential. In both solvents this step is followed by electrodeposition of copper metal.[37] The appearance of different responses at different electrode materials is not unusual, and can be attributed either to the occurrence of inner-sphere electrode mechanisms,[38] or to the formation of mercury-stabilized intermediates at the Hg electrode surface.[39]

Table 4 summarizes the electrochemical results obtained for compounds **I–VI**. We believe that the

[a] Potentials are measured against a s.c.e. $E' = 0.5(E_p^c + E_p^a)$ · E_p values refer to peak potentials at a scanning rate of 200 mV s^{-1}.

E values obtained by averaging the cathodic and anodic peak potentials provide a good approximation of the formal electrode potentials, albeit the experimental conditions prevented us reaching the $i_{p(c)}/i_{p(a)} = 1$ requirement. In those cases where, even at the highest scan rates, it was not possible to reveal the presence of a peak directly associated to a response in the reverse scan, the E_p value is given. To make the results comparable in the two solvents one may recall that for the nominally solvent independent ferrocene–ferrocenium couple[40] the E^o value is +0.38 V in MeCN and +0.44 V in dmso. Therefore, differences in potentials greater than 60 mV should be considered as the solvent effect.

The results given in Table 4 for the heterodinuclear compounds **I–III** show that the electrochemistry occurring at the second metal ion, M^{2+}, is well out of the redox activity at the copper site. More importantly, within experimental error, the Cu(II) → Cu(I) reduction potentials in these systems when measured with an Hg electrode are independent of the metal ion M^{2+}. This observation finds analogy to the reported electrochemical behaviour of some heterodinuclear macrocyclic complexes.[6(b)] In a previous study we reported[26] that in $[Cu_2L_2^2](ClO_4)_2 \cdot 2H_2O$ complex, the reduction of both the copper sites occurs at the same potential (−0.05 V) in dimethylformamide on an Hg electrode. In the present work we note that, although reduction of both the Co^{2+} ions occurs at the same potential (−1.54 V) in dmso for $[Co_2L_2^2]^{2+}$ species, in the case of dinickcl(II) and diamanganese(II) complexes irreversible reductions occur at two different potentials.

MONONUCLEAR RHENIUM(III) AND RHENIUM(II) COMPLEXES OF 1,2-BIS(DIPHENYLPHOSPHINO)ETHYLENE: THE STRUCTURE OF *TRANS*-$ReCl_2(dppee)_2$

MOHAMMED BAKIR, PHILLIP E. FANWICK and RICHARD A. WALTON*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 24 *July* 1986; *accepted* 1 *September* 1986)

Abstract—The mononuclear rhenium(III) complexes *trans*-$[ReX_2(dppee)_2]X \cdot nH_2O$ (X = Cl or Br, dppee = $Ph_2PCH{=}CHPPh_2$) have been prepared by the reaction of $(n\text{-}Bu_4N)_2Re_2X_8$ with dppee in methanol–conc. HX; in the case of X = Cl, ethanol may also be used as the reaction solvent. These salts undergo anion exchange reactions with ClO_4^- and/or PF_6^-. The rhenium(II) complex *trans*-$ReCl_2(dppee)_2$ can be prepared by the cobaltocene reduction of *trans*-$[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ and the reaction of $Re_2Cl_6(PBu^n_3)_2$ with dppee in refluxing ethanol. The spectroscopic and electrochemical properties of $[ReX_2(dppee)_2]^+$ have been investigated. Cyclic voltammetry (in 0.1 M tetra-*n*-butylammonium hexafluorophosphate–CH_2Cl_2 with a Pt-bead electrode) shows reversible redox processes at $E_{1/2}$(ox) *ca* +1.5 V, $E_{1/2}$(red) *ca* −0.2 V, and $E_{1/2}$(red) *ca* −1.4 V vs Ag–AgCl that correspond to the Re(IV)–Re(III), Re(III)–Re(II) and Re(II)–Re(I) couples, respectively. The single-crystal X-ray crystal structure of *trans*-$ReCl_2(dppee)_2$ has confirmed its octahedral geometry. This complex crystallizes in the monoclinic space group $P2_1/c$ with the following unit-cell dimensions: $a = 11.321(2)$ Å, $b = 13.011(2)$ Å, $c = 17.242(3)$ Å, $\beta = 95.79(2)°$, $V = 2527(1)$ Å^3, and $Z = 2$. The structure was refined to $R = 0.041$ ($R_w = 0.070$) for 2430 data with $F^2 > 3.0\sigma(F^2)$. The Re—Cl and Re—P distances are 2.422(2) and 2.405(2) Å, respectively.

A few instances are known where reactions of the quadruply bonded octahalodirhenate(III) anions $[Re_2X_8]^{2-}$ (X = Cl or Br) with phosphine ligands give rise to magnetically dilute rhenium(III) complexes rather than the more usually encountered multiply bonded dirhenium complexes that possess the Re_2^{6+}, Re_2^{5+} or Re_2^{4+} cores.[1,2] Examples include the di-μ-halo bridged complexes $Re_2(\mu\text{-}X)_2X_4(LL)_2$, where LL = $Ph_2PCH_2CH_2PPh_2$ or $Ph_2PCH_2CH_2AsPh_2$,[3–5] and $[ReCl_2(dppa)_2]PF_6$, where dppa = $Ph_2PNHPPh_2$.[6] In recent studies dealing with the synthesis and characterization of the α- and β-isomers of the triply bonded dirhenium(II) complexes $Re_2X_4(dppee)_2$ [dppee = 1,2-bis(diphenylphosphino)ethylene],[7] we have isolated salts of the mononuclear rhenium(III) cations $[ReX_2(dppee)_2]^+$ and the neutral rhenium(II) analogue *trans*-$ReCl_2(dppee)_2$. In this paper we describe the synthesis and properties of these complexes together with details of the crystal structure of the rhenium(II) complex, the latter species being a rare example of a neutral mononuclear compound containing this rather uncommon oxidation state.

EXPERIMENTAL

Starting materials

The following compounds were prepared by standard literature procedures: $(n\text{-}Bu_4N)_2Re_2X_8$ (X = Cl or Br)[8,9] and $Re_2Cl_6(PBu^n_3)_2$.[10] The *cis*-isomer of dppee was obtained from Strem Chemicals and used as received.

All reactions were carried out under a dry nitrogen atmosphere, and all solvents were deoxygenated by purging with N_2 gas for at least 15 min prior to use.

Syntheses

(*A*) $[ReX_2(dppee)_2]X$. (i) $[ReCl_2(dppee)_2]Cl \cdot nH_2O$. A mixture of $(n\text{-}Bu_4N)_2Re_2Cl_8$ (0.20 g,

* Author to whom correspondence should be addressed.

0.175 mmol), dppee (0.60 g, 1.51 mmol) and 10 cm^3 of methanol that contained 8 drops of conc. hydrochloric acid was refluxed for 22 h, cooled to room temperature and then filtered in air. The yellow filtrate was evaporated to dryness, the yellow solid recrystallized from CH_2Cl_2–diethyl ether, and the crystals washed with water, hexanes and diethyl ether, and then vacuum dried: yield 0.09 g (46%). Found: C, 53.8; H, 4.3. Calc. for $C_{52}H_{52}Cl_3O_4P_4Re$ (i.e. $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$): C, 54.0; H, 4.2%. The presence of water of crystallization was confirmed by IR spectroscopy (Nujol mull) which showed ν(OH) at 3295w and 3190w cm^{-1}, and an additional weak, sharp feature at *ca* 3660 cm^{-1}.

When the preceding reaction was carried out using ethanol as the reaction solvent in place of methanol–conc. HCl, work-up of the reaction filtrate gave the same product (based upon spectroscopic and electrochemical measurements) although it analysed closer to a dihydrate. Found: C, 55.3; H, 4.0. Calc. for $C_{52}H_{48}Cl_3O_2P_4Re$ (i.e. $[ReCl_2(dppee)_2]Cl \cdot 2H_2O$): C, 55.7; H, 4.3%. A conductivity measurement on an acetonitrile solution of this complex (1.5×10^{-4} M) showed that it behaved as a 1:1 electrolyte ($\Lambda_m = 167\ \Omega^{-1}\ cm^2\ mol^{-1}$).

Further proof as to the identity of these salts was provided by anion exchange reactions with KPF_6 and $NaClO_4$. A small quantity of $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ (0.10 g) was mixed with a three-fold excess of KPF_6 (0.05 g) and 10 cm^3 of methanol, and the mixture stirred at room temperature for 2 h. The bright yellow solid was filtered off, washed with methanol, hexanes and diethyl ether, and dried under vacuum: yield 0.095 g (86%). This product was identified on the basis of its spectroscopic and electrochemical properties; its IR spectrum (Nujol mull) showed the ν(P—F) mode of PF_6^- at *ca* 850s cm^{-1}. A similar synthetic procedure was used to prepare the related perchlorate salt: yield 90%. The IR spectrum (Nujol mull) of this orange-yellow solid showed ν(Cl—O) of ClO_4^- at 1090s cm^{-1}.

(ii) $[ReBr_2(dppee)_2]Br$. A mixture of $(n\text{-}Bu_4N)_2Re_2Br_8$ (0.10 g, 0.067 mmol), dppee (0.23 g, 0.580 mmol) and 10 cm^3 of methanol (to which eight drops of 48% hydrobromic acid had been added) was refluxed for 2 days, cooled to room temperature and filtered. The filtrate was allowed to evaporate slowly at room temperature to low volume (*ca* 2 cm^3) and the orange crystals that resulted were filtered off, washed with water, a small volume of methanol, hexanes and diethyl ether, and vacuum dried: yield 0.036 g (22%). Found: C, 50.5; H, 3.8; Br, 19.3. Calc. for $C_{52}H_{46}Br_3OP_4Re$ (i.e. $[ReBr_2(dppee)_2]Br \cdot H_2O$): C, 50.5; H, 3.75; Br, 19.4%. A solution of this complex in acetonitrile (1.0×10^{-3} M) had a conductivity typical of a 1:1 electrolyte ($\Lambda_m = 119\ \Omega^{-1}\ cm^2\ mol^{-1}$). Its IR spectrum (Nujol mull) showed ν(OH) at *ca* 3350w and *ca* 3200w cm^{-1}.

An exchange reaction with a methanol solution of KPF_6, similar to that described in A(i), gave the yellow salt $[ReBr_2(dppee)_2]PF_6$: yield 73%. Its IR spectrum (Nujol mull) showed the ν(P—F) mode of PF_6^- at 853s cm^{-1}.

(*B*) $ReCl_2(dppee)_2$. This complex was isolated by two different procedures. The yellow complex $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ (0.1 g, 0.086 mmol) was mixed with cobaltocene (0.03 g, 0.159 mmol) and this mixture stirred in 10 cm^3 of CH_2Cl_2 for 30 min at room temperature. The orange-yellow solid was filtered off, washed with CH_2Cl_2, water, methanol, hexanes and diethyl ether, and vacuum dried: yield 0.08 g (83%). Found: C, 54.3; H, 4.3; Cl, 16.5. Calc. for $C_{53.75}H_{47.5}Cl_{5.5}P_4Re$ (i.e. $ReCl_2(dppee)_2 \cdot 1.75CH_2Cl_2$): C, 53.9; H, 4.1; Cl, 16.3%. This reaction proceeded similarly when acetone was used as the reaction solvent, but in this instance gave a product that contained acetone of crystallization; IR spectrum (Nujol mull) with ν(C=O) at 1713m cm^{-1}.

This same complex was obtained as a by-product of the reaction between $Re_2Cl_6(PBu^n_3)_2$ (0.10 g, 0.10 mmol) and dppee (0.26 g, 0.656 mmol) in refluxing ethanol (10 cm^3) for 4 days. The yellow-green insoluble product was filtered off, washed with hexanes and diethyl ether, and dried. It was then washed with CH_2Cl_2 to leave insoluble orange-yellow $ReCl_2(dppee)_2$: yield *ca* 30%.

X-ray structure determination on $ReCl_2(dppee)_2$

A batch of $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ was dissolved in methanol and diethyl ether carefully layered over this solution. Diffusion afforded primarily yellow crystals of this rhenium(III) complex, together with a few orange-yellow crystals. The yellow crystals lost solvent of crystallization and were unsuitable for crystal structure analysis. The orange-yellow crystals proved to be those of the more interesting complex $ReCl_2(dppee)_2$ and were of a quality adequate for a single crystal X-ray structure analysis.

A single crystal of $ReCl_2(dppee)_2$ of dimensions $0.18 \times 0.14 \times 0.07$ mm was mechanically separated and mounted on a glass fiber with epoxy resin. The crystal was indexed, and data were collected on an Enraf–Nonius CAD 4 diffractometer, equipped with a graphite monochromator and a standard focus molybdenum X-ray tube. The crystal data and information relating to data collection and structure refinement are listed in Table 1. Further

[c] $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$.

[d] $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(F_o)$.

[e] Goodness of fit $= [\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

details of the crystal data collection and reduction methods are described elsewhere.[11]

The structure was refined in the monoclinic space group $P2_1/c$. Three standard reflections were monitored after every hour of beam exposure during data collection and displayed no systematic variation in intensity. The Re, P, Cl and C atoms were refined anisotropically. Hydrogen atoms were not included in the final least-squares refinement. The final residuals were $R = 0.041$ and $R_w = 0.070$ and the final-difference Fourier map displayed no peaks of chemical significance.

All calculations were performed on a PDP 11/34 computer using the Enraf–Nonius structure determination package. An empirical absorption correction was applied,[12] and the linear absorption coefficient was 26.99 cm^{-1}. The least-squares program minimized the function $w(|F_o| - |F_c|)^2$, where w is a weighting factor defined as $w = 1/\sigma^2(F_o)$. Corrections for anomalous dispersion were applied to all atoms. Further details of the data set and the structure solution and refinement may be obtained from Dr P. E. Fanwick. Table 2 lists selected intramolecular bond distances and angles. Tables listing atomic positional parameters (S1), thermal parameters (S2), a complete listing of bond distances (S3) and bond angles (S4) are available as supplementary material.

Physical measurements

IR spectra were recorded as Nujol mulls using IBM Instruments IR/32 and 9198 FTIR spectrometers for the regions 4000–400 and 400–200 cm^{-1}, respectively. Electronic absorption spectra were recorded as CH_2Cl_2 solutions on a HP8451A or IBM 9420 spectrophotometer and as Nujol mulls on the IBM 9420. Electrochemical measurements were made in CH_2Cl_2 containing tetra-*n*-butylammonium hexafluorophosphate (TBAH) as supporting electrolyte. $E_{1/2}$ values were determined as $(E_{p,a}+E_{p,c})/2$ and were referenced to the silver–silver chloride (Ag–AgCl) electrode at room temperature, and are uncorrected for junction potentials. Voltammetric experiments were performed using a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard model 7035 x–y recorder. Conductivity measurements were performed on acetonitrile solutions using an Industrial Instruments Inc. Model RC-16B2 conductivity bridge. Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

Synthesis and properties of $[ReX_2(dppee)_2]^+$ (X = Cl *or* Br) *and* $ReCl_2(dppee)_2$

The reaction of $(n\text{-}Bu_4N)_2Re_2X_8$ (X = Cl or Br) with the phosphine ligand $Ph_2PCH{=}CHPPh_2$ (abbreviated as dppee) in methanol–conc. HX or ethanol solution affords the yellow-orange mononuclear rhenium(III) species $[ReX_2(dppee)_2]X\cdot nH_2O$. These results provide further evidence as to the proclivity of bidentate phosphines to cleave the quadruple bond of the $[Re_2X_8]^{2-}$ anions to give six-coordinate magnetically dilute rhenium(III) complexes. This has previously been demonstrated in the case of the ligands $Ph_2PCH_2CH_2PPh_2$ (dppe) and $Ph_2PNHPPh_2$ (dppa) which have been found to produce $[ReX_2(dppe)_2]^+$ (X = Cl or Br),[13] $Re_2(\mu\text{-}Cl)_2Cl_4(dppe)_2$[3–5] and $[ReCl_2(dppa)_2]^+$[6] under certain conditions. The formulation of these complexes is supported by their conversion to the ClO_4^- and/or PF_6^- salts via simple anion exchange reactions with $NaClO_4$ and KPF_6, by their behavior as 1 : 1 electrolytes in acetonitrile solution, and by the close similarity of their electronic absorption spectra (see Table 3) to the related spectral data published pre-

Table 3. Cyclic voltammetric and electronic absorption spectra data for rhenium(III) complexes of dppee

Complex	Electronic absorption spectra[a] (nm)	Voltammetric half-wave potentials[b]		
		$E_{1/2}$(ox)	$E_{1/2}$(red)(1)	$E_{1/2}$(red)(2)
$[ReCl_2(dppee)_2]Cl\cdot 4H_2O$	455sh, 424 (2750)	+1.55	−0.22	−1.40
$[ReCl_2(dppee)_2]PF_6$	455sh, 424 (2610)	+1.55	−0.24	−1.40
$[ReCl_2(dppee)_2]ClO_4$	455sh, 424 (2990) ~480sh, 428[c]	+1.58	−0.22	−1.40
$[ReBr_2(dppee)_2]Br\cdot H_2O$	450 (5170) 510sh, 460[c]	+1.53	−0.12	−1.26

[a] Recorded in CH_2Cl_2 solutions (unless otherwise stated) in the region 900–350 nm: ε_{max} values are given in parentheses.

[b] In V (Ag–AgCl). Recorded on solutions in 0.1 M TBAH–CH_2Cl_2 using a Pt-bead electrode. Data obtained at $v = 200$ mV s^{-1}.

[c] Nujol mull spectrum.

viously for $[ReX_2(dppe)_2]X$ (X = Cl or Br),[13] $[ReCl_2(dppa)_2]PF_6$[6] and *trans*-$[ReCl_2(dmpe)_2]Cl$ (dmpe = $Me_2PCH_2CH_2PMe_2$);[14] for example, λ_{max} values for a solution of $[ReCl_2(dppa)_2]Cl$ in CH_2Cl_2 are 470 (ε = 1800) and 425 (ε = 2500) nm.[6]

Of the compounds isolated in the present study only $[ReCl_2(dppee)_2]Cl$ has been reported previously.[15,16] In the previous partial characterization of this compound, which has been formulated as the *trans*-isomer,[16] it was found to have a solid-state magnetic moment of 2.0 BM. In the present study we find that the hydrate has μ_{eff} = 2.3 BM for a solution in CH_2Cl_2.[17] The low-frequency IR spectrum (Nujol mull) of a sample of $[ReCl_2(dppee)_2]PF_6$ shows a single ν(Re—Cl) mode at 338s cm^{-1} which supports its assignment as the *trans*-isomer; similar results have been reported previously for *trans*-$[ReCl_2(dppa)_2]PF_6$ [ν(Re—Cl) at 333 cm^{-1}][6] and *trans*-$[ReCl_2(dmpe)_2]Cl$ [ν(Re—Cl) at 315 cm^{-1}].[14]

The close relationship between these dppee complexes is revealed by cyclic voltammetric measurements on solutions in 0.1 M TBAH–CH_2Cl_2 (see Fig. 1). The $E_{1/2}$ values (vs Ag–AgCl) for the processes that are assigned to the Re(IV)–Re(III), Re(III)–Re(II) and Re(II)–Re(I) couples are listed in Table 3. In the case of $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ and $[ReBr_2(dppee)_2]Br \cdot H_2O$, irreversible processes associated with the oxidation of the outer-sphere halide ion are seen at $E_{p,a}$ = +1.13 V (for Cl^-), and $E_{p,a}$ = +0.85 and +1.05 V (for Br^-) vs Ag–AgCl. For the metal-based couples we find that the $i_{p,a}/i_{p,c}$ ratios are close to unity. The values of $E_{p,a} - E_{p,c}$ are *ca* 100 mV at scan rate (ν) = 200 mV s^{-1}, and increased slightly with an increase in sweep rate. These properties are (with our cell configuration) and this solvent system consistent with electron transfer processes that approach reversibility.[18] These electrochemical redox properties are very similar to those exhibited by the previously characterized complex $[ReCl_2(dppa)_2]PF_6$.[6] Using a sample available from our earlier study, we find that a solution of this complex in 0.1 M TBAH–CH_2Cl_2 displays processes at $E_{p,a}$ = +1.38 V, $E_{1/2}$(red)(1) = −0.22 V, and $E_{1/2}$(red)(2) = −1.61 V vs Ag–AgCl. Cyclic voltammetric measurements on 0.5 M *n*-Bu_4NClO_4–DMF solutions of *trans*-$[ReCl_2(dmpe)_2]Cl$ have established[14] that the Re(III)–Re(II) and Re(II)–Re(I) couples occur at −0.398 and −1.548 V vs Ag–AgCl, respectively.

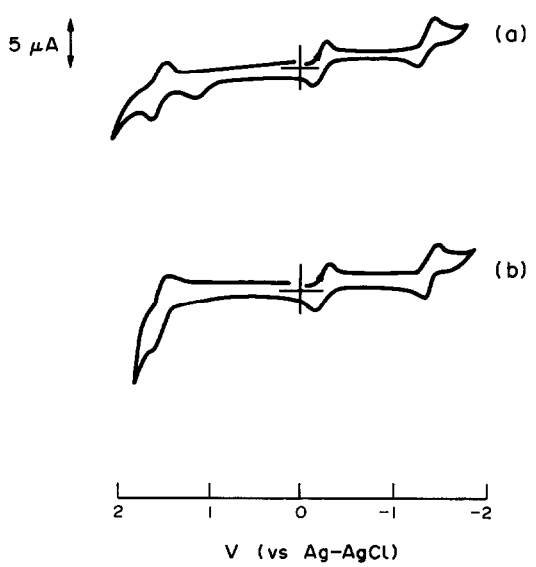

Fig. 1. Cyclic voltammograms (recorded at ν = 200 mV s^{-1} using a Pt-bead electrode) for 0.1 M TBAH–CH_2Cl_2 solutions of: (a) $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$, and (b) $[ReCl_2(dppee)_2]ClO_4$.

In the case of $[ReCl_2(dppee)_2]Cl \cdot xH_2O$, the accessibility of the Re(III)–Re(II) couple has been demonstrated by its chemical reduction to $ReCl_2(dppee)_2$ using cobaltocene dissolved in CH_2Cl_2 or acetone. This rhenium(II) complex has also been isolated as one of the products of the reaction between $Re_2Cl_6(PBu^n_3)_2$ and dppee in refluxing ethanol and was obtained, in single-crystal form, as a minor contaminant in batches of crystalline $[ReCl_2(dppee)_2]Cl \cdot nH_2O$. It is not very soluble in polar and nonpolar solvents although it was sufficiently soluble in 0.1 M TBAH–CH_2Cl_2 to show that it displayed similar cyclic voltammetric behavior to that of $[ReCl_2(dppee)_2]Cl \cdot nH_2O$, with the exception that the process at *ca* −0.2 V now corresponds to an oxidation of the bulk complex and the wave ($E_{p,a}$ = +1.13 V) due to free Cl^- is no longer present. The electronic absorption spectrum of $ReCl_2(dppee)_2$ recorded as a Nujol mull shows λ_{max} at 398 nm as the most intense lower-energy feature.

Structural characterization of trans-$ReCl_2(dppee)_2$

The correspondence between the cyclic voltammetric behavior of $[ReCl_2(dppee)_2]Cl \cdot nH_2O$ and $ReCl_2(dppee)_2$ implies that no isomerization process follows this one-electron redox change, i.e. that both species possess a *trans*octahedral structure. This has been confirmed by a single-crystal X-ray structure analysis of a sample of $ReCl_2(dppee)_2$ that was found, by chance, to be present in a batch of crystalline $[ReCl_2(dppee)_2]Cl \cdot 4H_2O$ (see Experimental).

An ORTEP view of the $ReCl_2(dppee)_2$ molecule is shown in Fig. 2. The crystallographic data are contained in Table 1, while Table 2 lists the key

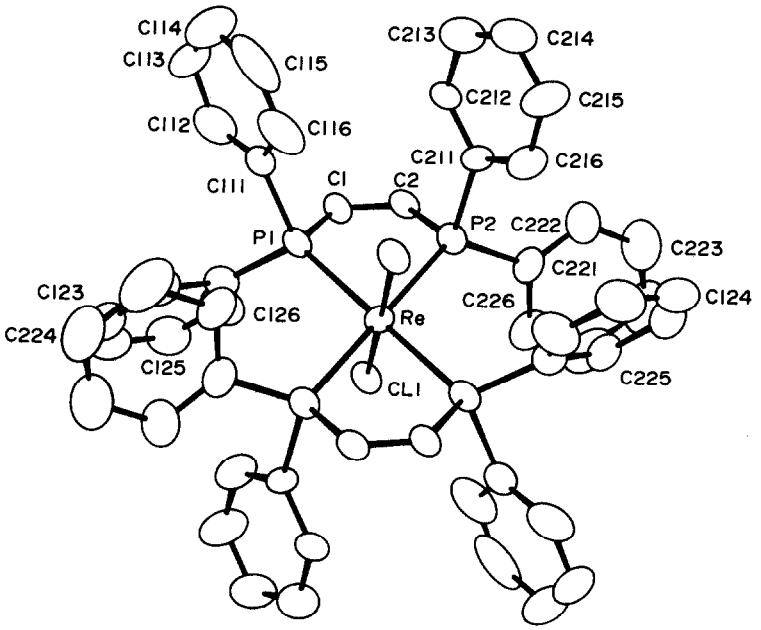

Fig. 2. ORTEP representation of $ReCl_2(dppee)_2$ in which atoms are given as their 50% probability ellipsoids. Unlabeled Cl, P and C atoms are related to the corresponding labeled atoms by an inversion center.

bond distances and angles.* The structure is clearly that of the *trans*-isomer as had been inferred from the previously discussed electrochemical data. The complex contains two chelating dppee ligands in which the C(1)—C(2) bond distance [1.36(1) Å] remains that of a typical C=C bond which is uncoordinated to a metal center. The Re—P distances [2.405(2) Å] are a little shorter than those found for the rhenium(III) complex *trans*-$[ReCl_2(dmpe)_2]Cl$ [2.438(2) Å];[14] this may reflect a slight shortening due to some small measure of Re-to-P π-bonding in the case of the rhenium(II) complex $ReCl_2(dppee)_2$. It is difficult to make informative comparisons with Re—P distances in dirhenium(II) complexes of the type $Re_2X_4(LL)_2$ (X = halide, LL = bidentate phosphine), since even in the cases where the ligands LL are chelating, e.g. α-$Re_2Cl_4(dmpe)_2$[19] and α-$Re_2Cl_4(dppp)_2$ [dppp = $Ph_2P(CH_2)_3PPh_2$],[20] these bond lengths show considerable variability [2.337(2) and 2.401(2) Å in these two instances]. The Re—Cl distance of 2.422(2) Å is, as expected, significantly longer than the comparable distance in the *trans*-$[ReCl_2(dmpe)_2]^+$ cation [2.337(1) Å]. While the Cl—Re—Cl unit is perfectly linear, some distortion in the equatorial ReP_4 plane is reflected by the range of Cl—Re—P angles that are observed (80–99°); this clearly reflects the conformational demands of the Re—P—CH=CH—P chelate rings.

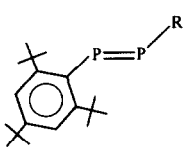
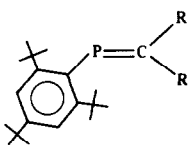
(*Received* 7 *July* 1986; *accepted* 1 *September* 1986)

Abstract—The crystal and molecular structures of two bulky phosphines containing the 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$ group are reported. Compound **1**, [2,4,6-(*t*-Bu)$_3$C$_6$H$_2$P(SiMe$_3$)$_2$], crystallizes in the monoclinic space group $P2_1/c$; $a = 9.450(8)$, $b = 17.154(6)$, $c = 17.790(5)$ Å, $\beta = 101.19(5)°$. *Compound* **2**, [2,4,6-(*t*-Bu)$_3$C$_6$H$_2$POCH$_2$CH$_2$O], also crystallizes in the monoclinic space group $P2_1/c$: $a = 18.224(5)$, $b = 9.394(2)$, $c = 12.321(2)$ Å, $\beta = 107.28(2)°$. Structural features resulting as a consequence of the bulky 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$ group, in particular the geometry at phosphorus, are discussed.

There is currently considerable interest in phosphorus compounds containing the 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$ group, since, by virtue of its large steric bulk, a range of unusual low-coordinate complexes may be stabilized. Examples of two-coordinate phosphorus include diphosphenes (**A**)[1] and



A



B

phospha-alkenes (**B**),[2] whilst many novel three-coordinate species have also been isolated such as the dithio- and methyleneoxophosphoranes (**C**[3] and **D**[4]). In addition, this degree of steric protection has enabled compounds such as primary phosphine sulphides and oxides (**E** and **F**)[5] and RP(H)(halogen) type phosphines (**G**)[6] to be prepared and characterized. Herein we report the structural characterization of two phosphines containing the 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$ group: [2,4,6-(*t*-Bu)$_3$C$_6$H$_2$P(SiMe$_3$)$_2$] (**1**) and [2,4,6-(*t*-Bu)$_3$C$_6$H$_2$POCH$_2$CH$_2$O] (**2**).

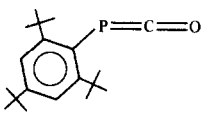
RESULTS AND DISCUSSION

The bis(trimethylsilyl)-substituted phosphine (**1**) can be prepared by sequential lithiation and silylation of the primary phosphine, 2,4,6-(t-Bu)$_3$C$_6$H$_2$PH$_2$, and is a key intermediate in the synthesis of the only known, stable phosphaketene (**3**) reported by Appel and Paulen[7,8] via its reaction



3

with phosgene ($COCl_2$). However, the apparent unreactivity of **1** towards other main-group element dichlorides, for example R_2SiCl_2[9] *vis-à-vis* phosphasilene synthesis,[10] was indicative of severe steric congestion at the phosphorus centre. In order to probe this hypothesis further, an X-ray crystal structure determination of **1** was undertaken. The results are shown in Fig. 1 whilst pertinent bond distance and angle data are collected in Table 1.

Examination of Fig. 1 reveals that the phosphorus centre is indeed sterically well-shielded both by the *ortho* t-Bu and Me$_3$Si groups. Most notable, however, is the geometry at phosphorus. The sum of angles at phosphorus [343.2(1)°] indicates a close-to-planar configuration, although this is somewhat distorted from an idealized (albeit rather flattened) trigonal pyramid as evidenced by the widely disparate C(1)—P(1)—Si bond angles [C(1)—P(1)—Si(1) = 127.0(1) and C(1)—P(1)—Si(2) = 105.2(1)°]. One factor which may contribute to a flattened geometry at phosphorus is partial delocalization of the P lone pair into vacant silicon 3d orbitals. However, the P—Si bond lengths [P(1)—Si(1) = 2.238(1) and P(1)—Si(2) = 2.255(1) Å] are in accord with a single-bond value predicted from the sum of the covalent radii of P and Si, i.e. 2.23 Å. There is therefore no evidence for P → Si π-donation. We suggest that the primary factor responsible for both the above observations is intramolecular steric congestion.

Table 1. Selected bond distances (Å) and angles (°) for **1**

Bond distances	
P(1)—Si(1)	2.238(1)[a]
P(1)—Si(2)	2.255(1)
P(1)—C(1)	1.844(3)
Bond angles	
Si(1)—P(1)—Si(2)	111.03(6)
Si(1)—P(1)—C(1)	127.0(1)
Si(2)—P(1)—C(1)	105.2(1)

[a] Numbers in parentheses are estimated standard deviations in the least significant digit.

The use of models indicates that the observed conformation about the P(1)—C(1) bond is the only one that is sterically tenable in that it minimizes close contacts between the Me$_3$Si and *ortho* t-Bu groups. Moreover these contacts are further reduced by a flattening of the geometry at phosphorus. The reason for the asymmetry in the angles

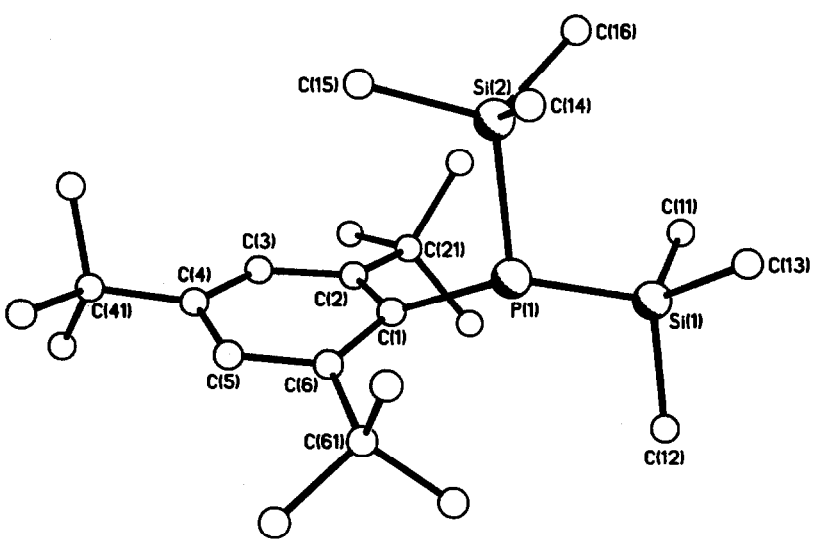


Fig. 1. Molecular structure of **1** showing the atom-numbering scheme. Hydrogen atoms omitted for clarity.

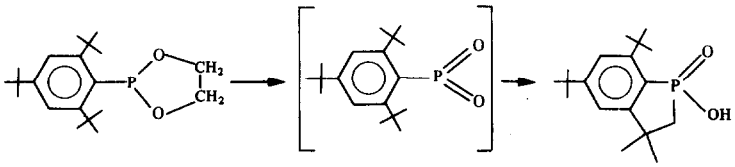
at phosphorus is less clear but is probably also steric in origin. It is possibly associated with the observation that the phosphorus atom is significantly out of the arene ring mean plane (0.85 Å), a factor which has been noted previously in phosphorus compounds containing this arene group[11] and discussed in terms of the large intramolecular strain associated with the *t*-Bu groups.

The synthesis of **2** was mentioned previously in a communication.[12] However, here we provide details of the synthesis. Under flash vacuum pyrolysis conditions, the phosphonite (**2**) eliminates ethene to produce the phosphinate (**4**) *via* a proposed dioxophosphorane intermediate (**5**).[12]



2 **5** **4**

The molecular structure of **2** is illustrated in Fig. 2 and selected bond distances and angles are collected in Table 2. In contrast to **1**, the geometry at phosphorus is markedly pyramidal [sum of angles = 291.4(1)°]. While this is undoubtedly due to the constraint imposed by incorporation into the PO_2C_2 ring, the assymetry in the C(1)—P(1)—O bond angles is considerably less than that for the corresponding C(1)—P(1)—Si angles in **1** [C(1)—P(1)—O(1) = 100.7(1), C(1)—P(1)—O(2) = 97.8(1)°]. Since the $O_2(CH_2)_2$ group in **2** is much smaller than the two Me_3Si groups in **1**, this supports the contention that the asymmetry in **1** is steric in origin. Note, however, that, in **2**, the phosphorus atom is also significantly removed from the arene ring mean plane (0.82 Å). Further structural and synthetic studies on phosphorus compounds containing this bulky arene are in progress.

EXPERIMENTAL

Synthesis

All manipulations were performed under a dry nitrogen atmosphere employing standard inert atmosphere techniques. All solvents were dried prior to use.

[2,4,6-(*t*-Bu)$_3$C$_6$H$_2$P(SiMe$_3$)$_2$] (**1**). This compound was prepared according to the method of Appel and Paulen.[7,8]

[2,4,6-(*t*-Bu)$_3$C$_6$H$_2$POCH$_2$CH$_2$O] (**2**). A THF solution (80 cm^3) of Li[2,4,6-(*t*-Bu)$_3$C$_6$H$_2$][13] (5.0 g, 20 mmol) was added dropwise to an Et_2O solution (20 cm^3) of 2-chloro-1,3,2-dioxaphospholane[14] (2.66 g, 21 mmol) at 0°C. After stirring the reaction mixture for an additional 12 h at room temperature, the solvents were removed *in vacuo*, and the residue extracted with *n*-hexane. Filtration followed by sol-

vent stripping afforded crude **2** which was purified by recrystallization from Et_2O. Yield of white, crystalline **2** = 5.3 g (79%), m.p. 76–78°C. The $^{31}P-\{^1H\}$ NMR spectrum of **2** (32.384 MHz) comprised a singlet at δ +169.

X-ray studies

General operating procedures and listings of programs used in the crystallographic studies reported herein have been given previously.[15] Crystal data for the structures of **1** and **2** are presented in Table 3.

Suitable single colourless crystals of **1** and **2** were mounted on an Enraf–Nonius CAD4-F diffractometer. Initial lattice parameters were determined from a least-squares fit to 25 accurately centred reflections, $15 \leqslant 2\theta \leqslant 20°$, and subsequently refined using higher-angle data. These indicated a monoclinic lattice for which data were collected for one independent quadrant, $+h+k\pm l$. Systematic absences observed were $0k0$ absent for k odd and $h0l$ absent for l odd, thus uniquely determining the space group as $P2_1/c$ (No. 14).

Data were corrected for the effects of Lorentz, polarization and decay, but not for absorption. Both structures were solved by direct methods using MULTAN[16] which revealed the location of most non-hydrogen atoms. All others were revealed by subsequent difference Fourier analysis and refined by full-matrix least squares with anisotropic thermal parameters. Hydrogen atoms were placed in calculated positions 0.95 Å from their respective carbon atoms, and were included in the structure factor calculation. Final refinements converged smoothly and revealed no chemically significant peaks in the final-difference map.

SOME TRANSITION METAL COMPLEXES OF NEW TERDENTATE LIGANDS: BIS[2-(DIPHENYLPHOSPHINO)ETHYL]BENZYLAMINE AND BIS[2-(DIPHENYLARSINO)ETHYL)BENZYLAMINE

M. M. TAQUI KHAN,* V. VIJAY SEN REDDY and H. C. BAJAJ

Discipline of Coordination Chemistry and Homogeneous Catalysis, Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, Gujarat, India

(*Received* 29 *April* 1986; *accepted* 4 *September* 1986)

Abstract—Complexes of the terdentate ligands bis[2-diphenylphosphino)ethyl]benzylamine (DPBA) and bis[2-(diphenylarsino)ethyl]benzylamine (DABA) with Co(II), Ni(II), Pd(II), Pt(II), Rh(III), Ir(III), Rh(I) and Ir(I) are reported. The ligand DPBA reacts with Co(II) ion to form two types of complexes: a high-spin, paramagnetic, tetrahedral Co(II) complex of composition [CoCl(DPBA)]Cl and a low-spin, paramagnetic, square-planar complex of composition [CoBr(DPBA)]$B(C_6H_5)_4$. The reaction of DPBA with Ni(II) ion in methanol yields low-spin, diamagnetic, square-planar complexes of type [NiX(DPBA)]Y [X = Cl, Br or I; Y = Cl or $B(C_6H_5)_4$]. Four-coordinate, square-planar, cationic complexes of type $[MY(L)]^+$ [M = Pd(II), Pt(II), Rh(I) or Ir(I); Y = Cl or $P(C_6H_5)_3$; L = DPBA or DABA], were obtained on reaction of L with various starting materials containing these metal ions. Reaction of DPBA and DABA with rhodium and iridium trichlorides gave octahedral, neutral complexes of general formula $[MCl_3(L)]$ (M = Rh or Ir, L = DPBA or DABA). All the complexes were characterized on the basis of their elemental analysis, molar-conductance data, magnetic susceptibilities, electronic spectra, IR spectral measurements, and ^1H and $^{31}P-\{^1H\}$ NMR spectral data.

During the past few years, transition metal complexes of tertiary phosphines and arsines have been studied extensively, because of their chemistry and utility as catalysts in a number of reactions.[1,2] The chemistry of the metal complexes is governed[3–13] by the electronic and steric properties of the ligands and the oxidation state and coordination number of the metal ion.

The metal complexes of mixed donor ligands containing N, P, As and O have also gained considerable importance due to their catalytic activity in various homogeneous reactions.[14–16]

In our earlier communication[17] we reported the synthesis of two new terdentate ligands containing N and P or As as donor atoms, bis[2-(diphenylphosphino)ethyl]benzylamine (DPBA) and bis [2-(diphenylarsino)ethyl]benzylamine(DABA) and their complexes with Ru(II) and (III). These ligands which have a hard donor amino group confer the necessary nucleophilicity and the soft donor phosphino or arsino groups stabilize the low-valent metal centers. Both of these properties are very important in homogeneous catalytic reactions.[18,19]

In the present paper the synthesis and characterization of complexes of Co(II), Ni(II), Pd(II), Pt(II), Rh(III), Ir(III), Rh(I) and Ir(I) with the ligands DPBA and DABA are reported.

RESULTS AND DISCUSSION

Reaction of the ligand DPBA with cobalt(II) salt in a 1:1 ratio in methanol gave stable, paramagnetic, tetracoordinate complexes of formulation [CoX(DPBA)]Y [X = Cl, Y = Cl(**1**); X = Br, Y = $B(C_6H_5)_4$(**2**)]. The molar-conductance values (Table 1) of complexes **1** and **2** are indicative of 1:1 electrolytes,[20] suggesting a four-coordinate geometry for Co(II) in these complexes.

The far-IR spectrum of complexes **1** and **2** exhibit intense bands at 310 and 265 cm^{-1}, respectively, for

ν(Co—Cl) and ν(Co—Br) stretching frequencies, respectively, supporting the above formulation. The band at 540 cm^{-1} in both complexes **1** and **2** can be assigned to the ν(Co—P) frequency. From the conductivity and far-IR data, it can be proposed that all the three donor atoms of the ligand DPBA are coordinated to the metal ion with one of the halides inside the coordination sphere of the metal ion. This is in contrast to the earlier observation made by Sacconi and Morassi[10] on complexes containing similar ligands.

The ^{31}P–$\{^1H\}$ NMR spectra (Table 2) of complexes **1** and **2** exhibit resonances at 40.38 and 33.18 ppm, respectively, indicating that the two ends of the coordinated phosphorus atoms of DPBA are magnetically equivalent. The downfield coordination chemical shift in both the complexes is considerable compared to the free ligand (Table 2).

The electronic spectrum of **1** in dichloromethane is consistent with a tetrahedral structure. The band in the visible region at 629 nm is assigned[10,21,22] to the $^4A_2(F) \rightarrow {}^4T_1(P)$ (ν_3) transition. This band is further split into a number of components, indicating the presence of considerable deviation from T_d-symmetry. The fine structure is caused[23] by spin–orbit coupling which both splits the $^4T_1(P)$ state and allows the transitions to the neighboring doublet states to gain some intensity. The magnetic moment (Table 1) also corroborates a tetrahedral, Co(II) complex, with paramagnetism near to the spin-only value.[24,25] Complex **1** is therefore a tetrahedral Co(II) species.

The electronic spectrum of **2** in dichloromethane in the visible region shows only a broad band at 500 nm. The magnetic moment of 2.51 BM suggests **2** to be a low-spin Co(II) complex with considerable spin–orbital contribution. Taking the magnetic moment and the colour of the complex into consideration, complex **2** can be tentatively assigned a square-planar geometry with two ends of the phosphorus atoms *trans* to each other.

Reaction of DPBA with Ni(II) halides gave diamagnetic, cationic complexes of formulation $[NiX(DPBA)]^+$ [X = Cl (**3**), Br (**4**) or I (**5**)], best isolated as tetraphenyl borate complexes. Complexes **3–5** are air-stable and behave as 1 : 1 electrolytes[20] in acetone (Table 1), indicating a four-coordinate geometry for Ni(II). The far-IR spectra show bands due to ν(Ni—X) (X = Cl, Br or I) frequencies at 340, 255 and 250 cm^{-1} in complexes **3–5**, respectively, suggesting the presence of one halide group inside the coordination sphere of the metal ion and the coordination of all the donor atoms of the ligand DPBA to the metal ion. The far-IR spectra of complexes **3–5** also show ν(Ni—P) stretching frequencies at 535, 510 and 500 cm^{-1}, respectively.

The ^{31}P–$[^1H]$ NMR spectra (Table 2) of complexes **3–5** show sharp singlets at 22.10, 26.76 and 35.84 ppm, respectively, with a considerable downfield shift upon coordination of DPBA to form five-membered rings, indicating the magnetic equivalency of the two *trans* phosphorus atoms of the ligand DPBA. The downfield shift decreases in the order I > Br > Cl, in line with the decreasing po-

[a] Positive chemical shifts downfield from 85% H_3PO_4.
[b] s = singlet, d = doublet, t = triplet.

larizability of the coordinated halide ions. This unusual downfield shift may be explained on the basis of the increased π-acidity of the coordinated halide group in passing through Cl to I. Because of the increased π-acidity of coordinated halide the σ-basicity of the coordinated phosphine increases due to a synergic effect causing an increase in the downfield shift with an increase in the π-acidity of the halogen.

The electronic spectra of complexes **3–5** in dichloromethane contain a single strong band at 490 nm (20,408 cm^{-1}), 505 nm (19,802 cm^{-1}) and 540 nm (18,518 cm^{-1}), respectively, in the visible region. This absorption refers to transitions which have *d*-orbital character $d_{xy} - d_{x^2-y^2}$, and confirms the square-planar geometry of the complexes.[26,27] The energy of the band increases in the order $I^- < Br^- < Cl^-$ as expected from the spectrochemical series for the halides. Complexes **3–5** are thus square-planar and analogous to the complexes with the ligands bis(2-diphenylphosphinoethyl)sulphide[28] and bis(2-diphenylphosphinoethyl)cyclohexylamine[10] with a *trans* arrangement of the phosphorus atoms.

Complex **6** is hygroscopic and behaves as a 1 : 1 electrolyte in acetone (Table 1). The far-IR spectrum shows bands at 310 and 540 cm^{-1}, which can be assigned to ν(Ni—Cl) and ν(Ni—P) stretching frequencies. Complex **6** displays an electronic spectrum identical to that of complex **3**, due to the presence of the same cationic species, $[NiCl(DPBA)]^+$, being present in both complexes. The complex shows a band at *ca* 20,000 cm^{-1}, which is characteristic of a square-planar geometry. The geometry assigned to complex **6** is similar to that of complex **3**.

The terdentate ligand DABA failed to react with Co(II) and Ni(II) metal salts.

Reactions of DPBA and DABA with palladium dichloride in a 1 : 1 mole ratio in methanol gave cationic species of the formulation $[PdClL]^+$ [L = DPBA (**7**) or DABA (**8**)], best isolated as tetraphenyl borate salts. The complexes have conductance values in accord with the presence of a 1 : 1 electrolyte (Table 1). The far-IR spectra of **7** and **8** exhibit ν(Pd—Cl) frequencies at 345 and 330 cm^{-1}, respectively. Bands at 545 and 470 cm^{-1} are due to stretching modes of ν(Pd—P) and ν(Pd—As), respectively.

The $^{31}P-\{^1H\}$ NMR spectrum (Table 2) of complex **7** exhibits a single resonance at 32.23 ppm, indicating the magnetic equivalence of the two phosphorus ends of the ligand DPBA and also suggests a square-planar geometry for the complex with phosphorus atoms *trans* to each other. Based on the above data, complexes **7** and **8** can be assigned a square-planar geometry similar to other known Pd(II) complexes,[7,29] with mono- and terdentate tertiary phosphine ligands. The electronic spectral data of complexes **7** and **8** are discussed along with complexes **9** and **10**.

Treatment of K_2PtCl_4 with DPBA and DABA in a 1 : 1 mole ratio gave four-coordinate, cationic complexes of type $[PtClL]^+$ [L = DPBA (**9**) or DABA (**10**)]. These complexes appear to be square-planar, analogous to the other known complexes of similar type of tridentate ligands reported earlier.[7] Both the complexes exhibit molar conductance values in accord with their formulation as 1 : 1 electrolytes (Table 1).

The far-IR spectra of **9** and **10** show peaks at 330 and 318 cm^{-1}, respectively, corresponding to the ν(Pt—Cl) stretching frequency.[30] The strong peaks at 520 and 470 cm^{-1} in **9** and **10** are due to ν(Pt—P) and ν(Pt—As) vibrational modes, respectively.

The electronic spectra of complexes **7–10** are consistent with a square-planar geometry of the complexes. Complexes of Pd(II) and Pt(II) which are pale yellow and creamish white, respectively, show the bands characteristic of *d–d* transition of square-planar cations. Complex **7** exhibits a band at 341 nm (29,326 cm^{-1}), whereas complex **8** shows a shoulder at 360 nm (27,778 cm^{-1}). Similarly, complexes **9** and **10** exhibit bands at 322 nm (31,056 cm^{-1}) and 359 nm (27,855 cm^{-1}) respectively. The molar extinction coefficient values are slightly higher than the conventional values for *d–d* transitions due to the LMCT character of these bands. A comparison of the energies of the lowest-energy *d–d* band in the corresponding complexes of DPBA and DABA showed that the expected spectrochemical order is observed, i.e. the bands in the DABA complexes are shifted to a lower energy compared to the DPBA ligand, as envisaged from ligand field considerations whenever a phosphorus donor is replaced by an arsenic donor.[31] Comparison of the electronic spectra of complexes **3**, **7** and **9** show that as the size of the metal ion increases in the triad Ni < Pd < Pt the lowest-energy *d–d* transition decreases in the order Pt > Pd > Ni. This hypsochromic shift to larger wavenumbers is due to the increase in the covalency of the complexes because of the increase in the size of the *d*-orbitals of the metal ions. Such a higher degree of metal–ligand bonding can be established in square complexes, by means of the non bonding d_{xz}, d_{yz} and p_z orbitals. The intense bands in all the complexes, around 250 nm can be assigned to the π–π^* transitions of the phenyl rings.

The $^{31}P-\{^1H\}$ NMR spectrum of complex **9** exhibits a singlet (with ^{195}Pt satellites) at 28.16 ppm. The platinum–phosphorus coupling constant was calculated from its ^{195}Pt satellites. The spectrum

shows the two-coordinated phosphorus ends of the DPBA ligand are magnetically equivalent and *trans* to each other confirming the above formulation. A ^1J(Pt–P) coupling constant value of 2722.16 Hz has been observed for complex **9**, which is appreciably higher when compared to those of earlier reports for similar phosphorus atoms *trans* to other phosphorus atoms in square-planar Pt(II) complexes[32] of types *trans*-L_2PtCl_2 and $[L_3PtCl]^+$ [$L = R_n(C_6H_5)_{3-n}P$, where $n = 1$, 2 or 3, and R = alkyl]. It has been reported in these complexes that the coupling constant value increases in every case in both the *cis* and *trans* series in going from trialkyl- to dialkylphenyl-, and to the alkyldiphenylphosphines. This corresponds to the increasing π-acceptor character of the phosphines as the number of phenyls on the phosphorus increases. Thus, the high coupling constant of complex **9** can be ascribed to the increased $d\pi$–$d\pi$ bonding between P and Pt due to the presence of phenyl groups on the two phosphorus atoms.

The reaction of rhodium trichloride with the ligands DPBA and DABA in 1 : 1 mole ratios in boiling methanol gave diamagnetic, yellow Rh(III) complexes of formulation $[RhCl_3L]$ [L = DPBA (**11**) or DABA (**12**)]. Complexes **11** and **12** have low molar-conductivity values in DMF solutions[20] (Table 1), indicating the nonelectrolytic nature of the complexes. Hence, an octahedral geometry has been assigned to complexes **11** and **12**. Such complexes can exist as facial or meridional isomers. The far-IR spectrum of **11** shows bands due to ν(Rh—Cl) stretching frequencies at 316, 295 and 262 cm^{-1}, whereas complex **12** exhibits ν(Rh—Cl) frequencies at 312, 293 and 281 cm^{-1}. These frequencies are in much closer agreement with the ν(Rh—Cl) frequencies for a facial type of isomer.[6,7,33] The far-IR spectra of **11** and **12** also show bands due to ν(Rh—P) and ν(Rh—As) frequencies at 540 and 480 cm^{-1}, respectively.

The ^{31}P–$\{^1H\}$ NMR spectrum of complex **11** shows a doublet centered at 35.20 ppm, with ^1J(Rh–P) = 119.6 Hz, suggesting the magnetic equivalence of the two phosphorus ends of the ligand DPBA.

The electronic spectra of complexes **11** and **12** show bands at 411 nm (24,331 cm^{-1}), 429 nm (23,310 cm^{-1}) and 377(sh) nm (26,525 cm^{-1}), respectively, in conformity with an octahedral Rh(III) species.[34] These *d–d* bands with LMCT character can be assigned to the transitions from the $^1A_{1g}$ ground state to the $^1T_{1g}$ and $^1T_{2g}$ upper states. The intense bands in the UV region can be assigned to the π–π^* transitions and LMCT bands. A facial configuration with *cis* phosphorus or arsenic atoms of the ligands is proposed for complexes **11** and **12**.

Treatment of hydrated iridium trichloride with DPBA and DABA in methanol gave neutral, octahedral complexes of type $[IrCl_3L]$ [L = DPBA (**13**) or DABA (**14**)]. Both the complexes exhibit very low conductance values (Table 1) in DMSO, indicative of a non-ionic nature of the complexes. Hence, they appear to be octahedral, iridium(III) complexes with the ligands occupying three coordination positions. Here also, such complexes can exist either in facial or meridional configurations.

The far-IR spectra of both the complexes show a broad intense signal at 320 cm^{-1} due to ν(Ir—Cl) mode. Peaks at 510 and 475 cm^{-1} in **13** and **14** can be assigned to ν(Ir—P) and ν(Ir—As) frequencies, respectively.

The ^{31}P–$\{^1H\}$ NMR spectrum of complex **13** exhibits a single peak at 29.31 ppm, confirming the equivalency of the phosphorus atoms of the ligand DPBA.

Due to solubility reasons, the electronic spectra of concentrated solutions of **13** and **14** could not be taken.

A meridional configuration or a facial configuration of the ligands is proposed for **13** and **14**.

Square-planar, cationic complexes of type $[Rh(PPh_3)L]^+$ [L = DPBA (**15**) or DABA (**16**)] were synthesized by reacting the Rh(I) complex $RhCl(CO)(PPh_3)_2$ with the ligands DPBA and DABA, respectively. The reaction in boiling acetone or methanol resulted in displacement of one of the coordinated triphenylphosphine groups and carbon monoxide from the starting complex, to give diamagnetic complexes of the above formulation. The molar-conductance values (Table 1) of both the complexes are in accord with their formulation as 1 : 1 electrolytes. The far-IR spectra of the complexes do not show any band around 300 cm^{-1}, indicating the total absence of the chloride ion inside the coordination sphere of the metal ion. Both the complexes show bands characteristic of a ν(Rh—P) stretch, due to the coordinated PPh_3 at 510 cm^{-1}. The complexes also display strong bands at 540 and 470 cm^{-1}, due to ν(Rh—P) and ν(Rh—As) modes, respectively.

The ^{31}P–$\{^1H\}$ NMR spectrum of complex **15** gave a well-resolved spectrum (Fig. 1), consistent with a square-planar, four-coordinate $[Rh(PPh_3)(DPBA)]^+$ cation. It exhibits a pair of doublets centered at 25.03 and 21.52 ppm, which can be assigned to the two equivalent *trans* phosphorus atoms (P_A) (structure **I**) of the ligand DPBA, with $^1J(Rh–P_A)$ = 119.62 Hz. The doublet of doublet can be explained on the basis of the splitting of two equivalent phosphorus atoms (P_A) by a rhodium nucleus ($I = 1/2$) to give a doublet which in turn is split again by the phosphorus atom (P_B) into

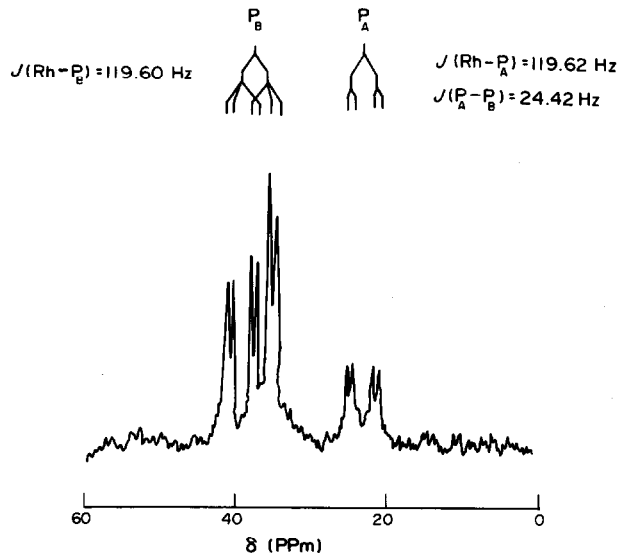

Fig. 1. The $^{31}P-\{^{1}H\}$ NMR spectrum of complex $[Rh(PPh_3)(DPBA)]Cl$.

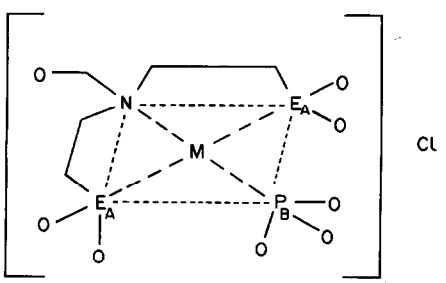
two doublets. There are three more doublets in the downfield region centered at 41.29, 37.96 and 35.48 ppm, that are assigned to the phosphorus atom (P_B), which is first split by the rhodium nucleus and in turn by the two equivalent phosphorus atoms (P_A) of the ligand (Fig. 1). The coupling constants are $J(Rh–P_B) = 119.60$ Hz and $^{2}J(P_A–P_B) = 24.42$ Hz. The chemical shifts are in agreement with the earlier reported work.[35]

The $^{31}P-\{^{1}H\}$ NMR spectrum of complex **16** exhibits a doublet centered at 34.09 ppm (Table 2) with $^{1}J(Rh–P) = 118.19$ Hz, which can be assigned to the coordinated phosphorus atom of the lone triphenylphosphine group.

The spectra in and near the visible region of **15** and **16** show weak *d–d* transition bands with LMCT character at 384 nm (26,042 cm^{-1}) and 451 nm (22,172 cm^{-1}), and 364 nm (27,510 cm^{-1}) and 299 nm (33,388 cm^{-1}), respectively, which are typical[36] of many d^8 complexes. A similar trend of the band shifting to the longer wavelengths has been observed in the case of DABA complex. The bands in the high-energy region can be attributed to the $\pi–\pi^*$ and charge-transfer bands.

The proposed structures of **15** and **16** are shown in **I**.

Reactions of DPBA with $IrCl(CO)(PPh_3)_2$ in boiling acetone resulted in displacement of one of the two coordinated triphenylphosphine groups and CO, to give a cationic Ir(I) complex of type $[Ir(PPh_3)(DPBA)]^+$ (**17**). The molar conductance of **17** (Table 1) is indicative of a 1 : 1 electrolyte. The cationic formulation of complex **17** is also supported by the complete absence of the ν(Ir—Cl) stretching frequency around 300 cm^{-1} in the far-



M = Rh or Ir, E = P or As

I

IR spectrum of the complex. The intense peaks at 515 and 545 cm^{-1} can be assigned to the ν(Ir—P) modes of coordinated $PPh_3$and the ligand DPBA, respectively.

The $^{31}P-\{^{1}H\}$ NMR spectrum of complex **17** also corroborates the above formulation. The spectrum exhibits two resonances, a downfield doublet centered at 35.69 ppm, and a triplet centered at 3.75 ppm. The doublet due to the splitting of a P_A by P_B (structure **I**) is assigned to the equivalent phosphorus atoms (P_A) of the ligand DPBA. The appearance of a triplet, which can be assigned to the phosphorus atom (P_B) of the triphenylphosphine, is due to the splitting of P_B by the two equivalent phosphorus atoms (P_A). The small coupling constant $J(P_A–P_B)$ of $\sim$ 24 Hz, may be due to the presence of P_A and P_B *cis* to each other. The proposed structure of **17** is shown as structure **I**.

The ^{1}H NMR spectra of complexes **7–12**, **16** and **17** could be obtained satisfactorily in $CDCl_3$. All the complexes exhibited broadened resonance signals due to phenyl and methylene protons, with

considerable downfield shift, when compared to those of free ligand[17] [DPBA: phenyl = 7.2δ(m); —CH_2CH_2— = 2.58δ(m), 2.10δ(m) and —CH_2— = 3.56δ(s): DABA: phenyl = 7.0(m); —CH_2CH_2— = 2.60δ(m), and 2.05δ(m) —CH_2 = 3.50δ(s)]. The phenyl resonances in the complexes occur as an asymmetric multiplet between 7.2 and 7.5δ. The methylene protons of the benzyl group occur as a singlet between 3.6 and 4.9δ. The methylene protons of CH_2CH_2 bridges occur as broadened, complex asymmetric multiplets, between 2.8 and 3.9 and 2.3 and 2.9δ, corresponding to the methylene protons attached to diphenylphosphino or arsino group and amine center, respectively. The complex asymmetric multiplets are possibly due to the interaction of neighbouring methylene protons followed by the coupling of the ^{31}P nuclear spin (in DPBA). For the remaining complexes the ^1H NMR could not be obtained satisfactorily owing to either the paramagnetic nature of the complexes or insufficient solubility.

Some of the earlier workers[37] have observed a large downfield chemical shift, upon coordination of tertiary phosphines to form five-membered chelate rings, in ^{31}P NMR. A similar effect of a large downfield shift has been observed upon coordination of the ligand DPBA to form five-membered chelate rings in the present work. By ^{31}P–$\{^1H\}$ NMR studies it has been confirmed that both the phosphorus ends of the ligand DPBA coordinate to the metal atom in all the complexes.

EXPERIMENTAL

The compounds $CoX_2 \cdot xH_2O$ (X = Cl or Br) and $NiX_2 \cdot xH_2O$ (X = Cl, Br or I) used were BDH Analar grade. Rhodium trichloride, iridium trichloride trihydrate, palladium dichloride and potassium tetrachloroplatinate were purchased from Strem Chemicals (U.S.A.). The complexes $RhCl(CO)(PPh_3)_2$ and $IrCl(CO)(PPh_3)_2$ were prepared by published procedures.[38] All solvents used in this work were of reagent grade, and were purified and dried before use. All preparations were carried out in an atmosphere of dry nitrogen.

The ligands DPBA and DABA were synthesized as reported earlier.[17] Microanalysis, melting points, conductivity and magnetic-susceptibility measurements were done as reported,[39,40] and are given in Table 1. Far-IR spectra of the complexes in the 600–100-cm^{-1} region were obtained using Nujol mulls pressed between polyethylene plates. The IR spectra were recorded on a Nicolet FT-IR model 200SX spectrometer. The electronic spectra (900–190 nm) were recorded in dichloromethane and chloroform using Shimadzu UV 240 and Beckman DU-7 spectrophotometers. Proton NMR spectra in $CDCl_3$ were recorded at 100 MHz on a JEOL FX-100 spectrometer using tetramethyl silane as reference. The proton-decoupled ^{31}P NMR spectra were taken in the indicated solvents (Table 2) using a JEOL FX-100 spectrometer operating at 40.3 MHz in the Fourier transform mode. The samples were placed in a 10-mm NMR tube and a capillary of deuterium oxide for the lock. 85% phosphoric acid was used as an external standard.

Preparation of the metal complexes

Chlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *aminecobalt*(II)*chloride*, [CoCl(DPBA)]Cl. To a refluxing methanolic solution of $CoCl_2 \cdot 6H_2O$ (0.10 g, 0.42 mM), the ligand DPBA (0.22 g, 0.42 mM) was added under a nitrogen atmosphere to get a green solution. After refluxing the reaction contents for 4–5 h, the solution was evaporated to dryness by a roto-evaporator *in vacuo*, to get a bluish-green precipitate, which was then washed with water and CCl_4, and dried over P_4O_{10} *in vacuo*. The compound was recrystallized from an acetone–*n*-hexane mixture. Yield 0.161 g (58%).

Bromobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *aminecobalt*(II)*tetraphenylborate*, [CoBr(DPBA)]B$(C_6H_5)_4$. To a refluxing methanolic solution of $CoBr_2$ (0.10 g, 0.45 mM) the ligand DPBA (0.24 g, 0.92 mM) was added, when a maroon-red solution was formed. After 4–5 h of refluxing 2 mol of $NaBPh_4$ was added to the cooled solution, when a shining red precipitate was obtained. The product was filtered, washed with methanol and diethyl ether, and recrystallized from an acetone–methanol mixture. Yield 0.130 g (60%).

Chlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *aminenickel*(II)*tetraphenylborate*, [NiCl(DPBA)]B$(C_6H_5)_4$, *bromobis*(2-(*diphenylphosphino*)*ethyl*)*benzylaminenickel*(II)*tetraphenylborate*, [NiBr(DPBA)]$B(C_6H_5)_4$, *and iodobis* (2-(*diphenylphosphino*)*ethyl*) *benzylaminenickel*(II)*tetraphenylborate*, [NiI(DPBA)]$B(C_6H_5)_4$. To refluxing methanolic solutions of $NiCl_2 \cdot 6H_2O$ (0.10 g, 0.42 mM), $NiBr_2 \cdot 3H_2O$ (0.10 g, 0.46 mM), and NiI_2 (0.10 g, 0.32 mM), the ligand DPBA was added, 0.22 g (0.42 mM) in the case of the chloride, 0.24 g (0.46 mM) in the case of the bromide, and 0.17 g (0.32 mM) in the case of the iodide, under an N_2 atmosphere and further refluxed for 4–5 h. To the cooled solutions a 2-mol excess of $NaB(C_6H_5)_4$ was added to get a saffron-red compound in the case of the chloro complex **3**, shining red in the case of the bromo complex **4**, and blackish-red in the case of the

iodo complex **5**. The products were filtered, washed with methanol and ether, and dried. The complexes **3–5** were recrystallized from an acetone–methanol mixture. Yield 0.31 g (78%) in the case of **3**, 0.36 g (80%) in the case of **4**, and 0.28 g (83%) in the case of **5**.

Chlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *aminenickel*(II)*chloride*, [NiCl(DPBA)]Cl. The procedure adapted for this complex is analogous to that described above for complexes **3–5**, except that after refluxing the reaction contents for 4–5 h the solution was evaporated to dryness to get a red precipitate, which was washed and dried and stored in a vacuum desiccator because of its hygroscopicity. Yield 0.18 g (65%).

Chlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *aminepalladium*(II)*tetraphenylborate*, [PdCl(DPBA)]$B(C_6H_5)_4$, *and chlorobis*(2-(*diphenylarsino*) *ethyl*) *benzylaminepalladium* (II) *tetraphenylborate*, [PdCl(DABA)]$B(C_6H_5)_4$. After refluxing the yellow methanolic solutions of $PdCl_2$ (0.10 g, 0.56 mM) and the ligands [DPBA (0.30 g, 0.56 mM) or DABA (0.35 g, 0.56 mM)] for 4–5 h, the reaction contents were cooled and a 2-mol excess of $NaB(C_6H_5)_4$ in methanol was added, when a yellow precipitate was obtained in both cases. The complexes were filtered, washed with hot methanol and diethyl ether, and recrystallized from a dichloromethane–methanol mixture. Yield 0.29 g (52%) (DPBA), and 0.3 g (51%) (DABA).

Chlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *amineplatinum*(II)*chloride*, [PtCl(DABA)]Cl, *and chlorobis*(2 - (*diphenylarsino*)*ethyl*)*benzylamineplatinum* (II) *chloride*, [PtCl(DABA)]Cl. To an acetone solution of the ligand [DPBA (0.128 g, 0.24 mM) and DABA (0.149 g, 0.24 mM)] the compound K_2PtCl_4 (0.100 g, 0.24 mM) in 2–3 cm^3 of water was added, and the solution slightly warmed for 2–3 h. The resulting pale yellow solutions in both the cases were concentrated to a small volume and the complexes precipitated by the addition of diethyl ether to get a creamish white precipitate in both cases. The complexes were filtered, washed, dried and recrystallized from an acetone–diethyl ether mixture. Yield 0.192 g (88%) (DPBA), and 0.180 g (88%) (DABA).

Trichlorobis(2 - (*diphenylphosphino*)*ethyl*) *benzyl aminerhodium*(III), [$RhCl_3$(DPBA)], *and trichlorobis*(2 - (*diphenylarsino*)*ethyl*)*benzylaminerhodium* (III), [$RhCl_3$(DABA)]. To the refluxing methanolic solution of $RhCl_3$ (0.10 g, 0.47 mM), the ligand [DPBA (0.253 g, 0.47 mM) or DABA (0.294 g, 0.47 mM)] in 5 cm^3 benzene was added slowly over a period of 1 h, under an N_2 atmosphere. A silky yellow precipitate settled down in both the cases after refluxing for 4–5 h. The precipitates were filtered, washed and recrystallized from a dichloromethane–diethyl ether mixture. Yield 0.14 g (40%) (DPBA), and 0.158 g (40%) (DABA).

Trichlorobis(2 - (*diphenylphosphino*)*ethyl*)*benzyl* - *amineiridium*(III), [$IrCl_3$(DPBA)], *and trichlorobis*(2 - (*diphenylarsino*)*ethyl*)*benzylamineiridium* (III), [$IrCl_3$(DABA)]. To a refluxing methanolic solution of the ligand [DPBA (0.302 g, 0.56 mM), or DABA (0.35 g, 0.56 mM)] was added $IrCl_3 \cdot 3H_2O$ (0.10 g, 0.28 mM), and the solution further refluxed for 4–5 h, when a greyish green complex was obtained in the case of **13** and a greenish complex in the case of **14**. The products were filtered, washed with methanol and diethyl ether, and recrystallized from hot dimethylsulphoxide. Yield 0.10 g (45%) (DPBA), and 0.115 g (44%) (DABA).

Triphenylphosphinebis(2 - (*diphenylphosphino*) *ethyl*)*benzylaminerhodium*(I)*chloride*, [Rh(PPh_3) (DPBA)]Cl, *and triphenylphosphinebis* (2- (*diphenyl arsino*)*ethyl*)*benzylaminerhodium*(I) *chloride*, [Rh (PPh_3)(DABA)]Cl. To a refluxing acetone solution of the ligand DPBA (0.125 g, 0.21 mM) and a methanolic solution of DABA (0.130 g, 0.21 mM), was added the Rh(I) complex $RhCl(CO)(PPh_3)_2$ (0.150 g, 0.21 mM). After 3–4 h of refluxing the yellow homogeneous solutions in both the cases were concentrated to a small volume and the complexes precipitated by diethyl ether. The yellow products were filtered, washed with diethyl ether and recrystallized from a methanol–diethyl ether mixture. Yield 0.180 g (89%) (DPBA), and 0.125 g (57%) (DABA).

Triphenylphosphinebis(2 - (*diphenylphosphino*) *ethyl*)*benzylamineiridium*(I)*chloride*, [Ir(PPh_3) (DPBA)]Cl. $IrCl(CO)(PPh_3)_2$ (0.100 g, 0.12 mM) was added to a refluxing methanolic solution of DPBA (0.068 g, 0.12 mM) and further refluxed for 3–4 h. The solution was then concentrated and diethyl ether added to get a creamish white precipitate which was filtered, washed with ether and recrystallized from a dichloromethane–diethyl ether mixture. Yield 0.055 g (57%).

THE CRYSTAL STRUCTURES OF TWO HETEROPOLYTUNGSTATE SALTS CONTAINING ANIONS DERIVED FROM α-OCTADECATUNGSTODIPHOSPHATE(6−): $(NH_4)_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 8H_2O$ AND $(Me_2NH_2)_8[\alpha_2\text{-}P_2Co(H_2O)W_{17}O_{61}]\cdot 11H_2O$

TIMOTHY J. R. WEAKLEY

Department of Chemistry, Dundee University, Dundee DD1 4HN, U.K.

(*Received* 18 *May* 1986; *accepted* 4 *September* 1986)

Abstract—The anions in $(NH_4)_{10}[\alpha_1\text{-}P_2W_{17}O_{61}]\cdot 8H_2O$ (I) and $(Me_2NH_2)_8[\alpha_2\text{-}P_2Co(H_2O)W_{17}O_{61}]\cdot 11H_2O$ (II) both have the $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ structure with one "cap" W atom and its terminal oxygen atom missing (I), and a $Co(H_2O)^{2+}$ group in place of one "cap" W atom and its terminal oxygen (II). Both anions have approximate mirror symmetry but are disordered in the crystal; in I the anion lies on a crystal inversion centre in two equally-weighted orientations, and in II the Co atom appears as two $Co_{0.5}W_{0.5}$ composite atoms on either side of a crystallographic mirror plane. Crystal data include [diffractometer, Mo radiation, and $|F| \geqslant 3\sigma(F)$]: I, *Cmca*, $a = 18.080(8)$, $b = 17.945(7)$, $c = 21.546(8)$ Å, $Z = 4$, $R = 0.067$ for 1384 data; II, *Pnam*, $a = 28.052(11)$, $b = 15.069(12)$, $c = 20.638(17)$ Å, $Z = 4$, $R = 0.069$ for 3057 data.

The $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ anion contains two α-$A\text{-}PW_9O_{34}$ units (each derived from the well-known $[\alpha\text{-}PW_{12}O_{40}]^{3-}$ anion by the removal of a set of three corner-sharing WO_6 octahedra) which are linked through corner-sharing with the elimination of six oxygen atoms.[1,2] The anion has point symmetry D_{3h}, and contains only two structurally-distinct types of W atoms: six "cap" atoms on vertical mirror-planes, grouped in two sets of three, and 12 "belt" atoms which do not lie on mirror-planes and are grouped in two sets of six. Nevertheless base attack in aqueous solution at pH > 6 initially removes just one W atom and its terminal oxygen to give $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$.[3,4] This can then react[5,6] with various $Z^{x+}(aq)$ cations to give products $[P_2Z(OH_y)W_{17}O_{61}]^{(12-x-y)-}$ in which Z is believed to occupy a W site of the original $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ anion. It will also form bonds to larger cations through, presumably, the outer four oxygens adjacent to the vacant W site to give complexes of type $[Ce(P_2W_{17}O_{61})_2]^{16-}$.[7,8] The precise location, cap or belt, of the vacancy in $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ has been disputed. The ^{31}P NMR spectrum of this anion[9] and the results of polarographic studies of the anion and some derived species[10] have been taken to indicate a belt vacancy. However, the presence of a cap vacancy was deduced from ESR measurements on the derivative $[\alpha_2\text{-}P_2V(IV)W_{17}O_{61}]^{8-}$;[11] from the incomplete ($R = 0.19$) crystal structure analysis of $K_{16}[Ce(P_2W_{17}O_{61})_2]\cdot aq$;[8] and from the pattern of line intensities, consistent only with mirror symmetry, in the ^{183}W NMR spectrum of $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$.[12] Also, it has been briefly reported[13] that the Sn atom in $[\alpha_2\text{-}P_2(Bu^nSn)W_{17}O_{61}]^{7-}$ occupies a cap position. The X-ray structural analyses reported in this paper show that a cap atom is missing in $(NH_4)_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 8H_2O$ (I) and that a cap substituent is present in $(Me_2NH_2)_8[\alpha_2\text{-}P_2Co(II)(H_2O)W_{17}O_{61}]\cdot 11H_2O$ (II).

EXPERIMENTAL

Preparation of I *and* II

The preparation of I was exactly analogous to the procedure[4] for the K^+ salt. The compound was recrystallized from hot (70°C) water to give tablets bounded by {001} and {110} faces. Compound II was prepared as described previously,[6] or by the reaction of equimolar $[P_2W_{17}O_{61}]^{10-}$ and Co^{2+} in aqueous solution at 40°C followed by the addition of excess $(Me_2NH_2)Cl$; the crude product was redissolved in water, reprecipitated, and finally recrystallized twice from hot water to give prisms

with prominent {011} faces. Crystals of both compounds suitable for X-ray work were obtained by allowing slightly supersaturated aqueous solutions to stand at room temperature.

Crystallographic studies

The choice of salts for structural study was restricted not only by the availability of well-diffracting crystals of suitable size (eliminating, for instance, $K_{10}[P_2W_{17}O_{61}]\cdot aq$ which is always obtained as tiny laths) but by the requirement that the space-group and number of anions in the cell be consistent with a disorder-free structure. The K^+ and Rb^+ salts of $[X_2Z(II)(H_2O)W_{17}O_{61}]^{8-}$ (X = P or As; Z = Mn, Co, Ni or Zn), for example, are rhombohedral (R3 or $R\bar{3}$) with one anion in the primitive cell;[6,14] consequently, if the anion has the $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ structure the Co atom must be disordered over three or six sites. Preliminary Weissenberg photographs of **II** indicated space-groups *Pnam* or $Pna2_1$ which for $Z = 4$ respectively impose mirror-symmetry or no symmetry on the anion. In the case of **I**, the possible space-groups *Cmca* or $C2_1ca$ respectively impose C_{2h}- or C_2-symmetry on the anion ($Z = 4$), neither of which is consistent with a well-ordered "defect" P_2W_{18}-type anion. Moreover, Weissenberg photographs showed a number of additional diffuse reflections at positions forbidden by the C-centering, and also regions of diffuse background scattering. Despite these indications of disorder, the structural analysis of **I** was undertaken in the hope that the heavy-atom framework at least could be distinguished.

Crystal data

I, $(NH_4)_{10}[P_2W_{17}O_{61}]\cdot 8H_2O$. Orthorhombic, *Cmca*, $a = 18.080(8)$, $b = 17.945(7)$, $c = 21.546(8)$ Å, $Z = 4$, $d_{calc.} = 4.26$ g cm^{-3}; Mo radiation ($\lambda = 0.71069$ Å), $\mu = 286$ cm^{-1}.

II, $(Me_2NH_2)_8[P_2Co(H_2O)W_{17}O_{61}]\cdot 11H_2O$. Orthorhombic, *Pnam*, $a = 28.052(11)$, $b = 15.069(12)$, $c = 20.638(17)$Å, $Z = 4$, $d_{calc.} = 3.66$ g cm^{-3}; Mo radiation ($\lambda = 0.71069$ Å), $\mu = 230$ cm^{-1}.

Data collection

Data for **I** and **II** were collected on an Enraf–Nonius CAD-4 diffractometer by ω–2θ scans in the 2θ ranges 2–40° (**I**) and 2–48° (**II**), after the refinement of cell parameters from the setting angles of 25 reflections in the 2θ ranges 22–24° (**I**) and 24–26° (**II**). In neither case was there evidence of crystal deterioration during data collection. The numbers of reflections for **I** were: total, 3635; unique, 1702; reflections with $|F| \geqslant 3\sigma(F)$, 1384. The corresponding figures for **II** are: 7603, 6962 and 3057 reflections.

Structure solution and refinement

The SHELX-76 program[15] was used for all calculations other than absorption correction. Approximate positions of the P and W atoms were readily obtained in each case by use of the direct-methods sub-programs EEES and TANG on the assumption that the centrosymmetric choice of space group (**I**, *Cmca*; **II**, *Pnam*) indicated by the *E* statistics was the correct one. The oxygen atoms of the anions were located in difference syntheses alternating with cycles of least-squares refinement. The presence of the Co atom in **II** as two composite atoms, $M = Co_{0.5}W_{0.5}$, related by the crystallographic mirror-plane was suggested by the appreciably larger value of U_{iso} for M when treated as W, and by the short M..M^i distance compared with other W..W distances. Separate Co and W positions at the M site could not be distinguished. After isotropic refinement of the P, Co and W atoms in **I**, and all anion atoms in **II**, the original set of unmerged $|F|$ values was subjected to an empirical absorption correction by means of the program DIFABS,[16] and refinement was continued after remerging the data. *Ab initio* structure solutions were also attempted with assumption of the alternative non-centrosymmetric space-groups, $C2_1ca$ for **I** and $Pna2_1$ for **II**. Essentially the same structures appeared [and in particular the same kinds of disorder (see Discussion)], with numerous strong correlations between the parameters for atoms related by symmetry in the original space-groups. Therefore the centrosymmetric space-groups were retained. A number of inter-anion atoms were located; but in the case of **II** it was clear that the $Me_2NH_2^+$ cations and lattice H_2O molecules were highly disordered, no C_2N units being clearly discernible, and only the strongest difference peaks were included (arbitrarily, as N) in the last cycles of refinement. Convergence was reached for **I** at $R = 0.067$, wR $(= [\Sigma w\Delta^2/\Sigma wF^2]^{1/2}) = 0.091$ for 1384 data, 180 parameters, full matrix, $w = [\sigma^2(F) + 0.0016F^2]^{-1}$ in the last cycle; and for **II** at $R = 0.069$, $wR = 0.090$ for 3057 data, 247 parameters, blocked matrix, $w = [\sigma^2(F) + 0.0026F^2]^{-1}$ in the last cycle.

DISCUSSION

Bond lengths and other intra-anion distances are shown in Table 1 for **I**, and in Table 2 for **II**. Atomic

coordinates and thermal parameters have been deposited as supplementary data.

The heavy-atom framework in the parent $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ anion[2] is retained in the anion of **I**, but with a vacancy at one cap position. The anion has symmetry m (C_s), but occupies a site of crystallographic symmetry $2/m$(C_{2h}) in two equally-weighted orientations related by the inversion centre midway between the P atoms (or equivalently, by the crystal diad axis normal to the P..P vector). This disorder is illustrated in Fig. 1. The act of inversion brings each belt W atom into near coincidence with an atom of the other belt, to give "composite" belt atoms W(1,2,3) whose components could not be resolved. In $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$, WO_6 octahedra in the same belt share edges and corners alternately,[2] with averaged W..W distances of 3.36 and 3.68 Å, respectively; in **I**, the apparent W..W distances within each belt have intermediate values, 3.48–3.53 Å. The other W..W distances (Table 1) are clearly consistent with edge-sharing between WO_6 octahedra in the same cap, with corner-sharing between adjacent cap and belt octahedra, and with corner-sharing between octahedra in different belts. The composite belt atoms W(1,1^{i},2,2^{i},3,3^{i}), where "i" denotes reflection at $x = 0$, are coplanar [maximum deviation 0.020 Å for W(2,2^{i}), towards centre of anion]. Their mean plane is parallel to the plane of the atoms of the unbroken cap, W(4,4^{i},6) (dihedral angle 0.16°). Distortions arising from the removal of a W atom from the other cap are shown by the displacement of the remaining atoms W(5,5^{i}) from the W(4,4^{i},6) plane by 0.14 Å (away from the centre of the anion), and by the angles between the P..P vector and the normals to the W(1,1^{i},2,2^{i},3,3^{i}) and W(4,4^{i},6) planes, respectively 1.1 and 1.3°. Oxygen atoms of the anion were also located, with the restriction that a number of oxygen atoms in one orientation of the anion nearly coincide with oxygens in the superimposed inverse orientation (par-

ticularly atoms shared between WO_6 octahedra in the same belt or in different belts); in such cases only composite atoms could be located, except for O(11) and O(11A) which are shared between W(1) and W(1^{i}). Therefore too much significance should not be attributed to the apparent bond lengths (Table 1). Oxygen atoms in PO_4 tetrahedra and in cap WO_6 octahedra were clearly resolved. It was possible to disentangle the superimposed structures, and a view of a single orientation of the anion is shown in Fig. 2.

The $[P_2Co(H_2O)W_{17}O_{61}]^{8-}$ anion in **II** is shown

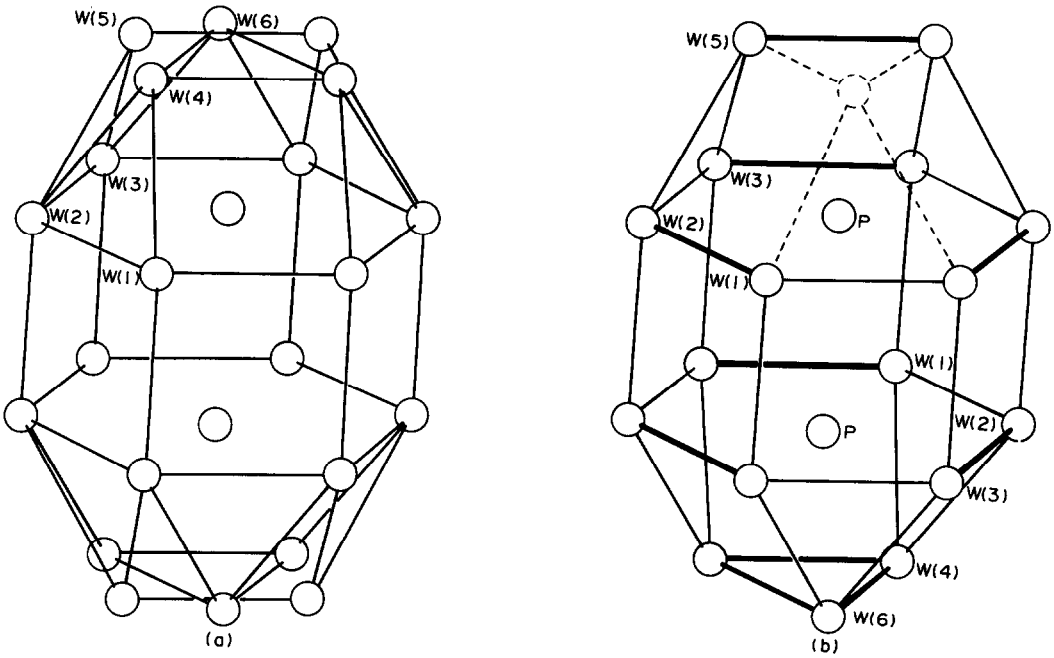

Fig. 1. $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ anion in **I**. (a) The heavy-atom framework ($2/m$ symmetry) apparent from diffraction data. (b) The anion framework (m-symmetry) in one of the two superimposed orientations. Thick lines imply that WO_6 octahedra share edges, and thin lines that they share corners. The dashed lines indicate the missing W atom and its connections.

in Fig. 3. As expected from the results for **I**, the Co substituent occupies a cap position, on one of the vertical mirror-planes of the parent $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$ anion of D_{3h}-symmetry.[2] However, this mirror-plane does not coincide with the crystallographic mirror-plane which bisects the anion in **II**, passing through P(1), P(2), W(1) and W(10); instead, the Co atom is distributed equally over the sites M(9) and M(9^i) related by the crystallographic mirror-

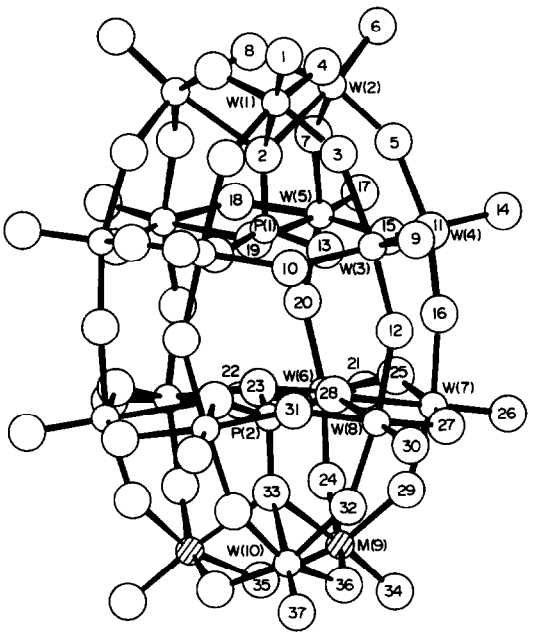

Fig. 3. $[\alpha_2\text{-}P_2Co(H_2O)W_{17}O_{61}]^{8-}$ anion in **II**. Atoms P(1), P(2), W(1) and W(10) lie on a crystal mirror plane. Each hatched atom [M(9)] is composite ($Co_{0.5}W_{0.5}$).

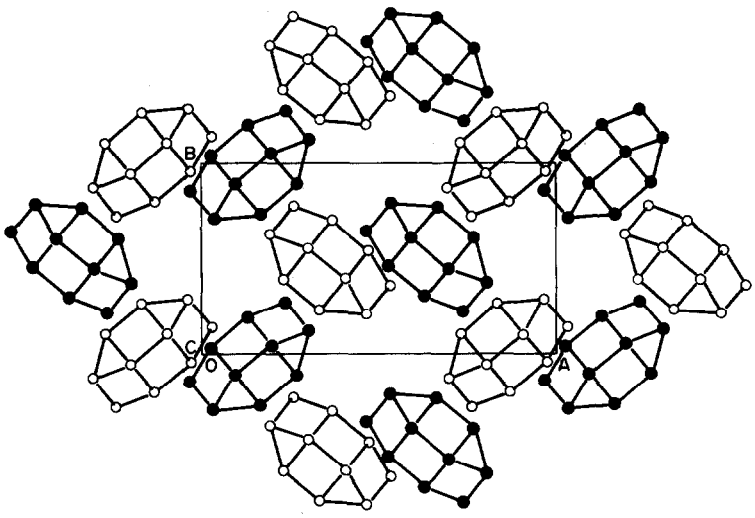

Fig. 4. Packing of anions (represented by their heavy-atom frameworks) in **II**. Filled and open circles denote anions lying on mirror planes at $z = \frac{1}{4}$ and $z = \frac{3}{4}$, respectively. The view is down the *c*-axis.

plane as composite atoms M = $Co_{0.5}W_{0.5}$. The situation is analogous with that in $Na_2(NMe_4)_4[\alpha\text{-}HPW_{11}O_{39}]\cdot 7H_2O$,[17] whose anion has a defect $[\alpha\text{-}PW_{12}O_{40}]^{3-}$ structure; there the tungsten vacancy is observed as two half-vacancies related by a crystallographic mirror-plane which does not coincide with the true mirror-plane of the anion. In **II**, the M(9)..M(9^i) distance of 3.24 Å is significantly shorter than the W(10)..M(9) distance in the same cap (3.34 Å) and the W..W distances in the other cap (3.37 Å), and approaches the shorter Co..Co distances found for edge-sharing CoO_6 groups in $[P_5Co_9W_{27}O_{119}H_{17}]^{16-}$ (3.20–3.21 Å)[18] and $[P_2Co_4W_{18}O_{70}H_4]^{10-}$ (3.16 and 3.19 Å).[19] Other W..W distances and W—O bond lengths in $[\alpha_2\text{-}P_2Co(H_2O)W_{17}O_{61}]^{8-}$ (Table 2) are similar to corresponding distances in $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$. The terminal oxygen atom O(34) on M(9) is H_2O for M = Co and is unprotonated for M = W. The former assignment is supported by the observation[20] that changes in the solution spectrum of the anion in the region of the ligand-field band of Co at 18,300 cm^{-1} are seen in the presence of potential ligands such as N_3^-, NCS^-, pyridine and methylpyridines, and in mixed solvents (H_2O–MeCN and H_2O–dmso); similar changes have been observed for $[PCo(H_2O)W_{11}O_{39}]^{5-}$ and interpreted[21] as showing the replacement of ligand H_2O at Co.

The packing of the anions in and near one unit cell of **II** is shown in Fig. 4. The anions form layers normal to *c*, in a loose approximation of hexagonal packing, the distances between centroids of neighbouring anions ranging from 13.6 to 16.4 Å. There are voids above and below each anion in the *c*-direction, and also channels extending parallel to *c*. The $Me_2NH_2^+$ cations and lattice water molecules, few of whose atoms could be located, are disordered in these spaces.

COCONDENSATION REACTION OF DISULPHURDINITRIDE WITH NICKEL ATOMS: THE PREPARATION OF $Ni(S_2N_2H)_2$

J. DEREK WOOLLINS*

School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

(*Received* 4 *July* 1986; *accepted* 4 *September* 1986)

Abstract—The utility of metal atom vapour synthesis in the preparation of metalla-sulphur–nitrogen compounds has been investigated. Reaction of nickel atoms with disulphurdinitride, S_2N_2, gave, after extraction with methanol, $Ni(S_2N_2H)_2$ in *ca* 15% yield.

Cocondensation reactions between metal vapours and organic ligands have become widely accepted for the preparation of organometallic compounds and the advantages of this method have been discussed.[1,2] We are involved in the preparation of metalla-sulphur–nitrogen compounds[3–5] and one important area is the development of rational, general syntheses. A particularly important group of compounds are those which involve the disulphurdinitrido dianion or its protonated analogue $S_2N_2H^-$ since they can adopt[6] stacking structures in, for example, compounds of type $[Pt(S_2N_2H)(PR_3)_2]X$. We have developed a number of wet chemical routes to these complexes but, to date, attempts to extend the range of metals have been unsuccessful. An alternative strategy is the direct reaction of disulphurdinitride with metal atoms. Here we report on the first successful preparation of an M–S–N complex $[Ni(S_2N_2H)_2$ (**1**)] by metal vapour synthesis.

EXPERIMENTAL

CARE: the procedure described involves S_4N_4 and S_2N_2, both of which are known to be explosive.

The apparatus used (Fig. 1) consisted of a section for the preparation of S_2N_2 based on the design of Mikulski[7] and a reactor similar to that used by Timms.[8] Youngs stopcocks and greaseless taps were used throughout. The nickel vapour was generated using a multifilament consisting of two 15-cm strands of 0.4-mm tungsten wire and 5 cm of 0.3-mm nickel wire; this could be used for three or four runs before becoming too brittle to handle.

Preparation of S_2N_2

In a typical experiment the apparatus was charged with S_4N_4 (0.7 g, freshly recrystallized from benzene) and silver wool (1.0 g BDH MAR grade). After evacuating the system to 10^{-5}–10^{-6} torr overnight the temperature of the furnace around the silver wool was brought to 300°C and an oil bath was placed around the lower part of the apparatus (with only 0.5 cm between the top of the oil bath and the bottom of the furnace). The temperature of the oil bath was raised to 90°C and the cold finger filled with liquid nitrogen. Within a few minutes a light tan coloured coating could be seen on the cold finger. The reaction was maintained until no S_4N_4 remained, usually 8–10 h. After this time tap (a) was closed, U-tube (1) surrounded by liquid N_2 and the liquid N_2 in the cold finger was blown out with a stream of N_2. Pumping overnight (with U-tube (1) surrounded by liquid N_2) gave pure S_2N_2 in the U-tube. In a typical run *ca* 0.4 g of S_2N_2 was obtained. At this stage if the taps on the U-tube are closed and it is surrounded by a salt–ice bath polymerization occurs and lustrous bronze crystals of $(SN)_x$ are obtained after 2–3 days.

NOTE: S_2N_2 is extremely explosive and can spontaneously detonate at room temperature!

Preparation of $Ni(S_2N_2H)_2$

The W/Ni filament was slowly warmed to its operating temperature (*ca* 1350°C) and the reactor

* Present address: Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

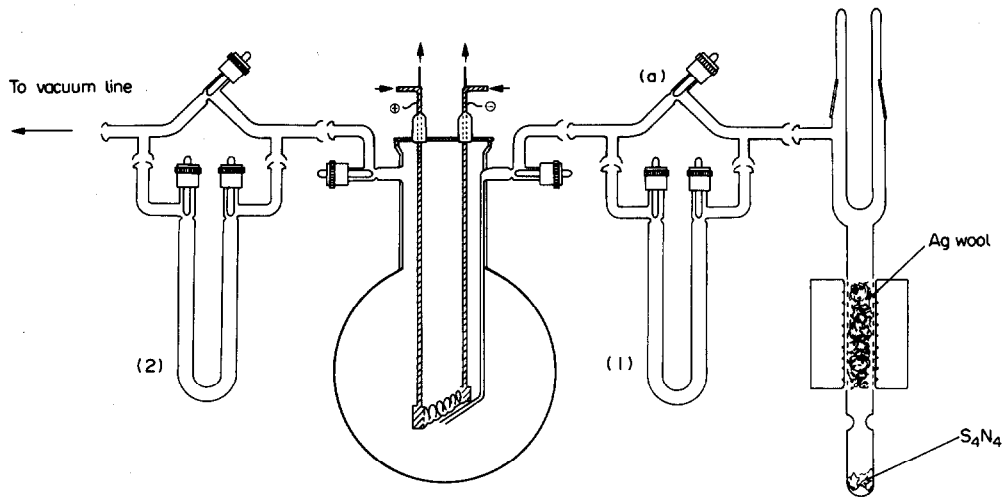

Fig. 1. Apparatus used for the preparation and reaction of S_2N_2 with nickel vapour.

surrounded by liquid N_2 whereupon the liquid N_2 trap surrounding U-tube (1) was replaced by a salt–ice bath allowing S_2N_2 to sublime over into the reaction vessel. At these temperatures in 2 h all of the S_2N_2 sublimed into the reactor and *ca* 45 mg of nickel was evaporated. At the end of the reaction the liquid N_2 was removed from around the reactor and U-tube (2) cooled to enable excess S_2N_2 to be sublimed off overnight.

Attempts to sublime the remaining dark coloured solid in the reactor onto a liquid-N_2 cold finger were unsuccessful. However, it was possible to obtain a violet solution by extraction of the solid with cold methanol. Evaporation of this methanol solution gave **1**, which was identified by UV–VIS and IR spectroscopy.[9,10] Yields varied between 15 and 30 mg of product, depending on the weight of nickel evaporated but were never less than 10% and were generally *ca* 15%.

RESULTS AND DISCUSSION

Cocondensation reaction of nickel atoms with S_2N_2 proceeds to give a dark solid which did not sublime at 10^{-4} torr and 90°C. This material may be a polymeric S_2N_2 adduct and is probably similar to the intractable solid reported[11] from the reaction of $Ni(CO)_4$ and S_4N_4. On treatment with methanol the known complex **1** is obtained:

$$Ni(g) + S_2N_2 \rightarrow [Ni(S_2N_2)]_x \xrightarrow{MeOH} Ni(S_2N_2H)_2.$$

It has been reported[12] that reaction of finely divided nickel powder with S_2N_2 in methanol also gives rise to **1** in low yield and so as to ascertain if this process was occurring here we performed some blank experiments. Thus we condensed nickel vapour followed by S_2N_2 and did not sublime away any S_2N_2 at the end of the process. Extraction with methanol did not result in immediate formation of **1** with the UV spectrum consisting of a single band (λ_{max} 268 nm) due to S_2N_2. If the unfiltered extract, which contained flakes of nickel, was allowed to stand after 5 days a UV–VIS spectrum corresponding to *ca* 5 mg of **1** was observed. In the vapour synthesis procedure excess S_2N_2 was sublimed out of the reactor before addition of methanol. Also we observed an immediate colouration of the alcohol on its addition in the cocondensation reactions and the alcohol was filtered directly after extraction in this case. Clearly, the product obtained derives from the cocondensation reaction and not a simple reaction between nickel and a solution of S_2N_2.

Although the yield obtained here using a relatively complex procedure is not as good as the traditional wet chemical method the results obtained do suggest that the vapour synthesis technique may offer some potential in the preparation of metalla-sulphur–nitrogen compounds and further studies would be worthwhile.

(*Received* 21 *July* 1986; *accepted* 4 *September* 1986)

Abstract—Kinetic studies were carried out for the electron-transfer reactions of [Cu(II)L][ClO_4]$_2$ [L = 1,6-bis(2-pyridyl)-2,5-dithiahexane, 1,7-bis(2-pyridyl)-2,6-dithiaheptane, or 1,8-bis(2-pyridyl)-3,6-dithiaoctane] with ferrocene (fc) and 1,1′-dimethylferrocene (Me_2fc), and of [Cu(II)L′$_2$][ClO_4]$_2$ [L′ = 4-(alkylmercaptomethyl)imidazole; alkyl = Me, Et, Pr^n, CH_2Ph or Bu^t] with fc in acetonitrile at 25°C. The electron-transfer reactions are suggested to proceed via a precursor complex, [Cu(II)L · Red], existing in an equilibrium state:

$$[Cu(II)L]^{2+} + Red \rightleftharpoons[Cu(II)L \cdot Red]^{2+} \xrightarrow{k_{et}} [Cu(I)L]^{+} + Red^{+} \quad (Red = fc \text{ or } Me_2fc).$$

In a previous paper dealing with the electron-transfer reactions of Cu(II)N_2S_2 type complexes, bis[(4-alkyl- and phenylmercaptomethyl)imidazole] copper(II) diperchlorate (alkyl = Pr^n, CH_2Ph or Bu^t) and 1,6-bis(4-imidazolyl)-2,5-dithiahexanecopper(II) diperchlorate, as a model of an active site of blue copper (Type I) proteins with ferrocene, we reported the formation of a precursor complex prior to the electron transfer.[1] In order to further understand the mechanism for the electron-transfer reaction of the Cu(II)N_2S_2 type complexes, we have undertaken a study of the reactions of the copper(II) complexes coordinated by pyridyl nitrogen and thioether sulfur atoms with ferrocene (fc) and 1,1′-dimethylferrocene (Me_2fc).

This paper reports the kinetics of the electron-transfer reactions of [Cu(II)L][ClO_4]$_2$ [L = 1,6-bis(2-pyridyl)-2,5-dithiahexane (**1**), 1,7-bis(2-pyridyl)-2,6-dithiaheptane (**2**), and 1,8-bis(2-pyridyl)-3,6-dithiaoctane (**3**)] with fc and Me_2fc, and of [Cu(II)L′$_2$][ClO_4]$_2$ [L′ = 4-(alkylmercaptomethyl)-imidazole; alkyl = Me (**4**), Et (**5**), Pr^n (**6**), CH_2Ph (**7**) and Bu^t (**8**)] with fc in acetonitrile.

EXPERIMENTAL

Materials

The Cu(II)N_2S_2 type complexes **1–3**[2,3] and **4–8**[4] were prepared according to the literature. Commercially available fc and Me_2fc were purified by sublimation and recrystallization before use, respectively.

Kinetic measurements

Reaction rates were determined by monitoring the decay of absorbance at a wavelength in the 300–400-nm range absorbed by the copper(II) complexes in acetonitrile using a Union RA-103 stopped-flow spectrophotometer equipped with a 0.2- or 1.0-cm quartz cell in a cell-holder thermostatted at 25±0.2°C. All the kinetic measurements were carried out under pseudo-first-order conditions with at least five-fold excess amounts of fc or Me_2fc relative to the copper(II) complexes (9.7×10^{-5}–1.2×10^{-4} mol dm^{-3}) under a nitrogen atmosphere. Observed pseudo-first-order rate constants, k_{obsd}, were obtained by the least-squares curve fitting using a Union System 77 microcomputer.

RESULTS AND DISCUSSION

Complexes **1–3** exhibit a strong absorption band due to the sulfur-to-copper charge-transfer transition at 330–370 nm.[4] When either the copper(II) complex was mixed with fc or Me_2fc in acetonitrile, the charge-transfer band was weakened in intensity and a band due to the ferrocenium (fc^+) or 1,1′-dimethylferrocenium cation (Me_2fc^+) concurrently appeared at 618 (fc^+) or 652 nm (Me_2fc^+). This is indicative of the occurrence of the redox reaction [eqn (1)]:

$$[Cu(II)L]^{2+} + Red \rightarrow [Cu(I)L]^{+} + Red^{+}, \quad Red = fc \text{ or } Me_2fc \quad (1)$$

being similar to the reaction of bis[4-(alkyl- and phenylmercaptomethyl)imidazole]copper(II) diperchlorates (alkyl = Pr^n, Bu^t or CH_2Ph) and 1,6-bis(4-imidazolyl)-2,5-dithiahexanecopper(II) diperchlorate with fc.[1]

The pseudo-first-order rate constants, k_{obsd}, obtained in the reaction of **1** with excess amounts of fc are listed in Table 1. No linear relation can be seen between the k_{obsd} value and the initial concentration of fc ([fc]), as depicted in Fig. 1. This is suggestive of the existence of a pre-equilibrium process [eqn (2)] prior to the electron-transfer reaction [eqn (3)]:

Table 1. k_{obsd} for the reaction of complex **1** (1.08×10^{-4} mol dm^{-3}) with fc in acetonitrile containing $[Bu^n_4N][BF_4]$ (0.1 mol dm^{-3}) at 25°C

[fc] (mol dm^{-3})	k_{obsd} (s^{-1})
1.06×10^{-3}	1.28±0.02
1.76×10^{-3}	2.08±0.09
2.64×10^{-3}	2.69±0.10
3.52×10^{-3}	3.36±0.19
5.28×10^{-3}	4.61±0.16

$$[Cu(II)L]^{2+} + fc \overset{K}{\rightleftharpoons} [Cu(II)L\cdot fc]^{2+}, \quad (2)$$

$$[Cu(II)L\cdot fc]^{2+} \xrightarrow{k_{et}} [Cu(I)L]^{+} + fc^{+}, \quad (3)$$

where K is the formation constant of a precursor complex, $[Cu(II)L\cdot fc]^{2+}$, and k_{et} is the rate constant of the electron-transfer process. According to this scheme, the k_{obsd} value in the presence of large excess amounts of fc can be expressed by eqn (4), which is transformed to eqn (5):

$$k_{obsd} = \frac{k_{et}K[fc]}{1+K[fc]}, \quad (4)$$

$$\frac{1}{k_{obsd}} = \frac{1}{k_{et}K[fc]} + \frac{1}{k_{et}}. \quad (5)$$

This equation predicts a linear relation between k_{obsd}^{-1} and $[fc]^{-1}$. In fact, there can be seen a linear relation between these values, as shown in Fig. 2, supporting the reaction mechanism of eqns (2) and (3). The K and k_{et} values determined from the slope

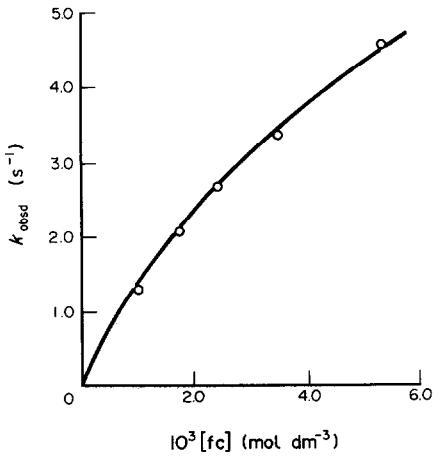

Fig. 1. Plot of k_{obsd} against [fc] for the reaction of complex **1** with fc in acetonitrile at 25°C.

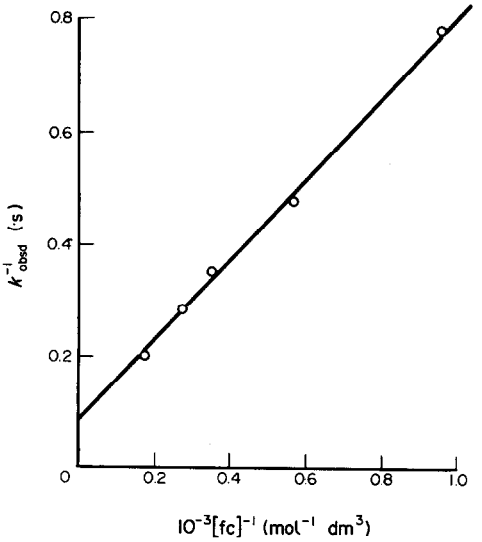

Fig. 2. Plot of k^{-1}_{obsd} against [fc]$^{-1}$ for the reaction of complex **1** with fc in acetonitrile at 25°C.

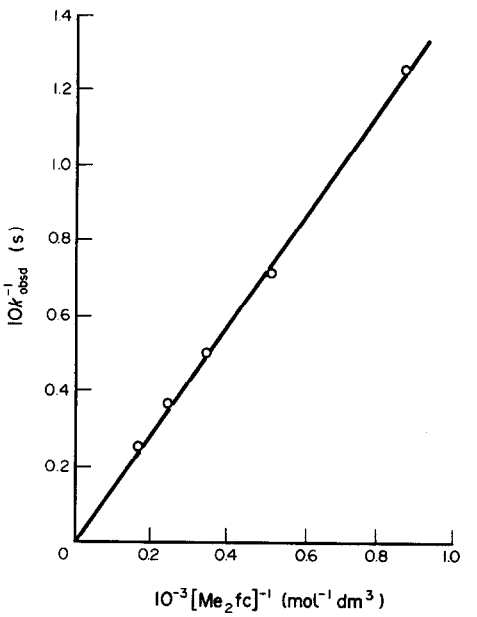

Fig. 3. Plot of k^{-1}_{obsd} against [Me$_2$fc]$^{-1}$ for the reaction of complex **1** with Me$_2$fc in acetonitrile at 25°C.

of the straight line and the intercept, respectively, are shown in Table 2, together with those values obtained similarly for the reactions of **2** and **3** with fc.

In the reaction of **1** with Me$_2$fc, however, there exists a linear relation between k^{-1}_{obsd} and the reciprocal of the initial concentration of Me$_2$fc, [Me$_2$fc]$^{-1}$, as shown in Fig. 3. This result may be explained in terms of the relation $K \ll k_{et}$, which may arise either from a K value small enough to be neglected or from a sufficiently large k_{et} value so that the reciprocal value can be neglected in eqn (5), under the assumption of the mechanism shown by eqns (2) and (3). Reactions of **2** and **3** with Me$_2$fc were similarly analyzed. Kinetics of the reactions of **4**–**8** with fc in acetonitrile were also analyzed in the same manner as those of the reactions of **1**–**3** with Me$_2$fc. The k_2 ($= k_{et}K$) values for the reactions of **1**–**3** with Me$_2$fc and of **4**–**8** with fc are listed in Table 3.

Another mechanism for the electron-transfer reaction without the formation of any precursor complexes may be considered as reported for the reaction of bis[2,9-dimethyl-4,7-bis(sulfonyloxyphenyl)-1,10-phenanthroline]copper(II) diperchlorate with sodium hexacyanoferrate(II) in water.[5] This reaction has been formulated as eqns (6) and (7):

$$[\text{Cu(II)L}]^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{Cu(II)L}]^{2+*} \qquad (6)$$

Table 2. K and k_{et} values for the reactions of the copper(II) complexes with fc in acetonitrile containing [Bu$^n_4$N][BF$_4$] (0.1 mol dm^{-3}) at 25°C

Complex	K (mol^{-1} dm^3)	k_{et} (s^{-1})

7	32.0±2.3	0.72
8	44.2±4.0	0.73

[a] In acetonitrile containing [Bu$^n_4$N][BF$_4$] (0.1 mol dm^{-3}) at 25°C.

[b] $E^{0\prime} = (E_{pc} + E_{pa})/2$ (Ref. 4).

$$[Cu(II)L]^{2+*} + Red \xrightarrow{k_{et}} [Cu(I)L]^{+} + Red^{+}. \quad (7)$$

where $[Cu(II)L]^{2+}$ and $[Cu(II)L]^{2+*}$ stand for the solvated species and the desolvated, active species for the electron transfer, respectively. When the condition $[[Cu(II)L]^{2+}] \ll [Red]$ is satisfied, one can derive eqn (8) from eqns (6) and (7):

$$\frac{1}{k_{obsd}} = \frac{k_{-1}}{k_1 k_{et}[Red]} + \frac{1}{k_1}. \quad (8)$$

Under such a reaction scheme, both plots of k_{obsd}^{-1} against $[fc]^{-1}$ and of k_{obsd}^{-1} against $[Me_2fc]^{-1}$ for the reactions of a copper(II) complex with fc and Me_2fc should give the same intercept. In the reaction of **1** with Me_2fc, however, a plot of k_{obsd}^{-1} against $[Me_2fc]^{-1}$ has an intercept with nearly zero (Fig. 3), which is in contrast to the appreciable non-zero intercept in the reaction of **1** with fc (Fig. 2). Similar results have been obtained for the reactions of **2** and **3** with Me_2fc. In view of these facts, the mechanism shown by eqns (6) and (7) for the electron-transfer reaction is not applicable for the present reactions of the copper(II) complexes with fc and Me_2fc.

The K values (42–110 mol^{-1} dm^3) for the present copper(II)–fc precursor complexes are larger than those (9.7–32.3 mol^{-1} dm^3)[1] for the corresponding precursor complexes formed in the reactions of the $Cu(II)(N_{imidazole})_2S_2$ complex with fc. This result may be explained in terms of the higher electron-accepting abilities of the present $Cu(II)(N_{pyridine})_2S_2$ complexes, which involve the pyridyl group having more effective π-acceptor property than the imidazolyl group.[6] This is consistent with the fact that the redox potentials of **1–3** (0.49–0.64 V vs SCE in acetonitrile) are positively higher than those of the $Cu(II)(N_{imidazole})_2S_2$ complexes (0.23–0.37 V vs SCE in acetonitrile).[1] The k_{et} value also increases with raising the redox potential of the $Cu(II)(N_{pyridine})_2S_2$ complex. The same tendency was seen in the reactions of $Cu(II)(N_{imidazole})_2S_2$ with fc.[1]

The formation of a precursor complex has not been detected not only in the reactions of complexes **1–3** with Me_2fc but also in those of **4–8** with fc. In the former reactions, a steric hindrance of the methyl groups of Me_2fc may cause fairly small K values. Such a steric hindrance, however, may not be significant in the latter reactions concerned with fc. Since complexes **4–8** exhibit sufficiently positive redox potentials (0.66–0.73 V vs SCE in acetonitrile) (Table 3), K values can be expected as large as those observed for the reactions of **1–3** with fc and fairly large k_{et} values are deduced for the reactions of **4–8** with fc.

LIGAND FIELD ANALYSIS OF TRIS(AMINOACIDATO)COBALT(III) COMPLEXES WITH GLYCINATO(N,O) AND β-ALANINATO(N,O) METAL CHELATE RINGS

S. R. NIKETIĆ* and W. URLAND†

Max-Planck Institut für Festkörperforschung, D-7000 Stuttgart-80, F.R.G.

(*Received* 29 *July* 1986; *accepted* 4 *September* 1986)

Abstract—In addition to showing a well-known demarcation between facial and meridional configurations the ligand field spectra of $Co(\beta Ala)_x(Gly)_{3-x}$ ($x = 1$ or 2) [βAla = β-alaninato(N,O) ring, and gly = glycinato(N,O) ring] complexes provide a rare example of a marked difference in the observed splitting pattern of the $^1T_{1g}(O_h)$ level among the three possible meridional isomers generated by cyclic permutation of chelate rings with respect to the pseudo three-fold axis. Angular overlap calculations which consider an anisotropy of the metal–carboxylate oxygen donor interaction reproduce fairly well the ligand field spectra of the complete series of $Co(\beta Ala)_x(Gly)_{3-x}$ ($x = 0$, 1, 2 or 3) complexes.

From their first description at the beginning of this century[1] tris(aminoacidato)cobalt(III) complexes have frequently been a focus of current chemical research: in connection with optical-activity studies,[2–5] proton[3] and ^{13}C NMR studies,[6] characterization of the species with three six-membered β-alaninato chelate rings,[7] "mixed" glycinato–β-alaninato species,[8] and α-hydrogen exchange reactions.[9]

An interesting feature of these systems is the influence of the chelate ring enlargement (from five-membered glycinato to six-membered β-alaninato) on their electronic[8] and circular dichroic‡ spectra.

The complete series of complexes $Co(\beta Ala)_x(Gly)_{3-x}$ [$x = 0$, 1, 2 or 3; βAla = β-alaninato(N,O) ring; and Gly = glycinato(N,O) ring] included in this investigation consists of the following 12 geometrical isomers (Fig. 1). For each of the species containing the rings of the same kind (i.e. $x = 0$ and 3) there are two isomers: facial (*fac*) and meridional (*mer*). The "mixed" complexes with two Gly and one βAla ring ($x = 1$), or vice versa ($x = 2$), comprise one *fac* and three *mer* forms, the

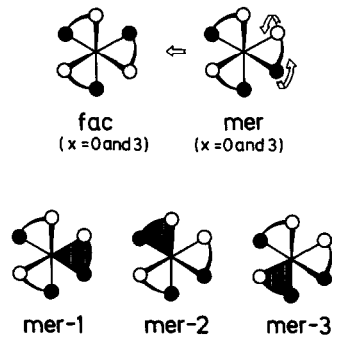

Fig. 1. Isomerism in tris(aminoacidato)cobalt(III) complexes. *First row*: facial and meridional configurations of $Co(Gly)_3$ or $Co(\beta Ala)_3$. The arrows indicate the "*trans*" ring inversion that changes the meridional into the facial configuration. *Second row*: three possible meridional isomers for "mixed" $Co(\beta Ala)_x(Gly)_{3-x}$ ($x = 1$ or 2) structures. The hatched ring indicates the one which is different from the other two: βAla(N,O) for $x = 1$ or Gly(N,O) for $x = 2$. They can be uniquely labelled by the *trans* pair of donor atoms from the rings of the same type as, for example, *mer*(N,O), *mer*(N,N) and *mer*(O,O).

‡Unpublished work carried out at the Chemistry Department A, The Technical University of Denmark, Lyngby, with Olav Overgaard Nielsen, Torben Steen Nielsen and Kirsten Vilholm, in 1971. In part presented at the 21st Meeting of the Serbian Chemical Society, Belgrade, 1978.

latter being generated by cyclic permutation of the chelate rings with respect to the pseudo three-fold axis.

All the isomers are known. Geometrical configurations of tris(glycinato)cobalt(III) complexes have been deduced from their electronic spectra[10] and later reconfirmed.[2-6] X-ray crystal analysis of the *mer* isomer is available.[9] Tris(β-alaninato)cobalt(III) isomers were assigned in a similar way[7] and the crystal structure of the *mer* isomer was also reported.[11] For the "mixed" complexes ($x = 1$ and 2) the electronic spectra[8] distinguish *fac* from *mer* isomers and, in addition, show the subtle but distinct differences among the *mer* isomers within both series ($x = 1$ and 2).*

The present study was initiated in order to find out how well a complete ligand field analysis based on the angular overlap model (AOM)[12-14] formalism may explain the electronic structures of tris(aminoacidato)cobalt(III) complexes. The AOM approach, through its principles of additivity and transferability of σ- and π-contributions of individual ligators, appears to be particularly well suited for this study which aims at explaining the effect of substituting a five-membered Gly with a six-membered βAla chelate ring, and the differences among the triads of *mer* isomers in "mixed" species (for $x = 1$ and 2).

METHODOLOGY

Wave functions

In the present treatment a complete basis of 210 Russell–Saunders free-ion functions $|d^6; \alpha LSJM_J\rangle$ was used. Since (as will be shown below) all the perturbations are applied simultaneously, the choice between a strong- and a weak-field basis was immaterial, and the free-ion basis was chosen for computational convenience.

Hamiltonian

Omitting the spherically symmetric central-field terms, as usually, the Hamiltonian consisted of three terms: ligand field potential $\hat{V}_{LF}$, electron repulsion operator $\Sigma\, e^2/r_{ij}$, and spin–orbit coupling operator $\Sigma\, \xi(t_i)\hat{l}_i \cdot \hat{s}_i$.

Matrix elements

Many-electron matrix elements of the ligand field potential are expanded by expressing $\hat{V}_{LF}$ as a superposition of spherical harmonics $\hat{Y}_k^q$ and evaluated using the standard methods of tensor operator algebra.[15,16] Coefficients of the expansion $R_k c_{kq}$ are expressed as linear combinations of one-electron matrix elements (transformed from the complex into the real *d*-basis). Finally, each of the 15 distinct one-electron matrix elements is parametrized as a sum of σ-, π- etc. contributions from each ligator atom according to the AOM formalism.[12-14] Matrix elements of electron repulsion and spin–orbit coupling operators are also evaluated using the standard tensor operator methods.[15,16] The former are parametrized with Slater–Condon parameters F_2 and F_4 (or Racah parameters B and C), and the latter with the one-electron spin–orbit coupling constant ζ.[15] All reduced matrix elements needed for these calculations were taken from Nielson and Koster's tables.[17]

Energy level calculation

Basic perturbation matrices are set up for each parameter value and summed to form the total (generally complex) Hamiltonian matrix which is diagonalized to give the perturbed eigenvalues. A symmetry analysis of eigenvectors is then performed yielding the composition of the levels expressed in percentage of the free-ion terms which is needed for intensity calculations (see below).

Spectra simulation

Individual spectral bands are assumed to be Gaussian on the wavenumber scale. In order to reconstruct actual spectral profiles three parameters (position, intensity and half-width) are required for each component band. Intensities were calculated using the "spin-only" formula of Schroeder.[18] This very crude approach considers only the spin-allowedness of a transition and expresses a transition probability as a sum of squared products of the components from ground- and excited-state eigenvectors having the same spin multiplicity. Intensities were assumed to be proportional to transition probabilities normalized to match the sum of oscillator strengths of the components of $^1T_{1g}$. Band half-widths were kept constant at about 1700 cm^{-1}. This value is within the range suggested by Jørgensen[19] and indeed gives the best fit to the spectra of *fac* isomers having the unresolved band of $^1T_{1g}$ parentage.

Parameter optimization

The search for the optimum ligand field parameters was carried out in two stages. First, the

* Characteristic differences were also observed in IR, proton and ^{13}C NMR spectra. Unpublished results of N. M. Kostić and S. R. Niketić. In part presented at the 21st Meeting of the Serbian Chemical Society, Belgrade, 1978.

parameters were varied (one or two at a time, in 100- and 50-cm^{-1} steps) in sufficiently large domains. During this preliminary optimization process intensities were estimated using Schroeder's formula (as described above) and simulated spectral profiles compared qualitatively to the experimental ones. The aim of this coarse adjustment of parameters was two-fold: (i) to locate the most probable narrow ranges for each parameter, and (ii) to identify plausible positions of the overlapped bands in experimental spectral profiles.

Final optimization was performed using the SPIRAL algorithm of Jones.[20] The method was devised for non-linear least-squares problems and is claimed[20] to be superior to the standard (Marquardt's and Powell's) algorithms. Only the band positions were fitted (including the overlapped bands positioned according to the results of the preliminary optimization). Computed band profiles were generated using the Schroeder's model to obtain relative intensities from the eigenvectors calculated with the "best-fit" parameter set. This overall tactic was imposed by the quality of experimental data (therefore, spectral deconvolution was not attempted) as well as by the limitations of the theoretical model (therefore, point-by-point fitting was not tried).

PARAMETRIZATION

As a starting point we considered the Hamiltonian parameters for the CoN_6 chromophore. Initial values for the electron repulsion parameters ($F_2 = 1141.3$ and $F_4 = 104.46$ cm^{-1}) as well as the AOM parameter for ammine nitrogen [$e_\sigma(N) = 8000$ cm^{-1}] were taken from the best-fit parameters* which reproduce the low-temperature high-resolution polarized single-crystal spectrum of the $[Co(NH_3)_6]^{3+}$ ion.[21] These parameters were subjected to the optimization procedure as described below. The choice of other AOM parameters was of prime importance. Namely, from the outset, two equally justifiable parametrization schemes appeared to be possible: one based on distinction between ligators from five- and six-membered metal chelate rings leading to the two sets of parameters for nitrogen and oxygen, and the other based on the assumption that AOM parameters for nitrogen and oxygen donors are the same irrespective of the ring size, and that any differences in the interaction with metal *d*-orbitals is due to geometrical factors. In the latter case we need only three AOM parameters: $e_\sigma(N)$, $e_\sigma(O)$ and $e_\pi(O)$. As usual, an π-interaction of ammine nitrogen is not involved so that $e_\pi(N) = 0$ is assumed throughout.

In addition to being more in the spirit of AOM, the second parametrization scheme was selected on the basis of the similarity between the internuclear metal–ligand M–L distances in five- and six-membered aminoacidato metal chelate rings. From eight crystal structure determinations[22] furnishing data on 13 crystallographically distinct isolated cobalt(III) glycinato(N,O) chelate rings the mean M—N distance is 1.96(2) Å and the mean M—O distance is 1.91(2) Å.† Similar data but from a smaller available collection[22] of six unique isolated cobalt(III) β-alaninato(N,O) chelate rings from four crystal structure reports yield for mean M—N and M—O distances values 1.95(2) and 1.91(1) Å, respectively.†

The assumed equivalence between the corresponding metal–ligand distances in five- and six-membered rings is further corroborated, in case of M—N, by the similarity in M—N stretching frequencies in vibrational spectra of $[Co(en)_3]^{3+}$ and $[Co(tn)_3]^{3+}$ ions[24] (en = ethylenediamine, tn = trimethylenediamine) and by the values of ^{59}Co NMR parameters[25] for tris(diamine) cobalt(III) complexes with chelate rings of various sizes. Molecular-orbital calculations are not available for aminoacidato complexes of cobalt(III), but analogous studies[26] of copper(II) and nickel(II) complexes show that differences in the average bond overlap densities of M—L bonds in five- and six-membered aminoacidato complexes are of the same order of magnitude as between different α-aminoacidato complexes (i.e. within the series of five-membered chelate ring structures).

Therefore, as a starting value, the $e_\sigma(O)$ parameter was set at 7000 cm^{-1} in line with the postulated lower ligand field strength of oxygen compared to ammine nitrogen coordinated to cobalt(III). However, the variation of this parameter over a wide range (6000–8000 cm^{-1}) was investigated. In contrast to a nitrogen donor, carboxylate oxygen may be involved in M–L π-bonding requiring an $e_\pi(O) \neq 0$ in AOM analysis. Such a possibility has already been anticipated.[8] Moreover, as will be demonstrated below, the anisotropy

* Table III of Ref. 21 gives *Dq*, *B* and *C* values which were here converted into the corresponding $e_\sigma(N)$, F_2 and F_4.

† However, when the internuclear distances from individual structure determinations are treated as mean values and their estimated standard deviations taken into consideration, we obtain, after Hamilton,[23] the following results: 1.955(1) and 1.907(1) Å for M—N and M—O distances, respectively in five-membered glycinato(N,O) rings, and 1.945(2) and 1.913(2) Å for M—N and M—O distances, respectively, in six-membered β-alaninato(N,O) rings.

of metal–oxygen (M–O) π-interaction has been found to be essential for explaining the characteristic splitting patterns in the spectra of *mer*-isomers of tris(aminoacidato)cobalt(III) complexes with "mixed" Gly–βAla coordination spheres. To our knowledge, the anisotropy of the carboxylate oxygen–metal bond has not been examined hitherto in cobalt(III) complexes. In a recent similar AOM study[27] of tris(glycinato)chromium(III) the M—O bond was treated as if it had axial symmetry, but a concurrent study[28] of cobalt(II) complexes with oxygen donor ligands did consider M—O bond anisotropy. Therefore, we have experimented with $e_{\pi\perp}(O)$ in the range 600–1800 cm^{-1} and set $e_{\pi\parallel}(O) = 0$ with the reference plane for each oxygen donor defined by itself, M and N of the same chelate ring.

Arguments in support of this parametrization stem also from structural evidence. The bond angle on the oxygen donor is 129.2(21) and 115.9(10)° for six-membered βAla rings (from crystal structure data on six individual rings) and five-membered Gly rings (from crystal structure data on 13 individual rings), respectively.[22] These angles together with bond lengths and angles around the carbonyl carbon and torsional angles involving coordinated carboxylate in Gly and βAla chelate rings[22] define a local geometry which is consistent with a simple bonding picture comprising a formally sp^2 oxygen donor (with its p-orbital perpendicular to the σ-framework) which is engaged in a partly delocalized π-system of the carbonyl group.

The effective one-electron spin–orbit coupling constant for cobalt(III) is not known but has been estimated[29] to be in the range 500–600 cm^{-1}. The ζ value of 580 cm^{-1} has been quoted both in a textbook[30] and in a more recent paper.[31] We have followed Wilson and Solomon[21] and adopted an upper limit value of 600 cm^{-1} which was kept fixed in all computations.

GEOMETRIES

Of 12 complex species studied in this work two have been previously characterized by X-ray structural analysis: *mer*-$Co(Gly)_3$[9] and *mer*-$Co(\beta Ala)_3$.[11] For the AOM analysis positions and orientations of donor atoms in these two *mer* isomers were taken from the crystal structure coordinates and M–L torsional angles, respectively. The corresponding *fac* isomers were generated by transposing the "*trans*" N–M–O rings of *mer* structures (rotation by 180° around the axis bisecting the N—M—O bite angle) and averaging to C_3-symmetry (cf. Fig. 1).

Insofar as the chelate-ring size did not have substantial influence on individual M—L bond characteristics enabling one to use the common set of AOM parameters, it is critical in defining the donor atom positions in the coordinate frame of the central metal atom. The N—M—O angle ("bite angle") is 85.3(8)° for five-membered Gly rings and 94.3(6)° for six-membered βAla chelate rings.[22] Using the simple formulae of solid trigonometry pertaining to the rectangular tetrahedron defined by one ligator position in the coordinate frame of the metal atom (Fig. 2) it is possible to relate the bite angle to other geometrical descriptions[32–35] which define the coordination octahedron in a trigonal tris (bidentate) structure. Two independent geometry descriptors are needed to fully specify the coordination octahedron in a tris(bidentate) structure. In addition to the bite angle it is, therefore, common to define, for example either the twist angle (ω)[32] or the tilt angle (θ)[33] or the ratio s/h[34] (here s = octahedron edge, and h = octahedron height along the molecular C_3-axis). From the above-mentioned crystal structures[9,11] we note that an increase in the bite angle is concurrent with an increase in ω and a decrease in θ and the s/h ratio. In other words, the change from five-membered Gly to six-membered βAla rings in tris(aminoacidato)cobalt(III) complexes gives rise to a trigonal elongation of the coordinate octahedron. A similar phenomenon is well-established both experimentally[35] and computationally[36,37] in tris(diamine)cobalt(III) complexes (Table 1).

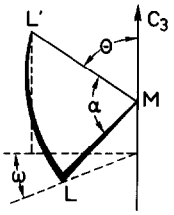

Fig. 2. Definition of bite (α), twist (ω) and tilt (θ) angles in an octahedral trigonal tris(bidentate) structure.

These structural regularities are observed in the construction of the *fac* structures (for $x = 0$ and 3) and the composite structures of "mixed" Gly–βAla complexes ($x = 1$ and 2). The latter eight structures were composed by placing the appropriate chelate ring (Gly or βAla) in the required sequence with respect to the (pseudo) three-fold molecular axis. Since the AOM analysis requires only the ligator coordinates this step was simplified by constructing three coplanar lines radiating from the centre, $2\pi/3$ apart from each other, which are taken as bisectors of the bite angles, and by fixing ligator positions with respect to these lines according to chosen bite and twist angles (cf. Fig. 2).

Table 1. Deformations of coordination octahedra in tris(bidentate)cobalt(III) complexes with five- and six-membered metal chelate rings

Structure[a]	Ring size	Bite angle (α) (°)	Twist angle (ω) (°)	Reference
Octahedron		90.0	60.0	
$[Co(en)_3]^{3+}$	5	85.44	52.69	32, 35
$[Co(tn)_3]^{3+}$	6	94.51	62.34	32, 35
$Co(Gly)_3$	5	85.93	55.25	9
$Co(\beta Ala)_3$	6	94.16	61.83	11

[a] Averaged to C_3-symmetry. Abbreviations: en = 1,2-diaminoethane(N,N), tn = 1,3-diaminopropane(N,N), Gly = glycinato(N,O) ring, βAla = β-alaninato(N,O) ring.

DISCUSSION

The ligand field spectra of tris(aminoacidato)cobalt(III) complexes consist of two broad bands.[2-5,7,8,10] There is no doubt about their assignment to the two spin-allowed singlet transitions. However, like the majority of room-temperature solution spectra of cobalt(III) complexes the low-symmetry components of the $^1T_1$ and $^1T_2$ parentage overlap to such an extent that the spectra are of very little use for detailed analysis. In spite of the low information content of the available experimental data the present analysis did reach conclusions concerning the questions raised in the introduction, demonstrating the utility (but also the limitation) of the AOM approach in a frequently encountered situation with respect to the available spectroscopic evidence.

In an attempt to overcome the lack of sufficiently accurate information about the component peak positions in the observed spectra, we have supplemented the initial (exploratory) optimization of ligand field parameters by introducing qualitative comparison between the observed and computed spectral profiles. Although, such an approach required an introduction of additional degrees of freedom in the model, the fact that we are dealing with a complete set of 12 members of the $Co(\beta Ala)_x(Gly)_{3-x}$ ($x = 0$, 1, 2 or 3) system enabled us to rely not only on the transferability of ligand field (and AOM) parameters within the series but also on the transferability of these additional variables required for spectra simulation (i.e. relative intensities and band half-widths), thus eliminating some of the uncertainty inherent in the analysis.

Parameter optimization was carried out by gradually increasing the number of structures taken into the study simultaneously. It consisted of the following steps. We have first considered the simplest of the structures, namely *fac*-$Co(Gly)_3$, and have varied F_2, F_4 and AOM parameters for nitrogen and oxygen donors, one at a time, mapping the parameter space in sufficiently wide intervals for each parameter.

Parameter fitting was not attempted at this stage because the number of parameters exceeded by far the experimental information. However, this search disclosed various patterns of dependence of calculated band positions on ligand field parameters which, in combination with general physico-chemical experience, such as $e_\sigma(N) > e_\sigma(O) > e_\pi(O)$, helped in defining the most probable narrow ranges for each of the parameters. With a moderately good parameter set the analysis was extended to *mer*-$Co(Gly)_3$ and, upon further (but not complete) refinement, to both *fac*- and *mer*-$Co(\beta Ala)_3$. The analysis showed that the basic spectral features[7,10] (e.g. greater splitting of the $^1T_1$ and $^1T_2$ levels, and a greater splitting of both levels in *mer* than in *fac* isomers) are well reproduced. We look at this well-known result as a starting point for the further analysis of spectral features which are not easily explainable within a conventional ligand field treatment: namely, at this stage we were not able to reproduce the significant difference in the splitting pattern of $^1T_1$ level between *mer*-$Co(Gly)_3$ and *mer*-$Co(\beta Ala)_3$.[7] Different mode of deformation of the coordination octahedron in these two systems obviously does not exert sufficient influence on the electronic energy levels of cobalt(III) ion to account for the observed spectral properties.

However, the other principal difference between five- and six-membered aminoacidato chelates is the conformational flexibility of βAla rings in the latter systems. Experimental* and computational† results show sufficient grounds to argue that six-membered βAla metal chelate rings may adopt conformations having different endocyclic torsional angles. Looking at the M–O interaction, the range of energetically accessible ring conformations are char-

* Mainly the results of crystal structure analyses of β-alaninato(N,O) chelates including the systems with substituted and fused rings. Cf. Ref. 22.

† A conformational analysis of tris(aminoacidato)cobalt(III) complexes based on the consistent force field (CFF) approach[36-38] is being carried out in parallel. Preliminary results show that βAla rings are very flexible and that with conventional[38] parametrization equilibrium conformations do not always correspond to those which emerge from crystal structure studies. A full account of this work will be presented elsewhere.

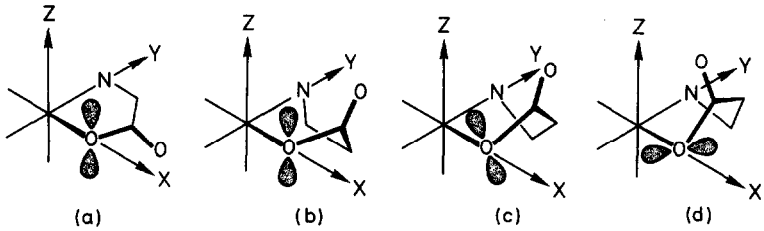

Fig. 3. Simplified sketches of Gly(N,O) and βAla(N,O) metal chelate rings showing: (a) an almost planar Gly(N,O) ring with oxygen-donor *p*-orbital perpendicular to the ring (in this case *XY*) plane; and (b), (c) and (d) a range of βAla(N,O) ring conformations spanning a $\pi/2$ interval of torsional angles around the M—O bond. The energetically favourable "twist-boat" form (c) is intermediate between two "boat" forms, (b) and (d).

acterized with a substantial variation in the M–O torsional angle and, therefore, in the M–O π-interaction. If the M–O torsional angle in an almost planar Gly ring is taken as zero, its value (and thus the orientation of the oxygen donor *p*-orbital with respect to the metal atom coordinate system) in the βAla ring may vary in the range of $-60°$ to $+60°$ (Fig. 3).

The adopted AOM parametrization [$e_{\pi\perp}(O) \neq 0$ and $e_{\pi\parallel}(O) = 0$] together with the consideration of torsional angles around the M—O bond in *mer*-Co(βAla)$_3$ taken from the result of crystal structure analysis[11] do in fact predict the differences in the splitting of the octahedral $^1T_1$ state between *mer*-Co(Gly)$_3$ and *mer*-Co(βAla)$_3$ which accord with the experimental data.

In the next step a full optimization of ligand field parameters was performed *simultaneously* on all four "non-mixed" species using the SPIRAL algorithm. This was necessary in order to ensure that the number of parameters be less than the number of observable band positions to be fitted. The resultant best-fit parameters are given in Table 2.

With calculated band positions and intensities and a constant band half-width the simulated spectra are in full agreement with the experimental ones (Table 3 and Fig. 4).

In order to apply the concept of anisotropy of the M–O interaction in our AOM scheme the orientation of the oxygen donor with respect to the M—O bond axis has to be specified. As this information is lacking for the *fac* isomer of Co(βAla)$_3$ we have attempted to look at the variation of calculated energy levels of *fac*-Co(βAla)$_3$ for a range of plausible ring conformations within the approximation of C_3 molecular symmetry. The results (Fig.

Table 2. "Best-fit" parameter set[a] optimized on four non-mixed isomers of Co(βAla)$_x$(Gly)$_{3-x}$ ($x = 0$ and 3) (in $cm^{-1} \times 10^3$)

$e_\sigma(N) = 8.0$[b]	
$e_\sigma(O) = 7.4$	$e_{\pi\perp}(O) = 1.7$

[c] Shoulder.

5) obtained with the "best-fit" parameter set (Table 2) show that although A and E components of the $^1T_1$ and $^1T_2$ octahedral parentage are sensitive to the variation in the M–O torsional angle their baricenter changes only slightly. It is close to the experimentally observed value for a range of ring conformations. Variation in the difference in energy between baricenters from $^1T_1$ and $^1T_2$ is too small to be used for comparison with the observed spectrum.

Reversal in the order of A and E levels on an energy scale as a function of chelate ring conformation (cf. Fig. 5) is of no consequence for the interpretation of electronic spectrum under the assumption of the O_h holohedrized symmetry of the *fac* isomer but might be of interest in optical-activity studies.

As a final step, the "best-fit" parameter set (Table 2) was used to calculate the energy levels of "mixed" tris(aminoacidato)cobalt(III) complexes. Again having no experimental indication about the βAla ring conformations in the "mixed" species the twist-boat form [cf. Fig. 3(c)], being one of the energetically favourable forms,* was assumed in all cases. Immediate results were encouraging: they showed that simulated spectra of the triads of *mer* isomers in both series (i.e. for $x = 1$ and 2) are indeed different. Moreover, the differences are—in a qualitative way—similar to the observed ones in most cases (Fig. 6).

CONCLUSIONS

An ultimate justification for the present analysis would be the possibility of assigning geometrical configurations to the *mer* isomers of "mixed" $Co(\beta Ala)_x(Gly)_{3-x}$ species ($x = 1$ or 2). However, the available spectroscopic data are not sufficiently informative to provide the required degree of reliability in such assignment. Furthermore, it

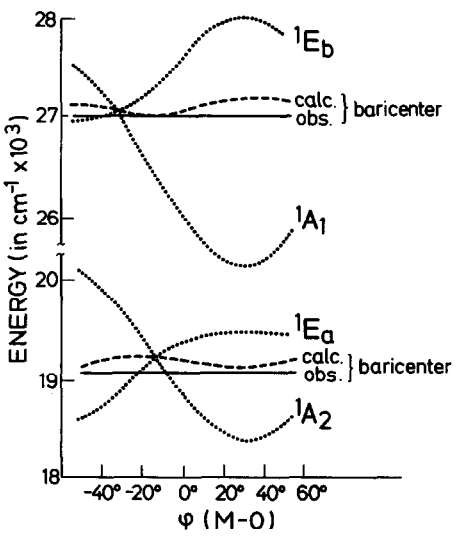

Fig. 5. Variation of energy levels with M–O torsional angle in *fac*-$Co(\beta Ala)_3$ having C_3 molecular symmetry. Zero torsional angle is defined for a conformation in which the *p*-orbital on the oxygen donor is perpendicular to the plane defined by the O, M and N of that ring.

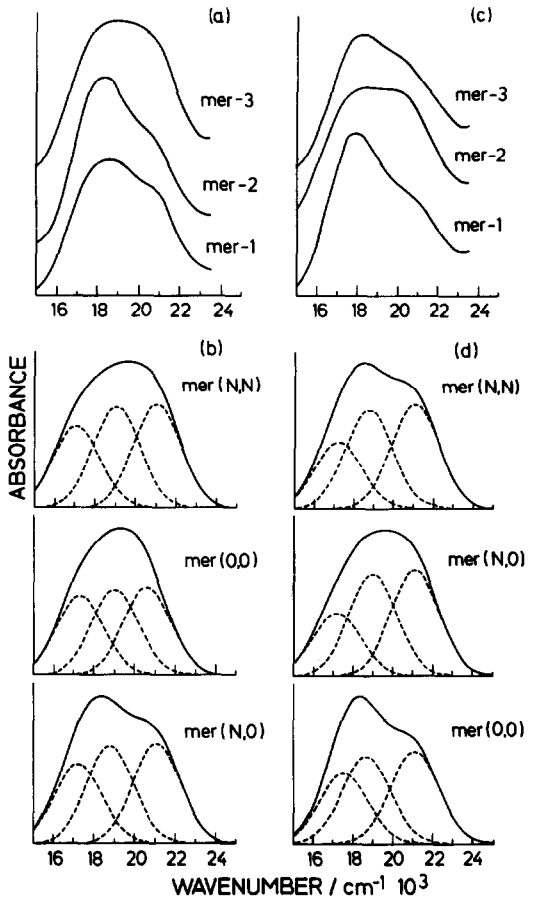

Fig. 6. Comparison of the experimental band shape for the ${}^1T_{1g} \leftarrow {}^1A_{1g}$ transition of: (a) three *mer* isomers of $Co(Gly)_2(\beta Ala)$ numbered in the elution order (Ref. 8), and (c) three *mer* isomers of $Co(\beta Ala)_2(Gly)$ numbered in the elution order (Ref. 8), with the simulated band shape for: (b) *mer*(N,N)-, *mer*(O,O)- and *mer*(N,O)-$Co(Gly)_2(\beta Ala)$, and (d) *mer*(N,N)-, *mer*(N,O)- and *mer*(O,O)-$Co(\beta Ala)_2(Gly)$. For the nomenclature of *mer* isomers see caption to Fig. 1. For the comment on assignment see Conclusion.

would be rational to base the assignment on combined data from different experimental techniques together with the AOM modelling. The results discussed above are, in fact, not intended to offer an assignment, but rather to demonstrate that a compact AOM parametrization related in a natural way to the local features of the ligand field of the cobalt (III) ion in those systems is indeed able to account for the *d–d* spectral pattern and differences among the 12 isomers of $Co(\beta Ala)_x(Gly)_{3-x}$. This parametrization is built on the idea of metal–carboxylate π-anisotropy which is proved to be successful in providing the link between chelate ring conformation and electronic properties, and convenient with respect to the transferability among the related systems. At least two possible lines of further development of this AOM approach are envisaged. One is to refine the conformational analysis of βAla chelate rings in order to reduce the range of possible ring conformations, and hence the interval for plausible M–O torsional angles. The other is to strive to obtain more information from *d–d* spectra (e.g. at low temperature) and thus to improve the accuracy in the refinement of AOM parameters. By extending this kind of analysis to other systems (in particular to conformationally restricted ones) we hope to accumulate the body of knowledge about AOM parameters necessary for the AOM to become an efficient complementary tool for stereochemical studies in transition metal chemistry.

SOLVENT EFFECT ON THE SYNERGIC EXTRACTION OF PRASEODYMIUM(III) AND NEODYMIUM(III) WITH 1-PHENYL-3-METHYL-4-BENZOYL-5-PYRAZOLONE AND 1,10-PHENANTHROLINE

LUO MINGRUN,* CAO ZIQING and ZHANG FENGMEI

Department of Chemistry, Anhui Normal University, Wuhu, Anhui, People's Republic of China

(*Received* 29 *July* 1986; *accepted* 4 *September* 1986)

Abstract—The solvent effect on the synergic extraction of praseodymium(III) and neodymium(III) with 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (HPMBP, HA) and 1,10-phenanthroline (phen, B) from a nitric acid medium have been studied by two-phase titration and the slope analysis method. It is found that the synergic reaction in the organic phase (denoted by subscript *o*) can be expressed as follows:

$$LnA_3HA_o + B_o = LnA_3B_o + HA_o.$$

The synergic equilibrium constants (K_s^x) in four different solvents were determined by experiment and calculated on the basis of the regular-solution theory. By comparing the theoretical and experimental values of ln K_s^x, good agreements were observed in the π-donor solvent series of benzene, toluene and xylene, but not in carbon tetrachloride.

Recently the solvent effect on the synergic extraction with acetylacetone (acac-H) and 1,10-phenanthroline (phen) has been quantitatively discussed on the basis of the regular-solution theory by Nakamura *et al.*[1] Li and Xu have also studied the solvent effect on the synergic extraction with 1-phenyl-3-methyl-4-benzoyl-5-pyrazoline (HPMBP, HA) and neutral ligands by the two-phase titration method, but they have announced that the regular-solution theory is too simple to be extensively applicable.[2] In this paper, we try to apply the regular-solution theory to the synergic extraction system with HPMBP and phen in four inert organic solvents—benzene, toluene, xylene and CCl_4. We found that, when extracting with HPMBP alone, the extracted chelate complex forms a self-adduct in the organic phase and the synergic agent phen competes with the undissociated form of the chelating acid HA in the synergic extraction equilibrium just as reported elsewhere.[3] In the system studied the regular-solution theory can be applied satisfactorily to the benzene, toluene and xylene solvent series, but with some restrictions to CCl_4.

EXPERIMENTAL

Reagents

HPMBP was obtained in A.R. grade and purified by recrystallization from 1:3 chloroform–petroleum ether (m.p. 91–92°C). phen of A. R. grade was used as obtained.

The rare earth stock solution was prepared by dissolving a known amount of neodynium or praseodymium oxide (99.99%) in concentrated nitric acid, evaporating to near dryness and diluting to a certain volume. The accurate concentration of rare earth ions was determined by titration with EDTA using xylenol orange as indicator. The working solutions were buffered with 0.01 M NaAc, the pH value adjusted to about 4 and the rare earth concentration was diluted to 1×10^{-4} M with 0.1 M $NaNO_3$ solution.

The four organic solvents were purified by ordinary methods[4] and the purity was checked by index of refraction. The experimental values (1.4970 for xylene, 1.4965 for toluene, 1.5010 for benzene and 1.4593 for CCl_4) were very close to that in the literature.[5]

Apparatus

The concentration of rare earth ions in the aqueous phase was determined with a 721 spectrophotometer.

The pH value was measured with a pH S-3C pH meter.

Determination of the partition coefficiency (P_s) *and the acid dissociation constant* (K_{HS}) *of phen*

We adopted the two-phase titration method of Dyressen[6] to determine P_s by titrating a mixture of a 0.025 M phen organic solution and a 0.1 M $NaNO_3$ aqueous solution with a 0.1000 M standard HNO_3 solution (N_2 protected) potentiometrically. K_{HS} was determined by titrating similarly a saturated solution of phen in a 0.1 M $NaNO_3$ solution but in the absence of the organic phase. The end point was determined by Gran's method.[7]

Extraction of Pr(III) *and* Nd(III)

Equal volumes (10 cm^3) of the aqueous and organic solutions were placed in a 50-cm^3 stoppered beaker and stirred with magnetic stirrer for 10 min. (It has been proved by experiment that the result is just the same with shaking in an equilibrium tube for 1 h and the equilibrium can be achieved.) The concentration in the aqueous phase was determined spectrophotometrically[8] and the concentration in the organic phase was determined by the subtraction method.

RESULTS AND DISCUSSION

P_s *and* K_{HS} *of phen*

We have adopted all the symbols used by Li and Xu,[6] but made some modifications to the expressions to suit the phen system.

In the following expressions ( ) and [ ] indicate concentration and activity, respectively, subscript *o* denotes species in the organic phase, and no subscript denotes species in the aqueous phase. For simplicity the charge symbols are omitted.

$$pK_{HS} = pH - \log\frac{(phen)}{(phenH)}, \quad (1)$$

$$(phenH) = \frac{V_{HNO_3}C_{HNO_3} - V_{NaOH}C_{NaOH}}{V} + (OH) - (H), \quad (2)$$

$$C_H = (H) + (phenH), \quad (3)$$

$$\bar{n} = \frac{V_{HNO_3}C_{HNO_3} + V(OH) - V(H)}{V_o^o C_{phen}^o}, \quad (4)$$

$$\log(1+P_s) = pK_{HS} + \log\left(\frac{1-\bar{n}}{\bar{n}}\right) - pH. \quad (5)$$

In the absence of the organic phase:

$$C_{phen} = (phen) + (phenH),$$

$$pK_{HS} = pH - \log\frac{C_{phen}V^o - V_{HNO_3}C_{HNO_3} + V(H) - V(OH)}{C_{HNO_3}V_{HNO_3} - V(H) + V(OH)}. \quad (6)$$

The dissociation constant (pK_{HS}) of phenH can be calculated from eqn (6) to be 5.00, just between the literature values of 5.04[1] and 4.96.[9] The P_s can be calculated from eqns (4) and (5). The results are shown in Table 1. Those of xylene and toluene were first determined in this paper, and those of CCl_4 and benzene are very close to the literature values.[1]

The solubility parameter of phen (δ_s) was calculated according to the relationships deduced by Li and Xu based on the Hildebrand regular-solution theory.[6]

$$Q_s = \log\lambda' + \frac{V_s\delta_o^2}{4.575T} = \frac{2V_s\delta_s}{4.575T}\delta_o + K, \quad (7)$$

where $\lambda' = P_s/(1000d/M)$, V_s is the molar volume of phen (142 ml mol^{-1}),[1] and δ_o is the solubility parameter of the solvent. We plotted Q_s against δ_o and by linear regression the intercept $b = -14.06$, the slope $m = 2.45$ and the correlation coefficient

Table 1. Partition coefficients and other parameters of phen

Solvent	δ_o	Log P_s	Log λ'	$\frac{V_s\delta_o^2}{4.575T}$	Q_s
Benzene	9.15	0.51	−0.5411	8.87	8.33
Toluene	8.9	0.32	−0.6535	8.40	7.74
Xylene	8.8	0.20	−0.7106	8.21	7.50
CCl_4	8.6	0.16	−0.8555	7.84	6.98

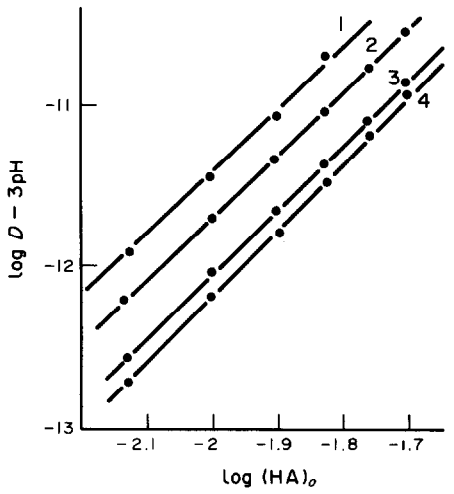

Fig. 1. Extraction of Pr(III) with various C_{HA} in different organic solvents: (1) CCl_4, (2) benzene, (3) toluene, and (4) xylene.

$r = 0.9996$. From eqn (7):

$$\delta_s = \frac{m4.575T}{2V_s}.$$

The calculated δ_s of phen equals 11.56 (at 20°C), slightly lower than that in the literature.[1]

Exraction of Pr(III) *and* Nd(II) *with HPMBP*

We had studied the extraction of rare earth ions by HPMBP in chloroform[10] and the results agreed with those of Roy and Nag.[11] In this paper we have changed the solvent to CCl_4, benzene, toluene and xylene. The results are shown in Figs 1 and 2.

By the slope analysis method the composition of the extracted complex is proved to be LnA_3HA. The extraction equilibrium can be expressed as

$$Ln^{3+} + 4HA_o = LnA_3HA_o + 3H^+, \quad (8)$$

$$K_{ex} = \frac{(LnA_3HA)_o(H^+)^3}{(Ln^{3+})(HA)_o^4},$$

$$\log K_{ex} = \log D - 3pH - 4\log (HA)_o.$$

In the presence of acetate ions, $\log D$ must be corrected by

$$\log D = \log D_{(expl.)} + \log Y,$$

$$\log Y = 1 + \sum_1^n \beta_i (Ac^-)^i.$$

We treat our data according to the following expressions[2] to calculate the solubility parameters (δ_{MA}) of LnA_3HA:

$$\log \beta^o_{310} = \log K_{ex} + 3pK_{aE} + \log K_d, \quad (9)$$

$$Q_{310} = \log \beta^o_{310} + \log \frac{M_1 d_2}{d_1 M_2} + \frac{V_{HA}\delta_o^2}{4.575T}$$

$$= \frac{2\delta_{MA}V_{MA}}{4.575T}\delta_o + K, \quad (10)$$

where $V_{MA} = V_{LnA_3HA}$. V_{MA} can be calculated by comparing with that of $Dy(acac)_3$ and $Y(acac)_3$ (269 $cm^3\ mol^{-1}$),[1] $V_{HA} = 241\ cm^3 mol^{-1}$,[6] and $V_{acac} = M/d = 102.57\ cm^3\ mol^{-1}$.

$$V_{acac} : V_{HA} = V_{Ln(acac)_3} : V_{LnA_3}.$$

Substituting the known values into the above equation, we get $V_{LnA_3} = 632\ cm^3\ mol^{-1}$. Then:

$$V_{MA} = V_{LnA_3} + V_{HA} = 873\ cm^3\ mol^{-1}.$$

The calculated $\log \beta^o_{310}$ and Q_{310} of PrA_3HA and NdA_3HA are shown in Table 2.

When we plot Q_{310} against δ_o we get two nearly straight lines. The slope of each line calculated by linear regression equals 14.77 and 14.69 for PrA_3HA and NdA_3HA, respectively. From expression (10) the slope equals $2V_{MA}\delta_{MA}/4.575T$, so we can get the δ_{MA} of PrA_3HA and NdA_3HA. The values are 11.34 and 11.28, respectively.

We also plot $\log \beta^o_{310}$ against $3pK_{aE} + \log K_d$, when the relationship between benzene, toluene and xylene is nearly linear.

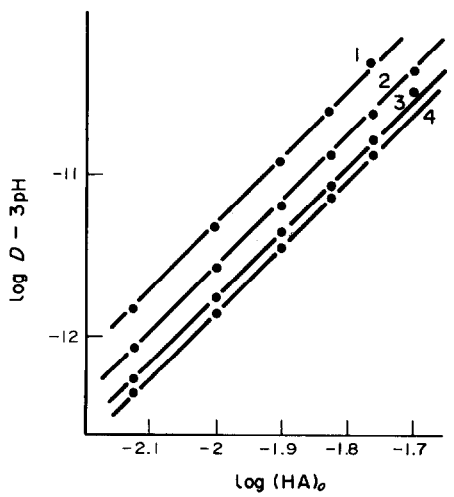

Fig. 2. Extraction of Nd(III) with various C_{HA} in different organic solvents: (1) CCl_4, (2) benzene, (3) toluene, and (4) xylene.

Synergic extraction of Pr(III) *and* Nd(III) *with HBMBP and phen*

By the slope analysis method, the compositions of the synergic extracted complexes are proved to be PrA_3B and NdA_3B, the same as in the chloroform system (see Figs 3–6).

Table 2. Log β^o_{310} and Q_{310} of PrA_3HA and NdA_3HA

Solvent	HA		PrA_3HA		NdA_3HA	
	$pK_{aE}{}^a$	$\log K_d{}^a$	$\log \beta^o_{310}$	Q_{310}	$\log \beta^o_{310}$	Q_{310}

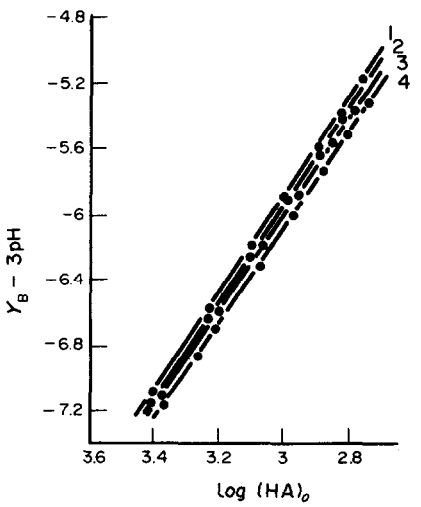

Fig. 3. Synergic extraction of Pr(III) with various C_{HA} and constant C_B in different organic solvents. (1) benzene, (2) toluene, (3) xylene, and (4) CCl_4. $C_B = 1 \times 10^{-4}$ M, $Y_B = \log D - \log (B)_o$.

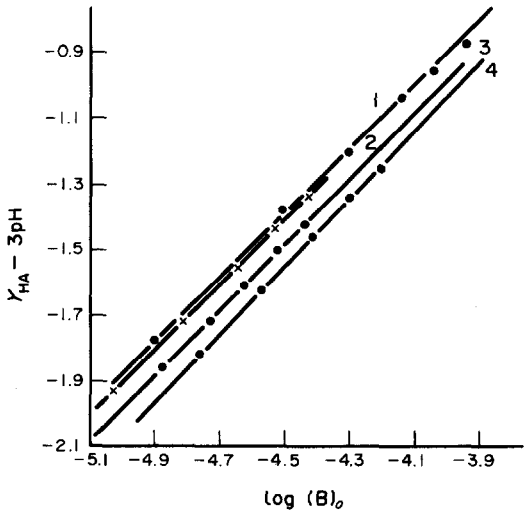

Fig. 5. Synergic extraction of Pr(III) with constant C_{HA} and various C_B in different organic solvents: (1) benzene, (2) toluene, (3) xylene, and (4) CCl_4. $C_{HA} = 5 \times 10^{-4}$ M, $Y_{HA} = \log D - 3 \log (HA)_o$.

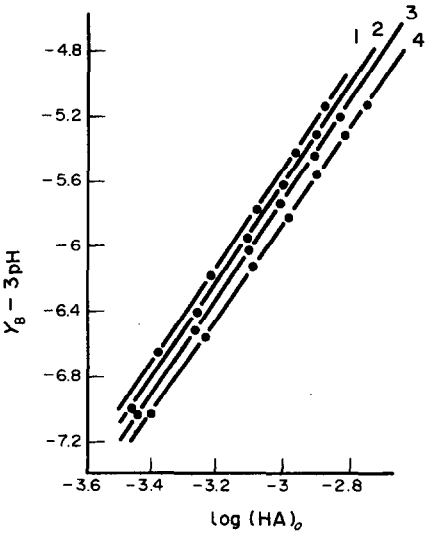

Fig. 4. Synergic extraction of Nd(III) with various C_{HA} and constant C_B in different organic solvents: (1) xylene, (2) toluene, (3) benzene, and (4) CCl_4. $C_B = 1 \times 10^{-4}$ M, $Y_B = \log D - \log (B)_o$.

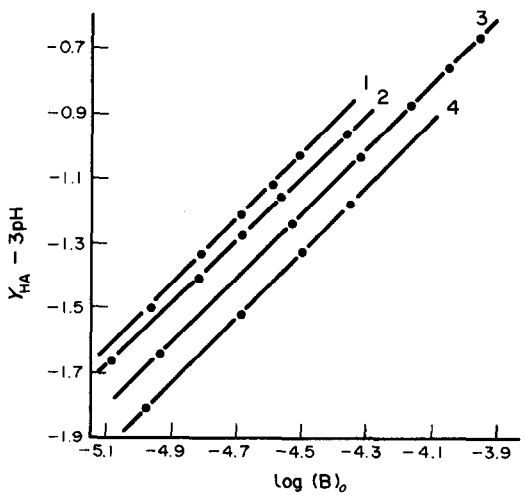

Fig. 6. Synergic extraction of Nd(III) with constant C_{HA} and various C_B in different organic solvents: (1) xylene, (2) toluene, (3) benzene, and (4) CCl_4. $C_{HA} = 5 \times 10^{-4}$ M, $Y_{HA} = \log D - 3 \log (HA)_o$.

The synergic extraction equation can be written as:

$$Ln^{3+} + 3HA_o + B_o = LnA_3B_o + 3H^+, \quad (11)$$

$$K_{s.e.} = \frac{(LnA_3B)_o(H^+)^3}{(Ln^{3+})(HA)^3(B)_o},$$

$$\frac{DY[H^+]^3}{(HA)_o^3(B)_o}$$

$$\log K_{s.e.} = \log D - 3pH - 3\log(HA)_o - \log(B)_o,$$

$$\log D = \log D_{(exp)} + \log Y.$$

Let $[Ln(III)]_o$ be the concentration of combined Pr(III) or Nd(III) in the organic phase. Then the equilibrium concentration of HA and B in the organic phase can be calculated from the following expressions:

$$(HA)_o = \frac{C_{HA} - 3[Ln(III)]_o}{1/K_d(1 + K_a/[H])}, \quad (12)$$

$$(B)_o = \frac{C_B - [Ln(III)]_o}{1 + (1 + [H]/K_{HS})P_s}. \quad (13)$$

We can use the same method to get the solubility parameters for the extracted complex from the following expressions:

$$\log \beta^o_{301} = \log K_{s.e.} + 3pK_{aE} + \log P_s, \quad (14)$$

$$Q_{301} = \log \beta^o_{301} + \log \frac{M_1 d_2}{d_1 M_2} + \frac{V_{MS}\delta_o^2}{4.575T}$$

$$= \frac{2\delta_{MS}V_{MS}}{4.575T}\delta_o + K, \quad (15)$$

where V_{MS} is the molar volume of the synergic extracted complex:

$$V_{MS} = V_{LnA_3} + V_s = 774\,cm^3\,mol^{-1}.$$

The calculated $\log \beta^o_{301}$ and Q_{301} of PrA_3B and NdA_3B are shown in Table 3.

When we plot Q_{301} against δ_o we also get two nearly straight lines. By linear regression we get the slope $m = 12.58$ for PrA_3B and $m = 12.46$ for NdA_3B. From the slope expression we get $\delta_{MS} = 10.89$ for PrA_3B and $\delta_{MS} = 10.79$ for NdA_3B. When we plot $\log \beta^o_{301}$ against $3pK_{aE} + \log P_s$, the relationship between benzene, toluene and xylene is also linear.

Synergic extraction in the organic phase

The synergic extraction reaction in the organic phase can be assumed to be:

$$LnA_3HA_o + B_o = LnA_3B_o + HA_o \quad (16)$$

or

$$MA_o + S_o = MS_o + A_o,$$

and the constant of the synergic extraction reaction can be expressed as $\log K_s$. Since:

$$\text{eqn (16)} = \text{eqn (11)} - \text{eqn (8)},$$

$$\log K_s = \log K_{s.e.} - \log K_{ex}. \quad (17)$$

The solvent effect on this synergic extraction can be quantitatively discussed by considering the activity coefficients of the different species in the four solvents. A thermodynamic equilibrium constant (K_s^o) is defined as follows:

$$K_s^o = \frac{X_{MS}X_A}{X_{MA}X_S}\frac{\gamma_{MS}\gamma_a}{\gamma_{MA}\gamma_s} = K_s^x\frac{\gamma_{MS}\gamma_a}{\gamma_{MA}\gamma_s}. \quad (18)$$

The activity coefficient γ can be calculated from the equation based on the Hildebrand regular-solution theory for a very dilute solution.[1]

$$\ln \gamma_c = \frac{V_c}{RT}(\delta_c - \delta_o)^2. \quad (19)$$

From the molar volume and solubility parameters of the four species in eqn (16) the activity coefficient can be calculated according to eqn (19). When we plot $\ln K_s^x$ against $\ln(\gamma_{MS}\gamma_A/\gamma_{MA}\gamma_S)$ the intercept equals the thermodynamic equilibrium constant ($\ln K_s^o$) and the theoretical $\ln K_s^x$ can be calculated from the following equation:

$$\ln K_s^x = \ln K_s^o + \ln \frac{\gamma_{MA}\gamma_S}{\gamma_{MS}\gamma_A}. \quad (20)$$

The results are shown in Tables 4 and 5.

Table 3. Log β^o_{301} and Q_{301} of PrA_3B and NdA_3B

		PrA_3B		NdA_3B	
Solvent	$3pK_{aE} + \log P_s$	$\log \beta^o_{301}$	Q_{301}	$\log \beta^o_{301}$	Q_{301}
Benzene	23.10	26.22	75.25	26.41	75.44
Toluene	22.61	25.69	72.20	26.03	72.54
Xylene	21.83	24.86	70.40	25.32	70.86
CCl_4	22.06	25.01	68.45	25.23	68.67

Table 4. Extraction equilibrium constants of Pr(III)

Solvent	log K_{ex}	log $K_{s.c.}$	log K_s	ln K_s^x(exp)	ln $\frac{\gamma_{MS}\gamma_A}{\gamma_{MA}\gamma_S}$	ln K_s^x(calc.)
CCl_4	−3.44	2.95	6.39	14.72	−5.21	17.01
Xylene	−4.18	3.03	7.21	16.60	−4.78	16.58
Toluene	−4.05	3.08	7.13	16.42	−4.56	16.36
Benzene	−3.75	3.12	6.87	15.82	−4.01	15.81

Linear regression: $b = 11.70$, $m = -1.028$, $r = -0.9983$ (except for CCl_4). Adjusted $\ln K_s^o = 11.80$.

Table 5. Extraction equilibrium constants of Nd(III)

Solvent	log K_{ex}	log $K_{s.c.}$	log K_s	ln K_s^x(exp)	ln $\frac{\gamma_{MS}\gamma_A}{\gamma_{MA}\gamma_S}$	ln K_s^x(calc.)
CCl_4	−3.30	3.17	6.47	14.90	−5.31	17.18
Xylene	−3.77	3.49	7.26	16.72	−4.87	16.74
Toluene	−3.75	3.42	7.17	16.51	−4.65	16.52
Benzene	−3.60	3.31	6.91	15.91	−4.07	15.92

Linear regression: $b = 11.77$, $m = -1.017$, $r = -0.9999$ (except for CCl_4). Adjusted $\ln K_s^o = 11.87$.

The plots of $\ln K_s^x$ against $\ln(\gamma_{MS}\gamma_a/\gamma_{MA}\gamma_S)$ are close to a straight line with a slope of −1 for xylene, toluene and benzene, but not for CCl_4. Again the calculated values of $\ln K_s^x$ are in good agreement with the experimental constants for xylene, toluene and benzene, but not for CCl_4 (Tables 4 and 5). The abnormal behavior in CCl_4 can be rationalized by the following comparison.

In the extraction by HPMBP, the values of $\log K_{ex}$ are in such order: CCl_4 > benzene > toluene > xylene. However, in the synergic extraction the $\log K_s$ of the reaction in the organic phase are in the reverse order: xylene > toluene > benzene > CCl_4. This experimental fact confirms that in the synergic reaction phen competes with HA. The more stable the self-adducts LnA_3HA, the more difficult is the formation of LnA_3B. But why the LnA_3HA self-adduct is most stable in CCl_4 is a question to be further investigated. We can conclude that, in the system studied, the regular-solution theory can be applied to the π-donor solvent series of benzene, toluene and xylene, but not to CCl_4. We agree with Li and Xu in saying that the Hildebrand regular-solution theory is too simple to be widely applicable but it is still useful for systems in different inert solvents which are very similar in structure.

SYNERGIC EXTRACTION OF Cd(II) WITH MIXTURES OF 4-METHYL-*N*-8-QUINOLINYLBENZENESULPHONAMIDE AND TRI-*n*-BUTYLPHOSPHATE OR TRI-*n*-OCTYLPHOSPHINE OXIDE DISSOLVED IN TOLUENE

(*Received* 7 *August* 1986; *accepted* 4 *September* 1986)

Abstract—The distribution equilibria of Cd(II) from 0.1 mol dm^{-3} KNO_3 with mixtures of 4-methyl-*N*-8-quinolinylbenzenesulphonamide and the organophosphorus compounds tri-*n*-butylphosphate (TBP) or tri-*n*-octylphosphine oxide (TOPO) dissolved in toluene have been investigated. The composition of the extracted species and values of the corresponding stoichiometric extraction constants have been deduced following both graphical and numerical treatments of experimental data. Synergic effects are bigger with TOPO than with TBP in agreement with its greater ability to displace water molecules from the coordination sphere of the metal ion.

The commercial extractant reagent LIX 34 (Henkel Corp.) was introduced by Kordosky *et al.*[1] and its chemical structure, an 8-alkarylsulphonamidoquinoline, and synthesis were disclosed by Virnig[2] in 1977. Although more emphasis has been given to the LIX 34–Cu(II) system, including equilibria, kinetic studies and pilot plant evaluations,[1,3–5] the extraction of some other metals including Zn(II), Cd(II), Pb(II) and Hg(II) has also been reported.[6–11] Synergic effects on the extraction of Zn in the presence of neutral donors have been claimed although no data on the composition of the extracted species has been indicated.[9] No synergism was found when mixtures of LIX 34 and carboxylic or alkylphosphoric acids were employed.[3,8] The present work was undertaken in order to explore the existence of synergism on the extraction of Cd(II) with mixtures of 8-sulphonamidoquinoline derivatives and neutral donors. The synthesized reagent 4-methyl-*N*-8-quinolinylbenzenesulphonamide was chosen as a model compound closely related to the active component in LIX 34[12] but available in a higher state of purity, and therefore allowing the determination of significant constant values, which are of paramount importance in the design of any liquid–liquid extraction procedure. Some chemical and extractive properties of the reagent have been published elsewhere.[12–15] The organophosphorus compounds tri-*n*-butylphosphate (TBP) and tri-*n*-octylphosphine oxide (TOPO) have been chosen since their interaction equilibria with the reagent are known.[16] On the other hand their different basic properties allow one to study the influence of the basicity of the neutral donor on the extraction equilibria.

EXPERIMENTAL

Reagents and solutions

4-Methyl-*N*-8-quinolinylbenzenesulphonamide was synthesized and purified as described previously.[17] TBP (Merck p.a.), TOPO (Eastman–Kodak p.a.) and toluene (Scharlau p.a.) were used as received. Stock solutions containing Cd(II) were prepared in distilled deionized water from $Cd(NO_3)_2 \cdot 4H_2O$ (Merck p.a.) and its ionic content was checked by evaporating an aliquot and weighing the residue. All other chemicals used were of analytical-reagent quality and used without further purification.

Experimental technique

Equal volumes (10 cm^3) of both organic and aqueous phases were mechanically shaken in special stoppered test tubes at 293 ± 2 K for at least 40 min. Preliminary experiments had shown that equilibrium was reached in about 20 min with both synergic mixtures. The aqueous phase contained 5.0×10^{-4} mol dm^{-3} Cd(II) in 0.1 mol dm^{-3} KNO_3. The concentration of 4-methyl-*N*-quinolinylbenzenesulphonamide was 1.0×10^{-2} mol dm^{-3} whereas the concentration of the organophosphorus compounds was varied in the ranges 2.3×10^{-2}–7.8×10^{-1} mol dm^{-3} for TBP and 2.0×10^{-3}–1.0×10^{-2} mol dm^{-3} for TOPO. Organic mixtures had been preconditioned with the proper nitrate solution prior to use in order to avoid volume changes. After phase separation by centrifugation, the H^+ concentration in the aqueous phase was evaluated potentiometrically using a combined glass electrode. The distribution coefficient (D), defined as the ratio between the total organic and aqueous metal concentration, was determined after removing aliquots of both phases for analysis of Cd(II) by A.A.S. The copper content of the organic phase was measured by stripping the metal into 1.0 mol dm^{-3} sulphuric acid. All the data which did not fulfill the mass balance for cadmium within 4% were rejected.

RESULTS AND DATA TREATMENT

The extraction of Cd(II) from nitrate medium with the synergic mixtures of 4-methyl-*N*-8-quinolinylbenzenesulphonamide (HR) and the organophosphorus compounds TBP or TOPO (generically denoted as S), can be represented by the following general equilibrium:

$$Cd^{2+} + rNO_3^- + pHR_{org} + qS_{org} \rightleftharpoons Cd(NO_3)_rR_pS_{q,org} + pH^+, \quad (1)$$

where the absence of polynuclear metal complexes and molecules of the chelating agent solvating the extracted species has been implied. Both facts have been proved in a former work[18] when studying the extraction of several metal ions, including Cd(II), from the same ionic medium using the chelating reagent in toluene.

The distribution coefficient of the metal ion can be expressed as:

$$D = \sum_r \sum_p \sum_q K'_{rpq}[HR]^p_{org}[S]^q_{org}[NO_3^-]^r h^{-p}, \quad (2)$$

where h stands for $[H^+]$ and K'_{rpq} is a conditional extraction constant defined by:

$$K'_{rpq} = K_{rpq}\alpha_{Cd}^{-1}, \quad (3)$$

K_{rpq} being the stoichiometric equilibrium constant for reaction (1) and α_{Cd} the side-reaction coefficient of the metal ion due to the formation of nitrate complexes in the aqueous phase.

Experimental data of type $\log D = f(\text{pH})$ obtained at constant chelating agent concentration and different concentration levels of the two organophosphorus compounds are shown in Figs 1 and 2, respectively. From the slope values (ranging from 1.84 to 1.90) of the straight lines obtained, and taking into account the electroneutrality condition of the extracted species in the organic phase, it can be inferred that the stoichiometric coefficients of the predominant extracted complex have the values $p = 2$ and $r = 0$.

According to eqn (2), values of the stoichiometric coefficient q can be deduced from the plots of the function $\log D - p \log [HR] = f(\log [S]_{org})$ obtained at constant pH values. Distribution coefficient data for the plots were obtained from the intercepts of the experimental $\log D = f(\text{pH})$ with straight lines par-

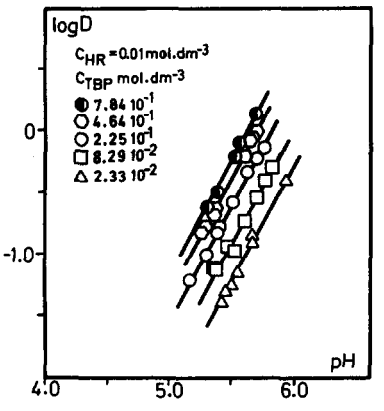

Fig. 1. $\log D$ vs pH for Cd(II) extraction at constant chelating reagent and different TOPO concentrations. Continuous lines were drawn using constants given in Table 1.

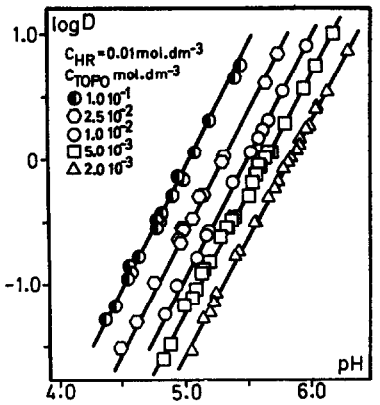

Fig. 2. $\log D$ vs pH for Cd(II) extraction at constant chelating reagent and different TBP concentrations. Continuous lines were drawn using constants in Table 1.

allel to the abscissa axis. Taking into account the proved monomeric behaviour of the reagent in toluene,[17] the free-extractant concentration used in the plots was calculated from the mass balance of the reagents:

$$C_S = [S]_{org}(1+\beta_{11}[HR]_{org}), \quad (4)$$

$$C_{HR} = [HR]_{org}(1+K_D^{-1}+K_{a1}^{-1}K_D^{-1}h + K_{a2}K_D^{-1}h^{-1}+\beta_{11}[S]_{org}), \quad (5)$$

where K_D, K_{a1} and K_{a2} are, respectively, the distribution and acidity constants of the chelating reagent, and β_{11} represents the equilibrium constant for the formation of the 1:1 adduct between the chelating agent and the organophosphorus compounds in the organic phase. Values of these constants had been previously determined.[16,19] In the above mass balances, the concentration of the extractants bound to the metal ion has been disregarded since a high extractant/metal concentration ratio was used in the experiments.

Figure 3 shows that the plots of the experimental function $\log D - 2\log[HR]_{org} = f(\log[S]_{org})$ at different pH values follow, in both systems, an upward curve when increasing the concentration of the organophosphorus compounds, having a limiting slope value of 1. Consequently, the main extracted species seems to have the stoichiometries CdR_2 and CdR_2S, respectively.

In order to confirm the validity of this extraction model, and determine the values of the extraction constants, a grahical curve fitting treatment was carried out. According to the model eqn (1) will take the form:

$$D = K'_{020}[HR]_{org}^2 h^{-2} + K'_{021}[HR]_{org}^2[S]_{org}h^{-2}. \quad (6)$$

Equation (6) can be rearranged and reduced to:

$$Y = 1 + X, \quad (7)$$

Y and X being the following normalized variables:

$$Y = DK'^{-1}_{020}[HR]^{-2}_{org}h^2, \quad (8)$$

$$X = K'_{021}K'^{-1}_{020}[S]_{org}. \quad (9)$$

Since the experimental function $\log D - 2\log[HR]_{org} = f(\log[S]_{org})_{pH}$ and the theoretical $\log Y = \log(1+X) = f(\log X)$ only differ in constant values:

$$(\log D - 2\log[HR]_{org}) - \log Y = \log K'_{020} + 2pH, \quad (10)$$

$$\log X - \log[S]_{org} = \log K'_{021}K'^{-1}_{020}, \quad (11)$$

from the differences in both axes in the position of best fit between the functions (Fig. 3), values of $\log K'_{020} + 2pH$ and $\log K'_{020}K'^{-1}_{021}$ were, respectively, deduced. The straight lines, slopes close to 2 and 0, respectively, obtained when plotting the former differences as a function of pH are in agreement with the proposed model. As an example of

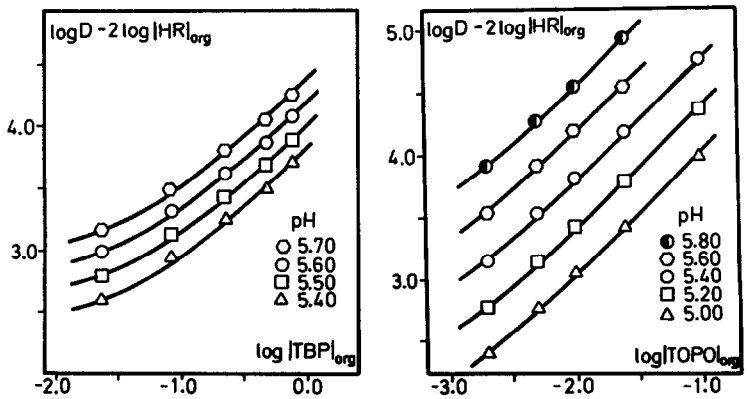

Fig. 3. Position of best fit between the theoretical $\log Y = f(\log X)$ (continuous lines) and experimental data $\log D - 2\log[HR]_{org} = f(\log[S]_{org})$ at different constant pH values in the presence of TBP or TOPO.

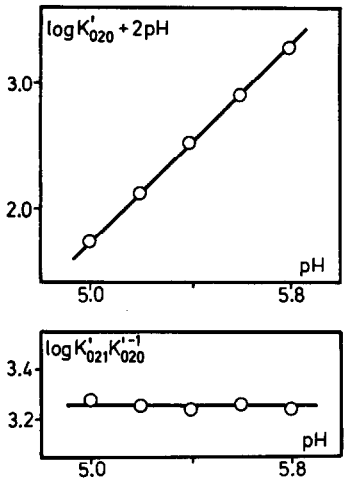

Fig. 4. Differences on both axes between experimental and theoretical functions in Fig. 3 as a function of pH.

the plots, Fig. 4 shows the ones obtained for the extraction of Cd(II) in the presence of TOPO. Graphical values of the stoichiometric extraction constants were calculated from the conditional values derived in the former treatment and published cadmium nitrate complex constants.[20] Table 1 shows the values of the extraction constants graphically derived.

The experimental data were finally treated numerically by means of the LETAGROP–DISTR program[21] in order to refine the values of the extraction constants as well as to look for new models of species which could improve the goodness of the fit. The error square sum (U) extended to the total number of experimental data (N_p) and defined as:

$$U = \sum_{N_p} (\log D_{\text{calc.}} - \log D_{\text{exp}})^2, \qquad (12)$$

was used in the minimization process. D_{exp} represent the experimental distribution coefficient and $D_{\text{calc.}}$ the corresponding value calculated by the program for the model tested after solving the mass balance equations of the components of the system. Therefore, the best model is the one which gives the lowest values of both U and the mean standard deviation $\sigma(\log D) = (U/N_p)^{1/2}$.

The calculations were performed taking the set of species and extraction constants graphically derived as the starting input and considering the influence on the minimized function when partially varying or adding new species to the model. The results obtained are summarized in Table 2.

Table 1. Values of the stoichiometric equilibrium constants for the extraction of Cd(II) with mixtures of 4-methyl-*N*-8-quinolinylbenzenesulphonamide (HR) and the organophosphorus compounds TBP or TOPO dissolved in toluene

[a] Proposed model.

Two species models different to the one graphically derived give rise, in both systems, to worse fits of the experimental data. However, the inclusion in the model of the mixed complex $Cd(NO_3)R$ improves the fit to the data and eliminates systematic errors. The existence of the mixed species can explain the slight deviations to lower values than 2 of the slopes of the $\log D = f(\text{pH})$ data for all the concentrations of TBP and TOPO studied. The values of the equilibrium extraction constants calculated by the program are shown in Table 1 and are in good agreement with the values graphically deduced.

CONCLUSIONS

The extraction of Cd(II) from nitrate medium by mixtures of 4-methyl–*N*-quinolinylbenzenesulphonamide and the organophosphorus compounds TBP or TOPO dissolved in toluene takes place mainly by the formation of the chelate CdR_2 and the adduct CdR_2S. Experimental data in both systems are better explained by the inclusion in the model of the mixed species $Cd(NO_3)R$. Although support by independent methods should be desirable to conclude about its presence, it should be pointed out that mixed species of this type have been also postulated in the extraction of several metal ions, including Cd(II) with 8-sulphonamidequinoline derivatives.[18,22] Moreover, a similar complex has been proved to be even predominant in the extraction of Cu(II) with 4-methyl–*N*-8-quinolinylbenzenesulphonamide in the presence of TBP.[23] On the other hand, a fairly good agreement between the values of its extraction constant have been found in the present work in the two systems studied.

On the basis of the extraction data, the constants for the adduct formation in the organic phase (β_s) represented by the reaction:

$$CdR_{2,org} + S_{org} \rightleftharpoons CdR_2S_{org} \qquad (13)$$

mainly responsible of the synergic effect in the systems, were calculated taking into account that:

$$\beta_s = K_{021}K_{020}^{-1}. \qquad (14)$$

A higher constant value and consequently a larger synergic effect was obtained with TOPO ($\log \beta_s = 3.60$) than in the presence of TBP ($\log \beta_s = 1.55$). The result is in agreement with the order of basicity and the capacity of water displacement of the organophosphorus compounds. The different synergic efficiency can be appreciated in Fig. 5, where the percentage of Cd(II) extraction as a function of pH has been plotted in the absence and presence of the solvating extractants.

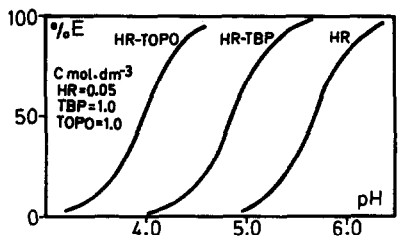

Fig. 5. Percentage extraction of Cd(II) as a function of pH with the chelating reagent and the synergic mixtures.

IRON(III) AMINO ACID COMPLEXES: EVIDENCE FOR THE EXISTENCE OF A SPIN EQUILIBRIUM

J. MARY ELIZABATHE and P. S. ZACHARIAS*

School of Chemistry, University of Hyderabad, Hyderabad 500134, India

(*Received* 26 *February* 1986; *accepted after revision* 16 *September* 1986)

Abstract—Iron(III) amino acid complexes of general composition Fe(amino acid)(OH)Cl · $2CH_3OH$ were synthesized and investigated. The analytical and other physical data support this formulae. The spectral, variable-temperature magnetic and Mössbauer data suggest the presence of a spin equilibrium involving $S = \frac{1}{2}$ and $S = \frac{3}{2}$ spin states, and this is attributed to the large distortions in the compounds.

Investigations on iron(III) amino acid complexes have been very few compared to other transition metals, probably due to the preparative difficulties of these compounds. Of the few iron(III) amino acid complexes known, DL-methionine has been reported to yield either 1 : 1 or 1 : 3 compounds.[1,2] Trimeric iron(III) compounds have been reported for some other amino acids.[3,4] Since the available structural data on either 1 : 1 or 1 : 3 type amino acid complexes are very limited, it was decided to investigate them systematically as part of our general investigations on the amino acid complexes.[5–7] Attempts to repeat the synthesis of 1 : 3 type complexes by the procedure given earlier[2] were unsuccessful, an observation made previously also.[1] This paper describes the syntheses of and investigations on 1 : 1 type iron(III) complexes by spectral, magnetic and Mössbauer methods.

EXPERIMENTAL

Methanol and ether were distilled over $Mg(OMe)_2$ and $LiAlH_4$, respectively, before use. All the preparative work was carried out under dry nitrogen. Preparation of all the complexes was carried out by a general procedure as given below.[1]

Preparation of the lithium salts of amino acids

A mixture of amino acid (10 mmol) and lithium hydroxide (12 mmol) in methanol (30 cm^3) was stirred at 50°C for 30 min. The unreacted lithium hydroxide was filtered off and the filtrate on cooling gave the lithium salt as a white solid. This was filtered and dried *in vacuo*.

Preparation of the iron(III) *complexes*

To a stirred solution of the lithium salt of amino acid (5 mmol) in methanol (20 cm^3) was added anhydrous iron(III) chloride (5 mmol) in methanol (10 cm^3). On addition of ether (100 cm^3) to the resultant reddish brown solution a pale yellow complex separated out, which was filtered and dried. The complex was purified from methanol and ether. Some compounds are highly hygroscopic and hence some of the physical measurements could not be done on them. The variable-temperature magnetic-moment data on some selected compounds are given below. The compounds are represented by their composition with the abbreviated form of the amino acid. These abbreviations are explained in Table 1.

Variable-temperature magnetic-moment data (T *in* K, μ_{eff} *in* BM)

Fe(met)(OH)Cl · $2CH_3OH$: 295, 3.49; 240, 3.3; 200, 3.10; 160, 2.89; 110, 2.59; 86, 2.47; 44, 2.37; 28, 2.22; 14, 2.12.

Fe(asn)(OH)Cl·$2CH_3OH$: 297, 3.21; 244, 3.10; 200, 2.98; 160, 2.72; 130, 2.58; 110, 2.48; 84, 2.29; 60, 2.12; 40, 2.02; 30, 1.96; 25, 1.95; 16, 1.90.

Fe(phe)(OH)Cl·$2CH_3OH$: 297, 3.49; 238, 3.32; 204, 3.14; 160, 2.94; 130, 2.78; 110, 2.66; 85, 2.46; 40, 2.12; 32, 2.05; 18, 1.94.

C, H, N and Cl analyses were done by the Australian Microanalytical Service and Fe content was estimated gravimetrically by the oxine method. Room-temperature magnetic-susceptibility measurements were done on a Bruker BM-6 susceptibility set up and variable-temperature measurements using a Sartorius microbalance. IR spectra were recorded on a Perkin–Elmer Model 297 Spectrophotometer and ESR spectra using a JEOL JES FE-3X spectrometer. A PARC 6001 Photo Acoustic Spectrometer was used for electronic spectra of solids whereas solution measurements were carried out on a Cary 17D Spectrophotometer. Mössbauer spectra were recorded employing a constant-acceleration Elscint drive in conjunction with a multichannel analyzer (Promeda). Differential scanning calorimetry was done using a Perkin–Elmer DSC-4.

RESULTS AND DISCUSSION

The analytical data are presented in Table 1 on some selected compounds only since other compounds are highly hygroscopic. The data agree with a general composition of Fe(amino acid)(OH)Cl·$2CH_3OH$, where amino acid stands for the corresponding monoanion. The presence of chlorine is confirmed from the analytical data. The conductances of these complexes in methanol is of the order ~ 60 mho cm^2 mol^{-1}, and are given in Table 1. A reasonable range of conductance values for 1:1 electrolytes[8] is 80–115 mho cm^2 mol^{-1}. Thermogravimetric analysis showed a weight loss corresponding to two molecules of methanol. The TGA data are given in Table 1. Differential scanning calorimetric experiments on a few selected compounds support the TGA results. There is a broad band at ~ 3400 cm^{-1} in the IR spectra of the complexes. Although such bands are associated with OH groups, this cannot be considered as a conclusive proof for its presence since the OH groups of the solvent CH_3OH molecules can also give a band at this position. The overall com-

position satisfies the +3 oxidation state of the metal ion in the complexes.

The room- and low-temperature magnetic-moment values are collected in Table 2. The room-temperature magnetic-moment values are in the range 3.2–3.5 BM. The two known compounds Fe(met)(OH)$NO_3 \cdot 2CH_3OH$ and Fe(met)(OH)Cl·$2CH_3OH$ are reported to have μ_{eff} values of 6.39 and 4.21 BM, respectively.[1] On the basis of this observation, the nitrato compound was assigned an octahedral geometry with iron in the +3 oxidation state. No explanation was given for the low μ_{eff} value of the chloride complex. The trimeric iron(III) amino acid systems of general composition $[Fe_3O(\text{amino acid})_6(H_2O)_3](NO_3)_7$ have μ_{eff} values in the range 2.8–3.6 BM. The Fe^{3+} centre in these compounds is in octahedral geometry and hence μ_{eff} values of ~ 5.9 BM would have been expected for them. The low μ_{eff} values have been attributed to the antiferromagnetic interactions in these trinuclear systems.[4] The 1:3 complexes of type Fe(amino acid)$_3$ have been reported to be octahedral high-spin complexes with μ_{eff} values of ~ 5.6 BM.[2]

The room-temperature μ_{eff} values of 3.2–3.5 BM reported in Table 2 for the present compounds are too small for high spin ($S = \frac{5}{2}$) complexes ($\mu_{eff} \sim 5.9$ BM) or too large for low spin ($S = \frac{1}{2}$) iron(III) complexes ($\mu_{eff} \sim 2.00$ BM). For iron(III) compounds of intermediate spin ($S = \frac{3}{2}$), the expected μ_{eff} value is ~ 4.0 BM. The intermediate μ_{eff} values observed for the present iron(III) amino acid complexes can result from: (i) antiferromagnetic type interactions assuming a trimeric structure, (ii) a spin equilibrium between the low- and high-spin states, and (iii) a quantum mechanical mixing of spin states. However, a trimeric structure[4] of type $[Fe_3O(\text{amino acid})_6(H_2O)_3]Cl_7$ does not fit with the analytical data and hence is not considered for discussion. The second and third alternatives differ in that the spin equilibrium systems contain molecules which have two magnetically distinguishable pure spin states,[9] whereas the spin-admixed system contains only a

single magnetic species with magnetic properties different from those of either of the pure spin states.[9-11] The variable-temperature magnetic and other spectral data do not favour a spin-admixed system and hence will not be considered in detail. The spin equilibrium may involve the low-spin ($S = \frac{1}{2}$) and high-spin ($S = \frac{5}{2}$) forms, the low-spin ($S = \frac{1}{2}$) and intermediate-spin ($S = \frac{3}{2}$) forms, an intermediate-spin ($S = \frac{3}{2}$) and high-spin ($S = \frac{5}{2}$) forms, or all the three forms. The possibility of an equilibrium between spin states $S = \frac{3}{2}$ and $S = \frac{5}{2}$ can be easily eliminated from the low-temperature μ_{eff} values. At the lowest temperature investigated (14 K), the systems tend to approach a lower limit value of ~ 2.0 BM. Such limiting values are possible only for an $S = \frac{1}{2}$ ground state. Therefore, an equilibrium involving $S = \frac{3}{2}$ and $S = \frac{5}{2}$ spin forms for these complexes does not appear to be satisfactory. The limiting low-temperature μ_{eff} values for some selected compounds are given in Table 2 and the complete low-temperature data are presented in Experimental.

The second alternative is to consider an equilibrium between low- and high-spin states. Equilibria of the type $S = \frac{1}{2} \rightleftharpoons S = \frac{5}{2}$ are well-characterized for several iron(III) compounds. Tris(dithiocarbamato) iron(III) compounds,[12] tris(monothiocarbamato) iron(III) complexes,[13,14] tris(monothio-β-diketonato) iron(III) complexes,[15,16] $[Fe(X\text{-}Sal)_2trien]^+$ and $[Fe(AcacX)_2 trien]^+$ complexes,[17,18] $[Fe(X\text{-}Salmeen)_2]^+$,[19] $[Fe(SalAPA)_2]ClO_4$[20] and $[Fe(3\text{-}X\text{-}Salbenz)_2]^+$ complexes[21] are some examples of these well-studied systems. For systems containing Fe—S or Fe—Se bonds, the large reduction in the Racah interelectronic repulsion parameters produces strong enough ligand fields to produce spin-crossover phenomena.[22] For the $[Fe(X\text{-}Salmeen)_2]^+$ series and their hexadentate analogues with Fe—N and Fe—O bonds, the large tetragonal distortion is mainly responsible for their equilibrium behaviour.[19] For $[Fe(3\text{-}X\text{-}Salbenz)_2]^+$ complexes, two cation sites, one in a low-spin state and another as a mixture of low- and high-spin states cause the spin-crossover phenomenon.[21]

In addition, in systems like tris(4-morpholinecarbodithioato) iron(III), the equilibrium properties are considerably altered due to the presence or change in the solvent molecules in the lattice of the compounds in much the same way as varying the temperature or pressure.[23] For the unsolvated complex (FeM), the equilibrium is between low- and high-spin forms whereas for the dichloromethane solvated complex (FeMDc), the equilibrium changes to a quartet state ($S = \frac{3}{2}$) and the high-spin ($S = \frac{5}{2}$) state. For the benzene solvated complex (FeMBz), the low-temperature magnetic moment corresponds to that of the low-spin ($S = \frac{1}{2}$) ground state and it increases with increase in temperature, attaining a highest value of 3.5 BM at 300 K, representing an equilibrium situation between low- and intermediate-spin forms. Such a change in equilibrium induced by solvent molecules is possible when $S = \frac{1}{2}$, $S = \frac{3}{2}$ and $S = \frac{5}{2}$ states are all low-lying so that a small perturbation of the metal–ligand bond alters the balance between the states. In this example, the trigonal distortion causes the $^2T_2$ ($S = \frac{1}{2}$) state to split into $^2A_1$ and ^2E levels, and the $^4T_1$ ($S = \frac{3}{2}$) state into ^4E and $^4A_2$ levels. The ^4E component falls below the $^6A_1$ level. This makes the $S = \frac{3}{2}$ state thermally more accessible with respect to ^6A ($S = \frac{5}{2}$) state, thereby inducing an equilibrium between low- and intermediate-spin states.

In an analogous manner, it can be visualized that it is the large distortions from the idealized geometry that are mainly responsible for spin-crossover situations in the amino acid complexes. The reasons mentioned earlier for the $S = \frac{1}{2} \rightleftharpoons S = \frac{5}{2}$ spin equilibrium of other well-studied systems do not appear to be applicable in the present case. Such large solvent-induced distortions are very likely for these compounds of general composition Fe(amino acid)(OH)Cl·$2CH_3OH$. These distortions can split the $^2T_2$ and $^4T_1$ states and the $S = \frac{3}{2}$ state becomes thermally more accessible than the $S = \frac{5}{2}$ state. In other words, the spin equilibrium can be assumed to involve the states $S = \frac{1}{2}$ and $S = \frac{3}{2}$ rather than the states $S = \frac{1}{2}$ and $S = \frac{5}{2}$. The μ_{eff} vs T plots (Fig. 1) of these compounds resemble very closely those of iron(III) systems distorted by the presence of solvent molecules.[23,24] Assuming a μ_{eff} value of 1.9

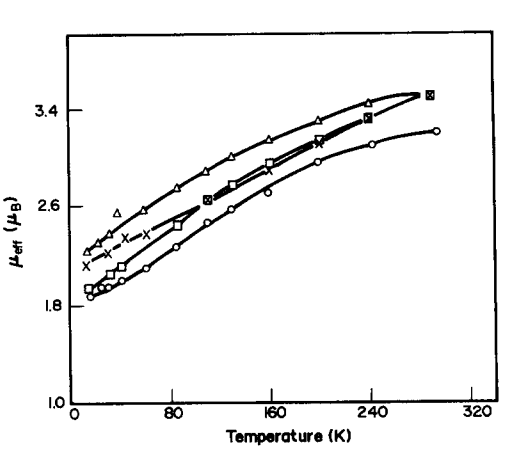

Fig. 1. μ_{eff} vs T plots of the iron(III) amino acid complexes: (—×—) Fe(met)(OH)Cl·$2CH_3OH$, (—○—) Fe(asn)(OH)Cl·$2CH_3OH$, (—□—) Fe(phe)(OH)Cl·$2CH_3OH$, and (—△—) Fe(his)(OH)Cl·$2CH_3OH$.

BM for the low-spin state ($S = \frac{1}{2}$) configuration and 3.9 BM for the intermediate-spin state ($S = \frac{3}{2}$), the room-temperature μ_{eff} value of 3.49 BM for Fe(met)(OH)Cl·CH_3OH would suggest 26% of $S = \frac{1}{2}$ and 74% of $S = \frac{3}{2}$ spin population. For other compounds also, the percentage composition is of the same order.

The electronic spectra were recorded both in the solid phase and in methanol solution. In general, the electronic transitions for iron(III) systems are spin-forbidden and hence weak, and are often masked by charge-transfer bands. However, in several spin-equilibrium systems, the high-spin ($S = \frac{5}{2}$) form has been characterized by a transition at ~ 18,000–20,000 cm^{-1} and the low-spin ($S = \frac{1}{2}$) form by another transition at ~ 14,000–16,000 cm^{-1}.[17,18,25] For a few cases with $S = \frac{3}{2}$ ground state a band at ~ 10,000 cm^{-1} is reported.[26] For the equilibrium $S = \frac{1}{2} \rightleftharpoons S = \frac{5}{2}$, the broad electronic band at ~ 10,000 cm^{-1} can be of $^4E \rightarrow {}^6A$ origin[26] and the ~ 20,000 cm^{-1} shoulder can be tentatively assigned to the $^2T_2 \rightarrow {}^2T_1$, ^2A transition of the low-spin system.[24,27]

Mössbauer spectra have been investigated for all complexes to further characterize their structures. Representative Mössbauer spectra are presented in Fig. 2. The isomer shift (δ) and quadrupole splitting (ΔE) values at room temperature are collected in Table 2. The δ values are ~ 0.6 mm s^{-1} (wrt SNP) and the ΔE value ~ 0.78 mm s^{-1}. These compounds show one quadrupole doublet at all temperatures. For systems with equilibrium, two types of Mössbauer spectral pattern can arise, depending on the relaxation time relative to the effective quadrupole period. If the time required for relaxation from one spin state to the other is larger compared to the quadrupole period, then a spectrum characteristic of individual spin states is observed. If the relaxation time is less than the effective quadrupole period, an averaged spectrum results.

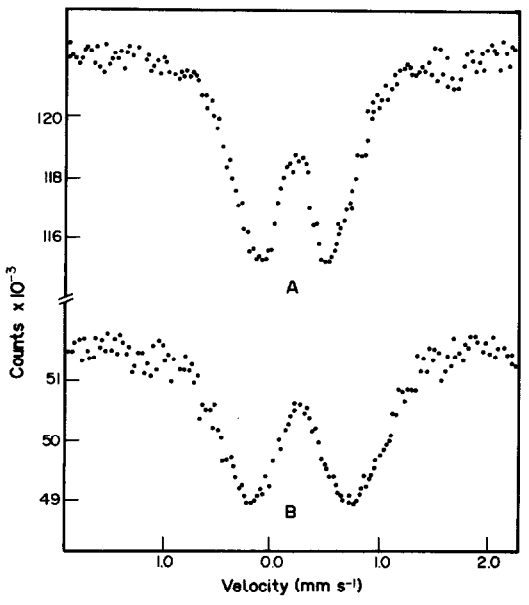

Fig. 2. Mössbauer spectra of Fe(met)(OH)Cl·$2CH_3OH$: (A) at 297 K, and (B) at 88 K.

Several iron(III) dithiocarbamato complexes, shown to be cases of low-spin–high-spin equilibrium, show an averaged Mössbauer spectrum.[24,28,29] This has been explained on the basis of distortion in the compounds. For instance, in a ligand field of perfect cubic symmetry, the energy levels simply cross and, since there is no interaction between the states, Mössbauer spectra should be a superimposition of the spectra of two individual states. When the ligand field has a lower than cubic symmetry, spin–orbit coupling allows the states to mix, resulting in rapid exchange between the low- and high-spin states. An averaged Mössbauer spectrum results from this.[28] Alternatively, a single mixed spin state can also provide an averaged Mössbauer spectrum. However, Mössbauer data cannot distinguish between them.[24]

It should be pointed out that the ΔE values for these compounds are relatively low compared to ΔE values of 2–3 mm s^{-1} reported for several $S = \frac{1}{2}$ or $S = \frac{3}{2}$ systems.[30,31] However, there are also several known cases of low and intermediate spin with ΔE values of less than 1 mm s^{-1} and values ranging from 1 to 2 mm s^{-1}.[13,30,31] When the temperature is lowered, the quadrupole interaction increases and there is an increase in the linewidth of the peaks (ΔE ~ 0.9 mm s^{-1}). The low-temperature Mössbauer data are also shown in Table 2. In fact, ΔE is expected to increase as the population of the low-spin state increases at low temperatures. The broadening of the linewidths results from the increased spin–lattice relaxation times. At liquid-nitrogen temperature (88 K), Fe(met)(OH)Cl·$2CH_3OH$ contains about 84% of the low-spin form and 16% of the $S = \frac{3}{2}$ form (deduced from μ_{eff} values).

The ESR spectrum of a polycrystalline sample of Fe(met)(OH)Cl·$2CH_3OH$ gave a line with an effective g value of 4.21 and another very broad line at a g value of 1.99. The g values for a few other compounds are: Fe(val)(OH)Cl·$2CH_3OH$, 4.35 and 2.04; and Fe(leu)(OH)Cl·$2CH_3OH$, 4.28 and 2.05. For iron(III) systems with an $S = \frac{3}{2}$ ground state in axial symmetry, ESR lines are observed,[32,33] with effective g values of 4.61 and 2.0. Although for the Fe(met)(OH)Cl·$2CH_3OH$ type compounds, $S = \frac{3}{2}$ is not the ground state, it is inferred to be

energetically close to the ground state. This might induce ESR transitions similar to those with $S = \frac{3}{2}$ ground states.

Thus the experimental results can be summarized to suggest the existence of an $S = \frac{3}{2}$ state thermally accessible to $S = \frac{1}{2}$, which is the ground state configuration, thereby providing the spin-crossover possibility. This results from the large distortions in the complexes.

STRUCTURE AND STABILITY OF SOLID AND MOLTEN COMPLEXES IN THE $MgCl_2$–$AlCl_3$ SYSTEM

M.-A. EINARSRUD, H. JUSTNES, E. RYTTER* and H. A. ØYE

Institute of Inorganic Chemistry, The Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway

(*Received* 10 *April* 1986; *accepted* 20 *September* 1986)

Abstract—A visual determination of the phase diagram of the $MgCl_2$–$AlCl_3$ system reveals the formation of two intermediate compounds. One of these compounds is $MgAl_2Cl_8$ crystallizing with a monoclinic unit cell, space group $I2/c$, with dimensions $a = 12.873(1)$ Å, $b = 7.8959(7)$ Å, $c = 11.617(1)$ Å, $\beta = 92.348(8)°$ and $z = 4$. The two crystal modifications of anhydrous magnesium chloride and the lattice parameters of aluminium chloride have been reexamined. Lattice energies for α- and β-$MgCl_2$ have been measured, respectively, as 661(1) and 646(4) kcal mol^{-1}. The liquidus curve on the acidic side has been used to estimate the activity of aluminium chloride. Fourier-transform IR spectra of melts with compositions ranging from 0 to 30 mol% $MgCl_2$ have been interpreted in terms of Al_2Cl_6, strongly perturbed $Al_2Cl_7^-$ and $AlCl_4^-$ entities. In particular, the tetrachloroaluminate ion acts as both a tri- and a bidentate ligand towards Mg^{2+}. Neutral species, e.g. $Mg(AlCl_4)_2$ and $Mg(Al_2Cl_6)(AlCl_4)Cl$, dominate in the melt. *Ab initio* molecular-orbital calculations have been performed to obtain a better understanding of the $Mg^{2+} \cdots AlCl_4^-$ interaction.

The $MgCl_2$–$AlCl_3$ system is of considerable fundamental and industrial importance. Anhydrous $MgCl_2$ is used as a support material in third-generation Ziegler–Natta catalysts for production of stereoregular polypropylene. More recent $MgCl_2$ supports have been modified with $AlCl_3$,[1,2] whereas the chloroaluminate species in the molten and gaseous states are related to new aluminium processes.[3] As part of a more general spectroscopic investigation of the complex formation of $AlCl_3$ in molten chlorides,[4–6] the present system represents an extension to a highly polarizing counterion.

A previous investigation of the phase diagram of $MgCl_2$–$AlCl_3$ (0–30 mol% $MgCl_2$) by Kendall *et al.*[7] indicated the formation of a 1:2 compound. However, the narrow range and limited number of data prompted the present redetermination of the liquidus curve. Belt and Scott[8] confirmed the formation of magnesium chloroaluminate ($MgAl_2Cl_8$) by X-ray powder diffraction and pointed out a possible isomerism with $CoAl_2Cl_8$.[9]

Anhydrous $MgCl_2$ has been known to exhibit two different crystal modifications, a high-temperature form[10] (α-$MgCl_2$) made from thermal decomposition of hydrates and a low-temperature modification[11] (β-$MgCl_2$) produced by chemical dehydration. An extensively milled $MgCl_2$, as employed for the support material of third-generation Ziegler–Natta catalysts, may be looked upon as a mixture of the two forms. Action therefore was taken to determine any difference in the closest coordination sphere of magnesium and to measure accurate lattice parameters.

EXPERIMENTAL

The high-temperature α-form of $MgCl_2$ was prepared by decomposition of magnesium chloride hexahydrate (99%, E. Merck AG, F.R.G.) in a flow of HCl gas (25–600°C) followed by 3 times vacuum distillation (1000°C) in quartz cells. β-$MgCl_2$ was produced by chemical dehydration of $MgCl_2 \cdot 6H_2O$ in refluxing thionyl chloride (75°C) for 3 days. Excess $SOCl_2$ was distilled off, and the product dried *in vacuo* $AlCl_3$ (99%, Fluka AG, Switzerland) was purified by 3 times distillation in sealed quartz tubes.

Needle-shaped crystals of $MgAl_2Cl_8$ were synthesized by fractional crystallization. A mixture of

* Author to whom correspondence should be addressed.

25 mol% α-$MgCl_2$ in $AlCl_3$ was kept at 190°C for 12 h and then melted at 250°C in a tilting furnace to ensure a homogeneous mixture. The quartz tube with the melt was quenched in ice-water. The mixture was again melted in a zone refinement furnace, and $MgAl_2Cl_8$ was solidified as the cell was lowered at a rate of 0.6 mm h^{-1} through the furnace. Alternatively, single crystals were made from a 1 : 3 mixture of $MgCl_2$ and $AlCl_3$ by gas-phase transportation from 230 to 170°C. Crystallization times were 12–80 h. Attempts to prepare the compound $MgAlCl_5$ by these methods failed.

The liquidus in the $MgCl_2$–$AlCl_3$ phase diagram was determined by visual inspection. The melting points in the acidic region of the diagram were observed while the quartz tubes with the mixtures were shaken in a nitrate bath. The temperature in the bath was increased by 0.2–0.5°C and allowed to stabilize for 5–6 h when approaching the melting point. On the basic side of the diagram, however, the melting points were observed visually in a shaking quartz furnace, giving a considerably larger uncertainty, particularly in the 50–70 mol% $AlCl_3$ region.

Neutron powder diffractograms were obtained by the OPUS III diffractometer accommodated at a radial channel of the JEEP II reactor (2 MW, central thermal flux 3×10^{13}) at the Institute of Energy Technology, Kjeller. The monochromatic beam is produced by reflection from the (111) planes of a squashed Ge crystal, and has a wavelength of 1.877(1) Å. The instrument utilizes a multidetector system consisting of five ^3He detectors spaced 10° apart, and each of these covers a range of 80° for the diffraction angle (2θ). The detectors are cylindrical with diameter 5 cm and an active length of 20 cm. They are filled with ^3He gas to a pressure of 4 atm. Each detector has a Soller collimator of 10′ opening angle with plates made of gadolinium oxide coated Mylar foils. The diffractometer is operated through a Mycron microcomputer which allows programming of both the temperature variation of the sample and the scanning procedure. A step length of 0.05° was used, and a range of 5–80° for the diffraction angle was recorded. The sample holder was an aluminium cylinder with inner diameter 12 mm, wall thickness 1 mm and length 40 mm. The lid was sealed with Araldite glue.

IR transmission spectra of the solid samples were recorded in the frequency range 300–800 cm^{-1} with a Perkin–Elmer 580B ratio recording IR spectrophotometer. The samples were Nujol suspensions between CsI windows. The resolution of the spectra is about 5 cm^{-1}. Far-IR spectra to 50 cm^{-1} were recorded with a Bruker IFS 113v Fourier-transform IR spectrometer. The radiation source was an Hg lamp, the beam splitter a 6.0 μm Mylar film, and the detector a He-cooled Ge bolometer. For the low-frequency spectra, the samples were in a Nujol suspension between polyethylene windows. The spectra were recorded with 96 scans, mirror velocity 0.235 cm s^{-1}, resolution 1 cm^{-1}, and a triangular apodization function.

The specular reflection spectra of the molten mixtures were obtained with the Bruker IFS 113v Fourier-transform instrument. The spectra were recorded of thin films (*ca* 1 μm) pressed against a diamond window (type IIA, D. Drukker & Zn., Amsterdam, Netherlands) by a gold-plated nickel piston. Details of the cell and procedure have been described previously.[6,12] Thick samples (2–3 mm) were used as reference to avoid false band splitting.[13,14] The averaged spectra consisted of 500 single scans obtained with a DTGS detector at a resolution of 8 cm^{-1}. A 3.5-μm Mylar beam splitter was used in the frequency range 150–700 cm^{-1}, whereas a 12-μm Mylar was employed between 90 and 210 cm^{-1}.

RESULTS

The phase diagram of $MgCl_2$–$AlCl_3$ is drawn in Fig. 1 together with detail of the acidic region ($X_{AlCl_3} > 0.67$). The diagram indicates the formation of two intermediate compounds. The presence of $MgAl_2Cl_8$ was verified by X-ray and neutron powder diffraction, chemical analysis, morphology, IR and Raman spectroscopy and X-ray investigations

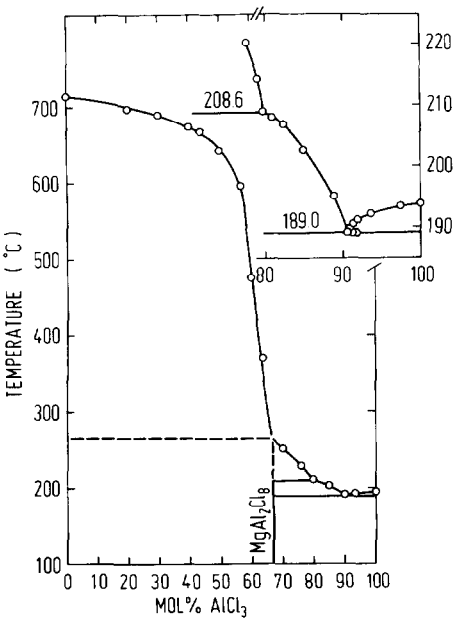

Fig. 1. The $MgCl_2$–$AlCl_3$ phase diagram.

of single crystals. Attempts to prepare $MgAlCl_5$ failed. Neither could the possible existence of both a high- and a low-temperature modification of $MgAl_2Cl_8$ be verified. The melting point of $AlCl_3$ under its own equilibrium pressure was determined to be 193.8°C.

The refinement of the crystal structures is based on a Rietveld analysis of the individual neutron powder diffraction patterns shown in Fig. 2. The calculations were performed by a computer program developed by Wiles and Young.[15] In all analyses, the 2° ranges 46–48 and 54–56° were excluded to avoid contribution from the sample holder. Listings of diffraction angles and calculated and observed integral intensities of the reflections can be obtained from the authors. The complete profiles also are available.

Solid $MgCl_2$

Fourteen reflections with diffraction angles between 16 and 77° were the basis for the refinement of α-$MgCl_2$. The final *R*-factors were $R_B = 0.038$ (the error of fit for the integral intensities of all the considered reflections) and $R_p^w = 0.121$ (the error of fit for each measured point in the intensity profile weighted by the inverse square of their standard deviations). The obtained unit-cell parameters are given in Table 1. In this structure, the magnesium atom is placed at the origin, while the chlorine atom is in the special position $(0, 0, z)$. The final atomic position and isotropic temperature factors refined to $z = 0.2551(2)$, $B(\mathrm{Mg}) = 1.9(2)$ and $B(\mathrm{Cl}) = 1.4(1)$ Å^2. These values correspond to the scale factor $C = 0.118(2)$, half-width parameters $u = 3.2(1)$, $v = -1.8(1)$ and $w = 0.34(2)$, preferred orientation parameter $G = 0.27(1)$ and an asymmetry parameter applied for the first reflection $A = 2.0(2)$. The preferred-orientation parameter is necessary in the structure determination of this compound because of the pronounced flake shape of the crystallites.

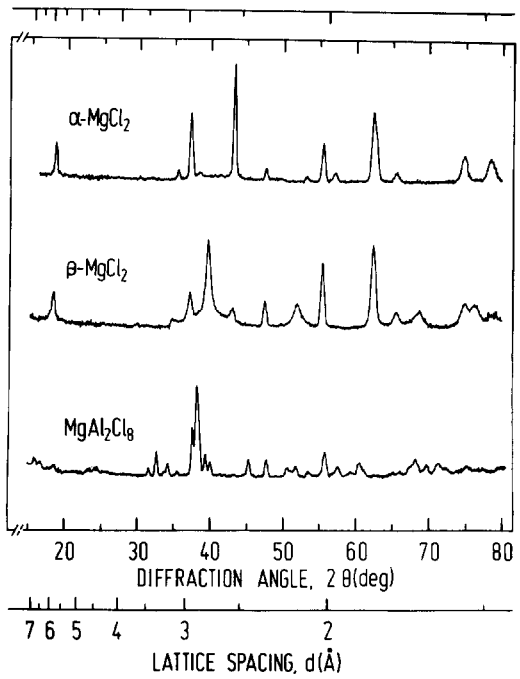

Fig. 2. Neutron powder diffraction patterns of the two crystal modifications of $MgCl_2$ and $MgAl_2Cl_8$.

The intensity profile of β-$MgCl_2$ in Fig. 2 shows that this compound is contaminated by a small amount of the α-phase. The refinement was performed by using separate scale factors for the two modifications and the already obtained structural parameters for α-$MgCl_2$. The two scale factors refined to $C(\beta) = 0.114(3)$ and $C(\alpha) = 0.0040(2)$. Because of the structural similarities, it was possible to calculate the amount of α-$MgCl_2$ as 9.5 mol%. The refinement of β-$MgCl_2$ is based on 17 independent reflections in the 2θ range 16–80°, and the *R*-factors refined to $R_B = 0.061$ and $R_p^w = 0.337$. The unit cell parameters have been included in Table 1. In the structure of β-$MgCl_2$, the magnesium atom is placed at the origin, while the chlorine atom is in the special position $(1/3, 2/3, z)$. The final atomic position $z = 0.235(3)$ was obtained.

Table 1. Unit cell parameters for the two modifications of $MgCl_2$

	α-$MgCl_2$		β-$MgCl_2$	
Parameter	Neutron	X-ray[16]	Neutron	X-ray[11]
a (Å)	3.6435(1)	3.640(4)	3.6376(5)	3.641(3)
c (Å)	17.689(2)	17.673(15)	5.897(2)	5.927(6)

[a] Recalculated, different from the value given in Ref. 16.

The isotropic temperature factors were transferred from α-$MgCl_2$ as attempts to refine them gave preposterous values because of the diffuse reflections in the diffractogram due to the small crystallites in the sample. The positional parameter and the temperature factors match the half-width parameters $u = 14(2)$, $v = -16(2)$ and $w = 5.3(4)$, and the preferred-orientation parameter $G = 0.31(2)$. No significant improvement or change in structural parameters and R_p^w were obtained by using a Lorentzian profile function instead of the standard Gaussian one, although the half-width parameters were reduced to *ca* $\frac{1}{3}$.

The lattice energies for α- and β-$MgCl_2$ were measured to 661(1) and 646(4) kcal mol^{-1}, respectively. The low-temperature β modification was found by differential scanning calorimetry to be metastable with a transition temperature of *ca* 520°C at a heating rate of 20°C min^{-1}.

The IR spectra of the two modifications of anhydrous magnesium chloride (Fig. 3) are virtually identical. The frequencies, relative intensities and assignments in terms of the D_{3d} factor group are 407 m ($\nu_1+\nu_4$, E_u), 372 m ($\nu_2+\nu_3$, E_u), 329 sh ($\nu_1+\nu_2-\nu_3$, E_u), 276 sh ($\nu_1+\nu_4-\nu_3$, $A_{1u}+A_{2u}E_u$), 248 vs (ν_2, A_{2u}), 185 m (ν_4, E_u), 140 w ($\nu_2+\nu_3-\nu_1$, E_u) and 126 w ($\nu_2-\nu_3$, E_u). It cannot be excluded, however, that some of the shoulders and weak bands appear due to traces of oxychlorides.

Solid $MgAl_2Cl_8$ *and* $MgCl_2$–$AlCl_3$ *melts*

The suggested structure of $MgAl_2Cl_8$ is based on *c*-axis oscillation and zero-level Weissenberg X-ray photographs of a single crystal. This crystal was not suitable for a complete single-crystal analysis because of extended mosaic structure. The unit-cell axes obtained from the X-ray photographs are comparable with the values for $CoAl_2Cl_8$ obtained by Ibers.[9] Furthermore, the systematic extinctions ($h00$ and $0k0$ for h, k = odd and $hk0$ for $h-k$ = odd) can be explained by the space group for the cobalt compound, and the symmetry elements of the space group are reflected in the observed Laue symmetry. $MgAl_2Cl_8$ thus was assumed to be isomorphous with cobalt(II) tetrachloroaluminate ($CoAl_2Cl_8$), and the trial model was given atomic coordinates from this compound.

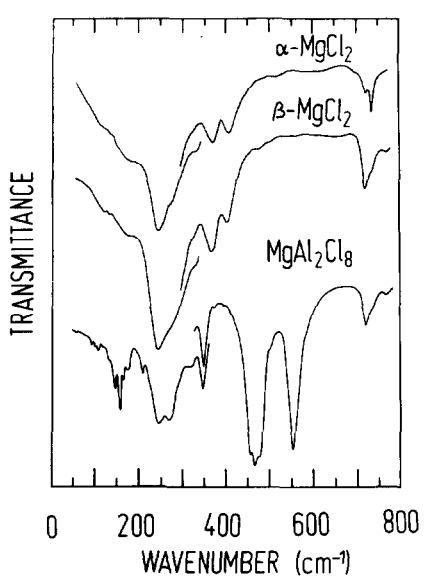

Fig. 3. IR spectra of the two crystal modifications of $MgCl_2$ and $MgAl_2Cl_8$.

The analysis of the neutron diffraction pattern for $MgAl_2Cl_8$ (Fig. 2) was complicated by a rather large contribution from $AlCl_3$. The combined analysis of the total diffraction pattern for the two phases was initially based on the structural data for $AlCl_3$ taken from Ketelaar *et al.*[17] Since, however, their unit-cell dimensions gave calculated peaks displaced from the observed ones, it was necessary to refine the axes of $AlCl_3$ as well. In addition, the preferred-orientation parameter of $AlCl_3$ had to be varied independently. The refinement took into account 194 reflections for $MgAl_2Cl_8$ and 73 reflections for $AlCl_3$ in the 2θ range 15–80°. The final *R*-factors were $R_B = 0.018$ for $MgAl_2Cl_8$, $R_B = 0.011$ for $AlCl_3$ and $R_p^w = 0.163$. The parameters for the monoclinic unit cell of $MgAl_2Cl_8$ with space group $I2/c$ and four formula units are given in Table 2 together with results obtained for several isomorphous compounds.[9,18,19] Monoclinic unit-cell dimensions of $AlCl_3$ with space group $C2/m$ and four formula units are $a = 5.933(2)$ Å, $b = 10.255(3)$ Å, $c = 6.180(4)$ Å and $\beta = 108.24(3)°$.

The derived atomic positions for $MgAl_2Cl_8$ are given in Table 3. The *y*-coordinates of magnesium and aluminium were fixed in their ideal positions (0.00 and 0.25, respectively) during the refinement. Otherwise they would arrive at values (0.04 and 0.22) leading to unlikely bonding distances without a significant better fit ($R_p^w = 0.159$). The applied set of atomic coordinates corresponds to scale factors $C(MgAl_2Cl_8) = 0.058(1)$ and $C(AlCl_3) = 0.073(4)$, common half-width parameters $u = 3.3(2)$, $v = -1.8(2)$ and $w = 0.36(4)$, common overall isotropic temperature factor $B = 4.0(1)$ Å^2 and preferred-orientation parameters $G(MgAl_2Cl_8) = 0.19(1)$ and $G(AlCl_3) = 0.34(3)$.

Because of the ill-conditioned *y*-coordinates of magnesium and aluminium compared with $CoAl_2Cl_8$ [$y(Co) = 0.0017(12)$ and $y(Al) = 0.2516(18)$], another model, with the chain in the middle of the *ab* plane of the unit cell (Fig. 6)

Table 2. Unit cell parameters for isomorphous MAl_2Cl_8 compounds (M = Mg, Co, Ni or Ti)

Parameter	Mg	Co[a]	Ni[b]	Ti[c]
a (Å)	12.873(1)	12.81(2)	12.72(1)	13.000(3)
b (Å)	7.8959(7)	7.75(1)	7.672(7)	7.711(2)

translated one-half of the repetition length along the c-axis, was tried out. It turns out that only the y-coordinate of aluminium is altered. The new model has the space group $C2/c$, which explains equally well the observed systematic extinctions and Laue symmetry. However, the fit for the unit-cell axes was less satisfactory and the R-factors, standard deviations and overall temperature factor increased. Hence, the first model was assumed to be correct, although some mixing of the two or lack of stoichiometry is possible.

The IR spectra of solid $MgAl_2Cl_8$ and $MgCl_2$ are compared in Fig. 3. The IR reflectances of the different molten compositions are shown in Fig. 4, whereas the wavenumbers of melts and solid $MgAl_2Cl_8$ are listed in Table 4.

DISCUSSION

Solid $MgCl_2$

The unit-cell dimensions for α–$MgCl_2$ obtained by neutron diffraction in this work compare excellently with the recent reinvestigation by X-ray diffraction (Table 1). This agreement gives us confidence in the somewhat less well defined wavelength of the neutrons compared to X-rays. For β-$MgCl_2$, the discrepancy is larger. In particular, the c-axis (and volume) found by Bassi *et al.*[11] seems too large. In this context it is pertinent to point out that a comparison between the Debye–Scherrer results of these authors with the lattice spacings calculated from the present unit cell axes, gives as good a fit as for the unit cell parameters from the literature.

[b] The numbering of fundamentals refers to the idealized T_d- and D_{3d}-symmetries of $AlCl_4^-$ and $Al_2Cl_7^-$, respectively (see Ref. 6). For Al_2Cl_6, see Ref. 25. Ionic entities are parts of neutral species.

The layer structures ($CdCl_2$ and CdI_2) of the two modifications of anhydrous $MgCl_2$ both contain a two-dimensional net as a common structural unit. This unit, a Cl–Mg–Cl sandwich, has D_{3d}-symmetry around magnesium. Distances and angles for α-$MgCl_2$ are Mg—Cl = 2.518(2), Cl—Cl = 3.643(1) within a closed-packed layer, Cl—Cl = 3.477(2) between layers in a sandwich, Cl—Cl = 3.771(3) Å between sandwiches and Cl—Mg—Cl = 87.31(7)° in a sandwich. The values for the β-compound are within $2\sigma(\alpha)$ with the exception Cl—Cl(within layer) = 3.638(1) Å. Thus, the difference between the two modifications is mainly due to the stacking of the Cl–Mg–Cl sandwiches along the *c*-axes; α-$MgCl_2$ consists of a cubic close packing of anions, while β-$MgCl_2$ is based on a hexagonal close packing. Both modifications have the magnesium atoms placed in all octahedral holes between every second chlorine layer.

The $CdCl_2$ stacking arrangement found in the high-temperature α-modification gives a more ionic character because of closer secondary Mg^{2+}–Cl^- interactions. However, the ionic part of the lattice energy has been calculated by Hoppe[20] to be 589.7 (α-$MgCl_2$) and 589.8 kcal mol^{-1} (β-$MgCl_2$). These values correspond to Madelung constants of 4.486 and 4.481, respectively. In order to determine the influence of the packing sequence on the Madelung constant, a calculation was made on β-$MgCl_2$ where the shape of the sandwiches, and the distance between them, were as determined for α-$MgCl_2$. The resulting Madelung constant is 4.472, which means that the cubic close packing has about 0.3% higher ionic character than the hexagonal arrangement. Even though the standard deviations of the structural parameters for β-$MgCl_2$ are rather large, it may look as if the structure of this modification is adjusted to achieve a higher ionic lattice energy. The considerably larger difference[21] in the Madelung constants for $CdCl_2$ (4.489) and CdI_2 (4.382) using idealized structures is probably due to a different *z*-parameter.

The interpretation of the IR spectra in Fig. 2 of $MgCl_2$ can be understood from the correlation

Table 5. Correlation diagram for α- and β-$MgCl_2$[a]

Basis	Site	Sandwich	Factor group	Acoustic mode	Optical mode
Mg	D_{3d}	D_{3d}	D_{3d}

diagram in Table 5. The same diagram is applicable for α- and β-$MgCl_2$ as both have site symmetry D_{3d} for magnesium, site symmetry C_{3v} for chlorine, D_{3d}-symmetry for the structural unit (sandwich) and factor group D_{3d}. There is only one formula unit in the Bravais cell, and thus a total of six optical and three acoustic modes are expected. An examination of the correlation diagram shows that two IR-active and two Raman-active vibrations are predicted. The observed far-IR frequencies for α- and β-$MgCl_2$ are equal within the uncertainty limits, as expected from the structure determinations. The assignments in terms of IR-active fundamentals, $\nu_2(A_{2u}) = 248$ and $\nu_4(E_u) = 185$ cm^{-1}, and combination bands lead to the Raman-active fundamentals $\nu_1(A_{1g}) = 223$ and $\nu_3)(E_g) = 125\,cm^{-1}$. These values may be compared with the results of Anderson *et al.*,[22] 243 (A_{1g}), 225 (A_{2u}) and 176 cm^{-1} (E_u). Note the apparent interchange of the A_{1g} and A_{2u} values. The Raman-active E_g mode was not observed for $MgCl_2$, but other isomorphous chlorides were reported to have the E_g frequency in the range 130–170 cm^{-1}.[22]

Solid $MgAl_2Cl_8$

The structure of $MgAl_2Cl_8$ can be described within a hexagonal close packing of the chlorine atoms. Magnesium and aluminium atoms are placed, respectively, in one-eighth of the octahedral and tetrahedral holes between alternating layers. The atoms are arranged in such a way that infinite chains of composition $(MgAl_2Cl_8)_n$ are formed with propagation direction along the *c*-axis of the unit cell. The site symmetry of the magnesium is C_2, which is the symmetry of the infinite chain as well. The two-fold rotation axis is perpendicular to the chain, and intersects it through the magnesium atom. A drawing of the chain is shown in Fig. 5

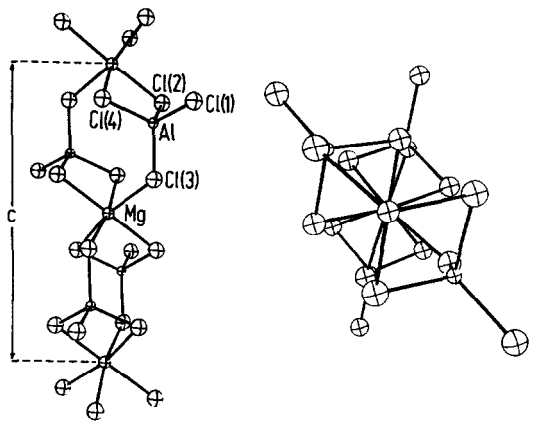

Fig. 5. The repeating part, C, of the infinite chain in $MgAl_2Cl_8$. The right drawing is turned 90° compared to the left and lacks the three upper and the three lower chlorine atoms for clarity.

and interatomic distances are given in Table 6. The bonding distances comply well with the corresponding values for $CoAl_2Cl_8$:[5] Co—Cl 3.45(1)–3.47(1) and Al—Cl 2.11(2)–2.19(2) Å. The standard deviations do not allow elaborate discussions of the bonding within the $MgCl_6$ and $AlCl_4$ units. It is noteworthy, however, that the rather short chlorine–chlorine contact distance of 3.28 Å is across the double chlorine bridge between Al and Mg (3.30 Å for $CoAl_2Cl_8$).

Table 6. Interatomic distances (Å) in $MgAl_2Cl_8$

Bonding distances			
Mg—Cl(2)	2.50(1)	Al—Cl(1)	2.17(4)
Mg—Cl(3)	2.59(3)	Al—Cl(2)	2.24(4)
Mg—Cl(4)	2.49(3)	Al—Cl(3)	2.13(3)
		Al—Cl(4)	2.11(3)

Non-bonding distances within the chain			
$AlCl_4$ group		Between groups	
Cl(1)—Cl(2)	3.66(3)	Cl(2)—Cl(3)	3.52(2)
Cl(1)—Cl(3)	3.52(2)	Cl(2)—Cl(3)	3.84(2)
Cl(1)—Cl(4)	3.50(2)	Cl(2)—Cl(4)	3.63(2)
Cl(2)—Cl(3)	3.58(2)	Cl(2)—Cl(4)	3.63(2)
Cl(2)—Cl(4)	3.28(2)	Cl(3)—Cl(3)	3.60(1)
Cl(3)—Cl(4)	3.59(2)	Cl(3)—Cl(4)	3.69(3)
		Cl(4)—Cl(4)	3.48(1)

Non-bonding distances between chains			
Cl(1)—Cl(2)	3.71(2)	Cl(1)—Cl(3)	3.82(2)
Cl(1)—Cl(2)	3.77(2)	Cl(1)—Cl(4)	3.68(2)
Cl(1)—Cl(3)	3.74(2)	Cl(2)—Cl(3)	3.88(2)

The chains are kept together by interactions between electron-deficient bridging chlorines and electron-rich terminal chlorines from neighbouring chains. It is seen from the stereographic drawing in Fig. 6 that one might expect van der Waals' forces between bridging chlorines from different chains as well. However, the non–bonding distances shorter than 3.90 Å within and between chains given in Table 6, show that only one bridge–bridge distance is below this limit and that terminal–bridge distances are significantly shorter.

The vibrational correlation digram for the infinite chain in $MgAl_2Cl_8$ is given in Table 7. The basis is taken in the 15 degrees of freedom of the unperturbed ligand $AlCl_4$ with T_d-symmetry. Fundamental frequencies of the $AlCl_4$ unit as found[23] in NH_4AlCl_4 have been included in Table 7. The ν_1-mode is the symmetric stretch, ν_2 is a Cl–Al–Cl deformation, ν_3 is the antisymmetric stretch and ν_4

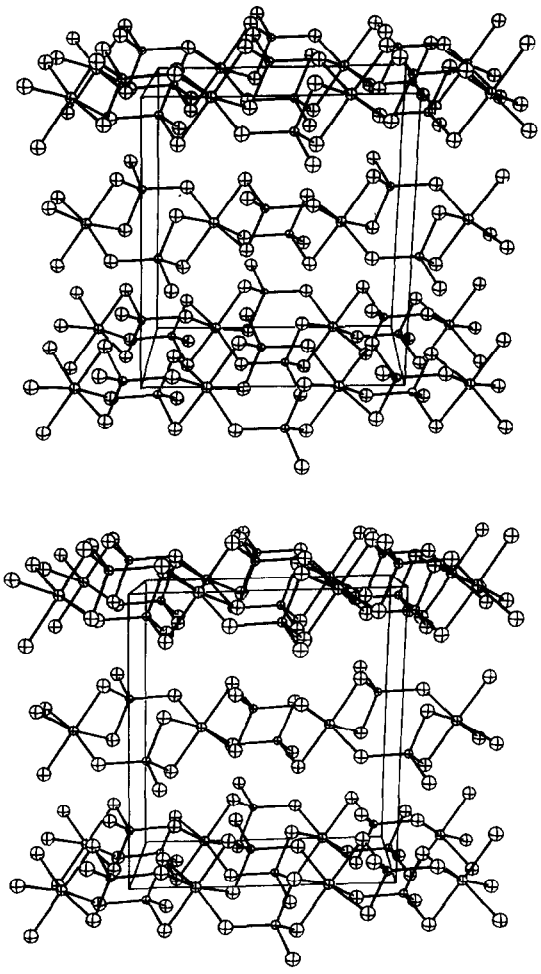

Fig. 6. A stereographic plot of the unit cell of $MgAl_2Cl_8$. The viewer looks along the *b*-axis, and the *a*-axis points upwards in the paper plane.

Table 7. Correlation diagram for the vibrations of an $MgAl_2Cl_8$ chain[a]

Basis	Free $AlCl_4^-$	Perturbed $AlCl_4^-$	$AlCl_4^-$ site	$(MgAl_2Cl_8)_{2n}$ factor	Ligand modes	Ligand vibrations	Skeletal

[b] IR-active species are underlined, Raman-active species underdashed. The acoustic modes are crossed out.

is a deformation. However, since the $AlCl_4^-$ group in the chain has three chlorines bridged to magnesium and one terminal chlorine, the T_d-symmetry is strongly perturbed to a C_{3v}-symmetry as shown in the first part of the diagram. This "chemical correlation" is in turn correlated to the site symmetry (C_1) of the $AlCl_4$ group and then to the symmetry of the chain (C_2). Even though both the *A*- and *B*-representations of the factor group are IR-active, the main effect probably is the "chemical perturbation" of the $AlCl_4$ ligand.

Five bands with their origin in the antisymmetric stretch (ν_3) are observed at 552, 502, 476, 468 and 457 cm^{-1}. The characteristics split into two groups by the chemical perturbation of the $AlCl_4$ entity, as previously found for $TiAl_2Cl_8$,[24] is clearly seen in Fig. 3. The band at 347 cm^{-1} (and possibly 318 cm^{-1}) is the symmetric stretch, IR-inactive for the free ligand (T_d), but activated by the "chemical perturbation" (C_{3v}). Bending modes (ν_4) are observed at 211, 176, 165 and 157 cm^{-1}, whereas ν_2 occur at 146, 134 and 122 cm^{-1}. Two of the Mg—Cl stretching fundamentals appear at 271 and 245 cm^{-1}, and further skeletal modes (librations) are found at 108, 103 and 94 cm^{-1}.

Because of the fine splitting of the absorption band at 468 cm^{-1} into three or four components, we conclude that this frequency corresponds to the *E*-representation and 552 cm^{-1} to the A_1-representation (C_{3v}). These assignments are confirmed by force field calculations. The calculations also show that the frequencies of 211 and 157 cm^{-1} belong to the A_1- and *E*-representations (C_{3v}), respectively, of the ν_4-mode.

Molten $MgCl_2$–$AlCl_3$

Vibrational spectra of molten alkali chloride–$AlCl_3$ mixtures show the presence of the anions $AlCl_4^-$ and $Al_2Cl_7^-$, with some evidence for cation–anion interactions, particularly for Li^+.[4,6] Accordingly, it is expected that the IR reflectance spectra of the acidic $MgAl_2Cl_8$ melts can be interpreted in terms of perturbed anionic entities. If the polarizing power of magnesium is high enough to cause directional Mg—Cl bonds, ion pairs, clusters etc. may be formed. The spectra are interpreted in terms of both the perturbed anion and cluster models.

The magnesium cation can distort the $AlCl_4^-$ group from T_d to C_{3v}- or C_{2v}-symmetry depending on its action as a tri- (mono-) or bidentate ligand. Figure 4 shows that both configurations seem to be present. First it may be noted that the appearance of the totally symmetric stretch, $\nu_1(A_1)$, at 341 cm^{-1} verifies that distortions do take place. The frequencies of 573, 498 and 404 cm^{-1} may reflect the splitting of the antisymmetric stretch, $\nu_3(F_2)$, of tetrahedral $AlCl_4^-$, upon perturbation from T_d to C_{2v}, and the strong bands at 573 and 452 cm^{-1} have their origin in the descent in symmetry from T_d to C_{3v}.

The latter two frequencies may be compared with the solid values 552 and 468 cm^{-1}. Evidently, the interactions are stronger in the melt. A partial explanation of this fact is a lower coordination number of Mg^{2+} in the molten state. Prevalence of smaller entities like $(AlCl_4)Mg(AlCl_4)$, where all bridging chlorine atoms of a given tetrachloroaluminate ion ate bonded to the same magnesium atom, also may contribute to the increased splitting. The accidental degeneracy at 573 cm^{-1} deserves a comment. A parallel situation is found for solid $TiAl_2Cl_8$ and $TiAl_2Cl_8 \cdot C_6H_6$ where C_{3v}-symmetry gives rise to bands at 552 and 466 cm^{-1}, whereas C_{2v} gives 554, 504 and 442 cm^{-1}.[24]

In analogy with Li^+–$Al_2Cl_7^-$ melts,[6] it is proposed that the strong polarizing power of the magnesium cation stabilizes a bent (C_s) rather than a linear (D_{3d}) structure of $Al_2Cl_7^-$. This interaction is manifested by the observed splitting of $\nu_{11}(E_u)$ from 525 cm^{-1} for molten[6] KAl_2Cl_7 to 596 and 500 cm^{-1} upon perturbation from D_{3d} to C_s-symmetry. The corresponding values for $LiAl_2Cl_7$ are 570 and 514 cm^{-1}. Thus, the counterions with high charge/radius ratios strongly perturb both the symmetric Cl–$AlCl_3$ tops of $Al_2Cl_7^-$. Other absorptions in the magnesium system at 376 and 339 cm^{-1} are Al—Cl stretching fundamentals of the $Al_2Cl_7^-$ group, whereas the band at 170 cm^{-1} is a bending mode. The broad band at 280–290 cm^{-1} probably is a direct observation of $Mg^{2+} \cdots AlCl_4^-$ interaction, cf. the Mg—Cl frequency situated at 271 cm^{-1} for solid $MgAl_2Cl_8$. At higher $AlCl_3$ contents, strong bands of Al_2Cl_6 at 615, 472, 410 and 315 cm^{-1} appear.

Although the above interpretation in terms of Al_2Cl_6 and the distorted anions $Al_2Cl_7^-$ and $AlCl_4^-$ is perfectly valid, auxiliary information discussed below together with intensity considerations give further insight into the melt structure. It is seen that the spectra in Fig. 4 essentially are superpositions of $Mg(AlCl_4)_2$ and Al_2Cl_6 with a small contribution from $Al_2Cl_7^-$. Simply, Mg^{2+} destabilizes any $Al_nCl_{3n+1}^-$ ($n \geqslant 2$) polymer. At intermediate compositions, 80 and 85 mol% $AlCl_3$, the seemingly abrupt disappearance of Al_2Cl_6 and the frequency variations in the terminal Al—Cl stretching region around 450 cm^{-1}, point to distortions of Al_2Cl_6 as the Mg^{2+} concentration is increased. The interaction between a magnesium ion and a chloroaluminate species may be formulated in terms of

molecular complexes as

mol% $AlCl_3$	
50	Mg^{2+}, $AlCl_4^-$, Cl^-
67	$Mg(AlCl_4)_2$
80	$Mg(Al_2Cl_6)(AlCl_4)_2$, $Mg(Al_2Cl_6)_2Cl_2$.

Similar complexes obtained by substitution of $Al_2Cl_7^-$ for $AlCl_4^-$ exist in low concentrations. Furthermore, it is possible that more lattice like structures to some extent are formed by polymerization, cf. the $Mg(AlCl_4)_2$ chain in the solid. Some dissociation into ionic species is expected.

This melt model is supported by the following additional information:

(a) Due to a strong, polarized band characteristic for each of the species $AlCl_4^-$, $Al_2Cl_7^-$ and Al_2Cl_6, Raman spectroscopy is better suited than IR spectroscopy to estimate concentrations.[26,27] Comparison of relative concentrations with stoichiometric restrictions leads to the conclusion for the similar acidic $MgCl_2$–$GaCl_3$ system, that some chlorine atoms must be bonded to magnesium only.[27] The same results may be inferred from a preliminary Raman study of the present system.[28]

(b) Raman spectra show that the amount of $Al_2Cl_7^-$ ($Ga_2Cl_7^-$) relative to $AlCl_4^-$ ($GaCl_4^-$) and Al_2Cl_6 (Ga_2Cl_6) is reduced when the polarizing power of the counterion increases.[4,14,27,28] The following series of diminishing $Al_2Cl_7^-$ concentration may be constructed: Cs > K > Li > Mg > Zn.

(c) The terminal IR-active Al—Cl stretching vibrations of C_{2v} perturbed $AlCl_4^-$ follow a smooth trend which may be correlated with polarizing power. Giving the antisymmetric and the symmetric mode, the frequencies (cm^{-1}) are:

	"$[Al(AlCl_4)]^{2+}$"	$[Zn(AlCl_4)]^+$ [5,14]	$[Mg(AlCl_4)]^+$	$[Ti(AlCl_4)]^+$(s)
Asymmetric	614	585	573	554
Symmetric	473	482	498	504

The hypothetical ion $[Al(AlCl_4)]^{2+}$ is part of Al_2Cl_6. The titanium values[24] for solid $Ti(AlCl_4)_2(C_6H_6)$ are in the molten state expected to become close to the $[Mg(AlCl_4)]^+$ data.

(d) Contrary to the alkali chloride[29] and calcium chloride[30] mixtures with $AlCl_3$, no indication of an immiscibility gap was found in the present phase diagram investigation of the $MgCl_2$ system. As Al_2Cl_6 can dissolve less than 1 mol% ionic species, there is a strong case for the prevalence of neutral entities in acidic $MgCl_2$–$AlCl_3$ melts.

(e) Attempts by vapour pressure studies on acidic $MgCl_2$–$AlCl_3$ mixtures failed to establish any liquid phase in the range $0.67 < X_{AlCl_3} < 1$ for vapour pressures of 1 atm or less. This observation is also contrary to the mixture with alkali chloride (and calcium chloride) and show that $MgCl_2$ does not donate Cl^- as easily to $AlCl_3$, forming an ionic melt, as alkali chloride and calcium chloride.

Activity of acidic melts

As discussed above, the $AlCl_3$ vapour pressure and corresponding activity could not be obtained from boiling point method studies. Such information can, however, be calculated from the lowering of the $AlCl_3$ freezing point. The change in freezing point is so small that the difference in C_p can be neglected. The following equation is valid for the liquidus line to the right in Fig. 1:

$$\ln a_{AlCl_3} = -\Delta H^o_{fus}(AlCl_3)\left[\frac{\Delta T}{RT_{liq}T_{fus}}\right],$$

where ΔT is the freezing point depression. Further:

$$a_{Al_2Cl_6} = P_{Al_2Cl_6}/P^o_{Al_2Cl_6} = a^2_{AlCl_3}.$$

From the ΔT values of 0.6 and 1.6°C at $X_{AlCl_3} = 0.974$ and 0.936, respectively, and setting $\Delta H_{fus}(AlCl_3) = 8450$ cal, Al_2Cl_6 activities of 0.980 and 0.943 are found.

Based on these data the activity coefficient function:

$$\gamma_{AlCl_3} = 1 + 0.6(1 - X_{AlCl_3}) \quad (X_{AlCl_3} > 0.7),$$

is proposed. This equation gives for instance $a_{Al_2Cl_6} = 0.74$ for 75 mol% $AlCl_3$. It is hence understood that the vapour pressures above the $MgCl_2$–$AlCl_3$ liquids were higher than 1 atm.

It is concluded that the activity of $AlCl_3$ in $MgCl_2$–$AlCl_3$ mixtures show a positive deviation from ideality, but the deviation is not so strong that liquid–liquid immiscibility occurs. When, however, the composition $Mg(AlCl_4)_2$ is approached, negative deviation may prevail as the Al^{3+} ion is saturated with respect to Cl^-.

Molecular-orbital calculations

In order to gain a clearer understanding of the energetics when $AlCl_4^-$ and Mg^{2+} interact, molecular-orbital calculations on the *ab initio* Hartree Fock level were performed on $[MgAlCl_4]^+$ (C_{3v})

Table 8. *Ab initio* calculated properties of $[MgAlCl_4]^+$ and $MgAlCl_5$[a]

Parameter	$[MgAlCl_4]^+$ (C_{3v})	$[MgAlCl_4]^+$ (C_{2v})	$MgAlCl_5$ (C_{2v})
Al—Cl_t	2.028	2.046	2.062

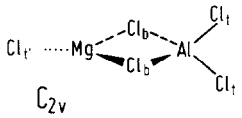
C_{3v}



C_{2v}

with tridentate Mg, $[MgAlCl_4]$ (C_{2v}) and $MgAlCl_5$ (C_{2v}). The computations were done with the gradient program GAUSSIAN 80 employing a minimal STO-3G basis.[31] The results after optimizing all geometrical parameters are given in Table 8. It may be of interest to compare the bond lengths in Table 8 with the calculated values for $AlCl_4^-$ (T_d), 2.113 Å, and $MgCl_2$ ($D_{\infty h}$), 2.090 Å.

The two $[MgAlCl_4]^+$ structures probably correspond to the only energy minima when Mg^{2+} is moved around the $AlCl_4^-$ ion.[32] The C_{3v} structure is favoured by 11.1 kcal mol^{-1} relative to C_{2v}. These results agree with the conclusions from the IR spectroscopic investigations; both modifications are present in the melt, but with a higher concentration of the C_{3v} structure. In a calculation on $LiAlCl_4$ it was verified that the alternative C_{3v} structure with a monodentate counterion is unstable.[32]

The geometrical parameters seem to be reasonable, both the absolute values and, in particular, terminal–bridge differences and the shifts from species to species. For instance, Al—Cl_t < Al—Cl_b (cf. 2.065 and 2.252 Å observed in Al_2Cl_6[33]), Cl_t—Al—Cl_t > Cl_b—Al—Cl_b (123.4 and 91.0° in Al_2Cl_6[33]) and one terminal bond (2.028 Å in Table 8) is stronger than two adjacent terminal bonds (2.046 Å). The latter effect also is seen in the Al—Cl_b bonds.

Due to the low coordination number imposed on magnesium in the models, the Mg—Cl_b distances are short compared to the observed bond lengths in $MgAl_2Cl_8$(s) (see Table 6). Naturally, bidentate magnesium give stronger Mg—Cl_b than tridentate magnesium, mainly because of the reduced Mg–Al repulsion. Adding another terminal chlorine to magnesium forming $MgAlCl_5$ gives the expected reduction in the counterion influence on $AlCl_4^-$.

Abstract—X-ray crystallographic studies on the lithium diphenylphosphide adducts $(Me_2NCH_2CH_2)_2NMe \cdot LiPPh_2$ (**1**) and $Me_2NCH_2CH_2NMe_2 \cdot LiPPh_2$ (**2**) are reported. **1** is monomeric, with a terminal PPh_2 unit containing a pyramidally coordinated phosphorus atom attached to the four-coordinate metal atom by a Li—P bond of length 2.567(6) Å. **2** crystallizes as dimers, $(Me_2NCH_2CH_2NMe_2 \cdot LiPPh_2)_2$, with bridging PPh_2 units containing (distorted) tetrahedrally coordinated phosphorus atoms: their planar $(LiP)_2$ rings are roughly square-shaped (mean P—Li—P angle 91°, mean Li—P distance 2.61 Å). Discussion of features of these structures is facilitated by *ab initio* MO calculations on the model systems $LiPH_2$ and $(LiPH_2)_2$. Cryoscopic molecular mass measurements and high-field $^7Li/^{31}P$ NMR spectroscopic studies on solutions of **1** and **2** indicate that both solid-state structures are retained in arene solution, though some dissociation of **2** into monomers is apparent.

Lithium diphenylphosphide, $LiPPh_2$, which has long been a key reagent for the synthesis of diphenylphosphido-bridged metallic and metalloidal systems,[1] has recently been receiving attention in its own right. Interest has centred on its states of association and structures in both the crystal and solution phases. Three adducts have been structurally characterized by X-ray crystallography. The crown ether adduct $(12\text{-crown-4})_2 \cdot LiPPh_2$[2] is of interest in crystallizing in the ionic form $[Li \cdot (12\text{-crown-4})_2]^+[PPh_2]^-$. The two crown ether molecules sandwiching each metal ion generate an unusual eight-coordinate environment for the metal and prevent significant lithium–phosphorus bonding. By contrast, the diethyl ether and tetrahy-

drofuran adducts $Et_2O \cdot LiPPh_2$ and $(THF)_2 \cdot LiPPh_2$ crystallize with zig-zag lithium–phosphorus chain structures in which the formally two-centre two-electron Li—P bonds have mean lengths of 2.49 and 2.63 Å, respectively.[3] NMR studies on their solutions suggest that they may dissolve as cyclic dimers or tetramers.[4,5] In 1,4-dioxane, $(LiPPh_2)_n$ appears from cryoscopic studies[6] to exist as monomers and dimers.

Hitherto, studies of $LiPPh_2$ complexes have been confined to those containing donor molecules which attach through oxygen. In this work, we report on the effects of complexation by nitrogen donors, specifically the chelating amines pentamethyldiethylenetriamine {PMDETA [$(Me_2NCH_2CH_2)_2$ NMe]} and tetramethylethylenediamine [TMEDA ($Me_2NCH_2CH_2NMe_2$)]. Accordingly, crystals of both $(PMDETA \cdot LiPPh_2)_n$ (**1**) and $(TMEDA \cdot LiPPh_2)_n$ (**2**) have been synthesized, isolated and subjected to X-ray diffraction studies which have, for the first time, established unequivocally that the lithium diphenylphosphide can, when complexed, adopt both monomeric ($n = 1$ for **1**) and dimeric ($n = 2$ for **2**) structures. *Ab initio* MO calculations have been performed on the related *uncomplexed* hypothetical species, $LiPH_2$ and $(LiPH_2)_2$, in order to gauge the influence the donor molecules exert on the geometry of **1** and **2**.

In addition, high-field $^7Li/^{31}P$ NMR spectroscopic and cryoscopic relative molecular mass (crmm) studies have been carried out in an attempt to shed light on the natures of the new complexes in aromatic hydrocarbon solutions.

EXPERIMENTAL

Lithium diorganophosphides, in common with most other lithium organic derivatives, are extremely air- and moisture-sensitive. Accordingly, all syntheses and manipulations of products were carried out using standard inert atmosphere techniques.

Synthesis of $(PMDETA \cdot LiPPh_2)_n$ (1)

n-Butyl-lithium (5.0 cm^3 of a 2.0 mol dm^{-3} solution in hexane, 10 mmol) was added to a frozen solution of diphenylphosphine (1.86 g, 10 mmol) in toluene (5.0 cm^3). Warming to room temperature produced a yellow solid, which dissolved on addition of PMDETA (3.0 cm^3, 14.4 mmol). Slow cooling then afforded pale orange crystals of **1** which were recrystallized from toluene; yield 85%, m.p. 128°C (Found: C, 69.1; H, 9.2; Li, 1.9; N, 11.2; P, 8.5. $C_{21}H_{33}LiN_3P$ requires: C, 69.0; H, 9.0; Li, 1.9; N, 11.5; P, 8.5%). ^7Li NMR: (20°C) singlet, δ −0.96 ppm; (−80°C) singlet, δ −0.94 ppm. ^{31}P NMR: (20°C) singlet, δ −22.11 ppm; (−80°C) singlet, δ −23.63 ppm. Crmm measurements: $n = 0.96 \pm 0.08$ for a 0.01 mol dm^{-3} solution.

Synthesis of $(TMEDA \cdot LiPPh_2)_n$ (2)

n-Butyl-lithium (5.0 cm^3 of a 2.0 mol dm^{-3} solution in hexane, 10 mmol) was added to a chilled solution of diphenylphosphine (1.86 g, 10 mmol) in TMEDA (3.0 cm^3, 20 mmol). Warming to room temperature gave a yellow solution. Refrigeration then afforded pale yellow crystals of **2** which were recrystallized from a hexane–toluene mixture; yield 88%, decomp. from 196°C (Found: C, 70.0; H, 8.4; Li, 2.2; N, 9.1; P, 10.1. $C_{18}H_{26}LiN_2P$ requires: C, 70.1; H, 8.4; Li, 2.3; N, 9.1; P, 10.1%). ^7Li NMR: (20°C) singlet, δ −0.39 ppm; (−80°C) 1:2:1 triplet, δ −0.19 ppm; $J(^{31}P–^7Li)$ 45 Hz. ^{31}P NMR: (20°C) broad singlet, δ −30.17 ppm; (−80°C) 1:2:3:4:3:2:1 septet, δ −33.34 ppm; $J(^{31}P–^7Li)$ 45 Hz. Crmm measurements: $n = 1.67 \pm 0.08$ for a relatively concentrated solution, 0.04 mol dm^{-3}; $n = 1.05 \pm 0.08$ for a relatively dilute solution, 0.02 mol dm^{-3}.

High-field ^7Li (139.96-MHz) and ^{31}P (145.78-MHz) NMR spectra were recorded on a Bruker WH360 NMR spectrometer. Samples were prepared in [$^2H_8$]toluene, made up in a glove box and sealed under nitrogen prior to examination. ^7Li chemical shifts (δ) are quoted relative to external phenyl-lithium in [$^2H_8$]toluene (*E* value 38.863 882 MHz). ^{31}P chemical shifts are quoted relative to external 85% H_3PO_4.

Relative molecular mass measurements in benzene were carried out cryoscopically with a Beckmann-type apparatus which was modified slightly to handle air-sensitive materials.

Crystallography

(**1**) $C_{21}H_{33}LiN_3P$, $M = 365.4$, orthorhombic, *Pbca*, $a = 8.5590(4)$, $b = 16.3324(7)$, $c = 32.357(2)$ Å, $V = 4523.1$ Å^3, $Z = 8$, $D_c = 1.073$ g cm^{-3}, $F(000) = 1584$, $\mu = 1.11$ mm^{-1} for Cu-K_α radiation ($\lambda = 1.54184$ Å). Of 6413 reflections measured with a Siemens AED2 diffractometer at 295 K ($2\theta_{max} = 125°$), 3597 were unique ($R_{int} = 0.033$), and 2412 with $F > 4\sigma(F)$ were used for structure determination by automatic direct methods.[7] Blocked-cascade refinement to minimize $\Sigma w\Delta^2$ [$\Delta = |F_o| - |F_c|$, $w^{-1} = \sigma^2(F) + 0.00049F^2$] with anisotropic thermal parameters for non-H atoms and constrained H atoms [C—H = 0.96 Å, aromatic H on ring external bisectors, H—C—H = 109.5°

for aliphatic H, $U(H) = 1.2U$ eq (C)] gave $R = 0.068$, $R' = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.078$, a satisfactory analysis of variance, and no significant features in a final-difference map.

(**2**) $C_{36}H_{52}Li_2N_4P_2$, $M = 616.7$, triclinic, $P\bar{1}$, $a = 15.960(2)$, $b = 19.791(2)$, $c = 21.090(2)$ Å, $\alpha = 71.628(5)$, $\beta = 77.242(5)$, $\gamma = 67.525(4)°$, $V = 5803.5$ Å^3, $Z = 6$ (two dimers and two half-dimers in the asymmetric unit), $D_c = 1.059$ g cm^{-3}, $F(000) = 1992$, $\mu = 1.21$ mm^{-1} for Cu-K_α radiation. 14,988 reflections measured, 14,542 unique ($R_{int} = 0.029$), 6583 with $F > 4\sigma(F)$. Structure solution by direct methods $w^{-1} = \sigma^2(F) + 0.00246F^2$ in refinement; phenyl rings constrained as ideal rigid hexagons (C—C = 1.395 Å), no H atoms included because of program memory restrictions; $R = 0.111$, $R' = 0.145$.

Tables of atomic coordinates and other crystallographic data have been deposited with the Editor and with the Cambridge Crystallographic Data Centre.

DISCUSSION

Figure 1 shows the molecular structure of **1**, which is monomeric. The terminal PPh_2 unit is bonded to the four-coordinate metal atom by a two-centre two-electron Li—P bond of length 2.567(6) Å. Such terminal PR_2 units are expected in phosphide adducts, $(donor)_nLiPR_2$, where association is prohibited by either excessively bulky R substituents or by suitable Lewis bases such as PMDETA. However, at present only one other such system appears to have been structurally characterized, namely $(THF)_3 \cdot LiP(PPh_2)_2C_6H_4$,[8] in which the Li—P distance [2.580(7) Å] like that in **1** exceeds slightly the sum of the normal covalent radii for Li (1.34 Å) and P (1.10 Å).[9] In the chelate compounds TMEDA·$Li(PPh_2)_2CH$[10] and TMEDA·$Li(PMe_2CH_2)_2AlMe_2$,[11] which each contain a pair of four-coordinate phosphorus atoms (cf. three-coordinate in **1**), the P → Li dative linkages are similar in length, being 2.582 and 2.606(5) Å, respectively.

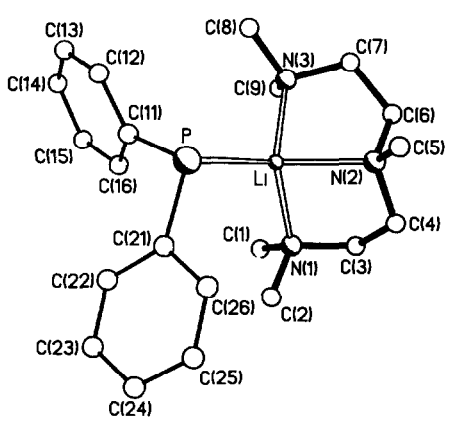

Fig. 1. Molecular structure of (PMDETA·$LiPPh_2$) (**1**). H atoms have been omitted for clarity.

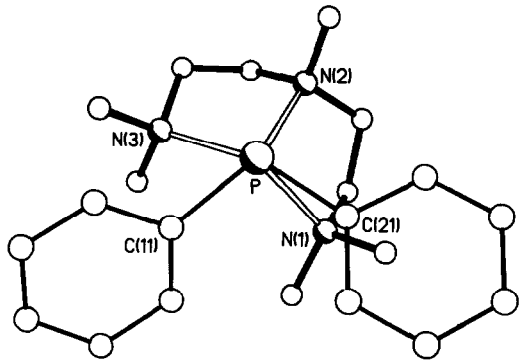

Fig. 2. An alternative view of **1** looking down the P—Li bond.

The geometry about the phosphorus atom in **1** is pyramidal while about the lithium it is pseudo-tetrahedral. From Fig. 2, which shows an alternative view looking down the P—Li bond, it can be seen that the PC_2 and LiN_3 units are neither eclipsed nor fully staggered with respect to each other. The characteristic "embrace" of PMDETA fills three of the four metal valence-shell atomic orbitals leaving one available for the binding of the phosphido ligand. The N → Li bond lengths and N—Li—N bond angles (given with other selected bond lengths and bond angles in Table 1) show no significant differences from those in the related systems PMDETA·$Li[CH(SiMe_3)_2]$[12] and PMDETA·$Li(C_2B_{10}H_{10}Me)$.[13]

Ab initio calculations[14–18] on the uncomplexed $LiPH_2$ using geometry optimization procedures show that a pyramidal conformation is favoured over a planar form by 5.6 kcal mol^{-1} (66-31G**). This is an interesting result on comparison with the optimized geometries of lithiated ammonia $LiNH_2$[19,20] for which planar conformations are preferred over the corresponding pyramidal geometries. Such a difference can be rationalized by examining the electronic distribution of $LiNH_2$ and $LiPH_2$, where the main electronic difference is that in $LiNH_2$ the hydrogen atoms are positively charged (+0.20 e) and thus coupled with the highly positive Li (+0.58 e), causing $LiNH_2$ to adopt a planar conformation, while in $LiPH_2$ the hydrogens carry a slight negative charge (−0.06 e) and hence a pyramidal arrangement of $LiPH_2$ is stabilized by the interactions between them and the highly positive

Table 1. Selected bond lengths (Å) and angles (°) for **1**

lithium (+0.47 e). The calculated Li—P bond distance is 2.391 Å so a comparison with the crystal structure data on complex **1** shows that the effect of the ligands is to lengthen the Li—P bond by *ca* 0.18 Å.

In the X-ray structure analysis of **2**, four independent dimeric (i.e. $n = 2$) molecules were found; these are shown in Fig. 3. There are, as discussed below, differences in their respective bond lengths and bond angles, but their gross structural features are the same. The basic molecular structure, a planar four-membered ring system, is well known in $(donor \cdot LiX)_n$ chemistry, where X is a first-row element. Examples are: X = C, $(TMEDA \cdot LiPh)_2$[21] and $(TMEDA \cdot LiCH_2SCH_3)_2$;[22] X = N, $(HMPA \cdot LiN{=}CBu^t_2)_2$[23] [HMPA = $(Me_2N)_3P{:}O$] and $[Et_2O \cdot LiN(CH_2Ph)_2]_2$;[24] X = O, $(THF \cdot LiOCBu^t_3)_2$[25] and $[(H_2O)_2 \cdot Li \cdot (\mu_2\text{-}HMPA)]_2^{2+} \cdot 2Cl^-$.[26] This is the first time, however, that a lithio-phosphine coordination complex has been found to have a $(LiP)_2$ ring structure. Although the uncomplexed, sterically crowded, phosphidolithium $\{LiP[CH(SiMe_3)_2]_2\}_2$[27] contains a similar ring, it fails to retain such on complexation; addition of TMEDA leads to monomer formation.

Both the Li and P atoms in each of the molecules of **2** are in distorted tetrahedral environments. The metal coordination sphere accommodates the two N atoms of bidentate TMEDA and a pair of μ_2-P atoms. Table 2 lists the important bond lengths and bond angles in the four crystallographically distinct molecules. Considering all four molecules the mean ring angle at Li is 91° while at P it is 89° and the mean Li—P ring distance is 2.61 Å. Unfortunately, the rather high R value (0.111) negates a com-

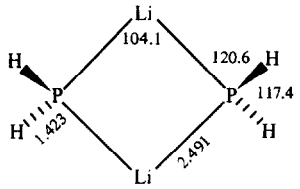

Fig. 4. 66-31G optimized geometry of $(LiPH_2)_2$: angles in degrees, distances in Å.

parison of the angles/lengths within individual dimers.

It is quite clear that complexation greatly influences the size and shape of the $(LiP)_2$ ring; the dimensions of the uncomplexed systems $\{LiP[CH(SiMe_3)_2]_2\}_2$[27]—measured experimentally from a crystal structure determination—and $(LiPH_2)_2$— theoretically determined by our *ab initio* MO calculation—bear this out. The former adopts a slightly asymmetric rhomboidal structure with Li—P—Li angles of 72.0(3) and 72.4(3)° and P—Li—P angles of 108.1(3) and 107.5(3)°; the Li—P bond lengths are significantly shorter than those in **2** and range from 2.456 to 2.481 Å. As noted earlier, the groups attached to phosphorus in this compound are exceptionally bulky, in contrast to the smaller phenyl groups in **2**. Therefore, for more direct comparison we have carried out an *ab initio* geometry-optimized calculation (at the 66-31G level) on the $(LiPH_2)_2$ cyclic dimer. The dimensions of the resulting D_{2h} structure (shown in Fig. 4) agree reasonably well with those of $\{LiP[CH(SiMe_3)_2]_2\}_2$[27] (the P—Li—P angles and Li—P distances optimize to 104.1° and 2.491 Å, respectively), indicating that the steric natures of the *exo* ligands have no pronounced bearing on ring geometry. From angle considerations one could visualize the "complexed" ring being converted to its uncomplexed form by "pulling-out" the structure along the P...P axis, and thereby causing an elongation of the ring bonds. The fact that such bonds actually shorten, however, can be attributed to the lower coordination numbers of the uncomplexed metal atoms (i.e. 2, cf. 4 in the TMEDA adduct) and so a greater *s* character of the Li—P bonds. From energy considerations we calculate the energy of dimerization of $LiPH_2$ to be 55 kcal mol^{-1} and so less favourable than the corresponding association of isovalent $LiNH_2$ units by 19 kcal mol^{-1}.[20] This arises from a less polarized charge distribution in $LiPH_2$ where the Li and P atoms have a charge of +0.47 and −0.36 e, respectively, compared to that in $LiNH_2$ where Li and N carry +0.58 and −0.98 e charges, respectively.

As alluded to earlier, the propensity of lithium to form dimeric ring structures extends to its organonitrogen derivatives. A number of examples could be cited but the most apt for comparison is the lithium amide $[TMEDA \cdot LiN(Ph)Me]_2$.[28] Here the ring angles at Li and N span 90° much more markedly, being 97.6 and 82.4°, respectively, while the mean Li—N bond length is only 2.19 Å, cf. 2.61 Å for the Li—P bonds in **2**. Two-centre bonds to phosphorus atoms are generally about 0.4 Å longer than analogous bonds to nitrogen atoms.

Recently a further link between LiN and LiP structural chemistry was established by the independent X-ray crystallographic characterizations of $\{PMDETA \cdot [LiN(CH_2)_3CH_2]_3\}_2$[29] and $\{THF \cdot [Li_2(\mu_3\text{-}Bu^t_2P) \cdot (\mu_2\text{-}Bu^t_2P)]\}_2$[30] which display both μ_2- and μ_3-type bonding interactions: the essential feature common to both compounds is a ladder-type framework generated by the lateral association of two $(LiN)_2/(LiP)_2$ rings. On the basis of these observations it is highly likely that laddered structures of infinite lengths will prevail in the total absence of donors. Lithium diphenylphosphide itself may well possess this type of polymeric structure (the possible framework of which is illustrated in Fig. 5); its physical properties (i.e. high melting point and arene insolubility) support this. Furthermore, it is particularly noteworthy that starting from such a "parent" structure one can visualize, by breakage of selected numbers of Li—P bonds in the presence of donors, the formation of the zig-zag chains, the ladders, and the dimers and monomers referred to in this paper.

Finally, we have employed crmm measurements and high-field $^7Li/^{31}P$ NMR spectroscopic studies to shed light on the solution natures of **1** and **2** in aromatic solvents. The results obtained are detailed in Experimental.

For **1**, the cryoscopic data (measured in benzene) are compatible with a monomeric structure as its mean solution state of association (*n*) is 0.96. The NMR spectra (recorded in $[^2H_8]$toluene at 20 and −80°C) are consistent with this interpretation showing the singlet ^7Li and ^{31}P resonances expected for a pyramidal phosphorus system. Conversely, the corresponding low-temperature spectra of adduct **2** exhibit well-resolved 1:2:1 triplet (^7Li) and 1:2:3:4:3:2:1 septet (^{31}P) patterns, indi-

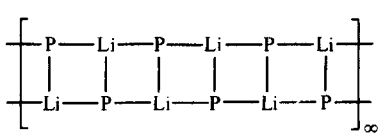

Fig. 5. Framework of the proposed structure of $(LiPPh_2)_\infty$.

cating that the solid-state dimeric structure is probably retained in relatively concentrated solutions. However, cryoscopic studies reveal that under more dilute conditions (indeed, too dilute for meaningful NMR spectra to be obtained in a reasonable time) **2** dissociates appreciably: n falls dramatically from 1.67 to 1.05 on halving the solution concentration (from 0.04 to 0.02 mol dm^{-3}), implying a substantial preponderance of monomer at the lower concentration.

(*Received* 21 *July* 1986 ; *accepted* 20 *September* 1986)

Abstract—Introduction of halogeno and phenoxy substituents onto the methine carbons of the symmetrical and unsymmetrical Schiff bases, bis-(acetylacetone)ethylenediimine, salicylaldehydeacetylacetoneethylenediimine, and *o*-hydroxyacetophenoneacetylacetoneethylenediimine, has been performed through the use of halogenosuccinimides and sodium phenoxide. The related [Co(Chel),2py]ClO_4 and RCo(Chel), H_2O (Chel = quadridentate ligand) complexes have been synthesized and characterized. The influence of these substituents on the electrochemical properties and behaviour of the Co—C bond have been investigated. It appears that halogen-substituted complexes exhibit less negative potential values for the Co(III)–Co(II) couple than do unsubstituted complexes. However, all alkylated complexes are reactive toward CH_3SnCl_3 while ^1H NMR and EPR measurements point to the occurrence of the homolytic cleavage of the Co—C bond.

Small organocobalt complexes have played an important role in giving insight into many aspects of the processes involving B_{12}-dependent enzymes. Within the framework of this model approach, we have focused our attention on the study of alkyl transfer reactions between cobalt and tin centres.[1–3] Although no direct evidence has been given so far that tin compounds may be alkylated under biotic conditions,[4,5] the factors which may influence this transfer have received considerable study and speculation, due to the large increase in use of organotin compounds over the last 20 years.[6–11]

We have previously considered model systems involving, on the one hand, some alkyl cobalt complexes, RCo(Chel) (Chel is a quadridentate ligand such as BAE, DMG, Salen† ...) and, on the other hand, CH_3SnCl_3 or $(CH_3)_2SnCl_2$.[1–3] The resulting data have shown that the behaviour of the Co—C bond strongly depends on the nature of the equatorial ligand Chel and, therefore, may be altered by introducing suitable substituents onto the ligand framework.

It is well known that electrophilic and nucleophilic substitution may be achieved on the methine carbons of complexed H_2BAE.[12,13] For instance, we succeeded in preparing [Co(X_2BAE), 2Py]ClO_4 complexes[14] from the parent complex [Co(H_2BAE), 2Py]ClO_4, but all attempts to introduce substituents onto the corresponding alkylated complexes RCo(H_2BAE) have failed due to the instability of the Co—C bond.

Recently,[15] we have shown that this difficulty

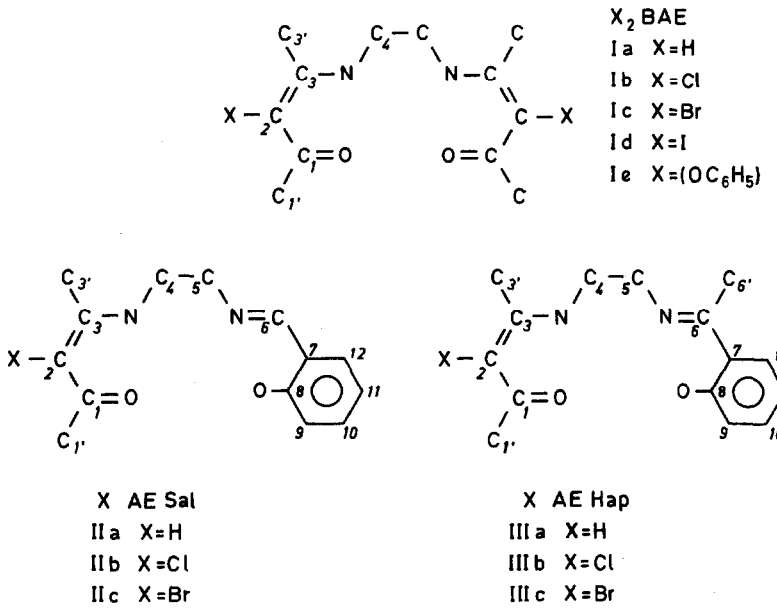

Fig. 1. Schematic representation of ligands.

may be overcome by making use of Schrauzer's method.[16] This implies that the free substituted ligands may be prepared. In some instances,[17] they have been obtained by demetallation of the related nickel(II) or copper(II) complexes but this process is tedious and results in low yield.

In the present paper, we report on the possibility of preparing three types of substituted ligands, i.e. X_2BAE, XAESal and XAEHap (Fig. 1). Of particular importance is the fact that the use of non-symmetrical ligands (HAESal and HAEHap) allows the preparation of monosubstituted species which are expected to give a smooth modulation of the properties of the derived cobalt complexes.

RESULTS AND DISCUSSION

As described in Experimental, halogeno substituents are easily introduced onto the methine carbons of H_2BAE, HAESal and HAEHap by reacting these unsubstituted ligands with the suitable halogenosuccinimides. The X-substituted ligands are stable compounds except the iodo derivatives which are light-sensitive and must be stored at low temperature. The results of elemental analyses are quoted in Table 1. The ligands have been further characterized by NMR (^{1}H and ^{13}C) spectroscopy. The relevant data are collected in Tables 2 and 3. The spectral patterns (chemical shift and multiplicity of the signals) confirm the nature of the species and, more particularly, the occurrence of substitutions on the methine carbons. The influence of the substituents is clearly perceptible in the ^{1}H spectra but it may be recognized that only the BAE moiety of the molecule is significantly perturbed. No attempt has been made to analyse fully the complex spectra of the Salen moiety but the ^{1}H nuclei of the benzenoid ring give two sets of signals with maxima at 7.30 and 6.90 ppm for XAESal, and 7.35 and 6.80 for XAEHap, irrespective of the nature of the X-substituent. Returning to the BAE moiety, it appears that the two $C\underline{H}_3$ are shifted to lower magnetic fields in the order (H, Cl, Br, I) expected on the basis of simple electronegativity arguments.

These ligands have been used to prepare the complexes [Co(Chel), 2Py]ClO_4 and RCo(Chel), R being CH_3 or C_2H_5. Due to the instability and/or low solubility, ^{13}C spectra could only be obtained for nonalkylated complexes. The NMR data are quoted in Tables 4–7. As was the case for the free ligands, the effects of the substituents are restricted to the BAE part of the molecules.

In previous papers,[2,3] we have shown that the redox potentials of the Co(III)–Co(II) couple affords a convenient evaluation of the inductive effects of the ligands onto the cobalt centre. However, it is known that in the alkyl complexes, RCo(Chel), difficulties in measuring the redox potential may arise from cleavage of the Co—C bond and/or cobalt–axial base bond upon reduction and, eventually, from the irreversible nature of the reduction process.[18,19] For these reasons, it is more advisable to consider the nonalkylated complexes which are readily soluble in pyridine and lead, in this solvent, to a one-electron reversible (or quasi-reversible) reduction process. Thus they give more

reliable data as regards the effect of changing the equatorial ligand than the alkylated complexes do. Furthermore, we have observed in several instances that the data related to the two series of complexes show very similar trends.[2]

The $E_{1/2}$ values obtained for the Co(XAESal) and Co(XAEHap) complexes are reported in Table 8 together with some pertinent results available in the literature. Looking first at the unsubstituted complexes, it appears that the nonsymmetrical complex **IIa** lies between the symmetrical {$E_{1/2}$ Co(III)–Co(II) for [Co(III)(Salen), 2py]ClO_4 = −0.39 V}[20] ones so that use of nonsymmetrical ligands leads to a modulation of the redox properties of the metal centre. Further modulation results from introducing substituents onto the ligand framework. As expected on the basis of inductive arguments, the halogen-substituted complexes exhibit potential values less negative than do the unsubstituted complexes. On decreasing the overall donor power of the equatorial ligand the Co(III)–Co(II) polarographic wave shifts towards less negative values in agreement with a reduction in the electron density on the cobalt atom. The most important variations of $E_{1/2}$ are observed for the Co(X_2BAE) complexes where substitutions occur on both halves of the equatorial ligand. The effects are reduced by half in going to the Co(XAESal) series where only the BAE moiety is substituted. Feeble variations are observed for the Co(XAEHap) complexes. The difference between these two series may result from the electron-releasing effect of the third methyl group in the XAEHap ligands.

Of particular importance is the fact that two complexes, namely Co(BrAESal) and Co(ClAESal), are characterized by potential values greater than −0.4 V. We have previously observed that the behaviour of the Co—C bond in various types of RCo(Chel) complexes was correlated with the $E_{1/2}$ [Co(III) → Co(II)] values and, as regards the $MeSnCl_3$–RCo(Chel) systems, that $E_{1/2} \cong -0.4$ V was a limiting value.[3] On the basis of this empirical correlation, both RCo(XAESal) complexes would be unreactive towards $MeSnCl_3$. Surprisingly, they are found to be reactive. A study (^{1}H NMR, spin-trapping EPR, and chromatography) of $MeSnCl_3$–MeCo(XAESal) (X = Cl or Br) shows that homolytic cleavage of the Co—C bond occurs in both cases.

This abnormal behaviour may originate in a lengthening of the Co—B bond (B being the axial

base, i.e. pyridine) which would favour the reduction Co(III) → Co(II) since Co—B bond lengths in Co(II) complexes are expected to be longer than in Co(III) complexes.[22–24] Another possibility would be related to an increased flexibility of the XAESal ligands which could adopt a nonplanar conformation resulting in an increased stability for the Co(II) form. Alternatively, one may suggest that the reactivity of the Co—C bond would be enhanced by some structural particularities. For instance, steric interactions between the alkyl group axially coordinated to the cobalt atom and the equatorial ligand could be responsible for the observed abnormality. Recent theoretical work[25] supports the view that the Co—C linkage is particularly susceptible to angular distortion and/or steric hindrance. However, at this point we can only speculate as to the reasons for the seemingly abnormal behaviour of the Co(XAESal) complexes. Structural determinations are needed to clarify this point. Work is in progress to obtain suitable crystals of RCo(AESal) complexes.

EXPERIMENTAL

Synthesis

Ligands. BAE was prepared following the procedure reported by Martell *et al.*[26] We have previously described the synthesis of AESal and AEHap ligands.[21]

X_2BAE, XAESal and XAEHap (X = Cl, Br, I or OC_6H_5) have been obtained through a method similar to that used recently to prepare X_2BAE-substituted compounds with X = C_6H_5NHCO and C_6H_5NHCS.[15] In a typical run, bromosuccinimide (2×10^{-2} mol) was added to a solution of BAE (10^{-2} mol) in acetonitrile at 10°C. The mixture was stirred for 2 h. The white precipitate of Br_2BAE was filtered out, dried and recrystallized in a chloroform–ethanol mixture. I_2BAE, BrAESal and BrAEHap were obtained in a similar way. For X = Cl, it was necessary to add water (60 cm^3) to obtain complete precipitation. The iodo derivative was very light-sensitive.

$(C_6H_5O)_2$BAE was prepared by addition of sodium phenoxide (2×10^{-2} mol) to Br_2BAE (2×10^{-2} mol) dispersed in acetonitrile (40 cm^3), with magnetic stirring for 48 h. Solvent evaporation afforded an oily product. A white precipitate was obtained on adding water and acetone (20 cm^3). The white product was filtered off and dried in dynamic vacuum.

Complexes. [Co(III)(Chel), 2py]ClO_4 complexes were synthesized according to Costa's procedure[27] modified by Averill and Broman.[28]

The brown-red alkylated complexes, RCo(Chel), H_2O, were prepared according to Schrauzer's

procedure.[16] In chloroform, they gave the characteristic green coloration of pentacoordinated RCo-Chel species. Almost all these species were light-sensitive and unstable at room temperature, specifically the iodo and the phenoxy derivatives which could not be obtained pure.

Measurements

Electrochemical measurements were carried out as previously described.[29] A platinium auxiliary electrode and an Ag–AgCl reference electrode were used in conjunction with a dropping mercury electrode. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker WH90 spectrometer using $CDCl_3$ as internal reference.

CYCLOMETALLATION—III.* REGIOSELECTIVITY IN Pd(II) CYCLOMETALLATED COMPLEXES

J. M. VILA, A. SUAREZ, M. T. PEREIRA, E. GAYOSO and M. GAYOSO†

Departamento de Química Inorgánica, Facultad de Química, Universidad de Santiago de Compostela, Spain

(*Received* 1 *May* 1986; *accepted* 16 *September* 1986)

Abstract—Cyclometallated complexes derived from organic ligands where two initial metallation sites are present have been synthesized. The preferred palladation position is discussed on the basis of electronic and steric effects, and the regioselectivity of the cyclometallation is characterized by means of IR and ^{1}H NMR spectroscopy. The spectral studies show that the less favored position is not attached to the metal atom. Acetato- and halogeno-bridged dimers, as well as phosphine monomers derived from the latter, have been obtained and studied by spectroscopical methods.

Cyclometallation reactions have aroused great interest in the past,[2–5] not only because of their importance in themselves but also because they provide good starting materials in organic synthesis.[6–8] The question of regioselectivity in these complexes has arisen before[9–11] in those cases where two cyclometallation sites are possible. As a continuation of our studies on cyclometallated compounds[12–14] we now report the preparation and characterization of the complexes derived from *N*-(3,4-dimethoxybenzylidene)-2,4,6-trimethylaniline (**I**), *N*-(4-methoxy-3-methylbenzylidene)-2,4,6-trimethylaniline (**II**) and *N*-(3,4-methylenedioxobenzylidene)-2,4,6-trimethylaniline (**III**). We discuss the preferred cyclometallation site which can be well defined by means of IR and ^{1}H NMR spectroscopy.

EXPERIMENTAL

Solvents were purified by the standard methods.[15] Chemicals were reagent grade. Palladium(II) acetate was purchased from Fluka. Elemental analyses were carried out in a Perkin–Elmer Elemental analyzer 240-B. Palladium was analyzed by atomic absorption in a Varian Techtron AA-G spectrophotometer. The syntheses of the acetato-bridged dimers were carried out under dry N_2. IR spectra were recorded on a Perkin–Elmer 180 spectrophotometer. ^{1}H NMR spectra were obtained in $CDCl_3$ solutions, with $(CH_3)_4Si$ as the standard ($\delta = 0$ ppm), and were recorded on either a Varian CFT-20 or a Bruker WM-250 spectrometer.

Preparation of the complexes

$[Pd\{4'\text{-}CH_3O\text{-}5'\text{-}CH_3C_6H_2C(H)=N\text{-}2,4,6\text{-}(CH_3)_3C_6H_2\}(CH_3COO)]_2$. In a 100-cm^3 round-bottomed flask, 0.39 g (1.46 mmol) of **II** and 0.3 g (1.34 mmol) of palladium acetate were added in 25 cm^3 of glacial acetic acid, to give a clear solution. After refluxing for 2 h the solution was cooled and the acetic acid removed *in vacuo*. The residue was diluted with water and extracted with dichloromethane. The combined extract was dried with anhydrous sodium sulphate, filtered and then concentrated *in vacuo* to give a yellow solid, which was column chromatographed on silica gel, eluting with

dichloromethane to remove any unchanged starting materials. Elution with dichloromethane–ethanol (1%) gave the desired complex, which was recrystallized from dichloromethane–*n*-hexane, giving a yellow powder. Attempts to produce crystals were unsuccessful.

$[Pd\{4'\text{-}CH_3O\text{-}5'\text{-}CH_3C_6H_2C(H)=N\text{-}2,4,6\text{-}(CH_3)_3C_6H_2\}X]_2$ (X = Cl *or* Br). To 0.1 g of the acetato-bridged dimer dissolved in acetone, giving a clear solution, a solution of sodium chloride or sodium bromide in water ($\simeq 10^{-2}$ M) was added. A solid immediately precipitated. After stirring for 1 h at room temperature, the solid was filtered off and dried *in vacuo*.

$[Pd\{4'\text{-}CH_3O\text{-}5'\text{-}CH_3C_6C(H)=N\text{-}2,4,6\text{-}(CH_3)_3C_6H_2\}(X)P(C_6H_5)_3]$ (X = Cl *or* Br). To a suspension of 0.05 g of the halogeno-bridged dimer in 10 cm^3 of acetone, $P(C_6H_5)_3$ was added in a dimer–phosphine (1 : 2) molar ratio to give a clear solution. After stirring for 2 h, a solution of acetone-water (1 : 3) was added and a solid precipitated. The solid was filtered off and dried *in vacuo*.

The analogous complexes were prepared in the form described above. The amounts used in their preparation can be seen in Table 1. The analytical data, color and yield for the complexes are collected in Table 2.

RESULTS AND DISCUSSION

We have previously studied the preparation and characterization of cyclometallated complexes[1,12–14] in which the organic ligand presented only one possible cyclometallation site, or two equivalent ones which would afford the same product no matter which carbon atom of the phenyl ring was attacked by the metal atom. We are now interested in studying ligands that may give rise to different compounds depending on the carbon atom to which the metal atom is attached in the final product; by means of IR and ^1H NMR spectroscopies we have achieved this. In the complexes derived from **I** the halogeno-bridged dimers were too insoluble for the determination of their NMR spectra; nevertheless, we can assume that what can be said regarding the cyclometallation site of the phenyl ring for the **I** acetato-bridged complex holds in the halogeno-bridged ones, since the latter derive from the former by a metathesis reaction which should render the same complexes save for the bridging ligands. Furthermore, this also applies to the phosphine monomers, which are synthesized from the halogeno-bridged dimers.

Two possible cyclometallation sites, 2 and 6, are present in the mentioned ligands, the electrophilic attack[16] of the palladium atom on either one of them being influenced by both electronic and steric effects. In ligand **I** the C(6) atom was preferred. The methoxy group at C(4) decreases the value of electrophilic palladation at C(2) and C(6). Furthermore, the C(2) position is deactivated by the electron-withdrawing inductive effects of the adjacent methoxy group, which, on the other hand, activates the C(6) position by its strongly *para* directing mesomeric effect. Added to this a steric effect of the C(3) methoxy group, it all accounts for metallation

not ocurring at the C(2) position, but rather at C(6). As we have described before,[1] attempts to prepare cyclometallated complexes where a methoxy group *ortho* to the metallation site is present have been unsuccessful. For reasons given there we think that it is mainly a strong steric effect by the methoxy group that prevents metallation of the carbon atom *ortho* to it.

In ligand **II**, also the C(6) site is preferred. Again the C(4) methoxy group has a deactivating effect on the C(2) and C(6) atoms, whereas the 3-methyl group is expected to highly activate electrophilic attack at the *para* C(6) position. We do not believe that the methyl group has a strong steric effect so as to prevent palladation at C(2) because, as we have already shown,[14] complexes with a methyl group *ortho* to the metallation site can be obtained in high yield. In this case it is only a matter of electronic effects which favor the C(6) site for palladation.

For ligand **III** we see no reason why palladation should not occur on any one of the C(2) and C(6) atoms; in fact, a mixture of isomers might be possible. However, in contrast to the complexes obtained by Barr and Dyke[9,17] where cyclopalladation occurred at the 6-position, we have obtained complexes in which it takes place through the 2-position, and no isomer with the metal bound to the C(6) atom was found.

The ^1H NMR spectra for the **I** and **II** dimer complexes show two H(1) singlets due to the H(6′) and H(3′) protons. The initial double doublet of protons H(5) and H(6) disappears, upon metallation to the C(6) atom, as is expected. For the **III** dimer complexes, the initial double doublet of H(5) and H(6) protons still holds, and the H(2) singlet disappears. In the phosphine monomers the great amount of phenyl protons does not allow a correct assignment in this region. The data are shown in Table 3.

Further evidence for these situations can be obtained from the IR spectra of the complexes, by studying the bands in the 900–800-cm^{-1} region, and which are due to the different substitution pattern of the phenyl ring.

In the **I** and **II** complexes the band at 825–805 cm^{-1} due to two adjacent protons in a 1,2,4-substituted phenyl ring disappears, as is expected if the metallation takes place at the C(6) atom, leaving two solitary protons on the ring. The 1,2,3,4-phenyl substitution produced by palladation at the C(2) atom in the **III** complexes leaves two adjacent protons on the ring which gives rise to a band at 810–

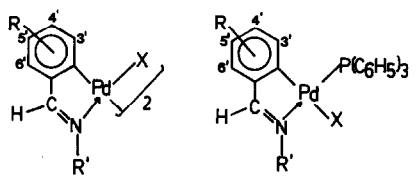
[a] The numbers in parentheses apply only to the **I** and **II** complexes. J in Hz.

[b] This signal integrates for six protons.

CH_3O signals in the phosphine monomers: **Id** 3.81 and 2.88, **Ie** 3.71 and 2.82, **IId** 2.85, and **IIe** 2.84.

800 cm^{-1} in the IR spectrum that would otherwise be absent.

With this in mind, and as we have discussed before,[1,12-14] the complexes may be formulated as follows with a d^8 palladium atom in a 2+ oxidation state:



a: X = CH_3COO d: X = Cl

b: X = Cl e: X = Br

c: X = Br

I: R = 4′,5′-$(CH_3O)_2$; R′ = 2,4,6-$(CH_3)_3C_6H_2$

II: R = 4′-CH_3O-5′-CH_3; R′ = 2,4,6-$(CH_3)_3C_6H_2$

III: R = 3,4-OCH_2O; R′ = 2,4,6-$(CH_3)_2C_6H_2$

The numbers on the phenyl rings apply only to the I and II complexes; for the III complexes the notation of the free ligand holds.

The present compounds are all remarkably air-stable solids ranging in color from orange-yellow to light yellow. Except for the halogeno-bridged dimers, which are only sparingly soluble in chloroform and dichloromethane and totally insoluble in alcohols, the complexes are soluble in the more common organic solvents, and insoluble in water.

They all show a shift of the νCN band towards lower wavenumbers (Table 2) with respect to the parent organic ligand, the magnitude of which shows that the metal atom is bound through the nitrogen lone pair[14,18-20] and not to the C=N double bond. Further evidence of this is the 0.43–0.57-ppm upfield shift of the azomethine proton signal,[14,21] as is depicted in Table 3.

The acetato-bridged ligands have characteristic bands in the IR spectrum at 1590m and 1420m cm^{-1} (**Ia**), 1582s and 1412m cm^{-1} (**IIa**), and 1580m and 1432m cm^{-1} (**IIIa**), the separations between them show the acetato ligand to be bridging between the metal atoms[14,22] (Table 2).

In the ^{1}H NMR spectra an H(6) singlet, 1.70 (**Ia**), 1.71 (**IIa**) and 1.63 (**IIIa**), is found in each case (Table 3). This peak has been assigned to the two acetate-methyl groups, so that they are equivalent, therefore rendering the organic ligands in a *trans* disposition.[23,24] The upfield shift of this signal, compared to that of palladium(II) acetate (δ 2.04 ppm) may be due to the through-space shielding environment of the unmetallated phenyl ring.[1,14]

The chloro-bridged dimers have a *trans* geometry as have been shown by IR[25] and X-ray studies;[26] they show two $\nu PdCl_b$ bands in the IR spectrum. The higher-frequency band is attributed to the Pd—Cl bond *trans* to nitrogen, and the lower frequency one to the Pd—Cl bond *trans* to the phenyl

carbon atom, owing to the higher *trans* influence of a phenyl carbon atom than that of a nitrogen atom.[27,28]

In the phosphine monomers, as we have shown before[1,12–14] the phosphine ligand is *trans* to the nitrogen atom, and the halogen ligand to the carbon atom. The high *trans* influence of the latter weakens the Pd—Cl bond and thus the $\nu PdCl_t$ vibration frequency appears at lower wavenumbers than could be expected should the halogen atom be *trans* to a weak *trans* influence ligand[27] (Table 2). Further proof can be drawn from the ^1H NMR spectra of the monomer complexes. The C(4) methoxy group signal suffers an upfield shift with respect to its position in the free ligand and the dimer complexes due to the aromatic shielding cone of the phosphine ligand (Table 3), which can only take place with this ligand *trans* to the nitrogen atom.[1] In complexes **Ia**, **IIa** and **IIb** the H5(3′) proton signal is shifted upfield by 0.59–0.75 ppm compared to the parent free ligand, whereas in **IIIa–c** it is only shifted 0.18–0.29 ppm. This could be due to a flow of charge from the d^8 palladium atom[29] which would be more notorious in the **I** and **II** complexes as in them H5(3′) is *ortho* to the σPd—C bond, whereas in the **III** complexes H(5) would be *para* to this bond, and hence farther away, so that the effect would be less intense in these cases.

MIXED-LIGAND COMPLEXES OF Ru(III) AND Rh(III): ESR STUDIES ON SOME Ru(III) COMPLEXES

H. K. GUPTA and S. K. DIKSHIT*

Department of Chemistry, Indian Institute of Technology, Kanpur 208016 (UP), India

(*Received* 6 *May* 1986; *accepted after revision* 16 *September* 1986)

Abstract—Reactions of 2-mercapto-3-phenyl-4-quinazolinone (LH) with $RuCl_3 \cdot xH_2O$ and $RhCl_3 \cdot xH_2O$ afforded the compounds $[RuL_2Cl(H_2O)]H_2O$, $[RuL_2Cl \cdot DMF]$ and $RhL(LH)Cl_2 \cdot 2H_2O$. Reactions of LH with $RuCl_3 \cdot xH_2O$ in the presence of *N*-heterocyclic bases led to the formation of complexes of type $[RuL_2ClB] \cdot H_2O$ (B = pyridine, 3-picoline or imidazole) and $[RuLCl_2(o\text{-phen})]H_2O$ (*o*-phen = 1,10-phenanthroline). These complexes were characterized on the basis of analytical, conductivity, magnetic, IR and electronic spectral and ESR studies. Tentative structures for the complexes are proposed.

Studies on the complexing behaviour of biologically active ligands containing thioamide group have been the subject of investigations in our laboratory.[1–3] Recently the complexes of Pd(II), Pt(II) and Ru(II) with ligands containing a thioamide group reported from our laboratory have been selected for anticancer screening by the National Cancer Institute, Bethesda, Maryland, U.S.A. The effect of various ligands and metal ions on metal–ligand covalency, *d*-orbital splitting and distortion of complexes have been of considerable interest in the field of coordination chemistry. The low-spin d^5-configuration is a good probe of molecular structure and bonding since *g* values of such complexes vary widely, owing to the structure of the complex and the degree of metal–ligand covalency. Although a large number of $d^5(t_{2g}^5)$ complexes have been studied, the application of ESR was mainly limited to the first-row transition series. Only a few Ru(III) complexes have been subjected to ESR studies.[4–8] In view of the biological activity of the complexes and diverse coordinating ability of the ligand 2-mercapto-3-phenyl-4-quinazolinone (LH) we were prompted to study the Ru(III) and Rh(III) complexes. Recently, we have reported the interaction of LH with Co(II), Ni(II), Pd(II), Pt(II) and Pt(IV) ions in the presence and absence of various *N*-heterocyclic bases.[9,10] The ligand (LH) has been used for the estimation of copper[11] and Dave *et al.* have reported the interaction with Cu(II), Co(III) and Ni(II).[12]

The IR spectrum of LH in the solid state displays a ν(NH) absorption band at *ca* 3250 cm^{-1} but no ν(SH) absorption band at *ca* 2500 cm^{-1}, indicating that, in the solid state, the ligand exists as a thione (**1**) and not as a thiol (**2**) tautomer.

EXPERIMENTAL

All the chemicals used were either AR or chemically pure grade. Sulphur and chloride were estimated gravimetrically. Ruthenium was estimated on a IL-751 atomic absorption spectrophotometer after the complex had been decomposed by heating with a mixture of H_2SO_4 and HNO_3. Electronic spectra were recorded on a Cary model 17D UV–visible spectrophotometer. The IR spectra were obtained on a Perkin–Elmer 580 spectrophotometer in KBr in the range 4000–250 cm^{-1}. Melting points of the complexes were recorded on a Fisher–John melting-point apparatus and are uncorrected. The ESR spectra were recorded on 109E-line century series EPR spectrometer at *X*-band frequencies at 293 K using DPPH ($g = 2.0036$) as internal stan-

[c] d = decomposes.

dard. Magnetic susceptibilities were measured by a parallel-field vibrating sample magnetometer (VSM) model 150A at 293 K.

The ligand LH was prepared by a literature method.[13,14]

Preparation of complexes

$RhL(LH)Cl_2 \cdot 2H_2O$. A solution of $RhCl_3 \cdot xH_2O$ (0.26 g, 1 mmol) in DMF (10 cm^3) was added to a filtered solution of LH (0.508 g, 2 mmol) in DMF (25 cm^3). The resulting solution was heated under reflux with constant stirring for an hour. The solution was allowed to cool at room temperature. Addition of excess ammonia solution to it precipitated a yellow complex which was centrifuged, washed with water, alcohol and ether, and dried at 80°C.

$[RuL_2Cl \cdot DMF]$. A solution of $RuCl_3 \cdot xH_2O$ (0.26 g, 1 mmol) in DMF (10 cm^3) was added to a filtered solution of LH (0.5 g) in DMF (25 cm^3). The resulting solution was refluxed for an hour. The solution was concentrated to about 5 cm^3 on a water bath: on cooling a violet precipitate resulted which was filtered, washed with alcohol and ether, and dried at 80°C.

General method of preparation of $[RuL_2ClB]H_2O$ [B = H_2O, *pyridine* (py), 3-*picoline* (3-pic) *or imidazole* (imid)] *and* $[RuLCl_2(o\text{-phen})]H_2O$ (*o*-phen = 1,10-*phenanthroline*). A filtered alkaline (pH 9–10) ethanolic solution (25 cm^3) of LH (0.5 g, 2 mmol)* was added to an aqueous solution (50 cm^3) of $RuCl_3 \cdot xH_2O$ (0.26 g, 1 mmol) containing the appropriate heterocyclic base† solution. The resulting solution was heated under reflux for 15 h. The resultant precipitates were filtered, washed thoroughly with water, a little amount of alcohol and ether. The compounds were recrystallized from methanol.

RESULTS AND DISCUSSION

Microanalytical data as well as sulfur, metal and chloride estimations are in good agreement with stoichiometry proposed for complexes (Table 1). All complexes were found to be nonconducting in methanol.

IR spectra

The ligand LH contains a thioamide group (H—N—C=S) and gives rise to four characteristic thioamide bands, namely, I, II, III and IV, in the region of 1500, 1300, 1000 and 800 cm^{-1}, and have contributions from $\delta(C—H)+\delta(N—H)$, $\nu(C=S)+\nu(C=N)+\nu(C—H)$, $\nu(C—N)+\nu(C—S)$,

* 0.25 g of LH in the case of $[RuLCl_2(o\text{-phen})]H_2O$.

† 5 cm^3 of pyridine, 3-picoline, 5 cm^3 of an ethanolic solution of 1,10-phenanthroline (0.2 g, 1 mmol) or 5 cm^3 of an aqueous solution of imidazole (0.07 g, 1 mmol).

and ν(C⋯S) modes of vibrations, respectively[15–18] (Table 2).

The disappearance of the ν(NH) band of the ligand at 3250 cm^{-1} from the spectra of all complexes except $RhL(LH)Cl_2 \cdot 2H_2O$ indicates the displacement of N—H hydrogen by Ru(III) and Rh(III), and formation of a metal–nitrogen bond. The presence of weak broad band at 3240–3260 cm^{-1} in the IR spectrum of $RhL(LH)Cl_2 \cdot 2H_2O$ indicates that one ligand is present as LH.

The weakening and broadening of ν(NH) after complexation can be tentatively assigned to Rh(III)—N bond formation.

The presence of a broad band in the region of 3400–3500 cm^{-1} in the spectra of complexes is assigned as ν(OH) of water. The broad band at 3360–3420 cm^{-1} in the spectra of $[RuL_2Cl(imid)] \cdot H_2O$ may be assigned as mixed band of ν(NH) of imidazole and ν(OH) of water.

The ν(C=O) band of the ligand at 1660 cm^{-1} shifts towards a higher wavenumber by 10–30 cm^{-1} in the spectra of complexes, indicating the non-involvement of the C=O group in metal bonding. The ν(C=O) of DMF in the $[RuL_2Cl \cdot DMF]$ complex is probably merged with the band present at 1690 cm^{-1} in the IR spectrum of the complex. ν(C=O)[19] in DMF appears at 1683 cm^{-1}, hence coordination of DMF through its N atom is likely.

The thioamide band I of the ligand at 1540 cm^{-1} shifts to a lower wavenumber by 20–35 cm^{-1} in the spectra of the complexes. This indicates M—N bond formation as the thioamide band I has its principal contribution from δ(C—H)+δ(N—H).

The thioamide band II of the ligand at 1345 cm^{-1} either splits or shifts to a lower wavenumber as a result of coordination as band II has a contribution from ν(C=S)+ν(C=N)+ν(C—H).

The thioamide band III [ν(C—N)+ν(C—S)] is relatively weak in the spectra of the complexes. The thioamide band IV ν(C⋯S) of the ligand at 770 cm^{-1} changes its position by ± 10 cm^{-1} in the spectra of the complexes. A red shift of 25–55 cm^{-1} in band IV usually indicates bonding through sulphur and a blue shift of 40–90 cm^{-1} in this band indicates bonding through nitrogen. However, if there is simultaneous coordination through nitrogen and sulphur, there may not be much of a shift in band IV.[20] Hence the small shift of band IV is attributed to simultaneous coordination through nitrogen and sulphur. In contrast with soft metal ions, similar ligands are reported to coordinate through sulphur only.[21]

New bands of weak to medium intensity in the region 250–500 cm^{-1} in the spectra of the complexes may be assigned to the coupled vibrations ν(M—Cl), ν(M—N) and ν(M—S).[22]

In the spectra of the complexes, there seems to be extensive mixing between the bands of the ligand and those of the bases, hence the characteristic frequencies of *N*-heterocycles did not occur at their standard positions.

Magnetic moments and electronic spectra

The magnetic-susceptibility measurements at room temperature show that the magnetic moments of ruthenium complexes lie in the range 1.7–2.1 BM (Table 1) corresponding to one unpaired electron. The rhodium complex was found to be diamagnetic.

The electronic spectrum of LH in DMF exhibits

a strong peak at 295 nm and a weak shoulder at 262 nm which are assigned to a $\pi \rightarrow \pi^*$ intraligand (IL) transition.[23]

The electronic spectra of the Ru(III) complexes show bands in the 645–655-, 525–565- and 415–465-nm regions (Table 3) which may be assigned to $^2T_{2g} \rightarrow {}^4T_{1g}$, $^2T_{2g} \rightarrow {}^4T_{2g}$ and $^2T_{2g} \rightarrow {}^2A_{2g}$, $^2T_{1g}$ transitions,[24] respectively.

In the spectra of Ru(III) complexes, some of these transitions could not be observed, probably because of masking by a strong charge-transfer (CT) and/or an IL transition. A band or shoulder around 295–310 nm is assigned to the IL transition. Another band at 330 nm in the spectrum of $[RuL_2Cl(py)]H_2O$ may be assigned to an M → L or L → M CT transitions.

The rhodium complex shows only IL transitions. All other expected transitions[24] were probably masked by IL bands.

ESR spectra

To interpret the ESR data, we have used the theory as described by Bleaney and O'Brien which has been successfully applied to many complexes.[4–6]

The ESR measurement does not determine the sign of g_i components, nor the correspondence of g_1, g_2 or g_3 to g_x, g_y or g_z. It only gives the absolute principal g values. Therefore, we considered all possible combinations for acceptable results. For axially symmetric molecules g_z is assigned to the unique component and only eight possible sign combinations were taken, whereas for molecules with lower symmetry 48 possible combinations were considered.

A Fortran IV computer program on a DEC-1090 system was used for all these calculations. The experimental g values and approximate values of the starting vector (approximate values of A, B, C and k, keeping the normalization condition $A^2+B^2+C^2 = 1$, in mind) were fed into the program. For each set in turn, values of A, B, C and k were found by use of the Newton–Raphson method. The computer program was then tested by using literature-reported[5] data.

For all of the possible combinations the values of A, B, C, k, Δ/λ and V/λ were obtained, and reasonable combinations were selected (Table 4) by considering the following conditions. (1) Solutions with $0.75 < k < 2.0$ were examined while a defi-

nition of k requires $0.75 < k < 1.0$ as a large value of k can be obtained if the assumptions made in the theory are not strictly valid.[4,25–27] (2) Kramer's doublets obtained from the knowledge of A, B and C should be coincident with those of the ground state obtained from the matrix of spin–orbit coupling and low-symmetry field, for the observed ESR spectra were due to the lowest Kramer's doublets. (3) For molecules showing three featured spectra, 48 combinations usually lead to six solutions with identical k values. These solutions differ only in their ordering of real one-electron d-functions and in the value of the coefficients A, B, and C. In such cases we made a choice by taking the pair corresponding to $g_z \approx 2.0$. (4) The tetragonal distortion (Δ) is assumed to be larger than the rhombic distortion (V), which seems reasonable if we consider the structure of the complexes examined.

As a consequence, two possible fits (Table 4) for $[RuL_2Cl\cdot DMF]$ and $[RuL_2Cl(py)]H_2O$ were limited to the following: $g_1 = -g_x$, $g_2 = g_y$, $g_3 = g_z$; or $g_1 = g_y$, $g_2 = -g_x$, $g_3 = g_z$. These solutions are equivalent with each other, differing only in the choice of the x- and y-axes, in other words, differing in the signs of both the coefficient C and V/λ values, and it is difficult to reject either of the two, although assignments giving a negative V/λ value were chosen and reported for $[RuX(NH_3)_5]^{2+}$ (X = Cl or Br).[28]

For an axially symmetric molecule, $[RuLCl_2(o\text{-phen})]H_2O$ there are two acceptable fits. Both fits produce a small Δ/λ ($\Delta < \lambda$) corresponding to a small axial distortion. The value of k is in the range 0.95–1.10, and the estimated energy of electronic transitions between Kramer's doublet lies in the range 1400–1800 cm^{-1}. [Here we assume $\Delta \approx 1000$ cm^{-1}, arbitrarily considering a reduction from the free-ion value of 1180 cm^{-1} for Ru(III).] These transitions fall in the IR range of the spectrum and may get obscured by vibrational transitions.

The fit (1) for $[RuL_2Cl(o\text{-phen})]H_2O$ is chosen here, the sign of g_y is positive and both g_x and g_z are negative ($B > A$, C) and the results show that the hole is in the t_2^o (d_{xy}) orbital. Similar assignments have been reported for β-diketonate complexes of Ru(III).[5] The ordering of the one-electron real functions is one where the doubly degenerate level $t_2^{\pm}$ ($d_{xz} \pm d_{yz}$) lies the lowest. The orbital energies of some of the complexes are given in Table 5. For the compounds with three distinct components, two fits were found and results are not very much different from each other. The highest lying orbital is d_{xy} and the ground state may be either: (a) d_{yz}, or (b) d_{xz}. It is difficult to decide between the two possibilities. The positive value of Δ/λ found in this work means that the d_{xy}-orbital lies at a higher energy than the d_{xz}- and d_{yz}-orbitals, thus supporting the order of d-orbital energies listed in Table 5.

Table 5. Energies of three Kramer's eigenstates and calculated d-orbital energies for the complexes[a]

Compound	E/λ	E_1/λ	E_2/λ	$\Delta E_1/\lambda$	$\Delta E_2/\lambda$	d-Orbital order	Energies (λ cm^{-1})
$[RuL_2Cl\cdot DMF]$	−1.093	0.326	0.525	1.419	1.618	$YZ < XZ < XY$	−0.177, 0.015, 0.162
						$XZ < YZ < XY$	−0.177, 0.015, 0.162

						$XZ < YZ < XY$	−0.058, 0.009, 0.050
$[RuLCl_2(o\text{-phen})]H_2O$	−1.281	0.141	0.5	1.422	1.781	$e(XZ,YZ) < b_2(XY)$	−0.21, 0.42
	−1.035	0.436	0.5	1.471	1.535	$e(XZ,YZ) < b_2(XY)$	−0.33, 0.66

[a] E is lowest energy of ground-state Kramer's doublet.

For the complexes studied the value of k is in the range 0.95–1.21. The 0.953 value for the orbital reduction factor k for the compound $[RuLCl_2(o\text{-phen})]H_2O$ is as expected since *o*-phenanthroline is known to behave as a π-bonding ligand and forms strong metal–ligand covalent bonds. The value of k greater than 1.0 is also not surprising as many other factors besides covalency are responsible for the variation in the value of k[4,25–27] and moreover the complexes of π-bonding ligands such as PPh_3 and $AsPh_3$ are reported to have k values greater than 1.0.[5] An important contribution to the large values of k is, probably, the presence of low-lying CT states. Since 4*d* and 5*d* electrons are less tightly bound to the metal atom, the molecular-orbital formation occurs readily and as a result the CT states have a lower energy than most crystal field states.[29]

Thus the ESR study of $[RuL_2Cl \cdot DMF]$ and $[RuL_2Cl(py)]H_2O$ compounds indicates the rhombic distortion, $g_x \neq g_y \neq g_z$, for these complexes and axial symmetry, $g_x = g_y \neq g_z$ for the $[RuLCl_2(o\text{-phen})]H_2O$ complex.

On the basis of analytical, conductivity, magnetic, spectroscopic and ESR data, a distorted octahedral geometry is assigned to Ru(III) and Rh(III) complexes, assuming that LH is bidentate and coordinated through the nitrogen and sulphur of the thioamide group.

(*Received* 3 *June* 1986; *accepted* 16 *September* 1986)

Abstract—A new series of amino acid Schiff base Ni(II) complexes of 2-hydroxy-1-naphthaldehyde with glycine, L-alanine, L-valine, L-leucine, DL-isoleucine, DL-norleucine, L-serine and L-aspartic acid has been prepared by constituent combination. The structure of the complexes is investigated by microanalysis, conductance, electronic and IR spectral measurements. It is concluded that the bivalent anions of the Schiff bases coordinated to Ni(II) as a tetradentate ligand (O–N–O–O), in the case of the aspartic acid moiety, or as a tridentate ligand (O–N–O) in the case of the other amino acid moieties. The structure of the Ni(II) complexes is suggested to be square planar.

Though much attention has been paid to metal complexes of Schiff bases derived from salicylaldehyde and amino acids,[1–10] there is little in the literature on using 2-hydroxy-1-naphthaldehyde (naph). Only MacDonald *et al.*[11] investigated the Cu(II) complexes of naphthylidene polyfunctional amino acids. Accordingly, the work of this paper describes the synthesis as well as elucidation of the chemical structure of a series of new Ni(II) complexes of Schiff bases derived from naph and some bi- and tridentate α-amino acids. The amino acids applied in this investigation are glycine (gly), L-alanine (ala), L-valine (val), L-leucine (leu), DL-isoleucine (isoleu), DL-norleucine (norleu), L-serine (ser), and L-aspartic acid (asp).

EXPERIMENTAL

All chemicals used were A.R. products and were used without further purification.

Preparation of complexes

The general method used for preparation of the different complexes under investigation is the constituent combination method which has proved to be an excellent synthetic procedure. Quantitative yields of the Ni(II)–*N*-naphthylideneamino acid complexes were obtained by adding an alcoholic solution of Ni(II) chloride to an alcoholic solution of stoichiometric amounts of both naph and amino acid. Sodium carbonate was added to the reaction mixture and then it was gently refluxed on a water bath for 3 h. After cooling a crystalline product obtained. The collected solid complexes were washed with water and ethanol, and then dried. The analytical data of the different Ni(II) complexes synthesized along with their decomposition temperatures are given in Table 1.

Physical measurements

The electrolytic conductances were measured at 25°C using a Pye conductance bridge. The UV and visible electronic spectra were carried out using matched 1-cm^3 stoppered silica cells on a Pye–Unicam SP 100 spectrophotometer. The IR spectra of the complexes were recorded in potassium bromide using a Perkin–Elmer 599 B IR spectrophotometer.

[b] Measured in DMF.
[c] Insoluble in ethanol or DMF.

RESULTS AND DISCUSSION

Chemical analysis and molar-conductance measurements

The results of microanalysis of the prepared Ni(II) naphthylideneamino acid complexes (Table 1) suggest the general molecular formula [Ni (II)(naph)(amino acid)] for the synthesized complexes. This reveals the behaviour that the divalent anions of the naphthylideneamino acids are coordinated to the central Ni(II) ion. Except in the case of Ni(II)–naphthylideneaspartic acid complexes which is insoluble in ethanol or DMF, the measured molar-conductance values for the DMF or ethanolic solutions of the other prepared Ni(II) complexes are very low (< 10.0 Ω^{-1} cm^2 mol^{-1}) as given in Table 1. This suggests a non-electrolytic nature for these complexes.

Electronic spectra

The recorded visible spectra of the different Ni(II)–naphthylideneamino acid complexes in DMF (Fig. 1) show two main bands at 408 and 396 nm (ε_{max} = 3000–12,200 and 6200–13,000 l mol^{-1} cm^{-1}, respectively). Furthermore a broad weak band or shoulder is observed in the range 560–530 nm (ε_{max} = 40–800 l mol^{-1} cm^{-1}). This spectral behaviour suggests a square planar structure for the different Ni(II)–naphthylideneamino acid complexes since it was reported before that the visible spectra of square planar Ni(II) complexes are characterized by an absorption band in the 666–400-nm region (ε_{max} = 50–500 l mol^{-1} cm^{-1}) followed by a more intense one in the 434–330-nm region.[12] The high excitation energy visible band observed in the spectra of the Ni(II) complexes (λ_{max} = 396 nm) can be presumably ascribed to an intramolecular charge-transfer transition liable to take place in the complexed ligand, naphthylideneamino acid.

IR spectra

The IR of all Ni(II) complexes show a broad band at 3300 cm^{-1}, supporting the presence of a water molecule in each complex as indicated by the chemical-analysis data listed in Table 1. The broad band appearing in the 1630–1615-cm^{-1} region in the IR spectra of all complexes can be considered as an overlapped band due to two stretching vibrations, antisymmetric coordinated COO^- and C=N. Since it has been reported that the stretching vibration of the phenolic C—O usually appears near 1530 cm^{-1} [13] the band that appeared in the IR spectra of all complexes in the 1540–1525-cm^{-1} region can be attributed to phenolic C—O stretching.

The IR spectrum of the synthesized Ni(II)–naphthylideneaspartic acid complex does not show

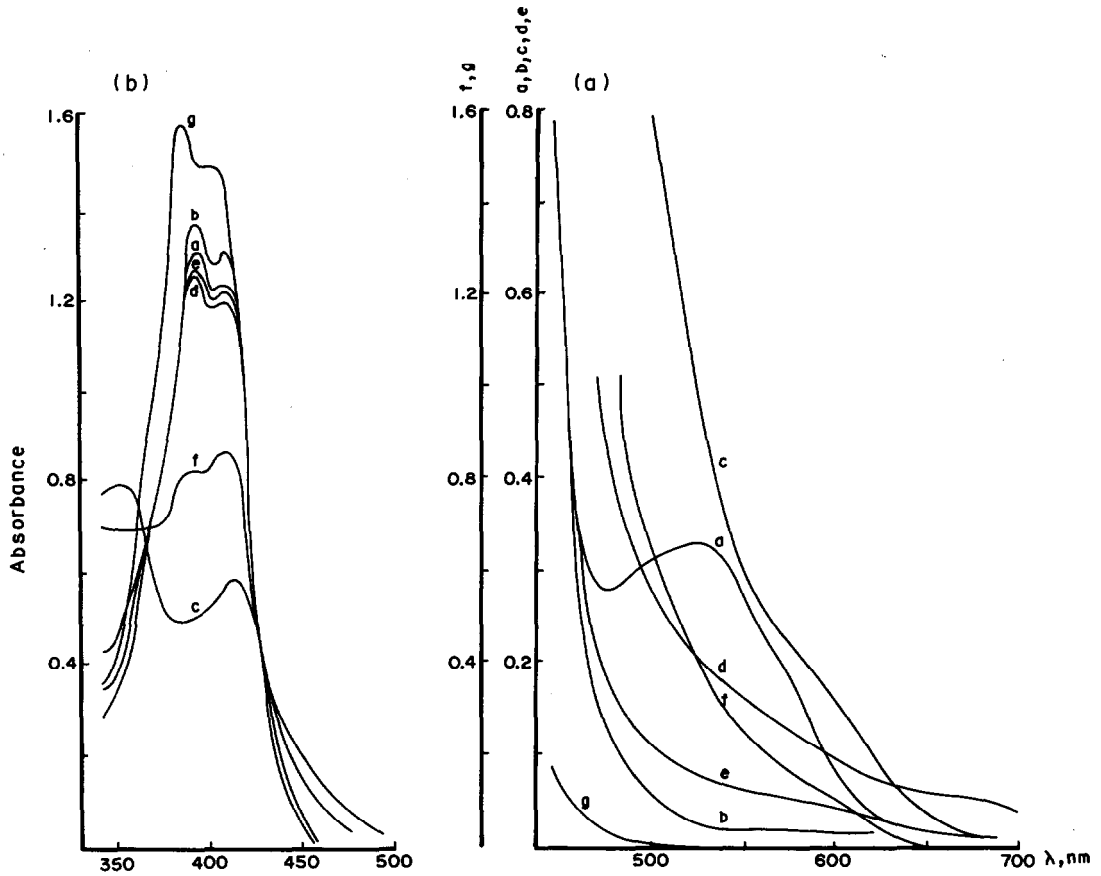

Fig. 1. Visible electronic absorption spectra of 2×10^{-3} M (700–500 nm) (a) and 1×10^{-4} M (500–340 nm) (b) Ni(II)–*N*-naphthylideneamino acid complexes in DMF: (a) gly, (b) ala, (c) val, (d) leu, (e) isoleu, (f) norleu, and (g) ser.

an absorption band due to unionized uncoordinated COO stretching which usually appears at 1750–1700 cm^{-1}.[14] This indicates that the Schiff base naphthylideneaspartic acid coordinated to Ni(II) as a trivalent anion tetradentate (O–N–O–O) ligand. With respect to the amino acid serine, the binding ability of the alcoholic oxygen was estimated to be comparatively weak in an acid or neutral medium.[15] Accordingly, in the case of the Schiff base naphthylideneserine the possibility that the serine moiety OH group takes part in complex formation can be ruled out. This is what is observed since the molar-conductance measurement of the Ni(II)–naphthylideneserine complex shows the nonelectrolytic nature of such a complex i.e. it behaves as a bivalent anion tridentate (O–N–O) ligand.

Conclusions

The important conclusions that can be drawn from this study can be summarized as follows:

(i) Except for the Schiff base naphthylideneaspartic acid, the other naphthylideneamino acids studied coordinate to the central Ni(II) as bivalent anion tridentate O–N–O ligands where two five- and six-chelated rings are formed. The bonding sites are the oxygens of the *o*-hydroxy and α-carboxyl groups belonging to the naphthylideneamino acid moieties. The third bonding site is the azomethine nitrogen atom. The structure of such complexes can be represented schematically (Fig. 2).

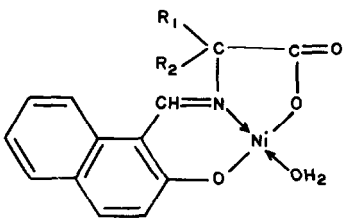

Fig. 2. Ni(II)–naphthylideneamino acid complexes (square planar structure) $R_1 = H$; $R_2 = H$ (gly), CH_3 (ala), $CH(CH_3)_2$ (val), $CH_2CH(CH_3)_2$ (leu), $CH(CH_3)CH_2CH_3$ (isoleu), $CH_2CH_2CH_2CH_3$ (norleu), or CH_2OH (ser).

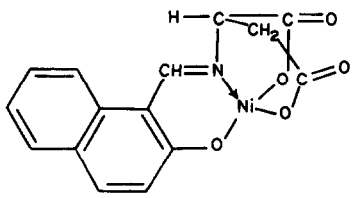

Fig. 3. Ni(II)–naphthylideneaspartic acid complex (square planar structure).

(ii) The dianions of naphthylideneaspartic acid are coordinated to Ni(II) as a O–N–O–O tetradentate ligand where three chelated rings are formed. The additional fourth bonding site is the oxygen β-carboxyl group of the aspartic acid moiety. The structure of this complex can be represented as in Fig. 3.

MONONUCLEAR AND BINUCLEAR LANTHANUM(III) COMPLEXES OF MACROCYCLIC LIGANDS DERIVED FROM 2,6-DIACETYLPYRIDINE

O. P. PANDEY

Department of Chemistry, Gorakhpur University, Gorakhpur 273009, India

(*Received* 10 *June* 1986 ; *accepted* 16 *September* 1986)

Abstract—Two novel series of complexes of types $[La(DAPCH)X_2]X$ and $[La(DAPTC)X_2]X$ (DAPCH = a potentially pentadentate ligand derived from 2,6-diacetylpyridine and carbohydrazide; DAPTC = a potentially tridentate ligand derived from 2,6-diacetylpyridine and thiocarbohydrazide; X = Cl, Br or NO_3) have been synthesized and characterized by elemental analyses, conductance measurements and IR spectral data. All these complexes contain terminal hydrazinic nitrogen atoms with an unshared electron pair and may take part in nucleophilic condensations. Therefore, the reactions of these complexes with 2,6-diacetylpyridine have also been studied which cause ring closure and formation of macrocyclic ligand complexes. Two types of cyclic products, viz. mononuclear $[La(mac)X_2]X$, $[La(mac')X_2]X$ and binuclear $[La_2(mac)X_4]X_2$, $[La_2(mac')X_4]X_2$ (mac- = macrocyclic ligand derived from DAPCH and 2,6-diacetylpyridine; mac′ = macrocyclic ligand derived from DAPTC and 2,6-diacetylpyridine; X = Cl, Br or NO_3) have been isolated by carrying out the reactions by different methods. The IR spectra of these cyclic products are reported.

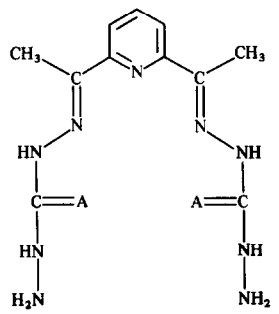
Much research on macrocyclic complexes has been focused on species containing a first-row transition metal ion and a tetradentate ligand.[1] The majority of the ligands contain nitrogen donor atoms and are coordinated in a planar manner to the metal ion.[2–11] The formation of macrocyclic complexes depends significantly on the dimension of the internal cavity, on the rigidity of the macrocycle, on the nature of its donor atoms and on the complexing properties of the anion involved in the coordination.[1,12,13] These ligands are also of theoretical interest since they are capable of furnishing an environment of controlled geometry and ligand field strength.[5,6]

The coordination chemistry of polyaza macrocyclic ligands towards lanthanides has been studied[14–19] and papers have appeared on crown ether and cryptand complexes of lanthanide ions.[20–24]

In this paper, the synthesis and characterization of lanthanum(III) macrocyclic complexes derived from the condensation of 2,6-diacetylpyridine, carbohydrazide or thiocarbohydrazide is reported.

RESULTS AND DISCUSSION

The condensation reactions of 2,6-diacetylpyridine with carbohydrazide or thiocarbohydrazide in ethanol in the presence of sodium acetate give rise to the ligands DAPCH or DAPTC:



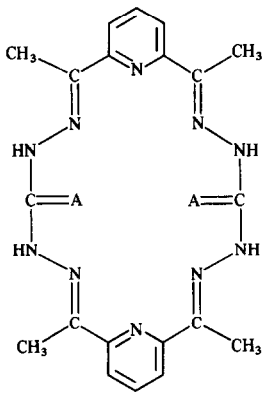
A=O (DAPCH) or S (DAPTC)

These ligands react with a lanthanum salt in a 1 : 1 molar ratio and form ring-opened complexes:

$$LaX_3 + DAPCH \rightarrow [La(DAPCH)X_2]X,$$

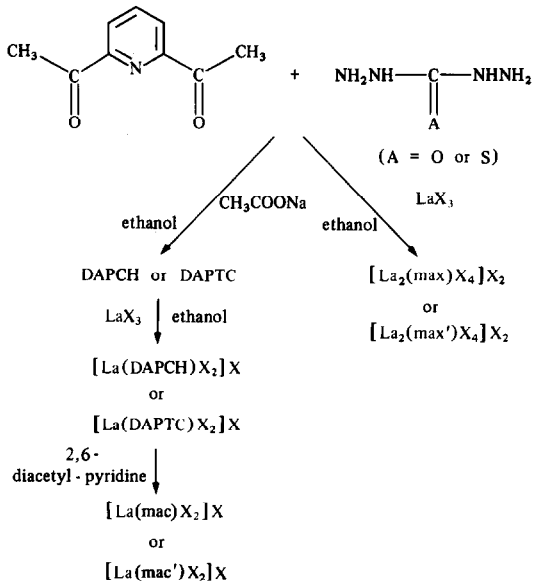
$$LaX_3 + DAPTC \rightarrow [La(DAPTC)X_2]X.$$

It appears that, in the above complexes, the two terminal amino groups remain uncoordinated and can take part in condensation reactions with diketones, and, therefore, the reactions of above complexes with 2,6-diacetylpyridine have been carried out which result in the formation of complexes with the following types of macrocyclic ligand:



A = O (mac) or S (mac')

However, if the reactions are carried out *in situ*, i.e. the metal salt, carbohydrazide or thiocarbohydrazide and 2,6-diacetylpyridine are mixed together in ethanol and refluxed, an entirely different binuclear product is obtained. The reaction is proposed as follows:



The metal to ligand stoichiometry of all these products has been established on the basis of elemental analysis (Table 1). The complexes have high melting points. The mononuclear lanthanum complexes behave as 1 : 1 electrolytes and binuclear complexes as 1 : 2 electrolytes in dimethylformamide. Since these cyclic products could not be isolated in the absence of metal ion, lanthanum(III) appear to act as a kinetic "template".

IR spectra of parent DAPCH or DAPTC complexes

These ligands show bands due to the pyridine ring, amine groups, hydrazine or azomethine groups, and amide groups (DAPCH) or thioamide groups (DAPTC).

The IR spectrum of the ligand DAPCH shows bands at 1675, 1500, 1260, 660 and 530 cm^{-1} which may be assigned[25,26] to amide-I [ν(C=O)], amide-II [ν(CN)+δ(NH)], amide-III [δ(NH)], amide-IV [ϕ(C=O)] and amide-VI [π(C=O)] vibrations, respectively. In the lanthanum complexes, all these bands except amide-I show upward shifts ($\sim$ 60–30 cm^{-1}), whereas amide-I band shows a downward shift ($\sim$ 35–20 cm^{-1}). These changes in amide group vibrations indicate that the amide oxygen (ketonic) takes part in coordination to the metal atom.[25] This has further been confirmed by the appearance of new bands at *ca* 490–70 cm^{-1} assignable[27] to ν(La—O). The IR spectrum of the ligand DAPTC shows bands at *ca* 1560, 1210, 1080 and 770 cm^{-1} which are assigned[28] to thioamide-I, -II, -III and -IV vibrations, respectively. The ligands containing an HN—C=S group can undergo thione $\rightleftharpoons$ thiol tautomerism. However, the appearance of four thioamide bands in DAPTC indicates the existence of the ligand in the thione form. The thioamide-IV band has been found to have a maximum ν(C=S) contribution.[28] In the lanthanum complexes, all these bands remain at the same position, indicating the non-coordination of the thioamide sulphur to the lanthanum atom.

Both the ligands show a weak band at *ca* 1640 cm^{-1} which can be assigned to the ν(C=N) vibration of the azomethine linkage. The appearance of a weak ν(C=N) band is in accord with the observations of several other workers.[29,30] The band due to ν(C=N) appears at slightly lower wavenumbers ($\sim$ 1625–1610 cm^{-1}) in the complexes, suggesting[29] that nitrogen atoms of the azomethines are coordinated to the lanthanum atom. The bands appearing in the 400–350 cm^{-1} region may be assigned[27] to ν(La—N) vibrations.

The pyridine ring vibrations most affected by pyridine nitrogen coordination to a metal atom are 8a (pyridine ring deformation), 6a (in-plane ring defor-

[a] DAPCH = 2,6-diacetylpyridine-bis(carbohydrazone), DAPTC = 2,6-diacetylpyridine-bis(thiocarbohydrazone), mac = macrocyclic ligand derived from DAPCH and 2,6-diacetylpyridine, mac' = macrocyclic ligand derived from DAPTC and 2,6-diacetylpyridine.

mation) and 16b (out-of-plane deformation).[31,32] These vibrations appear at *ca* 1580, 620 and 410 cm^{-1}, respectively, in the free ligands. In all the complexes, these bands show a shift to a higher energy ($\sim$ 30–10 cm^{-1}), indicating coordination of the pyridine nitrogen to the lanthanum atom.[30] The ν(La–Py) vibrations are located at *ca* 280–250 cm^{-1}.

The ligands also show a broad band at *ca* 3250 cm^{-1} along with two shoulders at *ca* 3300–3280 and 3230–3220 cm^{-1} which may be due to ν[sym(NH)] and ν[asym(NH)] vibrations. In the complexes, these bands persist, indicating non-coordination of the terminal amino groups to the metal atom.

IR spectra of macrocyclic products

The IR spectra of the macrocyclic complexes show few significant changes compared with the products. The $\nu(NH_2)$ bands disappear. Only one band is observed in the ν(NH) region at *ca* 3200 cm^{-1} which may be due to secondary amino group,

establishing the condensation of the primary amino group with 2,6-diacetylpyridine. This is further supported by the appearance of a very weak band at *ca* 1635 cm^{-1} in the $[La(mac)X_2]X$ or $[La(mac')X_2]X$ complexes, establishing the formation of an azomethine linkage. In the binuclear macrocyclic complexes, this band disappears, which may be taken as evidence of the coordination of the azomethine nitrogen to another metal atom. Further, the medium or weak bands appearing at *ca* 1570, 620, and 420 cm^{-1} in the $[La(mac)X_2]X$ or $[La(mac')X_2]X$ complexes may be due to[31] 8a, 6a and 16b vibrations of the non-coordinated pyridine moiety. In binuclear mactrocyclic complexes, these bands shift to a higher frequency and overlap with the coordinated pyridine ring vibrations of the first metal. As a result broad bands appear at *ca* 1590, 630 and 425 cm^{-1}. This confirms the coordination of the second pyridine nitrogen to another metal. The spectral features in conjunction with the intense colour of the complexes support the formation of macrocyclic ligand complexes. The intense colour originates from a high degree of conjugation present in macrocyclic systems.

In addition to the above bands, the nitrato complexes of lanthanum show bands at *ca* 1550–1535, 1270–1260 and 1040–1025 cm^{-1} due to $\nu[asym(NO_2)]$, $\nu[sym(NO_2)]$ and $\nu(NO)$, indicating the presence of coordinated nitrate groups in the complexes. In the chloro and bromo complexes, the bands appearing at *ca* 350–330 and 310–300 cm^{-1} may be assigned to ν(La—Cl) and ν(La—Br) vibrations, respectively.

EXPERIMENTAL

The ligands 2,6-diacetylpyridine-bis(carbohydrazone) (DAPCH) and 2,6-diacetylpyridine-bis(thiocarbohydrazone) (DAPTC) were prepared as reported in the literature.[33] Lanthanum salts were procured from B.D.H. Ltd.

Preparation of complexes of DAPCH and DAPTC, $[La(DAPCH)X_2]$ *and* $[La(DAPTC)X_2]X$ (X = Cl, Br *or* NO_3)

A general procedure was adopted to synthesize these complexes. The procedure involves the addition of the appropriate ligand (0.02 mol) to an aqueous ethanolic (60%) solution of the appropriate metal salt (0.02 mol). The mixture was refluxed for *ca* 6–8 h on a water bath. Light yellow or light brown masses which appeared immediately in the case of halo complexes, or on keeping the solution overnight in the case of nitrato complexes, were filtered, washed with ethanol and dried *in vacuo* at room temperature.

Preparation of mononuclear complexes of the macrocyclic ligand, $[La(mac)X_2]X$ *and* $[La(mac')X_2]X$ (*mac = macrocyclic ligand derived by condensation of DAPCH and 2,6-diacetylpyridine; mac' = macrocyclic ligand derived by condensation of DAPTC and 2,6-diacetylpyridine;* X = Cl, Br *or* NO_3)

A common procedure was followed to synthesize these complexes. 2,6-Diacetylpyridine dissolved in aqueous ethanol (60%) (0.02 mol in 50 cm^3) was added to the appropriate DAPCH or DAPTC complexes (0.02 mol) and refluxed for *ca* 18–20 h. The colour of the mixture was intensified and the precipitate obtained was filtered, washed with ethanol and hot water, and dried *in vacuo* at room temperature.

Preparation of binuclear complexes of the macrocyclic ligand, $[La_2(mac)X_4]X_2$ and $[La_2(mac')X_4]X_2$ (X = Cl, Br *or* NO_3)

A general procedure adopted to synthesize these complexes involved the addition of an excess of the appropriate metal salt to an aqueous ethanolic solution of 2,6-diacetylpyridine (0.01 mol) and carbohydrazide or thiocarbohydrazide (0.01 mol). The solution was refluxed for *ca* 20–24 h, when dark yellow, brown or orange coloured precipitates appeared which were filtered, washed thoroughly with ethanol and dried *in vacuo* at room temperature.

Microanalyses for carbon and hydrogen were performed by the C.D.R.I., Lucknow, and by the Department of Chemistry, B.H.U., Varanasi. Nitrogen was estimated by Kjeldahl's method, sulphur as $BaSO_4$, and chloride and bromide as their silver salts. Lanthanum was estimated gravimetrically as its oxide.

The details of physical measurements are the same as described earlier.[34]

(*Received* 20 *June* 1986; *accepted* 16 *September* 1986)

Abstract—Reaction of pentacarbonyl iron(0) with 1,2-quinone mono-oximes (qoH) gives the $Fe(qo)_2$ complexes as the main products together with various organic products. In the presence of aniline the main products are again the complexes $Fe(qo)_2$ which are accompanied by the formation of organic products and complexes of type $Fe(qo\text{-}A)_2$ where qo-A is a species arising from the coupling of the qo ligand with aniline. The formation of the latter type of complex and of the organic products is rationalized in terms of deoxygenation of the qo ligand. The complexes $Fe(qo)_2$ and $Fe(qo\text{-}A)_2$ have oligomeric structures as indicated by their magnetic properties and Mössbauer spectra. Both these types of complex react with pyridine to give dipyridine adducts.

Reactions of pentacarbonyl iron(0) with oximino, nitro and nitroso compounds have been described in several publications.[1–12] Nitro and nitroso compounds undergo deoxygenation to give products whose nature is generally accounted for in terms of nitrene intermediates.[5–9] For oximino compounds both deoxygenation and deoximation behaviour has been reported.[6,12] A number of reactions have been reported in which pentacarbonyl iron(0) reacts with a chelating ligand to give rise to an iron(II) complex,[13–20] e.g. the reaction of acetylacetone gives rise to bis(acetylacetonato)iron(II).[13] Hence, reaction of pentacarbonyl iron(0) with 1,2-quinone mono-oximes could also give rise to chelates in addition to products arising from reactions such as those indicated above involving the oxime group.

In this paper we report on the reactions of pentacarbonyl iron(0) with 1,2-naphthoquinone-2-oxime (**1a**), 1,2-naphthoquinone-1-oxime (**1b**) and 5-methoxy-1,2-quinone-2-oxime (**1c**). We also report on the interaction of **1a** and **1b** with pentacarbonyl iron(0) in the presence of aniline and on the interaction of pentacarbonyl iron(0) with the iron(III) complexes, $Fe(qo)_3$(qoH = **1a–1c**).

Interaction of pentacarbonyl iron(0) with the quinoneoximes (**1a–1c**) in refluxing tetrahydrofuran gave, in each case, the corresponding iron(II) 1,2-quinone mono-oximato complex, $Fe(qo)_2$ (**2**), as the main product and a mixture of small amounts of organic products (Scheme 1). The organic products isolated from the reaction of **1a** included 2-amino-N^4(1-hydroxy-2-naphthyl)-1,4-naphthoquinone 4-imine and 5-hydroxy-dibenzo[b,i]phenazin-12(6*H*)-one. For the reaction involving **1c** the predominant

* Author to whom correspondence should be addressed.

organic product was 2-amino-7-methoxy-3*H*-phenoxazin-3-one. The complexity of the mixture of organic products arising from 1*b* hindered characterization.

In the presence of aniline **1a** and **1b** again reacted with pentacarbonyl iron(0) to give the $Fe(qo)_2$ complex as the main product. In addition, iron(II) complexes of type $Fe(qo\text{-}A)_2$ (**3** and **4**), where qo-A is a species arising from the coupling of the qo ligand with aniline and various organic products, were formed. The predominant organic product isolated from both of these systems was 2-phenylamino-N^4-phenyl-1,4-naphthoquinone-4-imine. Other products isolated from the reaction involving **1a** were 2-amino-N^4-phenyl-1,4-naphthoquinone 4-imine, N^4-phenylamino-1,2-naphthoquinone and

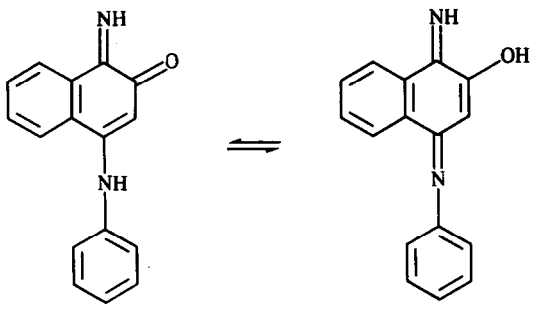
5a **5b** **6**



7a **7b**

5-hydroxy-dibenzo-[b,i]phenazin-12(6*H*)-one. For the system involving **1b**, N^4-phenylamino-1,2-naphthoquinone was also isolated. The nature of the ligands in the Fe(qo-A)$_2$ complexes **3** and **4** was established by isolating and characterizing the organic products formed from the reaction of the complexes with aqueous hydrochloric acid. In the case of the complex **3** the acidolysis led to the protonated ligand **5a**, which exists mainly as the amino tautomer **5b**. In contrast, acidolysis of complex **4** led to the quinone **6**. Similar behaviour was observed earlier for the analogous copper(II) complex which was obtained from the reaction of aniline with Cu(qo)$_2$ (qoH = **1b**).[21]

The iron(III) complexes Fe(qo)$_3$ (qoH = **1a–1c**) reacted readily with pentacarbonyl iron(0) in refluxing tetrahydrofuran to give the respective Fe(qo)$_2$ complexes in quantitative yield. No organic products were formed in these reactions.

The Fe(qo)$_2$ complexes obtained from the above reactions are oligomeric, as indicated by their magnetic properties and Mössbauer spectra, and as suggested previously for such complexes obtained by other routes.[22] By analogy, oligomeric structures (Fig. 1) are also suggested for the Fe(qo-A)$_2$ complexes. These compounds exhibit two doublets in their Mössbauer spectra and the values of their room-temperature magnetic moments (*ca* 3 BM) (Table 1) are in accord with the presence of both high-spin five-coordinate and low-spin six-coordinate iron atoms. The pyridine adducts of the Fe(qo-A)$_2$ complexes are six-coordinate diamagnetic species which lose pyridine at 160°C/0.3 mmHg to give the respective bischelates.

The formation of the complexes Fe(qo)$_2$ as the major products from the reactions between pentacarbonyl iron(0) and the quinoneoximes probably reflects their high insolubility in tetrahydrofuran and organic solvents in general. The organic products obtained from these reactions parallel closely those arising from reactions of the copper(II) complexes of these quinone oximes with aniline[21] or triphenylphosphine.[23] They can be accounted for in terms of deoxygenation of the protonated ligands to give the quinoneimine/nitrene **8** followed by hydrogen abstraction and/or coupling reactions. Their formation through deoxygenation of the chelated anionic ligands is unlikely, as suggested by the absence of any organic products in the reactions between the complexes Fe(qo)$_3$ and pentacarbonyl iron(0), and by the inertness of the Fe(qo)$_2$ complexes towards pentacarbonyl iron(0). When aniline is involved, products arising from coupling reactions of the quinoneimine/nitrene with aniline are also obtained. The formation of 2-phenylamino-N^4-phenyl-1,4-naphthoquinone-4-imine from both the reaction involving **1a** and that involving **1b** probably arises as a result of interaction of aniline with N^4-phenylamino-1,2-naphthoquinone.

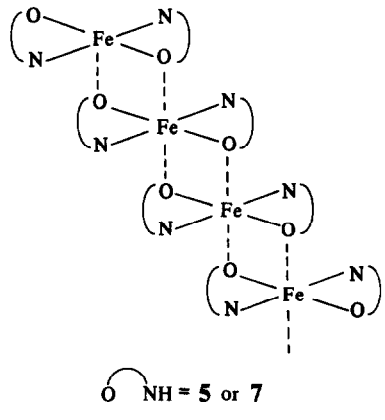


Fig. 1.

Table 1. Mössbauer parameters and room-temperature magnetic moments of iron(II) complexes derived from the mono-oximes of 1,2-naphthoquinone[a]

Complex	Δ (mm s^{-1})	δ(Fe) (mm s^{-1})	μ_{eff} (BM)
Fe(1-nqo)$_2$·2py	0.92	0.19	0.50
Fe(2-nqo)$_2$·2py	0.88	0.20	0.60
Fe(1-nqo)$_2$	0.79	0.08	3.08
	4.00	1.22	
Fe(2-nqo)$_2$	0.71	0.05	3.04
	3.99	1.22	
Fe(1-qo-A)$_2$ (**4**)	0.88	0.12	3.12
	3.27	0.47	
Fe(2-qo-A)$_2$ (**3**)	0.77	0.08	3.13
	3.40	0.92	

[a] All spectra were recorded at room temperature. No significant differences were observed when recording spectra at liquid-nitrogen temperature (77 K).

EXPERIMENTAL

Magnetic-susceptibility data, and also IR, NMR, electronic and Mössbauer spectra, were obtained as described earlier.[21,22]

Reaction between pentacarbonyl iron(0) *and* 1,2-*naphthoquinone*-1-*oxime*

Pentacarbonyl iron(0) (2.0 g, 10.2 mmol) and the mono-oxime (5.2 g, 30.0 mmol) were heated under reflux in dry tetrahydrofuran (50 cm^3) under nitrogen for 24 h. The mixture was filtered and the residue washed with tetrahydrofuran (2 × 10 cm^3) and dried at 100°C/0.1 mmHg to give green bis(1,2-naphthoquinone-1-oximato)iron(II) (2.56 g, 64%) (Found: C, 59.6; H, 3.2; Fe, 13.8; N, 6.9. Calc. for $C_{20}H_{12}FeN_2O_4$: C, 60.0; H, 3.0; Fe, 14.0; N, 7.0%).

Reaction between pentacarbonyl iron(0) *and* 1,2-*naphthoquinone*-2-*oxime*

Similarly, pentacarbonyl iron(0) (2.0 g, 10.2 mmol) and 1,2-naphthoquinone-2-oxime (5.2 g, 30.0 mmol) gave green bis(1,2-naphthoquinone-2-oximato)iron(II) (3.28 g, 82%) (Found: C, 59.8; H, 3.1; Fe, 13.9; N, 6.9. Calc. for $C_{20}H_{12}FeN_2O_4$: C, 60.0; H, 3.0; Fe, 14.0; N, 7.0%). The combined filtrate and washings were evaporated under reduced pressure to give a brown oil which was chromatographed on silica gel. Toluene eluted unreacted 1,2-naphthoquinone-2-oxime (0.42 g, 8% recovery) followed by 5-hydroxy-dibenzo[b,i]-phenazin-12(6*H*)-one (0.19 g, 4%), m.p. 280–283°C (decomp), *m/z* 312 (M^+) (identical TLC and IR to an authentic sample[21]). Toluene–ethyl acetate (1 : 1) eluted 2-amino-N^4-)1-hydroxy-2-naphthyl)-1,4-naphthoquinone 4-imine (0.28 g, 68%) m.p. 274–276°C, *m/z* 314 (M^+) (identical TLC and IR to an authentic sample[23]).

Reaction between pentacarbonyl iron(0) *and* 5-*methoxy*-1,2-*quinone*-2-*oxime*

Similarly, pentacarbonyl iron(0) (2.0 g, 10.2 mmol) and the mono-oxime 5-methoxy-1,2-quinone-2-oxime (4.6 g, 30.0 mmol) gave green bis(5-methoxy-1,2-quinone-2-oximato)iron(II) (1.8 g, 50%) (Found: C, 46.4; H, 3.6; Fe, 15.2; N, 7.3. Calc. for $C_{14}H_{12}FeN_2O_6$: C, 46.6; H, 3.8; Fe, 15.5; N, 7.6%). The combined filtrate and washings were evaporated under reduced pressure to give a brown oil which was chromarographed on silica gel. Toluene eluted 2-amino-7-methoxy-3*H*-phenoxazin-3-one (0.91 g, 25%) (identical TLC and IR to an authentic sample[23]).

Reaction between pentacarbonyl iron(0) *and* 1,2-*naphthoquinone*-1-*oxime in the presence of aniline*

Pentacarbonyl iron(0) (2.0 g, 10.2 mmol) and the mono-oxime (5.0 g, 29.0 mmol) were heated under reflux with aniline (4.4 g, 47.0 mmol) in dry tetrahydrofuran (100 cm^3) under nitrogen for 24 h. The mixture was stirred at ambient temperature for a further 16 h and filtered to give a green solid (2.7 g) which was stirred in pyridine for 72 h and chromatographed on silica gel. Light petrol (b.p. 30–40°C)–toluene (1 : 1) eluted 2-phenylamino-N^4-phenyl-1,4-naphthoquinone-4-imine (0.66 g, 7%); (Found: C, 81.5; H, 5.0; N, 8.6. $C_{22}H_{16}N_2O$ requires: C, 81.5; H, 4.9; N, 8.6%); ν_{max}(KBr) 1660 (C═O), and 3360 (N—H) cm^{-1}; δ[$(CD_3)_2So$] 181.8 (1C, CO), 6.6 (1H, s), and 6.7–8.7 (15H, br, m); *m/z* 324 (M^+). Toluene–ethyl acetate (3 : 1) eluted bis(1,2-naphthoquinone-1-oximato)dipyridineiron(II) (1.86 g, 33%) (Found: C, 63.8; H, 3.9; Fe, 9.9; N, 10.0. Calc. for $C_{30}H_{22}FeN_4O_4$: C, 64.5; H, 3.9; Fe, 10.0; N, 10.0%). Ethyl acetate eluted bis(4-phenylamino-1-imino-1,2-naphthoquinone)dipyridineiron(II) (1.08 g, 15%) (Found: C, 71.5; H, 4.0; Fe, 7.5; N, 11.7. $C_{42}H_{32}FeN_6O_2$ requires: C, 71.2; H, 4.5; Fe, 7.9; N, 11.9%.) Evaporation of the filtrate under reduced pressure gave a brown tar (8.0 g) which was chromatographed on silica gel. Light petrol (b.p. 30–40°C)–toluene (1 : 1) eluted 2-phenylamino-N^4-phenyl-1,4-naphthoquinone–4–imine (1.66 g, 18%) (identified by TLC). Toluene eluted N^4-phenylamino-1,2-naphthoquinone (0.53 g, 7.3%), m.p. 257–259°C (lit. 254–256°C[24]) (Found: C, 77.9; H, 3.9; N, 6.0. Calc for $C_{16}H_{11}NO_2$: C, 77.1; H, 4.4; N, 5.6%); *m/z* 249 (M^+).

Pyrolysis of bis(4-*phenylamino*-1-*imino*-1,2-*naphthoquinone*)*dipyridine iron*(II)

This bis(pyridine) iron(II) complex (1.0 g) was heated at 160°C and 0.3 mmHg for 1 h. The residue was green *bis*(4-*phenylamino*-1-*imino*-1,2-*naphthoquinone*)*iron*(II) (0.79 g) (Found: C, 69.4; H, 3.9; Fe, 10.1; N, 10.5. $C_{32}H_{22}FeN_4O_2$ requires: C, 69.8; H, 3.9; Fe, 10.2; N, 10.2%). The distillate, collected in a trap cooled in a solid carbon dioxide–ethanol bath, was shown to be pyridine (IR).

Reaction between bis(4-*phenylamino*-1-*imino*-1,2-*naphthoquinone*)*iron*(II) *and hydrochloric acid*

The bis(pyridine) iron(II) complex (0.2 g) was shaken with aqueous hydrochloric acid (15%, 50 cm^3) for 10 min. After neutralisation ($NaHCO_3$) chloroform was added and the mixture shaken for 5 min. The chloroform layer was separated from the

aqueous layer, which was then further extracted with chloroform. The combined chloroform extracts were dried ($MgSO_4$), filtered and evaporated under reduced pressure to give N^4-phenylamino-1,2-naphthoquinone (0.16 g, 90%) (identified by TLC).

Reaction between pentacarbonyl iron(0) and 1,2-naphthoquinone-2-oxime in the presence of aniline

Pentacarbonyl iron(0) (2.0 g, 10.2 mmol) and the mono-oxime (5.3 g, 31.0 mmol) were heated under reflux with aniline (4.6 g, 49.0 mmol) in dry tetrahydrofuran (100 cm^3) under nitrogen for 24 h. The mixture was stirred at ambient temperature for a further 16 h and filtered to give a green solid (2.3 g), which was stirred in pyridine for 72 h and chromatographed on silica gel. Light petrol (b.p. 30–40°C)–toluene (1 : 1) eluted 2-phenylamino-N^4-phenyl-1,4-naphthoquinone-4-imine (0.17 g, 2%) (identified by TLC). Toluene–ethyl acetate (3 : 1) eluted bis(1,2-naphthoquinone-2-oximato)dipyridine iron(II) (2.96 g, 52%) (Found: C, 65.1; H, 4.5; Fe, 10.6; N, 9.6. Calc. for $C_{30}H_{22}FeN_4O_4$: C, 64.5; H, 3.9; Fe, 10.0; N, 10.0%). Ethyl acetate eluted *bis(4-phenylamino-2-imino-1,2-naphthoquinone)dipyridineiron*(II) (0.48 g, 7%) (Found: C, 70.5; H, 4.1; Fe, 8.2; N, 12.2. $C_{42}H_{32}FeN_6O_2$ requires: C, 71.2; H, 4.5; Fe, 7.9; N, 11.9%). Evaporation of the filtrate under reduced pressure gave a brown tar (9.8 g) which was chromatographed on silica gel. Light petrol (b.p. 30–40°C)–toluene (1 : 1) eluted 2-phenylamino-N^4-phenyl-1,4-naphthoquinone-4-imine (2.7 g, 27%); identified by TLC, Ir and NMR) Toluene eluted 2-amino-N^4-phenyl-1,4-naphthoquinone-4-imine (1.1 g, 14.0%) (Found: C, 77.3; H, 4.1; N, 11.5. Calc. for $C_{16}H_{12}N_2O$: C, 77.4; H, 4.8; N, 11.3%); ν_{max}(KBr) 3495, 3380, 1660, 1620 and 1600 cm^{-1}; λ_{max}($CHCl_3$) 247 nm (log ε 4.25), 299 nm (log ε 4.06), 345 nm (log ε 3.72), and 445 nm (log ε 3.70); *m/z* 248 (M^+); followed by N^4-phenylamino-1,2-naphthoquinone (0.23 g, 3%); m.p. 256–259°C (lit. 254–256°C[24]) (identical by comparison with the sample isolated above; TLC and IR). Toluene–ethyl acetate (3 : 1) eluted 5-hydroxy-dibenzo[b,i]-phenazin-12(6*H*)-one (0.18 g, 4%) (identical TLC and IR to an authentic sample[21]).

Pyrolysis of bis(4-phenylamino-2-imino-1,2-naphthoquinone)dipyridine iron(II)

The bis(pyridine) iron(II) complex (1.0 g) was heated at 160°C/0.3 mmHg for 1 h. The residue was green *bis(4-phenylamino-2-imino-1,2-naphthoquinone)iron*(II) (0.8 g) (Found: C, 69.3; H, 3.8; Fe, 10.3; N, 9.8. $C_{32}H_{22}FeN_4O_2$ requires: C, 69.8; H, 4.0; Fe, 10.2; N, 10.2%). The distillate, collected in a trap cooled in a solid carbon dioxide–ethanol bath, was shown to be pyridine (IR).

Reaction between bis(4-phenylamino-2-imino-1,2-naphthoquinone)iron(II) *and hydrochloric acid*

The bis iron(II) complex (0.2 g) was shaken with aqueous hydrochloric acid (15%, 50 cm^3) for 10 min. After neutralization ($NaHCO_3$) chloroform was added and the mixture shaken for 5 min. The chloroform layer was separated from the aqueous layer, which was then further extracted with chloroform. The combined chloroform extracts were dried ($MgSO_4$), filterd and evaporated under reduced pressure to give 2-amino-N^4-phenyl-1,4-naphthoquinone-4-imine (0.12 g, 67%) (identified by TLC).

Reaction of pentacarbonyl iron(0) with tris(1,2-quinone mono-oximato)iron(III)

Pentacarbonyl iron(0) (*ca* 1.0 g, 1 mol. equiv.) and tris(1,2-quinone mono-oximato(iron)(III) [fe(qo)$_3$; qoH = **1a**, **b** or **c**] (1 mol. equiv.) were heated under reflux in dry tetrahydrofuran (50 cm^3) under nitrogen for 24 h. Bis(1,2-quinone mono-oximato)iron(II) was filtered off, washed with tetrahydrofuran (2 × 10 cm^3) and dried at 100°C/0.1 mmHg.

Product	% yield	Found (%) C	H	Fe	N
2a	98	59.5	3.2	13.9	6.9
2b	97	59.8	3.2	14.1	6.8

(*Received* 20 *June* 1986 ; *accepted* 16 *September* 1986)

Abstract—Polymeric complexes of the type Cu(X-dnr)·H_2O (X-dnrH_2 = 2,4 - dinitrosoresorcinol and 4 - ethyl -, 4 - chloro- or 5 - methyldinitrosoresorcinol) have been prepared by nitrosation of resorcinol, 4-ethylresorcinol, 4-chlororesorcinol and 5-methylresorcinol with sodium nitrite–acetic acid in the presence of copper(II) chloride. Nitrosation of 2 - methylresorcinol gives Cu(2 - Memnr)$_2$·$4H_2O$ (2 - MemnrH = 2 - methyl - 4 - nitrosorcinol). Reaction of the complexes Cu(X-dnr)·H_2O (X = H, 6-Et or 6-Cl) with hot pyridine gives the respective Cu(X-dnr)·py complexes. Magnetic-susceptibility studies indicate antiferromagnetic interaction through the X-dnr^{2-} ligand in the complexes Cu(X-dnr)·L (L = H_2O or py) and association of Cu(2-Memnr)$_2$ units in the complex Cu(2-Memnr)$_2$·$4H_2O$.

Metal complexes of 1,2 - quinonemono - oximes (2 - nitrosophenols) have synthetic, analytical and other uses.[1–3] We have previously reported that polymeric complexes of the type Ni(X-dnr)·$2H_2O$ where X-dnrH_2 (**1**) is 2,4 - dinitrosoresorcinol, 6 - ethyl - 2,4 - dinitrosoresorcinol or 5 - methyl - 2,4 - dinitrosoresorcinol are obtained by nitrosation of resorcinol, 4 - ethylresorcinol and 5 - methylresorcinol, respectively, in the presence of nickel chloride.[4] In contrast nitrosation of 2 - methylresorcinol in the presence of nickel chloride gives a bischelated complex derived from the mononitrosated resorcinol **2**.[4] In this paper we describe the preparation, characterization and magnetic properties of analogous copper(II) complexes.

EXPERIMENTAL

Elemental analyses were carried out by the microanalytical laboratory of the Polytechnic of North London. Copper was determined by atomic absorption with a Pye–Unicam SP9 spectrophotometer, after decomposing the complexes with concentrated sulphuric acid and hydrogen peroxide. IR spectra, magnetic susceptibilities and thermal gravimetric data were obtained as described earlier.[5] Magnetic moments were corrected for the diamagnetic effect of the ligands.[6]

Preparation of the complexes Cu(X-dnr)·H_2O (X = H, 6-Et, 6-Cl *or* 5-Me) *and* Cu(2-Memnr)$_2$·$4H_2O$ *by nitrosation of resorcinols*

The resorcinol (0.05 mol) in ethanol (100 cm^3) was added to a solution of copper(II) chloride dihydrate (8.5 g, 0.05 mol), acetic acid (20 cm^3) and sodium acetate (20 g) in water (120 cm^3). Sodium

nitrite (10 g) in water (60 cm^3) was added with stirring. The resulting mixture was stirred at 20°C for 1 week and then the *product* was filtered off, washed thoroughly by stirring with water (3 × 100 cm^3) and ethanol (3 × 100 cm^3) for several hours and dried at 50°C/0.1 mm (see Table 1 for analysis and other data).

Interaction of the complexes Cu(X - dnr) · H_2O (X = H, 6-Et *or* 6-Cl) *with pyridine*

The hydrated complex (*ca* 3 g) was heated under reflux in pyridine (100 cm^3) for 1 h. The reaction mixture was filtered hot, the filtrate was evaporated to dryness at 60°C/0.1 mm and the resultant residue of the *pyridine adduct* was washed with ethanol and ether, and dried at 50°C/0.1 mm.

RESULTS AND DISCUSSION

Bottei and McEachern[7] have reported that the interaction of copper sulphate pentahydrate with 2,4 - dinitrosoresorcinol in aqueous ethanol gave a polymeric product which they formulated as Cu(dnr). In contrast, Hunter and Webb[8] formulated the product of a similar reaction in methanol as [Cu(dnrH)$_2$(H_2O)$_2$] · $2H_2O$. We have obtained a polymeric complex of formula Cu(dnr) · H_2O by nitrosation of resorcinol in the presence of copper chloride. The analogous complexes Cu(5 - Mednr) · H_2O, Cu(6 - Etdnr) · H_2O and Cu(6 - Cldnr) · H_2O have been obtained similarly by nitrosation of 5 - methylresorcinol, 4 - ethylresorcinol and 4 - chlororesorcinol, respectively. Nitrosation of 2-methylresorcinol in the presence of copper(II) chloride, leads to mononitrosation and formation of the complex Cu(2 - Memnr)$_2$ · $4H_2O$. The formulation of the complexes was established by elemental analysis and IR spectroscopy. The position of nitrosation has been established as described previously.[4]

The complexes Cu(X - dnr) · H_2O (X = H, 6-Et, 6-Cl or 5-Me) were insoluble in ethanol, acetone, chloroform and diethyl ether, but dissolved in refluxing pyridine to give 1 : 1 adducts as shown by the isolation and characterization of the pyridine

adducts when X = H, 6-Et or 6-Cl. Thermal gravimetric analysis (Table 2) on all the hydrates showed that water was lost quantitatively between 100 and 150°C to give Cu(X-dnr) which decomposed between 160 and 190°C.

Magnetic susceptibilities for the complexes Cu(X - dnr)·H_2O (X = H, 6-Et, 6-Cl or 5-Me) and Cu(X-dnr)py (X = H, 6-Et or 6-Cl) were measured at room temperature and the calculated magnetic moments are given in Table 1. The magnetic moments at room temperature for both the hydrates and the pyridine adducts of Cu(X-dnr) studied fall in a range (1.0–1.6 BM) which is well below the limits expected for magnetically dilute copper(II) complexes. Generally, copper complexes have moments in the range 1.8–2.1 BM, independent of the co-ordination number.[6] A deviation from simple paramagnetic behaviour therefore is indicated for these copper complexes. A variable-temperature study of magnetic moments was carried out on Cu(6 - Cldnr) · py. The decreasing magnetic moment with temperature (Table 3) and the negative Weiss constant observed for the complex suggests antiferromagnetic behaviour. This may arise either through the bridging X-dnr^{2-} ligand or through association involving copper atoms in different chains of the polymer (**3**). The latter possibility is less likely because: (i) antiferromagnetic behaviour is also shown by the corresponding six-coordinate nickel(II) complexes Ni(X - dnr)·$2H_2O$ which have X-dnr bridges, and (ii) the pyridine adducts of analogous copper(II) complexes of 2-nitrosophenols are known to exhibit five-co-ordination.[5,9]

The relatively low magnetic moment of Cu(2-Memnr)$_2$·$4H_2O$ would suggest some association between Cu(2-Memnr)$_2$ units as found in related nickel complexes.[10]

and

A. LYČKA

Research Institute of Organic Syntheses, 532 18 Pardubice-Rybitví, Czechoslovakia

(*Received* 26 *March* 1985; *accepted* 25 *September* 1986)

Abstract—The temperature and concentration dependences of ^{119}Sn chemical shifts of triorganotin(IV) chlorides [R_3SnCl (R = *n*-butyl, benzyl or phenyl)] in deuteriochloroform and three coordinating solvents [S (S = pyridine, dimethyl sulphoxide or hexamethylphosphortriamide)] have been studied. The values of ^{119}Sn chemical shifts of the complexes $R_3SnCl.S$ formed have been determined from the temperature dependence, and the values of the thermodynamic parameters K_x, ΔG, ΔH and ΔS of these complexes have been calculated. The stability of complexes increases in the R-substituent series: *n*-butyl < benzyl < phenyl, and in the solvent series: pyridine < dimethyl sulphoxide < hexamethylphosphortriamide.

For the description of the equilibrium of formation of triorganotin(IV) complexes in solutions of coordinating solvents, which occurs only when the molar ratio of the components is 1:1, the simple equation[1] based on the knowledge of the concentration dependence of the chemical shift $\delta(^{119}Sn)$ was derived. The $\delta(^{119}Sn)$ of pure components of the equilibrium system, necessary for the calculation of the equilibrium constant, are obtained as limiting values by the extrapolation of this concentration dependence. In some systems it is difficult to implement such an extrapolation, because experimental data are limited to a narrow concentration range due to the specific physical properties of the system. In this paper we report on the $R_3SnCl(S)$ systems, where R is *n*-butyl (Bu), phenyl (Ph) or benzyl (Bz), and (S) is pyridine (py), dimethyl sulphoxide (dmso) or hexamethylphosphortriamide (hmpa), respectively, so that in such cases the necessary data can be obtained from the temperature dependences of the $\delta(^{119}Sn)$ parameter.

EXPERIMENTAL

Tri-*n*-butyl-, tribenzyl- and triphenyltin(IV) chlorides were prepared by known methods.[2,3] The ^{119}Sn NMR spectra were measured on a JNM-FX 100 spectrometer (JEOL, Japan) at 37.14 MHz. The ^{119}Sn chemical shifts were measured at $\pm$0.1-ppm digital resolution at various temperatures, and referred to external neat tetramethylstannane. The positive $\delta(^{119}Sn)$ values denote downfield shifts. An external ^{2}H lock was used in the measurements using py, dmso and hmpa. The temperature was measured with an accuracy of $\pm$1 K.

RESULTS AND DISCUSSION

Due to the limited sensitivity of the experimental equipment and the physical properties of the $R_3SnCl(S)$ system (R = Bu, Ph or Bz) studied the $\delta(^{119}Sn)$ values can be determined in the concentration region x (mole fraction) of the order of $\sim 10^{-2}$ and in the temperature regions 240–320 K with S = $CDCl_3$, 300–360 K (S = dmso or hmpa)

* Author to whom correspondence should be addressed.

and 240–300 K (S = py). The changes in $\delta(^{119}Sn)$ in the studied concentration range are very small (1–3 ppm) and therefore it is not possible to extrapolate to infinite dilution. The temperature dependences of $\delta(^{119}Sn)$ for all the studied triorganotin(IV) chlorides in $CDCl_3$ solution are also small, but in the coordination solvents they are sufficiently high, and in the temperature region studied the observed changes in $\delta(^{119}Sn)$ are ~60–100 ppm. This is manifested in Fig. 1 where the temperature dependences of $\delta(^{119}Sn)$ are shown for the $Bz_3SnCl(py)$ system with two concentrations ($x = 1.35 \times 10^{-2}$ and 5.11×10^{-2}, respectively) and for the $Bz_3SnCl(CDCl_3)$ system with $x = 2.12 \times 10^{-2}$.

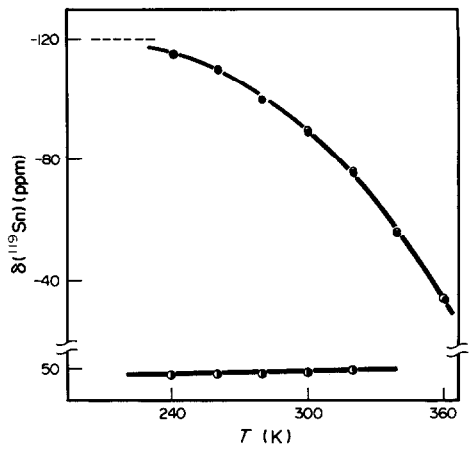

Fig. 1. Temperature dependence of ^{119}Sn chemical shifts of tribenzyltin(IV) chloride in pyridine (py) and $CDCl_3$. Concentration (mole fraction): (○) 1.35×10^{-2} (py), (●) 5.11×10^{-2} (py), (◑) 2.12×10^{-2} ($CDCl_3$).

The equilibrium constants (K_x) of the complex formation according to the reaction:

$$R_3SnCl + S \rightleftharpoons R_3SnCl(S)$$

were calculated from the original Hunter and Reeves equation[1] transferred to the form:

$$K_x = \frac{(\delta_o - \delta_A)[(\delta_{AB} - \delta_A) - x(\delta_o - \delta_A)]}{(\delta_{AB} - \delta_o)[(1-x)(\delta_{AB} - \delta_A) - x(\delta_o - \delta_A)]}$$

where x is the concentration of R_3SnCl (mole fraction), δ_o is the observed $\delta(^{119}Sn)$, and δ_A and δ_{AB} are the $\delta(^{119}Sn)$ of components R_3SnCl and $R_3SnCl(S)$, respectively.

For the $\delta(^{119}Sn)$ of the pure R_3SnCl component the value of $\delta(^{119}Sn)$ measured in a $CDCl_3$ solution was used. The $\delta(^{119}Sn)$ of the complex $R_3SnCl(S)$ was obtained by the optimalizing process for the parameter δ_{AB} supposing the linear dependence of $\ln K_x$ on T^{-1}, resp. ΔG on T. This presumption is consistent with the complex formation $R_3SnCl(S)$ with a component ratio of 1 : 1 and was justified in Ref. 4. Using a simple computer program, the selected values of $\delta(^{119}Sn)$ for complexes $R_3SnCl(S)$ (with a 0.5-ppm step) were gradually introduced into the expression for the equilibrium constant with the aim of finding the best correlation coefficient (r) of the linear regression of the function $\ln K \sim T^{-1}$. The values of r for the optimum linear regressions for the systems studied varied within the limits 0.985–0.999. The optimum values of $\delta(^{119}Sn)$ for the correlation of the individual systems are taken as the values for $R_3SnCl(S)$ complexes. The calculated values of K_x and the other thermodynamic quantities of the systems under study are given in Table 1.

The values obtained in this way correspond well with those obtained by another method.[5,6] The value of $\Delta H = -41.0$ kJ mol^{-1} obtained by Graddon and Rana[5] for the $Ph_3SnCl(py)$ system seems to be very high, which could be caused by an incorrect method used for its determination. The value of -33 kJ mol^{-1} for the heat of mixing for the $Ph_3SnCl(py)$ system[6] is clearly distorted by the heat of crystallization.

From our measurements we can conclude that in the studied group of complexes their stability increases (in agreement with K_x and/or ΔG values)

Table 1. Thermodynamic data for formation of $R_3SnCl(S)$ complexes at 300 K

System	K_x	$-\Delta G$ (kJ mol^{-1})	$-\Delta H$ (kJ mol^{-1})	$-\Delta S$ (J mol^{-1} K^{-1})
Bu_3SnCl–py	4.1±0.3	3.5±0.2	18.0±0.7	49±2
Bu_3SnCl–dmso	20.4±1.0	7.5±0.1	18.8±0.2	38±1
Bu_3SnCl–hmpa	25.2±2.2	8.0±0.2	14.5±0.1	21±1
Bz_3SnCl–py	4.7±0.0	3.9±0.0	20.1±0.6	54±2
Bz_3SnCl–dmso	23.8±0.7	7.9±0.1	18.1±0.1	34±1
Bz_3SnCl–hmpa	35.6±0.1	8.9±0.0	19.0±0.2	33±1
Ph_3SnCl–py	10.9±0.0	6.0±0.0	18.6±0.8	43±3
Ph_3SnCl–dmso	35.5±2.0	8.9±0.1	14.9±0.6	20±2
Ph_3SnCl–hmpa	176.1	12.9	21.9±0.3	30±1

in the series of substituents Bu < Bz < Ph, and in the series of coordinating solvents py < dmso < hmpa. Therefore, the most stable complexes are formed in systems with Ph_3SnCl and hmpa. The conversion into the complex is almost complete in this case.

THE PACKING SATURATION RULE AND THE PACKING CENTRE RULE: STRUCTURAL CHARACTERISTICS IN LANTHANIDE COORDINATION COMPOUNDS

FENG XI-ZHANG, GUO AO-LING, XU YING-TING, LI XING-FU*

Application Department, The Institute of High Energy Physics, Beijing, P.O. Box 2732, China

and

(*Received* 16 *October* 1985; *accepted after revision* 25 *September* 1986)

Abstract—The concepts of the Cone Packing Model, namely the Solid Angle Factor (SAF), Fan Angle (FA), Coordination Vector ($\mathbf{r}$), Gap and Hole have been introduced to describe steric packing around the metal centre. In a treatment of more than 160 structures of lanthanide coordination compounds, it was found that the sums of the ligand SAFs (SAS) are mainly in the region SAS = 0.78, $\sigma = 0.05$. This result provides concrete evidence that "coordination saturation" in the lanthanide compounds is actually saturation in the coordination space. The Packing Centre Rule has shown for the first time that the vector sum of the ligand SAFs, i.e. $\Sigma \mathrm{SAF} \cdot \mathbf{r}$, of each structure closely approaches zero with an average $\Sigma \mathrm{SAF} \cdot \mathbf{r}$ of 0.02 and a standard deviation of 0.015. The Packing Centre Rule indicates that there is a clear tendency for the ligands to distribute themselves so that the non-bonding repulsions are at a minimum.

Two major problems remain unclarified in lanthanide and actinide chemistry. Firstly, although "coordination saturation" is a well-accepted concept in coordination and organometallic chemistry and is extensively used as a criterion for the thermal stability and chemical reactivity of *d*-transition metal compounds, the concept is not clearly defined for the *f*-group analogues. There are two plausible arguments, of which the first refers to saturation in the valence orbital shell of the metal ion. Coordination saturation is achieved if the electron count reaches a certain limit (the electron configuration attains the "next inert gas" configuration, e.g. the 18- or 16-electron rules). Another argument is based on the occupation of the coordination space by the ligands. There is altogether a 4π solid angle around the metal ion and, when the metal is coordinated to enough ligands to prevent the entry of further more ligands into the coordination sphere, the space is believed to be saturated. The second interesting problem is concerned with the decisive factors in the molecular structure of coordination and organometallic compounds. In *d*-transition metal coordination compounds, the problem can be analysed in terms of the Crystal Field Stabilization Energy (CFSE). The structure which has the higher CFSE will be more stable than those with a lower CFSE. However, the CFSE is minimal in *f*-group metal compounds. There is a considerable flexibility in the coordination geometry adopted by their complexes whereas there is little gain or loss in CFSE. We have recently suggested that the structure of lanthanide and actinide coordination compounds is very similar to the packing in an ionic lattice so that the size of the ions plays a dominant role in their arrangement.[1]

The two approaches to the above problems are

* Author to whom correspondence should be addressed.

based on different models. The first approach is based on metal–ligand orbital interactions whereas the second is based on the geometrical packing. Since Tolman made the first attempt to describe steric crowding quantitatively,[2] there has been continued interest[3,4] in this subject. The idea of the solid angle was introduced by several authors[5–8] almost simultaneously to describe steric packing around the metal centre. Although we have reported many applications of the Cone Packing Model[9–13] in inorganic preparations and in explaining bonding in the products, a detailed treatment of the model itself has not yet been published. In the present paper we report our work on the structural characteristics of lanthanide coordination compounds and report the Packing Saturation and Uniform Packing Rules that we have determined.

A FEW CONCEPTS OF THE CONE PACKING MODEL

In dealing with a monomeric structure, a unit sphere of radius 1 Å is drawn with the metal ion as the centre. The ligands are centripetally projected onto the surface of the unit sphere in the first and second order, respectively. The first-order steric effect is due to the directly coordinating atoms and the second-order steric effect is due to the next layer of non-coordinating atoms which is usually at a distance of 3.5–4.5 Å from the metal ion (Fig. 1). The Solid Angle Factor (SAF) is defined as the solid angle of the ligand cone comprising the metal at the apex and the primary coordinating atom or group (the first-order SAF) or the whole ligand (the second-order SAF) divided by 4π. Geometrically, it refers to the ratio of the projected area to 4π, i.e. the area of the sphere surface. It actually represents the size of the ligand as viewed from the metal centre towards the ligand. The sum of the values of SAF of all the ligands coordinated to the metal centre represents the total occupancy of the ligands in the coordination sphere. It is apparent that this occupancy should not reach unity because there are gaps and holes among the ligands. Previously we have used the symbols c.a.f. and Σc.a.f. to express the SAF and the overall occupancy.[8] The symbols were later changed to SAF and SAS in order to avoid confusion with Tolman's Cone Angle concept.

The fan angle (FA) is defined as one-half of the angle subtended by the primary coordinating atom or group (the first-order FA) or the whole ligand (the second-order FA) in different symmetry planes using the van der Waals' sphere concept. In practice the FA of the second-order steric effect has the same meaning as the term "Cone Angle" as defined by Toman. Irregular ligands have more than one FA, so that the FA could be used to describe he shape of a ligand.

Coordination Vector ($\vec{r}$): this is a unit vector directed from the metal ion towards the primary coordinating atom. $\vec{r}$ is used to define the position of a ligand. The product of the ligand SAF and $\vec{r}$, i.e. $4\pi\text{SAF}\cdot\vec{r}$, expresses not only the projectional area of a specified ligand on the unit sphere but also indicates the location of that area.

It should be remarked here that the $\vec{r}$ of a chelating ligand is described by each of the individual vectors

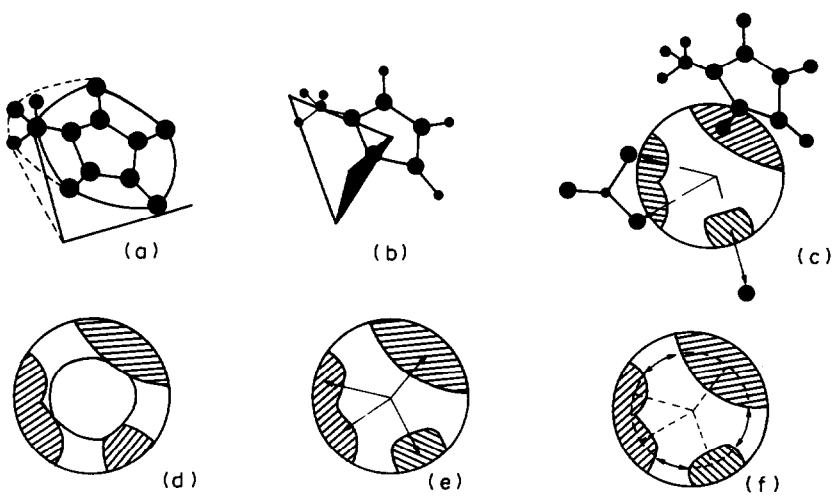

Fig. 1. Geometrical description of concepts of Cone Packing Model: (a) Solid Angle, (b) Fan Angle, (c) projection of ligands to the unit sphere, (d) hole among the ligands, (e) Coordination Vector ($\vec{r}$), and (f) gap between two ligands.

of the coordinating atoms rather than by their sum. For example, the $\vec{r}$ of bidentate nitrate is $\vec{r}_{O1}+\vec{r}_{O2}+\vec{\Delta}$, where $\vec{r}_{O1}$ and $\vec{r}_{O2}$ are the coordination vectors of the two oxygen atoms and $\vec{\Delta}$ is the coordination area of the overlapping part of the two atoms. The coordination vector of a plate-like ligand, e.g. cyclopentadienyl, is directed towards the centre of the ligand.

The vector sum of the values of SAF of all the coordinating ligands, $\Sigma \mathrm{SAF}_i \cdot \vec{r}_i$ throughout the metal ion, indicates the distribution of the areas in the sphere surface. If the ligands are concentrated at one side of the sphere and the other side is empty, the vector sum of the ligand SAF will be significantly high in this direction. Since $\Sigma \mathrm{SAF}_i \cdot \vec{r}_i$ of the most popular coordination geometry are always zero, we adopt it as one, but not a unique, criterion of uniformity in the packing of the ligands around the metal ion.

The Gap between two neighbouring ligands A and B is defined as the difference between the bond angle AMB and their FA sum, $G_{AB} = \measuredangle \mathrm{AMB} - (\mathrm{FA_A}+\mathrm{FA_B})$.

When the van der Waals' spheres of the coordinating atoms separate from each other the Gap is positive, when they are in contact the Gap is zero, and when they overlap the Gap is negative.

Holes among the ligands: The Hole is defined as the largest cone which could be inserted among the ligands present. Since it is an empty site for an incoming ligand, it is also described by SAF and $\vec{r}$. The Hole expresses the vacancy among the ligands discussed above. The steric packing in a reported structure could be studied using the above concepts by the following approach.

MATHEMATICAL TREATMENT

The published atomic lattice coordinates are transformed into rectangular coordinates by means of the following equations:

$$X = ax\sin\beta + by\sin\alpha\cos\phi,$$

$$Y = by\sin\alpha\sin\phi,$$

$$Z = cz + by\cos\alpha + ax\cos\beta,$$

$$\phi = \cos^{-1}\left(\frac{\cos\gamma - \cos\alpha\cos\beta}{\sin\alpha\sin\beta}\right),$$

where a, b and c and α, β and γ are the lattice parameters, and x, y and z the atomic lattice coordinates. $\vec{r}$ may be calculated from:

$$\vec{r} = (\vec{X}+\vec{Y}+\vec{Z})/R$$

$$R = (X^2+Y^2+Z^2)^{1/2}.$$

The distance between any two atoms may then be calculated. The FA $\theta = \sin^{-1}(v/l)$, where v is the van der Waals' radius of a specific atom and l is the bond length between metal ion and the coordination atom.

$$\mathrm{SAF} = \tfrac{1}{2}(1-\cos\theta).$$

The first-order packing refers to the packing in the primary coordination sphere.

Correction must be made for bidentate ligands for overlapping according to the following equation:

$$\Delta\mathrm{SAF} = (\pi v^2\psi/180 - dv\sin\psi)/(2\pi l^2\cos^2\eta)$$

where η is one-half of the angle L—M—L′ (L and L′ are the two coordinating atoms in one ligand): d is one-half the distance between the two atoms (Fig. 2) and $\psi = \cos^{-1}(d/v)$. The approximation comes from the shaded area when the two atoms are identical and are equidistant from the metal. More accurate corrections can be made if the two atoms are not identical or they are not equidistant from the metal ion.[8(b)]

The second-order steric packing has only been

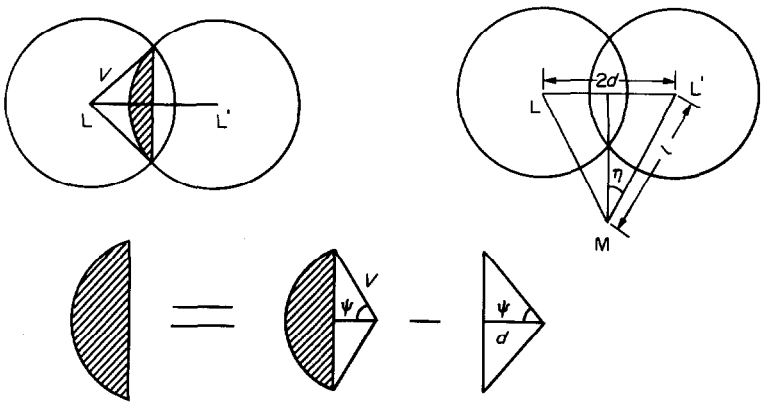

Fig. 2. Correction for overlapping of bidentate ligands.

[a]A full list for Table 2 is deposited as supplementary data.

treated for a few structures. The second-order SAS value is the sum of the SAFs of all atoms in the layer from 3.5 to 4.5 Å from the metal ion.

We have given two examples to show the calculation (Table 1). The values of SAS and $\Sigma SAF\cdot\vec{r}$ of some selected structures are listed in Table 2.

RESULTS AND DISCUSSION

Ligand packing around the metal centre is very similar to the packing of an ionic lattice in which:

(1) The SAS of all anions around a cation stays approximately constant regardless of the lattice character.

(2) The vector sum of the value of the SAF of all anions around a cation tends to be zero.

(3) The anions are in contact with each other in the lattice.

All three characteristics remain approximately true in structures of lanthanide coordination compounds.

The purpose of our work is to demonstrate that steric packing plays a dominant role in the molecular structures of lanthanide coordination compounds. Fluctuations in both the coordination number and the SAS values are analysed as follows: if the coordination saturation in *f*-group chemistry is explained on the basis of filling the valence orbitals with electrons, the formal coordination number in these structures should be distributed around certain electron counts with few exceptions. On the other hand, if coordination saturation is explained on the basis of filling up coordination space, the sum of the ligand SAFs will be concentrated around a value which represents the criterion of the proper packing. One ligand more in the coordination sphere will lead to steric overcrowding and one ligand less will lead to steric undercrowding. It is expected that the standard deviation of the ligand packing should therefore be within the SAF of one ligand (see Table 3).

In fact, we have found that the sum of the ligand SAFs are quite constant in spite of the change in the formal coordination number from 4 to 12 (Fig. 3). Steric packing increases steadily and slowly with

Table 3. Average steric packing and deviations for 164 structures[a]

Coordination number	Number of structures	$\Sigma SAF \cdot \vec{r}$	SAS
6	15	0.008 ± 0.009	0.742 ± 0.053
7	14	0.024 ± 0.009	0.729 ± 0.033
8	58	0.012 ± 0.009	0.766 ± 0.051
9	48	0.009 ± 0.01	0.793 ± 0.038
10	19	0.016 ± 0.008	0.812 ± 0.032
11	6	0.018 ± 0.007	0.814 ± 0.020
12	4	0.008 ± 0.005	0.891 ± 0.037

[a] General: $\Sigma SAF \cdot \vec{r} = 0.02 \pm 0.015$, $SAS = 0.78 \pm 0.05$*. The standard deviation is less than the SAF of the smallest ligand in our calculation.

the increasing formal coordination number. This phenomenon is very similar to the phenomenon in the packing of balls in a box in that the smaller the balls the higher the space occupancy. The values of SAS reach about 0.90 for structures of high coordination number, although the electron count has not yet achieved the inert-gas formalism. It was noticed that the gaps between the neighbouring ligands were almost zero or even negative, indicating a very crowded steric packing. It is definitely the steric repulsion that prevents more ligands entering the coordination space. Thus equilibrium is established and the CFSE is compensated for by the ligand non-bonding repulsions.

It is found that the structures of compounds with relatively lower SAS values always contain ligands which are bulky in the second order. A typical example is $LA[N(SiMe_3)_2]_3PPh_3O$. Although there are only four coordinating atoms in the first order with an SAS value of 0.423 [Table 1(a)], in the second-order steric crowding there are six silicon atoms, six carbon atoms and a phosphorus atom at distances from 3.45 to 3.91 Å around the lanthanum ion. The calculated SAS value in the second layer is 0.78. The second- and first-order steric effects have a cooperative effect with respect to each other. That is, if all the ligands in a molecule have little steric effect in the second order, then steric crowding in the first order would be higher then the average value of SAS e.g. $LnCl_6^{3-}$, $[Ln(NO_3)_6]^{3-}$ and $[Ln(NO_3)_5]^{2-}$ whereas ligands which are bulky in the second order always form complexes in which the SAS value is less than the average (e.g. with ligands containing $-Ph^-$, $-CMe_3^-$, $-NMe_2^-$ or $-SiMe_3^-$).

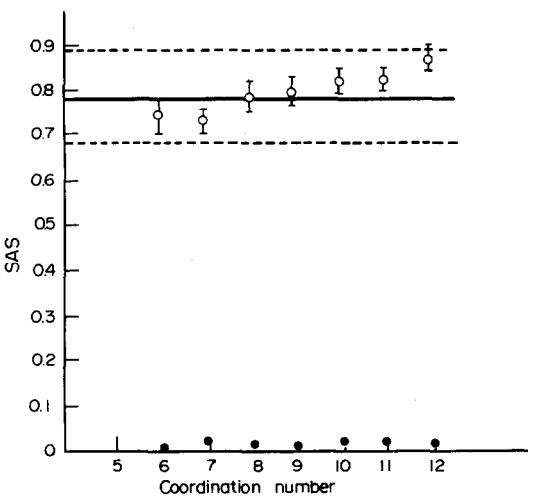

Fig. 3. The Packing Saturation Rule and the Packing Centre Rule. The stable region is described with a centre line at the SAS equal to the average steric crowding and two border lines of either gain or loss of one ligand with an SAF of 0.1.

The Packing Centre Rule: in a box filled with balls, in spite of the different sizes and different arrangements of the balls, the centre of gravity of the balls moves very little and it always coincides approximately with the centre of the box. We have found a similar result in studying the structures of lanthanide coordination compounds. The vector sums of the first-order ligand SASs in all the structures without exception approach zero (Table 3) regardless of the molecular geometries and the formal coordination numbers. This also occurs in ionic latice, for the lattice will change with the variation in the ionic radii of the anions around a cation, as well as vice versa. This behaviour is in clear contrast to the structures of main-group element compounds such as water and ammonia where the centres of gravity of the hydrogen atoms are apparently not close to the central atoms due to the lone pair of electrons. Thus the structures of lanthanide coordination compounds, being individual molecular structures, obviously retain the properties of ionic lattices. Since the crystal field stabilization energy is at a minimum and the molecular geometry is

Table 4. Molecular geometry of the coordination pattern MA_3B

Compound	Ligand	SAF	Reference	Bond angle (°) (thf/Cp)	Reference	Bond angle (°) (calc.) (thf/Cp)
$LaCp_3thf$				99.5 117.7	30	
$PrCp_3thf$	Cp	0.215		99.0 117.6	31	97.8

YCp_3thf				99.1 117.4	30	

very flexible, the bonds between the metal and the ligands are almost undirectional. Steric and static repulsion among the ligands lead to a uniform distribution of ligands.

The Packing Centre Rule is further proved by its application in predicting the molecular structures. For example, for the molecular geometry of MA_3B compounds, according to the rule (Fig. 4):

$$3SAF_A \cos(180-\theta) - SAF_B = 0,$$

the bond angle AMB is thus derived from the reported SAF values,[12(a)] and another bond angle is derived according to the sphere triangle function:

$$\phi = \cos^{-1}(\tfrac{3}{2}\cos^2\theta - \tfrac{1}{2}).$$

Some of the results are shown in Table 4. The calculated results are in good agreement with the reported ones.

Finally, non-bonding distances of the coordination polyhedron were calculated for many structures. In most cases, the distances are close to or less than the sums of the van der Waals' radii of the corresponding atoms in the neighbouring ligands. When the atoms are not in contact in the primary coordination sphere, the ligands would then be in either contact in the secondary layer or in contact with ligands in the other molecules. This phenomenon offers an explanation for the geometrical flexibility of the molecular structure and for the question how the ligands are fixed at their positions. Favourable orbital interaction seems to play no significant role in molecular geometry. A ligand remains at its position simply because its drifting is interlocked by other ligands in the neighbourhood.

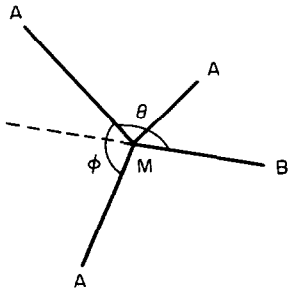

Fig. 4. Application of the Packing Centre Rule in calculating the molecular geometry of the structural pattern MA_3B ($\theta = \measuredangle AMB$, $\phi = \measuredangle AMA$): the vector sum must be zero along the MB direction.

(*Received* 6 *January* 1986; *accepted after revision* 25 *September* 1986)

Abstract—The mixed-ligand complexes $[Cu(den)en](ClO_4)_2$, $[Cu(den)Pn](ClO_4)_2$ and $[Cu(den)tn](ClO_4)_2$ (where den = diethylenetriamine, en = ethylenediamine, Pn = 1,2-diaminopropane, and tn = 1,3-diaminopropane) have been synthesized, and their IR, electronic and ESR spectral properties have been studied to understand the stereochemistry of these complexes both in the solid state and in DMF (dimethylformamide) or pyridine solutions. The metal appears to be five-coordinate in the solid state, formed with five nitrogens of the mixed ligand, and is found to change in solution, probably due to the attachment of a solvent molecule in the sixth coordination position. The equatorial and axial bond strengths are estimated in the solutions.

It is well known that IR and optical absorption spectra can be used to obtain information regarding the nature and number of ligating atoms in a metal complex, and that the ESR technique in most of the cases can easily detect the point symmetry and bond nature in copper(II) complexes.[1–7] Mixed-ligand complexes were found to be interesting due to the fact that the arrangement of ligating atoms around copper(II) was found to change as one goes from the solid to the solution state.[8] Therefore the authors have undertaken the synthesis of three mixed-ligand complexes with general formula $[Cu(den)L](ClO_4)_2$ [where den = diethylenetriamine, and L = en (ethylenediamine), Pn (1,2-diaminopropane) or tn (1,3-diaminopropane)] and carried out spectroscopic studies on them using IR, optical absorption and ESR techniques with the aim of understanding the stereochemistry of these complexes in both the solid and the solution state.

EXPERIMENTAL

Materials

En, tn, Pn and den were commercially available. $CuBr_2$ and $Cu(ClO_4)_2 \cdot 6H_2O$ were prepared according to literature methods.

Preparation of the complexes

All complexes were prepared by the following method.

To a hot solution of the appropriate salt (10 mmol) in methanol (150 cm^3) a hot solution of tridentate amine (10 mmol) and one of the bidentate amine (10 mmol) in the same solvent were slowly added. Isopropyl alcohol was added to the concentrated solution in order to promote crystallization.

All the complexes were filtered and dried *in vacuo* over P_4O_{10}.

Analysis

Nitrogen, carbon and hydrogen were analysed with a Perkin–Elmer 240 Elemental Analyser.

Physical measurements

The room-temperature electronic spectra of the solid compounds were recorded on a Schimadezer MPS 50L spectrophotometer. The IR spectra on CsI discs with Nujol mulls were recorded on a Perkin–Elmer 325 spectrophotometer.

ESR spectra of these complexes in polycrystalline and solution forms were recorded using Varian E-4, *X*-band and E-112 *Q*-band spectrometers having a 100- and 70-KHz magnetic field modulation, respectively. DPPH was used as a *g* marker. The errors in *g* and *A* (hyperfine line separation) are about ± 0.001 and ± 2 G, respectively.

RESULTS AND DISCUSSION

IR and electronic spectra studies

The analytical data and physical properties of these complexes are reported in Table 1. The compounds are microcrystalline or powder-like, intensely coloured, and they are very soluble in MeOH, H_2O, DMF (dimethylformamide) and pyridine. The principal near- and far-IR bands are reported in Table 2. The single band (occasionally doublet) of the amino groups at 3350–3320 cm^{-1} can be assigned to symmetric $\nu(NH_2)$, and the bands in the 3290–3225-cm^{-1} region to asymmetric $\nu(NH_2)$. A single band near 3200–3170 cm^{-1} is usually assigned to the ν(NH) stretching of a secondary amino group [possibly plus an uncoupled ν(NH) of the primary amino group] and the band near 1580 cm^{-1} is assigned to $\delta(NH_2)$. It appears that all the amino groups are coordinated to copper(II). The bands assigned to the perchlorate group are: ν_3 at 1080–1070 cm^{-1} and ν_4 at 625–620 cm^{-1}, which are typical of compounds with free ClO_4. The ν(Cu—N) stretching band occurs in the range 485–427 cm^{-1}, which confirms that the polyamines are coordinated by the nitrogens to the copper(II) ion.

The electronic spectra of solid compounds have a large asymmetric *d–d* band in the range 12,800–16,600 cm^{-1}, and a shoulder at a lower wavenumber in the range 11,600–12,800 cm^{-1}. This pattern is similar to that presented by the diffuse-reflectance spectra of $[Cu(dpt)L]X_2$ (where L = en or tn; dpt = 3,3′-diaminodipropylamine; X = Cl^-, Br^-, I^- or ClO_4^-) which have a five-coordinate distorted square pyramidal structure.[9].

ESR data

Polycrystalline spectra. Figure 1 shows the ESR spectra of the polycrystalline mixed-ligand copper(II) complexes at *Q*-band microwave frequencies. The principal *g* values are calculated using the Kneubuhl procedure[10] from which the useful parameters G $\{(g_3-2)/[(g_1+g_2/2)-2]\}$ and R $[(g_2-g_1)/(g_3-g_2)]$ are also calculated. These parameters for the three complexes are given in Table 3. The G value (4.97) of $[Cu(den)en](ClO_4)_2$ lies between 3.5 and 5.0, indicating that the *g* values obtained in the polycrystalline sample are near to the molecular *g* values, and hence the unit cell of this complex contains magnetically equivalent sites.[11–14] In the case of other two complexes the G values are found to be less than 3.5, indicating an exchange interaction among magnetically inequivalent copper(II) ions in the unit cell, and hence the *g* values obtained in polycrystalline samples will be different from the molecular *g* values.[15] It is also found that for values of R less than 1 the ground state of copper(II) will be either $d_{x^2-y^2}$ or d_{xy}. A d_{z^2} ground state for copper(II) is indicated by values of R greater than 1.[14] From Table 3 it is evident that the ground state of copper(II) in $[Cu(den)en](ClO_4)_2$ is either $d_{x^2-y^2}$ or d_{xy}, which indicates that this five-coordinate complex may have a square-based pyramidal structure. This ground state is supported by the fact that the low-field side of the spectrum is less intense than the high-field side of

Table 1. Analytical data of the mixed-ligand copper(II) complexes

[a] Calculated values are given in parentheses.

Table 2. IR and electronic spectra of the mixed-ligand copper(II) complexes

Complex	IR (cm^{-1}) Symmetric $\nu(NH_2)$	Asymmetric $\nu(NH_2)$	ν(NH)	$\delta(NH_2)$	ClO_4 ν_3	ν_4	ν(M—N)	Electronic spectra (cm^{-1})
$[Cu(den)en](ClO_4)_2$	3320vs	3270vs, 3235vs	3135vs	1575	1080	625vs	435s	12,500sh, 16,600
$[Cu(den)Pn](ClO_4)_2$	3340vs	3280vs	3150m	1575	1085vsbr	620vs	442m	11,600sh, 12,800 16,100sh
$[Cu(den)tn](ClO_4)_2$	3350vs	3290vs	3170vs	1575	1070vsbr	620vs	485m	11,800sh, 13,800

the spectrum.[8] Since R is greater than 1 in the case of the other two complexes the ground state appears to be d_{z^2}, indicating a compressed trigonal bipyramidal symmetry for these five-coordinate complexes, which is also supported by the fact that the low-field side of the spectrum is more intense than the high-field side of the spectrum.[16]

Solution spectra. The room-temperature spectra of these complexes in DMF and pyridine solutions of four hyperfine lines of copper(II) with a spin-dependent linewidth due to the tumbling motion of the microcrystalline unit in solution.[17] In frozen solutions the ESR spectra consists of four hyperfine lines as parallel features and an unresolved line as

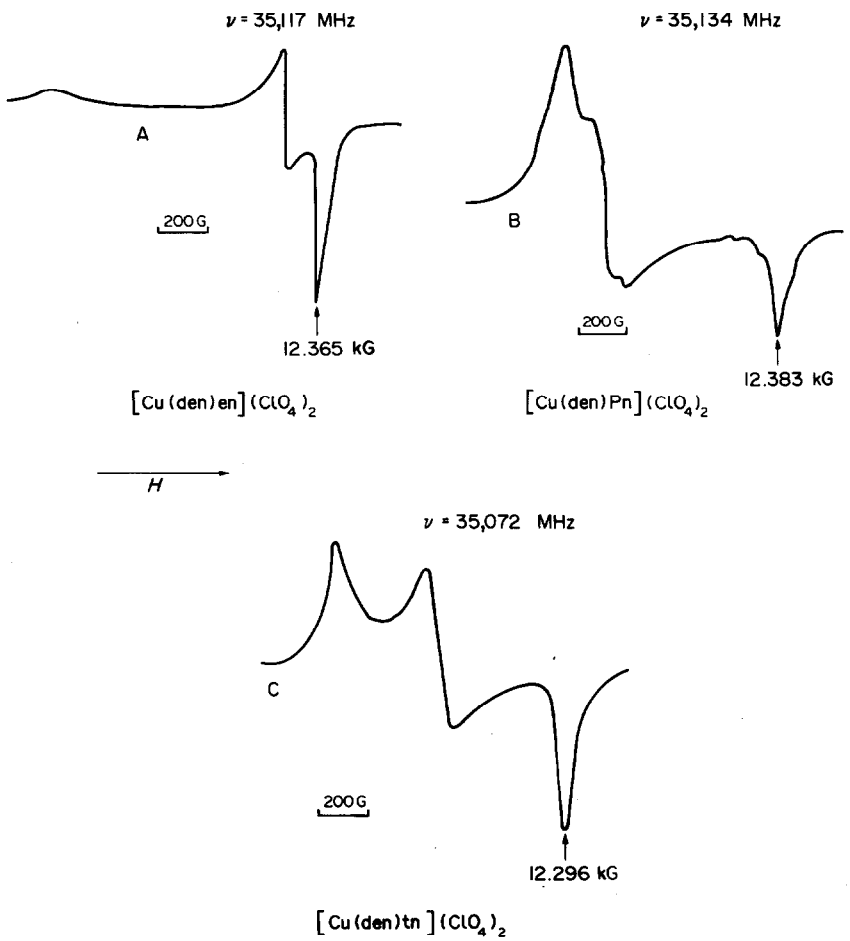

Fig. 1. ESR spectra of the polycrystalline mixed-ligand copper(II) complexes at Q-band (A, B and C) microwave frequencies.

Table 3. g Values of polycrystalline mixed–ligand copper(II) complexes

Complex	g_1	g_2	g_3	G	R	Ground state
$[Cu(den)en](ClO_4)_2$	2.029	2.055	2.209	4.97	0.124	$d_{x^2-y^2}$
$[Cu(den)Pn](ClO_4)_2$	2.027	2.137	2.167	2.03	3.00	d_{z^2}
$[Cu(den)tn](ClO_4)_2$	2.037	2.115	2.159	2.09	1.77	d_{z^2}

the perpendicular feature of the spectrum as shown in Fig. 2. The variation in the hyperfine line intensities of the parallel features of the spectrum can be due to the superposition of the perpendicular features over the parallel features of the spectrum. Low-intensity lines as the parallel features of the spectrum can also be seen which arise most probably due to the presence of a second species with a low population. The g and A values are calculated from the spectra following the usual procedure[18] for the highly populated species, and these values are given in Table 4. It can be seen from Tables 3 and 4 that the g values obtained in the polycrystalline sample of $[Cu(den)en](ClO_4)_2$ are not much different from those in the pyridine solution, indicating that the structure of the chromophore around the solid copper(II) is not disturbed much in pyridine solutions. From Table 4 it is evident that in the case of the DMF solution of $[Cu(den)tn](ClO_4)_2$ the $g_\parallel$ values are smaller and $A_\parallel$ are larger than the corresponding values in the pyridine solution. This is an indication that the solute–solvent interaction in pyridine is greater compared to DMF for the compound $[Cu(den)tn](ClO_4)_2$. The g and A values in both solutions are characteristic of nitrogen coordination.[19] Due to solute–solvent interactions the solvent molecules have probably occupied the sixth coordination position, converting the five-coordinate complexes into six-coordinate ones.

In the presence of axial bonds, $4s$ mixing will be present in the ground state and also the equatorial bonds will be weakened.[20] The σ-bond parameter (α^2) and the fraction of $3d$ character in the $3d$ $4s$ ground state of copper(II) (f^2), which give the strengths of the equatorial and axial bonds, respectively, can be obtained from the following equations:[21]

$$\alpha^2 f^2 = \frac{7}{4}\left[\frac{A_\parallel}{P} - \frac{|A|}{P} + \frac{2}{3}g_\parallel - \frac{5}{21}g_\perp - \frac{6}{7}\right], \quad (1)$$

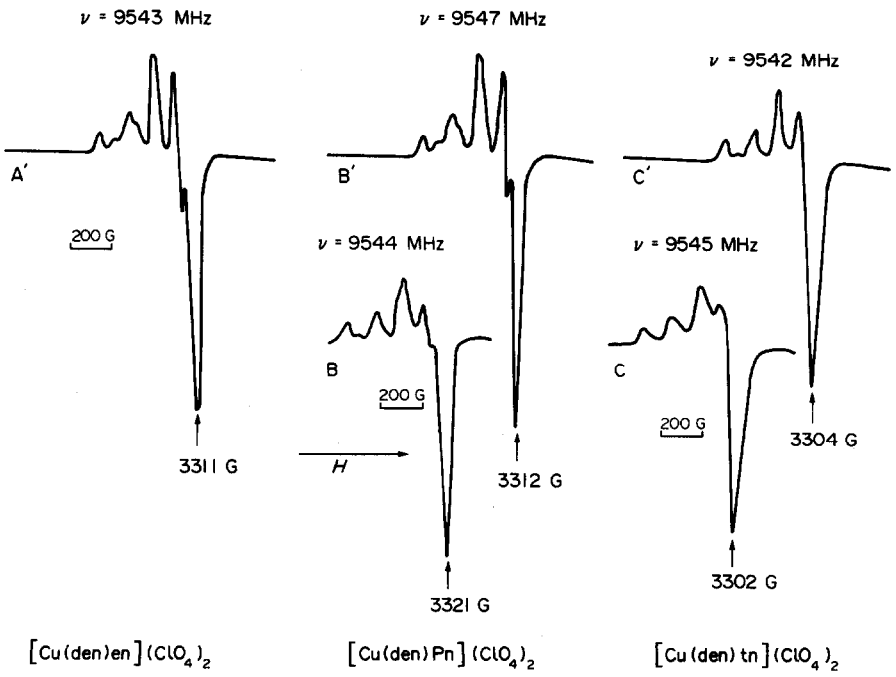

Fig. 2. ESR spectra of the mixed-ligand copper(II) complexes in frozen DMF (B and C) and pyridine (A′, B′ and C′) solutions.

Table 4. Spin-Hamiltonian constants of mixed-ligand copper(II) complexes in DMF and pyridine solutions

Complex	Solvent	g	A ($\times 10^{-4}$ cm^{-1})	$g_\parallel$	$g_\perp$	$A_\parallel$ ($\times 10^{-4}$ cm^{-1})	$A_\perp$ ($\times 10^{-4}$ cm^{-1})
$[Cu(den)en](ClO_4)_2$	Pyridine	2.106	64.7	2.200	2.059	173.9	10.10
$[Cu(den)Pn](ClO_4)_2$	DMF	2.099	64.4	2.190	2.053	176.2	8.6
	Pyridine	2.104	69.5	2.194	2.059	173.3	17.6
$[Cu(den)tn](ClO_4)_2$	DMF	2.103	66.5	2.179	2.065	172.2	13.6
	Pyridine	2.107	78.3	2.194	2.063	170.0	25.8

$$\alpha^2 = \frac{|A|}{PK_o} + \frac{\Delta g}{K_o} + \frac{0.0975(1-f^2)}{PK_o}, \qquad (2)$$

where P is a dipolar term ($2.0023 g_N \beta_e \beta_N \langle r^{-3} \rangle_{av} = 1194$ MHz[22]), and $K_o = 0.43$. In eqn(2) an electron in the 4s orbital has been assigned a value of 0.0975 cm^{-1}.[21,23] The values of α^2 and f^2 for all the complexes are given in Table 5. The value of α^2 in the case of the pyridine solution of $[Cu(den)tn](ClO_4)_2$ is found to be less and its f^2 value more than that of the corresponding values of the other complexes in solutions, indicating strong equatorial and weak axial bonds. On the other hand the α^2 values are more and f^2 values are less in the case of the pyridine solution of $[Cu(den)en](ClO_4)_2$ and the DMF solution of $[Cu(den)Pn](ClO_4)_2$, indicating weak equatorial bonds and strong axial bonds compared to the other cases.

Conclusions

Mixed-ligand copper(II) complexes with general formula $[(Cu(den)L](ClO_4)_2$ have been synthesized, and the IR, electronic and ESR spectral studies of the polycrystalline and solution forms show that:

(a) IR and electronic spectral studies indicate that these mixed-ligand copper(II) complexes are nitrogen-bonded five-coordinate complexes in solid state.

(b) ESR studies of polycrystalline samples indicate that $[Cu(den)en](ClO_4)_2$ has a square-based pyramidal CuN_5 chromophore and the unit cell contains all magnetically equivalent ions, whereas the complexes $[Cu(den)Pn](ClO_4)_2$ and $[Cu(den)tn](ClO_4)_2$ have compressed trigonal bipyramidal CuN_5 chromophores and the unit cell contains magnetically inequivalent ions with a strong exchange interaction among them.

(c) The solute–solvent interaction in the pyridine solutions of all these complexes is found to be more than that of the DMF solutions of these complexes. The chromophore of solid $[Cu(den)en](ClO_4)_2$ is found to be less disturbed in the pyridine solution of this complex. The equatorial bonds of $[Cu(den)tn](ClO_4)_2$ in a pyridine solution is stronger than other complexes in that solution. Except in the above case, in all the other solutions of these complexes, the presence of a 4s orbital in the ground state indicates axial bonds.

(*Received* 6 *January* 1986; *accepted after revision* 25 *September* 1986)

Abstract—The mixed-ligand complexes $[Cu(den)en](ClO_4)_2$, $[Cu(den)Pn](ClO_4)_2$ and $[Cu(den)tn](ClO_4)_2$ (where den = diethylenetriamine, en = ethylenediamine, Pn = 1,2-diaminopropane, and tn = 1,3-diaminopropane) have been synthesized, and their IR, electronic and ESR spectral properties have been studied to understand the stereochemistry of these complexes both in the solid state and in DMF (dimethylformamide) or pyridine solutions. The metal appears to be five-coordinate in the solid state, formed with five nitrogens of the mixed ligand, and is found to change in solution, probably due to the attachment of a solvent molecule in the sixth coordination position. The equatorial and axial bond strengths are estimated in the solutions.

It is well known that IR and optical absorption spectra can be used to obtain information regarding the nature and number of ligating atoms in a metal complex, and that the ESR technique in most of the cases can easily detect the point symmetry and bond nature in copper(II) complexes.[1–7] Mixed-ligand complexes were found to be interesting due to the fact that the arrangement of ligating atoms around copper(II) was found to change as one goes from the solid to the solution state.[8] Therefore the authors have undertaken the synthesis of three mixed-ligand complexes with general formula $[Cu(den)L](ClO_4)_2$ [where den = diethylenetriamine, and L = en (ethylenediamine), Pn (1,2-diaminopropane) or tn (1,3-diaminopropane)] and carried out spectroscopic studies on them using IR, optical absorption and ESR techniques with the aim of understanding the stereochemistry of these complexes in both the solid and the solution state.

EXPERIMENTAL

Materials

En, tn, Pn and den were commercially available. $CuBr_2$ and $Cu(ClO_4)_2 \cdot 6H_2O$ were prepared according to literature methods.

Preparation of the complexes

All complexes were prepared by the following method.

To a hot solution of the appropriate salt (10 mmol) in methanol (150 cm^3) a hot solution of tridentate amine (10 mmol) and one of the bidentate amine (10 mmol) in the same solvent were slowly added. Isopropyl alcohol was added to the concentrated solution in order to promote crystallization.

All the complexes were filtered and dried *in vacuo* over P_4O_{10}.

Analysis

Nitrogen, carbon and hydrogen were analysed with a Perkin–Elmer 240 Elemental Analyser.

Physical measurements

The room-temperature electronic spectra of the solid compounds were recorded on a Schimadezer MPS 50L spectrophotometer. The IR spectra on CsI discs with Nujol mulls were recorded on a Perkin–Elmer 325 spectrophotometer.

ESR spectra of these complexes in polycrystalline and solution forms were recorded using Varian E-4, *X*-band and E-112 *Q*-band spectrometers having a 100- and 70-KHz magnetic field modulation, respectively. DPPH was used as a *g* marker. The errors in *g* and *A* (hyperfine line separation) are about ± 0.001 and ± 2 G, respectively.

RESULTS AND DISCUSSION

IR and electronic spectra studies

The analytical data and physical properties of these complexes are reported in Table 1. The compounds are microcrystalline or powder-like, intensely coloured, and they are very soluble in MeOH, H_2O, DMF (dimethylformamide) and pyridine. The principal near- and far-IR bands are reported in Table 2. The single band (occasionally doublet) of the amino groups at 3350–3320 cm^{-1} can be assigned to symmetric $\nu(NH_2)$, and the bands in the 3290–3225-cm^{-1} region to asymmetric $\nu(NH_2)$. A single band near 3200–3170 cm^{-1} is usually assigned to the ν(NH) stretching of a secondary amino group [possibly plus an uncoupled ν(NH) of the primary amino group] and the band near 1580 cm^{-1} is assigned to $\delta(NH_2)$. It appears that all the amino groups are coordinated to copper(II). The bands assigned to the perchlorate group are: ν_3 at 1080–1070 cm^{-1} and ν_4 at 625–620 cm^{-1}, which are typical of compounds with free ClO_4. The ν(Cu—N) stretching band occurs in the range 485–427 cm^{-1}, which confirms that the polyamines are coordinated by the nitrogens to the copper(II) ion.

The electronic spectra of solid compounds have a large asymmetric *d–d* band in the range 12,800–16,600 cm^{-1}, and a shoulder at a lower wavenumber in the range 11,600–12,800 cm^{-1}. This pattern is similar to that presented by the diffuse-reflectance spectra of $[Cu(dpt)L]X_2$ (where L = en or tn; dpt = 3,3′-diaminodipropylamine; X = Cl^-, Br^-, I^- or ClO_4^-) which have a five-coordinate distorted square pyramidal structure.[9].

ESR data

Polycrystalline spectra. Figure 1 shows the ESR spectra of the polycrystalline mixed-ligand copper(II) complexes at *Q*-band microwave frequencies. The principal *g* values are calculated using the Kneubuhl procedure[10] from which the useful parameters G $\{(g_3-2)/[(g_1+g_2/2)-2]\}$ and R $[(g_2-g_1)/(g_3-g_2)]$ are also calculated. These parameters for the three complexes are given in Table 3. The G value (4.97) of $[Cu(den)en](ClO_4)_2$ lies between 3.5 and 5.0, indicating that the *g* values obtained in the polycrystalline sample are near to the molecular *g* values, and hence the unit cell of this complex contains magnetically equivalent sites.[11–14] In the case of other two complexes the G values are found to be less than 3.5, indicating an exchange interaction among magnetically inequivalent copper(II) ions in the unit cell, and hence the *g* values obtained in polycrystalline samples will be different from the molecular *g* values.[15] It is also found that for values of R less than 1 the ground state of copper(II) will be either $d_{x^2-y^2}$ or d_{xy}. A d_{z^2} ground state for copper(II) is indicated by values of R greater than 1.[14] From Table 3 it is evident that the ground state of copper(II) in $[Cu(den)en](ClO_4)_2$ is either $d_{x^2-y^2}$ or d_{xy}, which indicates that this five-coordinate complex may have a square-based pyramidal structure. This ground state is supported by the fact that the low-field side of the spectrum is less intense than the high-field side of

Table 1. Analytical data of the mixed-ligand copper(II) complexes

$[Cu(den)tn](ClO_4)_2$	3350vs	3290vs	3170vs	1575	1070vsbr	620vs	485m	11,800sh, 13,800

the spectrum.[8] Since R is greater than 1 in the case of the other two complexes the ground state appears to be d_{z^2}, indicating a compressed trigonal bipyramidal symmetry for these five-coordinate complexes, which is also supported by the fact that the low-field side of the spectrum is more intense than the high-field side of the spectrum.[16]

Solution spectra. The room-temperature spectra of these complexes in DMF and pyridine solutions of four hyperfine lines of copper(II) with a spin-dependent linewidth due to the tumbling motion of the microcrystalline unit in solution.[17] In frozen solutions the ESR spectra consists of four hyperfine lines as parallel features and an unresolved line as

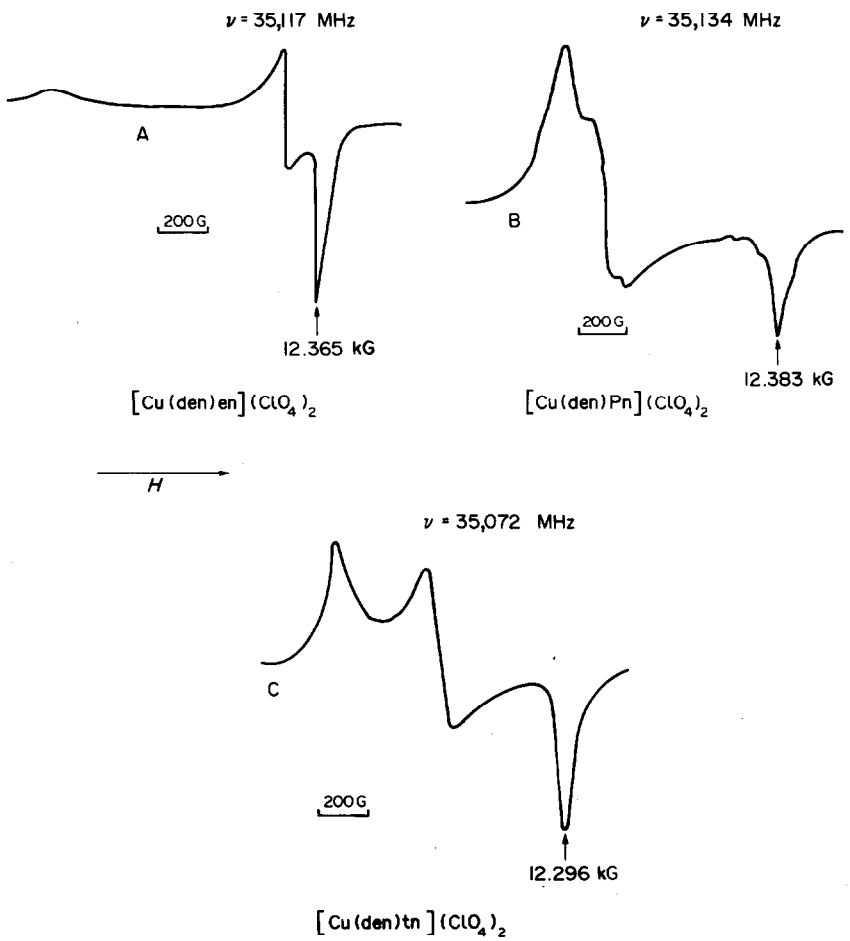

Fig. 1. ESR spectra of the polycrystalline mixed-ligand copper(II) complexes at Q-band (A, B and C) microwave frequencies.

Table 3. g Values of polycrystalline mixed–ligand copper(II) complexes

Complex	g_1	g_2	g_3	G	R	Ground state
$[Cu(den)en](ClO_4)_2$	2.029	2.055	2.209	4.97	0.124	$d_{x^2-y^2}$
$[Cu(den)Pn](ClO_4)_2$	2.027	2.137	2.167	2.03	3.00	d_{z^2}
$[Cu(den)tn](ClO_4)_2$	2.037	2.115	2.159	2.09	1.77	d_{z^2}

the perpendicular feature of the spectrum as shown in Fig. 2. The variation in the hyperfine line intensities of the parallel features of the spectrum can be due to the superposition of the perpendicular features over the parallel features of the spectrum. Low-intensity lines as the parallel features of the spectrum can also be seen which arise most probably due to the presence of a second species with a low population. The g and A values are calculated from the spectra following the usual procedure[18] for the highly populated species, and these values are given in Table 4. It can be seen from Tables 3 and 4 that the g values obtained in the polycrystalline sample of $[Cu(den)en](ClO_4)_2$ are not much different from those in the pyridine solution, indicating that the structure of the chromophore around the solid copper(II) is not disturbed much in pyridine solutions. From Table 4 it is evident that in the case of the DMF solution of $[Cu(den)tn](ClO_4)_2$ the $g_\parallel$ values are smaller and $A_\parallel$ are larger than the corresponding values in the pyridine solution. This is an indication that the solute–solvent interaction in pyridine is greater compared to DMF for the compound $[Cu(den)tn](ClO_4)_2$. The g and A values in both solutions are characteristic of nitrogen coordination.[19] Due to solute–solvent interactions the solvent molecules have probably occupied the sixth coordination position, converting the five-coordinate complexes into six-coordinate ones.

In the presence of axial bonds, $4s$ mixing will be present in the ground state and also the equatorial bonds will be weakened.[20] The σ-bond parameter (α^2) and the fraction of $3d$ character in the $3d$ $4s$ ground state of copper(II) (f^2), which give the strengths of the equatorial and axial bonds, respectively, can be obtained from the following equations:[21]

$$\alpha^2 f^2 = \frac{7}{4}\left[\frac{A_\parallel}{P} - \frac{|A|}{P} + \frac{2}{3}g_\parallel - \frac{5}{21}g_\perp - \frac{6}{7}\right], \quad (1)$$

	Pyridine	2.104	69.5	2.194	2.059	173.3	17.6
$[Cu(den)tn](ClO_4)_2$	DMF	2.103	66.5	2.179	2.065	172.2	13.6
	Pyridine	2.107	78.3	2.194	2.063	170.0	25.8

$$\alpha^2 = \frac{|A|}{PK_o} + \frac{\Delta g}{K_o} + \frac{0.0975(1-f^2)}{PK_o}, \qquad (2)$$

where P is a dipolar term ($2.0023 g_N \beta_e \beta_N \langle r^{-3} \rangle_{av} = 1194$ MHz[22]), and $K_o = 0.43$. In eqn(2) an electron in the 4s orbital has been assigned a value of 0.0975 cm^{-1}.[21,23] The values of α^2 and f^2 for all the complexes are given in Table 5. The value of α^2 in the case of the pyridine solution of $[Cu(den)tn](ClO_4)_2$ is found to be less and its f^2 value more than that of the corresponding values of the other complexes in solutions, indicating strong equatorial and weak axial bonds. On the other hand the α^2 values are more and f^2 values are less in the case of the pyridine solution of $[Cu(den)en](ClO_4)_2$ and the DMF solution of $[Cu(den)Pn](ClO_4)_2$, indicating weak equatorial bonds and strong axial bonds compared to the other cases.

Conclusions

Mixed-ligand copper(II) complexes with general formula $[(Cu(den)L](ClO_4)_2$ have been synthesized, and the IR, electronic and ESR spectral studies of the polycrystalline and solution forms show that:

(a) IR and electronic spectral studies indicate that these mixed-ligand copper(II) complexes are nitrogen-bonded five-coordinate complexes in solid state.

(b) ESR studies of polycrystalline samples indicate that $[Cu(den)en](ClO_4)_2$ has a square-based pyramidal CuN_5 chromophore and the unit cell contains all magnetically equivalent ions, whereas the complexes $[Cu(den)Pn](ClO_4)_2$ and $[Cu(den)tn](ClO_4)_2$ have compressed trigonal bipyramidal CuN_5 chromophores and the unit cell contains magnetically inequivalent ions with a strong exchange interaction among them.

(c) The solute–solvent interaction in the pyridine solutions of all these complexes is found to be more than that of the DMF solutions of these complexes. The chromophore of solid $[Cu(den)en](ClO_4)_2$ is found to be less disturbed in the pyridine solution of this complex. The equatorial bonds of $[Cu(den)tn](ClO_4)_2$ in a pyridine solution is stronger than other complexes in that solution. Except in the above case, in all the other solutions of these complexes, the presence of a 4s orbital in the ground state indicates axial bonds.

Table 5. Bond parameters of mixed-ligand copper(II) complexes

(*Received* 24 *March* 1986 ; *accepted after revision* 25 *September* 1986)

Abstract—The reactions of palladium(II) chloride with 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene and 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene are described. With 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene diimine fission is produced, giving rise to a product identified by elemental analysis, IR and Raman spectra, and X-ray diffraction, as *trans*-dichlorobis(aniline) palladium(II). The complex is soluble in dimethylformamide and crystallizes with two molecules of solvent. The substance crystallizes in the monoclinic space group $P2_1/n$. The X-ray data were refined to $R = 0.047$ and $R_w = 0.046$. Final distances are Pd—N = 2.060(5) Å and Pd—Cl = 2.299(2) Å. There are two bifurcated intermolecular N—H.... Cl and C—H.... Cl hydrogen bonds which, together with one more intermolecular hydrogen bond N—H....O, are responsible for the packing of the molecules. However, when 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene was treated with palladium chloride under the same conditions *cis* - dichloro - 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene was formed, as deduced from elemental analysis, and IR and Raman spectra.

As a part of our investigation of ligand systems containing N donor atoms we recently reported the synthesis, spectroscopic data and crystal structure of two diimines.[1]

Diimines are bidentate ligands and can coordinate two metallic centers, giving rise to highly interesting compounds.[2] The most likely reaction of these compounds would be, however, the chelation of a single metal ion by the bidentate ligand.[3–5]

The donating capacity of the nitrogen atoms of compounds similar to 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene can be modified by the presence of *para* substituents on the phenyl ring. These substituents increase the ring charge, favouring the bidentate complex.

In this work the formation of a stable complex of $PdCl_2$ with 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene was studied. In the resulting compound the ligand was bidentate. Likewise, we have studied the reaction between 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene and $PdCl_2$ in a methanol solvent.

EXPERIMENTAL

Starting materials

Solvents of commercial quality were purified and dried by standard methods. $PdCl_2$ (Merck, anhydrous) with a minimum Pd of 59% was used without further purification. The ligands 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene and 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene were kindly supplied by Drs J. Plumet and R. Alvarez-Osorio of the Universidad Complutense de Madrid.

Compound preparations

A stoichiometric amount of the diimine (molar ratio 2.3 : 1) was added to a suspension of $PdCl_2$ in MeOH at room temperature. The mixture was stirred for 13 h. The precipitate was then collected by filtration, washed with methanol followed by diethyl ether, and finally vacuum dried at room temperature.

The analytical composition of the product obtained with 1,4 - di(*p* - methoxyphenyl) - 2,3 - dimethyl - 1,4 - diazabutadiene was: C, 45.9; N, 5.9; H, 4.3. Calc. for $PdCl_2(C_{18}N_2O_2H_{20})$: C, 45,4; N, 5.9; H, 4.2%.

For the product obtained from 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene the composition was: C, 39.7; N, 7.7; H, 4.0. Calc. for $PdCl_2(C_{12}N_2H_{14})$: C, 39.9; N, 7.7; H, 4.0%. The product $PdCl_2(C_{12}N_2H_{14})$ was recrystallized from dimethylformamide for crystallographic structural determination.

Physical methods

Chemical analyses were carried out using standard methods. IR spectra were run in hexachlorobutadiene mulls in the range 4000–1300 cm^{-1} between NaCl windows, and in Nujol mulls in the range 1650–200 cm^{-1} between CsI windows. The Raman spectra were measured with a Jarrell–Ash 25–300 using a Kr^+ laser as a source of excitation.

Crystallography and structure determination

Recrystallization of $PdCl_2(C_{12}N_2H_{14})$ from dimethylformamide produced the compound $PdCl_2(C_{12}N_2H_{14})\cdot 2C_3NOH_7$, whose X-ray structure analysis is reported here. There crystals, light yellow needles, decomposed in air through loss of solvent, and the crystal used for data collection was mounted in a sealed 0.3-mm Lindemann glass capillary tube in the manner commonly used for proteins.[6] One crystal of dimensions $0.10\times0.30\times0.10$ mm^3 was chosen for the preliminary work of orientation, lattice constants, and space group determination, and finally for data collection.

Precise geometric and intensity data were collected at room temperature on an automated four-circle diffractometer (Enraf–Nonius CAD-4), equipped with an Mo X-ray tube and a graphite monochromator ($\lambda = 0.7093$ Å). The unit-cell parameters and orientation of the crystal with respect to the goniometer reference frame were determined by a least-squares fit to the angular positions of 25 reflections. The compound was found to be monoclinic with space group $P2_1/n$. The cell constants were determined (at *ca* 22°C) as: $a = 13.783(3)$ Å, $b = 5.977(5)$ Å, $c = 14.878(4)$ Å; $\beta = 111.87(1)°$, $Z = 2$, $V = 1137.0(9)$ Å^3, $d_x = 1.49$ g cm^{-3}. The data were collected using the θ–2θ scan technique in the range $2\theta(Mo-K_\alpha) \leqslant 60°$. Standard reflections which were periodically remeasured during the course of data collection showed a decline in intensity. Of the 3614 independent data, 2605 with $I > 2\sigma(I)$ were considered to be observed; only these data were used in the subsequent calculations. The usual Lorentz and polarization corrections were applied to the raw data. No absorption correction was applied, however, as the linear absorption coefficient of this compound is small (~ 10.6 cm^{-1} for $Mo-K_\alpha$).

Structure solution and refinement

The structure was solved by the heavy-atom technique. Dimethylformamide molecules were located from a difference Fourier map. The function $\Sigma w(|F_o|-|F_c|)^2$ was minimized, with the weighting scheme $w = 1$. In the calculations of F_c, the neutral atom scattering factors for Pd, Cl, N and C were taken from Ref. 7(a). The effects of the anomalous dispersion of Pd and Cl were included. The values of $\Delta f'$ and $\Delta f''$ were taken from Ref. 7(b). Anisotropic refinement of these atomic positions gave $R = 0.050$ and $R_w = 0.049$. The H atom positions were located from a difference synthesis. Each H atom was assigned the $B_{eq.}$ of the atom to which it was attached and included in all further calculations, but the parameters were not refined. The final cycle gave $R = 0.047$ and $R_w = 0.046$ with 124 variables.

Calculations were carried out with the X-ray system[8] and program PARST[9] on a Univac 1100/80 computer. The maximum residual on a difference map was 1.14 *e* Å^{-3}, near the Pd atom.

Atom positional parameters, observed and calculated structure factors, as well as final anisotropic thermal parameters and coordinates for the H

atoms are listed in supplementary material deposited with the Editor.

Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The preparation of $PdCl_2(C_{12}N_2H_{14})$ may proceed by the route given in Scheme 1.

The complex is soluble in dimethylformamide, acetone, slightly soluble in methanol, dichloromethane and cyclohexane, and insoluble in benzene and heptane.

In the case of the *cis* compound, $PdCl_2(C_{18}N_2O_2H_{20})$, the electron-donating characteristics of the methoxy group in the *para* position make the N atom negative. This increases the donating capacity of the N atom with respect to the Pd(II) ion. In this way, the attack of the methanol molecules after forming the complex is avoided and the adduct can be formed. On the other hand, in the absence of the electron-donating methoxy group, the positive charge appearing on the N atom after formation of the complex would give some electrophilic characteristics to be double bond, so that the nucleophilic methanol molecules would attack and split the bond of the azomethine group. The compound formed in this case is insoluble in dichloromethane, cyclohexane and ether, slightly soluble in acetone, and soluble in dimethylformamide. Unfortunately, no crystal suitable for X-ray analysis could be obtained.

IR and Ramana spectra

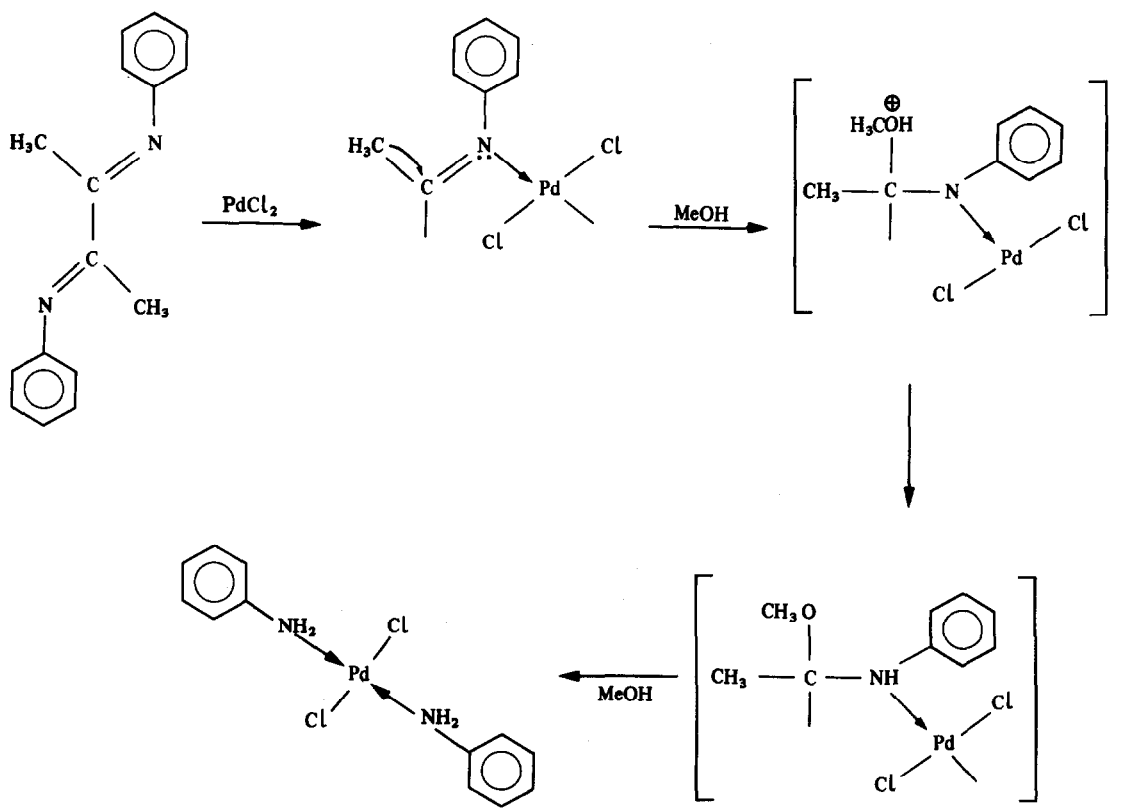
The IR and Raman spectra are discussed, particularly the metal–halogen and metal–ligand vibrations.

In order to interpret the IR spectra, we have divided these into two groups. From 4000 to 600 cm^{-1} all the bands are ligand bands.

In $PdCl_2(C_{18}N_2O_2H_{20})$ the bands at 2830 cm^{-1} (corresponding to the $-OCH_3$ group and 1632 cm^{-1} (corresponding to the —C=N— group) are shifted *ca* 10 cm^{-1} to lower frequencies with respect to those observed for the free ligand.

The product obtained in the reaction of $PdCl_2$ with 1,4 - diphenyl - 2,3 - dimethyl - 1,4 - diazabutadiene, $PdCl_2(C_{12}N_2H_{14})$, does not show a band corresponding to the —C=N— group, as well as three more bands corresponding to the C—H vibration in $-CH_3$.

Below 600 cm^{-1} the bands correspond to Pd—N and Pd—C vibrations. We attempted to assign the



Scheme 1.

bands observed in the IR spectra, taking into account the limitations imposed by the lack of a crystal structure for $PdCl_2(C_{18}N_2O_2H_{20})$.

Structural determination of *cis*- and *trans*-PdL_2Cl_2 or $PdL'Cl_2$ (where L and L' are mono- or bidentate ligands containing N donor atoms), shows that they have a square-planar coordination with bond angles of very nearly 90° about the Pd(II) ion. The selection rules for C_{2v} (*cis*) and D_{4h} (*trans*) symmetry may, therefore, reasonably be expected to apply, i.e. two ν(Pd—N) and two ν(Pd—Cl) IR-active bands for the *cis*-isomer and one of each for the *trans* isomer, and one ν(Pd—N) and one ν(Pd—Cl) Raman-active band in both isomers. The corresponding bending vibrations are expected to occur below 250 cm^{-1}.

The metal–halogen stretching vibrations are the most readily assigned. Often, it is particularly difficult to assign bands to the metal–nitrogen stretching. Although the Pd—N stretching frequency has been extensively investigated, the intensity of this vibration if often very weak and this frequency has not been reported by some authors who studied similar compounds.[10,11] Furthermore, a second difficulty in assigning the Pd—N frequencies arises from the overlap of the fundamental vibrations of the ligands with the Pd—N vibrations of the complex.

In *trans*-diammine dichloro-palladium, it would be expected that two prominent bands would appear in the Raman spectra of the complexes,[12] one near 500 cm^{-1} due to the symmetric metal–nitrogen stretching mode of vibration (B_{2g}) and the other the metal–chlorine symmetric stretching mode (B_{3g}) near 320 cm^{-1}. In the IR spectrum, the metal–nitrogen asymmetric stretching mode (B_{2u}) has a frequency close to that of the Raman-active metal–halogen stretching vibration.

In *cis*-diammine dichloro-palladium, as mentioned previously, two stretching vibrations of each type are expected in the IR spectra (A_1 and B_1 in C_{2v}-symmetry). The antisymmetric stretching vibration is the higher frequency of the two bands observed in the *cis* complexes for both the Pd—N stretching and Pd—X stretching modes.[13] In Raman spectra two vibrations (B_1) are expected.

The wavenumbers of the absorption bands in the far-IR region (600–250 cm^{-1}) are listed in Table 1. A "splitting" is observed in the bands near 300 cm^{-1} in the IR spectrum. The splitting may be due to an intermolecular crystal effect.

The Pd—Cl symmetrical vibration could be responsible for the band at 304 cm^{-1}. This vibration is theoretically Raman-inactive, but could become active as a consequence of certain geometrical distortions in the proximity of the Pd(II). Such distortions have been observed by means of X-ray diffraction in some Pd complexes.[14]

In the IR the broad band at 328 probably includes the ν_s(Pd—Cl).

Description of the structure

The complex consists of monomeric $PdCl_2(C_6H_7N)_2$ units and molecules of dimethylformamide as solvate.

The stereochemistry of the molecules is shown in Fig. 1.

The Pd atom is coordinated in a square-planar fashion to the Cl atoms and the N atoms. The Pd—N(1) and Pd—Cl distances of 2.054(5) and 2.300(2) Å, respectively, are comparable with values found in related complexes.[15–17]

Table 2 shows relevant interatomic distances and bond angles. Dimethylformamide molecules were found to be disordered.

The dihedral angle between the plane of the ring and the square plane around Pd is 109.1(1)°.

Crystal packing and hydrogen bonding

The packing of the molecules is completely determined by the N—H....Cl, C—H....Cl and N—H....O intermolecular hydrogen bonding.

Table 1. IR and Raman (R) assignments in the range 600–200 cm^{-1}

[a] Symmetry code: (0) x, y, z; (1) $-x+1, -y+1, -z+1$; (2) $-x+1, -y, -z+1$; and (3) $+x, +y-1, +z$.

There are two bifurcated hydrogen bonds, one involving H(12) which is shared by N(1) and Cl ($+x, +y-1, +z$) and Cl* ($-x+1, -y, -z+1$), and another involving H(7) which is shared by C(7) and Cl (x, y, z) and Cl* ($-x+1, -y+1, -z+1$). Another intermolecular hydrogen bond involves H(11) (see Table 3).

The distances of these hydrogen bonds agree well with the values published for other $PdCl_2$ complexes with ligands containing N donor atoms.[17,18]

Acknowledgements—We thank Professor García Ruano, of the Departamento de Química Organica de la Universidad Autónoma de Madrid, for many useful discussions, the Instituto de Química Inorgánica "Elhuyar" del C.S.I.C., Madrid, for recording the IR spectra, and Dr Fernández Herrero for recording the Raman spectra.

(*Received* 29 *April* 1986; *accepted after revision* 2 *September* 1986)

Abstract—The coordination compounds of Pd(II) and Pt(II) with thiodiacetic acid $[(H_2L)_2MX_2]$ [$H_2L = S(CH_2COOH)_2$, M = Pd or Pt, X = Cl or Br] were synthesized. Independently of the reaction conditions (aqueous or non-aqueous media) the complexes produced had the same structure. The vibrational spectroscopic data suggested that in the square-planar complexes of Pd(II) and Pt(II) the thiodiacetic acid is coordinated as a monodentate ligand through the sulphur atom and the oxygen atoms do not take part in the coordination to the central metal atom. The palladium complexes contain terminal metal–halogen bonds in the *trans* position but in the platinum complexes the *cis* configuration is more probable.

There is a growing interest in chelate sulphur-containing ligands which can be considered as simple models of biological systems. Studies on the complex formation between metal ions and these ligands can show how the direct synthesis of platinum and palladium complexes with coordination spheres of different stability can be carried out.

Studies on platinum and palladium coordination compounds with chelate ligands containing C—SH and COOH groups (such as cysteine[1–3]) showed that the ligand coordination depended on the reaction conditions.

Thiodiacetic acid is one of the simplest representatives of chelate ligands containing the S-donor functional group.[4] In complex formation thiodiacetic acid can be coordinated to a metal atom: (a) as a monodentate ligand through the sulphur atom or one of the oxygen atoms of the carboxylic group, (b) as a bidentate ligand through the sulphur atom and the oxygen atom of the carboxylic group, or (c) as a terdentate ligand through one sulphur and two oxygen atoms.

A number of thiodiacetic acid complexes with first-row transition metals (V, Cr, Mn, Fe, Co or Ni) are known.[5–6] The behaviour of thiodiacetic acid towards the ions of these metals has been studied in aqueous solution[5] and, according to the potentiometric and spectrophotometric data, the formation of 1:1 and 1:2 (metal: ligand) complexes has been established. Solid 1:1 complexes of type $ML \cdot nH_2O$ (M = Cr, Mn or Co, $n = 1$; M = Ni, $n = 3$) and the 1:2 complex Na_2NiL_2 have been prepared and characterized.[6] In these complexes thiodiacetic acid in the form of the thio-

* Author to whom correspondence should be addressed.

diacetate anion acts as a tridentate ligand, giving solid complexes of pseudo-octahedral symmetry.

The reaction of $K_2[PtCl_4]$ with  ,

yielding the compound  has been described,[7] but the authors did not discuss the structure of this complex and the bonding character of the ligand. Palladium complexes with thiodiacetic acid have never been reported previously.

The present work has involved the synthesis and investigations of IR and Raman spectra of some new Pd(II) and Pt(II) complexes with thiodiacetic acid.

EXPERIMENTAL

Materials

Starting substances for the preparation of Pd(II) and Pt(II) complexes with thiodiacetic acid were synthesized by methods described elsewhere: $S(CH_2COOH)_2$,[8] *trans*-$(C_6H_5CN)_2PdX_2$ (X = Cl or Br),[9] *cis*-$[(C_6H_5CN)_2PtCl_2]$,[10] and $K_2[MX_4]$ (M = Pt or Pd, X = Cl or Br).[11] All other chemicals were of analytical-reagent grade.

Spectra measurements

The IR spectra of the solid starting compounds and of complexes **I–VI** in the form of Nujol and Fluorolube mulls between CsI or KBr plates, or polyethylene windows, were obtained in the range 100–4000 cm^{-1} using a Bruker Fourier Spectrometer "IFS-113V". The Raman spectra of the powders H_2L and Na_2L, and of complexes **I** and **III** were obtained in the range 20–4000 cm^{-1} using a Raman or HG-2S spectrometer with an Ar^+-ion laser excitation at 5145 Å. The laser power varied from 50 to 200 mW.

Preparation of the complexes

All the complexes studied in this work were synthesized as follows.

$[(S(CH_2COOH)_2)_2PdCl_2]$ (**I**). Powdered thiodiacetic acid (0.0905 g, 0.6 mmol) was added to a filtered solution of *trans*-$[C_6H_5CN)_2PdCl_2]$ (0.1156 g, 0.30 mmol) in 15 cm^3 of benzene. The reaction mixture was stirred at room temperature for 3–4 h. The resulting yellow precipitate was filtered, washed in benzene and ethyl ether, and dried in air and *in vacuo*. The yield was 0.1342 g (93%).

$[(S(CH_2COOH)_2)_2PdBr_2]$ (**II**). 0.1418 g (0.94 mmol) of thiodiacetic acid was added to a filtered solution of *trans*-$[C_6H_5CN)_2PdBr_2]$ (0.2232 g, 0.47 mmol) in 15 cm^3 of benzene. The reaction mixture was stirred at room temperature for 3–4 h. The brown precipitate formed in the reaction was filtered, washed in benzene and ethyl ether, and dried *in vacuo*. The yield was 0.2497 g (93%).

$[(S(CH_2COOH)_2)_2PtCl_2]$ (**III**). 0.1281 g (0.27 mmol) of *cis*-$[C_6H_5CN)_2PtCl_2]$ was dissolved in 20 cm^3 of benzene for 2.5 h to complete dissolution and then filtered. 0.0842 g (0.54 mmol) of thiodiacetic acid was added to this solution. The reaction mixture was allowed to stir for 12 h. It was heated to 35–40° every 2 h. The yellow compound thus formed was filtered, washed in benzene and ethyl ether, and dried in air and *in vacuo*. The yield was 0.1228 g (79%).

$[(S(CH_2COOH)_2)_2PdCl_2]$ (**IV**). A solution containing 0.3109 g (0.95 mmol) of $K_2[PdCl_4]$ in 15 cm^3 of water was filtered and mixed with a filtered solution of 0.2859 g (1.90 mmol) of thiodiacetic acid in 10 cm^3 of water. Ten minutes after mixing, the resulting solution became green-yellow. It was evaporated under reduced pressure at 35–40°C, yielding a greenish-brown solid. This solid was dissolved in acetone, giving a potassium chloride precipitate which was filtered. The filtrate was left for slow crystallization and a pale-yellow compound was isolated. The yield was 0.3561 g (78%).

$[(S(CH_2COOH)_2)_2PdBr_2]\cdot 5H_2O$ (**V**). Filtered solutions of 0.5263 g (1.04 mmol) of $K_2[PdBr_4]$ in 15 cm^3 of water and 0.3133 g (2.08 mmol) of thiodiacetic acid in 10 cm^3 of water were mixed together. The colour of the resulting solution was unchanged. The solution was stirred at room temperature for 30 min and then evaporated under reduced pressure, forming a cherry-brown solid. The product was dissolved in acetone and the precipitated potassium bromide was removed by filtration. Slow crystallization of the filtrate gave a pale-brown powder. The yield was 0.5773 g (97%).

$[(S(CH_2COOH)_2)_2PtBr_2]$ (**VI**). A filtered solution of 0.3392 g (2.26 mmol) of thiodiacetic acid in 10 cm^3 of water was added to a filtered solution containing 0.6713 g (1.13 mmol) of $K_2[PtBr_4]$ in 15 cm^3 of water. The resulting solution became dark-red. After stirring and heating to 35–40°C for 5 min it became pale-yellow. The solution was evaporated dry under reduced pressure at 35–40°C. The solid was dissolved in acetone and the precipitated KBr was filtered off. Slow crystallization of the filtrate gave an orange product which was recrystallized from hot acetone. The product isolated after

removal of the solvent was dried in air and *in vacuo*. The yield was 0.4726 g (63%).

RESULTS AND DISCUSSION

Both aqueous and non-aqueous media were used to show the influence of the reaction conditions on the character of the H_2L interaction with Pd(II) and Pt(II) derivatives.

The reactions of *trans*-$[(C_6H_5CN)_2PdX_2]$ (X = Cl or Br) and *cis*-$[(C_6H_5CN)_2PtCl_2]$ with thiodiacetic acid (H_2L) using a 1:2 molar ratio in benzene solution produced the complexes $[(H_2L)_2PdCl_2]$ (**I**); $[(H_2L)_2PdBr_2]$ (**II**) and $[(H_2L)_2PtCl_2]$ (**III**). $[(H_2L)_2PdCl_2]$ (**IV**); $[(H_2L)_2PdBr_2]\cdot 5H_2O$ (**V**) and $[(H_2L)_2PtBr_2]$ (**VI**) were obtained in aqueous media using $K_2[PdX_4]$ (X = Cl or Br) and H_2L as starting compounds. An attempt to obtain a palladium complex containing four molecules of H_2L in the coordination sphere of palladium was not successful. The reaction of H_2L with *trans*-$[(C_6H_5CN)_2PdCl_2]$ in a 4:1 molar ratio only yields the product $[(H_2L)_2PdCl_2]$.

Analytical data for complexes **I–VI** are presented in Table 1.

All these complexes are thin, crystalline, coloured solids readily soluble in water and acetone, and insoluble in chloroform, carbon tetrachloride, ether and benzene.

A thermographic analysis of complexes **I, II, III** and **VI** showed that the complexes decompose before melting when heated in air (heating rate = 10°C min^{-1}). Decomposition of these complexes starts at 120°C for **I** and **III**, and at 170°C for **II** and **VI**, and is followed by endothermal effects.

The molecular weight of $[(H_2L)_2PdCl_2]$ was determined in aqueous solution using reverse ebullioscopy. The molecular weight value found is 480 (calc. 477.61) and suggested a monomeric structure for complex **I**.

The structure of complexes **I–VI** was established using vibrational spectroscopy. Spectra changes on going from the free ligand H_2L to complexes **I–VI** have been examined. The IR spectra of complexes **I** and **IV** and **II** and **V** are similar, showing that the structure of the complexes is the same whatever the method of synthesis.

The type of coordination of thiodiacetic acid to the metal atom was determined from the spectral changes obtained on going from the free ligand to complexes **I–VI**.

In the IR spectrum of H_2L the strong band of the asymmetric stretching vibration of the carboxylic group $\nu_{as}(COOH)$ at 1692 cm^{-1} was observed. The asymmetric stretching vibration of the deprotonated carboxylic group $\nu_{as}(CO_2^-)$ in thiodiacetate anion was found at 1592 cm^{-1} for the thiodiacetic acid sodium salt Na_2L. In the IR spectra of **I–VI** the $\nu_{as}(COOH)$ band at a frequency of about 1700 cm^{-1}, which is the same in H_2L and in complexes **I–VI**. This fact proves that the oxygen atoms of the carboxylic groups do not partake in the coordination with the central metal atom. Table 2 shows $\nu_{as}(COOH)$ as observed in the IR spectra of complexes **I–VI**.

The most pronounced changes in the IR spectra of **I–VI** and Raman spectra of **I** and **III** are observed in the low-frequency region (100–500 cm^{-1}), were metal–ligand and metal–halogen vibrations are manifest. Figures 1 and 2 show IR and Raman spectra in the low-frequency region of the ligand H_2L and of complexes **I** and **III**. In comparison with the free-ligand spectra, two new bands at 308 and 362 cm^{-1}, absent in the IR spectrum, were observed in the Raman spectrum of **I**.

A strong Raman line at 308 cm^{-1} is assigned to

the symmetric stretching vibration ν_s(PdCl), and the line at 362 cm^{-1} to the symmetric stretching vibration ν_s(PdS). The new bands at 350 and 370 cm^{-1}, observed in the IR spectrum and absent in the Raman spectrum, correspond to the asymmetric stretching vibrations ν_{as}(PdCl) and ν_{as}(PdS) respectively. The assignment is proved by the fact that on replacement of the chlorine atom by bromine, the band ν_{as}(PdCl) at 350 cm^{-1} in the IR spectrum of complex **II** disappears and a new band corresponding to ν_{as}(PdBr) appears at 253 cm^{-1}. The band of the Pd—S stretching vibration remains at 368 cm^{-1}.

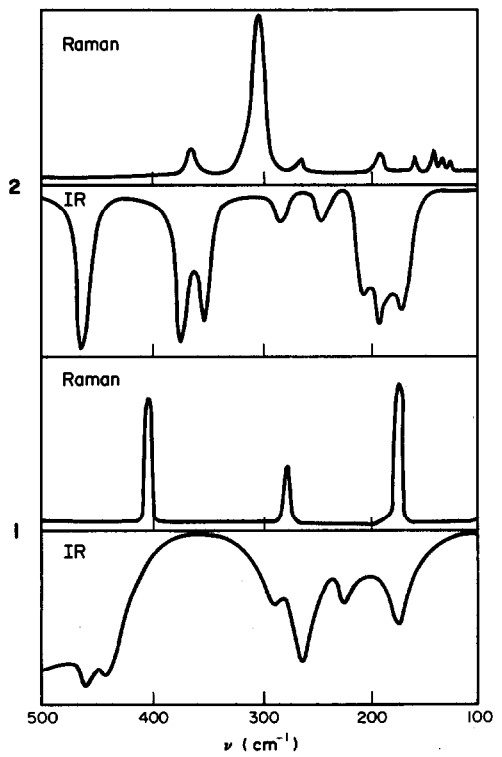

Fig. 1. Vibrational spectra of thiodiacetic acid (H_2L) (**1**) and of the complex $[(H_2L)_2PdCl_2]$ (**2**).

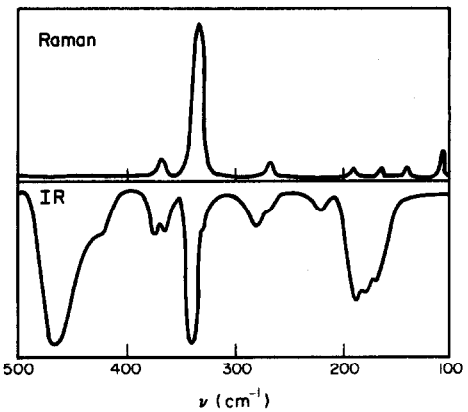

Fig. 2. Vibrational spectra of the complex $[(H_2L)_2PtCl_2]$.

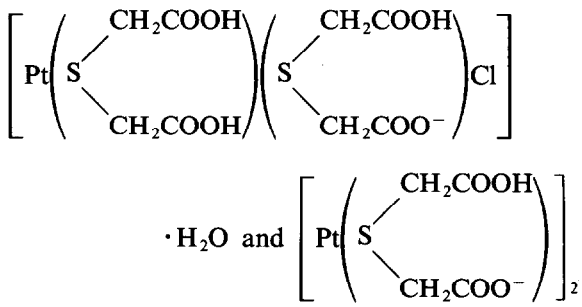
A comparison between IR and Raman spectral data solves the problem of geometric isometry for complex **I**. In the case of the *trans* configuration of metal–halogen bonds in square-planar complexes of type $[ML_2Cl_2]$(D_{2h}-symmetry), the symmetric metal–halogen vibration must appear only in the

Raman spectrum and is forbidden in the IR spectrum. On the other hand, the asymmetric metal–halogen vibration must be present only in the IR spectrum and is forbidden in the Raman spectrum (mutual exclusion rule). In the case of the *cis* configuration, moreover, the complexes $[ML_2Cl_2]$ have C_{2v}-symmetry and the metal–halogen vibrations are active both in the IR and in the Raman spectrum. The same is true for metal–sulphur vibrations. As follows from the data given in Table 2 and Fig. 1, complex **I** contains terminal metal–halogen bonds located in the *trans* position with respect to each other.

We have no Raman data for complex **II**, but its IR spectrum contains only one Pd—Br and only one Pd—S stretching band, from which we can conclude that this complex also shows a *trans* configuration.

In the case of the platinum complexes the situation is more difficult. Both in the IR spectrum of **III** and in the Raman spectrum only Pt—Cl stretching vibrations were found (Fig. 2). But the frequency of the strong Raman line at 338 cm^{-1} is near the strong IR band at 342 cm^{-1}. Due to the presence of the heavy Pt central atom, the separation distance between symmetric and asymmetric Pt—Cl vibrations is small.[11] We cannot be sure whether the second band is absent or present in the spectrum, because the bands are superimposed. The Pt—S stretching vibrations appear as the doublet 368/378 cm^{-1} in the IR spectrum. In consideration of this fact and also of the method of the synthesis of complex **III** from *cis*-$[Pt(C_6N_5CN)_2Cl_2]$ the *cis*-configuration seems to be more probable.



The *cis* configuration is also confirmed by the synthesis of the *cis* complexes when we used **III** as a starting compound (data to be published).

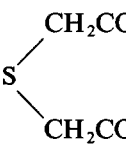
The IR spectrum of the complex **VI** is similar to the spectrum of **III**. The assignment of M—X (M = Pd or Pt, X = Cl or Br) and M—S (M = Pd or Pt) stretching vibrations proposed by us are in good agreement with literature data[12–15] for the related Pd(II) and Pt(II) complexes.

Thus, from the available spectral data we can conclude that, in the square-planar complexes **I–VI**, thiodiacetic acid is coordinated as a monodentate ligand through the sulphur atom and that chelate formation does not occur. This way of thiodiacetic acid coordination was unknown before.

It was interesting to compare the stability of the coordination sphere for the complexes $[(H_2L)_2MX_2]$ (M = Pd or Pt, X = Cl or Br) with that for triphenylphosphine (PPh_3) complexes. For this purpose the reaction of $[(H_2L)_2PdBr_2]$ (**II**) with PPh_3 was carried out. The aqueous solution of $[(H_2L)_2PdBr_2]$ (0.49 mmol) was stirred with the solution of PPh_3 (0.98 mmol) in ethyl alcohol and complex **VII** was produced. The yield was 81.62%.

In the IR spectrum of complex **VII**, the bands corresponding to the vibrations of thiodiacetic acid disappear and instead new bands due to the vibrations of the PPh_3 fragment of the emerging compound appear. The IR spectrum of complex **VII** in the region 400–4000 cm^{-1} is similar to that for *trans*-$[(PPh_3)_2PdCl_2]$. The band of the stretching Pd—Br vibration at 253 cm^{-1} remains in the IR spectrum of **VII**. All these results prove that PPh_3 replaces thiodiacetic acid in the inner coordination sphere yielding the complex *trans*-$[(PPh_3)_2PdBr_2]$, in agreement with the electron acceptor ability of neutral ligands.[16]

Thus, we have synthesized the unknown coordination compounds of Pd(II) and Pt(II) with thiodiacetic acid $[(H_2L)_2MX_2]$ (where H_2L =



, M = Pd or Pt, X = Cl or Br).

Independently of the reaction conditions (aqueous or non-aqueous media) the complexes produced are of the same structure. From the vibrational spectroscopy data we can conclude that in the above-mentioned square-planar complexes of Pd(II) and Pt(II) the thiodiacetic acid is coordinated as a monodentate ligand through the sulphur atom, and the oxygen atoms of the carboxylic groups do not take part in the coordination to the central metal atom. The palladium complexes **I**, **II**, **IV** and **V** contain metal–halogen bonds in the *trans* position. For the platinum complexes **III** and **VI** the *cis* configuration seems to be more probable.

VISIBLE ABSORPTION SPECTRAL MEASUREMENTS OF THE FORMATION OF THE COBALT PORPHYRIN DIOXYGEN COMPLEX USING A HIGH-PRESSURE CELL

KIAKI FUSE, TOSHIHIRO GOTO, KOICHI HASEGAWA, TAIRA IMAMURA* and MASATOSHI FUJIMOTO*

Department of Chemistry II, Faculty of Science Hokkaido University, Sapporo 060, Japan

(*Received* 17 *June* 1986 ; *accepted* 25 *September* 1986)

Abstract—The 1:1 complex formation between dioxygen and the *meso*-tetraphenylporphinatocobalt(II)pyridine complex in toluene was followed spectrophotometrically using a high-pressure cell. The values of the equilibrium constant K_p obtained are 0.0278, 0.0513, 0.0840, 0.157 and 0.278 atm^{-1} at −30, −36, −42, −48 and −54°C, respectively. The thermodynamic data are $\Delta H^{\ominus} = -10.1 \pm 0.6$ kcal mol^{-1} and $\Delta S^{\ominus} = -49 \pm 3$ eu at a standard pressure of 1 atm.

Studies of the reactions of metal complexes with molecular gases, O_2, N_2, CO_2 etc., are very interesting in relation to reactions such as oxygenation reactions, nitrogen fixation, and C_1 chemistry.

However, the gas adducts expected in the initial stages of the reactions are usually unstable or at very low concentration at room temperature, which causes difficulty in the characterization of those adducts. The concentrations of gas adducts are expected to be increased under the reaction conditions of high gas pressure and low temperature. In the present study a high-pressure cell was made for the trial and applied to the visible spectral measurements of the 1:1 complex formation between dioxygen and the *meso*-tetraphenylporphinatocobalt(II)pyridine complex, py·Co(II)TPP, in toluene.

EXPERIMENTAL

Co(II)TPP was synthesized by the literature method[1] and purified using a Soxhlet extractor. The complex was crystallized from the extracted ether solution and stored in a Schlenk tube under argon. Toluene, purified by successive treatments with H_2SO_4, H_2O, 5% NaOH and H_2O, and dried with $CaCl_2$ and 4A molecular sieves,[2] was distilled under argon before use. The volumes of the toluene solutions at low temperatures were corrected by extrapolations of the density–temperature linear relation obtained from the data[2] at 10, 20, 25 and 30°C to the low-temperature region. Pyridine was dried with 4A molecular sieves and distilled under argon. Absorption spectra were recorded on a Hitachi 808 spectrophotometer equipped with double-beam double monochromators.

The high-pressure cell (stainless steel, SUS 304)† with two optical windows was designed to measure the visible spectra of the solutions under a 150-atm pressure at low temperatures (> −80°C). The high-pressure cell system is illustrated schematically in Fig. 1. The Almax 1 glasses (Hoya glass works), usually used for adjustment of water level of a boiler, were used for the optical windows (33 mm in diameter × 16 mm thick) which withstand a 250 kg cm^{-2} (242 atm) high pressure. The transmittance of the glass were 27, 82 and 86% at 350, 400 and 450 nm, respectively. This tough window glass was used to avoid a sudden burst at high pressure.‡ The cell was dipped in a Dewar vessel (150-mm i.d.), with two optical windows (Pyrex), which is filled with dry ice–ethanol (4 l) as the cold source. Cloth bags containing dry ice were hung in the Dewar vessel from the edge of the vessel for the measure-

* Authors to whom correspondence should be addressed.

† Stainless steels such as SUS 410 which has a lower thermal expansion coefficient than SUS 304 must be of more practical use for avoiding gas leakage from the apparatus at low temperatures.

‡ Bengelsdijk and Drago[3] who measured the oxygenation reaction of Co(II)(PIXDME) using a similar high-pressure cell, have advised that the apparatus must be well-shielded and the oxygen pressure must never be increased rapidly.

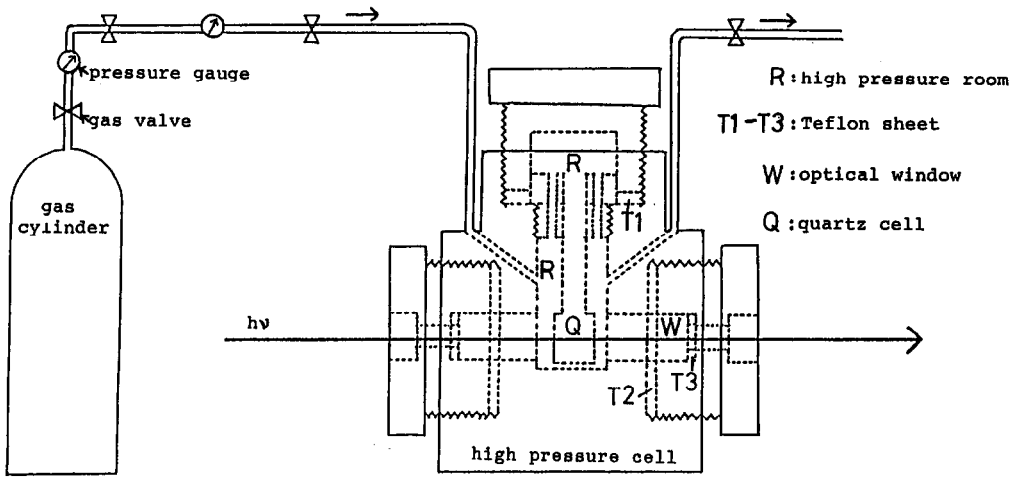

Fig. 1. Schematic diagram of the high-pressure cell system.

ments at −72°C. If dry ice was on the bottom of the vessel, many small bubbles from the dry ice interfered with the spectrophotometric measurements. When the spectral measurements were performed in the range of −72 to 0°C, the cold source of the bath was heated to an appropriate temperature. The bath was agitated continuously to maintain a constant temperature without a local temperature gradient. The high-pressure cell was connected to an oxygen cylinder with tubings (4-mm o.d.) through the pressure gauge [0–150 kg cm^{-2} (YR-506-2, Yamato Sangyo Co.)]. The valves (250K-1/4, CARP-316) for purging and stopping the oxygen gas were supplied by Fujikinzoku Kogyo. The temperature of the bath was monitored continuously using a copper–constantan thermocouple which was dipped in the middle portion of the Dewar vessel.

Measurements of the spectral changes using the high-pressure cell were performed as follows. Toluene was degassed by several freeze–pump–thaw cycles before the preparations of sample solutions in a glove bag filled with 1-atm pure dioxygen gas (>99.9% Nippon Sanso). The sample solutions containing Co(II)TPP and 1% (v/v) pyridine were prepared as quickly as possible to avoid any oxidation of the cobalt porphyrin before the measurements of the oxygenation reaction. The optical cuvette (10-mm path length) containing the sample solution was set up in the high-pressure cell, through which was passed dioxygen gas from a gas cylinder through tubings during the setting of the cuvette. It took about 1 h to equilibrate the reaction of the sample solution at a given pressure and temperature, and it needed about 2 h to measure a spectrum.

RESULTS AND DISCUSSION

Spectral measurements

Absorption spectrum of Co(II)TPP in toluene at −72°C has bands at 412 and 526 nm, and these bands shift to 410 and 535 nm when the solution contains 1% (v/v) (0.124 M) pyridine. This spectral change is due to the formation of a 1 : 1 pyridine adduct.[4] The equilibrium constants K_1 and the thermodynamic data have been reported to be $K_1 = 759$ M^{-1}† for py·Co(II)TPP and $K_1 = 485 \pm 29$ M^{-1}, $\Delta H^{\ominus} = -8.5$ kcal mol^{-1} and $\Delta S^{\ominus} = -16$ eu (cal mol^{-1} deg^{-1}) for py·Co(II)(*p*-CH_3)TPP[4] in toluene at 25°C. From these data, almost all (≃ 100%) the Co(II)TPP in 1% (v/v) pyridine–toluene was estimated to be the 1 : 1 pyridine adduct at lower temperatures than 0°C. The equilibrium constant K_2 for the 2 : 1 complex is much smaller than 1.[4] When oxygen gas was introduced into the sample solution at −72°C, the absorption spectrum showed new bands due to py·CoTPP·O_2 at 422 and 546 nm. The absorbance at 410 nm due to py·Co(II)TPP decreased with increasing oxygen pressure. The bands due to the pyridine adduct were recovered at −72°C when the solution was deoxygenated by freeze–pump–thaw cycles. If it takes a long time for the deoxygenation, the absorbance at 410 nm recovered is a little lower than that of the original solution, indicating the oxidation of a small amount of Co(II) porphyrin complex to the Co(III) complex.

The spectral changes in the visible region with

† Calculated from other data.[5]

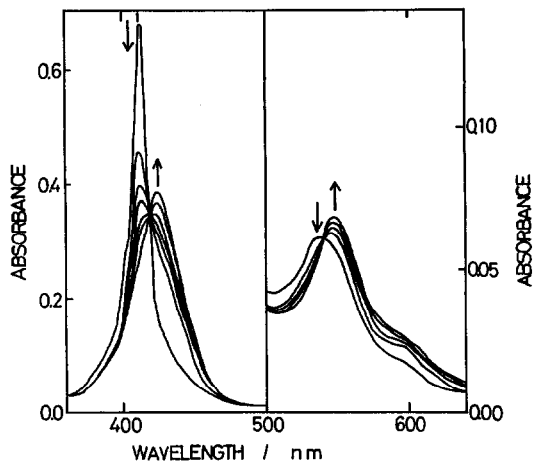

Fig. 2. Visible spectral changes accompanied by oxygen uptake at −40°C. First and final traces are the spectra at 1 and 60 atm, respectively.

increasing dioxygen pressure at −40°C are shown in Fig. 2. The absorbances at 410 and 535 nm due to py·Co(II)TPP decreased with a concomitant increase in the absorbances at 422 and 546 nm. More than 80% of complex is converted to the dioxygen adduct at 60 atm. This spectral changes showed isosbestic points. The diminution of the oxygen pressure from 60 to 1 atm caused the inverse spectral change, i.e. the absorbances at 422 and 546 nm decreased due to the deoxygenation reaction.

ESR spectra. The complex py·Co(II)TPP in toluene at −72°C shows an ESR spectrum ($g = 2.36$) analogous to the spectrum of B·Co(II)(p-OCH_3)TPP.[6] The signal height decreased on exposure to oxygen gas with the simultaneous appearance of a new spectrum at $g = 2.01$. The latter spectrum is similar to the spectrum of the dioxygen complex of the cobalt(II) protoporphyrin 1X-dimethyl ester.[7]

Thermodynamic data

For a general equilibrium reaction (1):

$$M + nL \rightleftharpoons ML_n \quad (K), \qquad (1)$$

if L has no absorption, the absorbance change can be expressed by $\log \{(A-A_0)/(A_\infty-A)\} = n \log [L] + \log K$, where A is the absorbance of the reaction system at a given wavelength, A_0 the absorbance due to the initial complex when [L] = 0, and A_∞ the limiting absorbance due to pure ML_n. The equation shows that n and $\log K$, respectively, can be evaluated from the slope and intercept of the linear plots, $\log \{(A-A_0)/(A_\infty-A)\}$ vs $\log [L]$, at a given temperature. In the following reaction (2):

$$py \cdot CoP + O_2 \rightleftharpoons py \cdot CoP \cdot O_2 \quad (K_p), \qquad (2)$$

A_0 and A_∞ are the absorbances of py·Co(II)TPP and py·CoTPP·O_2, respectively, and [L] can be expressed by pO_2, the equilibrium partial pressure of dioxygen. When A_∞ could not be obtained for a relatively high temperature system, e.g. at −30°C, the molar absorptivity of the dioxygen adduct evaluated at −72°C was used to determine the limiting absorbance. The absorbances for the plots were measured at 5–10 different pressures within the 10–90-atm range. The slope n obtained from the least-square plots fell in the range 0.96–1.03. The equilibrium constants obtained from the intercepts are summarized in Table 1, indicating a large dependence of the equilibrium constant K_p on the temperature. Thermodynamic data, $\Delta H^\ominus = -10.1 \pm 0.6$ kcal mol^{-1} and $\Delta S^\ominus = -49 \pm 3$ eu,† determined from the slope and the intercept of the van't Hoff plots (Fig. 3)

Table 1. Equilibrium constants and thermodynamic data for reversible O_2 binding to tetraphenylporphinatocobalt(II)pyridine in 1% (v/v) pyridine–toluene solution

Temperature (°C)	K_p (atm^{-1})	ln K_p
−30	2.78×10^{-2}	−3.58
−36	5.13×10^{-2}	−2.97
−42	8.40×10^{-2}	−2.48
−48	1.57×10^{-1}	−1.85
−54	2.78×10^{-1}	−1.28

$\Delta H^\ominus = -10.1 \pm 0.6$ kcal mol^{-1}
$\Delta S^\ominus = -49 \pm 3$ eu at standard pressure of 1 atm

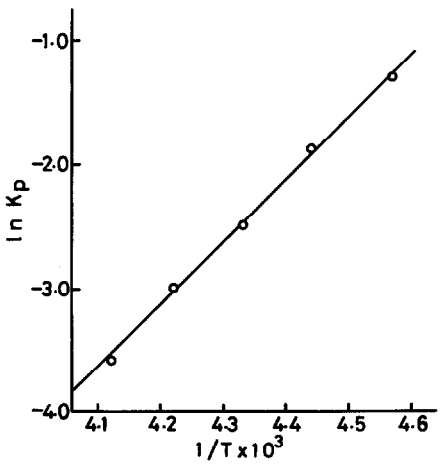

Fig. 3. van't Hoff plot for the oxygenation reaction of py·Co(II)TPP.

† Standard pressure is 1 atm. To convert to a standard pressure of 1 torr the quantity R ln 760 must be subtracted from this value. $\Delta S^\ominus = -62$ eu at a standard pressure of 1 torr.

do not differ significantly from the values of the cobalt(II) protoporphyrin 1X-dimethyl ester system[8,9] and cobalt(II) tetra(*p*-methoxyphenyl)porphyrin.[6] If the thermodynamic data, $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$, are extrapolated back to 25°C, the value of K_p is estimated to be 5.8×10^{-4} atm^{-1}, i.e. almost all the cobalt complexes exist as deoxygenated complexes at 1-atm dioxygen pressure. The K_p value for the system at −72°C is estimated to be 2.2 atm^{-1}, indicating at least 68% of cobalt(II). tetraphenylporphyrin exists as the dioxygen adduct at 1-atm pressure. Thus the equilibrium constants and the thermodynamic data of the 1 : 1 complex between dioxygen and α,β,γ,δ - *meso* - tetraphenylporphinatocobalt(II) in toluene were evaluated successfully by spectral methods using the high-pressure cell. We think the high-pressure cell is useful for spectrophotometric measurements of gas-participating reactions.

Abstract—The new ligands 1,4-diformylbenzene bishydrazone (DFBH) and 1,4-diacetylbenzene bishydrazone (DABH) have been prepared. DFBH forms complexes with transition metal(II) ions of types MX_2(DFBH) (M = Co, Ni, Mn, Zn or Cd, X = Cl; M = Co or Ni, X = SCN; M = Ni, X = Br) and $MX_2(DFBH)_2$ (M = Co, Ni, Mn, Zn, Cd or Hg, X = Cl; M = Ni or Mn, X = Br). DABH forms complexes of types $MX_2(DABH)_2$ (M = Co, Ni or Zn, X = Cl or Br; M = Co or Ni, X = Cl, Br or SCN) and $MX_2(DABH)_3$ (M = Co, X = Br or SCN; N = Ni X = Cl or SCN; M = Zn, X = Cl, Br or SCN). Electronic spectra, magnetic moments and IR spectra have been used to deduce probable structures of the complexes. All contain six co-ordinated metals in high-spin configurations except $ZnCl_2$(DFBH) and possibly $CdCl_2$(DFBH) which are tetrahedral. The reactions between cobalt(II) halides and DABH in acetone yield the tetrahedral complexes CoX_2(DABAZ), where DABAZ = the acetone azine of 1,4-diacetylbenzene hydrazone.

In order to use bishydrazones as chelating agents we have in recent years characterized complexes of the bishydrazones of 1,2-dicarbonyl compounds. Thus tetrahedral chelates are obtained from diacetylbisdimethylhydrazone[1] and diacetyl bismonomethylhydrazone[2] with several transition metal (II) ions while the bishydrazone of diacetyl forms octahedral chelates.[2] The resemblance between complexes of dimethylhydrazine [giving, for example,[3] tetrahedral $CoCl_2(Me_2NNH_2)_2$] and of hydrazine [giving[3] octahedral $CoCl_2(N_2H_4)_6$] with these bishydrazone complexes leads us to suspect that steric factors are largely responsible for the different co-ordination numbers. In contrast with the chelating bishydrazones, the bishydrazone of benzil forms pseudo-octahedral complexes, e.g.[4] $CoCl_2(PhC:NNH_2C:NNH_2Ph)_2$ which are probably polymeric with bidentate *N*-methine co-ordination of the ligand. All of these ligands contain the —N=C—C=N— grouping which is the characteristic group of some of the best known chelating agents, e.g. dimethylglyoxime, 2,2′-bipyridyl and 1,10-phenanthroline. The co-ordination chemistry of bishydrazones of 1,3-dicarbonyl compounds has not been studied because the reaction between these diketones and hydrazines leads to cyclization and the formation of pyrazoles. By increasing the carbonyl group separation, however, the bishydrazones can once again be obtained. In this paper we report on the ligands formed by reaction between hydrazine and 1,4-diformyl- and 1,4-diacetyl benzenes, i.e. DFBH (**1**) and DABH (**2**).

EXPERIMENTAL

Experimental techniques were as described previously[5] except that reflectance spectra were measured on a Perkin–Elmer 330 instrument over the range 40,000–6,6000 cm^{-1}. The anhydrous metal halides of cobalt, nickel and manganese were prepared by dehydration of the hydrated salts at 100°C *in vacuo*. The ligands 1,4-diformylbenzene bishydrazone (DFBH) and 1,4-diacetylbenzene bishydrazone (DABH) were prepared, by heating under reflux for 4 h, a mixture of the diketone (10 g) in absolute ethanol (250 cm^3) with an excess of hydrazine hydrate (25 cm^3). The bishydrazones crystallized on cooling to room temperature. Their analytical data are presented in Tables 1 and 2, and some of their IR bands in Table 4. DFBH was soluble in hot ethanol from which it could be recrystallized; DABH however had a very low solubility in ethanol but was more soluble in hot methanol. The ligands were further characterized by their melting points (DFBH, m.p. 157±1°C; DABH, m.p. 176±1°C) and NMR spectra in dimethylsulphoxide-d_6. [DFBH showed singlets at 6.85 ppm (NH_2 protons), 7.53 ppm (C_6H_4 protons) and 7.80 ppm (CH protons) from TMS with relative intensities 4:4:2; DABH showed singlets at 2.03 ppm (CH_3), 6.35 ppm (NH_2) and 7.63 ppm (C_6H_4) with relative intensities 6:4:4].

The preparation of complexes of DFBH was straightforward. The anhydrous metal salt and the ligand were dissolved in hot absolute ethanol, the solutions mixed and the mixture heated under reflux for 15 min. The mixture was filtered hot and the precipitate washed with hot ethanol and ether before being dried *in vacuo*. All reactions were carried out using reaction ratios of 4:1 and 1:4 (metal salt:ligand). For complexes of DABH, however, the low solubility of the ligand necessitated the use of a soxhlet apparatus. The metal salt was dissolved in methanol (which was a better solvent for DABH than ethanol) and the ligand contained in the thimble of a soxhlet extractor was continually extracted with hot methanol for several hours so that the extracts ran into the metal salt solution. For nickel and zinc complexes, precipitation occurred in the hot while the cobalt-containing solutions had to be cooled somewhat to achieve precipitation. The complexes were isolated as before.

The best solvent for DABH was acetone. Consequently, $CoCl_2$ (0.35 g, 2.7×10^3 mol) dissolved in hot acetone (25 cm^3) was added to DABH (2.05 g, 11×10^{-3} mol) dissolved in acetone (100 cm^2) and the mixture heated under reflux for 30 min. Upon cooling, a dark green precipitate formed; this was filtered off, washed with acetone and ether, and dried *in vacuo*. A similar reaction with $CoBr_2$ gave a dark blue-green precipitate but no compound precipitated when $Co(SCN)_2$ was used. Analytical data on these compounds were as follows. $CoCl_2$ complex—Found: C, 46.6; H, 5.44; N, 12.7. $CoCl_2C_6H_{22}N_4$ requires: C, 48.0; H, 5.55; N, 14.0%. $CoBr_2$ complex—Found: C, 39.4; H, 4.53; N, 10.9. $CoBr_2C_{16}H_{22}N_4$ requires: C, 39.3; H, 4.54; N, 11.5%.

RESULTS AND DISCUSSION

The addition–elimination reactions between hydrazine and 1,4-diformylbenzene and 1,4-diacetylbenzene produce the new ligands DFBH and DABH respectively, as crystalline solids. These have low solubilities in non-co-ordinating solvents but complexes have been prepared using hot ethanol as solvent for DFBH and hot methanol for DABH.

Complexes of DFBH have been prepared from Co(II), Ni(II), Mn(II), Zn(II), Cd(II) and Hg(II), and are of types MX_2(DFBH) and MX_2(DFBH)$_2$; their colours, analytical data and magnetic moments are given in Table 1. Complexes of DABH, however, have been isolated having the formulae MX_2(DABH)$_2$ (M = Co, Ni or Zn; X = Cl or Br; M = Co or Ni, X = NCS) and ; MX_2(DABH)$_3$ (M = Co, Ni or Zn, X = Cl; M = Co or Zn, X = Br; M = Ni or Zn, X = NCS); they are listed in Table 2. Unfortunately the complexes are insoluble in solvents such as chloroform and nitromethane so that measurements of solution spectra and molar conductivity have been precluded. The magnetic moments of the cobalt, nickel and manganese complexes of both ligands show that the complexes are all high-spin; the moments for the cobalt and nickel complexes are in the regions expected for six-co-ordinate metal ions, with much orbital contribution in the $t_{2g}^5 e_g^2$ cobalt(II) case and little in the $t_{2g}^6 e_g^2$ nickel(II) case. The electronic spectra of the cobalt (II) and nickel(II) complexes can also be assigned to transitions in pseudo-octahedral structures

(Table 3). The obvious tetragonality of the complexes is shown in the nickel(II) compounds where the $^3T_{1g}(F)$ level is often split into the two components ^3E_g and $^3A_{2g}$ of D_{4h}-symmetry. The band positions in the nickel complexes indicate[6] that the ligand field increases from N_2Cl_4 in $NiCl_2(DFBH)$ to N_4Cl_2 in $NiCl_2(DFBH)_2$ and to N_6 in $Ni(NCS)_2(DFBH)$. Unfortunately the *d–d* bands above 20,000 cm^{-1} are often obscured by the intense charge-transfer band which gives the com-

plexes their yellow colour or tinge. Similar ligand field changes are observable in the cobalt complexes but with less certainty because of the multiplicity of bands in the 18,000-cm^{-1} region. The spectra thus give evidence for co-ordination of the anions; the isothiocyanato complexes showing higher transition energies than their chloro analogues, which in turn show higher transition energies than the bromo analogues. The ligand field strengths of the two ligands being studied here are very similar to that of benzildihydrazone.[4]

Some important features of the IR spectra of the ligands and some of their complexes are shown in Table 4. The use of chloro, bromo and thiocyanato anions has enabled the identification of the mode of bonding of these moieties. Thus ν(M—Cl) in $ZnCl_2(DFBH)$ indicates terminal Zn—Cl bonds in a tetrahedral structure with bridging DFBH. In $ZnCl_2(DFBH)_2$ ν(Zn—Cl) moves to 225 cm^{-1} in the region expected[7] for terminal Zn—Cl bonds in an octahedral structure with two DFBH bridges between each zinc atom. Similarly the other MCl_2L_2 (L = DFBH or DABH) complexes show spectra consistent with their containing terminal M—Cl octahedral bonds. The absence of ν(M—Cl) in the mono-ligand complexes $CoCl_2(DFBH)$ and $NiCl_2(DFBH)$ is consistent with them containing bridging chlorides, the frequency of which is usually to be found below 200 cm^{-1}. The cadmium complex $CdCl_2(DFBH)$ shows a ν(Cd—Cl) at 275 cm^{-1} which is not present in $CdCl_2(DFBH)_2$ so that the mono-ligand complex might be the only other tetrahedrally coordinated complex with these ligands. The thiocyanato complexes all show ν(CN),

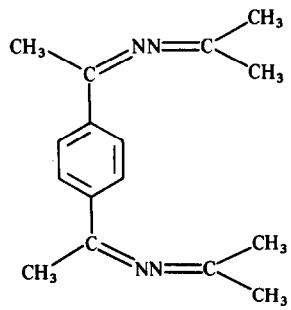
ν(CS) and δ(NCS) absorptions in the regions characteristically found for complexes containing terminal *N*-bonded isothiocyanate groups.[8] The ν(CS) band, being in the 788–800-cm^{-1} region, is probably too high in frequency for bridging thiocyanates which normally[9] give a band only a little higher than the free-ion value of *ca* 750 cm^{-1}. Further, bridging thiocyanates give[8,9] ν(CN) well above 2100 cm^{-1}. The occurrence of terminal *N*-bonded isothiocyanates is also in keeping with the electronic spectra in which no splitting of ν_1 or ν_2 is observed in the nickel complexes, and the ligand field is that of six N donor atoms around the metal with little distortion from octahedral symmetry.

The IR bands of principal interest in the ligands are ν(C=N) and ν(N—N) since the shift in these bands on complexing is often indicative of the mode of bonding of the ligand. We locate ν(C=N) in the ligands at 1580 cm^{-1} (DFBH) and 1586 cm^{-1} (DABH) this being the only band between 1500 cm^{-1} and the $\delta(NH_2)$ vibration at *ca* 1620 cm^{-1}. Very little shift in ν(C=N) occurs on complexing with the metal salts. A slight increase in ν(C=N) is usually observed[4,10] when the nitrogen atom of this bond (N^1) is bonded to a metal. The absence of such a shift in our complexes implies bonding of the ligand to metal via the aminic nitrogen atom (N^2). The N—H stretching modes ν_{as} and ν_s in the free ligands are at 3335 and 3158 cm^{-1} (DFBH), and 3328 and 3188 cm^{-1} (DABH). Upon co-ordination to the metal these frequencies are decreased; typically $CoCl_2$(DFBH) has ν_{as} at 3259 cm^{-1} and ν_s at 3115 cm^{-1}. Coordination by N^2 is again therefore implied. The N—N stretch in the ligands has been assigned to the bands at 1110 cm^{-1} (DFBH) and 1070 cm^{-1} (DABH) in accordance with the assignment in hydrazine[11] and other hydrazones.[1,2,4] The observed shift of ν(N—N) to higher frequencies upon bonding of the ligands is similar to that found in other hydrazone complexes.[1,2,4] Whilst bonding of hydrazone ligands to metals more usually occurs via N^1, coordination from N^2 is known to occur when bulky substituents occur on the imimic carbon atom.[12] It is noteworthy that, in complexes of benzildihydrazone, coordination by the azomethine nitrogen atom is favoured by the five-membered ring formation formed by the —N=C—C=N— grouping with the metal atom. No such possibility occurs with the present ligands. In the *mono-* and *bis*-ligand complexes prepared here then we believe the ligand to be bridging via the two —NH_2 groups, each —NH_2 group being bonded to a different metal atom. Curiously DABH forms *tris*-ligand complexes also. These do not appear to be *tris* chelates because there are no differences in the spectra of, for example, $NiCl_2(DABH)_2$ and $NiCl_2(DABH)_3$. The IR spectra of the *bis* and *tris* complexes are also similar and show no evidence of the presence of free ligand in the *tris* complexes. One possibility is that in the *tris* complexes the metal atoms are bonded to two anions, two nitrogen atoms from bridging hydrazones and two nitrogen atoms from unidentate hydrazones.

Whilst the inductive effect of the methyl groups in DABH would be expected to increase the basicity of the hydrazone over that of DFBH, the hydrazone of 1,4-dibenzoylbenzene would be expected to be appreciably less basic. We prepared this latter hydrazone and found that no complexes with cobalt(II) could be isolated even after many hours of heating the ligand and salt together in refluxing methanol.

The use of acetone as a solvent for DABH led to dark coloured cobalt complexes whose analytical data indicate them to be 1 : 1 complexes of the diacetone azine of DABH, i.e. the hydrazone has undergone an addition-elimination reaction with the acetone to give the azine DABAZ (**3**).



3

The magnetic moments of $CoCl_2$(DABAZ) and $CoBr_2$(DABAZ) are 4.6 and 4.5 BM, respectively, and their reflectance spectra confirm their tetrahedral structure, bands at 16,700 cm^{-1} (Cl^- complex) and 15,400 cm^{-1} (Br^- complex) being assigned to the $^4A_2 \rightarrow {}^4T_1(P)$ transition, and the bands at 9090 cm^{-1} (Cl^- complex) and 8700 cm^{-1} (Br^-) to the $^4A_2 \rightarrow {}^4T_1(F)$ transition. The IR spectra show ν(Co—X) at 340 and 315 cm^{-1} (X = Cl) and 264 cm^{-1} (X = Br), again clearly showing the halide ions to be terminal in tetrahedral structures. These complexes were unfortunately insoluble in organic solvents so other structural studies could not be undertaken; they may be polymeric with bridging and bidentate azines.

Abstract—The interaction of $MgMe_2$ or MeLi with $MOCl_4$ (M = W or Mo) leads to the paramagnetic (d^1) complexes $(Me_4MO)_2Mg(thf)_4$ and $(Me_4MO)Li(thf)_2$, respectively. The structure of $(Me_4WO)_2Mg(thf)_4$ has been determined by X-ray crystallography and shown to consist of Mg^{2+} co-ordinated by thf and square pyramidal Me_4WO^- units. The preparation of the diamagnetic rhenium(V) compound $(Me_4ReO)Li(thf)_2$ is also reported.

Prior to 1974 the only σ-bonded alkyl derivatives of high oxidation state tungsten that had been isolated were the methyl-, ethyl- and butyl-tungsten pentachlorides[1] and hexamethyl tungsten.[2] Increasing interest in the preparation of organo tungsten and molybdenum complexes, especially with the presence of an oxo ligand on the metal, is related to the reactivity of WCl_6[3] and $WOCl_4$[4] in combination with various alkylating agents as catalyst precursors in the alkene methathesis reaction. There are still relatively few tungsten and molybdenum oxo alkyls. These include the trigonal bipyramidal $MO(neopentyl)_3X$ (M = Mo or W, X = Cl or OR), prepared by the intereaction of $WOCl_4$ and dineopentylmagnesiumdioxane;[5] $W_2O_3(CH_2CMe_3)_6$ and WO_3R^- (R = CH_2CMe_3 or CH_2SiMe_3), prepared by hydrolysis of relevant alkylidyne complexes;[6] compounds of type $MoO_2R_2(bipy)$ (R = Me,[7] CH_2CMe_3[8] or CH_2Ph[9]); and MoO_3R^- species (R = Me, Et or Pr) observed in solutions.[10] Some oxo alkyls with a supporting cyclopentadienyl group, $(\eta^5\text{-}C_5H_5)W(O)_2(CH_2SiMe_3)(\eta^5\text{-}C_5H_5)W(O)(CH_2SiMe_3)_3$ and $(\eta^5\text{-}C_5H_5)W(O)(CHSiMe_3)(CH_2SiMe_3)$, have also been described,[11] the latter being the first instance of an oxoalkylidene complex prepared from an oxo alkyl complex. Tungsten alkyl and alkylidene compounds containing imido, neopentylidyne or cyclopentadienyl groups proved to be more readily accessible.[12]

All the above oxo alkyl complexes have M(VI) and the only compounds with a formal oxidation state (V) (d^1) are the metallabicyclic derivatives $\{[C_6H_4(CH_2)_2\text{-}o]_2WO\}_2Mg(thf)_4$[13] and $\{[(C_6H_4CH_2\text{-}2)]_2WO\}_2Mg(thf)_4$[14] prepared from the interaction of $WOCl_4$ and the appropriate di-Grignard reagent. Although the formation of such compounds has been initially attributed to the strong reducing properties of the relevant dianions we have shown that similar oxo complexes of rhenium(V) with unidentate alkyls[15] and aryls[16] can be easily obtained. We now extend our studies to methyl compounds of molybdenum, tungsten and rhenium.

Analytical data for the various compounds are collected in Table 1.

RESULTS AND DISCUSSION

Oxo methyl compounds of tungsten(V) *and rhenium*(V)

The alkylation of $WOCl_4$ by various methylating agents, including $HgMe_2$, $ZnMe_2$, $ZnMe_2$, $MgMe_2$ and MgMeI, has been thoroughly investigated by both Santini-Scampucci and Riess,[17] and Muetterties and Band[18] and $MeWOCl_3 \cdot OEt_2$ has been

isolated and characterized at low temperatures. It is surprising that no other species were obtained although when an excess of $MeMe_2$ was used the formation and subsequent decomposition of polymethylated tungsten derivatives was postulated.

The intereaction of $WOCl_4$ with three equivalents of $MgMe_2$ or six equivalents of MeMgCl in thf leads to good yields of a paramagnetic, orange-red crystalline complex of stoicheiometry $(Me_4WO)_2Mg(thf)_4$ that can be crystallized from toluene provided that a small amount of thf is always present. There are clearly several intermediates as indicated by colour changes from the early stages of the reaction at −78°C up to room temperature that are similar to those reported in the preparation of the chelating alkyl analogs.[13,14] The pale greenish solution formed initially at −78°C could be due to a reduced oxo (chloro)tungsten(V) species $[WCl_4O]^-$; the solution rapidly becomes reddish possibly due to $[WCl_5O]^{2-}$, and as the temperature approaches ambient levels turns to the final orange-red colour of the isolated product.

The IR spectrum of the compound shows peaks at 1030s.br, 1010sh, 945s, 920s.br and 880s.br cm^{-1} that can be assigned to skeletal vibrations of thf[19] and the $\nu(W{=}O)$ stretch—probably at 945 cm^{-1} by comparison with the rhenium analogue.[15] The broad band at 500 cm^{-1} is assigned to W—C vibrations,[13] and the bands at 360 and 310 cm^{-1} to Mg—O stretches.[20]

The compound is thermally stable—decomposition starts at *ca* 120°C—though less so than the rhenium analogue; it is exceedingly air-sensitive both in the solid state and in solutions, giving almost colourless products. Attempts to isolate the product from oxidation, possibly $WOMe_4$ whose rhenium analogue $ReOMe_4$ has long been known,[21] by regulating the oxidation step under various conditions were unsuccessful.

A diagram of the molecular structure is shown in Fig. 1; selected bond lengths and angles are given in Table 2. The molecule is isostructural with those of the analogous rhenium(V) complex,[15] and the definition of the structure is similarly affected by significant disorder in the orientation of the $Me_4W{=}O$ groups and the conformations of the thf molecules (see Experimental). Accordingly, the

geometry parameters for some parts of the molecule, especially the Me_4W and thf fragments, are very unreliable. The W—O—Mg and MgO_6 geometries are reasonable, however, and compare in an expected manner with the equivalent fragments in the Re compound. In particular, the W=O bond is some 0.04(1) Å greater than the Re=O distance.

The paramagnetic (d^1) $[WOMe_4]^-$ unit retains the square pyramidal geometry found for other similar d^1 or d^2 species, $ReOR_4$ (R = Me, CH_2SiMe_3, 2,4,6-Me_3-C_6H_2 or *o*-MeO-C_6H_4),[16,21] $ReOR_4^-$ [R = Me, CH_2SiMe_3 or *o*-$(CH_2O_2—C_6H_4]$,[15] and $W(\eta^5\text{-}C_5Et_3Me_2)Me_4$[12] from crystallographic studies or from ESR spectra; whereas d^0 cases, MO(neopentyl)$_3$X (M = Mo or W, X = Cl or OR),[5] $[W(\eta^5\text{-}C_5Me_5)Me_4]^+$,[22] $W(NPh)R_3X$ (R = Me, CH_2SiMe_3, CH_2CMe_3 or CH_2Ph; X = Cl or OR)[12] and the unstable $W(NPh)R_4$ (R = Me, CH_2SiMe_3),[12] all have been assigned trigonal bipyramidal structures. Although the two geometries are subject to facile interconversion[23] the tendency can be easily explained since the presence of non-bonding *d*-electrons on the equatorial plane forces the equatorial alkyl ligands below the plane to a square pyramidal geometry whereas the absence of *d*-electrons alows a trigonal bipyramidal geometry. On these grounds the d^0 complex $WOMe_4$ could be expected to be less stable than the d^1 species $[WOMe_4]^-$ or $ReOMe_4$ since in the former case the axial alkyl group *trans* to oxygen would be weakly bound; this is also clearly indicated by the relative instability of $W(NPh)R_4$ complexes compared to $W(NPh)R_3X$ (X–halide or alkoxide) compounds.

The interaction of $WOCl_4$ with six equivalents of MeLi in thf yields an orange-red, paramagnetic complex of stoichiometry $(Me_4WO)Li(THF)_2$ that can be crystallized from light petroleum as fine needles which collapse to a red powder *in vacuo* losing thf. The compound is soluble in aliphatic and aromatic hydrocarbons and ethers, but shows slow decomposition in halogenated solvents even in absence of air. The thermal stability of the complex is comparable to the magnesium solvate—decomposition starts at *ca* 110°C—but exhibits greater air sensitivity to, as yet, unidentified colourless products.

The IR spectrum shows broad bands at 1042s.br and 900s.br cm^{-1} that can be assigned to ν(W=O) and skeletal vibrations of the co-ordinated thf, but due to the broadness of the peaks further multiplicity is obscured and specific assignments cannot be made. The ν(W—C) stretch appears at 500 cm^{-1} and the Li—O vibrations at 420m and 380 cm^{-1}. The ESR spectrum is discussed below.

A thf-solvated lithium complex of identical stoicheiometry can also be obtained for rhenium by the interactionof $[Me_3NH][ReO_4]$ or Re_2O_7 with seven equivalents of MeLi per rhenium. This solvent-dependent compound crystallizes from light petroleum as orange-red needles. Rigorous exclusion of oxygen in the reaction mixture is essential since the compound oxidizes readily to the volatile, paramagnetic complex $ReOMe_4$.[21] the thermal stability of the rhenium compound is higher ($d > ca$ 175°C) only than the tungsten or molybdenum analogues.

The IR spectrum is uninformative in the ν(Re=O) stretch region due to the broadness of the co-ordinated thf peaks. The ν(Re—C) stretch appears at 518m cm^{-1} and the Li—O vibrations at 425 m and 360m cm^{-1}.

In contrast to the tungsten analogue the rhenium complex is diamagnetic; however, its ^1H NMR spectrum displays an unusual and not fully understood behaviour. At room temperature the methyl peaks are not observed but on lowering the temperature a very broad peak appears at *ca* 0°C which rapidly sharpens with decreasing temperature to give only a sharp singlet at δ 3.12 ppm at −60°C. The values for the co-ordinated thf are at δ 3.45 and 1.33 ppm. Even lower temperatures are needed in order to detect the methyl peak in the ^{13}C–$\{^1H\}$ spectrum; at −60°C only a weak band is observed for the methyl carbon at δ 27.84 ppm, whereas the co-ordinated thf appears at δ 67.97 and 25.53 ppm. Although in the case of the magnesium analogue[15] we attributed the broadening to non-rigid behaviour for the five-co-ordinate Me_4ReO grouping it now seems possible that the broadening could be attributed to unusually short spin–lattice relaxation times (T_1) probably due to coupling with the quadrupolar rhenium isotopes (^{185}Re and ^{187}Re, $I = \frac{5}{2}$). This has recently been shown to be the main relaxation pathway for Re–C interactions in $[Re_3(\mu\text{-}H)_4(CO)_{10}]^-$.[24] It has also been shown for this case that relaxation times increase with decreasing temperature, which might account for the sharpening of the peak at lower temperatures.

Oxo methyl compounds of molybdenum(V)

The interaction of $MoOCl_4$ with three equivalents of $MeMe_2$ or six equivalents of MeMgCl in thf affords good yields of an orange-red, paramagnetic complex of stoicheiometry $(Me_4MoO)_2Mg(thf)_4$. The compound can be obtained from toluene as fine orange-red plates; unlike the other thf-solvated magnesium complexes previously described, this compound is not particularly stable in aromatic hydrocarbons, and since toluene seems to be the only convenient solvent for crystallization there are obvious difficulties in its isolation. However, if the procedure of dissolving the extracts of the reaction and crystallizing the product from toluene is kept below 0°C the decomposition is minimal and the complex can be obtained pure as large plates; these can be separated from any black residue by hand picking under inert atmosphere. Once isolated the compound is thermally stable to *ca* 100°C and is soluble without decomposition in ethers and thf, though it is insoluble in aliphatic hydrocarbons and decomposes in halogenated solvents.

The reaction pathway is far from clear but reduction to molybdenum(V) probably precedes alkylation as it is known that $MeOCl_4$ decomposes rapidly to $MoOCl_3$[25] even at 25°C. The binding of four methyl groups is probably due to the small size of the ligand since a bulkier substituting aryl has been reported to yield a $MoOR_3$ complex (R = mesityl).[26] It is not thus surprising that the chelating *o*-xylenediyl ligand which gave isolable products in the case of tungsten[13] and rhenium[15] failed to yield analogous complexes for molybdenum. Schrock was also unable to prepare methylated species from the interaction of $(\eta^5\text{-}C_5Me_5)MoCl_4$ with various methylating agents,[12] whereas the tungsten analogue gave easily $(\eta^5\text{-}C_5Me_5)WMe_4$.

The IR spectrum shows the usual pattern of bands with the ν(Mo=O) stretch probably at 930s cm^{-1}, the ν(Mo—C) at 510 cm^{-1} and the Mg—O bands at 370 and 320 cm^{-1}.

When traces of oxygen were added to solutions of this very air-sensitive complex, a yellow-orange, extremely volatile and thermally unstable product could be detected, but could not be obtained in any substantial yield without extensive decomposition; it is probably $MoOMe_4$.

The interaction of $MoOCl_4$ with six equivalents of MeLi leads to the paramagnetic complex $(Me_4MoO)Li(thf)_2$ as red needles from light petroleum. The compound is stable in aliphatic hydrocarbons, ether and thf, though unstable in aromatic and halogenated hydrocarbons.

The thermal stability and air sensitivity of the complex is similar to that for the magnesium solvate.

Attempts to prepare tungsten and molybdenum complexes with the bulkier alkyls, neopentyl, trimethylsilylmethyl and benzyl, gave only oily thermally unstable materials.

ESR spectra of molybdenum and tungsten complexes

The ESR spectrum of $(Me_4WO)_2Mg(thf)_4$ at 98 K in a frozen toluene solution is characteristic of a

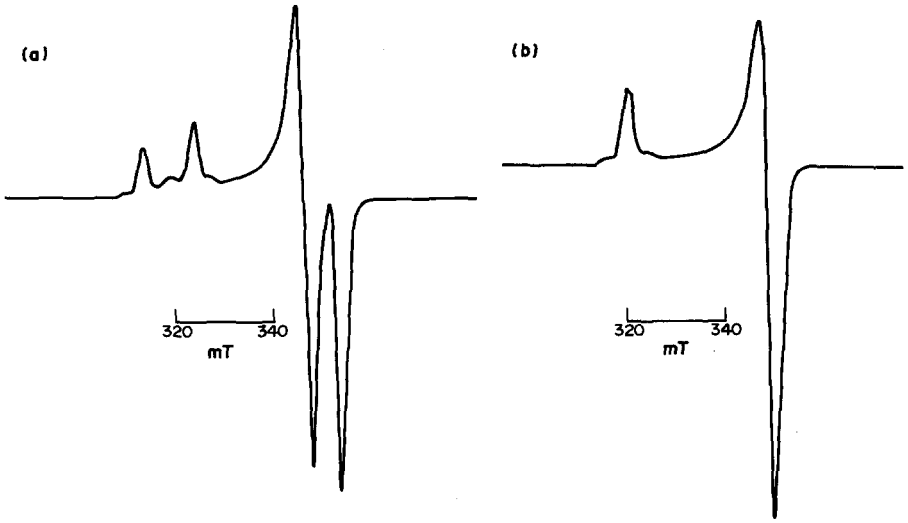

Fig. 2. ESR spectra (*X*-band) of: (a) $(Me_4WO)_2Mg(thf)_4$, and (b) $(Me_4WO)Li(thf)_2$ in toluene at 98 K.

square pyramidal molecule with $S = \frac{1}{2}$ (Fig. 2). The orientations in this axially symmetric spectrum are well separated, $g_{\parallel} = 2.075, g_{\perp} = 1.891$, but the most interesting feature is the splitting of the bands on each axis due to long range magnetic dipole–dipole interaction[27] between the two tungsten atoms in the molecule that give rise to a separation of *ca* 100 and 60 G for the parallel and perpendicular orientations, respectively. If this interaction is assumed to be of a purely dipole–dipole nature, the difference in the splitting along each axis can be roughly explained due to the term $3\cos^2 v - 1/r^3$, where v is the angle formed by the line joining the two tungstens and the external magnetic field, and r the tungsten–tungsten distance; for $v = 0°$ (parallel orientation) the interaction is expected to be twice as strong as that along the perpendicular axis ($v = 90°$). Hyperfine splitting due to ^{183}W ($I = \frac{1}{2}$, 14.40%) is also observed on both sides of the peaks for the parallel orientation but, due to the low natural abundance of the isotope, an accurate calculation of the hyperfine splitting cannot be made.

The ESR spectrum of $(Me_4WO)Li(thf)_2$ recorded under identical conditions (Fig. 2) suggests that the compound is a monomer at least in solution. The main features observed for the solvated magnesium analogue are once again evident in this spectrum, with a band appearing on each axis ($g_{\parallel} = 2.065$, $g_{\perp} = 1.902$) but no further splitting, due to interspace interaction, is observed. Hyperfine splitting with the ^{183}W isotope can also be seen while the substantial broadening of the bands—and probably four distinct unsymmetrical features on the shape of the curve at the parallel orientation—can be attributed to interaction with the ^{7}Li isotope ($I = \frac{3}{2}$, 92.58%).

Spectra of the molybdenum complexes appears to be more complicated since the parallel and perpendicular orientations are very closely spaced (the separation is estimated to be *ca* 100 G), and the hyperfine splitting arising from interaction with molybdenum isotopes (^{95}Mo: $I = \frac{5}{2}$, 15.72%; ^{97}Mo: $I = \frac{5}{2}$, 9.46%) has to be considered. However, the appearance of four dominant peaks in the spectrum of both the magnesium and the lithium solvate correlates better with the case of $(Me_4WO)_2Mg(thf)_4$, and both molybdenum complexes might be expected to be dimers in solution.

EXPERIMENTAL

Microanalyses were by Pascher, Bonn. Spectrometers: IR, Perkin–Elmer 683 (spectra in Nujol mulls, in cm^{-1}); NMR, Bruker WM-250 and JEOL FX-90Q (data in ppm relative to $SiMe_4$); ESR, Varian E12 (X-Band).

$WOCl_4$,[28] $MoOCl_4$,[29] $[Me_3NH][ReO_4]$[15] and Re_2O_7[30] were prepared by literature procedures. The tungsten and molybdenum oxo tetrachlorides were sublimed prior to use. Solvents were refluxed over sodium or sodium–benzophenone under argon, and distilled before use. The petroleum used has a b.p. of 40–60°C. All operations were carried out *in vacuo* or purified argon.

Tetrakis(tetrahydrofuran)magnesium bis[oxotetramethyl tungstate(VI)]

To a stirred solution of $WOCl_4$ (0.82 g, 2.40 mmol) in thf (30 cm^3) at −78°C was added MeMgCl (15 cm^3 of a 0.96 mol dm^{-3} solution in Et_2O, 14.4 mmol). The mixture was allowed to

warm to room temperature and stirring was continued for *ca* 1 h. The resulting orange-red solution was evaporated and the residue extracted with toluene (3×20 cm^3); the filtered extract was reduced to 40 cm^3 and cooled to -20°C to give orange-red polyhedra. The compound can be recrystallized from toluene–thf (1:1). Yield 0.28 g (28%). IR: ν(W=O), 945s; other, 1290m, 1240w, 1185m, 1170m, 1030s.br, 1010sh, 920s.br, 880s.br, 670m, 600m, 500m.br, 360m and 310m.

Bis(tetrahydrofuran)lithium[oxotetramethyl tungstate(V)]

To a solution of $WOCl_4$ (0.70 g, 2.05 mmol) in thf (30 cm^3) at -78°C with stirring was added MeLi (16.20 cm^3 of a 0.76 mol dm^{-3} solution in Et_2O, 12.31 mmol). The mixture was slowly allowed to warm to room temperature; the orange-red solution was evaporated and the residue extracted with light petroleum (3×20 cm^3). Filtration of the extracts, reduction to *ca* 40 cm^3, and cooling at -20°C gave orange-red needles. The compound can be recrystallized by dissolving the thf, followed by evaporation and extraction in light petroleum. Yield 0.22 g (26%). IR: 1290m, 1260w, 1240w, 1190m, 1170m, 1042s.br, 900s.br, 670m, 600m, 500m, 420m and 380m.

Tetrakis(tetrahydrofuran)magnesium bis[oxotetramethyl molybdate(V)]

To a stirred solution of $MoOCl_4$ (0.67 g, 2.64 mmol) in thf (30 cm^3) at -78°C was added MeMgCl (16.50 cm^3 of a 0.96 mol dm^{-3} solution in Et_2O, 15.84 mmol); the solution was allowed to warm and held at room temperature for *ca* 0.5 h. Evaporation and extraction of the residue at 0°C with pre-cooled toluene (3×20 cm^3) followed by filtration of the extracts at low temperature and reduction to *ca* 30 cm^3 led to orange-red plates on cooling at -20°C. The crystals are of analytical purity and can be separated from any black precipitate by hand picking. Yield 0.19 g (22%). IR: ν(Mo=O), 930s; other, 1290m, 1230w, 1180m, 1165w, 1035s, 1010sh, 920s.br, 880m.br, 675m, 600w, 510m, 370m and 320m. ESR: $g_\parallel = 1.967$, $g_\perp = 1.907$.

Bis(tetrahydrofuran)lithium[oxotetramethyl molybdate(V)]

To a stirred solution of $MoOCl_4$ (0.57 g, 2.25 mmol) in thf (30 cm^3) at -78°C was added MeLi (177 cm^3 of a 0.76 mol dm^{-3} solution in Et_2O, 13.45 mmol). The mixture was slowly allowed to warm to room temperature; the red solution was evaporated and the residues extracted with light petroleum (3×20 cm^3). Filtration of the extracts, reduction of *ca* 30 cm^3 and cooling at -20°C gave red needles, which were collected dissolved in thf. Evaporation and extraction in light petroleum gave the pure product on cooling. Yield 0.17 g (24%). IR: 1295m, 1250m, 1185m, 1160m, 1035s.br, 910s.br, 670m, 600m, 490m.br, 400m and 360m. ESR: $g_\parallel = 2.009$, $g_\perp = 1.924$.

Bis(tetrahydrofuran)lithium[oxotetramethyl rhenate(V)]

To a stirred suspension of $[Me_3NH][ReO_4]$ (1.0 g, 3.22 mmol) in thf (30 cm^3) at -78°C was added MeLi (29.7 cm^3 of a 0.76 mol dm^{-3} solution in Et_2O, 22.56 mmol). The mixture was allowed to warm up to room temperature and the resulting orange-red solution evaporated and the residues extracted with light petroleum (4×20 cm^3). Filtration of the extracts, reduction to *ca* 30 cm^3, and cooling at -20°C gave orange-red needles. Yield 0.31 g (23.5%). IR: 1290w, 1210w, 1170m.br, 1140sh, 1038s.br, 900s.br, 670m, 518m, 428m.br and 360m.br.

NMR (C_7D_8, -60°C): ^{1}H, 3.12 (3H, s, Me), 3.49 (2H, m, thf), and 1.33 (2H, m, thf); ^{13}C–{^{1}H}: 27.84 (s, Me), 67.97 (s, thf), and 25.53 (s, thf).

X-ray diffraction studies

The specimen used for structure analysis of $(Me_4WO)_2Mg(thf)_4$ was sealed under argon in a thin-walled capillary. All X-ray measurements were made on a CAD-4 diffractometer operating in the ω–2θ scan mode with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), following procedures previously described.[31] The structure was refined using full-matrix least squares, with the coordinates of the isomorphous rhenium compound as a starting point.[15] The same difficulties as those encountered with the rhenium compound were met—*viz.* disorder in the position of the set of four methyl groups attached to a tungsten and severe conformational disorder in the thf groups. The occupancies of the two sets of methyl carbons were fixed at 0.55 and 0.45, which gave comparable isotropic temperature factor coefficients for atoms of the two sets. A similar procedure was used to treat the carbons of the thf groups, each of which was split between two sites. The same occupancy factors were found to apply. Following the settled choice of occupancy factors, the partial carbons were allowed to refine anisotropically and, although some ellipsoids adopted rather anisotropic shapes,

all atoms remained positive definite and a significant reduction in the R value was achieved. Accordingly this model was considered to be acceptable. No hydrogen atoms were included, however. Details of the analysis are as follows:

Crystal data. $C_{24}H_{56}O_6MgW_2$, $M = 832.80$, triclinic, $a = 9.959(5)$, $b = 9.959(3)$, $c = 10.517(2)$ Å, $\alpha = 63.95(2)$, $\beta = 116.20(3)$, $\gamma = 104.09(3)°$, $V = 839.3$ Å^3, space group $P\bar{1}$, $Z = 1$, $D_c = 1.65$ g cm^{-3}, μ(Mo-K_α) = 66.03 cm^{-1}.

Data collection. $1.5 \leqslant \theta \leqslant 25°$, $T = 291$ K, 3251 data measured, 2941 unique, 2304 observed $[I > 2\alpha(I)]$; empirical absorption correction.

Refinement. 260 parameters, unit weighting scheme, $R = 0.032$. All calculations made on a DEC VAX 11/750 computer with programs as specified in Ref. 31.

Final atomic positional and thermal parameters, bond lengths and angles, and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

(*Received* 16 *September* 1986; *accepted* 10 *October* 1986)

Abstract—The interaction of $FeCl_2(dmpe)_2$ [dmpe = 1,2-bis(dimethylphosphino)ethane] with RCN (R = Me or Et) gives the partially substituted complex *trans*-$[FeCl(NCR)(dmpe)_2]Cl$ at room temperature, but in refluxing RCN in the presence of $NaBPh_4$ the product is *trans*-$[Fe(NCR)_2(dmpe)_2](BPh_4)_2$. The X-ray crystal structure of the acetonitrile complex has been determined. No reaction is observed between $RuCl_2(dmpe)_2$ and MeCN, although the disubstituted complex can be made in a similar way to the iron analogue. The interaction of *trans*-$[M(NCMe)_2(dmpe)_2][BPh_4)_2$ (M = Fe or Ru) with H_2 leads to the amine complexes *trans*-$[M(H_2NEt)_2(dmpe)_2](BPh_4)_2$. Although the ethylamine can be removed on refluxing in MeCN the complexes do not act as catalysts. Addition of MeCN to $FeCl_2(PMe_3)_2$ yields only the complex $[FeCl(NCMe)(PMe_3)_2]Cl$; $RuCl_2(PMe_3)_4$ reacts in refluxing MeCN in the presence of $NaBPh_4$ to give *trans*-$[Ru(NCMe)_2(PMe_3)_4](BPh_4)_2$.

We have recently reported the synthesis and reactivity of the Cr(II) nitrile complexes *trans*-$[CrCl(NCR)(dmpe)_2]^+$ and *trans*-$[Cr(NCR)_2(dmpe)_2]^{2+}$ [R = Me or Et, dmpe = 1,2-bis(dimethylphosphino)ethane].[1,2]

We now report the synthesis and characterization of the analogous complexes of Fe(II) and Ru(II), including the products of hydrogenation.

RESULTS AND DISCUSSION

1,2-*Bis*(*dimethylphosphino*)*ethane complexes*

Interaction of $FeCl_2(dmpe)_2$[3] with MeCN at room temperature leads to a pink solution of *trans*-$[FeCl(NCMe)(dmpe)_2]Cl$ (**1**) which can be isolated as bright pink crystals. A similar reaction has been reported for the complex $FeCl_2(depe)_2$ [depe = 1,2-bis(diethylphosphino)ethane],[4] where replacement of the second chloride could readily be accomplished by addition of $NaBPh_4$ at room temperature. If $NaBPh_4$ is added to a MeCN solution of **1** only *trans*-$[FeCl(NCMe)(dmpe)_2]BPh_4$ (**1b**) is isolated. Reaction of **1b** with excess $NaBPh_4$ in refluxing MeCN yields the bright yellow *trans*-$[Fe(NCNe)_2(dmpe)_2](BPh_4)_2$ (**2**), whose structure has been confirmed by X-ray crystallography (see below).

Unlike the analogous chromium complexes,[2] **1** and **2** are unaffected by air and methanol, and are 1 : 1 and 1 : 2 electrolytes, respectively, in MeCN.

The IR spectra of **1** and **2** are similar to their depe analogues, where the monosubstituted complex (**1**) shows a decrease in the C≡N stretch (2240 cm^{-1}) compared to "free" MeCN (2255 cm^{-1}). The decrease in the ν(C≡N) upon coordination may be due to decreased CN bond order caused by π-bonding between the metal *d*-orbitals and the π^*-orbitals of the CN group.[5] This π-bonding is pre-

* Authors to whom correspondence should be addressed.

sumably minimal for the disubstituted complex (**2**) as no change in the C≡N stretch is observed (2255 cm^{-1}).

Both **1** and **2** are diamagnetic, low-spin d^6, showing sharp ^1H NMR spectra with a slight down-field (more positive δ) shift of the methyl signal for the coordinated MeCN, compared to free MeCN.

Complex **2** has been made previously by the reduction of $FeCl_2(dmpe)_2$ with sodium naphthalide followed by addition of HSO_3CF_3 in MeCN.[6]

The use of proprionitrile leads to the formation of *trans*-[FeCl(NCEt)(dmpe)$_2$]X (**3**) (X = Cl or BPh_4) and *trans*-[Fe(NCEt)$_2$(dmpe)$_2$](BPh_4)$_2$ (**4**) (see Experimental).

The bright yellow complex *trans*-[Ru(NCMe)$_2$(dmpe)$_2$](BPh_4)$_2$ (**5**) can be prepared similarly. However no ionic species were observed when $RuCl_2(dmpe)_2$[7] was dissolved in MeCN (Λ_M = 34 ohm cm^2 mol^{-1}). Spectroscopically **5** is similar to the iron complex (see Experimental and Table 1).

X-ray crystallography

A diagram of the cation structure is shown in Fig. 1; selected bond lengths and angles are given in Table 2. The structure is analogous to that of the Cr(II) complex, the structure of which has been determined as the $CH_3CO_2^-$ salt.[1] The most interesting features of the geometry relate to the comparison between this structure and that of the Cr(II) complex which is low-spin d_2^4 paramagnetic. The M—N (nitrile) distances are essentially equal at 1.905(7) (Fe) and 1.906(6) Å (Cr), but the Fe—P distances [2.264 and 2.270(4) Å] are significantly shorter than the Cr—P distances [2.364–2.392(3) Å]. All other things being equal, we would expect Fe(II)—X distances to be considerably smaller than Cr(II)—X distances just on the basis of trends in bond radii. Additionally, we would expect M$d\pi \rightarrow$ P$d\pi$ back bonding to be maximized for the Fe(II) t_{2g}^6 system and thus further shorten the Fe—P bond relative to the Cr—P bond. It is possible therefore that some of the Fe—P shortening is due to π-bonding, and that perhaps the acetonitrile ligand in the Fe complex which appears not to be involved in any $d\pi$–$p\pi$ backbonding (see above) is also being squeezed out along the axis by the tighter packing of the two dmpe ligands.

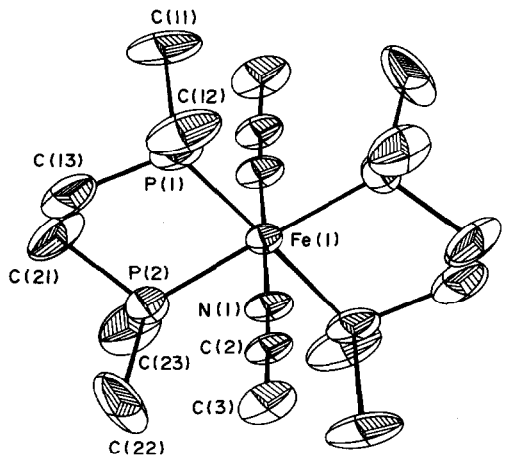

Fig. 1. Structure of the cation $[Fe(NCMe)_2(dmpe)_2]^{2+}$.

trans-[M(NCMe)$_2$(dmpe)$_2$](BPh_4)$_2$ (M = Fe or Ru) react readily with H_2 (3 atm) at room temperature in MeCN, to give the ethylamine complexes *trans*-[M(H_2NEt)$_2$(dmpe)$_2$](BPh_4)$_2$ [M = Fe (**6**) or Ru (**7**)].

The IR spectra show broad ν(N—H) bands about 3220 cm^{-1}. In addition to dmpe and BPh_4 peaks (Table 1) the ^1H NMR show a quartet [δ 3.30 ppm, J(H–H) = 7.0 Hz (**6**); 3.26 ppm, J(H–H) = 7.1 Hz (**7**)] and a triplet [δ 1.09 ppm, J(H–H) = 7.0 Hz (**6**); δ 1.09 ppm, J(H–H) = 7.1 Hz (**7**)] due to the ethyl group. The signal due to the amine N—H protons appears as a singlet partly overlapping the phosphine methylene signal.

The coordinated ethylamine can be liberated from **6** and **7** on refluxing in MeCN. We have, however, been unable to find suitable conditions for the catalytic hydrogenation of MeCN using **2** or **5** as catalysts, even under thermal (150°C, 1500 psi) or photochemical conditions (254 nm, 80 psi).

There has been considerable study of non-catalytic hydrogenation of nitriles using cluster complexes of iron, ruthenium and osmium.[8] Although direct hydrogenation of nitrile and imine groups has been observed,[8(c),9] the majority of these transformations have involved the formation of metal hydride intermediates. Catalytic reduction has recently been observed for $(C_5H_5)_2ScH$[10] and $[RuCl(dppb)(MeCN)_3]^+$ [dppb = 1,4-bis(diphenylphosphino)butane].[11]

Trimethylphosphine complexes

Addition of MeCN to $FeCl_2(PMe_3)_2$[12] at room temperature leads to an orange solution of [FeCl(NCMe)(PMe_3)$_2$]Cl (**8**) which can be isolated as bright orange crystals. Refluxing $FeCl_2(PMe_3)_2$ in MeCN with an excess of $NaBPh_4$ does not substitute the second chloride but forms the tetraphenylboron salt (**8b**). The complex is air-stable and a 1 : 1 electrolyte.

The IR spectrum of **8** contains two weaks bands in the C≡N stretch region. One is the ν(CN) band (2300 cm^{-1}) and the other (2310 cm^{-1}) a com-

bination band resulting from the symmetrical CH_3 deformation and the C—C stretch which borrows intensity from the ν(CN) band.[13] If CD_3CN is used the band at 2310 cm^{-1} is not present and the C≡N stretch becomes more intense. The complex is paramagnetic showing a broad ^1H NMR spectrum.

No reaction is observed between $RuCl_2(PMe_3)_4$[14] and MeCN; however on refluxing in the presence of two equivalents of $NaBPh_4$ *trans*-$[Ru(NCMe)_2(PMe_3)_4](BPh_4)_2$ (**9**) is formed.

Besides bands due to the phosphine and tetraphenylborate the IR spectrum contains a strong band at 2270 cm^{-1} due to coordinated MeCN. The ^1H NMR shows a down-field shift of the methyl CH_3 peak, whilst the *trans* configuration is confirmed by a singlet in the ^{31}P–$\{^1H\}$ NMR spectrum (δ −1.16 ppm).

No reaction is observed between **8** and **9** with hydrogen (100°C, 180 psi).

None of the above complexes show any evidence of reduction of the metal and the concurrent formation of the $(H \cdot MeCN)^+$ species, as has been found for the chromium complex.[2]

EXPERIMENTAL

Microanalyses were by Imerial College Laboratories. Melting points were determined in sealed capillaries and are uncorrected. IR spectra were recorded on a Perkin–Elmer 683 grating spectrometer in Nujol mulls (4000–400 cm^{-1}). NMR spectra (in CD_3CN) were recorded on a JEOL FX90Q spectrometer, and data are given in Table 1. Conductivities were determined in MeCN on a Data Scientific PT1-18 instrument. High-pressure reactions were carried out in a Berghof Autoclave. All manipulations were carried out under argon. Solvents were distilled and degassed before use. Analytical data are collected in Table 3.

trans - *Acetonitrile* - *bis*[1,2 - *bis*(*dimethylphosphino*)*ethane*] *chloroiron*(II) *chloride* (**1**)

To $FeCl_2(dmpe)_2$ (0.46 g, 1.08 mmol) was added MeCN (30 cm^3). As the solid dissolved the colour changed from green to pink. Stirring was continued until all the solid had dissolved. The solution was filtered, concentrated and cooled to −20°C to yield pink crystals. Yield 0.45 g (90%), m.p. 180°C.

IR : 2240m, 1420s, 1300m, 1285s, 1245m, 1145w, 1140w, 1075m, 1035m, 940vs, 895s, 840s, 800m, 740s, 705s, 645s.

Conductivity (MeCN): $\Lambda_M = 156\ \Omega\ cm^2\ mol^{-1}$.

The tetraphenylborate salt (**1b**) was obtained by the addition of one equivalent of $NaBPh_4$ to a MeCN solution of **1**. Filtration followed by removal of the solvent yielded a pink solid. Yield *ca* 100%, m.p. 217°C (dec.).

IR: 3060m, 3040m, 2240m, 1900w, 1880w, 1845w, 1750w, 1580m, 1425m, 1305m, 1280w, 1270m, 1105br.m, 1090s, 1040m, 935vs, 875m, 845m, 755m, 740s, 710s, 615s, 410m.

Conductivity (MeCN): $\Lambda_M = 151\ \Omega\ cm^2\ mol^{-1}$.

A MeCN (50 cm^3) solution of **2** (0.40 g, 0.37 mmol) was pressurized with H_2 (3 atm) in an autoclave. The solution was stirred at room temperature for 12 h. After releasing the pressure, the solution was transferred to a flask and cooled (−20°C) to give bright yellow crystals, further crystals were obtained on reducing of the filtrate. Yield 0.29 g (73%), m.p. 187°C (dec.).

IR: 3220w, 3060m, 3040m, 1950w, 1890w, 1835w, 1750w, 1580m, 1420m, 1310m, 1295s, 1270m, 1150m, 1140m, 1075m, 1065m, 1035m, 940s, 930s, 890s, 845m, 795m, 750m, 735s, 715s, 705m, 650m, 615s, 465w, 435m.

Conductivity (MeCN): $\Lambda_M = 210\ \Omega\ cm^2\ mol^{-1}$.

trans - *Bis*[1,2 - *bis*(*dimethylphosphino*)*ethane*] *bis*(*ethylamine*)*ruthenium*(II) *bis*(*tetraphenylborate*) (**7**)

As for **6** but using **5**. Yield *ca* 90%. m.p. 193°C (dec.).

IR: 3220w, 3020m, 1950w, 1870w, 1820w, 1575m, 1435m, 1300w, 1270m, 1185m, 1155m, 1150m, 1030s, 950m, 850m, 745vs, 730vs, 705vs, 620m, 610s, 605vs, 490m, 465m.

Conductivity (MeCN): $\Lambda_M = 217\ \Omega\ cm^2\ mol^{-1}$.

Acetonitrile chlorobis(*trimethylphosphine*) *iron*(II) *chloride* (**8**)

To solid $FeCl_2(PMe_3)_2$ (2.50 g, 139 mmol) was added MeCN (100 cm^3). The solution rapidly became bright orange and orange solid was deposited on stirring for 2 h. The solid was filtered and dried *in vacuo*. Further solid can be obtained on cooling the supernatant. Yield 1.98 g (65%), m.p. 145°C (dec.).

IR: 2310w, 2300w, 1440m, 1310m, 1290s, 1275w, 1100m, 1045m, 985m, 955vs, 945sh, 870m, 730s, 675m, 435w.

Conductivity (MeCN): $\Lambda_M = 123\ \Omega\ cm^2\ mol^{-1}$.

Refluxing a MeCN solution of **8** in the presence of $NaBPh_4$ (1 equivalent) yields the tetraphenylborate salt (**8b**). Yield *ca* 60%, m.p. 161°C (dec.).

IR: 3030m, 3020m, 2315w, 2300w, 1950w, 1890w, 1820w, 1750w, 1585m, 1425m, 1405w, 1305m, 1290m, 1265m, 1150s, 1100w, 1065m, 1040m, 1015w, 955m, 950s, 860m, 745vs, 735vs, 710vs, 630m, 620s, 605s, 490m, 470w.

Conductivity (MeCN): $\Lambda_M = 120\ \Omega\ cm^2\ mol^{-1}$.

trans - *Bis*(*acetonitrile*)*tetrakis*(*trimethylphosphine*) *ruthenium*(II) *bis*(*tetraphenylborate*) (**9**)

To a solution of $RuCl_2(PMe_3)_4$ (0.30 g, 0.63 mmol) in MeCN (100 cm^3) was added solid $NaBPh_4$ (0.43 g, 1.26 mmol). The solution was gently refluxed for 12 h, then cooled and the colourless solution filtered, concentrated and cooled to −20°C giving colourless crystals. Yield 0.46 g (65%), m.p. 148°C (dec.).

IR: 3035m, 2270m, 1950w, 1905w, 1835w, 1755w, 1570m, 1430m, 1425m, 1300m, 1290m, 1265s, 1150m, 1085m, 1025m, 940s, 845m, 740vs, 700vs, 625m, 610s, 600s, 505m, 500m, 470w.

Conductivity (MeCN): $\Lambda_M = 235\ \Omega\ cm^2\ mol^{-1}$.

X-ray crystallography

The crystal of $[Fe(NCMe)_2(dmpe)_2]BPh_4$ used for structure analysis was sealed under argon in a thin-walled glass capillary. All X-ray measurements were made on a CAD-4 diffractometer operating in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), following procedures previously described in detail.[15] The structure was solved and refined via the heavy-atom method and full-matrix least squares in a routine manner. All non-hydrogen atoms were refined anisotropically and, although most hydrogen atoms were located in difference maps, those on the phenyl and methylene groups were included in idealized positions and refined as parts of rigid groups with group isotropic U values; methyl hydrogens, however, were located experimentally and freely refined isotropically. Crystallographic details are as follows.

Crystal data. $[C_{16}H_{38}N_2P_4Fe]^+[C_{24}H_{20}B]^-_2$, $M_w = 1076.69$, triclinic, space group $P\bar{1}$, $a = 12.239(2)$, $b = 13.129(4)$, $c = 12.207(4)$ Å, $\alpha = 63.62(2)$, $\beta = 118.96(2)$, $\gamma = 117.10(2)°$, $V = 1463.4$, $Z = 1$, $D_c = 1.22$ g cm^{-3}, μ(Mo-K_α) = 4.03 cm^{-1}.

Data collection. $1.5 \leqslant \theta \leqslant 25$, $T = 293$, 3999 data recorded, 3777 unique, 2597 observed [$I > 1.5\sigma(I)$]. Empirical absorption correction.

Refinement. 349 parameters, unit weights, $R = 0.054$, $R_G = 0.0545$. All calculations were made on a DEC VAX11/750 computer using standard programs.[15]

Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Acknowledgements—We thank the S.E.R.C. for a studentship (A.R.B.) and for the provision of diffractometer and computing facilities, and Johnson Matthey PLC for the loan of the ruthenium.

AZOMETHINE DERIVATIVES OF ALUMINIUM CONTAINING Al—O—$SiMe_3$ GROUPS

K. K. CHATURVEDI, R. V. SINGH and J. P. TANDON*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 7 *May* 1986; *accepted after revision* 7 *October* 1986)

Abstract—The synthesis of azomethine derivatives of aluminium containing Al—O—$SiMe_3$ groups and resistant to hydrolysis is described. These have been prepared either by the equimolar reactions of bibasic tridentate or bibasic tetradentate azomethines, viz. *N*-(2-mercaptoethyl) salicylaldimine, *N*-(2-mercaptophenyl) salicylaldimine, salicylaldehyde sulphisoxazole, salicylaldehyde azine, salicylaldehyde semicarbazone, salicylaldehyde thiosemicarbazone, *o*-hydroxyacetophenone azine *N*,*N*′1,3-propylene-bis(salicylaldimine) and diacetyl bis(2-mercaptoanil), or of 1 : 2 molar reactions of monobasic bidentate imines viz. *N*-(2-mercaptophenyl) benzaldimine, benzaldehyde semicarbazone and benzaldehyde thiosemicarbazone with Me_3Si—O—$Al(OPr^i)_2$ in the medium of dry benzene. The resulting derivatives are coloured solids with sharp m.ps, non-volatile, non-electrolytes, soluble in chloroform, dimethylformamide and dimethylsulphoxide, and monomeric in nature. Their IR, ^1H NMR and electronic spectral data have been presented in support of the proposed structures.

Frisch[1] synthesized some binuclear compounds of arsenic containing the Si—O—As linkage by the interaction of alkyl or aryl chlorosilanes with arsonic acids, and which on hydrolysis yield polymers containing arsenic and silicon in the molar ratio 1 : 2. A number of patents concerning the complexes having Si—O—As type bonding appear in the literature.[2,3] Bradley and Thomas[4] were the first to utilize the transesterification method for the preparation of silyloxides of Ti(IV), Zr(IV), Nb(V) and Ta(V). A few reactions of alkoxides of lanthanides and trimethyl acetoxysilane with a variety of tridentate azomethines, possessing the O⌒N⌒S donor sequence have been reported from these laboratories.[5] However, reactions of aluminium isopropoxide and trimethylacetoxysilane with azomethins having N⌒S, O⌒N, O⌒N⌒S, O⌒N⌒N, O⌒N⌒N⌒O and S⌒N⌒N⌒S donor sequences do not seem to have been studied earlier. The present paper describes the synthesis and characterization of a few heteronuclear derivatives of type, Me_3Si—O—Al(SB), Me_3Si—O—Al(S′B′) and Me_3Si—O—$Al(S''B'')_2$ (where SB^{2-}, $S'B'^{2-}$ and $S''B''^{1-}$ = anions of different Schiff bases).

RESULTS AND DISCUSSION

The equimolar reaction of trimethylacetoxysilane $Me_3SiOOCCH_3$ with aluminium isopropoxide $Al(OPr^i)_3$ can be represented by the following equation:

$$(CH_3)_3SiOOCCH_3 + Al(OPr^i)_3 \rightarrow (CH_3)_3Si—O—Al(OPr^i)_2 + OPr^iOCCH_3.$$

The liberated isopropylacetate in the above reaction was simultaneously fractionated off as an azeotrope with cyclohexane and its estimation at regular intervals oxidimetrically indicated the extent to which the reaction had proceeded.

To the resulting solution of silyloxide of aluminium, an appropriate amount of azomethine [equimolar in the case of bibasic tri- (HO⌒N⌒XH) or tetradentate (HX⌒N⌒N⌒XH), and 1:2 in the case of monobasic bidentate (N⌒XH) was added. The liberated isopropanol was again fractionated

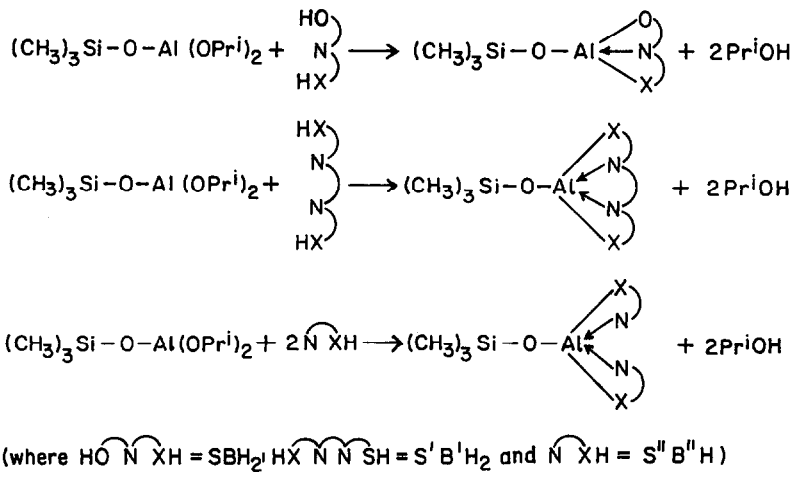
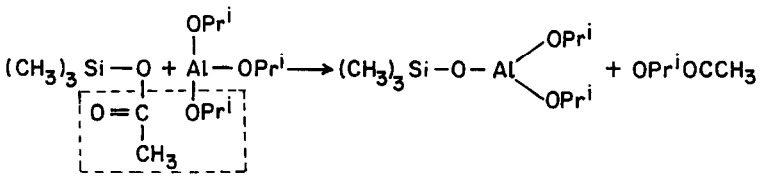
off till the reaction was complete (8–12 h):

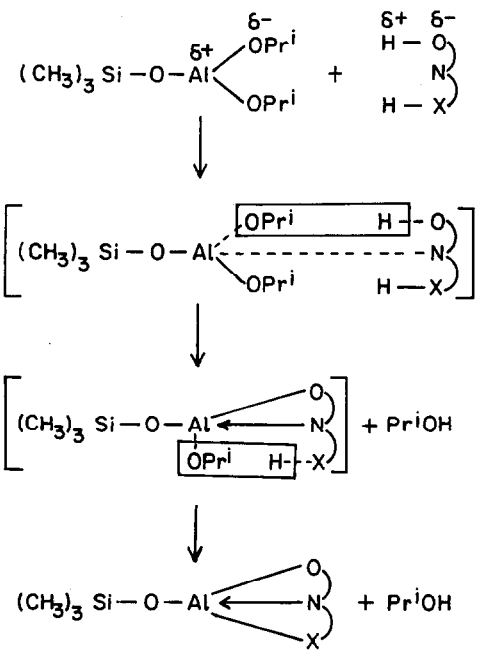


These reactions take place in two consecutive steps and the following reaction mechanism can possibly be advanced.

(i) The first step involving the reaction between aluminium isopropoxide and trimethylacetoxysilane is almost similar to the one suggested for the transesterification reaction and it may be illustrated as below:



(ii) The trimethylsilyloxide of aluminium diisopropoxide subsequently reacts with a bibasic tri- or tetradentate azomethine probably by an SN^2 type of mechanism as depicted below:



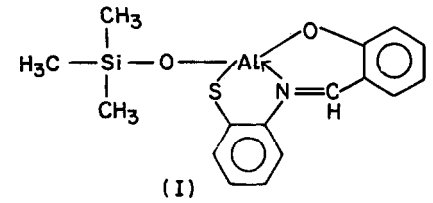
The resulting complexes are coloured solids, non-volatile and soluble in chloroform, dimethylformamide and dimethylsulphoxide. Their resistance to hydrolysis may be due to the water repellent properties of the organo-silicon group present in these derivatives. The molar conductance in dry dimethylformamide has been found to be below 15 Ω^{-1} cm^2 mol^{-1} at 10^{-3} M concentration, which is indicative of the non-ionic nature of these derivatives. The molecular-weight determinations indicate their monomeric nature.

It may, therefore, be inferred that in these newly synthesized complexes, the silicon atom is in the tetracoordinated environment,[5] whereas the aluminium atoms possibly are in tetra- or penta-coordination states as shown at top of next column.

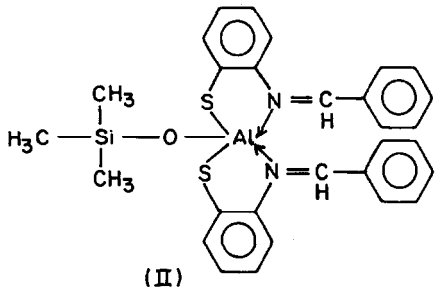
The proposed structures of the imine complexes are further supported by the IR, electronic and ^{1}H NMR spectral studies.

A strong and broad band in the 3400–3100-cm^{-1} region is observed in the IR spectra of the ligands and this may be due to the hydrogen-bonded OH or NH stretching vibrations. Further, the absence of ν(SH) in the 2600–2500-cm^{-1} region along with a ν(C=N) band at $\sim$ 1600 cm^{-1} in the ligands *N*-(2-mercaptoethyl) salicylaldimine ($C_9H_{11}ONS$), *N*-(2-mercaptophenyl)salicylaldimine ($C_{13}H_{11}ONS$) and diacetylbis(2-mercaptoanil) ($C_{16}H_{16}N_2S_2$) is strong evidence for the existence of benzothiazoline ring and not the imine form in these ligands.[6]

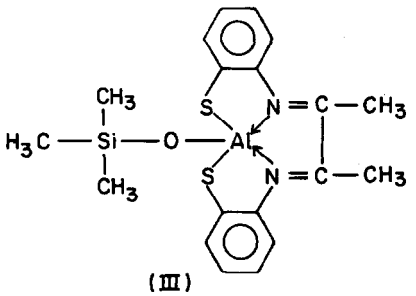
The IR spectra of aluminium complexes do not



(I)



(II)



(III)

show any band in the 3400–3100-cm^{-1} region, indicating the chelation of the phenolic oxygen and azomethine nitrogen of the ligands to the aluminium atom.[5] Further, the >C=N stretching vibration at 1635 cm^{-1} in the case of the ligand salicylaldehyde azine shifts towards a lower wavelength in the corresponding aluminium complex, which suggests the coordination of the azomethine nitrogen to the aluminium atom.[7]

In the case of complexes derived from *N*-(2-mercaptophenyl) salicylaldimine and diacetylbis(2-mercaptoanil), a strong band appearing at 1600 cm^{-1} may be assigned to the coordinated >C=N group which supports very well the fact that the resulting complexes are metal–imine complexes due to the rearrangement of the benzothiazoline structure[8] to give the imine form, which finally acts as a bibasic tri- or tetradentate ligand.

The C—O stretching modes of the phenolimine form of the ligands occur at ~ 1280 cm^{-1} and shift towards a higher frequency (~ 1300 cm^{-1}) due to complexation through the phenolic oxygen of the ligand moiety.

A band of medium intensity is observed in all the trimethylsilyloxide aluminium-bonded imine complexes in the 1250–1260-cm^{-1} region which may be assigned to the presence of a $-Si(CH_3)_3$ group, as also reported by Barraclough[9] in the case of trimethylsilanol.

The appearance of some new bands of strong to weak intensities in the spectra of metal imine complexes in the 900–920(s)-, 760–620(m,s)-, 570–430(m,w)- and 410–300(w)-cm^{-1} regions are due to ν(Si—O—Al), ν(Al—O),[10] ν(Al←N)[10-12] and ν(Al—S),[13] respectively. Barraclough *et al.*[9] have similarly assigned a strong band at 900 cm^{-1} in the case of a number of monomeric metal trialkylsilyloxides to Si—O stretching vibrations.

The electronic spectra of ligands derived from *o*-aminothiophenol show two bands at 250 and 310 nm, and these are fully consistent with the typical spectrum of benzothiazolines.[14] These transitions, which arise due to ϕ–ϕ^* and π–π^* benzenoid rings, remain unchanged in all the silyloxide aluminium-bonded imine complexes, whereas an additional band is also observed at ~ 415 nm due to n–π^* electronic transitions of the azomethine group, indicating the isomerization of the ligand on complexation.

However, the electronic spectra of other azomethines used in these investigations exhibit three bands around 245, 295 and 400 nm. The bands around 245 and 295 nm are possibly due to ϕ–ϕ^* and π–π^* transitions of the benzenoid ring in conjugation with the double bond of the azomethine group, and the band around 400 nm may be due to n–π^* transitions of bonding electrons present on the nitrogen of the azomethine group. In the corresponding complexes, there is no shift in the positions of the first two bands. However, the band around 400 nm undergoes a bathochromic shift of 20 nm in the complexes and this may be due to the coordination of the nitrogen of the azomethine group to the central aluminium atom.

Further, to confirm the bonding modes in these complexes, the ^1H NMR spectra of salicylaldehyde azine and its 1 : 1 complex with metal silyloxide have been recorded in $CDCl_3$ and the chemical-shift values [δ (ppm)] for different protons reveal the following salient point.

In the ligand, the hydrogen-bonded NH proton signal appears as a broad signal centred at δ 13.40 ppm which disappears in the corresponding azinate complex, showing the chelation of both phenolic oxygens of the ligand moiety to the aluminium atom after the deprotonation of both phenolic groups.

The proton signal for the azomethine proton (—C(H)=N) is observed at δ 7.95 ppm in the ligand, and it shifts downfield to δ 8.40 ppm in the spectrum of the aluminium complex due to the deshielding as

[a] Satisfactory carbon and hydrogen analyses were also obtained. Ligands **1**, **2**, **3**, **4**, **5**, **6**, **7**, **8**, **9**, **10**, **11** and **12** are *N*-(2-mercaptoethyl) salicylaldimine, *N*-(2-mercaptophenyl) salicylaldimine, salicylaldehyde sulphisoxazole, salicylaldehyde azine, salicylaldehyde semicarbazone, salicylaldehyde thiosemicarbazone, *o*-hydroxyacetophenone azine, *N*,*N*′-1,3-propylanebis(salicylaldimine), diacetylbis(2-mercaptoanil), *N*-(2-mercaptophenyl)benzaldimine, benzaldehyde semicarbazone and benzaldehyde thiosemicarbazone, respectively.

a result of coordinate bond formation between the nitrogen and aluminium.

The signal observed at δ 1.05 ppm in the complex is attributable to the methyl protons of the —$Si(CH_3)_3$ groups. Further, a downfield shift in the resonance signal of aromatic protons of the ligand has also been observed in the case of the metal complex as a result of the deshielding of the aromatic protons due to the coordination of the azomethine nitrogen to the aluminium atom.

EXPERIMENTAL

Throughout these investigations, a glass apparatus fitted with interchangeable standard ground joints was used.

The different Schiff bases used as ligands in the present investigations were prepared by the usual condensation[6,7] of a carbonyl compound (ketone/aldehyde) with the appropriate amine, aminothiol, sulphonamide or diamine. The ligands were further purified either by recrystallization or by distillation under reduced pressure.

Aluminium isopropoxide was prepared by the direct reaction of aluminium metal with isopropanol in the presence of mercuric chloride as a catalyst and distilled before use (85°C/0.6 mm). Found: Al, 13.2; OPr^i, 86.7. Calc.: Al, 13.2; OPr^i, 86.8%.

Trimethylacetoxysilane was obtained by the reaction between anhydrous sodium acetate and trimethyl chlorosilane in ether. The product was distilled before use (b.p. 103°C/740 mm). Found: Si, 21.1; OAc, 44.3, Calc.: Si, 21.2; OAc, 44.7%.

The binuclear Schiff base complexes of aluminium containing Al—O—$SiMe_3$ groups were synthesized by the reactions of aluminium isopropoxide in an equimolar ratio with trimethylacetoxysilane, $(CH_3)_3SiOOCCH_3$, in dry cyclohexane medium. The aluminium isopropoxide was refluxed under a fractionating column and the calculated amount of trimethylacetoxysilane diluted with dry cyclohexane was added. The reaction led to the liberation of isopropylacetate, $C_3H_7^iCOOCH_3$ which was continuously fractionated off azeotropically with cyclohexane at regular intervals for 8–10 h. When the liberated isopropanol/acetic acid corresponded to 1 mol, an equimolar amount of bibasic tri- or tetradentate azomethine was added to the resulting product, $(CH_3)_3Si$—O—$Al(OC_3H_7^i)_2$. However, in the case of monobasic bidentate ligands, the azomethine was added in a 1 : 2 molar ratio.

The reaction mixture was further refluxed for 8–14 h and the isopropanol liberated was again fractionated off and estimated oxidimetrically. The liberation of almost the theoretical amount of isopropanol in the azeotrope is an indication of the completion of the reaction. The excess of the solvent was then stripped off by distillation and the last traces of the volatile materials were removed under reduced pressure. The solid products so obtained were washed several times with anhydrous *n*-hexane and finally dried at 50–60°C/0.25 mm for about 4 h. The experimental details of these reactions along with the analyses of the products are recorded in Table 1.

The apparatus and instruments used for conductance measurements, molecular-weight determinations and electronic, IR and ^1H NMR spectral studies were the same as reported in our previous communications.[5,7] Silicon and aluminium were estimated gravimetrically as silicon dioxide and aluminium oxinate, respectively. Isopropanol was estimated oxidimetrically.[15] For the determination of the acetoxy group, a weighed amount of the compound was hydrolyzed and then titrated against a 0.05 N solution of sodium hydroxide using phenolphthalein as an indicator.

(*Received* 9 *July* 1986; *accepted* 7 *October* 1986)

Abstract—Direct reaction of elemental halogens with $Mo(CO)_4(R_2POPR_2)$ yielded seven-coordinate Mo(II) complexes of type $Mo(CO)_3X_2(R_2POPR_2)$ (R = phenyl or *p*-tolyl, X = I or Br). The structures of $Mo(CO)_3I_2(Ph_2POPPh_2)$ (**I**) and $Mo(CO)_3Br_2(tolyl_2POPtolyl_2)$ (**II**) have been determined by X-ray diffraction methods. Crystal data: $MoI_2P_2O_4C_{27}H_{20}\cdot C_2H_2Cl_4$, complex **I**, triclinic space group $P\bar{1}$; $a = 10.019(1)$, $b = 11.876(1)$, $c = 15.342(2)$ Å; $\alpha = 73.96(1)°$, $\beta = 79.12(1)°$, $\gamma = 78.19(1)°$, $Z = 2$, $D_{calc.} = 1.88$ Mg m^{-3}. The structure was solved by MULTAN on the basis of 5169 reflections to a final *R* value of 0.035. Crystal data: $MoBr_2P_2O_4C_{31}H_{28}$, complex **II**, monoclinic space group $P2_1/c$, $a = 15.932(2)$, b = 9.847(1), c = 21.360(2) Å, $\beta = 106.58(1)°$, $Z = 4$, $D_{calc.} = 1.62$ Mg m^{-3}. The structure was solved using MULTAN on the basis of 1588 reflections to a final *R* value of 0.097. Both structures approximate a pentagonal bipyramidal coordination geometry around the metal center. This stereochemistry is in accord with Kepert's prediction for chelate normalized bites of less than 1.1 (1.03 and 1.05, respectively, for the POP ligands). The equatorial plane contains both halides, the two phosphorus donors, and a carbonyl. The axial carbonyls are distorted from linearity by 8.5(2) and 13(2)°, respectively. Variable-temperature ^{31}P NMR studies of these and the related $Mo(CO)_3I_2(Ph_2PCH_2PPh_2)$ complex confirmed fluxional behavior. Furthermore, for each of the iodo complexes, equilibration with a second solution isomer was observed.

Coordination number seven remains a fascinating one since no uniquely favored stereochemistry exists.[1] Kepert has presented theoretical ligand–ligand repulsion energy caculations for structural preference in a variety of seven-coordinate metal complexes.[2] For the family of M(bidentate ligand)(unidentate ligand)$_5$ complexes, he predicted that a capped trigonal prismatic (**A**) or a pentagonal bipyramidal (**B**) structure should be favored where the chelate's normalized bite ($b = 2\sin\alpha/2$) is less than 1.1. Above this value, there are four stereochemistries of comparable energies including capped octahedrons (A–D).[1,2] Lippard has reported stereochemistry B (pentagonal bipyramid) for cationic $[Mo(\text{chelating phosphine})(CNR)_5]^{2+}$ complexes in spite of the range of normalized bites for dppm [bis(diphenylphosphino)-methane, $b = 1.06$] and dppe [bis(diphenylphosphino)-ethane, $b = 1.27$].[3] We have been interested in the coordination chemistry of the diphosphoxane (POP) ligand known to have an even smaller normalized bite than dppm. For example, $Mo(CO)_4(Ph_2POPPh_2)$ with $b = 1.06$ can be compared to a value of 1.11 in $Mo(CO)_4$(dppm).[4] Upon halogenation, the seven-coordinate $Mo(CO)_3X_2$(diphosphine) product may be expected to have an even smaller *b* value due to increased steric congestion. Furthermore, the geometries of several $Mo(CO)_3X_2$(diphosphine) complexes with higher *b* values are already known.[5] Of these, $Mo(CO)_3(Ph_2P(CH_2)_3PPh_2)I_2$ ($b = 1.33$) and $Mo(CO)_3(Ph_2P(CH_2)_2PPh_2)I_2$ ($b = 1.24$) have iodo-capped

* Author to whom correspondence should be addressed.

trigonal prismatic geometries (D). Unforunately the structure of $Mo(CO)_3I_2$(dppm) could not be determined though the W analogue was found to have stereochemistry B (pentagonal bipyramid), albeit in a disordered structure.[5]

We report here the halogenation reaction of $Mo(CO)_4(Ar_2POPAr_2)$ (Ar = phenyl or tolyl) and the solid-state structures of $Mo(CO)_3I_2(Ph_2POPPh_2)$ (**I**) and $Mo(CO)_3Br_2(tolyl_2POPtolyl_2)$ (**II**). In accord with Kepert's predictions, both of these were found to be pentagonal bipyramidal (stereochemistry B) with **I** featuring a very low diphosphine *b* value of 1.03 and a POP angle of only 99.9(2)°.

While detailed delineation of solution stereochemical processes for several classes of seven-coordinate complexes have appeared,[6] surprisingly little is known about the dynamical ^{31}P NMR behavior of the $M(CO)_3X_2$(diphosphine) family. We report here the variable-temperature ^{31}P NMR of complexes **I**, **II** and $Mo(CO)_3I_2$(dppm), a previously prepared compound.[5] In all three cases, fluxionality was confirmed. We also present evidence for the presence of a second solution isomer in the iodo complexes. Colton and coworkers have reported the existence of two $M(CO)_3I_2$(dppm) isomers in the solid state for both molybdenum and tungsten. These are all nonelectrolytes. The yellow (α) isomer is probably the expected seven-coordinate product while the orange (β) isomer has been postulated to be a six-coordinate complex with a monodentate dppm ligand.[5]* It was also mentioned that in solution IR data supported the presence of both species in equilibrium.[7-9] We present here NMR evidence that in solution at least, both major isomers are most likely seven-coordinate.

RESULTS AND DISCUSSION

Iodination and bromination of $Mo(CO)_4(Ar_2POPAr_2)$ proceeded readily at room temperature or below liberating CO to yield seven-coordinate complexes of type $Mo(CO)_3X_2(Ar_2POPAr_2)$ (X = Br or I, Ar = Ph or *p*-tolyl). These orange or orange-yellow solids are of limited stability as evident from CO loss and formation of black powders after several days of storage.

Iodination of $Mo(CO)_4(Ar_2POPAr_2)$ at room temperature afforded orange solids. X-ray quality crystals of complex **I** were grown from $C_2H_2Cl_4$ and CH_2Cl_2 solutions. IR carbonyl stretches are at 2038(w), 1970(s) and 1923(m) cm^{-1}. Asymmetric and symmetric POP stretches can be found at 815 and 760 cm^{-1}.[10] The *p*-tolyl analogue has Co stretches at 2046(w), 1956(s) and 1860(m) cm^{-1}. Its POP stretches are at 820 and 746 cm^{-1}.

Bromination of $Mo(CO)_4(Ph_2POPPh_2)$ at 0°C afforded a yellow and an orange solid. Their IR spectra are significantly different in both the carbonyl and POP regions. The yellow solid has bands at 2027(w), 1960(s) and 1890(s) cm^{-1} assignable to CO stretches in addition to a medium band at 847 cm^{-1} assigned to the asymmetric POP stretch. The orange product has CO bands at 1975(s) and 1883(s) cm^{-1} with POP stretches at 803 and 760 cm^{-1}. Unfortunately neither solid is sufficiently soluble for more detailed structural characterization. Bromination of the more soluble $Mo(CO)_4(tolyl_2POPtolyl_2)$ afforded a yellow-orange complex which can recrystallized from CH_2Cl_2. Complex **II** has CO stretches at 2049(w), 1975(sh) and 1961(s) cm^{-1}. The POP stretches are at 819 and 749 cm^{-1}.

Description of the structures

The structures of complexes **I** and complex **II** both feature seven-coordinate molybdenum atoms. The geometry about each metal is best described as a distorted pentagonal bipyramid (Figs 1 and 2). This stereochemistry has been reported in a series of $[Mo(CNR)_5(diphosphine)]^{2+}$ salts but has not been confirmed for $Mo(CO)_3X_2$(diphosphine) complexes. The equatorial plane in each case comprises one carbonyl carbon, C(3), both halogen atoms, and the two chelating phosphorus atoms, P(1) and P(2). Least-squares calculations for the equatorial atoms in complex **I** indicated significant distortions form planarity. Most serious is that of P(2) which is 0.734(3) Å out of the plane of the other four atoms. The pentagon in **II** is essentially planar with the maximum out-of-plane distance at only 0.06(2) Å for P(2). Each MoP(1)—O—P(2) chelate ring is also close to planarity with deviations of less than 0.04(3) Å. The apical positions are occupied by the remaining two carbonyl carbons, C(1) and C(2). There is no crystallographically required symmetry imposed on either structure.

The P—Mo—P angles in **I** and **II** are 61.96(4) and 63.0(4)°, respectively. The bite angles (*b*) are 1.03 for **I** and 1.05 for **II**. Thus the observed pentagonal bipyramids (stereochemistry **B**) are in accord with Kepert's prediction for ligands with small bites. In fact, complex **I** possesses the smallest such value known for a diphosphine ligand. Its diphosphoxane angle at 99.9(2)° is also remarkably

* A second solution isomer in low concentration has been suggested to account for the line-shape of the proton NMR in $TaH(CO)_2(Me_2PCH_2CH_2PMe_2)_2$.[7] Unsymmetrical diphosphines gave *cis*/*trans* isomers of $MX(CO)_2(PP')_2$.[8]

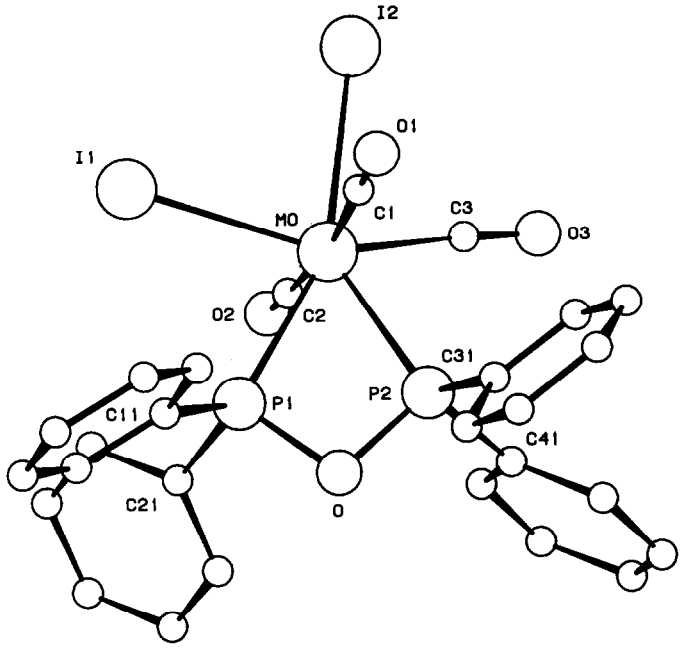

Fig. 1. Molecular structure of complex I.

low for a P—O—P group. This is consistent with a strained chelate ring crowded into the pentagonal equatorial region. The P—O distances in I are accordingly long at 1.638(3) and 1.668(3) Å, indicative of low multiple-bond character due to the unfavorable P—O—P angle. The corresponding POP angle in II of 106(1)° and P—O distances at 1.59(3) and 1.62(3) Å reflect some relief of this strain in the bromo structure.

There appears to be slight differences in the two types of metal–carbonyl distances in each structure. The apical Mo—C bonds are 2.04(1) and 2.05(1) Å in complex I while the corresponding values in II are 2.08(4) and 2.01(4) Å. The equatorial Mo—C bond in each case is marginally shorter at 2.02(1) and 1.93(4) Å, respectively. Apical C—Mo—C angles are 171.5(2)° in I and 167(2)° in II.

Values of the two Mo—P distances in I differ

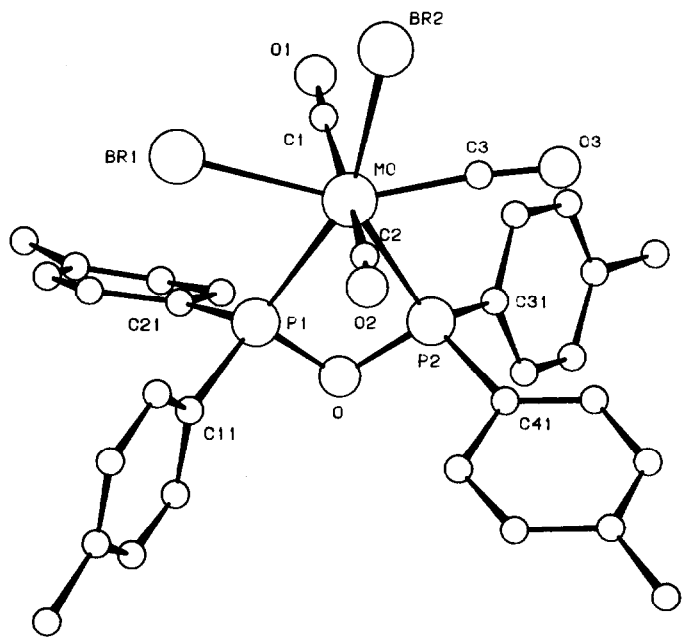

Fig. 2. Molecular structure of complex II.

Table 1. Comparisons of experimental angular coordinates of complexes **I** and **II** with calculated values for stereochemistries A and B

Ligand atom	Calculated[a] for stereochemistry B ϕ/θ	Calculated for stereochemistry A ϕ/θ	Complex **I** ϕ/θ	Complex **II** ϕ/θ
A	30	30	31	32
C	105/0	98/52	101/24	103/6
D	91/90	100/137	93/104	93/97
E	105/180	98/232	104/198	105/180
F	91/270	100/317	94/287	98/278
G	180	180	164/303	167/314

[a] Definitions of ϕ and θ, ligands A–G, and calculated values of angular coordinates for ligand bite $b = 1.0$ are from Table 4, Ref. 2.

significantly, being 2.471(2) and 2.446(1) Å. In **II**, they are closer at 2.46(1) and 2.44(1) Å. This discrepancy in Mo—P distances has been observed in the structures of $Mo(CO)_3I_2(Ph_2P(CH_2)_nPPh_2)$, $n = 2$ or 3, and has been rationalized as originating from the stronger *trans* influence of a carbonyl vs a halide ligand.[5] Such an argument is less persuasive in **I** and **II** since no phosphorus is close to being *trans* to a carbonyl group. Nevertheless the Mo—P bonds most clearly across (at 129.6 and 136°, respectively) from the equatorial carbonyl [C(3)] are indeed longer.

Comparison of stereochemistry with repulsion energy calculations

A comparison of the experimental angular coordinates for complexes **I** and **II** together with those calculated for stereochemistries A (capped trigonal pyramid) and B (pentagonal bipyramid) is tabulated in Table 1.[2]

It can be seen that structure **II** approximates stereochemistry B reasonably well except for ϕ(G) where the deviation is 13°, representing the slight nonplanarity of the Br(2) atom. The angular coordinates for complex **I** show more notable deviations. A major twist distortion for C(2), C(3), C(1) and I(1) (ligands F, C, D and E) can been seen in the θ deviations of 17, 24, 14 and 18°, respectively. This is in the direction towards a capped trigonal prism (stereochemistry A) of the type predicted by Kepert for small-bite ligands.[1] Additionally I(2) or ligand G is distorted away from the pentagonal plane by 16°. The more severe distortions in complex **I** compared to **II** and $W(CO)_3I_2(Ph_2PCH_2PPh_2)$ may be a result of the more congested coordination environment of **I**, consistent with its very low bite (1.03) and narrow POP angle [99.9(2)°].

Variable-temperature ^{31}P-31 *studies*

Temperature dependence of the ^{31}P NMR of complexes **I**, **II** and the related $Mo(CO)_3I_2(tolyl_2POPtolyl_2)$, as well as $Mo(CO)_3I_2(Ph_2PCH_2PPh_2)$, were examined. All were observed to be stereochemically nonrigid at ambient temperature.

The spectra for complex **I** in CH_2Cl_2 are as shown in Fig. 3. At 30°C, a broad singlet at about +92 ppm and a sharp singlet at +70.6 ppm were observed. At −60°C, the broad singlet collapsed into AB doublets at +81 and +112 ppm ($J = 193$ Hz) while the sharp singlet remained unchanged. At temperatures above 30°C, the sharp singlet increasingly broadened but coalescence was not observed as decomposition set in above 120°C. Simulation of the high-temperature spectra predicts an exchange barrier of about 17 kcal mol^{-1} for the two singlets. This spectral behavior is reversible as long as extensive decomposition is avoided. These results suggest the presence of two solution species, **IA** and **IB**, in equilibrium with **IA**:**IB** ratios of 1:0.14 at −60°C, 1:0.32 at 30°C, and 1:0.42 at 70°C. Assignment of the solid-state pentagonal bipyramidal structure featuring inequivalent phosphorus atoms to **IA** is consistent with its limiting AB spectrum. An estimate of its intramolecular rearrangement barrier yields the value 9.8 kcal mol^{-1}. The identity of **IB** can only be speculated upon. One possibility is a second isomer (stereochemistry A, B, C or D) featuring either equivalent phosphine sites or rapidly scrambling inequivalent sites. Another explanation would be dissociation of an iodide to give a six-coordinate cationic complex. This, however, would be contrary to the nonelectrolytic behavior of the complex in chlorinated hydrocarbons. Furthermore, reaction of complex **I** with silver tetrafluoroborate gave a

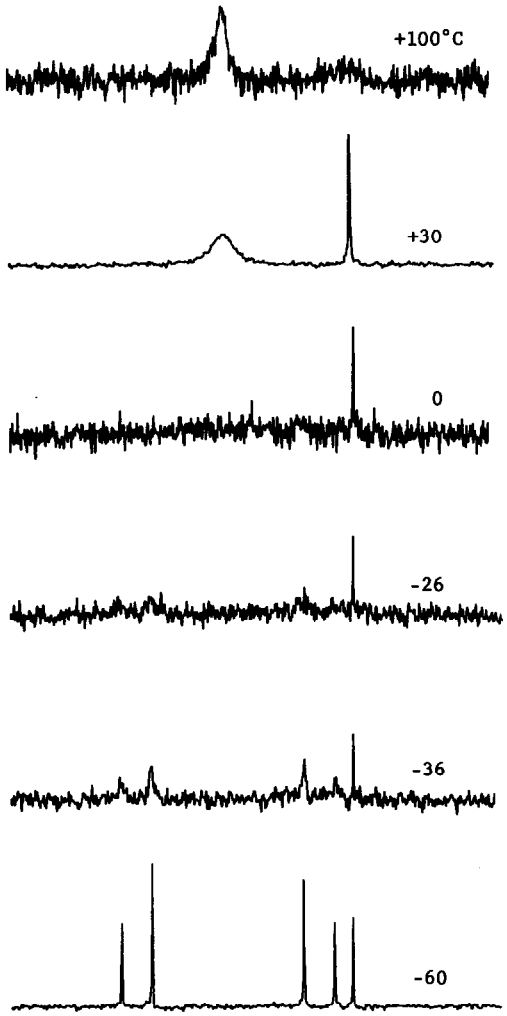

Fig. 3. Variable temperature $^{31}P-\{^1H\}$ NMR spectra of **I**.

cationic complex featuring a ^{31}P signal at +120 instead of +70.6 ppm. A third possibility of **IB** containing a monodentate diphosphoxane similar to that suggested for the β-isomer of $Mo(CO)_3I_2(PPh_2CH_2PPh_2)$ isolated by Colton also seems unlikely in light of its singlet resonance.[5,9] Even if rapid scrambling between the two ends is occurring, the observed average chemical shift of +70.6 ppm would be unreasonable since the known shift of the uncoordinated end of Ph_2POPPh_2 is at +109 ppm.[4,11] A likely structure of **IB** would be the polytopal isomer with stereochemistry A (capped trigonal prism). Observed distortions of the solid-state structure of complex **I** towards this geometry is in line with this hypothesis. An alternate structural assignment of **IB** as a symmetrically substituted pentagonal bipyramid retaining stereochemistry **B** cannot be ruled out.

The variable-temperature ^{31}P spectra of $Mo(CO)_3I_2(tolyl_2POPtolyl_2)$ are very similar with the limiting AB doublets centered at +81 and +111 ppm (J = 193 Hz) and the singlet at +76 ppm.

Complex **II** exhibited a featureless ^{31}P spectrum at 30°C. The slow exchange spectrum at −60°C, however, revealed two AB doublets centered at +91 and +119 ppm (J = 205 Hz). This is entirely consistent with its solid-state structure of a pentagonal bipyramid. Its rearrangement barrier is at 9.9 kcal mol^{-1}. A second solution isomer, if present, would be in much lower abundance.

The complex $Mo(CO)_3I_2(Ph_2PCH_2PPh_2)$ has been known for sometime. Two isomers were reported by Colton in both the solid state and in solution.[5] Their structures have not been determined but at least one is likely to be of stereochemistry **B** by analogy to complexes **I**, **II** and its tungsten analogue.[5] The room-temperature ^{31}P spectrum exhibited a singlet resonance at −22.5 ppm (Fig. 4). This broadened at lower temperatures while a small, sharp singlet appeared at −35.8 ppm. Below −30°C, the major signal collapsed into two sets of AB doublets one of which sharpened at −70°C (−5 and −30 ppm, J = 122 Hz). Below

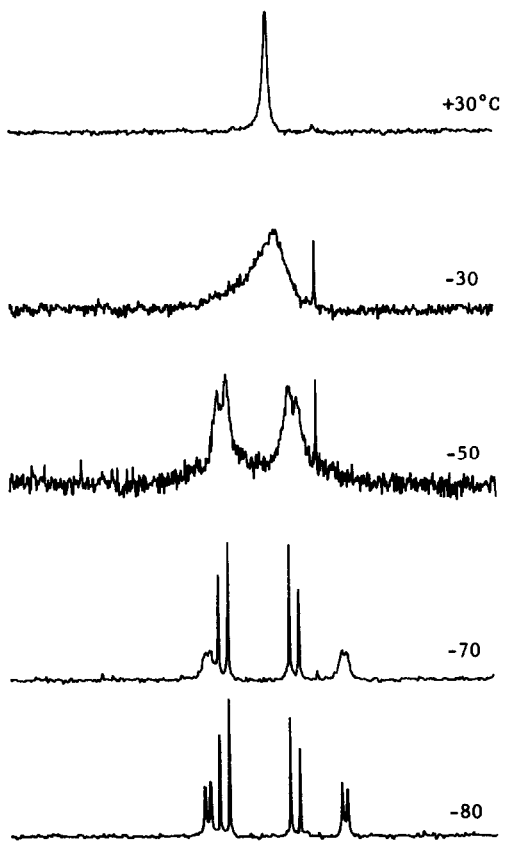

Fig. 4. Variable temperature $^{31}P-\{^1H\}$ NMR spectra of $Mo(CO)_3I_2(Ph_2PCH_2PPh_2)$.

−80°C, the other set eventually resolved into AB doublets at 0 and −47 ppm ($J = 68$ hz). The small singlet at −22.5 ppm, in the meantime, has diminished further into the baseline. Again, these spectra are consistent with the presence of two major solution isomers, both with inequivalent phosphoruses. The barriers to intramolecular scrambling for the two major isomers can be estimated to be 8.4 and 9.5 kcal mol^{-1}. The small singlet suggests presence of a minor third isomer at temperatures above −70°C that is also in equilibrium with the two major isomers. Exact structural assignment of each of these solution species is not yet possible. Nevertheless, the absence of any resonance at around −24 ppm normally assigned to the uncoordinated dppm argues against a six-coordinate geometry featuring a monodentate dppm ligand. We are therefore in favor of both major solution isomers being seven-coordinate with chelating diphosphines.

These data support the presence of significant amounts of a second solution isomer for all three iodo complexes. Interestingly, complex **II**, the bromo analogue of **I**, appears to exist as a single solution species. This along with the much less severe distortions of its solid-state structure from stereochemistry B suggest a higher preference for the pentagonal bipyramidal geometry by complex **II**. Finally, the different slow-exchange spectra for complexes **I**, **II** and $Mo(CO)_3I_2(Ph_2PCH_2PPh_2)$ further illustrate the sensitivity of seven-coordinate stereochemistry to relatively subtle changes in ligand environment.

EXPERIMENTAL

Standard inert-atmosphere techniques were used for reactions, purifications, and other manipulations.

Synthesis of complex **I**

To a stirred solution of 1 g of $Mo(CO)_4(Ph_2POPPh_2)$ (1.68 mmol) in 10 cm^3 CH_2Cl_2 was added dropwise 20.7 cm^3 of a solution of iodine in CH_2Cl_2 (20.6 mg cm^{-3}). Carbon monoxide evolved slowly and after 0.5 h the solution was concentrated *in vacuo* to about 15 cm^3 and 10 cm^3 hexane added slowly. A microcrystalline orange solid deposited over 3 h (0.667 g, 53%). Additional product can be obtained by workup of the mother liquor to give a combined yield of 75%. Found: C, 39.1; H, 2.4. Calc. for $C_{27}H_{20}I_2MoO_4P_2$: C, 39.5; H, 2.5%. X-ray crystals of **I** were grown from $C_2H_2Cl_4$ solution of **I** by layering with hexane.

Synthesis of complex **II**

The same procedure was followed as for **I** except that the bromination was carried out at 0°C. A combined yield of 73% of orange-yellow product was obtained. Found: C, 47.3; H, 3.8. Calc. for $C_{31}H_{28}Br_2MoO_4P_2$: C, 47.6; C, 3.6%. X-ray crystals were obtained by layering of a CH_2Cl_2 solution of **II** with *n*-hexane.

X-ray structural determination of **I**

Crystal data. $C_{27}H_{20}I_2MoO_4P_2 \cdot C_2H_2Cl_4$, triclinic, space group $P\bar{1}$, $a = 10.0185(6)$, $b = 11.8763(10)$, $c = 15.3419(16)$ Å, $\alpha = 73.960(8)°$, $\beta = 79.120(7)°$, $\gamma = 78.193(6)°$, $Z = 2$, $D_{calc.} = 1.88$ Mg m^{-3}. The diffraction intensities of an approximately $0.45 \times 0.3 \times 0.25$ mm crystal were collected with graphite-monochromatized Mo-K radiation using the θ–2θ scan technique with profile analysis to $2\theta_{max} = 50°$.[12] A total of 5965 unique reflections were measured, of which 5169 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Lorentz and polarization factors were applied but absorption correction was not calculated ($\mu = 2.45$ mm^{-1}). The cell parameters were obtained by least-square refinement of the setting angles of 40 reflections with $2\theta > 45°$(Mo-$K_{1\alpha} = 0.70932$ Å).

The structure was solved by Multan and refined with full-matrix least squares.[13] Where possible, H atom positions were calculated but their parameters were not refined. All heavy atoms were refined anisotropically. The solvent, tetrachloroethane, was located as a disordered molecule, C atoms with occupancy factors as 0.84 and 0.89, and Cl atoms as 0.84, 0.93, 0.83 and 0.83. The final residuals are R_F 0.035 and R_W 0.036 with counting statistics weights. All calculations were performed on the NRCVAX system of programs.[14] Scattering factors were taken from the *International Tables for X-ray Crystallography*.[15] Important distances and angles are listed in Table 2. Atomic positions, anisotropic thermal parameters and structure factors are included in the supplementary material.

X-ray structural determination of **II**

Crystal data. $C_{31}H_{28}Br_2MoO_4P_2$, monoclinic, space group $P2_1/c$, $a = 15.9322(19)$, $b = 9.8466(13)$, $c = 21.3601(22)$ Å, $\beta = 106.58(1)°$, $Z = 4$, $D_{calc.} = 1.62$ Mg m^{-3}. The diffraction intensities of an approximately $0.3 \times 0.2 \times 0.2$ mm crystal were collected as described above for **I**. During data collection, the crystal was observed to split from the display of the profile. The agreement factor

Variable-temperature ^{31}P *studies*

A JEOL FX-90Q NMR spectrometer with deuterium lock was used. Samples were studied in CH_2Cl_2 solution in 10-mm tubes. Temperature measurements were made using a thermocouple calibrated with a chemical shift thermometer. All ^{31}P chemical shifts are referenced to 85% phosphoric acid with positive downfields shifts.

Acknowledgement—We thank the National Science Foundation for an instrument grant towards the purchase of the FT-NMR spectrometer.

Abstract—The title complex has been prepared and characterized by X-ray crystallography [trigonal, $P\bar{3}$, $a = 10.884(1)$, $c = 8.784(1)$ Å, $Z = 1$, $R = 0.036$ for 747 Mo-K_α reflections]. The crystal structure comprises two types of columns: one of quasi tetrahedral $[\{(CH_2)_6N_4\}ZnCl_3]^-$ ions stacked along crystallographic three-fold axes, and a second kind composed of an alternate arrangement of $[Zn(H_2O)_6]^{2+}$ octahedra and chair-shaped hydrogen-bonded $(H_2O)_6$ "spacers" centered at $\bar{3}$ sites, consecutive moieties being linked by "intermolecular" O—H...O hydrogen bonds. Neighboring columns are further interconnected by lateral O—H...N and O—H...Cl hydrogen bonds to form a three-dimensional network.

Several products have been isolated from the reaction of 1,3,5,7-tetraazaadamantane [formula $(CH_2)_6N_4$, commonly known as hexamethylenetetramine and abbreviated as HMT] with zinc(II) halides in aqueous media, with or without the presence of HCl and alcohol. In the older literature, compounds of stoichiometries $(CH_2)_6N_4 \cdot ZnCl_2 \cdot HCl$[2] and $2(CH_2)_6N_4 \cdot 3ZnCl_2 \cdot 6H_2O$[3] were reported. Subsequently, the adducts $(CH_2)_6N_4 \cdot ZnX_2$ (X = Cl or Br) were obtained from crystallization in water–methanol and investigated by X-ray diffraction (lattice constants only)[4] and vibrational spectroscopy.[5] Recently Pickhardt and Dross reported that these two anhydrous complexes are isotypic, forming polymeric chains in the crystal lattice with tetrahedral Cl_2N_2 coordination about each metal atom.[6] In the present paper, we describe the preparation and X-ray crystal structure of the title complex, which can be re-formulated as $2(CH_2)_6N_4 \cdot 3ZnCl_2 \cdot 12H_2O$ for comparison with other related compounds.

EXPERIMENTAL

Preparation of $[Zn(H_2O)_6][\{(CH_2)_6N_4\}ZnCl_3]_2 \cdot 6H_2O$

This compound was obtained from slow evaporation of an aqueous solution of $(CH_2)_6N_4$ and $ZnCl_2$ in a 2 : 3 molar ratio. The crystals effloresced rapidly and turned milky in air, but underwent no apparent change if allowed to remain immersed in the mother liquor.

Crystal data

$C_{12}H_{48}N_8Cl_6O_{12}Zn_3$, $M = 905.38$; prismatic, $0.36 \times 0.32 \times 0.20$ mm sealed in 0.5 mm Lindemann glass capillary; trigonal, $P\bar{3}$ (No. 147),

* Part VII is Ref. 1.

† Author to whom correspondence should be addressed.

$a = 10.884(1)$, $c = 8.784(1)$ Å, $V = 901.2(2)$ Å^3, $D_m = 1.73(1)$ (flotation in CCl_4–$BrCH_2CH_2Br$, crystal turning milky), $D_c = 1.668$ g cm^{-3}, $Z = 1$, $F(000) = 464.76$; Nicolet R3m diffractometer, monochromatized Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 25.35$ cm^{-1}. Accurate unit-cell dimensions were obtained by least-squares refinement of the setting angles of 21 slowly centered reflections in the range $15 < 2\theta < 25°$, and data collection ($2\theta_{max} = 60°$, 783 unique reflections) and reduction followed established procedures in our laboratory.[7] Absorption correction (mean $\mu r = 0.20$, transmission factors 0.763–0.849) was applied using an empirical method based on a pseudo-ellipsoidal fit to azimuthal (ψ) scan data of selected strong reflections.[8]

Structure determination

Statistical distributions of normalized structure factors strongly favored the centrosymmetric space group $P\bar{3}$, which was subsequently confirmed in X-ray analysis. The structure was solved by direct phase determination, and all non-hydrogen atoms were subjected to anisotropic refinement. The methylene H atoms were generated geometrically, and three of the four independent water protons located from a difference Fourier map; these were included in structure-factor calculations with assigned isotropic temperature factors. Convergence was reached at $R = 0.032$, wR (on $|F_o|^2$) $= 0.051$ with $w = [\sigma^2(F_o) + 0.0002|F_o|^2]^{-1}$, and $S = 2.654$ for 63 variables and 747 observed [$|F_o| > 3\sigma(F_o)$] reflections.*

Computations were performed on a Data General Nova 3/12 minicomputer with the SHELXTL program package.[9] Analytic expressions of neutral atomic scattering factors were employed, and anomalous dispersion corrections were incorporated.[10]

RESULTS AND DISCUSSION

It is now well established that the presence of $(CH_2)_6N_4$ as a ligand tends to promote the occurrence of variable coordination geometries about different metal ions of the same kind in the same crystal lattice,[7,11] and the present complex provides yet another illustrative example. Figure 1 shows a perspective view of the discrete $[Zn(H_2O)_6]^{2+}$ and $[\{(CH_2)_6N_4\}ZnCl_3]^{-1}$ ions, which have crystallographically-imposed $\bar{3}$ and 3 molecular symmetries, respectively, and the "lattice" water molecule in the asymmetric unit, together with the system of atom numbering. Bond distances and angles are tabulated in Table 1.

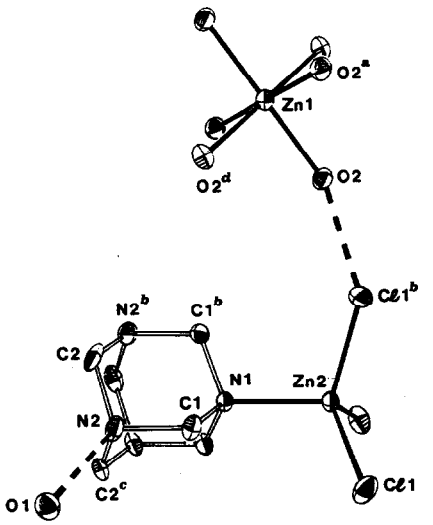

Fig. 1. Perspective view of the discrete molecular ions and lattice water molecule in $[Zn(H_2O)_6][\{(CH_2)_6N_4\}ZnCl_3]_2 \cdot 6H_2O$. Thermal ellipsoids are drawn at the 30% probability level, and hydrogen bonds are represented as broken lines. Atom numbering and symmetry transformations match those given in Table 1.

The $[Zn(H_2O)_6]^{2+}$ octahedron is slightly but significantly flattened along its $\bar{3}$ axis, as shown by the O(2)—Zn—O(2)^a angle of 91.1(1)°; otherwise the Zn(1)—O(2) bond of 2.086(2) Å is normal for the hexaaquazinc(II) moiety, as compared to distances in the range 2.056(2)–2.104(2) Å for the cation in the $[Zn(H_2O)_6]$(isonicotinate *N*-oxide) salt.[12] On the other hand, the quasi tetrahedral $[\{(CH_2)_6N_4\}ZnCl_3]^-$ anion is, to our knowledge, the first reported example of an aminotrichlorozinc(II) species. In fact, discrete tetrahedral anions of the type $[LZnCl_3]^-$ (L = organic ligand) are rare, and cases where L = acetone [Zn—Cl = 2.23 Å][13] and tetrahydrofuran [Zn—Cl = 2.240(3) Å, Cl—Zn—Cl = 112.9(1)–115.9(1)°][14] made their appearance only recently in the literature, whereas dichlorozinc(II) complexes of tetrahedral coordination geometry are commonly encountered. It is evident that the bond lengths and angles around the metal atom in the $[\{(CH_2)_6N_4\}ZnCl_3]^-$ anion (Table 1) are consistent with those in the *O*-donor analogues. As compared to relevant dimensions reported for polymeric $(CH_2)_6N_4 \cdot ZnCl_2$[6] [Zn—N = 2.111(8),

Zn—Cl = 2.221(4) Å, Cl—Zn—Cl = 119.3(2)°] and tetrahedral $[Zn(NH_3)_2Cl_2]$[15] [Zn—N = 2.024(2), Zn—Cl = 2.273(1) Å and Cl—Zn—Cl = 109.2(1)°], the present data reflect the difference in number of chloro ligands, and the fact that zinc(II) forms stronger bonds to primary amines than tertiary amines, with concomitant weakening of the Zn—Cl bonds in the former instance.

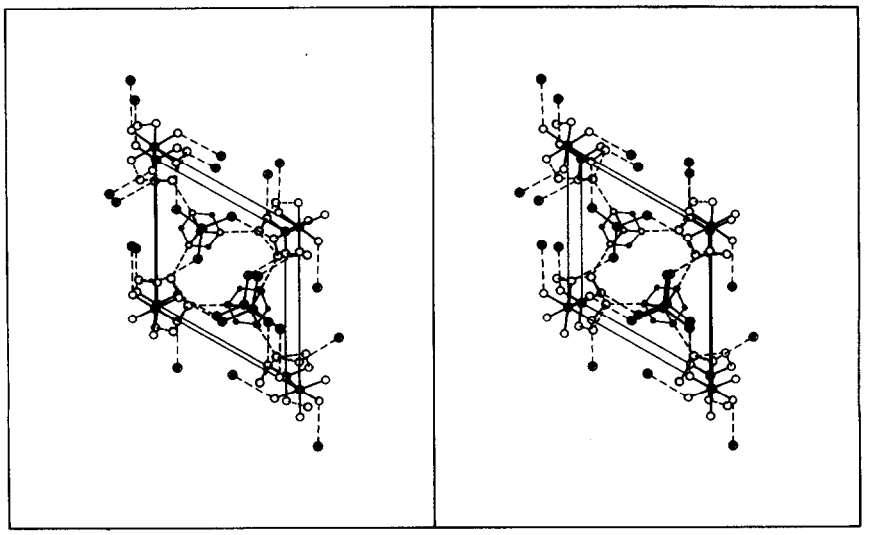

Fig. 2. Stereoview of the molecular packing. The origin of the unit cell lies at the lower left corner, with **a** pointing from left to right at a slant, **b** upwards, and **c** towards the reader. Hydrogen bonds are represented by broken lines, and atom types are differentiated by size and shading.

As illustrated in Fig. 2, the $[\{(CH_2)_6N_4\}ZnCl_3]^-$ ions are stacked in columns along the crystallographic three-fold axes. The $\bar{3}$ symmetry operation on O(1) generates a chair-like aggregate of six water molecules, forming a hydrogen-bonded $(H_2O)_6$ ring which serves as a "spacer" midway between a pair of $[Zn(H_2O)_6]^{2+}$ octahedra. Similar puckered $(H_2O)_6$ rings have been recognized as structural fragments in a variety of crystalline hydrates: well-known examples include the ice polymorphs,[16] polyhedral clathrate hydrates,[17] $(CH_2)_6N_4 \cdot 6H_2O$,[18] and other hydrate inclusion compounds.[19,20] Nevertheless, the occurrence of such a ring in a coordination compound is highly unusual. In the present complex, the $(H_2O)_6$ rings and cations occupying alternate $\bar{3}$ sites are linked by "intermolecular" O—H...O hydrogen bonds, giving rise to a second type of columnar stack. In the resulting crystal structure, the two types of columns interconnect laterally via O—H...N and O—H...Cl hydrogen bonds (involving lattice and ligand water molecules, respectively) to form a three-dimensional network (Fig. 2). Geometrical details of the hydrogen bonding are given in Table 1. It is seen that the bond configuration about the O(1) atom deviates markedly from regular tetrahedral, with O...O...O angles over a wide range of 88.7(2)–131.1(1)°.

The measured dimensions of the organic ligand (Table 1), which utilizes all four nitrogen lone pairs in stabilizing the crystal lattice, are in fairly good agreement with those of crystalline $(CH_2)_6N_4$ [C—N = 1.476(2) Å, C—N—C = 107.2(1)°, N—C—N = 113.6(2)°].[21] Deviation of the present cage system from idealized $\bar{4}3m$ symmetry is manifested by the significantly different C(1)—N(1) and C(2)^c—N(2) bond distances, and involvement in coordinate and hydrogen bonding leads to enlargement of the C—N—C angles in accordance with VSEPR expectations.

(*Received* 6 *October* 1986; *accepted* 10 *October* 1986)

Abstract—The reaction between $W_2X_2(OR)_4$ compounds [X = CH_2CMe_3 or OBu^t] and $HS_2P(OEt)_2$ (6 equivalents) in hydrocarbon solvents, produces a molecule of formula $W_2S_2[S_2P(OEt)_2]_4$ with corresponding elimination of alkane, alcohol and $[(EtO)_2PS]_2$. This tungsten compound has been characterized by IR, ^1H, ^{13}C, and ^{13}P NMR spectroscopy, electronic absorption spectroscopy and single-crystal X-ray crystallography. The molecule adopts a structure based on an edge-shared bioctahedron, with two bridging sulfides, two chelating dithiophosphate ligands and two dithiophosphate ligands bridging the metal–metal double bond. The W–W distance of 2.5987(11) Å along with the acute W—S—W angles of 67.74(8)°, are consistent with the metal–metal double bond formulation $\sigma^2\pi^2$. This structure is similar to the $W_2S_2(S_2CNEt_2)_4$ molecule prepared by Cotton *et al.* (*Inorg. Chem.* 1978, **17**, 2946).

Of all the compounds containing metal–metal multiple bonds, the group VI (Cr, Mo and W) metals show the most varied and fascinating coordination chemistry. The range of formal bond order extends from M–M single bonds to M–M quadruple bonds.[1] The chemistry of compounds containing M–M single, triple and quadruple bonds is quite extensive, but an exception is seen for M–M double bonds. The list of compounds containing M–M double bonds is comparatively short.[1]

We have been investigating the chemistry of M–M triply bonded compounds of formula M_2X_n (M = Mo or W, X = ligand atom, n = 6–12).[2] Of particular interest has been the higher metal coordination numbers of 5 and 6.[3–5] In this paper we wish to present our results concerning the reactions of $W_2X_2(OR)_4$ (X = alkyl or alkoxide) with dialkyldithiophosphoric acids.

Following our discovery of a general synthesis of compounds with the formula $M_2R_2(O_2CR')_4$ (M = Mo or W) [eqn (1)]:[6]

$$M_2R_2(OPr^i)_4 + 4R'CO_2H \xrightarrow[25°C]{\text{toluene}} M_2R_2(O_2CR')_4 + 4HOPr^i, \quad (1)$$

we wished to extend this series of compounds to include bidentate ligands other than carboxylates. Interest in compounds of formula $M_2R_2(O_2CR')_4$ arises from their unusual valence MO description of the M–M triple bond as $\pi^4\delta^2$.[7] Our choice of dialkyldithiophosphates seemed appropriate in that this ligand has somewhat different steric and electronic properties from carboxylates.

RESULTS AND DISCUSSION

Synthesis

The reaction of $W_2Np_2(OPr^i)_4$ (Np = CH_2CMe_3) with $(EtO)_2PS_2H$ in toluene does not produce a complex with the formula $W_2Np_2[S_2P(OEt)_2]_4$, but does produce a rather interesting molecule of formula $W_2S_2[S_2P(OEt)_2]_4$ (**1**). This green,

* Author to whom correspondence should be addressed.

diamagnetic, crystalline, air-stable, hydrocarbon-soluble compound can be isolated in approximately 60% crystalline yield according to eqn (2):

$$W_2Np_2(OPr^i)_4 + \geqslant 6HS_2P(OEt)_2 \xrightarrow[0°C]{\text{toluene}} W_2S_2[S_2P(OEt)_2]_4 + 2NpH + 4HOPr^i + [(EtO)_2PS]_2. \quad (2)$$

The phosphorus-containing by-product of eqn (2) was identified by ^{31}P NMR spectroscopy and has a chemical shift of δ 89.8 ppm in benzene-d_6.* The volatile product, neopentane, was identified in the ^1H NMR spectrum of the reaction mixture and has a chemical shift of 0.89 ppm in benzene-d_6.

There is some question as to how the neopentane was produced in eqn (2). It could be either produced by: (1) homolytic cleavage of the W—C bonds to produce Np$^\bullet$ radicals, which then abstracted H$^\bullet$; or by (2) acid protonolysis of the alkyl ligands. When the reaction was carried out at −78°C, a turquoise color could be detected before the final deep forest green was formed. When the reaction was monitored by ^1H NMR spectroscopy at −78°C, several intermediates were observed, but it was difficult to definitively assign any of these to $W_2[S_2P(OEt)_2]_6$.

It was also found that **1** can be prepared by the reaction of $W_2(OBu^t)_6$ with $(EtO)_2PS_2H$, according to eqn (3):

$$W_2(OBu^t)_6 + \geqslant 6HS_2P(OEt)_2 \xrightarrow[0°C]{\text{toluene}} \underset{\mathbf{1}}{W_2S_2[S_2P(OEt)_2]_4} + 6HOBu^t + [(EtO)_2PS]_2. \quad (3)$$

This result suggests that the neopentane produced in eqn (2) results from protonation of the alkyl ligands and that $W_2[S_2P(OEt)_2]_6$ is a likely, but not proven, intermediate in reactions (2) and (3).

When **1** was heated to 60°C in a sealed NMR tube, an orange solution was produced. The ^1H NMR spectrum of this product or products is very complicated. The most information is gained from the methylene signals. There are at least four $ABMX_3$ patterns in this region, which suggests that there is no plane of symmetry in this product(s). Perhaps the molecule has undergone further oxidative addition of sulfide ligands, but the thermolysis reaction has not yet been followed up.

*The ^{31}P NMR chemical shift of $(Et_2PS)_2$ is δ 52.5 and $(Ph_2PS)_2$ is δ 37.9 in toluene-d_8; PEt_3 is δ −20 and $P(OEt)_3$ is δ 86.[8]

NMR studies

The ^1H NMR spectrum of **1** at 25°C in benzene-d_6 is shown in Fig. 1. It is evident that this molecule has two different types of dithiophosphate ligands. The methylene protons of the ethyl groups display A_2MX_3 patterns with the slightly different $^3J_{PH}$ coupling of 9.7 and *ca* 7.0 Hz. This gives rise to the doublet of quartets at δ 4.35 ppm and the apparent pentet at δ 3.46 ppm.

The ^{31}P–$\{^1H\}$ spectrum of **1** shows that there are two different types of phosphorus nuclei in a 1:1 ratio. These signals occur at δ 194.0 and 127.4 ppm, and do not show coupling to ^{183}W. The ^1H-coupled spectrum reveals that the signal at δ 127.4 ppm becomes a triplet, with $^3J_{PH}$ = 9.6 Hz. This indicates that the ^{31}P signal at 127.4 ppm and the ^1H NMR signal at 4.35 ppm arise from the same ligand.

The ^{13}C NMR spectra, ^1H-coupled and decoupled, are shown in Fig. 2. It can be seen in the ^{13}C–$\{^1H\}$ spectrum that there are again two types of ethyl resonances. One of the methylene resonances at δ 65.37 ppm shows coupling to phosphorus of $^2J_{PC}$ = 10.4 Hz, while the other resonance at 65.99 ppm does not show coupling. Likewise, the methyl resonances have a similar pattern. The signal at δ 16.08 ppm shows a $^3J_{PC}$ = 8.3 Hz, while the signal at δ 15.75 ppm is a singlet.

We believe that the differences in the coupling constants of the two different ligands can be explained by the differences in the bite angles of the ligands (*vide infra*).

Solid-state and molecular structure

Good-quality crystals of **1** were grown from concentrated hexane solutions at −20°C. An ORTEP view of the molecule showing the atom numbering scheme used in the tables is given in Fig. 3, and a stereo view of the molecule is given in Fig. 4. Bond distances and angles are given in Tables 1 and 2, respectively.

The overall geometry of **1** is quite similar to that of $W_2S_2(S_2CNEt_2)_4$ (**2**) prepared and characterized by Cotton *et al.*[9] The W–W bond distance of **1** is 2.5987(11) Å, and is slightly longer than the W–W bond distance of **2** at 2.530(2) Å. Both of these molecules have two bridging sulfides. There are two significant indications that these molecules must have W–W double bonds: (1) the W–W distances are intermediate between W–W triple bonds, *ca* 2.3 Å, and W–W single bonds, *ca* 2.7 Å; and (2) the W—S—W angles are very acute, being *ca* 68°.

The bonding in d^n–d^n edge-shared bioctahedra of formula $L_4M(\mu\text{-}L)_2ML_4$ was first discussed in detail by Hoffmann and coworkers[10] who

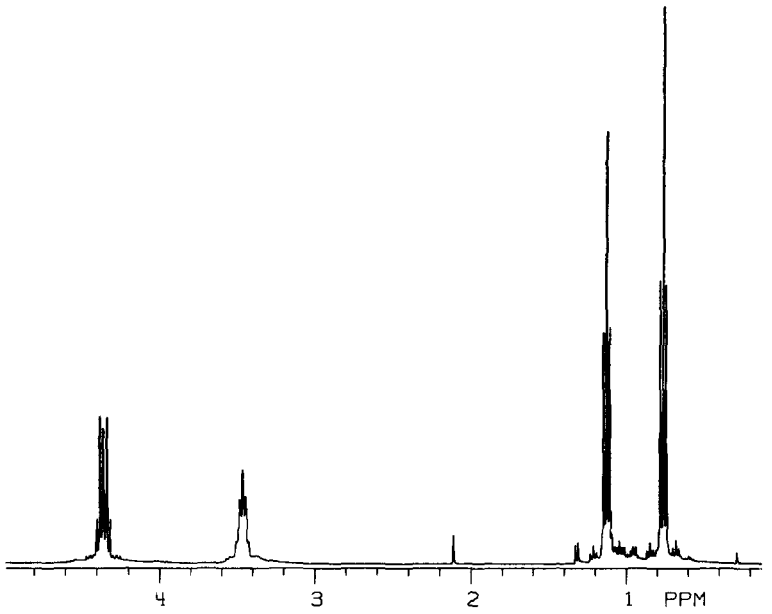

Fig. 1. ^{1}H NMR spectrum of $W_2S_2[S_2P(OEt)_2]_4$ in benzene-d_6 at 22°C (360 MHz).

showed that at certain metal–metal distances and with the μ-L groups having filled π-orbitals, the intuitive ordering of the t_{2g}–t_{2g} interaction $\sigma < \pi < \delta < \delta^* < \pi^* < \sigma^*$ of M–M bonding MOs will not hold. The problem arises most acutely for the δ- and δ^*-levels which may be inverted. In the present case of a d^2–d^2 dimer the M–M configuration of $\sigma^2\pi^2$ will remain. However, it should be noted that the M–M π-orbital will interact to some extent with the sulfur lone pairs of the dithiophosphate ligands. If the latter were dominant, which it clearly is not, then M–M π^* occupation would occur. For example, the M–M distance in **1** is notably shorter than the Mo–Mo distance in $[(HNMe_2)_2(Bu^tS)_2Mo(\mu\text{-}S)]_2$ [2.730(1) Å], which is a d^2–d^2 dinuclear compound having a central planar $[Mo(\mu\text{-}S)]_2$ moiety involving the fusing of trigonal bipyramids along a common axial–equatorial edge.[11] There the M–M MO description is probably $\sigma^2\delta^2$, and at best there is only effectively a single M–M bond at a distance of 2.7 Å. For a comparison with a non-bonding distance one may note the Zn–W distance [2.927(1) Å] in $[Zn(WS_4)_2]^{2-}$, which involves three fused tetrahedra: $S_2W(\mu\text{-}S)_2Zn(\mu\text{-}S)_2WS_2$.[12]

An interesting feature of **1**, not observed in **2**[9] is that the W_2S_2P unit of the bridging phosphate ligands is not planar, whereas the WS_2P unit of the chelated phosphate ligands is planar. This could be the result of the bite angle of the tetrahedral phosphorus not being conducive for forming a planar five-membered ring. It may well be that in the dithiocarbamate ligand, the CS_2 unit is flexible enough to allow for planarity in both the bridging and chelating ligands, and in any event for electronic reasons there is conjugation with the amido lone pair which is not possible for the dithiophosphate ligands.

A final point of interest to us is that the W—S distances to the chelating $S_2P(OEt)_2$ ligands

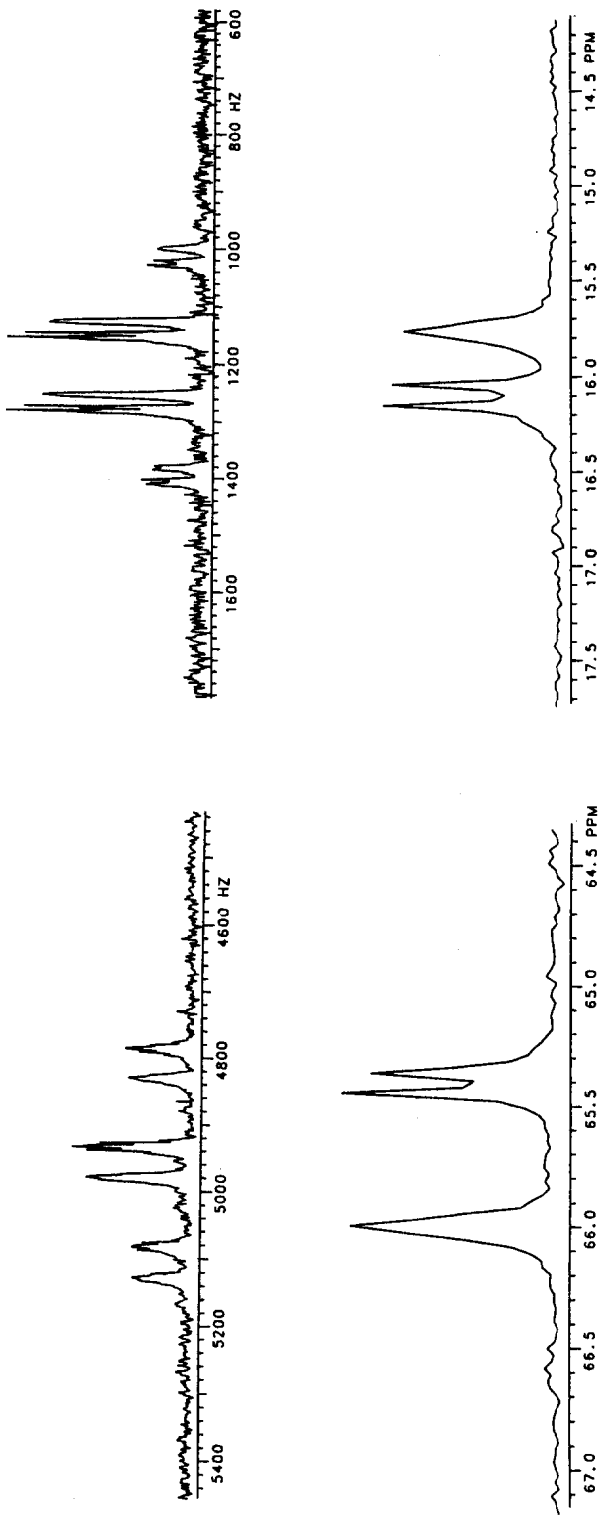

Fig. 2. ^{13}C NMR spectrum of $W_2S_2[S_2P(OEt)_2]_4$ (A), and $^{13}C\{^1H\}$ NMR spectrum (B) recorded in benzene-d_6 at 75 MHz.

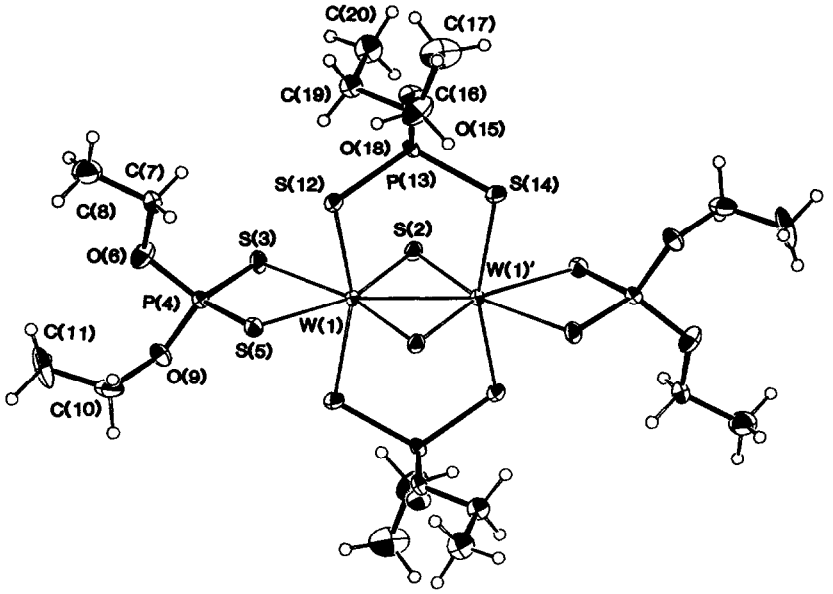

Fig. 3. ORTEP view of the centrosymmetric $W_2S_2[S_2P(OEt)_2]_4$ molecule giving the atom-numbering scheme used in the tables.

are longer than those to the bridging $S_2P(OEt)_2$ ligands. The difference, 2.57 vs 2.48 Å (averaged), is the same as noted for d^1–d^1 dinuclear compounds of formula $W_2(OPr^i)_6(O_2C_2R_2)_2$[13] and $Mo_2(OPr^i)_6(O_2C_6Cl_4)_2$, where $O_2C_6Cl_4$ is *ortho*-tetra-chlorobenzoquinone in its fully reduced form.[14] The reasoning for the differences in M—L_{ax} vs M—L_{eq} distances, though small, could have a similar origin as that invoked previously.[13]

Electronic absorption spectra

The electronic absorption spectra of both **1** and **2** are compared in Fig. 5. Both molecules are dark green and both show several absorption features between 300 and 750 nm. The spectrum of **1** has two well-resolved maxima at 645 nm (1.55×10^4 cm^{-1}) and 443 nm (2.26×10^4 cm^{-1}) as well as a series of absorptions between 400 and 300 nm. The spectrum of **2** is quite similar to **1** except for the inclusion of a new absorption at low energy [693 nm (1.44×10^4 cm^{-1})]. This transition at low energy does not appear to be present in the spectrum of **1** and thus may be due to: (1) a change in point group from C_{2h} in **1** to D_{2h} in **2**, or (2) a difference in the ligands supporting the molecules. A summary of the UV–visible spectral data is given in Table 3.

If it is assumed that the M–M δ- and δ^*-orbitals

are occupied and lie to lower energy than the M–M σ- and π-orbitals, because these represent sulfur-based orbitals, then we might look for the lowest-energy transition to be M–M $\pi \rightarrow \pi^*$. However, in the absence of a detailed MO calculation which reliably establishes the ground state electronic

structure, we must defer further speculation about such an assignment.

Concluding remarks

Compound **1** provides another example of a compound containing a metal–metal double bond. Since this molecule is quite similar to the **2** molecule,[9] we have been able to compare relatively subtle changes in the physical properties of these molecules. The electronic structure though not well understood, almost certainly has the valence MO configuration of $\sigma^2\pi^2$ for the M–M bond.

EXPERIMENTAL

All operations were carried out using standard Schlenk and Glove-box techniques with dry and oxygen-free solvents and atmospheres. Starting

materials were prepared via published procedures.[15,16] Diethyldithiophosphoric acid and diethyldithiuramdisulfide were purchased from Aldrich and the acid was degassed by two freeze–pump–thaw cycles.

^{1}H NMR spectra were run on a Nicolet NT-360 spectrometer at 360 MHz, and chemical shifts are reported in δ ppm with the ^{1}H impurity of benzene-d_6 set at δ 7.15 ppm. ^{13}C NMR spectra were run on a Varian XL-300 spectrometer at 75 MHz. ^{31}P NMR spectra were run on a Varian XL-100 at 40.5 MHz.

IR spectra were obtained on a Perkin–Elmer 283 spectrophotometer as Nujol mulls, between CsI salt plates and referenced to polystyrene at 1601 cm^{-1}.

Electronic absorption spectra were obtained on a Perkin–Elmer 330 spectrophotometer using matched 1.00- and 0.10-cm quartz cells. Spectral grade solvents were used without further purification, except for degassing.

Elemental analysis was performed by Alfred Bernhardt Microanalytisches Laboratorium, Elbach, West Germany.

Synthesis

$W_2S_2[S_2P(OEt)_2]_4$. In a Schlenk flask, 0.50 g (0.67 mmol) of $W_2Np_2[OPr^i)_4$ was dissolved in 10 cm^3 of toluene. The flask was cooled to 0°C in an ice bath. To this was added via a syringe, 0.69 cm^3 (4.1 mmol, 6 equivalents) of diethyldithiophosphoric acid. The solution immediately turned from yellow to turquoise, and then after several minutes turned dark green. After the solution had turned green the solvent was removed *in vacuo* to give a green waxy microcrystalline solid. Hexane was added and the green solution was filtered. The volume of the solution was reduced until several small crystals began to appear. The flask was then slowly cooled to −20°C. After 24 h large green cubes had formed. The solvent was removed via a cannula to yield 0.48 g of the product (61% yield based on tungsten). This compound is air-stable in the solid state for indefinite periods.

Analysis: Found: C, 16.5; H, 3.3; N, < 0.03; S, 27.4. Calc. for $W_2S_{10}P_4O_8C_{16}H_{40}$: C, 16.4; H, 3.4; N, 0.00; S, 27.3%.

IR (cm^{-1}): 272(mw), 310(mw), 452(w), 523(m), 539(m), 630(ms), 647(ms), 762(ms), 778(ms), 786(s), 948(vs), 957(vs), 970(vs), 999(vs), 1010(vs), 1032(vs), 1099(mw), 1160(mw), 1275(vw).

^{1}H NMR (22°C) (benzene-d_6): δ 4.35 (dq, $^3J_{HH}$ = 7.2 Hz, $^3J_{PH}$ = 9.7 Hz, C$\underline{H}_2$CH$_3$), δ 3.46 (p, $^3J_{HH}$ = 7.2 Hz, $^3J_{PH}$ = 7 Hz), δ 1.12 (t, $^3J_{HH}$ = 7.2 Hz, CH$_2$C$\underline{H}_3$), δ 0.76, (t, $^3J_{HH}$ = 7.2 Hz, CH$_2$C$\underline{H}_3$).

^{31}P–{^{1}H} NMR (22°C) (benzene-d_6): δ 193.96 [s, bridging $S_2P(OEt)_2$], δ 127.37 [s, chelate $S_2P(OEt)_2$].

^{13}C–{^{1}H} NMR (22°C) (benzene-d_6): δ 65.99 (s, $\underline{C}H_2CH_3$), δ 65.37 (d, $^2J_{PH}$ = 10.4 Hz, $\underline{C}H_2CH_3$), δ 16.08 (d, $^3J_{PH}$ = 8.3 Hz, $CH_2\underline{C}H_3$), δ 15.75 (s, $CH_2\underline{C}H_3$).

Melting point: 127–132°C, turns red with decomposition.

An alternative synthesis used $W_2(OBu^t)_6$[16] in place of $W_2Np_2(OPr^i)_4$ with the procedure described above. The yield was 52% based on tungsten.

$W_2S_2(S_2CNEt_2)_4$. The procedure of Cotton *et al.*[9] was used to prepare this compound. $W(CO)_3(NCMe)_3$ (1.0 g, 1.7 mmol), was placed in a Schlenk flask and dissolved in acetone. To this was added 2 equivalents (1.04 g, 3.4 mmol) of diethyldithiuramdisulfide using a solids addition tube. The solution was stirred for 24 h, after which a green powder had precipitated from a red solution. The solid was collected by filtration, to give 0.27 g (15% yield based on tungsten). The red product appeared to be $W(S_2CNEt_2)_4$ based on ^{1}H NMR.

^{1}H NMR (22°C) (benzene-d_6): δ 4.11 (q, $^3J_{HH}$ = 7.2 Hz, C$\underline{H}_2$CH$_3$), δ 3.34 (q, $^3J_{HH}$ = 7.2 Hz, C$\underline{H}_2$CH$_3$), δ 1.47 (t, $^3J_{HH}$ = 7.2 Hz, CH$_2$C$\underline{H}_3$), δ 0.92 (t, $^3J_{HH}$ = 7.2 Hz, CH$_2$C$\underline{H}_3$).

Crystallography. General operating procedures and a listing of programs have been given.[17] Crystal data for **1** are summarized in Table 4. An air-stable green-black crystal with dimensions 0.20 × 0.21 × 0.21 mm was selected and affixed to the end of a glass fiber with silicone grease, and then transferred to a Picker goniostat and cooled to −152°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with systematic absences and symmetry consistent with the monoclinic space group $P2_1/n$. Subsequent solution and refinement confirmed this choice.

Data were collected in the usual manner and Lorentz-polarization and absorption corrections applied yielding a unique set of 2456 reflections. Of these, 2445 reflections had $F > 3.0\,\sigma(F)$. The R on averaging was 0.020 for 644 reflections measured more than once.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques, and was refined by full-matrix least squares. Many of the hydrogen positions were visible in a difference Fourier map phased on the non-hydrogen structure after isotropic refinement. Subsequent refinements with anisotropic parameters for all non-hydrogen atoms and, with hydrogen positional and thermal parameters included as variables, resulted

in some of the C—H bonds being observed as uncomfortably long and also indicated that the carbon atoms of one of the ethoxy groups had gone non-positive definite. Attempts to locate a suitable disorder model for this ethoxy group were without success. Refinement was resumed with isotropic temperature factors for these two carbon atoms and anisotropic parameters for all other non-hydrogen atoms. The hydrogens were included in the succeeding cycles of least squares as fixed contributors at calculated positions and with thermal parameters of $1 + B_{iso}$ that of the carbon atoms to which they were bound. The final-difference map was essentially featureless, with the largest peak being 1.0 e Å^{-3} and located 0.3 Å from the tungsten atom.*

*Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

EXTRACTION OF Pd FROM ACIDIC HIGH-ACTIVITY NUCLEAR WASTE USING PUREX PROCESS COMPATIBLE ORGANIC EXTRACTANTS

R. G. SHULER, C. B. BOWERS, Jr, J. E. SMITH, Jr, V. VAN BRUNT and M. W. DAVIS, Jr*

Department of Chemical Engineering, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 11 *August* 1986; *accepted* 10 *October* 1986)

Abstract—Purex process compatible organic systems which selectively and reversibly extract Pd from synthetic mixed fission product solutions containing 3 M HNO_3 have been developed. This advance makes the development of continuous solvent extraction processes for its recovery more likely. The matrix solution consists of tributyl phosphate (TBP) and kerosene in a TBP/kerosene ratio of 0.667. The anion exchangers Aliquat 336 and Alamine 336 both selectively extract Pd from the synthetic mixed fission product solution. The most effective Pd extractant appeared to be the tertiary amine Alamine 336. In a concentration of 0.3 M in the organic matrix solution when contacted with an equal volume of aqueous phase containing 0.004514 M Pd a distribution coefficient ($D_{org/aq}$) of 1.95 was observed at 25°C. This was an order of magnitude greater than the distribution coefficient for any of the other species in the solution.

Reprocessing of nuclear fuel from commercial power reactors when combined with the use of breeder reactors would increase the power available from nuclear fuel by a factor of 100 and would also permit recovery of potentially valuable fission products such as Pd. If Pd were recovered from nuclear waste it would serve as a new source of the metal whose producer cost is set by the Soviet Union and the Union of South Africa.

This article summarizes research to define solvent extraction process chemistry that is compatible with the Purex process for reprocessing of commercial nuclear waste and specific for the economic recovery of useful fission products. Military nuclear waste could also be treated before neutralization.

The work reported here is concerned with the treatment of Purex process acidic waste in order to remove elements for which beneficial uses have been or may be found. It is of course understood that the recovery and purification of U and Pu would be an economic justification for commercial reprocessing. This economy results if the U use cycle includes a breeder reactor which allows the conversion of ^{238}U to ^{239}Pu reactor fuel and therefore increases the U power production potential by more than 100-fold over that of natural U which contains only 0.72% ^{235}U.

Using the ORIGEN-2 code (CCC-371) from the Oak Ridge National Laboratory and the conditions of operation for a PWR shown in Table 1, the isotopic composition of the Pd produced in the reactor was obtained.

On a basis of a metric ton of initial U metal 1.380 kg of Pd is produced. The isotropic composition as a function of cooling time is shown in Fig. 1. On

Table 1. Typical commercial power reactor fuel and operational conditions

Fuel	3.2% U-235
Burnup	33,000 MWD metric ton
Exposure	880 days in reactor
Neutron flux (specific power)	3.24×10^{14} cm^2 s^{-1}

the basis of a single commercial reprocessing plant, such as the AGNS plant, operating at 5 metric tons per day or 1500 metric tons per year approximately 7% of the U.S. Pd needs could be met (Moore,[1] Shuler,[2] and Davis and Van Brunt[3]. Of the six Pd isotopes produced only ^{107}Pd is very slightly radioactive, but it could have a restricted use in industrial applications without creating a health hazard.

Pd behavior from reprocessing flowsheets has been studied by Vialard and Germain.[4] They conclude that under certain conditions Pd will precipitate with most reagents used for partitioning. However, it appears in the waste stream at the Savannah River Plant. The basic behavior of most fission products in both nitrate and chloride media is discussed by Orth *et al.*[5] Recovery from waste streams has been performed by ion exchange. Use of liquid ion exchange reagents for selective recovery has been performed by Horwitz and Delphin.[6] As opposed to previous research, this paper focuses on the selective solvent extraction of Pd from a synthetic multielement mixed fission product solution with a Purex process compatible solution.

EXTRACTION OF Pd WITH TRIBUTYL PHOSPHATE (TBP)

The distribution of Pd in TBP–kerosene solutions is important because during primary decontamination in the Purex process, U and Pu are separated from most of the fission products by extraction with an organic solution containing 30 vol% TBP in kerosene. It is necessary to know whether large amounts of the Pd are extracted during this step or whether it remains with the other fission products (Lunichkina *et al.*,[7] De and Sen,[8]

Casey *et al.*,[9] and Gindon *et al.*[9]). Lunichkina *et al.*[7] reported maximum distribution ratios of Pd of about 1.3 and about 0.24 for solutions of 100% TBP and 30% TBP in decane, respectively, when the aqueous phase was at low acidity (0.4–0.8 M HNO_3). A rapid decrease in the $D_{org/aq}$ of Pd was observed when the molarity of HNO_3 exceeded 1 M.

Contacts made between solutions of 0.001 M Pd in varying HNO_3 concentrations (0.5, 1, 2, 3, 4, 6 and 9 M) and TBP–kerosene solutions of varying vol% TBP (30–70, 50–50, 70–80, 80–10 and 100% TBP) formed a fine black precipitate at the interface except for the 6 and 9 M HNO_3 solutions. The percent of Pd extracted increased with increasing TBP content, and it decreased with increasing HNO_3 concentration, although at 1.0 M there appeared to be a slight increase in percent removed over that at 0.5 M. This is in agreement with the maximum observed by Lunichkina *et al.*[7] at HNO_3 concentrations between 0.4 and 0.8 M. After settling for several days, much of the precipitate returned to the solution. Lunichkina *et al.*[7] also reported the formation of a solid phase containing Pd in certain systems. They attributed this to the reduction of Pd(II) to the metallic state due to the formation of TBP degradation products. For example: TBP is subject to hydrolysis (Alcock *et al.*,[11] and Siddall[12]); the reaction of water with TBP gives DBP (di-*n*-butyl phosphate) and butyl alcohol; HNO_3 also reacts directly to give DBP and butyl nitrate; and the formation of DBP is greatly increased if the solvent is held for protracted periods at temperatures above 50°C. DBP can be effectively removed by washing with almost any basic solution.

EXPERIMENTAL

As described in Shuler *et al.*[13] a synthetic mixed fission product solution was developed based on 1.4 M uranium. The mixture is given in Table 2. The experimental procedure for multielement analysis is provided in Shuler *et al.*[13] Utilizing an ICP-5000, inductively coupled plasma, all elements with the exception of Ru and Cs were analyzed. Flame atomic emmission using an Atomic Absorption spectrophotometer was used for the Ru and Cs analysis. Care was taken to optimize the operation conditions and the wavelengths of analysis to minimize interference. The conditions of analysis are given elsewhere (Shuler[2] and Shuler *et al.*[13]).

Alamine 336 and Aliquat 336 were evaluated as organic anion exchangers in this work. Their structures are shown in Fig. 2.

In order to have compatibility with the Purex process it was necessary to convert the Aliquat 336 chloride salt to the nitrate form. This was done by first preparing solutions containing the desired concentration of the chloride salt in TBP and kerosene and then equilibrating this with an equal volume of 3 M HNO_3 in a separatory funnel. The mixture was shaken for 30 min on a wrist action shaker and then allowed to separate. The aqueous layer was decanted and the procedure was then repeated two more times with fresh 3 M HNO_3.

Alamine 336

Fig. 2. Structures of organic anion exchangers.

After initial evaluation of the quarternary- and tertiary-amine extractability with single-element solutions, amine extractability with the synthetic mixed fission product solution was evaluated. The behavior of the quarternary- and tertiary-amine salts used in this work is thought to follow the mechanisms suggested by Koch.[14] Figure 3 shows the effect of temperature on the Pd distribution at the molarity conditions that provided the highest distribution coefficients with the mixed fission product solution. TBP concentration appeared to have little effect on the distribution of the Pd.[2] The high TBP/kerosene ratio of 0.667 was chosen to insure that there was no third-phase formation which had been observed at low TBP/kerosene ratios.[2]

The multielement mixed fission product solution distributions are reported in Tables 3 and 4. The 0.1 M Aliquat 336 (nitrate) solution is selective for Pd over all other components found in the solution. Table 4 shows the behavior of the tertiary amine Alamine 336 at 0.3 M. This solution appears to be highly selective for Pd over the other fission products.

BACK EXTRACTION STUDIES

It was found that the Pd could be recovered from the Alamine solution by back extraction with 8 M HNO_3 in two equal volume contacts. Eighty percent recovery was obtained with three equal volume contacts with a 3 M HNO_3 solution followed by one contact with a 2:1 aq:org volumetric ratio. Ninety-six percent recovery could be obtained from the Aliquat 336 solution. Under these processing conditions only two phase systems were observed.

RECOMMENDED PROCESS CHEMISTRY FOR Pd EXTRACTION

The experimental results indicated that from a synthetic mixed fission product solution, an organic

phase consisting of 0.3 M Alamine 336 in a 33 vol% TBP–66 vol% kerosene matrix would extract Pd with a $D_{org/aq}$ of 1.95. The Pd can be recovered from the solvent by back extraction with aqueous nitric acid.

CONCLUSION

This work has resulted in a Purex compatible organic solution that is highly selective for Pd recovery from mixed fission product solutions. Two phase systems without precipates were observed with the recommended process chemistry.

It appears that Pd can be selectively and reversibly extracted from commercial nuclear fuel if reprocessing is ever considered. This would involve treating the high-activity nuclear acidic waste after uranium and plutonium removal and prior to neutralization.

PREPARATION AND STRUCTURAL CHARACTERIZATION OF Os(II) AND Ru(II) COMPLEXES, $MCl_2(vdpp)_2$ [M = Os OR Ru, vdpp = 1,1-BIS(DIPHENYLPHOSPHINO)ETHENE]

F. A. COTTON,* M. P. DIEBOLD and M. MATUSZ

(*Received* 15 *July* 1986; *accepted* 15 *August* 1986)

Abstract—A reaction between $Os_2(O_2CCH_3)_4Cl_2$ and vdpp [vdpp = 1,1-bis(diphenylphosphino)ethene] was investigated. When the reactants, in the presence of LiCl, were heated in toluene $OsCl_2(vdpp)_2$, **1**, was formed. In a similar reaction $Ru_2(O_2CCH_3)_4Cl$ with vdpp afforded $RuCl_2(vdpp)_2$, **2**. The molecular structures of **1** and **2** were elucidated using X-ray crystallography. Single crystals of **1** and **2** grown from dichloromethane–hexane crystallize in the space group $P2_1/c$ with these cell dimensions: $a = 11.046(2)$ Å, $b = 18.168(3)$ Å, $c = 12.678(3)$ Å, $\beta = 110.24(2)°$ and $V = 2387(2)$ Å^3 for **1** and $a = 11.055(1)$ Å, $b = 18.199(3)$ Å, $c = 12.693(2)$ Å, $\beta = 110.16(1)°$, $V = 2392(1)$ Å^3 for **2**. The molecules of **1** and **2** are isostructural. Metal atoms reside on inversion centers relating the two halves of the molecules. The complexes are six-coordinate with two four-membered chelate rings and *trans* chlorine atoms. For $RuCl_2(vdpp)_2$ the P–M–P angle in the chelate ring is 73.13(2)° and the P–C–P angle in the chelate ring is 98.6(1)°. These values are 72.74(3)° and 97.9(2)°, respectively, for $OsCl_2(vdpp)_2$. There is a disordered dichloromethane solvent molecule present in the lattice and there are no unusual intermolecular contacts.

In our continuing effort to investigate the chemistry of multiple bonds between osmium and ruthenium atoms[1–3] we turned our attention to exploring the possibility of forming multiply bridged dimers with diphosphine ligands acting as the bridges. Initial experiments with dppe and dppm[4–5] indicated that only monomers were formed under a variety of conditions. We decided to employ vdpp [vdpp = 1,1-bis(diphenylphosphino)ethene] as a bridging ligand in the hope that the phosphine would favor a bridging mode of coordination because of the presumed strain a four-membered chelate ring would impose on the sp^2 carbon atom.

Our hope was not fulfilled and instead of dinuclear $M_2X_4(LL)_2$ type species we obtained the quasi-octahedral $MX_2(LL)_2$ (M = Os or Ru) complexes. These belong to a familiar class of M(II) compounds, some of which has been previously structurally characterized.[6] Rather than inventing any fictitious or *ex post facto* justification for the synthesis of **1** and **2**, we candidly report it as a failure to synthesize the desired dimers, albeit still a worthwhile chemical finding.

EXPERIMENTAL

All reactions were carried out in an inert atmosphere using standard Schlenk techniques. $Os_2(O_2CCH_3)_4Cl_2$ and $Ru_2(O_2CCH_3)_4Cl$ were prepared according to the literature procedures.[4,7] Vdpp was prepared as described previously.[8] All solvents were freshly distilled from appropriate drying agents.

Preparation of $OsCl_2(vdpp)_2$, 1

A round-bottomed flask was charged with 0.60 g (14 mmol) anhydrous LiCl and dried at 110–115°C for 2 h. The flask was removed from the oven and placed under vacuum for 15–20 min while it cooled. $Os_2(O_2CCH_3)_4Cl_2$ (0.10 g, 0.145 mmol), vdpp (0.40 g, 1.0 mmol) and toluene (10 cm^3) were added to the flask. The reaction mixture was refluxed with stirring for 2 days. It was cooled and filtered. The solid residue was extracted with dichloromethane and filtered to give a red colored

* Author to whom correspondence should be addressed.

solution. The volume of the solution was reduced to *ca* 10 cm^3 and hexane was layered on top of it. After several days a crop of dark red crystals was collected. Yield: *ca* 80 mg (52%).

Preparation of $RuCl_2(vdpp)_2$, **2**

A synthetic procedure analogous to that described above was used. The reaction was carried out in 30 cm^3 of toluene. From the filtrate a small crop of needle-shaped orange crystals was collected. From the dichloromethane solution a crop of block-shaped dark red crystals was collected. Yield, *ca* 60 mg (30%).

X-ray crystallography

Single crystals of **1** and **2** were mounted on the tip of a glass fiber. Cell constants were refined on a set of 25 high angle reflections and axial lengths were confirmed by partial rotation photographs. In the case of the osmium complex, **1**, empirical absorption corrections based on azimuthal scans near $\chi = 90°$ were applied. Data were corrected for Lorentz and polarization factors and processed according to procedures routine to this laboratory.[9] Heavy atom positions in **1** were determined from a Patterson map, and the solution of **2** was initiated by using the coordinates of heavy atoms from the structure of **1**. In each case remaining atoms (including hydrogen atoms on the phosphine ligand) were found by an alternating series of least-squares refinements and difference Fourier maps. Hydrogen atoms were included in the last refinement cycles and were allowed to refine freely. All atoms except hydrogen atoms were refined with anisotropic displacement parameters. All pertinent crystallographic data are presented in Table 1.*

RESULTS AND DISCUSSION

The reasons for conducting the reactions that lead to the formation of $OsCl_2(vdpp)_2$ and $RuCl_2(vdpp)_2$ were stated above. Both complexes belong to the well-known group of $MX_2(LL)_2$ compounds were LL is a chelating diphosphine (see Ref. 10 for reviews of Ru complexes and Ref. 11 for reviews of Os complexes).

Two isomers, *cis* and *trans*, are possible for these types of compounds and it is interesting that only the *trans* isomer was formed in the case of osmium. In the preparation of $RuCl_2(vdpp)_2$, there was also a small amount of an orange crystalline material, which might be the *cis* isomer.

Lithium chloride was included in these syntheses because of our recent success in synthesizing $Os_2(fhp)_4Cl$ (fhp = fluorohydroxypyridinato) in high yields when LiCl is present.[12] The formation of **1** is accompanied by the reduction of Os(III,III) to Os(II) and the formation of **2** is accompanied by the reduction of Ru(III,II) to Ru(II). Excess phosphine is the most likely reducing agent. One could suggest a more rational method of preparing **1** and **2** but we have made no attempt to explore alternative syntheses or to refine our present procedure.

As expected for Os(II) and Ru(II) complexes in octahedral environments, complexes **1** and **2** are diamagnetic, showing ^1H NMR spectra in $CDCl_3$ solution that consist of a multiplet centered at 7.24 ppm (C_6H_5) and a triplet at 5.93 ppm (CH_2) for **1** and 6.17 ppm for **2** ($J = J_{HP} + J_{HP'} = 9$ Hz for Os and 12 Hz for Ru). Both complexes crystallize in the monoclinic space group $P2_1/c$. In both cases a disordered molecule of dichloromethane is present in the lattice and located near an inversion center. There are two orientations of the CH_2Cl_2 molecule (related by the inversion center) and one orientation was chosen and assigned 0.5 occupancy. The positional parameters as well as isotropic-equivalent displacement parameters are given in the

supplementary material. In Table 2 selected bond distances and angles of both compounds are presented. A complete listing of bond distances and angles as well as general displacement parameters and calculated and observed structure factors is available as supplementary material. An ORTEP drawing of $OsCl_2(vdpp)_2$, **1**, is presented in Fig. 1.

Our original hope that the sp^2 bridging carbon would not permit the formation of a four-membered chelate ring was not realized. The P–C–P angles are 97.9(2)° and 98.6(1)° for **1** and **2**, respectively. These angles are larger than those found in the dppm complexes[6] (e.g. the P–C–P angle in *trans*-$RuCl_2(dppm)_2$ is 93.4(4)° and that in *cis*-$OsCl_2(dppm)_2$ is 94.4°), which would be expected when going from sp^3 to sp^2 carbon. It is uncertain whether this is related to increased strain of the four-membered ring since the corresponding angles in the free phosphine are not known. The Cl–M–P angles do not deviate significantly from 90°. Metal–chlorine distances range from 2.42–2.43 Å and metal–phosphorus distances range from 2.33–2.34 Å in both complexes. All other distances and angles are within expected ranges and require no further comment.

This study demonstrates that the formation of four-membered chelate rings is common, especially with the later transition metals. We are also exploring the significance of using LiCl in substituting carboxylate ligands with a variety of other ligands.

REACTIONS BETWEEN $W_2I_4(CO)_8$ AND PHOSPHINES UNDER FORCING CONDITIONS: ATTEMPTED DECARBONYLATION TO TUNGSTEN(II) DIMERS WITH QUADRUPLE METAL–METAL BOND—X-RAY MOLECULAR STRUCTURE OF $WI_2(CO)(dppm)_2$

F. ALBERT COTTON,* LARRY R. FALVELLO and RINALDO POLI

(*Received* 18 *July* 1986; *accepted* 24 *October* 1986)

Abstract—The reactions of $W_2I_4(CO)_8$ with bis(diphenylphosphino)methane (dppm) and PMe_3 have been studied under forcing conditions. From the dppm reaction a monocarbonyl compound has been isolated, which crystallizes as $3WI_2(CO)(dppm)_2 \times 2$ toluene. Crystal data: space group $C2/c$, $a = 31.141(8)$, $b = 25.447(7)$, $c = 20.135(6)$ Å, $\beta = 104.89(4)°$, $V = 15420(20)$ Å^3, $Z = 4$, $R = 0.0538$ for 4367 data with $F_o^2 > 3\sigma(F_o^2)$. The PMe_3 reaction afforded $WI_2(CO)_2(PMe_3)_3$ as the major product. No derivatives containing a metal–metal quadruple bond were detected in solution.

Recent investigations carried out in this Laboratory[1–4] led to the discovery of a new reaction, namely thermal decarbonylation of $Mo_2I_4(CO)_8$ in the presence of phosphines, which is at the same time a new reactivity path for compounds of the $Mo_2X_4(CO)_8$ type and a new synthetic method for $Mo_2X_4L_4$ or $Mo_2X_4(L–L)_2$ compounds with a metal–metal bond.

In an attempt to extend this method to the analogous tungsten complexes, the thermal reaction of $W_2I_4(CO)_8$[5] with selected phosphines was carried out. PMe_3 and bis(diphenylphosphino)methane (dppm), i.e. the phosphines which gave the best results with the molybdenum system,[1,2] were chosen. Quadruply bonded tungsten dimers could not be obtained and the isolated products were carbonyl complexes related to intermediates of the molybdenum reactions. These products and the mechanism of their formation are discussed here.

EXPERIMENTAL

All operations were carried out by standard Schlenck tube techniques under an atmosphere of purified argon. Solvents were dehydrated by conventional methods and distilled under dinitrogen. Instruments used were: IR, Perkin–Elmer mod 783; UV–visible, Cary 17. Solution IR spectra were recorded on expanded abscissa and calibrated with both $CO_{(g)}$ and $H_2O_{(g)}$. Elemental analyses were by Galbraith Laboratories Inc., Knoxville, Tennessee. $W_2I_4(CO)_8$[5] and PMe_3[6] were prepared by known procedures. Dppm was purchased from Strem Chemicals and used without further purification.

Reaction of $W_2I_4(CO)_8$ *with dppm*

$W_2I_4(CO)_8$ (0.52 g, 0.47 mmol) and dppm (0.40 g, 1.04 mmol) were dissolved in 50 cm^3 of toluene to produce, after gas evolution, an orange solution with IR bands at 2035m, 1962s, 1938m, 1908m and 1856w cm^{-1}. The solution was then refluxed and the reaction monitored by IR in the carbonyl stretching region. After *ca* 24 h all of the bands had practically disappeared and a new, weak band at *ca* 1775 cm^{-1} had grown. The mixture was filtered while hot and slowly cooled to room temperature. The red crystals that formed (compound **1**, *ca* 72 mg) were decanted, washed with *n*-hexane and dried *in vacuo*. Found: C, 50.4; H, 3.8. Calc. for $C_{167}H_{148}I_6O_3P_{12}W_3$: C, 51.6; H, 3.8%. IR (Nujol mull) (cm^{-1}): 1765s,

* Author to whom correspondence should be addressed.

1590w, 1575w, 1435m, 1355w, 1315w, 1160w, 1085m, 1030w, 1005w, 975w, 845w, 790m, 745s, 735s, 720m, 690s, 615w, 595w, 520m, 505m, 480m, 450w, 420m; (CH_2Cl_2 solution) (cm^{-1}): 1778. Subsequent work-up of the mother solution did not lead to the isolation of any pure crystalline material. UV–visible spectroscopy on this solution did not show any band in the 600–900-nm region.

Reaction of $W_2I_4(CO)_8$ *with* PMe_3

$W_2I_4(CO)_8$ (0.75 g, 0.69 mmol) was treated in 20 cm^3 of toluene with 0.30 cm^3 of PMe_3 (3.0 mmol). A yellow solution and a flocculent yellow precipitate were obtained after gas evolution. The solution had IR bands at 2071w, 2046w, 2014s, 1936s, 1907s and 1888vs cm^{-1}. The mixture was then warmed to reflux and at the same time irradiated with a UV-mercury lamp. The solid gradually dissolved and the color changed to red within 12 h. This solution had IR bands at 2017w, 1926vs, *ca* 1900w (sh), 1827vs and 1731m cm^{-1}. Color and IR spectrum did not change upon further treatment for an additional 24 h. UV–visible spectroscopy did not show any band in the 600–900-nm region. After evaporation to dryness, the residue was washed several times with hot *n*-hexane to give red solutions whose prominent IR band was at 1730 cm^{-1}, and to leave a yellow microcrystalline material. This was recrystallized by dissolution in toluene and slow diffusion of *n*-hexane to give large orange crystals (compound **2**, yield 0.33 g). Found: C, 18.7; H, 3.8. Calc. for $C_{11}H_{27}I_2O_2P_3W$: C, 18.3; H, 3.8%. IR (Nujol mull) (cm^{-1}): 1915s, 1820vs, 1430m, 1425m, 1415w, 1305m, 1300w, 1285m, 1275ms, 950s, 870w, 860w, 730m, 670w, 585w, 570w, 515w, 490w, 445w; (toluene solution) (cm^{-1}): 1925s, 1830s (asymmetric).

X-ray crystallography for compound **1**

Data collection and reduction were carried out by routine procedures. A semi-empirical absorption correction was applied according to the method described by North *et al.*[7] The structure solution and the early stages of refinement were performed with the Enraf–Nonius SDP software. On the basis of systematic absences, the space group could be either *Cc* or *C2/c*. Direct methods on the non-centrosymmetric space group showed three independent and equivalent arrangements of heavy atoms, which were initially assigned the WI_3 formulation. The positional parameters were in agreement with an extra symmetry element, this being a C_2-axis passing through a W and an I atom of one of the three WI_3 groupings. Refinement was thus attempted in the *C2/c* space group, which led to correct development of the structure. All iodine atoms which were not in a special position were first refined at full occupancy but I(2), I(3) and I(4) refined with unusually high thermal parameters. Chemical information and elemental analyses suggested that this compound might be a di-iodide derivative of tungsten; we therefore considered the possibility of having, in each independent molecule, one iodide atom disordered over two mutually *trans* positions. Assignment of a 0.5 occupancy factor to the above mentioned iodine atoms led to correct refinement. Subsequent alternate difference Fourier maps and least-squares full-matrix refinements showed the positions of all the atoms of the dppm ligands and the carbonyl carbon atoms. The latter ones were refined at half occupancy. The *R* factor was 0.070. The carbonyl oxygen atoms were not located on the difference Fourier map. Since they were expected to be at about the same position as the iodine atoms, they were introduced in the atom list starting with the same positions as those of the iodine atoms. Subsequent refinement was performed with the SHELX-76 package of programs. The phenyl rings were constrained to be perfect hexagons (C—C = 1.395 Å) and the C—O distances were restrained to a value of 1.14(2) Å, which is the distance found for the same bond in $MoI_2(CO)(dmpm)_2$[dmpm = bis(dimethylphosphino)methane], having a geometry similar to that of the present compound.[3] Isotropic refinement converged to $R = 0.068$. All the atoms were then allowed to behave anisotropically and refined. The carbonyl carbon and oxygen atoms did not refine well, most probably because of high correlation with the iodine atoms, and they were therefore left isotropic. At this point, the difference Fourier map showed peaks ascribable to a toluene molecule in a general position of the lattice, with the methyl groups disordered over two positions at bonding distance to two *ortho* carbons of the ring. Independent refinement of all parameters led to instability. To avoid this, the toluene ring was constrained to be a perfect hexagon (C—C = 1.395 Å), the methyl groups restrained at 1.47(10) Å from the corresponding ring atoms and with a constraint on their occupancies such that the sum of these be equal to 1. Finally the isotropic thermal parameters of all the carbon atoms of the toluene molecule were constrained to the same value, which was refined. Final refinement converged to $R = 0.0538$ ($R_w = 0.0670$). Significant crystal data are reported in Table 1, while selected bond distances and angles are reported in Table 2.

[b] $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w |F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
[c] Quality-of-fit = $[\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

RESULTS AND DISCUSSION

The reaction of $W_2I_4(CO)_8$ with phosphines and diphosphines had already been the subject of several studies.[5,8,9] Dppm was one of the ligands employed:[8] its reaction was shown to lead to the formation of $WI_2(CO)_3(dppm)$ and $WI_2(CO)_2(dppm)_2$ with 2 and 4 equivalents, respectively, per tungsten dimer at room temperature, and a reflux treatment of the dicarbonyl derivative in $CHCl_3$ gave rise to the formation of *trans*- and *cis*-$[WI(CO)_2(dppm)_2]I$.[9]

We used, for our reaction, a solvent (toluene) with a higher boiling point and less polarity than that used by Colton and Rix.[9] In agreement with their findings, we obtained a mixture of $WI_2(CO)_3(dppm)$ (bands at 2035m, 1962s and 1908m cm^{-1}; cf. with 2030m, 1960s, 1935m and 1910m cm^{-1} in acetone[9]) and small amounts of $WI_2(CO)_2(dppm)_2$ (bands at 1938m and 1856w cm^{-1}; cf. with 1940s and 1855s in CH_2Cl_2 or $CHCl_3$[8]) at room temperature; the appearance of the dicarbonyl derivative is presumably due to the small excess of the diphosphine over the 1:2 stoichiometry. When, however, the solution was refluxed, we obtained neutral compounds. $WI_2(CO)(dppm)_2$ (**1**), not previously reported, was obtained in low yields; other toluene-soluble, non-carbonyl-containing materials were also present but we were not able to isolate them in crystalline form. The lack of a visible absorption band in the 600–900-nm region, however, rules out the possibility

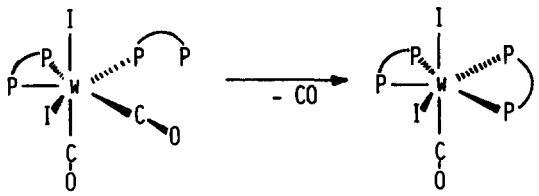
[a] Numbers in parentheses are estimated standard deviations in the least significant digits.

that the quadruply bonded dimer $W_2I_4(dppm)_2$ was present.*[10]

Although not certain, it would seem that, upon reflux, $WI_2(CO)_3(dppm)$ gives rise to the unidentified non-carbonyl materials, presumably containing a dppm/W ratio of 1, while $WI_2(CO)_2(dppm)_2$ produces compound **1**. A few complexes with a stoichiometry similar to that of $WI_2(CO)_2(dppm)_2$ have been structurally characterized {e.g. $MoCl_2(CO)_2(dpam)_2$,[11] $MoBr_2(CO)_2(dpam)_2$,[12] [dpam = bis(diphenylarsino)methane], $MoCl_2(CO)_2(dppm)_2$[11] and $MoI_2(CO)_2(dppm)_2$[13]} and found to be seven-coordinate with one chelating and one monodentate phosphine. By assuming that $WI_2(CO)_2(dppm)_2$ also has such a structure, the formation of **1** can easily take place by chelation of the second diphosphine *via* preliminary dissociation of a CO ligand (see Scheme 1). In the thermal treatment carried out by Colton and Rix,[8] on the other hand, the substitution of one iodide ligand occurs, presumably because of the higher polarity of the solvent.



Scheme 1.

The crystal structure of compound **1** exhibits two independent molecules of $WI_2(CO)(dppm)_2$, one in a general position and one located on a C_2-axis, which passes through W(2) and I(5). One molecule of toluene is also present in the asymmetric unit, so that the composition of the crystalline material is $3WI_2(CO)(dppm)_2 \times 2$ toluene. Figure 1 shows a view of the molecule which is on the general position. Both independent molecules show the same geometry around tungsten, which is fairly close to that of an ideal pentagonal bipyramid, and have identical structural parameters within the experimental error. One iodide ion and the two diphosphine ligands are in the equatorial plane, and the second iodide ion and the carbonyl ligand are in the axial positions. The symmetry imposes a 50:50 disorder of the axial iodide and carbonyl ligands in the molecule lying on the C_2-axis. In the other molecule, although this is not required by symmetry, the same ligands were also found to be 50:50 disordered among the two axial positions. Figure 1 shows only one of the two orientations, for clarity. This result can be easily explained by considering the presence of eight bulky phenyl groups which completely surround the I–W–CO core of the molecule. The packing of the molecules in the crystal is expected to be dominated by the van der Waals' interactions of the phenyl groups. The random disorder of the two possible orientations shows that the arrangement of the axial I–W–CO system does not appreciably influence the energy of the crystal.

The molecular structure is the same as that found[3] for $MoI_2(CO)(dmpm)_2$. The "bite" angles of the diphosphines in **1** are a little smaller [63.6(2), 63.9(2) and 63.7(2)°, compared with 65.7(2) and 66.1(2)° for $MoI_2(CO)(dmpm)_2$[3]], perhaps because of steric repulsion between the phenyl groups. The W—I distance, as expected,[14] is larger for the axial bonds [2.980(7), 2.984(5) and 2.985(6) Å] than for the equatorial ones [2.876(2) and 2.876(3) Å]. The W—P bond lengths are all close to 2.55 Å, which is *ca* 0.05 Å longer than those of the corresponding Mo–dmpm complex.[3]

It is interesting to compare the reactivity of $W_2I_4(CO)_8$ towards dppm with that of the corresponding molybdenum system. The reaction of $Mo_2I_4(CO)_8$ with dppm (1:2 molar ratio) under forcing conditions afforded $Mo_2I_4(dppm)_2$ (Mo—Mo) in high yields.[2] No similar compound appears to be formed from $W_2I_4(CO)_8$. Also, $MoI_2(CO)_2(dppm)_2$ was found to decompose in refluxing toluene and no formation of $MoI_2(CO)(dppm)_2$, analogous to **1**, could be observed.[3,13] Instead, such a decomposition reaction seemed to produce $Mo_2I_4(dppm)_2$ upon loss of diphosphine and CO. In the tungsten reaction, on the other hand, compound **1** was produced, which seemed to be rather stable in such conditions. It might be that the presumably higher energies of the W—P, W—I and W—CO bonds with respect to those of the Mo—P, Mo—I and Mo—CO bonds are capable of thermodynamically or kinetically stabilizing a highly crowded structure such as that of compound **1**. The same may not be true in the molybdenum system. It is worth noting in this respect that when the more basic and less sterically demanding dmpm ligand was employed, $MoI_2(CO)(dmpm)_2$ was obtained, and this was found to be fairly stable in refluxing toluene.[3]

The room-temperature reaction of $W_2I_4(CO)_8$

* $W_2Cl_4(PMe_3)_4$ has the $\delta \rightarrow \delta^*$ absorption at 657 nm, *ca* 80 nm red-shifted with respect to the same band of $Mo_2Cl_4(PMe_3)_4$.[10] Since $Mo_2I_4(dppm)_2$ has the $\delta \rightarrow \delta^*$ maximum at 707 nm,[2] the hypothetical $W_2I_4(dppm)_2$ compound is expected to have the same band at a higher wavelength, around 800 nm.

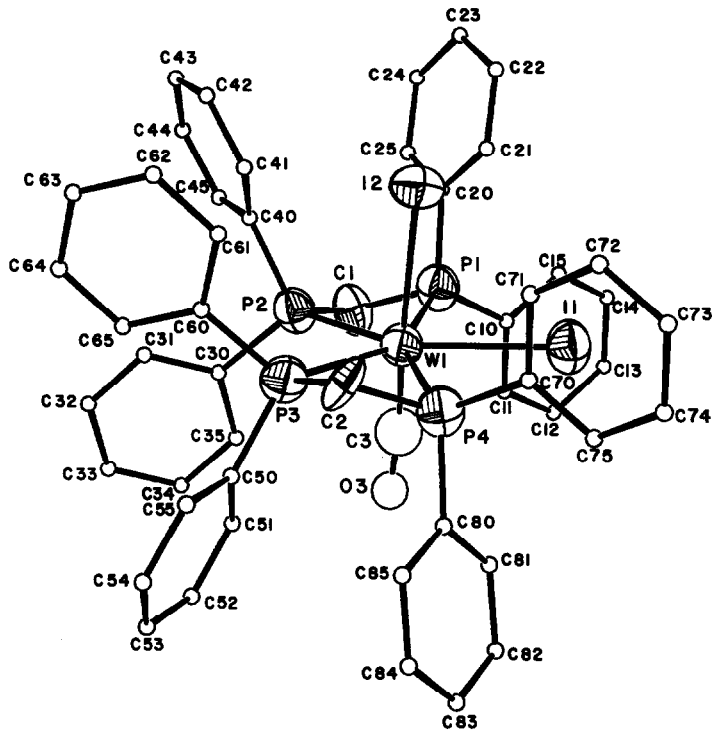


Fig. 1. ORTEP view of the molecule of compound **1** which lies in a general position. Atoms I(3), C(4) and O(4) have been omitted for the sake of clarity. For the same reason, the phenyl carbon atoms have been drawn with arbitrary radii.

with PMe_3 produced a solution containing several products, as judged from the complexity of the IR spectrum. Some of the bands could presumably be assigned to $WI_2(CO)_3(PMe_3)_2$ [the room-temperature interaction of $W_2I_4(CO)_8$ with PPh_3 was reported[5] to afford the tricarbonyl derivative, $WI_2(CO)_3(PPh_3)_2$]. After prolonged reflux with simultaneous UV irradiation, $WI_2(CO)_2(PMe_3)_3$ (**2**) was the major product, isolated in *ca* 33% yield with respect to tungsten (49.5% with respect to PMe_3). The fate of the rest of the tungsten is unknown, although small amounts of a more soluble material, having an IR band at 1731 cm^{-1}, were detected by IR spectroscopy; the position of the IR band suggests that this compound may be a monocarbonyl derivative of tungsten(II). Again, visible absorption bands in the 600–900-nm region were not detected in the final solution, which means that tungsten(II) dimers with a quadruple bond between the metals did not form. This is again in contrast with the results of the same reaction on molybdenum systems.[1,4]

The formation of tungsten–tungsten quadruple bonds by decarbonylation of tungsten(II) carbonyl derivatives proves then to be a difficult, if not impossible, reaction, contrary to what was found for the analogous molybdenum systems. One factor contributing to this might be the higher stability of the tungsten(II) carbonyls with respect to those of molybdenum(II), as suggested by higher W—CO bond energies, at least for M(0) derivatives.[15] Also, the molybdenum–molybdenum quadruple bond is generally less reactive than the same bond between tungsten(II) ions, and thus more likely to remain intact once formed. Both these factors should cause the decarbonylation of tungsten(II) carbonyls to be more difficult and, in turn, the reaction of $W_2X_4L_4$ (W—W) systems with CO to be easier. A few reactions of $W_2Cl_4(PR_3)_4$ systems with CO have actually been studied and reported to be more facile than those of the corresponding molybdenum(II) dimers.[16]

SYNTHESIS OF DIVALENT ARYLOXY- AND DIORGANOAMIDO-LANTHANIDES FROM BIS(PENTAFLUOROPHENYL)LANTHANIDE(II) COMPLEXES

G. B. DEACON,* C. M. FORSYTH and R. H. NEWHAM

Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

(*Received* 2 *February* 1987; *accepted* 23 *February* 1987)

Abstract—The complexes $M(OR)_2(thf)_3$ (M = Yb or Eu, R = 2,6-Bu^t_2-4-MeC_6H_2; M = Yb, R = 2,4,6-$Bu^t_3C_6H_2$ or 2,6-$Bu^t_2C_6H_3$; thf = tetrahydrofuran) and $M(NR_2)_2(thf)_4$ (M = Yb or Eu, R_2N = carbazol-9-yl; M = Yb, R_2N = 2-phenylindol-1-yl) have been prepared by reactions of $(C_6F_5)_2M$ (M = Yb or Eu) with substituted phenols, carbazole, or 2-phenylindole.

Lanthanide(III) aryloxides, alkoxides and diorganoamide complexes are well established,[1–7] but much less is known of the lanthanide(II) derivatives. Complexes of bis[bis(trimethylsilyl)amido]-europium(II) and -ytterbium(II)[8–10] and anionic derivatives $Na\{M[N(SiMe_3)_2]_3\}$(M = Yb or Eu)[10] have been characterized crystallographically, whilst $Yb[N(SiMe_3)_2]_3^-$ has been generated electrochemically.[5] Recently $M[N(SiMe_3)_2]_2$(dme) (M = Yb, Eu, or Sm; dme = 1,2-dimethoxyethane) have been prepared by redox transmetallation from $Hg[N(SiMe_3)_2]_2$ and the ytterbium complex converted into $(Bu^tO)_2Yb$ by alcoholysis.[11] Divalent ethoxides of ytterbium and samarium have been prepared by metathesis from the diiodides.[12]

We now report facile syntheses of some bis-(aryloxy)- and bis(diorganoamido)-ytterbium(II) and -europium(II) compounds by acidolysis of the corresponding bis(pentafluorophenyl)lanthanides[13,14] with bulky phenols and secondary amines [reactions (1) and (2)]. The preparations were carried out in purified tetrahydrofuran (thf) under purified nitrogen.

(M = Yb or Eu, R_2N = carbazol-9-yl;

M = Yb, R_2N = 2-phenylindol-1-yl)

Solutions of the organolanthanide reactants were obtained by redox transmetallation between $(C_6F_5)_2Hg$ and the lanthanide metal[13,14] and were filtered before addition of stoichiometric amounts of the phenols or amines as solids or solutions in tetrahydrofuran. Rapid reaction generally occurred but the reaction mixtures were stirred for 16–24 h at room temperature. Some complexes, $Yb(OR)_2$ (R = 2,6-Bu^t_2-4-MeC_6H_2, 2,4,6-$Bu^t_3C_6H_2$ or 2,6-$Bu^t_2C_6H_3$) and bis(2-phenylindol-1-yl)ytterbium(II), were also prepared by reaction between bis(pentafluorophenyl)mercury, the phenol or 2-phenylindole (R_2NH), and an excess of ytterbium

* Author to whom correspondence should be addressed.

metal in tetrahydrofuran at room temperature.

$$(C_6F_5)_2Hg + 2ROH\,(\text{or } 2R_2NH) + Yb$$

$$Yb(OR)_2\,[\text{or } Yb(NR_2)_2] + 2C_6F_5H + Hg\downarrow. \quad (3)$$

The initial step is presumably the redox transmetallation synthesis of $(C_6F_5)_2Yb$, and it has been shown that ytterbium does not react with 2-phenylindole or 2,6-di-*t*-butyl-4-methylphenol in the absence of $(C_6F_5)_2Hg$.

The products precipitated from solution in the case of the sparingly soluble bis(carbazol-9-yl)lanthanides. In other cases, the compounds were isolated by evaporation to dryness [after filtration where reaction (3) was used] or by evaporation to low volume, addition of hexane and crystallization. All were obtained as highly air-sensitive yellow solids and had the analytical compositions, $M(OR)_2(thf)_3$ and $M(NR_2)_2(thf)_4$. The infrared spectra of the complexes showed no absorption above 3100 cm^{-1} establishing loss of the OH and NH protons in reactions (1)–(3). Intense absorption at 1035–1020 cm^{-1} and 880–860 cm^{-1} in the spectrum of each complex is attributable to ring stretching modes of tetrahydrofuran, shifted from the free ligand values, 1070 and 912 cm^{-1}, as expected on coordination.[15] The UV/Vis/near IR spectra (300–1500 nm) of the bis(carbazol-9-yl)lanthanides in 1,2-dimethoxyethane show intense bands (ε 2000–9000) at 300–400 nm attributable to 5d ← 4f transitions and L ← M charge transfer.[16–18] There was no absorption near 1000 nm for the ytterbium complex, hence the presence of ytterbium(III) can be eliminated. Brief exposure to air generated absorption of free carbazole and ytterbium(III). The UV/Vis/near IR spectra of $M(OR)_2(thf)_3$ (M = Yb or Eu; R = 2,6-Bu^t_2-4-MeC_6H_2) in tetrahydrofuran also show intense absorption at 300–400 nm. Unusually, complexes of lanthanide(III) ions with bulky aryloxide ligands are soluble in petroleum ether,[6] but the present bis(aryloxy)lanthanide(II) complexes are insoluble. Whilst this may indicate associated structures by contrast with the monomeric lanthanide(III) aryloxides,[6] it may simply be a reflection of greater ionic character for lanthanide(II) derivatives; see e.g. the hydrides.[19]

Reactions (1)–(3) further indicate the synthetic value of bis(pentafluorophenyl)lanthanide(II) reagents, which have previously been used in C-acid displacements with phenylacetylene[20] and cyclopentadiene[21] to give the corresponding diorganolanthanides, as well as in organic synthesis.[22,23] The present reactions reflect greater acidity for phenols[24] and carbazole[25] than pentafluorobenzene.[26]

THE SOLUTION CONSTITUTION OF THE ROUSSIN ESTER $Fe_2(SBu\text{-}t)_2(NO)_4$

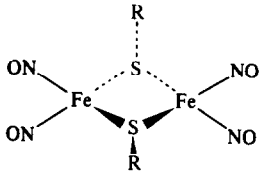
ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL* and IAN L. JOHNSON

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

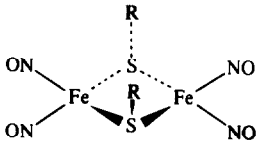
(*Received* 27 *August* 1986; *accepted after revision November* 1986)

Abstract—The ^1H and ^{15}N NMR spectra of the Roussin ester $Fe_2(SBu\text{-}t)_2(NO)_4$ show that in solution it exists as a mixture of two isomeric forms (**I** and **II**), of C_{2h}- and C_{2v}-symmetry, respectively. Unlike other similar esters, $Fe_2(SR)_2(NO)_4$, the isomers are present in non-equal proportions: the equilibrium constant $K = [\mathbf{II}]/[\mathbf{I}]$ is unchanged in the temperature range 220–298 K, indicating that entropy factors are primarily responsible for the unequal abundance of **I** and **II**.

The X-ray structure analysis of the ethyl ester of Roussin's red salt, $Fe_2(SEt)_2(NO)_4$, showed[1] the molecule to be centrosymmetric, having approximate C_{2h} molecular symmetry. However, in solution a series of esters $Fe_2(SR)_2(NO)_4$ (R = Me, Et, *n*-Pr, CH_2Ph[2] or Ph[3]) were shown by ^1H NMR spectroscopy to exist in solution as an equimolar mixture of two isomeric forms, and activation parameters were measured[2] for their interconversion for R = Me, Et, *n*-Pr, *i*-Pr and CH_2Ph. In the cases of R = Me and *i*-Pr, the identities of the isomers as having C_{2h}- and C_{2v}-symmetry **I** and **II**, respectively, were rigorously established[4] using ^{15}N NMR spectroscopy on 99% ^{15}N-enriched samples.



I



II

However in the case of R = *t*-Bu, we did not in our earlier work[2] observe any splitting of the single even at 223 K, and the question of the solution structure of $Fe_2(SBu\text{-}t)_2(NO)_4$ could not be resolved. Here we present results from ^1H and ^{15}N NMR spectroscopy which establish the solution structure of $Fe_2(SBu\text{-}t)_2(NO)_4$.

The ^{15}N NMR spectrum of $Fe_2(SBu\text{-}t)_2(^{15}NO)_4$ consists of a singlet, and a pair of doublets which comprise an AX spin system (Table 1). As previously,[4] the singlet is assigned to the C_{2h} isomer (**I**) in which all the nitrosyl ligands are identical: the AX spectrum is assigned to the C_{2v} isomer (**II**), in which two nitrosyl ligands bound to each iron are in different environments: no long range $^4J(^{15}NFeSFe^{15}N)$ was resolved, consistent with earlier observations[4] on $Fe_2(SMe)_2(^{15}NO)_4$ and $Fe_2(SPr\text{-}i)_2(^{15}NO)_4$.

For $Fe_2(SMe)_2(^{15}NO)_4$ and $Fe_2(SPr\text{-}i)_2(^{15}NO)_4$, the integrated intensities showed[4] that the C_{2h} and C_{2v} isomers exist in equal abundance at 298 K, as deduced[2] earlier from the ^1H spectra. In the ^{15}N spectrum of $Fe_2(SBu\text{-}t)_2(^{15}NO)_4$, however, the intensities show that the C_{2h} isomer (**I**) is very much the minor isomer, present in 26 ± 1% abundance at both 298 and 220 K. The constancy of the equilibrium constant $K = [\mathbf{II}/\mathbf{I}]$ over this temperature range implies that for the isomerization **I** → **II** $\Delta H^\ominus$ is effectively zero: a K value of 2.85 ± 0.15 gives $\Delta S^\ominus$ for isomerization as 8.7 ± 0.4 J K^{-1} mol^{-1}. The entropy differences which give rise to the unequal abundance of **I** and **II** presumably arises from a differential solvation of the two isomers: specific solvation of Roussin esters $Fe_2(SR)_2(NO)_4$ has been invoked[5] previously to rationalize ASIS observations. If this is so, then the two isomers should exhibit equal abundances in the vapour phase.

Table 1. ^{15}N NMR data for $Fe_2(SR)_2(^{15}NO)_4$

Compound	T (K)	C_{2h} isomer δ (ppm)	C_{2v} isomer δ (ppm)	J (Hz)
$Fe_2(SMe)_2(^{15}NO)_4$[a]	298	30.5(s)	23.1(d), 36.2(d)	2.8
$Fe_2(SPr\text{-}i)_2(^{15}NO)_4$[a]	298	30.2(s)	26.7(d), 35.7(d)	2.6
$Fe_2(SBu\text{-}t)_2(^{15}NO)_4$	298	38.8(s)	31.1(d), 37.1(d)	3.0
	220	36.6(s)	28.8(d), 35.6(d)	3.1

[a] Data from Ref. 4.

$CDCl_3$ solution, there is a single resonance at $\delta = 1.43$ ppm, which shows no perceptible broadening until the freezing point of the solvent is approached. Hence in this solvent the protons in the two isomers are fortuitously isochronous. In toluene-d_8 solution, the ASIS phenomenon shifts the sharp ($\nu_{1/2} = 0.5$ Hz) room-temperature resonance to $\delta = 1.22$ ppm. However, on cooling, the spectrum was resolved into two peaks separated at 80 MHz by 1.2 Hz at 260 K and 1.7 Hz at 240 K. Because of the small peak separation, accurate integration was not possible, but an approximate estimate of the peak areas was consistent with the value of K deduced from the ^{15}N spectrum. The coalescence temperature was determined as 289 K.

EXPERIMENTAL

Samples of $Fe_2(SBu\text{-}t)_2(^{14}NO)_4$ and $Fe_2(SBu\text{-}t)_2(^{15}NO)_4$ were prepared from $Fe_2(SBu\text{-}t)_2(CO)_6$ by use of ^{14}NO gas in $CHCl_3$ solution and $Na[^{15}NO_2]$ in DMF solution, according to published procedures.[2,4] $Fe_2(SBu\text{-}t)_2(^{14}NO)_4$ was identified and characterized by mass spectrometry, ^1H and ^{13}C NMR spectroscopy, and IR spectroscopy: $\nu(^{14}NO)$, 1770, 1743 cm^{-1}. $Fe_2(SBu\text{-}t)_2(^{15}NO)_4$ was characterized by ^{15}N NMR and IR-spectroscopy: $\nu(^{15}NO)$, 1739, 1712 cm^{-1}. ^{15}N NMR spectra were recorded relative to external $CH_3{}^{15}NO_2$ in the FT mode on the Brüker WH-360 spectrometer of the Science and Engineering Research Council regional NMR service at the University of Edinburgh, using spectral conditions and parameters as previously described.[4]

COMMUNICATION

A NOVEL SIX-VERTEX COORDINATION POLYHEDRON IN THE CRYSTAL STRUCTURE OF THE $CuBr_2$ COMPLEX OF 1,6-BIS(BENZIMIDAZOL-2-YL)-2,5-DIOXAHEXANE

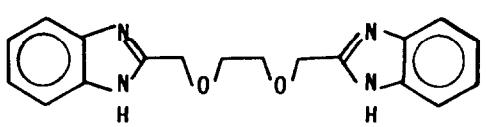
WILLIAM CLEGG* and JOYCE C. LOCKHART

Department of Inorganic Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 8 *September* 1986; *accepted* 1 *December* 1986)

Abstract—A novel polyhedron has been discovered in the coordination geometry of the $CuBr_2$ complex of 1,6-bis(benzimidazol-2-yl)-2,5-dioxahexane. A rhombus or lozenge-shaped base (BrNBrN) shares its edges with four BrNO triangles and its Br vertices with two BrOO triangles, all six triangles lying on one side of the base. The polyhedron may be derived from an octahedron (with a *trans*-Br_2, *cis*-O_2, *cis*-N_2 arrangement of vertices) by breaking the N...N edge and bringing the N atoms into coplanarity with the Br atoms.

We have previously reported the preparation of some polydentate and macrocyclic ligands incorporating benzimidazole, and of complexes of these with transition-metal ions.[1] The determination of one of these complexes, formed from $CuBr_2$ and the ligand 1,6-bis(benzimidazol-2-yl)-2,5-dioxahexane (**1**) has revealed a novel coordination polyhedron for the Cu atom.



1

EXPERIMENTAL

The preparation of the complex has already been described.[1] It was recrystallized from a methanol–chloroform mixture.

Crystallography

$C_{18}H_{18}Br_2CuN_4O_2$, $M_r = 545.7$, orthorhombic, *Pccn*, $a = 8.940(1)$, $b = 10.634(1)$, $c = 20.455(2)$ Å, $V = 1944.6$ Å^3, $Z = 4$, $D_c = 1.864$ g cm^{-3}, $F(000) = 1076$, $\mu = 5.22$ mm^{-1} for Mo-K_α radiation ($\lambda = 0.71073$ Å). Of 2828 reflections measured with a Stoe–Siemens AED2 diffractometer at 295K ($2\theta_{max} = 50°$), and corrected for absorption by semi-empirical methods, 1725 were unique ($R_{int} = 0.034$), and 1068 with $F > 4\sigma(F)$ were used for structure determination by automatic direct methods.[2] Blocked-cascade refinement to minimize $\Sigma w\Delta^2$ [$\Delta = |F_o| - |F_c|$, $w^{-1} = \sigma^2(F)$] with anisotropic thermal parameters for non-H atoms, constrained H atoms [C—H = 0.96 Å, aromatic H on external ring angle bisectors, H—C—H = 109.5° for aliphatic H, $U(H) = 1.2U_{eq}(C)$] and an isotropic extinction correction [$F_c' = F_c/(1 + xF_c^2/\sin 2\theta)^{1/4}$, $x = 6.4(6) \times 10^{-7}$] gave $R = 0.066$, $R' = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.043$, a satisfactory analysis of variance, and no significant features in a final difference synthesis.

RESULTS AND DISCUSSION

The molecular structure is shown in Fig. 1, and the bond lengths and angles for the coordination of Cu are given in Table 1. A crystallographic C_2-axis passes through the Cu atom, bisecting the C(12)—C(12′) bond. The Cu atom is coordinated by the oxygen and two nitrogen atoms of ligand **1** and by two bromine atoms. The six-vertex polyhedron thus formed has a geometry never documented

previously, and *outré* even in Cu(II) chemistry (Fig. 2). The Cu atom is bonded strongly to two N and two Br atoms which form a basal plane with essentially a rhombus or lozenge shape (Br and N atoms deviate by only ±0.03 Å from their mean plane; N...Br edges are 3.12 and 3.18 Å long, the axes of the rhombus are a shorter N...N of 3.96 Å and a longer Br...Br of 4.90 Å). The Cu atom lies 0.22 Å above this basal plane, displaced towards the two O atoms, to which it is more weakly bonded. The O...O line is approximately parallel to the N...N line, forming six triangular faces, all above the basal rhombus: four BrNO triangles share one BrN edge each with the rhombus, while the two BrOO triangles, with a common O...O edge, share only their Br vertices with the rhombus (Fig. 2). The O...N edges are 2.69 Å long, O...O is 2.64 Å, and the Br...O edges group as two at 3.71 Å and two slightly longer at 3.98 Å.

The relationship between the observed polyhedron (with six vertices, 11 edges and seven faces) and an octahedron (six vertices, 12 edges and eight faces) may be seen by reference to Figs 1 and 2(a). If both N atoms are displaced downwards from the basal plane (away from the O atoms), the N—Cu—N angle and N...N distance decrease; with sufficient displacement, a N...N edge may be considered to form and the rhombus is converted to two NBrN triangular faces of an actahedron.

The long Cu—O distance, forced by the ligand architecture, is reminiscent of the even longer Cu—O bond (3.08 and 3.14 Å in two independent molecules) notable in the most recent (1.8 Å resolution) determination of an azurin structure,[3] in which a peptide oxygen (of GLY45) is held in a peptide loop over a planar arrangement of imidazole nitrogens (HIS46 and HIS117) and cysteinyl sulphur (CYS112) around copper, the trigonal bipyramid in this case being completed by a long Cu—S (MET121) of 3.13 Å *trans* to Cu—O.

In the present structure, the coordination geometry is such as to leave one side of the Cu atom

essentially unligated. This vacant side is, however, protected by the bulky benzimidazole groups protruding on the same side as is shown by the space-filling representation in Fig. 3.

Future extensions of this work will be concerned with exploiting the pocket formed on one side of the lozenge-shaped basal coordination plane (which may be compared with the lacunar complexes of Busch *et al.*[4]), with a view to new host–guest formulations.

THE REACTIONS OF SOME PENTAAMMINE(*o*-SUBSTITUTED BENZOATO)CHROMIUM(III) CATIONS IN PERCHLORIC ACID AND WATER

RODNEY L. WILLIAMSON and JAMES C. CHANG*

Department of Chemistry, University of Northern Iowa, Cedar Falls, IA 50614, U.S.A.

(*Received* 7 *July* 1986; *accepted after revision* 1 *December* 1986)

Abstract—The reactions of pentaammine(*o*-fluorobenzoato)-, pentaammine(*o*-bromobenzoato)- and pentaammine(*o*-nitrobenzoato)chromium(III) cations in 0.01 M perchloric acid solution and water have been studied at 21°C. It was found that the reaction in acid was the release of ammonia but in water it was aquation to the pentaammineaquachromium(III) cation. The aquation rates in water decrease in the order *o*-fluorobenzoate, *o*-bromobenzoate and *o*-nitrobenzoate complexes, suggesting an associative mechanism.

The mechanism of the aquation of some pentaammine- and pentaaqua complexes of chromium(III) has been suggested to be I_a, based upon studies of pressure effects.[1,2] Since one of the chemical methods to distinguish between dissociative and associative mechanisms is by changing the size of the leaving group,[3] we have undertaken a study of the aquation of some pentaammine (*o*-substituted benzoato)chromium(III) cations in order to see whether any difference in the aquation rates could be detected with different size substituents.

EXPERIMENTAL

Pentaammine(*o*-fluorobenzoato)chromium(III), pentaammine(*o*-bromobenzoato)chromium(III) and pentaammine (*o*-nitrobenzoato)chromium(III) perchlorates were prepared by a method similar to that used by Jackman *et al.*[4] and Chang *et al.*[5] In a typical preparation, 10 mmol of an acid in 10 cm^3 of dimethylformamide (dmf) and 5 mmol of dicyclohexylcarbodiimide in 5 cm^3 of dmf were stirred for 30 min, after which the white precipitate of dicyclohexylurea was filtered off. To the filtrate was added 1.0 mmol of pentaammineaquachromium(III) perchlorate in 10 cm^3 of dmf, pretreated with 5 mmol of *N*,*N*-dimethylbenzylamine. The solution was stirred for 20 min at room temperature, then 50 cm^3 of absolute ethanol and 300 cm^3 of diethyl ether were added to the mixture to produce a red oil. The solvent was decanted, and the oil was dissolved in 20 cm^3 of a 1:1 ethanol–acetone mixture. Again 200 cm^3 of diethyl ether was added to this mixture, and a solid compound precipitated upon vigorous stirring. The percentage yield was about 20%. Found: C, 18.6; H, 4.4; N, 13.4. Calc. for $CrC_7H_5O_2(NH_3)_5$: C, 18.6; H, 4.2; N, 14.8%. Found: C, 16.3; H, 4.0; N, 12.5. Calc. for $CrC_7H_5O_2Br(NH_3)_5$: C, 15.7; H, 3.5; N, 13.0%. Found: C, 18.2; H, 3.9; N, 15.6. Calc. for $CrC_7H_5NO_4(NH_3)_5$: C, 16.7; H, 3.8; N, 16.7%.

All visible absorption spectra were measured using a Cary 14 recording spectrophotometer. The rate of aquation was followed by observing the decrease in the absorbance of aqueous solutions of the complexes at 490 nm. The rate of release of NH_3 in 0.01 M $HClO_4$ was followed by the analysis of NH_3, eluted from Dowex AG50W-X8 columns, with Nessler's reagent.

RESULTS AND DISCUSSION

It was observed that the pentaammine(*o*-substituted benzoato)chromium(III) cations reacted in 0.01 M $HClO_4$ by the release of NH_3. Actually, the odor of NH_3 could be detected from the solid

Table 1. Rate constants for the hydrolysis of $[Cr(X\text{-}C_6H_5COO)(NH_3)_5]^{2+}$ cations in perchloric acid (k_{NH_3}) and water (k_{aq}) at 21°C

X	k_{NH_3} (s^{-1})	k_{aq} (s^{-1})
F	1.87×10^{-5}	8.32×10^{-4}
Br	1.89×10^{-5}	4.10×10^{-4}
NO_2	2.50×10^{-5}	1.35×10^{-4}

compounds, upon storage, even in the dark. This loss of NH_3 in the solid state resulted in the fairly poor elemental analyses. Other Cr(III) complexes undergoing Cr—N bond rupture in solution have been reported. $[Cr(ox)(en)_2]^+$ hydrolyzed in acidic solution to give $[Cr(ox)(H_2O)(en)(enH)]^{2+}$,[6] and α-$[Cr(ox)(trien)]^+$ hydrolyzes to give $[Cr(ox)(H_2O)(trienH)]^{2+}$.[7] House[8] has found that $[Cr(ox)(NH_3)_4]^+$ aquates in dilute $HClO_4$ to give $[Cr(ox)(H_2O)(NH_3)_3]^+$, and Linck[9] has found that some bis(1,2-ethanediamine)chromium(III) complexes also undergo Cr—N bond rupture in acidic solutions. The rate constants of the NH_3 release (k_{NH_3}) for the three complexes studied were about the same at 21°C (see Table 1); therefore it seemed that a common intermediate was involved in the Cr—N bond rupture process. Several mechanisms for the bond rupture have been proposed,[10-12] but our data are insufficient to favor any mechanism.

The visible absorption spectra of the three complexes in water all resemble the spectrum of the acetatopentamminechromium(III) cation[10] with maxima at 488 ± 2 and 366 ± 1 nm, and a minimum at 423 ± 1 nm. A repeated scan of the spectra showed isosbestic points, and the spectra of all three complexes changed to one that resembled the spectrum of $[Cr(H_2O)(NH_3)_5]^{3+}$; therefore in aqueous solutions these complexes aquate to the pentaammineaquachromium(III) cation. The observed isosbestic points [listed as wavelength (nm) and molar absorptivity (in parentheses) ($dm^3\ mol^{-1}\ cm^{-1}$)] are as follows: *o*-fluorobenzoate complex, 555 (19), 442 (25), 399 (22); *o*-bromobenzoate complex, 556 (20), 434 (26), 329 (22); o-nitrobenzoate complex, 555 (18), 452 (34). Plots of $\ln(A_t - A_\infty)$ vs time gave good straight lines from which the rate constants of aquation (k_{aq}) at 21°C were evaluated (see Table 1).

The rate constants of aquation in water showed a decreasing trend from the *o*-fluorobenzoate complex to the *o*-bromobenzoate complex to the *o*-nitrobenzoate complex. Since the acid dissociation constants of the three *o*-substituted benzoic acids are of the same order of magnitude, the difference in the aquation rates must not be caused by the base strength of the benzoates. Also, the aquation occurs in water but not in acid so that the base strength of the benzoate anions probably had little effect on the reaction rates. The inductive effects of the three substituents are in the increasing order F^- to Br^- to NO_2^- as the Taft substituent constants are 0.17, 0.29 and 0.83, respectively, evaluated from the reaction rates of substituted naphthoic acids and naphtholates.[13] This order of the inductive effect predicts that the *o*-nitrobenzoate complex should react the fastest and the *o*-fluorobenzoate complex the slowest, but the observed rates are just the reverse. However, the steric effect of these substituents are in the increasing order NO_2^- to Br^- to F^- as the steric substituent constants are −0.75, 0.00 and +0.49, respectively.[14] This order of the steric effect predicts that the *o*-fluorobenzoate complex should react the fastest and the *o*-nitrobenzoate complex the slowest, and this is the order found in our study. Thus we have found that a larger leaving group reacted slower than a smaller leaving group in these pentaammine(carboxylato)chromium(III) complexes, and an associative mechanism is indicated.

Several complexes of type *cis*-$[Cr(A)_2(en)_2]^+$ (A^- = propionate, isobutyrate or pivalate) have been prepared,[15] and preliminary studies have indicated that the complexes with a large leaving group (pivalate or 2,2-dimethylpropionate) aquate slower than that with a small leaving group (propionate). Details of this study will be reported later.

MOLECULAR STRUCTURE OF TETRAKIS[BENZENETHIOLATOTRIMETHYLPLATINUM(IV)], $(\mu_3\text{-SPh})_4(PtMe_3)_4$

DON C. CRAIG and IAN G. DANCE*

School of Chemistry, University of New South Wales, PO Box 1, Kensington, NSW 2033, Australia

(*Received* 17 *September* 1986; *accepted* 22 *December* 1986)

Abstract—The crystal structure of the title compound is reported, and the geometry and symmetry of the three-fold bridging by the arylthiolate ligand with two-fold symmetry is assessed. Pt—S bond lengths are differentiated by only 0.04 Å. Crystal data: $C_{36}H_{56}Pt_4S_4$, $M = 1897.4$, tetragonal, space group $P4_32_12$, $a = 14.187(1)$, $c = 40.399(6)$ Å, $U = 8131.11$ Å^3, $Z = 8$.

In the substantial number of metal thiolate complexes now characterized structurally[1] some abnormal geometries have appeared around triply-bridging thiolate ligands. For instance, in the crowded molecule $Ag_6(SC_6H_4Cl)_6(PPh_3)_5$ (**1**),[2] two of the S atoms have two S—Ag bonds and the S—C bond virtually coplanar, with the third S—Ag bond inclined at an angle of 67 or 63°. A similar stereochemistry occurs in $(\mu_3\text{-SPh})_2(\mu\text{-SPh})_2(CuPPh_3)_4$ (**2**).[3] In **1** even further deviation from the expected tetrahedral stereochemistry for $M_3(\mu_3\text{-SR})$ occurs with some S atoms lying *outside* their Ag_3C coordination polyhedra. In some cases the thiolate S atom primarily bridges two metal atoms, pyramidally, with a longer secondary connection to another metal atom.[1]

This abnormal non-three-fold geometry at triply-bridging thiolate is observed for aryl substituents, which confer non-three-fold (mirror) symmetry on the ligand. The question arises as to whether electronic (or steric) factors in the arylthiolate ligands could be responsible for dissymmetric triple bridging. Arguments have been presented for the occurrence of M—SAr π-bonding in $(ArS)_2(Pr^iO)MoMo(OPr^i)(SAr)_2$,[4] which could cause such dissymmetry.

The $(\mu_3\text{-SR})_4(PtMe_3)_4$ series of high-symmetry cubanes[5] provide a good test of these questions, and therefore we have determined the molecular structure of the compound with R = Ph (**3**). The structure of the member with R = Me, (**4**), in which the substituent need not break the molecular symmetry, has been reported.[5]

RESULTS AND DISCUSSION

The molecular structure of **3** is shown in Fig. 1, and dimensions are provided in Table 1. The molecular symmetry is close to S_4, the highest possible, with the virtual S_4 axis bisecting the Pt1--Pt4 and Pt2--Pt3 vectors. Dimensions averaged under this symmetry (standard deviation of the sample in parentheses) are: Pt—S 2.51(2) Å, Pt--Pt 3.83(1) Å, S--S 3.20(2) Å, Pt—C 2.09(2) Å, S—Pt—S 79.4(6)°, C—Pt—C 88(2)°, S—Pt—C(*cis*) 96(3)°; the value of S—Pt—S is indistinguishable from that of **4**, but the values of Pt—S and Pt--Pt are *ca* 0.03 Å larger.

Close examination of the molecular structure reveals minor but significant metrical features associated with the orientations of the phenyl rings. The plane of each phenyl ring can be twisted at most by 30° from a Pt—S bond, when viewed along the C—S bond as shown in Fig. 2: that is the smallest Pt—S—C—C torsional angle (ϕ) must lie in the range 0–30°. It can be seen from Table 1 that these angles range from 3 to 15°, indicating a

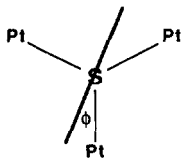

Fig. 2. Conformations and torsional angle (ϕ) for triply-bridging arylthiolate, viewed along the C—S bond. The thick line represents the plane of the arylthiolate ligand.

weak tendency of the ligand plane to adopt the "eclipsed" symmetrical conformation with $\phi = 0$ rather than the "staggered" symmetrical conformation with $\phi = 30°$. The Pt—S bond which is closest to the plane of the ligand substituent is slightly longer than the other two: the mean of the four close Pt—S bond lengths is 2.532(9) Å, and of the other eight Pt—S lengths is 2.494(19) Å. Note that the four longer Pt—S bonds follow the pseudo S_4 molecular symmetry. There is no significant expansion of the Pt—S—C angles in the plane closest to the ligand plane.

Therefore we conclude that any inherent (intramolecular) reduction in threefold symmetry of bonding at triply-bridging arylthiolate is virtually insignificant, being not more than a 0.04-Å elongation of the M—S bond almost coplanar with the aryl group.

EXPERIMENTAL

A sample of **3** provided by Dr Appleton was crystallized from $CHCl_3$.

Crystallographic studies

$C_{36}H_{56}Pt_4S_4$, $M = 1897.4$, tetragonal, space group $P4_32_12$, $a = 14.187(1)$, $c = 40.399(6)$ Å, $U = 8131.11$ Å^3, $Z = 8$, $D_c = 2.28\,g\,cm^{-3}$, $\mu_{Mo} = 140.9\,cm^{-1}$. Crystal size: 0.15 by 0.17 by 0.20 mm.

Intensities for 6294 reflections were measured with an Enraf–Nonius CAD-4 diffractometer in θ–2θ scan mode ($2\theta_{max} = 46°$) using graphite-monochromatized molybdenum radiation ($\lambda = 0.71069$ Å). Data were corrected for absorption. After determination of the space group, 3314 data with $h \leqslant k$ were selected for structure solution and refinement. Of these, 2725 with $I > 3\sigma(I)$ were considered observed. The structure was solved in space group $P4_12_12$ using MULTAN-80[6] and Fourier methods. Phenyl hydrogens were included in calculated positions and assigned temperature factors equal to those of the atom to which bonded; methyl hydrogens did not appear in a difference Fourier and were omitted. Least-squares refinement of positional and anisotropic thermal parameters for the non-hydrogen atoms converged to give R (R_W) = 0.041 (0.053). Reflection weights used were $1/\sigma^2(F_o)$ with $\sigma(F_o)$ being derived from $\sigma(I_o) = [\sigma^2(I_o) + (0.04I_o)^2]^{1/2}$. Atomic scattering factors and anomalous dispersion parameters were from *International Tables for X-ray Crystallography*.[7]

The structure was subsequently refined in the enantiomorphous space group $P4_32_12$, and gave $R(R_W) = 0.034$ (0.046), indicating this to be the correct assignment.*

Acknowledgments—This research was supported by the Australian Research Grants Scheme. We thank Dr Appleton for provision of the sample of **3**.

COMMUNICATION

SYNTHESIS AND CHARACTERIZATION OF NOVEL MACROCYCLIC ANTIMONY CARBOXYLATES CONTAINING DISULFIDE BONDS

RYOKI NOMURA,* MASATAKA YAMAMOTO, AKIHISA TAKABE and HARUO MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Oka, Suita, Osaka 565 (Japan)

(*Received* 9 *December* 1986; *accepted* 12 *January* 1987)

Abstract—Novel 18- and 22-membered ring cyclic antimony carboxylates which contained two S—S bonds were synthesized in the one-pot oxidative-coupling/condensation reaction of triphenylstibine oxide with thioglycolic or β-thiopropionic acids, respectively.

Recently, much attention has been given to the preparation of organoantimony heterocycles. For example, the reactions of several classes of organoantimony(V) compounds with glycolic acid derivatives,[1] phenols and related compounds,[2–4] dibasic acids,[5] glycols[6] and dioxetanes[7] produced organoantimony heterocycles in which chalcogen atoms (O or S) were directly bonded to the central antimony atom. However, the reported heterocycles contain less than 14-membered rings. In this communication, we describe the preparation and characterization of novel cyclic antimony carboxylates which have two S—S moieties and possess the largest ring among the antimony heterocycles reported, and their complexability with alkaline picrates.

A mixture of triphenylstibine oxide [Ph_3SbO (10 mmol)] and thioglycolic or β-thiopropionic acid (10 mmol) was heated at 80°C for 6 h in benzene (20 cm^3) and unexpected macrocyclic antimony carboxylates (**Ia** and **b**) were obtained in 98 and 95% yields, respectively. The molecular-weight measurement (VPO, $CHCl_3$) revealed that **I** were 2:4 (based on the starting carboxylic acid) cyclocondensates. Spectral and analytical data† are also consistent with the proposed macrocyclic structure.

The C=O stretching frequency was so high as to suggest that the central antimony atom was bound to a COO group by an ester type linkage. Signals of methylene protons in **Ib** split into a characteristic $A_2A'_2$ type dd pattern which resembled those of dithiodipropionic acid (**IIb**). In general, triorganoantimony(V) compounds are known to react with thioglycolic acid or *o*-aminophenols to give a stable 1,3,2λ^5-oxathiastibolane[1] or 1, 3, 2λ^5-oxazastibolane[4] ring (a 1:1 or 2:2 condensate), respectively. Consequently, it is very interesting that the reactions selectively gave 2:4 condensates but not 1:1 or 2:2 ones.

Previously, we have found that Ph_3SbO oxidizes thiols to the corresponding disulfides and also

catalyzes the oxidative coupling.[8,9] The functionalized thiol, β-thiopropionic acid (10 mmol), was selectively converted to **IIb** in 95% yield at 80°C for 2 h in the presence of Ph_3SbO (1 mmol). Accordingly, it is presumed that a chemoselective condensation of Ph_3SbO with thiol groups gave triphenylantimony dimercaptides which underwent reductive-elimination to afford **IIb** in the initial stage of the reaction. The controlled reactions of Ph_3SbO with one equivalent amount of dithiodiglycolic acids **IIa** or **IIb** gave the 2:2 (based on the starting diacids) condensates quantitatively even at room temperature. Similarly, thiodiglycolic and thiodipropionic acids gave corresponding antimony heterocycles having two sulfide bonds (**III**) quantitatively in CH_2Cl_2 at room temperature. Although organoantimony(III) is known to give 2:2 cyclocondensates containing up to a 14-membered ring,[10] the isolation of such 2:2 condensates is reported here for the first time for organoantimony(V) derivatives.

Because **I** possessed several donating sites such as two disulfide bonds and four carboxylate linkage in their 18- or 22-membered ring structures and are soluble in most organic solvents, **I** can be expected to be effective host molecules. Thus, we attempted to investigate their complexability with alkaline metal ions by means of the picrate method.[11] The results are shown in Table 1. It was found that **Ib** showed very large values of K_e, namely, the values of log K_e were larger than 7 for Na^+, K^+ and Rb^+.[12] Just a small difference among K_es for individual ions was observed. However, since the formation of any alkaline metal carboxylates was not detected with ^1H and ^{13}C NMR spectra both in aqueous and organic layers during the complexation runs, the Sb–OC(O) linkage did not cleave under these conditions. The detailed investigation is currently under way.

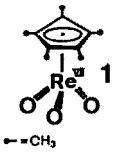
CONTENTS

1. INTRODUCTION

When the title compound trioxo(η^5-pentamethylcyclopentadienyl)rhenium(VII) (1) was discovered in our laboratory by Ricardo Serrano 2 years ago,[1] there was much surprise about the existence and stability of this material. In addition, nobody would have predicted such a pleasant and versatile chemistry as has developed since. Some basic, synthetically useful reactions have been described in a number of publications,[2–15] and a first comprehensive review was given recently.[16] The present up-dated account is aimed at the disclosure of novel key results that we have obtained since the above-mentioned review article was submitted (12 August 1985).[16] It is our declared intention to focus our peers' eyes to a field that, as we feel, shall turn out to gain extensively in



1

importance within the scopes of both organometallic and inorganic chemistry in future years. Not only synthetic uses of "organometallic oxides" can be thought of (e.g. construction of unprecedented heterocycles involving metal oxide structural entities, stabilization of high-valent transition metals etc.) but there are also obvious applications in the field of catalysis such as oxidation of unsaturated organic molecules (e.g. olefins and acetylenes) as well as olefin metathesis type reactions. Since it is always demanding to first investigate the chemistry of a given key compound before laborious

†Author to whom correspondence should be addressed.

catalytic studies are done, we have decided to provide ourselves with as clear a picture as possible of the title compound's chemistry and the further chemical transformations of derivatives arising therefrom.

2. HISTORICAL SKETCH

A remark regarding the history of compounds such as (**1**)[1,17] should be made at this point. Oxides and oxohalides of transition metals (vanadium, chromium, molybdenum and tungsten) stabilized by π-aromatic ligands such as the unique cyclopentadienyl ligand have occasionally been observed from time to time for more than 20 years. Thus, Fischer's Munich laboratory reported on the synthesis of the vanadium compounds $(\eta^5\text{-}C_5H_5)VOX_2$ (X = Cl or Br) way back in 1958,[18] before Green *et al.* got hold of related molybdenum derivatives such as $(\eta^5\text{-}C_5H_5)MoO_2$ *and* $(\eta^5\text{-}C_5H_5)MoO_2Cl$.[19] Other organometallic oxides exhibiting terminal oxo functionalities have been made since then but their number is still quite small:

$(\eta^5\text{-}C_5H_5)_2Mo_2O_4$ (*cis*)[a]	Green (1964)[19]
$(\eta^5\text{-}C_5H_5)_2Mo_2O_5$	Green (1964)[19]
$(\eta^5\text{-}C_5H_5)_2WO$	Green (1972)[20]
$(\eta^5\text{-}C_5Et_5)WO_2(O^tBut)$	Schrock (1984)[21]
$(\eta^5\text{-}C_5Me_5)_2Cr_2O_4$ (*trans*)[a]	Herberhold (1985)[22]
$(\eta^5\text{-}C_5Me_5)_2Mo_2O_4$ (*cis*)[a]	Herrmann (1985),[23,24] Arzoumanian (1985)[25]
$(\eta^5\text{-}C_5Me_5)_2Mo_2O_5$	Herberhold (1985)[22]
$(\eta^5\text{-}C_5Me_5)_2W_2O_4$	Herrmann (1985)[23,24]
$(\eta^5\text{-}C_5H_4CH_3)_2MoO$[a]	Green (1972),[20] Tyler (1985)[26]
$(\eta^5\text{-}C_5H_5)WO(\pi\text{-}C_2H_2)R$ [R = Me or C(=O)Me]	Alt (1985)[27]
$(\eta^5\text{-}C_5H_5)WOR_3$ and $(\eta^5\text{-}C_5H_5)WO_2R$[a] (R = CH_2SiMe_3)	Legzdins (1985)[28]
$[\{\eta^5\text{-}(\text{-}CH_2C_5Et_4)\}WO_2(O\text{-}^tC_4H_9)]_2$	Schrock (1985)[29]

[a]X-ray structurally confirmed compounds.

Other organometallic oxorhenium complexes that have appeared in the literature are $ReO(\pi\text{-}C_2H_2)_2I$,[30] $Re(CH_3)_4O$,[31] $Re(CH_3)_3O_2$,[32] $Re(CH_3)O_3$,[33] $Re(CH_2SiMe_3)_4O$,[31] $Re_2(CH_2SiMe_3)_6O_3$,[31,34] $Re_2(CH_3)_6O_3$,[34] and $Re(O^tBut)O_3$.[34] The siloxy derivative $Re(OSiMe_3)O_3$[35] may prove to be starting material for new organometallic rhenium(VII) compounds. Wieghardt's recent compound $[(\eta^3\text{-}C_6N_3H_{12})ReO_3]^+BF_4^-$[36] looks like a "more inorganic" congener of our title complex **1**. High-nuclearity organometallic oxides are not considered here (cf. review in Ref. 37), with the remarkable compounds $(\eta^5\text{-}C_5H_5)_4$,[38] $(\eta^5\text{-}C_5H_5)_5V_5O_6$,[39] and $(\eta^5\text{-}C_5H_5)_6Ti_6O_6$[40] representing special highlights in this field.

If we are willing to disregard oxohalide and other mixed-ligand compounds for a moment, then it becomes evident that we really were lucky to trace down the title compound **1**: together with its manganese and technetium congeners, it is the only mononuclear compound in the series $(C_5R_5)MO_x$ that one might believe to show reasonable stability, provided the metal center is assumed to be present in its highest possible oxidation state according to the rules of the Periodic Table (Chart 1). Thus, for the scandium, yttrium and lanthanum compounds, the general composition $(C_5R_5)MO$ would be the logical extrapolation of compound **1**'s stoichiometry but it is quite clear that aggregation of this monomeric species that has a total of only two ligands would occur. The situation with respect to the vanadium, niobium and tantalum monomers of composition $(C_5R_5)MO_2$ is not yet clear; the vanadium compound $(\eta^5\text{-}C_5H_5)VO_2$ was described in a hardly available journal in 1974[41] but its true existence is still a questionable one since convincing synthetic, spectroscopic and structural data never became available. Three-coordinate, pentavalent Group-V transition metals may be achievable; they are expected to be structural analogues of the low-valent carbonyl series $(\eta^5\text{-}C_5R_5)M(CO)_2$, with M representing the elements cobalt, rhodium and iridium. However, the electronic nature of the oxo ligands could also give rise to dimerization of the monomeric species. By way of contrast, transition metals of the even-numbered groups do not provide us with diamagnetic monomeric compounds of composition $(C_5R_5)MO_x$ in their

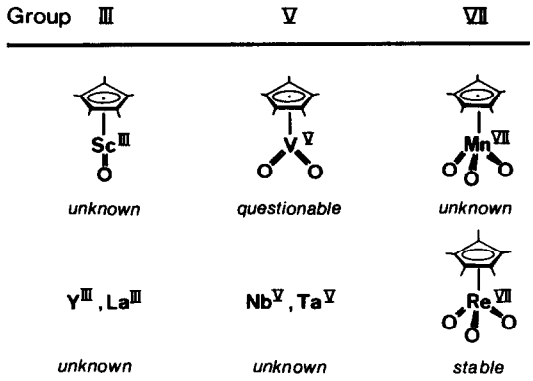

Chart 1.

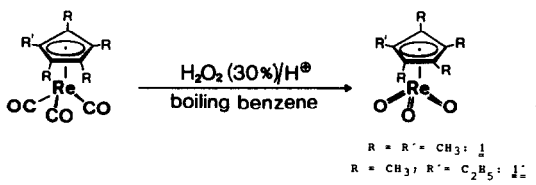
highest possible oxidation states; here, only dimers or oligomers are possible, and the well-established compound $(\eta^5\text{-}C_5Me_5)_2Mo_2O_5$ containing an additional oxo ligand in a bridging function may be quoted in this context.[22]

From what has been said in this brief section, it becomes quite obvious that clear lines are still missing in organometallic metal oxide chemistry from all possible points of view. Hence, this field deserves systematic investigations with respect to synthesis, chemical reactivity, structural chemistry, and bonding theory. Only a very few steps directed towards these areas have been made up to the present.

3. SYNTHESIS OF TRIOXO(η^5-PENTAMETHYLCYCLOPENTADIENYL)RHENIUM(VII)

Construction of metal oxide structures in inorganic coordination or organometallic compounds (monomeric or oligomeric species) follows treatment of appropriate precursors (e.g. metal carbonyls and alkyls) with various reagents such as elemental oxygen, hydrogen peroxide, nitrous and nitric oxide, trimethylamine oxide, nitrobenzene, *t*-butyl hydroperoxide, or the nickel complex $[^t\text{But-NC}]_2\text{Ni}(\eta^2\text{-}O_2)$. Another possible strategy involves introduction of stabilizing organic ligands such as cyclopentadienyl (η^5) or benzene (η^6) into precursors like transition metal oxides or halides. However, this method has not yet been very successful, probably due to uncontrolled redox reactions occurring at the high-valent metal (reduction) and at the organic ligand (oxidation) (e.g. reaction of ReO_3Cl with $M^+C_5R_5^-$).[15]

The title complex **1** is nowadays easily accessible according to Scheme 1 by treatment of the low-valent carbonyl precursor species $(\eta^5\text{-}C_5Me_5)Re(CO)_3$ with concentrated aqueous hydrogen



Scheme 1.

peroxide in a boiling two-phase water–benzene system; yields as high as 80% can be reached, depending a little on the purity of the starting materials and the reaction conditions. Purification of **1** is commonly achieved by means of column chromatography on silica and subsequent recrystallization from *n*-hexane–methylene chloride solutions at below ambient temperatures. The closely related derivative trioxo(η^5-ethyltetramethylcyclopentadienyl)rhenium(VII) (**1'**) has just been synthesized by Jun Okuda along exactly the same lines (see Experimental). In this particular case, suitable single crystals could be obtained, in contrast to what we had experienced for the title compound **1**.

The molecular geometry of **1'** is depicted in Fig 1(a) and (b), giving proof that we are indeed dealing with a mononuclear species containing short rhenium–oxygen bonds. The three ReO

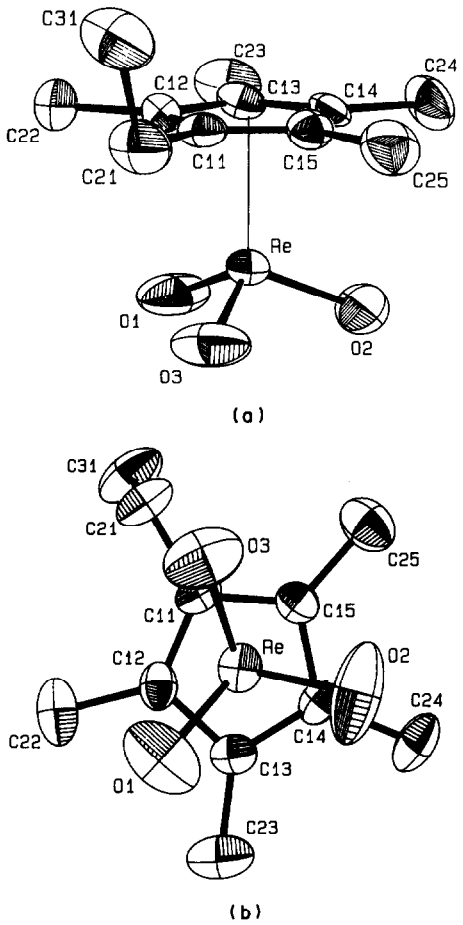


Fig. 1. Molecular structure [ORTEP representation, projection view down the five-membered π-ligand] of the trioxorhenium(VII) compound (η^5-C_5Me_4Et)ReO_3 (1'). Thermal ellipsoids correspond to 50% probability. Selected bond lengths (pm) and angles (°): Re—O(1) 166.4(4), Re—O(2) 171.6(4) Re—O(3) 170.7(3), Re—C(11) 239.2(3), Re—C(12) 239.2(3), Re—C(13) 243.0(4), Re—C(14) 241.8(3), Re—C(15) 238.5(4); 0(1),Re—O(2) 106.7(2), O(2)—Re—O(3) 104.7(2), O(1)—Re—O(3) 105.6(2); sum of angles within the ReO_3 core 317.0°.

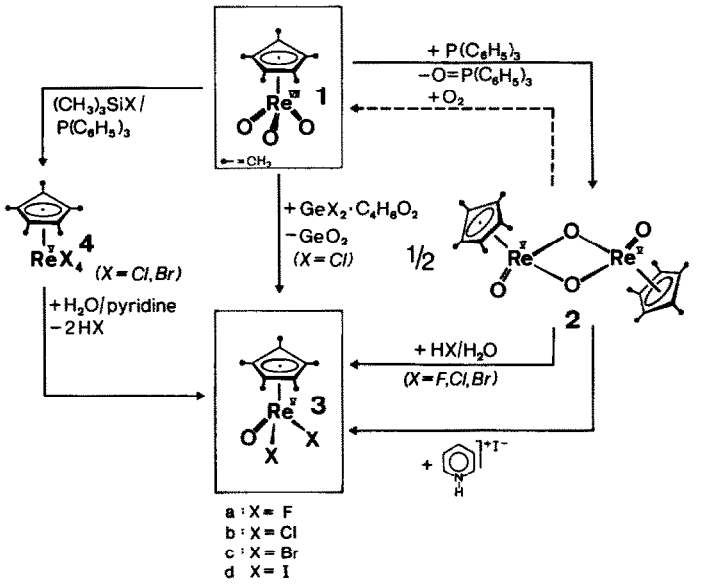
interatomic distances of *ca* 170 pm are consistent with ordinary double bonds. It thus appears that terminal oxo groups act as powerful π-donor ligands in this particular case too. The overall geometry of the compound is best described as a slightly distorted trigonal pyramid if the five-membered π-ligand is considered to be the apex of this polyhedron.

No oxygen–oxygen contacts are present according to the recorded distances; the O, Re, O angles amount to approximately 105°, and the sum of these three angles is 317.0°. In contrast to the structures described below, the π-bonded hydrocarbon ligand is coordinated to the metal atom in a symmetrical fashion but the metal–carbon distances warrant a comment: they are *all* rather long compared to structurally related compounds (see Section 6 and Table 1). Whether this rhenium–carbon bond lengthening in compounds of type **1** does result in any significant weakening of the bond towards an easier replacement of the cyclopentadienyl ligand remains an issue to be pursued in the future. Cycloaddition reactions at the ReO_3 fragment and reductions to lower-valent derivatives do not involve replacement of this π-ligand. The only cases in which we have observed at least partial elimination of this ligand are limited to the synthesis of the trinuclear, ionic cluster compound [(η^5-C_5Me_5)$ReO(\mu$-$O)_2(\eta^5$-C_5Me_5)] containing two perrhenate counter-ions, the formation of the tetranuclear species [(η^5-C_5Me_5)$ReO(\mu$-$O)_2(\eta^5$-C_5Me_5)$Re(OReO_3)_2$].[5] and the synthesis of the glykolato complex [($\eta^5C_5Me_5$)$Re(OCH_2CH_2O)(\mu$-$O)_2(\eta^5C_5Me_5$)$Re(OReO_3)_2$].[48]

4. OXOHALIDE DERIVATIVES OF RHENIUM(V)

Most effective and useful is the reduction of the title compound **1** to the oxohalide complexes of composition $(\eta^5\text{-}C_5Me_5)ReOX_2$. Several synthetic routes have been worked out in our laboratory. Most elegantly, Flöel has exploited the high thermodynamic stability of germanium dioxide when she treated the title compound **1** with the dioxane adduct of germanium dichloride ($GeCl_2 \cdot C_4H_8O_2$) to make the dichloro rhenium(V) complex **3b** in 75% yield (Scheme 2). An indirect but

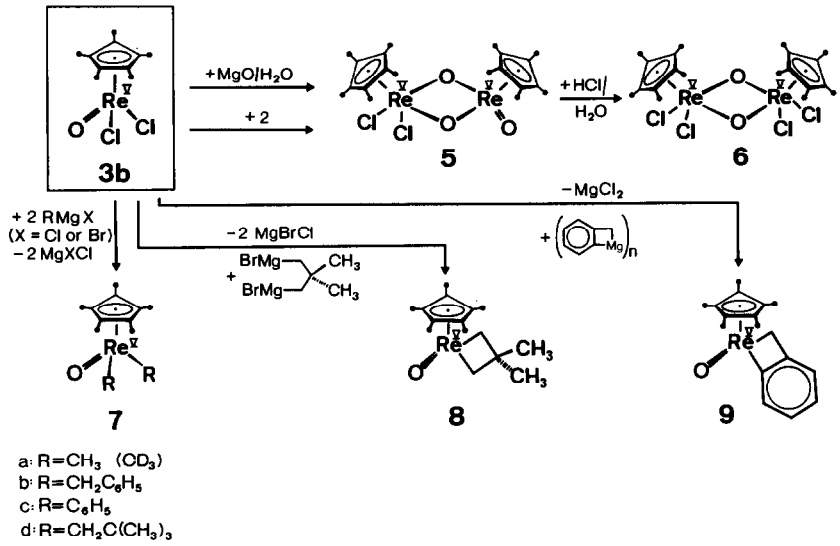


Scheme 2.

nevertheless high-yield access to compounds **3a–d** involves the isolable dinuclear intermediate **2** that is reportedly obtained via reductive deoxygenation of **1** with triphenylphosphane in the absence of oxygen. Due to the achievements of Küsthardt, compound **2** is quantitatively converted in fast reactions to the mononuclear difluoro, dichloro and dibromo derivatives **3a–c** when treated with aqueous hydrogen fluoride, chloride and bromide, respectively, at room temperature. According to Kulpe, the diiodo compound **3d** is best obtained by using pyridinium hydrochloride ($C_5H_6N^+I^-$), starting from the same precursor **2** (Scheme 2).

A further two-step synthetic procedure towards the oxohalide complexes of type **3** involves the intermediates **4** of composition $(C_5Me_5)ReX_4$. These latter compounds have been isolated for X = Cl and Br [**4b** and **c** (Scheme 3)] but their exact nature has not yet been resolved since solutions appear to contain at least two species, suggesting the existence of both monomeric and dimeric units.[42] In any case, hydrolysis with stoichiometric amounts of water and pyridine (formation of pyridinium chloride and bromide, respectively) at room temperature straightforwardly yields the desired mononuclear oxohalide derivatives **3b** and **3c** according to Scheme 2. It is obvious that the tetrahalides of type **4** are subject to partial hydrolysis only (replacement of *two* halide ligands by *one* oxo ligand). Complete hydrolysis occurs, however, when these tetrahalides are treated with a large excess of water in an acetone solution, yielding the dimer $(\eta^5\text{-}C_5Me_5)_2Re_2O_4$ (**2**). As established by Okuda, the best and most convenient way of making compounds **4** is simultaneous treatment of the title compound **1** with chloro- and bromotrimethylsilane, respectively, plus triphenylphosphane (Scheme 2). Keeping in mind that the action of the Lewis base triphenylphosphane upon **1** gives the reduced dimer **2** [Re(V)], this intermediate is likely to be formed in the synthesis of **4**, too. This proposal has been confirmed by the observed clean transformation of **2** into **4** effected by the $(CH_3)_3SiX$ reagents. In other words, both the phosphane and the halosilanes are responsible for stepwise deoxygenation of the precursor compound **1**. Compounds **4** are also formed from **1** in the absence of triphenylphosphane but the yields are not so good.

Further hydrolysis of the mononuclear oxohalides **3** may be achieved under basic conditions: treatment of the dichloro derivative **3b** with magnesium oxide in the presence of water gives the unusual dimer **5**, as has been established by Kulpe (Scheme 3).[43] The formation of this particular



Scheme 3.

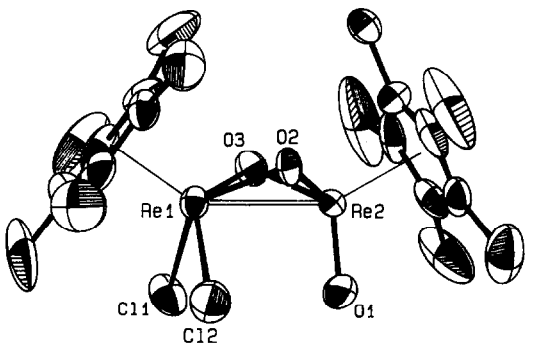


Fig. 2. ORTEP drawing of the molecular structure of the dinuclear oxohalide complex $(\eta^5\text{-}C_5Me_5)_2Re_2O_3Cl_2$ (**5**). Thermal ellipsoids correspond to 50% probability. Selected bond distances (pm) and angles (°): Re(1)—Re—(2) 269.1(<1), Re(1)—Cl(1) 239.5(1), Re(1)—Cl(2) 239.7(1), Re(1)—O(3) 202.0(3), Re(2)—O(1) 168.1(3), Re(2)—O(2) 185.9(3), Re(2)—O(3) 186.5(3), Re(1)—O(2) 202.1(3); Re(1),O(2),Re(2) 87.7(1), Re(1),O(3),Re(2) 87.6(1). The coordination geometry of the π-bonded ring ligands is discussed in Section 6 (see also Table 1).

compound may be viewed as a result of the condensation of unchanged $(\eta^5\text{-}C_5Me_5)ReOCl_2$ (**3b**) with its (hypothetical) hydroxy derivative $(\eta^5\text{-}C_5Me_5)ReO(OH)_2$. [The methoxy derivative $(\eta^5\text{-}C_5Me_5)ReO(OMe)_2$ of this latter species, however, proved stable under ordinary conditions.[16]] It is interesting to note that **5** does also result from the combination of **3b** with the highly reactive dimer **2** in the sense of a metathesis-type reaction; it has in fact repeatedly been observed that the dimeric rhenium(V) compound **2** is a useful synthetic source for the $(\eta^5\text{-}C_5Me_5)ReO_2$ fragment. Compound **5** is a straightforward (quantitative) coupling product between these two species (Scheme 3).

The terminal oxo ligand remaining in compound **5** can be effectively replaced by two chloro ligands by means of hydrochloric acid, without any breakdown of the dinuclear Re_2O_2 core structure. An X-ray crystallographic study carried out by Herdtweck revealed the *cis* stereochemistry of this molecule (approximate C_s-symmetry). The metal centers adopt distorted tetragonal-pyramidal [Re(1)] and trigonal-pyramidal [Re(2)] coordination geometries (Fig. 2). Small distortion of the π-bonded ring ligand at Re(1) only is evident from Fig. 3 and will be discussed separately in Section 6.

Similar reductive deoxygenation reactions have been carried out by Jun Okuda with the ethyltetramethylcyclopentadienyl compound **1'**, as summarized in Scheme 4. Once again, exhaustive deoxygenation occurs by means of the reagent combination $(CH_3)_3SiX/P(C_6H_5)_3$, yielding the

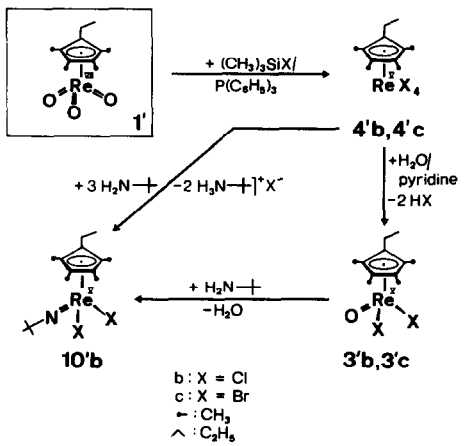

Scheme 4.

tetrahalide derivatives **4'b** (X = Cl) and **4'c** (X = Br). In contrast to the observations made with the pentamethylcyclopentadienyl congeners **4b** and **c**, these latter compounds are much more soluble in common organic solvents; for this simple reason, they promise a broader variety of chemical reactions. Hydrolysis with water and pyridine cleanly results in the formation of the rhenium(V) oxohalides **3'b** and **3'c**, respectively. Furthermore, the novel imido derivative (η^5-C_5Me_4Et-$ReCl_2(N^tBut)$) (**10'b**) is obtained in virtually quantitative yield when **4'b** is treated with excess *t*-butylamine in a toluene solution (see Experimental). Since imido (NR) groups, like oxo ligands, are capable of stabilizing metal centers in high oxidation states by virtue of their pronounced π-donation, one can expect another field of extensive chemistry here.[44] Imido complexes of the present type may not only be synthesized by the above methodology ($L_xMX_2 + H_2NR \rightarrow L_xM{=}NR + 2HX$) but also by decarboxylative coupling of organometallic oxides with isocyanates ($L_xM{=}O + (\eta^5\text{-}C_5Me_5)_2Mo_2(N^tBut)_4$.[45] with a recent example being the molybdenum compound $(\eta^5\text{-}C_5Me_5)_2Mo_2(N^tBut)_4$.[45]

5. OXOALKYL COMPOUNDS OF RHENIUM(V)

The oxohalide compounds of type **3** offered a unique possibility to further extend our work on oxoalkyl rhenium(V) compounds (Scheme 3). Whilst the parent dimethyl derivative **7a** is accessible through reductive deoxygenation of the title compound **1** by means of trimethylaluminium or

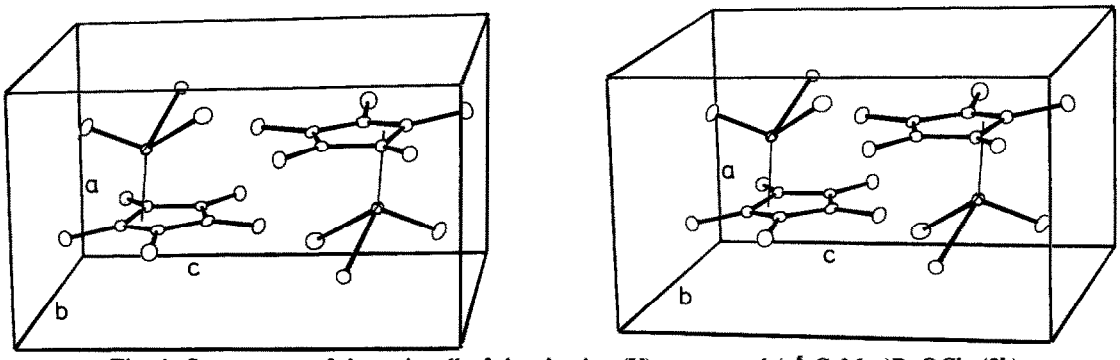

Fig. 4. Stereo view of the unit cell of the rhenium(V) compound $(\eta^5\text{-}C_5Me_5)ReOCl_2$ (**3b**).

dimethylzinc,[16] several homologues of this series, including the benzyl (**7b**), phenyl (**7c**), and neopentyl derivatives (**7d**) were synthesized in isolated yields around 70% by Martina Flöel using the Grignard approach. This synthetic route requires much experimental care because the precursor compound **3b** is also susceptible to messy reactions at the oxo ligand if the reactions with the Grignard compounds are not carried out carefully enough; thus, very clean Grignard compounds in the right stoichiometry must be used in these preparations. The novel metallacycles **8** and **9** became accessible in a collaborative effort with the Bickelhaupt group (Amsterdam).[46] Scrupulously dried glassware and starting materials are the crucial prerequisites for the successful preparation of these latter compounds too.[46,47]

6. STRUCTURAL AND ELECTRONIC CONSIDERATIONS

Although we are dealing here with rather handy compounds, some intriguing structural aspects are to be considered. In an extensive series of accurate X-ray structural determinations,[48] Herdtweck has accumulated ample evidence for highly distorted π-coordination of the five-membered ring ligands in several key compounds under discussion. This effect has been documented in all $(\pi\text{-}C_5Me_5)Re$ complexes in which the metal atom exhibits an additional set of *different* ligands with distorted tetrahedral coordination, e.g. $(C_5Me_5)ReL(L')_2$. One prominent example is the oxohalide compound $(\eta^5\text{-}C_5Me_5)ReOCl_2$ (**3b**) presented in Figs 4–6. The stereoview of Fig. 4 gives an excellent

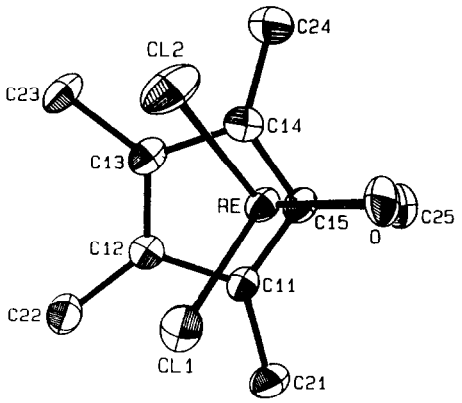

Fig. 6. ORTEP projection of compound **3b**'s molecular structure down the orthonormal vector between the plane of C(11), C(14), C(15) and the metal atom (thermal ellipsoids at 50% probability).

impression of how enormously the π-coordination of the pentamethylcyclopentadienyl ligand is distorted from the center of gravity. The two molecules present in the triclinic unit cell are arranged such that the out-of-centroid shift of the π-ligands is intermolecularly counterbalanced. If we disregard this peculiarity for a moment, then the basic structure of each molecule is described as a distorted trigonal pyramid, with two chlorine and one oxo ligand occupying the basal positions. The angle between the two chlorine ligands is much smaller [85.4(1)°] than the Cl(1/2), Re, O angles [105.3(2) and 106.2(2)°], with the sum of angles within the pyramidal $ReOCl_2$ entity amounting to 296.9°. This geometry is rather trivial but nevertheless entails distortion of π-coordination at the opposite ring ligand. It becomes clear from Fig. 5 that, unlike the architecture of the trioxo compound **1'** [Fig. 1(b)], the metal atom is no longer situated below the centroid of a regular pentagon but is rather shifted approximately parallel to the best plane of this ligand so that the carbon atoms C(15), C(11) and C(14) are much closer to the metal [218.0(6), 222.5(5) and 222.5(6) pm, respectively] than the two remaining ring atoms C(12) and C(13) [247.7(6) and 247.5(6) pm, respectively]. Taking into account that the bond between the more distant carbon atoms C(12) and C(13) is significantly shorter [139.3(8) pm] than the four other inter-ring distances (143.8–146.2 pm), a η^3-allyl/η^2-olefin-type coordination of the pentamethylcyclopentadienyl ring must be concluded.

Where does this acentric π-coordination arise from? Structural comparison with related compounds listed in Table 1 provides some help in answering this question. It is to be noted that: (i) the distances between rhenium and the attached pentamethylcyclopentadienyl ligand are generally somewhat shorter in low-valent compounds such as $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ and $(\eta^5\text{-}C_5H_4SiMe_3)Re(CO)_3$ (Table 1),[49–55] and that (ii) substantial out-of-centroid coordination only occurs in rhenium compounds that display *different* ligands around the metal atom.

Structural details of the low-valent reference compound tricarbonyl(η^5-pentamethylcyclopentadienyl)rhenium(I) have not yet become available but rhenium–carbon distances of roughly 230–235 pm seem to be a pretty good extrapolation from the data of closely related compounds (cf. Table 1). If we now compare with the recorded rhenium–carbon distances of the structurally analogous high-valent oxo derivative **1'**, then we encounter a significant bond lengthening in this latter case (Fig. 1(a) and (b), Table 1). The rhenium–carbon distances of 238–243 pm are close to the set of *longer* distances in the unsymmetrical rhenium(V) derivatives $(\eta^5\text{-}C_5Me_5)ReOR_2$ (R = Cl, I, CH_3 or $CH_2C_6H_5$), while the π-bonded organic ligand, however, is rather symmetrically attached to the metal atom in the case of **1'** [Fig. 1(a) and (b)].

The conclusion to be drawn from these findings is quite obvious now: The oxo ligand, like nitrido ("naked" N) and carbyne (CR) groups, is a notorious π-donor ligand which property results in a strong *trans* effect, primarily labilizing the bonds on the opposite side of a given polyhedron. The selected compounds $(\eta^5\text{-}C_5Me_4Et)ReO_3$ (ReO_3-fragment) and $(\eta^5\text{-}C_5Me_5)ReOCl_2$ ($ReOCl_2$-fragment) demonstrates how dramatic this *trans* effect of terminal oxo ligands can be. Future studies have to show as to whether these architectural distortions of π-coordination within the class of compounds considered here do entail chemical consequences.

Table 1. Intramolecular distances between π-bonded cyclopentadienyl ligands and the metals attached to them [compounds containing (π-C_6Me_5)Re groups]

[a]The π-bonded C_5 ring ligands are assigned *one* position around the metal.

[b]Standard deviations refer to the least significant digit(s). If no entry is made, the standard deviation is less than 1 in the last given digit.

[c]Distorted pentamethylcyclopentadienyl ligand.

[d]Including ReRe bond.

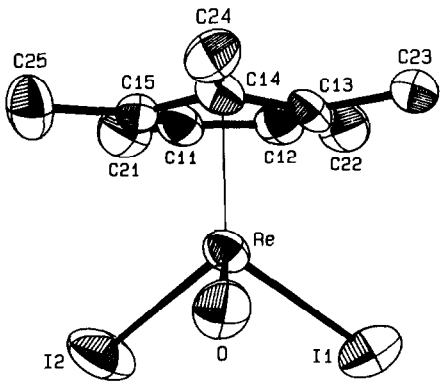

Fig. 7. The diiodo derivative (η^5-C_5Me_5)$ReOI_2$ (**3d**): ORTEP representation, with the thermal ellipsoids being at 50% probability. Selected bond lengths (pm) and angles (°): Re—O 168.7(3), Re—I(1) 268.1(< 1), Re—I(2) 267.6(< 1), Re—C(11) 253.5(4), Re—C(12) 251.7(4), Re—C(13) 223.7(4), Re—C(14) 218.6(4), Re—C(15) 225.4(4); I(1),Re,I(2), 88.8(< 1), I(1),Re,O 99.4(1), I(2),Re,O 101.7(4). The sum of angles within the $ReOI_2$ core amounts to 289.9°.

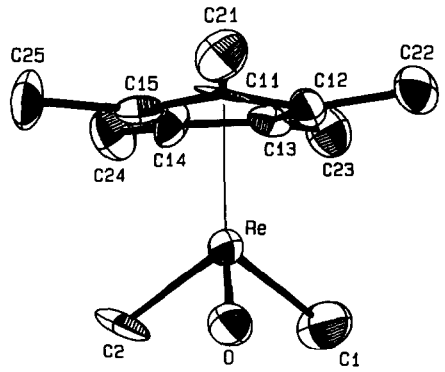

Fig. 8. The dimethyl derivative (η^5-C_5Me_5)$ReO(CH_3)_2$ (**7a**): ORTEP representation, with the thermal ellipsoids being at 50% probability. Selected bond lengths (pm) and distances (°): Re—C(1) 212.9(12), Re—C(2) 216.1(10), Re—O 168.1(7), Re—C(11) 213.7(9), Re—C(12) 223.1(9), Re—C(13) 249.9(9), Re—C(14) 249.7(9), Re—C(15) 223.5(9); C(1),Re,C(2) 81.7(5), C(1),Re,O 97.0(4), C(2),Re,O 99.8(4); sum of angles within the $ReOC_2$ core 278.5°. The C(13)—C(14) bond [137.3(13) pm] is shorter than the other four CC bonds within the five-membered π-ligand (143–145 pm).

The picture does not basically change as we move to related compounds of composition (C_5Me_5)$ReOR_2$:[48] thus, the diiodo derivative (η^5-C_5Me_5)$ReOI_2$ (**3d**) shown in Fig. 7 just adds to the conclusions drawn from the above-mentioned structures (Figs 1 and 4–6). The differences in rhenium–carbon bond lengths are again around 30 pm (!), with the two longer ReC distances being *trans* to the Re=O group. Although the bulkier iodo ligands (compared with Cl) may contribute to this effect by steric (through space) repulsions a little bit, the dominating reason is due to the electronic properties of the terminal oxo ligand. Otherwise, the Re—C(13) and Re—C(15) bonds [223.7(4) and 225.4(4) pm] should be about as long as the Re—C(11) and Re—C(12) bonds [253.5(4) and 251.7(4) pm, respectively]. Figures 9 and 11 should be compared with Figs 1(b) (title compound) and 8 (oxodichloro complex **3b**).

The same findings and interpretations apply to the dialkyl series (C_5Me_5)$ReOR_5$ [R = CH_3 (**7a**) or $CH_2C_6H_5$ (**7b**)]. Boths compounds (Figs 8–11) adopt the same overall geometry, with the distortion of the hydrocarbon π-ligand being even more pronounced than what we have observed for the dichloro and diiodo derivatives **3b** and **3d**. The bond length difference is as high as 37 pm (compound **7b**), and the five-membered ligand is no longer planar! Still, halogen vs alkyl substituents at the rhenium atom do not appear to greatly influence the structural details in compounds of analogous composition.

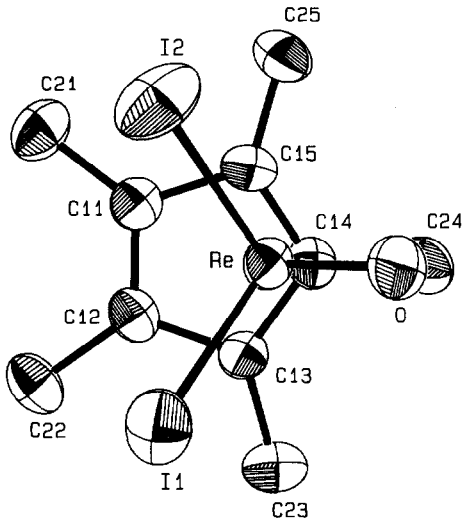

Fig. 9. Projection of compound **7a**'s molecular structure viewed down onto the best plane of the π-bonded pentamethylcyclopentadienyl ligand.

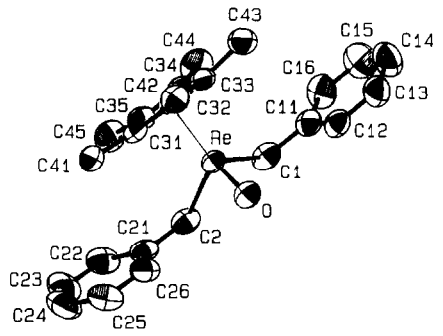

Fig. 10. The dibenzyl derivative $(\eta^5\text{-}C_5Me_5)ReO(CH_2C_6H_5)_2$ (**7b**): ORTEP representation, with the thermal ellipsoids being at 50% probability. Selected bond lengths (pm) and distances (°): Re—C(1) 217.5(3), Re—C(2) 216.3(3), Re—O 168.6(2), Re—C(31) 226.8(3), Re—C(32) 215.6(3), Re—C(33) 225.9(3), Re—C(34) 252.2(3), Re—C(35) 252.2(3); C(1),Re,C(2) 83.1(2), C(1),Re,O 98.6(1), C(2),Re,O 98.4(1); sum of angles within the $ReOC_2$ core 280.1°. The C(34)—C(35) bond length [139.0(4) pm] is shorter than the other four CC bonds within the five-membered π-ligand [143.4(4)–144.7(4) pm].

The comparative compilation of structural data presented in Table 1 gives the following general information:

(i) There are two arbitrary sets of rhenium–carbon (C_5Me_5 ring ligand) bond distances, smaller or larger than *ca* 235 pm.

(ii) The longer bonds are approximately *trans* to oxorhenium (ReO) groups. There is not too much of a difference, however, as to whether we are dealing with terminal or bridging oxo groups to cause this *trans* effect; in this respect, comparison may be drawn between compounds of type $(\eta^5\text{-}C_5Me_5)ReOX_2$ on the one hand, and the dimer $(\eta^5\text{-}C_5Me_5)_2Re_2(\mu\text{-}O)_2OCl_2$ (**5**) on the other hand.

(iii) The stronger the *trans* effect comes to the fore, the shorter are the remaining rhenium–carbon distances. The latter ones may then even be much shorter [e.g. 214–223 pm in compound **7a** (Figs 10 and 11)] than in low-valent compounds containing exclusively π-acceptor ligands such as carbon monoxide [e.g. 230 pm (*average*) in $(\eta^5\text{-}C_5H_4SiMe_3)Re(CO)_3$ (Table 1)].

(iv) The *trans* effect is not an additive one, because otherwise the rhenium–carbon bond lengthening in the title compound's congener **1'** (*d*Re—C 238–243 pm) should be even stronger, approaching *ca* 250 pm (cf. Table 1).

(v) The kind of distortion of the rhenium–cyclopentadienyl bonding depends on the coordination

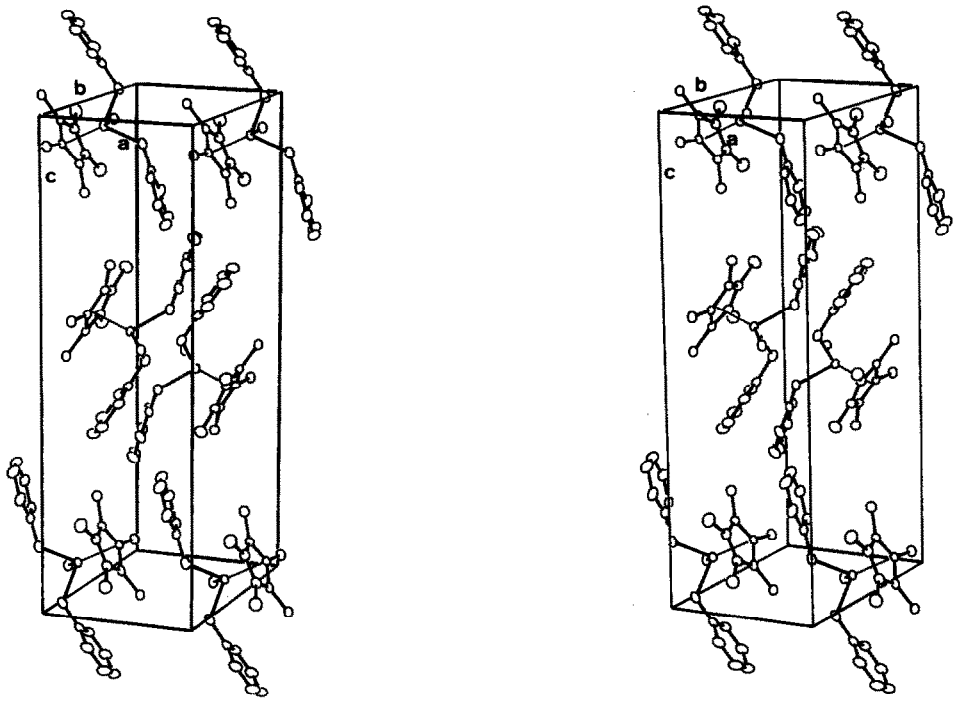

Fig. 11. Stereoview of compound **7b**'s unit cell.

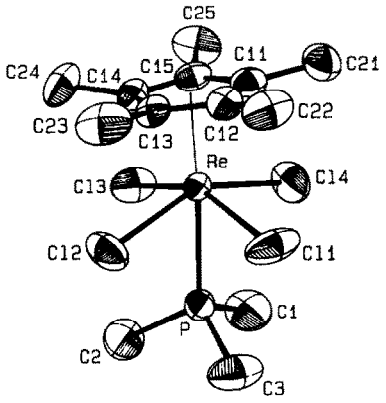

Fig. 12. Structure of the rhenium(V) compound $(\eta^5\text{-}C_5Me_5)ReCl_4(PMe_3)$ in the crystal (ORTEP representation, thermal ellipsoids at 50% probability). Selected bond distances (pm) and angles (°): Re—Cl(1) 238.5(2), Re—Cl(2) 239.4(2), Re—Cl(3) 243.6(2), Re—Cl(4) 240.6(2), Re—P 260.6(2), Re—C(11) 236.9(6), Re—C(12) 246.7(6), Re—C(13) 240.3(6), Re—C(14) 225.9(6), Re—C(15) 225.4(6); Cl(1),Re,Cl(2) 85.9(1), Cl(1),Re,Cl(4) 85.8(1), Cl(1),Re,P 78.6(1), Cl(2),Re,P 72.7(1). The sum of the angles within the $ReCl_4$ core amounts to 323.0°. The CC bond lengths within the five-membered π-ligand vary between 139.9 and 144.4 pm.

number (c.n.). Thus, in compounds of type $(\eta^5\text{-}C_5Me_5)ReL(L')_2$ (c.n. 4) the out-of-centroid distortion is directed towards one ring carbon atom (η^3-allyl/η^2-olefin coordination; *two* short and *three* long ReC bonds), while in compounds of type $(\eta^5\text{-}C_5Me_5)ReL_4$ (c.n. 5) two ring carbon atoms are closest to the metal (*one* short and *four* long ReC bonds).

Not yet clear is the origin of the asymmetry of π-bonding observed for the rhenium(V) compound $(\eta^5\text{-}C_5Me_5)ReCl_4(PMe_3)$. The overall structure is derived from an octahedron, with the five-membered ring ligand and the trimethylphosphane occupying positions *trans* to each other. The four chlorine ligands are skipped towards the phosphane, probably because of the bigger steric

requirements of the C_5Me_5 ligand (Fig. 12, Table 1).

The terminal rhenium–oxygen bond lengths are in the order of 168–172 pm in all compounds considered here. For the sake of comparison, some compounds may be quoted:

$KReO_4$	172.3(4) pm	Ref. 56
ReO_3Cl	170 pm	Ref. 57
$ReO_3(OSiMe_3)$	165 pm	Ref. 58
$Cs_2[ReO_3Cl_3]$	170(2) pm	Ref. 59
$(L_3)ReO_3^+$ (L_3 = *cyclo*-$C_6H_{12}N_3$)	175.6(5) pm	Ref. 60

The mononuclear rhenium(V) compounds of composition $(\eta^5\text{-}C_5Me_5)ReR_4$ (R = halogen or alkyl) contain rhenium in a d^2 electronic configuration. The possible singlet and triplet spin states are present in a temperature-dependent equilibrium, as we have demonstrated by means of ^1H NMR spectroscopy: the signal of the methyl groups (at the ring ligand and/or at the metal) experiences a paramagnetic (low-field) shift upon going from low to high temperatures, indicating a higher paramagnetic spin population at increasing temperatures.[14,43,47] A particularly nice example to amplify this is the square-pyramidal rhenium(V) derivative $(\eta^5\text{-}C_5Me_5)ReBr_2Me_2$.[14] Further attempts are being made to determine the energetics of these spin equilibrium phenomena. Another elegant tool for determining both the electronic situation within organometallic Re_xO_y cores and for establishing possible fluctionality within those metal oxide structures is available through ^{17}O NMR, particularly of ^{17}O-labelled compounds.[43]

7. FURTHER PERSPECTIVES

We have stumbled into an ostensibly rich field of research which once again holds promise of furnishing strong interlinks between inorganic (metal oxide) and organometallic chemistry.[61] High oxidation states of the participating transition metals is not at all the pivotal prerequisite of approaching compounds that contain both organic ligands and oxo groups. Low and high oxidation numbers of the metals are attainable for π-aromatic functionalities as well as for oxo groups, and a plethora of possible ligand combinations lies between the extremes. It is good to know that a potent oxidizing agent such as rhenium(VII) "doesn't chew up the organic ligand".[62] The title compound **1** convincingly amplifies this statement.

Where are we heading to? Further extension of our preparative work warrants high priority, including the "relatives" of rhenium: vanadium and niobium likewise are quite oxophilic and thus promise new "organometallic oxides", related and certainly surprising ones too. First attempts along this perspective have already been made in our research group. On the other hand, the synthetic future of rhenium compounds reviewed in this paper has just begun. Suffice to say that products like the amazing hexahydrido(η^5-pentamethylcyclopentadienyl)rhenium(VII), $(\eta^5\text{-}C_5Me_5)ReH_6$, synthesized by Okuda[63] from $(\eta^5\text{-}C_5Me_5)ReCl_4$ and $LiAlH_4$ presents another new key compound in high-valent organorhenium chemistry. It will be of interest to see how various oxidation states of rhenium interconvert with each other, both electrochemically (cyclovoltammetry) and on a preparative scale. Finally, the major perspective is directed towards catalysis. Do alkylrhenium(V) compounds such as $(\eta^5\text{-}C_5Me_5)ReO(CH_3)_2$ produce species containing alkylidenerhenium(V) ($Re{=}CH_2$) fragments upon thermolysis and can such units be generated by other means? If yes, is olefin metathesis[64] feasible at such fragments? Note that rhenium like molybdenum and tungsten is known to constitute the most effective olefin metathesis metal![64] Moreover, what is the fate of alkynes once coordinated to rhenium in high and intermediate oxidation states? Shall we find ourselves in a position of modelling organometallic oxides related to the mechanistically completely unclear SOHIO "ammonoxidation" process? A further possible utilization of oxorhenium and related compounds may be found in the functionalization of unsaturated organic compounds; reactivity patterns known from osmium tetroxide chemistry could arise here (e.g. glycols from olefins).[65] Upon considering the broad range of organometallic oxides landmarked by "david" $(\eta^5\text{-}C_5Me_5)ReO_3$ and "goliath" $[\{(\eta^5\text{-}C_7H_8)Rh\}_5(cis\text{-}Nb_2W_4O_{19})_2]^{3-}$,[66] then a rich harvest is to be expected during the years to come.

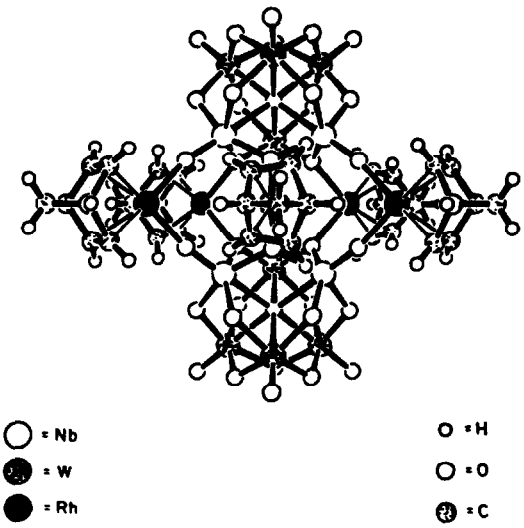

Fig. 13. SCHAKAL drawing of the C_{2v} structure of Klemperer's "organometallic oxide" $[\{(\eta^5\text{-}C_7H_8)Rh\}_5(cis\text{-}Nb_2W_4O_{19})_2]^{3-}$ [taken from Ref. 66(a)].

8. EXPERIMENTAL

Trioxo(η^5-1-ethyl-2,3,4,5-tetramethylcyclopentadienyl)rhenium(VII) (1')

A mixture of $(\eta^5\text{-}C_5Me_4Et)Re(CO)_3$* (1.00 g, 2.38 mmol) in benzene (35 cm^3) and conc. sulfuric acid (0.5 cm^3) in aqueous hydrogen peroxide (30%, 25 cm^3) was refluxed for 7 h under vigorous stirring. After approximately 2 h the organic layer turned dark red, and more hydrogen peroxide (5 cm^3) was added. The yellow organic phase was separated from the bluish-green aqueous layer, the latter one being extracted with toluene (3 × 5 cm^3). The combined extracts were washed with $NaHCO_3$ solution (5%) and water, and then dried over anhydrous $MgSO_4$. The solvent was removed *in vacuo* and the crude product recrystallized from toluene–*n*-hexane (1:2) at *ca* −30°C as bright yellow needles. Yield 400 mg (44%). From the aqueous phase *ca* 35% of Re was recovered as $KReO_4$ by concentrating this solution and subsequent addition of excess potassium hydroxide. Compound 1' melts at 145°C under decomposition.

Spectroscopic characterization. IR (KBr, cm^{-1}): 920 s (νReO_3 sym.), 887 vs (νReO_3 asym.), and 405 m (δReO_3). ^1H NMR (C_6D_6, 28°C): δ 2.17 (q, 2H, J_{HH} = 7.7 Hz, CH_3CH_2), 1.76 (s, 6H_3, CH_3) 1.62 (s, 6H, CH_3), and 0.74 (t, 3H, J_{HH} = 7.7 Hz, CH_3CH_2). ^{13}C NMR (C_6D_6, 28°C): δ 122.0 (CH_3CH_2C), 120.0 (CH_3C), 119.9 (CH_3C), 18.8 (CH_3CH_2), 13.2 (CH_3CH_2), 9.94 (CH_3), and 9.68 (CH_3). EI-MS (70°C, 70 eV): *m/z* 384 (M^+, parent ion).

Elemental analysis. Found: C, 34.3, H, 4.5, O, 12.4, Re, 47.0%. Calc. for $C_{11}H_{17}O_3Re$ (383.45): C, 34.5, H, 4.5, O, 12.5, Re, 48.6%.

(t-Butylimido)dichloro(η^5-pentamethylcyclopentadienyl)rhenium(V)

$(C_5Me_5)ReCl_4$ (225 mg, 0.49 mmol) was added as a solid to a solution of *t*-butyl amine (1.50 g, 20.5 mmol) in 5 cm^3 of toluene at room temperature. A dirty green solution formed from which a colorless solid separated. After filtration, the solvent was removed *in vacuo* to leave a dark brown oil which was extracted with pentane (2 × 3 cm^3). The olive-green residue was then recrystallized repeatedly from tetrahydrofuran–*n*-hexane (1:4) at *ca* −30°C to give blue-green, well-shaped crystals. Yield 125 mg (56%). M.p. 133–134°C.

*This starting compound was prepared by analogy with $(\eta^5\text{-}C_5Me_5)Re(CO)_3$ from $Re_2(CO)_{10}$ (Strem Chemicals) and 1-ethyl-2,3,4,5-tetramethylcyclopentadiene according to the procedure given in Refs 14, 15, 43, 67. Characterization: elemental analysis, ^1H and ^{13}C NMR, IR, and EI-MS [J. Okuda, unpublished results, Technische Universität München (1986)].

Spectroscopic characterization. IR (KBr, cm^{-1}): 1249 s [$(CH_3)_3C$], 338 and 332 m (νReCl). ^1H NMR (C_6D_6, 28°C): δ 1.83 (s, 15H, C_5Me_5), and 1.18 [s, 9H, $(CH_3)_3C$]. ^{13}C NMR (C_6D_6, 28°C): δ 107.9 (C_5Me_5), 76.0 [$(CH_3)_3C$], 31.4 [$(CH_3)_3C$] and 12.7 (C_5Me_5). EI-MS (90°C, 70 eV): *m/z* 463 (M^+, 21%), 407 ($M^+ - C_4H_8$, 100%), 390 ($M^+ - C_4H_{11}N$, 20%), 371 ($M^+ - C_4H_9 - Cl$, 65%), and 354 ($M^+ - C_4H_{11}N - Cl$, 24%).

Elemental analysis. Found: C, 36.3, H, 5.3, N, 3.0, Cl, 15.0, Re, 40.3%. Calc. for $C_{14}H_{24}Cl_2NRe$ (463.46): C, 36.3, H, 5.2, N, 3.0, Cl, 15.3, Re, 40.2%.

Dichloro(oxo)(η^5-1-ethyl-2,3,4,5-tetramethylcyclopentadienyl)rhenium(V) (**3'b**)

A suspension of $(C_5Me_4Et)ReCl_4$ (350 mg, 0.73 mmol) in 75 cm^3 of toluene was treated in a dropwise manner with a mixture of water (15 mg, 0.8 mmol), pyridine (140 mg, 1.6 mmol), and tetrahydrofuran (2 cm^3). The purple starting material rapidly dissolved and a green solution formed with concomitant deposition of a pale, greenish precipitate consisting of pyridinium hydrochloride and traces of $[(\eta^5\text{-}C_5Me_5Et)ReOCl_2]_2$. After filtration, the solvent was removed *in vacuo*. The crude product was then recrystallized at *ca* −30°C from methylene chloride–diethyl ether (1:5) as green platelets. Yield 200 mg (65%). M.p. 175°C.

Spectroscopic characterization. IR (KBr, cm^{-1}): 957 s (νReO), 353, and 338 mw (νReCl). ^1H NMR (C_6D_6, 28°C): δ 1.96 (q, 2H, CH_2, J_{HH} = 7.7 Hz), 1.66 (s, 6H, CH_3), 1.61 (s, 6H, CH_3), and 0.73 (t, 3H, CH_3, J_{HH} = 7.7 Hz). EI-MS (100°C, 70 eV): *m/z* 422 (M^+, 100%), and 386 (M^+ − HCl, 82%).

Elemental analysis. Found: C, 31.2, H, 4.1, Cl, 16.5%. Calc. for $C_{11}H_{17}Cl_2ORe$ (422.36): C, 31.3, H, 4.0, Cl, 16.8%.

Tetrachloro(η^5-1-ethyl-2,3,4,5-tetramethylcyclopentadienyl)rhenium(V) (**4'b**)

To a solution of $(\eta^5\text{-}C_5Me_4Et)ReO_3$ (300 mg, 0.8 mmol) in 5 cm^3 of toluene triphenylphosphane (205 mg, 0.8 mmol) followed by chlorotrimethylsilane (1.30 g, 12 mmol) was added at room temperature. The color of the mixture changed over a period of 1 h from brown to green, and finally to purple. The black purple crystals deposited were isolated by decanting off the supernatant solution which was discarded. The crystals were washed with toluene and diethyl ether. Yield 325 mg (85%). Analytically pure samples were obtained by repeated recrystallization from methylene chloride–diethyl ether (1:1) at *ca* −30°C. M.p. 145°C (dec.).

Spectroscopic characterization. IR (KBr, cm^{-1}): 330 ms (νReCl). EI-MS (100°C, 70 eV): *m/z* 476 (M^+ − Cl), 406 (M^+ − 2Cl), and 371 (M^+ − 3Cl).

Elemental analysis. Found: C, 27.7, H, 3.6, Cl, 29.9, Re, 38.7%. Calc. for $C_{11}H_{17}Cl_4Re$ (477.27): C, 27.7, H, 3.6, Cl, 29.7, Re, 39.0%.

Acknowledgements—The work summarized here would not have been possible without the active and continuous support of the Fonds der Chemischen Industrie, HOECHST Aktiengesellschaft, DEGUSSA AG, Chemische Werke Hüls AG, the BASF Aktiengesellschaft and the German Bundesministerium für Forschung und Technologie. We express our gratitude for the financial help that we have been receiving from these companies and institutions. Miss Juliane Geisler (text) and Mister Krebs (drawings) gratefully acknowledged for the preparation of this manuscript.

(*Received* 30 *June* 1986; *accepted after revision* 24 *October* 1986)

Abstract—The reasons why borane is captured by aromatic 2-amino-*N*-heterocycles in water are described. The key intermediate is found to be a chelate complex which contains borane, an amine and a metal ion.

Although amine–borane complexes are prepared by several methods,[1,2] the preparations are done under absolutely anhydrous conditions and sometimes in an atmosphere of dry nitrogen. In a previous communication,[3] we reported the first method for synthesizing an aromatic 2-amino-*N*-heterocycle borane in aqueous media. The reaction required a metal salt whose role we would like to describe in this paper.

RESULTS AND DISCUSSION

Borane adducts of some nitrogen heterocyclic compounds such as 2-aminopyridine and 2-amino-4-methylpyridine were prepared by the reaction of a Lewis base with trimethylamine–borane (and dimethylsulfide–borane), thereby resulting in a base displacement.[4,5] This transfer may also be possible by use of borane in tetrahydrofuran solution (BH_3–THF). However, these reactions require both anhydrous and nitrogen atmospheric conditions which sometimes are inconvenient for the organic chemist. On the other hand, amine–borane complexes are synthesized using a metal borohydride according to eqns (1)[1,2] and (2)[6] which should be worked up under anhydrous conditions. In contrast, we synthesized 2-aminopyridine–borane (**2a**) and its analogs (**2b–2f**) in aqueous solutions [eqn (3)].[3] When compared with eqn (2), there is the presence of a particular metal ion in eqn (3) in the place of a hydrochloride in eqn (2), and the presence of the 2-amino group in aromatic *N*-heterocycles. These two factors were examined to see whether they were involved in the reaction of eqn (3).

The results of the test for the ability of the one factor, namely the presence of amino group, are summarized in Table 1. Neither 4-aminopyridine nor 8-aminoquinoline would form their borane complexes; however, 8-amino-1,2,3,4-tetrahydroquinoline was obtained in a trace amount from the latter compound. It has already been reported that amidine compounds such as benzamidine and 1,5-benzodiazepine derivative were readily deaminated by this method, even without using a metal salt,[7] and that 2-aminomethylpyridine was converted to pyrazine and oxazole derivatives.[8] On the basis of the results described in Table 1, it is apparent that the 2-amino group in aromatic *N*-heterocycles is essential to the formation of the corresponding amine–borane complexes in

eqn (3). Meanwhile, 2-amino-6-methylpyridine (**1e**) afforded the corresponding borane complex (**2e**) in a very low yield though it is a stronger base than 2-aminopyridine (**1a**). This fact clearly indicates that the methyl substituent at the 6-position in pyridine ring causes great steric hindrance to the coordination between the boron and the ring nitrogen. Similar phenomena have already been observed by Brown *et al.*[9]

Next, many metal ions were evaluated as the

other one of the two factors, and it was found that Ni^{2+} and Co^{2+} ions were much more effective than other metal ions (Scheme 1). Although nickel nitrate was best to yield 2-amino-4-methylpyridine–borane (**2c**), we selected cobalt chloride as the metal ion source for studying the reaction mechanisms because the reactions of cobalt chloride with sodium borohydride in several solvents have been investigated. For example, there are mainly three kinds of reaction solvent, i.e. water [eqn (4)],[10] ethanol [eqn (5)],[11] and tetrahydrofuran [eqn (6)].[12] These reactions gave cobalt borohydride, a complicated cobalt hydride (LnCoH), and cobalt boride or cobalt metal in eqns (4) and (5). It was only in the latest study [eqn (6)] that the formation of borane was recognized under anhydrous conditions and a nitrogen stream. It has also been reported that the reactions of sodium borohydride with chlorides of Fe(III),[13] Hg(I),[14] Sb(III),[14] Bi(III)[15] and Sn(II)[16] gave borane. These reactions, however, were carried out in diglyme or without a solvent, but not in water or alcohol. Our results as shown in eqn (3) suggested that borane could be generated by the reaction of cobalt chloride with sodium borohydride even in aqueous media. The borane was presumably captured by both 2-aminopyridine (or its analogs) and the metal ion through a stabilized intermediate. We attempted to clarify this presumption by isolating the intermediate from the reaction. When a solution of cobalt chloride in water was added to a solution of 2-amino-4-methylpyridine (**1c**) and sodium borohydride in water, a black powder immediately appeared, part of which was filtered off, washed with water and dried in a vacuum desiccator. During the drying the black powder turned gray. It was found that the gray powder contained 2-amino-4-methylpyridine–borane (**2c**) and 3% of cobalt, but no chlorine. On stirring the above reaction mixture (pH 9.5) for 3 h, the black precipitates were hydrolyzed to **2c** and green gelatinous precipitates which were found to be the products obtained by hydrolysis of cobalt chloride at pH 9.5 under air, presumably a mixture of cobaltous hydroxide and cobaltous oxychloride.[17] On the other hand, when nickel nitrate was used in place of cobalt chloride in the above reaction, a similar black powder was obtained and was not readily hydrolyzed. When dried in a vacuum desiccator, the black powder was also converted to a gray one which contained **2c** and nickel. The elemental ratio of the gray powder was Ni : C : N = 1 : 6 : 2 which indicated that the Ni^{2+} ion might be coordinated with at least one molecule of **2c**. The amine–borane complex **2c** was readily isolated from these intermediates by extraction with chloroform. The difference between the nickel-containing intermediate and the cobalt-containing intermediate is observed in their stability towards water, namely the former is more stable than the latter. On the basis of these results, we proposed a possible structure for the intermediate as shown in Scheme 2 where all requirements for eqn (3) were filled.

It is clear in Scheme 2 that a metal ion must coordinate to a nitrogen of an amidine moiety of a *N*-heterocycle. In order to confirm this kind of chelation, we utilized adenine (**3a**) and its 9-methyl derivative (**3b**) because interactions between metal

(Ni^{2+}), Co^{2+}, $(Co^{2+}) \gg Mg^{2+}$, Al^{3+}, Ca^{2+}, (Cr^{3+}), (Mn^{2+}), Fe^{2+}, (Cu^{2+}), Zn^{2+}, (Ag^{+}), Sn^{2+}, Sb^{3+},

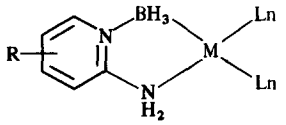

Scheme 2.

ions and these nucleic acid bases have extensively been studied. When 9-methyladenine (**3b**) was reacted with cobalt chloride in ethanol, a 9-methyladenine–cobalt chloride complex [a blue polymer (**6**)] was obtained, where the adenine nucleus utilizes N(1) and N(7) sites in binding to the metal ion.[18] Complex **6** reacted with sodium borohydride in water to give 9-methyladenine–borane (**8**). The possible structure of the intermediate of **8** might be **7** as shown in Scheme 3. On the other hand, adenine (**3a**) whose most preferred binding site for Co^{2+} ion coordination is the N(9) position[19] did not afford adenine–borane (**4**), but the 9-deprotonated adenine salt (**5**) (Scheme 4).

Coordination sites of borane to **1a** and **3b** were studied by UV (Table 2) and ^{1}H NMR spectral analyses. It has already been found that the protonation site is N(1) in both **1a**[20] and **3b**.[21] These protonated amines showed the bathochromic shifts in **1a**, and the blue shifts in **3b** in their UV spectra. Since **2a** showed similar shifts to those of the protonated compound of **1a**, the borane would coordinate to N(1) of the ring nitrogen.[5] On the other hand, **8** did not show the blue shifts. Moreover, the signal of amino protons of **2a** in ^{1}H NMR was observed at 5.67 ppm which was 1 ppm lower than that of **1a**. In contrast, the signal of amino protons of **8** was observed at 8.93 ppm which was 1.87 ppm lower than that of **3b**. This larger shift observed in **8** (about twice that of **2a**) indicates that the amino nitrogen might directly contact with borane. Therefore, the borane does not coordinate to the ring nitrogen N(1) of **3b**, but to the amino nitrogen.

$$CoCl_2\cdot 6H_2O \xrightarrow[H_2O]{NaBH_4} Co(BH_4)_2 + Co_nB_m + LnCoH \quad (4)$$

$$CoCl_2\cdot 6H_2O \xrightarrow[EtOH]{NaBH_4} LnCoH,\ Co\ \text{and/or}\ Co(BH_4)_2 \quad (5)$$

$$CoCl_2 \xrightarrow[\text{anhydrous THF}]{NaBH_4} CoH_2 + BH_3 + NaCl \quad (6)$$

As Scheme 5 shows, there are three kinds of bonding between a metal ion and borohydride anion,[22] and only one example has been reported

for cobalt metal which has the bidentate coordination.[23] Since it is thought that an amine–borane complex is equivalent to the borohydride anion, the bonding between the metal and the borane which is coordinated with the amine would be similar to that described above.

In conclusion, the role of the metal ion in eqn (3) is both to produce borane from sodium borohydride and to form a chelate complex with the aromatic 2-amino-*N*-heterocycle which is able to capture borane in aqueous media. The amine–boranes listed in Table 1 were found to have properties of both the primary amine–borane and pyridine–borane,[24] namely the former is very effective for stereo- and chemoselective reductions of aldehyde and ketons,[25] and the latter shows many interesting reactions in acid media.[26]

EXPERIMENTAL

Melting points were determined by using a Yamato Scientific stirred liquid apparatus and are uncorrected. IR* and UV spectra were recorded on JASCO IR-G and Hitachi 200-20 spectrophotometers, respectively. ^{1}H NMR spectra

* All amine–borane complexes obtained here showed their characteristic absorption bands in the 2250–2400-cm^{-1} region.

were run on Varian EM-90 and T-60 spectrometers with $(CH_3)_4$ Si as the internal standard. The mass spectra were run on JEOL OlS and DX-300 (equipped with JMA-3100) spectrometers. Elemental analyses were performed on a Perkin–Elmer 240B instrument, and the results were within ± 0.36 of theoretical values of C, H and N. The X-ray fluorescence analyses (Cl and metals) were performed on a Rigaku Geiger Flex 3063P instrument. Metals were also determined on a Shimadzu Atomic Absorption/Flame Emission spectrophotometer (AA-630-02).

*General procedure for the reaction of amine with sodium borohydride in the presence of cobalt chloride**

A solution of $CoCl_2 \cdot 6H_2O$ in 10 cm^3 of water was gradually added to a mixed solution of 1 g of amine and 1 g of $NaBH_4$ in 100 cm^3 of water with stirring. After 3 h, the reacted solution was extracted with chloroform (40 $cm^3 \times 3$), and the extract was dried with Na_2SO_4. The dried solution was evaporated at 30–40°C under a reduced pressure to give products which were purified by column chromatography ($CHCl_3$ as eluant).

Yield 75%; m.p. 94–95°C; mass analysis, *m/z* 121.098 [$M^+ - 1$], calc. for $C_6H_{10}BN_2$, 121.094 [M−H]; ^1H NMR [$CDCl_3 + (CD_3)_2SO$] δ 2.13 (3H, s, CH_3), 2.60 (3H, bq, $J = 55$ Hz, BH_3), 6.20 (2H, b, NH_2), 6.60 (1H, d, 3-H), 7.23 (1H, dd, 4-H), 7.70 (1H, d, 6-H).

2-*Amino*-6-*methylpyridine–borane* (**2e**)

Yield 2%; m.p. 51–52°C; mass analysis, *m/z* 121.096 [$M^+ - 1$], calc. for $C_6H_{10}BN_2$, 121.094 [M−H].

2-*Aminopyrimidine–borane* (**2f**)‡

Yield 43%; m.p. 111–112°C; mass analysis, *m/z* 108.076 [$M^+ - 1$], calc. for $C_4H_7BN_3$, 108.073 [M−H].

Cobalt-containing intermediate

A solution of $NaBH_4$ (0.5 g, 13 mmol) of 50 cm^3 of water was added to a solution of $CoCl_2 \cdot 6H_2O$ (0.5 g, 2.1 mmol) and **1c** (0.45 g, 4.2 mmol) in 50 cm^3 of water with stirring. A black powder simultaneously appeared with bubbling. The powder was collected, washed with water and dried in vacuum desiccator over P_4O_{10} to give a gray powder. Elemental analysis: C, 53.4; H, 8.4; N, 21.1; Co, 3.0; Cl, o%. C:H:N = 5.8:11:2. The gray powder (100 mg) was treated with chloroform, and the mixture was filtered off. The filtrate was evaporated to give **2c** (90 mg).

Nickel-containing intermediate

A black powder was obtained by use of $Ni(NO_3)_2 \cdot 6H_2O$ in place of $CoCl_2 \cdot 6H_2O$ in the above experiment. When dried over P_4O_{10} in a vacuum desiccator, a gray powder was obtained. Elemental analysis: C, 32.7; H, 5.5; N, 12.7; Ni, 24.0%. C:(H):N:Ni = 6:(12):2:0.9.

* The optimum molar ratio for the reaction was determined as $CoCl_2$:**1c**:$NaBH_4 = 1:2:6$ from the viewpoint of the yield of **2c**.

† The values in parentheses are the corresponding chemical shifts of the starting amine.

‡ Bubbles occurred during ^1H NMR measurement in $(CD_3)_2SO$.

9-Methyladenine–borane (**8**)

The cobalt chloride–9-methyladenine complex (**6**) (260 mg) was dissolved in 40 cm^3 of water to give a pink solution. $NaBH_4$ (260 mg) was gradually added to the solution with stirring. After 3 h, the mixed solution was extracted with chloroform (30 $cm^3 \times 4$). The extract was dried with Na_2SO_4, and evaporated below 30°C under reduced pressure to give a powder (70 mg) which was decomposed at 257°C. TLC ($CHCl_3 : CH_3OH = 9 : 1$), two spots (**8** and 9-methyladenine); mass analysis, *m/z* 162.094 [$M^+ - 1$], calc. for $C_6H_9BN_5$, 162.095 [M − H]; ^1H NMR [$(CD_3)_2SO$] δ* 3.78(3.69) (3H, s, CH_3), 8.30(8.03) (1H, s, 8-H), 8.43(8.12) (1H, s, 2-H), 8.93(7.03) (2H, b, NH_2). BH_3 signals could not be determined clearly because of both very diluted solution and broadening. The powder was decomposed on a silica gel column.

9-Deprotonated adenine salt (**5**)

Adenine (1 g) and $CoCl_2 \cdot 6H_2O$ (1 g) were dissolved in 100 cm^3 of water. $NaBH_4$ (1 g) was gradually added to the mixture with stirring. After 3 h, the reaction mixture was filtered off, and the filtrate was extracted with chloroform, but nothing was obtained. The residues were treated with 100 cm^3 of hot ethanol and the mixture was filtered off. The filtrate was evaporated to give 170 mg of powder. Elemental analysis: Co, 1.2%. ^1H NMR [$(CD_3)_2SO$] δ* 6.93(6.97) (2H, b, NH_2), 8.02(8.05) (1H, s, 8-H), 8.06(8.10) (1H, s, 2-H), (12.50) (1H, b, NH). The powder was readily converted to adenine by hydrolysis.

THE REACTIONS OF IRON(III) BROMIDE AND IRON(II) THIOCYANATE WITH AMMONIA AND THEIR REDUCTIONS WITH ALKALI METALS IN LIQUID-AMMONIA SOLUTIONS OF ALKALI METAL CYANIDES

ELAINE S. DODSWORTH, PETER J. O'GRADY, DAVID NICHOLLS* and DAVID ROBERTS

Donnan Laboratories, The University, Liverpool L69 3BX, U.K.

(*Received* 29 *August* 1986; *accepted* 24 *October* 1986)

Abstract—Iron(II) thiocyanate dissolves in liquid ammonia to form ammines $Fe(NCS)_2 \cdot 8NH_3$, $Fe(NCS)_2 \cdot 7NH_3$ and $Fe(NCS)_3 \cdot 5NH_3$; these evolve ammonia at room temperature to form the diammine $Fe(NCS)_2(NH_3)_2$ which has a tetragonal structure with thiocyanate bridges. Iron(III) bromide is also soluble in ammonia but with partial ammonolysis. Reduction of these compounds, and of iron(II) bromide, with potassium or caesium in ammonia solutions of the appropriate alkali metal cyanide yields cyanoferrates(0). Only $Cs_4Fe(CN)_4$ has been isolated in a pure state; it is oxidized by ammonium cyanide in ammonia to $Cs_4[Fe(CN)_6]$.

One of the most fascinating features of liquid ammonia as a solvent lies in its ability to dissolve alkali metals without reaction and thereby to produce solutions which act as very strong and homogeneous reducing agents. Whilst metal carbonyl chemistry is extensive, compounds containing transition metals in zero oxidation state bonded to cyanide ion have only been isolated using alkali metal solutions in liquid ammonia. The first of these, potassium tetracyanonickelate(0), $K_4Ni(CN)_4$, was prepared by Eastes and Burgess[1] in 1942 and subsequently many other cyanometallates(0) have been isolated. In recent years these have included compounds of the early transition elements e.g. $K_4Ti(CN)_4$,[2] $K_2V(CN)_2 \cdot 0.5NH_3$[3] and $K_5Zr(CN)_5$,[4] and indeed low oxidation state cyanides have now been isolated for all of the first-row transition elements except iron and copper. We report here our attempts to prepare an iron(0) cyano complex. One of the problems encountered in preparing such compounds is the availability of suitable starting materials. Complex cyanides in high oxidation states are not usually reducible to cyanometallates(0) by an alkali metal in ammonia solutions, so that simple salts of the metal (for solubility reasons these are usually bromides or thiocyanates) must be used as starting materials. It is then desirable to know how these salts react themselves with liquid ammonia so that the nature of the species present is understood. We here thus also report on the reactions of iron(II) thiocyanate and iron(III) bromide with ammonia.

The reactions of the iron(II) halides with liquid ammonia have been well studied,[5,6] they form the ammines $FeCl_2 \cdot 10$, 6, 2 and $1NH_3$, $FeBr_2 \cdot 6$, 2 and $1NH_3$, and $FeI_2 \cdot 6$ and $2NH_3$. Unfortunately these have very limited solubilities in ammonia. Iron(III) chloride and bromide are reported[7] to be considerably more soluble in ammonia but the authors report that this is probably accompanied by some ammonolysis. We chose to study the reactions of iron(II) thiocyanate and iron(III) bromide with ammonia, these being the two most likely soluble starting materials for preparing iron compounds in liquid ammonia.

RESULTS AND DISCUSSION

Iron(II) thiocyanate gives a brown solution in liquid ammonia at −36°C. The vapour pressure–composition isotherm in this system at −36°C is shown in Fig. 1. Apart from a saturated solution dissociation vapour pressure (~ 430 mmHg), the

* Author to whom correspondence should be addressed.

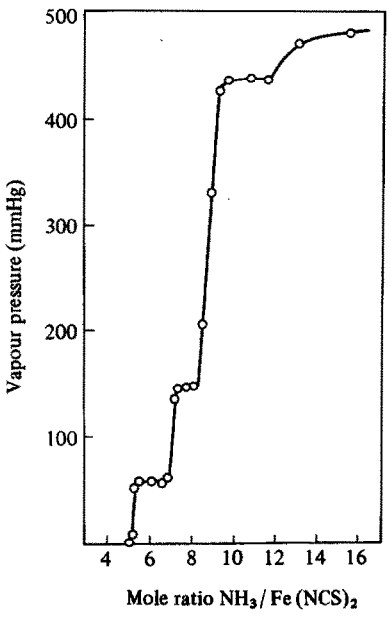

Fig. 1. Vapour pressure–composition isotherm for the $Fe(NCS)_2$–NH_3 system at −36°C.

isotherm shows univariant portions at 140 and 50 mmHg. These two plateaux correspond to the dissociations:

$$Fe(NCS)_2 \cdot 8NH_3(s) \rightleftharpoons Fe(NCS)_2 \cdot 7NH_3(s) + NH_3(g),$$

$$Fe(NCS)_2 \cdot 7NH_3(s) \rightleftharpoons Fe(NCS)_2 \cdot 5NH_3(s) + 2NH_3(g).$$

By measuring the ammonia vapour pressure over each of these systems at various temperatures and using the integrated form of the van't Hoff isochore, we calculate the enthalpies of these dissociations to be 34.9 and 85.9 kJ mol^{-1}. Such heats of dissociation show that the ammonia molecules being evolved are only held by weak ion-dipole type forces. At −36°C, the stable phase is $Fe(NCS)_2 \cdot 5NH_3$; on warming this phase to room temperature, three further molecules of ammonia are evolved to give the diammine $Fe(NCS)_2 \cdot 2NH_3$. This has a magnetic moment of 5.1 BM, showing it to contain high-spin iron(II); its solid-state reflectance spectrum shows bands at 13,300 and 7300 cm^{-1}, which we assign to the $^5B_{2g} \rightarrow {}^5A_{1g}$ and $^5B_{2g} \rightarrow {}^5B_{1g}$ transitions in a tetragonal structure. Such large splittings of the ^5E_g (O_h) state are common[8] in tetragonal iron(II) complexes; our band positions are very close to those found[9] for $Fe(py)_2(NCS)_2$, which is known to have a tetragonal structure with bridging thiocyanates. The IR spectra of $Fe(NCS)_2$ and $Fe(NCS)_2 \cdot 2NH_3$ are assigned in Table 1. The spectrum of the diammoniate again resembles that of $Fe(NCS)_2(py)_2$ in so far as the thiocyanate modes are concerned and is consistent[10] with linear bridging thiocyanates. We do not locate the ν(Fe—SCN) band; this is expected[9] to be below 200 cm^{-1}.

Iron(III) bromide gives a brown solution in ammonia at −36°C; the vapour pressure–composition isotherm for this system is shown in Fig. 2. This clearly shows the presence of ammonium bromide in the mixture, the univariant portions at 40 and 30 mmHg corresponding[11] to the dissociations:

$$NH_4Br \cdot 3NH_3(s) \rightleftharpoons NH_4Br \cdot 1.5NH_3(s) + 1.5NH_3(g),$$

$$NH_4Br \cdot 1.5NH_3(s) \rightleftharpoons NH_4Br(s) + 1.5NH_3(g).$$

The overall length of these steps is approximately one molar ratio of ammonia to iron(III) bromide, i.e. there is thus approximately one-third of a mole of ammonium bromide present per mole of starting iron(III) bromide. The composition of the orange-brown mixture when all ammonia is removed at −36°C is $FeBr_3 \cdot 6.3NH_3$; this represents a mixture of approximately $\frac{2}{3}[Fe(NH_3)_6]Br_3 + \frac{1}{3}[Fe(NH_3)_5(NH_2)]Br_2 + \frac{1}{3}NH_4Br$ which has deposited from the equilibrium:

$$[Fe(NH_3)_6]Br_3 + NH_3 \rightleftharpoons [Fe(NH_3)_5(NH_2)]Br_2 + NH_4Br.$$

The orange-brown powder has a composition close to $FeBr_3 \cdot 6NH_3$ at room temperature; the IR spectrum of this solid clearly shows the presence of ammonium ions. We thus confirm the assumption

of earlier workers[7] that iron(III) bromide dissolves in liquid ammonia with partial ammonolysis.

In our efforts to isolate an iron(0) cyanide complex we chose initially to attempt the reduction of potassium hexacyanoferrate(II). Watt[12] has reported that reduction of potassium hexacyanoferrate(III) by potassium in liquid ammonia proceeds only as far as the hexacyanoferrate(II). We confirm that no reduction of hexacyanoferrate(II) by potassium occurs in liquid ammonia at temperatures up to −40°C. The reaction of iron(III) bromide with an excess of potassium cyanide and potassium in liquid ammonia proceeds rapidly even at −78°C with the vigorous evolution of hydrogen and the formation of a dark coloured precipitate in a yellow solution. After filtration and washing of the precipitate, a black, pyrophoric powder was obtained. Although numerous experiments were performed with widely varying $K:KCN:FeBr_3$ ratios, no consistent stoichiometric formula could be derived from the analytical data which showed in every case only K, Fe, C and N to be present with up to 1% H [with an average stoichiometry of approximately $K_2Fe(CN)_2$]. The IR spectra of the black solids were the same, showing ν(CN) at 2040(w), 2000(s) and 1960(s) cm^{-1}, and ν(Fe—C) at 582(m) and 568(m) cm^{-1}. The solids were however ferromagnetic and the electronic spectrum (diffuse reflectance) showed only increasing absorption between 9000 and 30,000 cm^{-1}, so that no *d–d* bands could be observed. Clearly a low oxidation state cyanide complex of iron arises in this reaction. The vigorous effervescence in the reaction probably arises initially from the reaction of ammonium bromide (ammonolysis product of $FeBr_3$) with potassium but the continued decoloration of the alkali metal solution must occur through catalysis by one of the products. The ferromagnetism suggests that the catalyst may be iron metal and/or iron nitride. Iron and Fe_3N are known[14] to be the reduction products of iron(II) bromide with potassium in ammonia. A very similar product [of stoichiometry $K_{1.5}Fe(CN)_{1.5}$] was obtained when either iron(II) bromide or iron(II) thiocyanate was used as the starting material so that the ammonolysis of iron(III) bromide was not solely responsible for the vigorous effervescence and non-integral stoichiometry of the product.

The reaction of caesium with iron(II) or iron(III) bromide or with iron(II) thiocyanate in the presence of excess caesium cyanide proceeds with less hydrogen evolution to give a green-grey precipitate of $Cs_4Fe(CN)_4$. Unlike the black precipitates obtained when potassium is the reductant, this product is air- and moisture-sensitive, but not pyrophoric, suggesting that the pyrophoricity of the black compounds may be due to the presence of finely divided iron. The caesium compound has ν(CN) at 2040, 1995 and 1950 cm^{-1}, and ν(Fe—C) at 560 cm^{-1}; the spectrum is very similar to those obtained in the potassium reductions. When the sample was exposed to the atmosphere and the spectrum rerun, the peak at 2040 cm^{-1} grew and the other cyanide stretches disappeared. It is possible, therefore, that the 2040-cm^{-1} band in "$Cs_4Fe(CN)_4$" may be due to the presence of $Cs_4[Fe(CN)_6]$ formed during handling of the sample. The occurrence of ν(CN) at 1995 and 1950 cm^{-1} is indicative of much back bonding to π^*-orbitals on CN^-, and these bands are in the region found for other metal(0) cyanide complexes, e.g. $K_4Ti(CN)_4$ (1943 cm^{-1})[2] and $K_4Ni(CN)_4$ (1985 cm^{-1}),[13] so that we believe our green-grey product to be caesium tetracyanoferrate(0). Its electronic spectrum showed a band at 11,800 cm^{-1} with a shoulder on the high-frequency side (12,700 cm^{-1}), with intense change-transfer absorption above 30,000 cm^{-1}. We cannot assign this spectrum presently but hope to continue structural studies on $Cs_4Fe(CN)_4$ in due course. Unfortunately, this compound is also ferromagnetic.

It is interesting that caesium reduction has produced a stoichiometric compound. Caesium is the strongest reducing agent that can be used for this work; its electrode potential in ammonia is only slightly more negative[15] than that of potassium. The metals with more negative potential, however,

e.g. lithium, all have ammonia-insoluble amides, so that contamination of the insoluble product with amides is inevitable. We believe that the products obtained in the potassium reduction are mixtures of $K_4Fe(CN)_4$ with iron metal and possibly iron nitride.

The reaction of $Cs_4Fe(CN)_4$ with an excess of ammonium cyanide in ammonia proceeds with effervescence to give insoluble caesium hexacyanoferrate(II). The iron(0) compound is thus oxidized according to:

$$Cs_4Fe(CN)_4 + 2NH_4CN \rightarrow Cs_4[Fe(CN)_6] + H_2 + 2NH_3.$$

This oxidation is similar to that observed with other[16] cyanometallates(0) except that chromium(0) and cobalt(0) are oxidized to the +3 state by ammonium cyanide. In the iron case the +2 state is stabilized (as is the +3 state in cobalt) by the t_{2g}^6 configuration which gives the maximum propensity for π-bonding to the vacant π^*-orbitals on CN^-.

EXPERIMENTAL

Reactions, tensimetric studies and manipulations in liquid ammonia were carried out in vacuum apparatus as described elsewhere.[15] Magnetic and spectroscopic methods were as previously described.[3] Iron(II) thiocyanate was prepared in aqueous solution from iron(II) sulphate and barium thiocyanate under a nitrogen atmosphere in a Schlenk apparatus. The filtrate was evaporated, extracted with ethanol, and the filtered extract evaporated. The product was extracted with ether to remove the red colour of iron(III) thiocyanate and the remaining grey-green solid evacuated at 100°C (Found: C, 14.7; N, 16.6; S, 36.9; IR shows H_2O absent; $Fe(NCS)_2$ requires: C, 14.0; N, 16.3; S, 37.3%). Iron(II) and iron(III) bromides were ex Aldrich. Ammonium cyanide was prepared as described previously.[16] Caesium cyanide was prepared by passing hydrogen cyanide through a 50 wt % solution of caesium hydroxide to which an equal volume of ethanol had been added. An extraction with a small amount of ether removed brown oily contaminants, and then further ether was added to precipitate the caesium cyanide which was filtered off, washed with ether and dried *in vacuo* at 100°C (Found: CN^-, 16.2; IR shows H_2O and –OH absent; CsCN requires: CN^-, 16.4%).

Reaction of $Fe(NCS)_2$ *with ammonia*

A measured excess of ammonia was condensed on to a weighed quantity of $Fe(NCS)_2$ *in vacuo* and the vapour pressure–composition isotherm constructed at −36°C. After removal of all ammonia at 20°C, the brown product was removed from the vacuum apparatus under an atmosphere of dry nitrogen (Found: C, 11.8; H, 3.0; N, 29.9; S, 31.3; $Fe(NCS)_2(NH_3)_2$ requires: C, 11.7; H, 2.9; N, 27.2; S, 31.1%).

Reaction of $FeBr_3$ *with ammonia*

Similarly the orange-brown product obtained in this system at room temperature was analysed for ammonia as a check on the values obtained in the vapour pressure–composition isotherm (Found: NH_3, 25.6; $FeBr_3 \cdot 6NH_3$ requires: NH_3, 25.7%; IR spectrum shows in addition to NH_3 modes, bands at 1730 and 1400 cm^{-1} assignable to NH_4^+).

Reduction of $FeBr_3$ *with caesium in the presence of caesium cyanide*

$FeBr_3$. Liquid ammonia (~ 100 cm^3) was condensed on to a mixture of $FeBr_3$ (1.6 g, 5.4×10^{-3} mol) and CsCN (7.7 g, 4.8×10^{-2} mol); caesium (5g, 3.8×10^{-2} mol) was then added under an atmosphere of argon and the mixture cooled to −78°C and re-evacuated. Effervescence occurred and the blue colour of the solution disappeared after about 10 min to leave a green-grey precipitate in a colourless solution. The mixture was filtered and the precipitate washed 8 times with liquid ammonia (~ 50 cm^3) until no further white solids (CsCN, $CsNH_2$ and CsBr) were being extracted. The residue was then evacuated at room temperature before being removed from the apparatus under dry argon.

$FeBr_2$ *and* $Fe(NCS)_2$. Similar products were obtained using $FeBr_2$ (0.69 g, 3.2×10^{-3} mol), CsCN (5.86 g, 3.7×10^{-2} mol) and caesium (5 g, 3.8×10^{-2}), or $Fe(NCS)_2$ (0.58 g, 3.4×10^{-3} mol), CsCN (6.18 g, 3.9×10^{-2} mol) and caesium (5 g, 3.8×10^{-2} mol). Effervescence occurred also in these reactions but the blue solutions remained for longer periods than in the $FeBr_3$ reactions. Analytical data on these products are given in Table 2.

Table 2. Analytical data (%) on $Cs_4Fe(CN)_4$

Starting materials	Cs	Fe	C	N	H
$FeBr_3$, Cs and CsCN	76.2	8.5	6.8	8.3	0.2
$FeBr_2$, Cs and CsCN	74.7	7.7	6.7	7.8	0.3
$Fe(NCS)_2$, Cs and CsCN	78.5	7.8	6.6	7.1	0.3
$Cs_4Fe(CN)_4$ requires	76.9	8.1	6.9	8.1	0

Reaction of $Cs_4Fe(CN)_4$ *with* NH_4CN

An excess of ammonium cyanide (~ 5 g) was sublimed into the reaction vessel containing liquid ammonia (~ 100 cm^3) and a sample of $Cs_4Fe(CN)_4$ (~ 1 g) which had been prepared *in situ*. The reaction was maintained at −78°C for several hours with intermittent agitation. A green-yellow solution slowly formed with mild effervescence. The mixture was then allowed to warm to −33°C and then filtered. The yellow insoluble product was washed several times with liquid ammonia before being dried by evacuation at room temperature and removed from the apparatus under dry nitrogen [Found: C, 10.1; N, 11.1; H, absent; $Cs_4Fe(CN)_6$ requires: C, 9.7; N, 11.3%; IR spectrum showed ν(CN) at 2095(sh), 2065(sh) and 2040 cm^{-1}, ν(Fe—C) at 580 cm^{-1}, and δ(FeCN) at 400 cm^{-1}. Vacuum-dried $K_4Fe(CN)_6$ has ν(CN) at 2092, 2070 and 2040 cm^{-1}, ν(Fe—C) at 578 cm^{-1} and δ(FeCN) at 410 cm^{-1}].

NITRILOTRIACETIC ACID, THIOUREA AND CYSTEINE LIGANDS IMMOBILIZED ON CELLULOSE FOR THE UPTAKE OF TRACE METAL IONS

E. MENTASTI,* C. SARZANINI, M. C. GENNARO and V. PORTA

Dipartimento di Chimica Analitica, Università di Torino, Via P. Giuria, 5, 10125 Torino, Italy

(*Received* 8 *September* 1986; *accepted* 24 *October* 1986)

Abstract—Functionalized celluloses containing nitrilotriacetic acid, thiourea and cysteine have been prepared for the uptake of a series of trace metal ions, namely Al(III), Ca(II), Cd(II), Co(II), Cu(II), Fe(III), Hg(II), Mg(II), Ni(II), Pb(II) and Zn(II). The recovery has been evaluated as a function of pH, and the capacities determined at the pH of maximum yield. The experimental yields obtained for the metal recoveries have been compared with the ones calculated with the aid of the computed distribution of metal–ligand species. The materials obtained may be utilized for the enrichment of trace metals, for the demetalization of solutions, and for speciation studies.

Many papers have been published regarding the use of chelating agents bound to cellulose for the concentration and removal of trace metal ions in solution.[1–4] In previous work from this laboratory the suitability of iminodiacetic acid (IDA),[5] *N*-methyliminodiacetic acid (MIDA)[6] and EDTA[7] to concentrate a large number of cations has been investigated.

The reactions to graft nitrilotriacetic acid (NTA), thiourea (THIO) and cysteine (CYS) onto commercial cellulose filters have been optimized for the application of chelating materials in concentration and speciation studies.

The uptake, capacity, recovery and enrichment of a series of metal ions such as Al(III), Ca(II), Cd(II), Co(II), Cu(II), Fe(III), Hg(II), Mg(II), Ni(II), Pb(II) and Zn(II) was evaluated. Matrix interferences were investigated using chloride, nitrate, phosphate and sulphate ions, competition between bound and free ligands was studied.

With the aid of a computer program and by comparison with the experimental data, the apparent stability constants of the complexes between metals and ligands grafted to the functionalized filters were evaluated. The degree of interaction between each of the metal ions and free or bound ligand on cellulose was calculated according to a described procedure.

The results showed a satisfactory agreement with the experimental values obtained in the competition reactions.

EXPERIMENTAL

Reagents and equipment

Metal stock solutions [1,000 mg l^{-1} (C. Erba) for atomic absorption] were diluted as required. High-purity water (HPW) prepared in a Milli Q Millipore equipment was used. NTA sodium salt, THIO, CYS and all other chemicals were analytical reagent-grade products.

All laboratory glassware, polyethylene and polypropylene equipments, were cleaned in 6 M nitric acid and repeatedly rinsed with HPW.

A d.c. plasma emission spectrometer Spectraspan IV (SMI, Andover, MA) and an ICP emission spectrometer Plasma-300 (Allied Analytical Systems, Waltham, MA) have been used for the metal measurements. Standard solutions and blanks were run in the same manner as the samples.

The pH measurements were made with an Orion 811 pH-meter equipped with a combined glass calomel electrode.

Adjustable Eppendorf pipettes were used to pre-

pare the solutions. A Millipore 47-mm glass-frit filtration unit was employed to ensure reproducible placement of the prepared filters.

Preparation of the filters

The chelating agents, NTA, THIO and CYS, were attached to cellulose according to the method described by Smits and Van Grieken.[8] The preparation reaction proceeds through preliminary chlorination with phosphorus oxychloride ($POCl_3$):

$$\text{Cell-OH} \xrightarrow[\text{DMF}]{POCl_3} \text{Cell-Cl}$$

where Cell-OH represents the cellulose filters and DMF is the solvent *N*,*N*-dimethylformamide. Whatman 41 cellulose filter discs (47 mm diam., 165 mg) were conditioned for 60 min in dry DMF. To maximize the chlorination yield the solvent was dehydrated with molecular sieves. The filters were successively added to a solution of $POCl_3$ in DMF [3% (v/v)] heated on a water bath to 90°C. Heating was continued for about 30 min. The brown filters obtained were washed with DMF, HPW, 5% NaOH, HPW, 5% HAc, HPW and DMF in that order. The filters again white, were then treated at 105–110°C for about 150 min in a saturated solution of NTA, THIO or CYS in DMF and HPW [3 : 1 (v/v)]. The filters were washed with HPW and air dried. In such conditions the following reactions occur:

$$\text{Cell-Cl} \begin{cases} \text{—N(CH}_2\text{COOH)}_3 \rightarrow \text{Cell-}\overset{+}{\text{N}}\text{(CH}_2\text{COOH)}_3 \\ \text{—SC(NH}_2\text{)}_2 \rightarrow \text{Cell-NH—CS—NH}_2 \\ \text{—HSCH}_2\text{CH(NH}_2\text{)} \rightarrow \text{Cell-NH—CHCH}_2\text{CH}_2\text{SH} \\ \qquad\qquad\qquad\qquad\quad | \qquad\qquad\qquad\qquad\quad | \\ \qquad\qquad\qquad\qquad \text{COOH} \qquad\qquad\qquad\quad \text{COOH} \end{cases}$$

RESULTS AND DISCUSSION

The chelating ability of the ligands grafted on cellulose has been evaluated by conducting a systematic concentration study as a function of pH. The functionalized filters were fitted in the filtering unit and conditioned at the desired pH. 100.0 cm^3 of 1.00 $\mu g\ cm^{-3}$ solution of each metal (previously brought to the desired pH between 1.0 and 8.0) were then filtered.

The metal uptake was then evaluated by releasing the metal from the filter with 10.0 cm^3 of 2.0 M HCl and determining each metal in the final solution by atomic emission spectrometry.

Table 1 reports the results obtained for all the functionalized celluloses with the investigated metals. Each entry is the mean of triplicate measurements, and independent replicates showed the standard deviation estimate to be within 5% for each entry in Table 1. Analysis of the metal fraction filtered through the filters gave values in agreement, again within 5%, with the fraction not recovered by the filters, proving that: (i) irreversible uptake by the filters was not operating, and (ii) systematic errors in the procedure were absent.

The values reported in Table 1 show a general trend with a sharp increase of recovery yield with increasing pH, followed by a nearly constant and almost quantitative uptake. Such behaviour parallels the coordinating ability of the investigated ligands as shown by their formation constants,[9(a)–(c)] the higher values corresponding to the larger high-yield portion. A somewhat reduced coordination ability was expected for the NTA ligand since after grafting on cellulose the nitrogen atom of the ligand becomes quaternary and therefore without coordinating ability.

As an example, Cu(II), which has a log β of 13.3 has a recovery > 92% between pH 3 and 8. Fe(III) and Hg(II) show a less favourable recovery yield due to the high tendency to hydrolyse which competes with the uptake by the filters.

Table 2 reports the evaluated capacities of the filters for each metal. They have been determined from the amount of retained metal when equilibrated with 100.0 cm^3 of solution containing 100.0 $\mu g\ cm^{-3}$ of each metal ion at the pH of maximum-uptake yield. Table 2 reports, for comparison purposes, also the results obtained for other functionalized celluloses previously investigated in our laboratory. As it can be seen a similar capacity is shown by ligands of different coordinating ability such as IDA, MIDA, EDTA and NTA; the values for THIO and CYS were somewhat lower with respect to the corresponding value for NTA, showing either a lower efficiency in the grafting reaction of the chlorinated filters or a decrease in the coordinating ability of the ligands after grafting on the filters.

The similar values within the polyaminocarboxylic ligand family support a similar coordinating behaviour for each member; in fact, as has been previously suggested, two IDA, MIDA and here NTA units anchored on cellulose may act

as an EDTA-like molecule with full saturation of the octahedral ligand field of the metals.[6,7]

The release of each metal has been investigated and the results for all metals were similar to the ones reported in Fig. 1 for Pb(II) and Cu(II). A 10.0-cm^3 portion of 2.0 M HCl proved to be adequate for the complete recovery of all metals from the filters. In order to characterize the mechanism of the uptake reaction between the bound ligand and metal ions, the experimental uptake yield has been compared with the one which can be theoretically computed according to the following model. If coordination is the only interaction responsible for the metal uptake on the filters, the uptake yield should be equal to the fraction of metal in a complex form in an homogeneous solution of the same volume as the one submitted to concentration and containing a number of micromoles of ligand as that present in the filter during the uptake experiments (this last quantity has been assumed to be equal to the one derived from the highest capacity showed by each filter with the investigated metals).[5-7]

Figure 2(a)–2(f) report, as examples, the experimental behaviour for Cu(II) and Pb(II) together with the behaviour computed with a computer program acording to the model reported above and using the complex formation stability constants and hydrolysis constants reported in Table 3 (the values reported have been chosen from the published

values to be as close as possible to the conditions of the present paper).

Since the shape of computed behaviour does not closely fit in all cases the experimental data, the immobilization on cellulose alters the behaviour displayed by the ligands in homogeneous solution; thus, as a result, increasing ligand rigidity after bonding to the substrate, and substrate interaction with the bound metal alters the stability constants reported in Table 3. In order to account for this effect, apparent stability constants for Cu(II) and Pb(II) have been used which gave the best agreement between experimental and computed points in Fig. 2(a)–2(f). The derived $*\beta$ values are reported in Table 3 together with the literature values.

As can be seen from Fig. 2, a good agreement was obtained in all cases and three different situations may be evidenced: (i) the recomputed values for the NTA filter are lower than the literature data; this can be explained considering that in the immobilized NTA a quaternary positive nitrogen is formed and consequently the chelating ability of the grafted ligand is reduced. (ii) The optimization of the data of Cu(II) with the THIO filters is more difficult. This is because only one cumulative stability constant ($\beta_{1,4}$) is available, while intermediate complex species are probably favoured with the immobilized ligand. (iii) The CYS filters show an improved affinity for the metals. This fact can be explained if one considers that two or more CYS groups can be immobilized in such a position so that they can bind simultaneously to the metals.

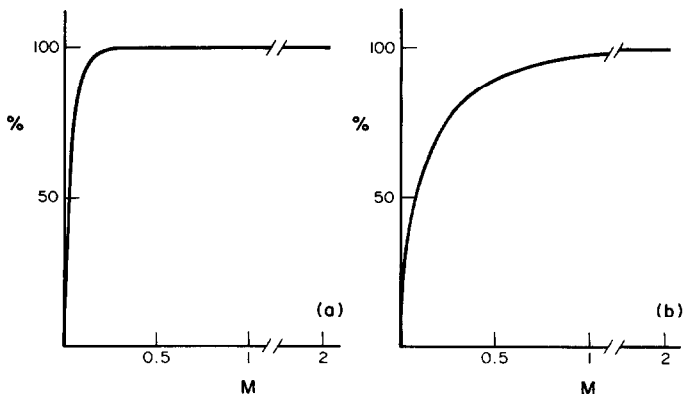

Fig. 1. Percent recovery yield for Pb(II) (a) and Cu(II) (b) from NTA filters as a function of the concentration of the stripping agent, 10.0 cm^3 HCl.

Table 3. Stability constants (β) and apparent constants ($*\beta$) (see Ref. 9 and text)[a]

Complex	Log β	Log $*\beta$

Cu_2CYS	14.0	14.0
$Cu_2H_2CYS_2$	48.8	48.8

[a] Expressed as log $\beta^{M_nH_{\pm p}L_q}{}_{nM,\pm pH,qL}$ values, where log β = literature value, and log $*\beta$ = computed apparent value.

This is evidenced in Table 3 since the greatest modification adopted for the $*\beta$ stability constants was the one for species CuH_2CYS_2.

All these observations are still valid if one considers the results obtained when the species distribution as a function of pH is computed in the case of competitive experiments. As described above, solutions containing Pb(II) or Cu(II) were fluxed through the functionalized filters in the presence of free NTA, THIO and CYS, alternatively, at different concentrations.

Table 4 reports, as an example, for Pb(II), the NTA filter and NTA, THIO or CYS free-ligand systems, the experimental and computed data obtained by taking into account, for the bound ligands, the assumption previously described and the apparent stability constants.

Experimental uptake data show that the chelating ability of NTA when bound to cellulose is practically maintained even in the presence of interfering ligands. The NTA filter is in fact able to fix > 90% of the total Pb(II) even from solutions containing cysteine and thiourea at a molar concentration of 2.4×10^{-3} M (i.e. at a molar ratio of 100 : 1 with respect to the metal concentration).

Rather surprising is the behaviour of the NTA filter when the competitive ligand is NTA itself. In fact, although the $*\beta$ value computed for the NTA filter is lower than the β-value reported for an aqueous solution, a recovery of ~ 40% of the total Pb(II) is still achieved from solutions containing an NTA molar concentration equal to about four-fold that assigned to NTA on the filter.

This unexpected behaviour is reflected in the comparison between computed and experimental

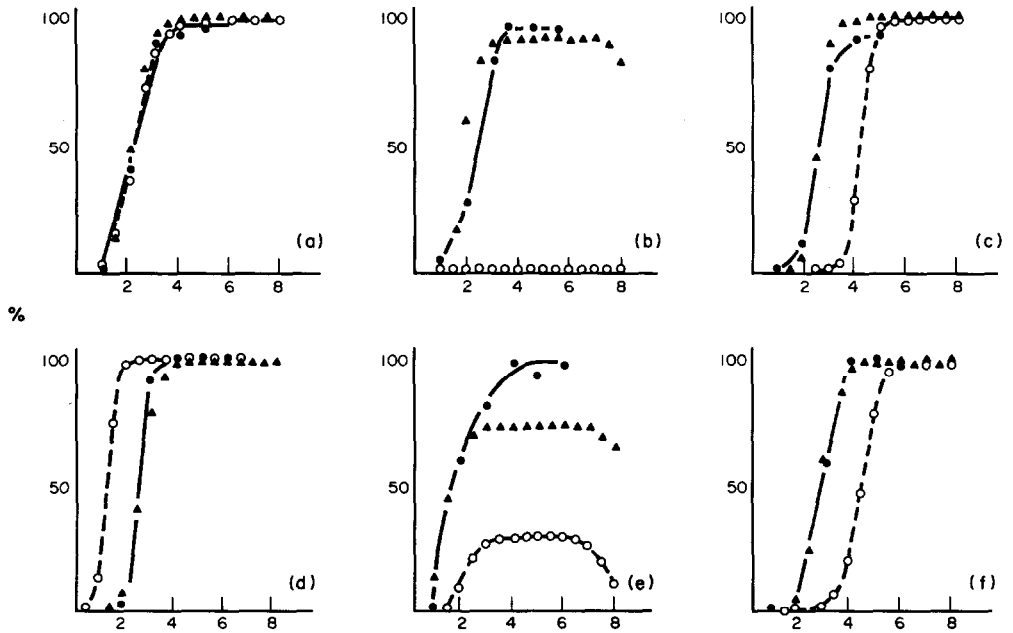

Fig. 2. (a) Experimental and computed percent recovery yield for Pb(II) onto NTA filters as a function of pH: (●) experimental, (○) computed with literature stability constants β of Table 3, (▲) computed with the apparent stability constants $*\beta$ of Table 3. (b) Pb(II), THIO filters; (c) Pb(II), CYS filters; (d) Cu(II), NTA filters; (e) Cu(II), THIO filters; (f) Cu(II), CYS filters.

Table 4. Comparison of computed (Comp.) and experimental (Exp.) (%) Pb(II) recovery (5.00 $\mu g\ cm^{-3}$ solutions) onto NTA filters in the presence of competitive species

L:M[a] molar ratio	% Recovery in the presence of					
	NTA		THIO		CYS	
	Comp.	Exp.	Comp.	Exp.	Comp.	Exp.
1:1	62.0	92.2	99.5	100.0	99.5	96.5
5:1	19.8	86.0	99.5	100.0	99.5	95.1

100:1	1.0	40.6	99.4	94.0	99.0	89.0

[a] L:M = competitive free ligand:metal molar ratio.

data (see Table 3). An explanation for this discrepancy could be the formation of mixed 1:2 metal:ligand complexes with one bound and one unbound NTA unit; this would still make possible the metal uptake even in the presence of excess free ligand in solution.

On the other hand, a good agreement is observed when THIO and CYS are the interfering ligands; both experimental and computed uptake values reported in Table 4 show the higher coordinating efficiency of these ligands when bound to cellulose, in agreement with previous findings for other systems.

Similar results were obtained also for the uptake of Cu(II). Competitive experiments obtained using THIO and CYS filters and, in turn, all the three free ligands as competitors, showed results parallel to those described above for the NTA filters.

Also interferences in the uptake of Pb(II) and Cu(II) from chloride, nitrate, sulphate and phosphate ions, present in concentrations ranging between 0.001 and 0.1 M, have been tested with all the three investigated filters. No significative differences in the uptake efficiencies were observed for the lower part of the investigated range, while uptake reductions of *ca* 5% for chloride and nitrate, *ca* 10% for sulphate, and *ca* 30% for phosphate ions were observed for concentrations of 0.1 M. Such uptake reductions are practically not relevant if one considers that the concentration range of such interfering species is, in real samples, much lower.

In conclusion, the prepared filters show a good efficiency for the uptake, recovery and enrichment of trace metal ions and may be conveniently used for speciation studies of transition-metal species.[10]

PROPERTIES OF α-BROMOVALERIC ACID AS EXTRACTING AGENT FOR COPPER(II)

YUKIO FUJII,* HIROMICHI YAMADA and MASATERU MIZUTA

Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11, Japan

(*Received* 9 *September* 1986; *accepted* 24 *October* 1986)

Abstract—Copper(II) was extracted with α-bromovaleric acid in benzene from 0.1 mol dm^{-3} (Na, H)ClO_4 aqueous solution at 25°C. The acid dissociation constant of the extracting agent was determined to be $K_a = 10^{-2.79}$ in aqueous solution at 25°C. The partition constant of the acid (HA) between the aqueous phase and benzene, and the dimerization constant of the acid in benzene were evaluated to be 2.6 and 56 in molarity, respectively. The dimeric copper(II) α-bromovalerate is responsible for the extraction:

$$2Cu^{2+} + 3(HA)_{2,o} \overset{K_{ex}}{\rightleftharpoons} Cu_2A_4(HA)_{2,o} + 4H_3O^+, \quad (\text{subscript } o = \text{organic phase})$$

with $\log K_{ex} = -7.87$. The complex formation of cupric ion with the acid anion observed in the aqueous phase was taken into consideration for calculation of the extraction constant. It was proved that the formation of dimeric copper(II) species is not prevented by the bromine at the α-position in the valeric acid.

Solvent extraction of metal carboxylates has been considerably studied in the past three decades.[1] Extraction of copper(II) alkanoates has received most attention for their extraction characteristics: the species extracted in nonpolar organic solvent has a dimeric form given by $Cu_2A_4(HA)_2$, where HA denotes the alkanoic acid.[2–5]

From the view point of solution chemistry and hydrometallurgy, α-halogenoalkanoic acids are of particular interest among many substituted homologues. The presence of the halogen at the α-position in a carboxylic acid modifies its properties.[6,7] However, the properties as an extracting agent are not known. More studies are, therefore, necessary for a full understanding of the effect of a halogen introduced in the α-position of a carboxylic acid on the coordination and extraction properties.

In this paper we report the results for the extraction of copper(II) with α-bromovaleric acid in benzene. The dimeric copper(II) α-bromovalerate, $Cu_2A_4(HA)_2$, was found to be extracted in benzene.

EXPERIMENTAL

Reagent

The extracting agent, α-bromovaleric acid (R.G.), was purified by distillation under reduced pressure. The purity of the middle fraction was 99.6±0.3% as determined by titration with standard alkaline solution.

Sodium perchlorate, copper(II) perchlorate and benzene were the same as presented previously.[6]

Procedure

Partition was carried out at 0.5×10^{-3}–1×10^{-3} mol dm^{-3} initial concentration of copper(II) in the aqueous phase and 0.1–1 mol dm^{-3} α-bromovaleric acid in the organic phase. 15 cm^3 of the aqueous and organic solutions were introduced into a 50-cm^3 stoppered centrifuge tube. The ionic strength in the aqueous phase was kept constant at 1.0 mol dm^{-3} so as to hold the activity coefficients of α-bromovalerate, cupric and hydrogen ions constant. The tube was shaken for 1 h in a water bath thermostatted at 25.0±0.2°C. This shaking time was

* Author to whom correspondence should be addressed.

found to be sufficient for complete equilibration. The acid concentration in the organic phase was determined by a two-phase titration with a standard alkaline solution. The copper(II) concentrations in the organic and/or aqueous phases were determined by complexiметry or spectrophotometry. The complex formation of cupric ion with α-bromovaleric acid in the aqueous solution was evaluated by e.m.f. measurements using a cupric ion selective electrode, Orion No. 94-24.

Apparatus

Measurements of pH were carried out with an Orion research microprocessor ionalyzer, M-901. Spectrophotometric measurements were performed on a Shimadzu double-beam spectrophotometer, M-UV210A.

RESULTS AND DISCUSSION

Liquid–liquid distribution of α-bromovaleric acid

In the extraction of a metal ion with a carboxylic acid HA, it is indispensable to have information about the following equilibria, the acid dissociation in the aqueous solution:

$$HA + H_2O \overset{K_a}{\rightleftharpoons} H_3O^+ + A^-,$$

$$K_a = [H_3O^+][A^-]/[HA], \quad (1)$$

the partition of carboxylic acid defined by the ratio of the concentration of the acid in a monomeric form in the organic phase to its concentration in the same form in the aqueous phase at equilibrium:

$$HA \overset{K_d}{\rightleftharpoons} HA_o, \quad K_d = [HA]_o/[HA], \quad (2)$$

and the dimerization of the monomeric acid in the organic phase:

$$2HA_o \overset{K_2}{\rightleftharpoons} (HA)_{2,o}, \quad K_2 = [(HA)_2]_o/[HA]_o^2, \quad (3)$$

where subscript *o* denotes the organic phase.

When the acid is distributed between the two phases, the analytical acid concentration in the aqueous and organic phases are, respectively, given by:

$$C_{HA} = [A^-] + [HA] \quad (4)$$

and

$$C_{HA,o} = [HA]_o + 2[(HA)_2]_o. \quad (5)$$

The distribution ratio measured at equilibrium is given by:

$$D = C_{HA,o}/C_{HA}$$

$$= (K_d + 2K_d^2K_2[HA])/(1 + K_a/[H_3O^+]). \quad (6)$$

By pH-metric titration the acid dissociation constant was determined to be $\log K_a = -2.79$ in the aqueous solution, 1.0 mol dm^{-3} (Na, H)ClO_4 at 25°C. According to eqn (6), a plot of $D(1 + K_a/[H_3O^+])$ vs [HA] should yield a straight line with intercept K_d and slope $2K_d^2K_2$. Figure 1 is the plot of the experimental data. The constants thus obtained are given in Table 1 together with those of some α-bromoalkanoic acids for comparison. These values of α-bromovaleric acid were used for calculation of the equilibrium concentrations: $[A^-]$, [HA], $[HA]_o$ and $[(HA)_2]_o$.

Extraction of copper(II) with α-bromovaleric acid

The chemical species of copper(II) carboxylate extracted in benzene being denoted as $(CuA_2(HA)_x)_j$, the extraction constant K_{ex} can be written as:

$$jCu^{2+} + j\left(1 + \frac{x}{2}\right)(HA)_{2,o}$$

$$\overset{K_{ex}}{\rightleftharpoons} (CuA_2(HA)_x)_{j,o} + 2jH_3O^+,$$

$$K_{ex} = [(CuA_2(HA)_x)_j]_o[H_3O^+]^{2j}$$

$$\times [Cu^{2+}]^{-j}[(HA)_2]_o^{-j(1+(x/2))}, \quad (7)$$

[g] Evaluated from the IR data in Ref. 17.

where x denotes the number of HA coordinated to the CuA_2 unit.

Now the analytical copper(II) concentration in the aqueous solution is given by:

$$C_{Cu,w} = [Cu^{2+}]\alpha_{Cu}, \quad (8)$$

where α_{Cu} refers to the side-reaction coefficient of formation of water soluble complex of copper: $\alpha_{Cu} = 1 + K_{CuA}[A^-]$. The plot used for the determination of K_{CuA} is shown in Fig. 2. The formation constant was found to be $\log K_{CuA} = 1.50$. This value is in agreement with the values for copper(II) bromoacetate and α-bromobutyrate[8] (see Table 1).

If the species of copper(II) carboxylate in benzene is denoted as $(CuA_2(HA)_x)_j$, the copper concentration in the organic phase is given by:

$$C_{Cu,o} = jK_{ex}[(HA)_2]_o^{j(1+(x/2))}(C_{Cu,w}\alpha_{Cu}^{-1}[H_3O^+]^{-2})^j. \quad (9)$$

As anticipated from eqn (9), the plot of $\log C_{Cu,o}$ vs $\log(C_{Cu,w}/\alpha_{Cu}) - 2\log[H_3O^+]$ should give a straight line with slope j at a certain concentration of dimeric α-bromovaleric acid in the organic phase. The plot is shown in Fig. 3. The slope of the straight lines is 2.0 providing the copper species in the organic phase is $Cu_2A_4(HA)_{2x}$. It is noteworthy that the dimeric species persists in the organic solvent down to $C_{Cu,o} = 10^{-4}$ mol dm^{-3}.

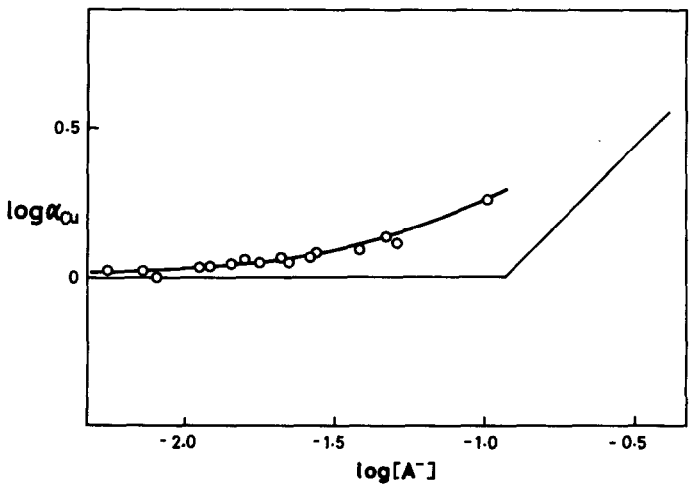

Fig. 2. Determination of the formation constant of copper(II) α-bromovalerate complex in the aqueous solution. Ionic strength: 1.0 (Na,H)ClO_4. α_{Cu} was obtained from e.m.f. measurement by using a cupric ion selective electrode. The solid curve denotes the theoretical one calculated by using $\log K_{CuA} = 1.50$. The straight lines are the asymptotes for the curve.

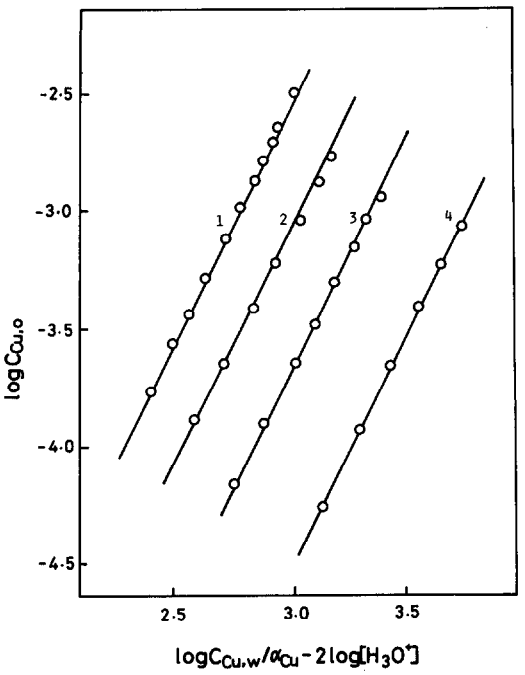

Fig. 3. Identification of the degree of polymerization of Cu(II) α-bromovalerate extracted in benzene. Aqueous ionic strength: 1.0 (Na,H)ClO_4. $C_{HA,o}$ (mol dm^{-3}): (1) 0.93, (2) 0.70, (3) 0.45, and (4) 0.23.

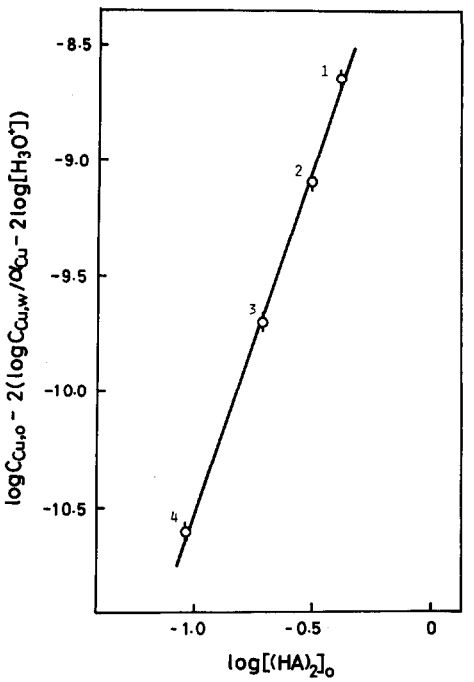

Fig. 4. Determination of the number of α-bromovaleric acid involved in the extracted species. Labelling as in Fig. 3.

Therefore eqn (9) can be rewritten as follows:

$$\log C_{Cu,o} - 2\{\log (C_{Cu,w}/\alpha_{Cu}) - 2\log [H_3O^+]\} = (x+2)\log [(HA)_2]_o + \log 2K_{ex}. \quad (10)$$

When the value of the left-hand side of eqn (10) is plotted against $\log[(HA)_2]_o$, the number of acid molecules participating in the extraction will be given by the slope. Figure 4 is the plot of the experimental data. The points were fitted to a straight line with slope 3.0, implying that the species $Cu_2A_4(HA)_2$ is correct. The corresponding extraction equilibrium is described as follows:

$$2Cu^{2+} + 3(HA)_{2,o} \underset{}{\overset{K_{ex}}{\rightleftharpoons}} Cu_2A_4(HA)_{2,o} + 4H_3O^+, \quad (11)$$

with $\log K_{ex} = -7.87$.

Absorption spectra in UV region

Copper(II) alkanoates have three absorption bands at about 300, 375 (shoulder) and 700 nm.[9,10] The second band at about 375 nm, which is characteristic of the dimeric copper(II) alkanoates, was also observed for the copper(II) α-bromovalerate extracted in benzene.

The band was then used to verify the extraction equilibrium given by eqn (11). The following equation is anticipated for the absorbance (A) at 375 nm:

$$A = \varepsilon[Cu_2A_4(HA)_2]_o = \varepsilon C_{Cu,o}/2, \quad (12)$$

where ε denotes the molar absorptivity per two copper atoms.

The plot of A against $C_{Cu,o}/2$ leads to a linear relation, down to $C_{Cu,o} = 10^{-4}$ mol dm^{-3}, with a slope of $\varepsilon = 126 \pm 10$. The absorptivity is comparable with that for copper(II) acetate in acetic acid ($\varepsilon = 102$),[11] copper(II) propionate in chloroform ($\varepsilon = 120$)[3] and copper(II) octanoate in heptane ($\varepsilon = 120$).[12] Our results indicate that the absorbance at 375 nm is directly proportional to the dimeric copper concentration. The results also suggests that the molar absorptivity is not significantly influenced by the bromine at the α-position.

Extracted species and extraction constant

Copper(II) alkanoates are extracted as a dimer, $Cu_2A_4(HA)_2$ in nonpolar organic solvents. The stability is so high that no appreciable amount of monomeric copper species can be detected in most nonpolar solvents, except for some system of sterically crowded carboxylic acids such as cyclohexanecarboxylic acid,[13] cyclopentylacetic acid,[14] tri-

Table 2. Extraction constant for copper(II) alkanoate, $Cu_2A_4(HA)_2$, at 25°C

[c] Calculated from the data in Ref. 17.

methylacetic acid[15] and versatic acid.[16] When such a bulky acid is used, monomeric copper species is found together with the dimer.

Bold and Bălușescu[17] proposed the monomeric copper(II) α-bromostearate, $CuA_2(HA)_2$, in the extraction of copper(II) with α-bromostearic acid in benzene. However, recalculation of their data using eqns (9) and (10) leads us to the dimeric copper species, $Cu_2A_4(HA)_2$. We, therefore, conclude that the formation of dimeric copper species is not prevented by the bromine at the α-position.

As shown in Table 2, the logarithmic extraction constants fell in region from −12.6 to −11.5 for a series of nonsubstituted acids and from −8.1 to −7.9 for α-bromoalkanoic acids. The constants for the latter have higher values than the former by a factor of about $10^{3.6}$. This implies that the extraction of copper(II) with α-bromoalkanoic acid starts from a lower pH region by about 0.9 pH units than the nonsubstituted acid systems. In addition, it is useful to consider the relation between the extraction constant and the acid dissociation constant. The relationship is formulated as:

$$\log K_{ex} = 1.7 \log K_a - 3.2. \qquad (13)$$

This equation indicates that the extraction constant becomes progressively higher as the acidity of the acid, K_a, increased. Equation (13) should be applicable in predicting the extraction constant of copper(II) carboxylate, $Cu_2A_4(HA)_2$, in the case when benzene is used as the organic solvent.

SOLVENT EXTRACTION STUDIES OF Hg(II) AND Zn(II) WITH DINONYL NAPHTHALENE SULFONIC ACID IN THE PRESENCE OF IMIDAZOLES

SUNG-MAO WANG* and JI-JEN CHIOU

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043, Republic of China

(*Received* 10 *September* 1986; *accepted* 24 *October* 1986)

Abstract—The extractions of Zn(II) and Hg(II) from hydrochloric acid solution using dinonylnaphthalene sulfonic acid (HD) as the cation exchanger have been studied. Zn(II) can be extracted from HCl solution by the following reaction:

$$Zn^{2+} + (HD)_{x,0} = (ZnH_{x-2}D_x)_0 + 2H^+,$$

where x is the number of aggregation of a HD micelle and the subscript 0 denotes the organic phase. However, the Hg(II) cannot be extracted because it predominantly forms an anionic complex, $HgCl_4^{2-}$, in the HCl solution. In the presence of an imidazole (Im), 2-methyl imidazole (2MIm), or histidine (His) ligand with the condition [L] < [HCl], Zn(II) forms a 1:1 complex, ZnL^{2+}, with the ligand, and thus the distribution ratio of Zn(II) decreases. The formation constants for $Zn(Im)^{2+}$, $Zn(2MIm)^{2+}$ and $Zn(His)^{2+}$ were calculated to be 4.32×10^7, 3.46×10^8 and 1.56×10^8, respectively. When [L] > [HCl], the pH of the solution rises and a rapid increase in the distribution ratio is observed for both Zn(II) and Hg(II) ions. The metal ions form ML_n^{2+} complexes, which in turn can be solubilized into the HD micelles by the following equation:

$$ML_n^{2+} + (HD)_{x,0} = (ML_nH_{x-2}D_x)_0 + 2H^+.$$

For Hg(II) insoluble complexes precipitate at pH > 4.5. The solid substances were isolated and analyzed to be $Hg(C_3H_3N_2)Cl$, $Hg(C_4H_5N_2)Cl$ and $Hg(C_6H_8N_3O_2)Cl\cdot 2H_2O$ for Im, 2MIm and His complexes, respectively. The precipitate dissociates to become soluble HgL_2^{2+} when the solution is shaken with HD in hexane solution. The extraction behavior of Hg(II) from HCl solution with HD in the presence of 2MIm has also been proved by NMR measurements.

A solution of dinonylnaphthalene sulfonic acid (hereafter denoted as HD) in non-polar organic solvents forms micelles and has been shown to serve as an analogue of a cross-linked resinous strong acid cation-exchanger.[1–4] The exchange reaction between M^{b+} and HD can be represented by the equation:

$$M_a^{b+} + (HD)_{x,0} = (MH_{x-b}D_x)_0 + bH_a^+ \quad (1)$$

where x is the number of aggregation of a HD micelle, and the subscripts a and 0 denote the aqueous and organic phases, respectively. The distribution ratio (D) is related to the equilibrium constant (K_{ex}) by:

$$D = K_{ex}\frac{[HD]_x}{[H^+]^b}. \quad (2)$$

From the logarithmic form of eqn (2), the log D vs log $[H^+]$ plot is expected to be a straight line with a slope of $-b$, which indicates the charge of the species extracted. However, the deviation from the expected slope was found when the metallic ion forms complexes in the solution.[2,3]

It is known that the Hg(II) ion forms anionic complexes with halide ions, and in this paper studies

*Author to whom correspondence should be addressed.

of the extraction behavior of Hg(II) and Zn(II) from HCl solution with HD and the effect of imidazole (Im), 2-methyl imidazole (2MIm) and histidine (His) on the extraction will be reported.

EXPERIMENTAL

Materials

HD was obtained as a 39% solution in *n*-heptane from R. T. Vanderbilt Co. (U.S.A.). Im was obtained from E. Merck (Darmstadt), 2MIm from Kokyo Kasei Co. (Japan), and His from Nutritional Biochemicals Corporation (U.S.A.). The *n*-hexane and all the other inorganic reagents were of highest-purity grade.

Preparation of radioisotopes

The high-activity radioisotopes ^{179}Hg and ^{65}Zn were prepared in the form of perchlorate by irradiating their oxides in the Tsing Hua Open Pool Reactor using a pneumatic tube system. The purity of radioisotopes was confirmed by γ-ray spectrometery.

Procedures

In solvent extraction experiments the aqueous phase normally was prepared to contain the cation (radioisotope) in a concentration of the order of 10^{-6} M and varying concentrations of acid solution. The organic phase contained HD in *n*-hexane with concentrations of the order of 10^{-3} formula weight per liter. Equal volumes (10 cm^3) of aqueous and organic phases were then mixed in polyethylene flasks, shaken at 25 ± 1°C for 1 h, and allowed to settle for 30 min. Aliquots of both phases were taken for the measurements of the radioactivity with an ORTEC model 1431 well-type γ scintillation counter. D is defined as:

$$D = \frac{\text{activity of tracer metal in organic phase}}{\text{activity of tracer metal in aqueous phase}}.$$

The pH titrations were carried out with a standard pH meter PHM62 Radio meter Copenhagen. ^1H NMR spectra were obtained using a JEOL-C60 NMR spectrometer.

RESULTS AND DISCUSSION

Extractions of Hg(II) *and* Zn(II) *from* HCl *solution*

The results of distribution measurements for ^{65}Zn and ^{197}Hg between HD in *n*-hexane and HCl solution are shown in Fig. 1. The slope of log D vs log $[H^+]$ plot was found to be -2 as expected for Zn(II). The extraction constant for Zn(II) was calculated to be 1.64 which is less than the value of 2.9 reported for the extraction of Zn(II) from $HClO_4$ solution.[2] The smaller value obtained from HCl solution may be ascribed to the formation of anionic complexes, $ZnCl_n^{2-n}$.

The Hg(II) ion was not to be extracted with HD from HCl solution at all as seen in Fig. 1. Since it is known that the Hg(II) in HCl forms $HgCl_n^{2-n}$ complexes and the stability constants β_2, β_3 and β_4 were reported to be 1.66×10^{13}, 1.17×10^{14} and 0.17×10^{15}, respectively,[5] the Hg(II) exists mostly as $HgCl_4^{2-}$ in HCl solution and naturally could not be extracted by a cationic exchanger such as HD.

Extraction of Zn(II) *from* HCl *solution in the presence of Im, 2MIm and His*

Zn(II) exists largely as aquated Zn^{2+} in HCl solution as indicated in Fig. 1, and it forms complexes, $Zn(HL)_n^{2+}$, with the ligand, HL, added to the solution. Since only Zn^{2+} ion is extracted into the HD phase, the D of Zn(II) may be expressed by:

$$D = \frac{[ZnH_{x-2}D_x]_0}{[Zn^{2+}]+[Zn(HL)^{2+}]+\cdots+[Zn(HL)_n^{2+}]} = \frac{[HD]_0K_{ex}}{[H^+]^2(1+K_1[HL]+K_1K_2[HL]^2+\cdots K_1K_2\ldots K_n[HL]^n)}, \quad (3)$$

where K_{ex} is the extraction constant and K_1, K_2, ... and K_n are the formation constants for $Zn(HL)^{2+}$, $Zn(HL)_2^{2+}$, ... and $Zn(HL)_n^{2+}$. Equation (3) may be rewritten as:

$$\frac{[HD]}{D[H^+]^2[HL]} = \frac{1}{K_{ex}[HL]} + \frac{K_1}{K_{ex}} + \cdots + \frac{K_1K_2\ldots K_n}{K_{ex}}[HL]^{n-1}. \quad (4)$$

Figure 2 shows the results of distribution measurements for Zn(II) between HD in *n*-hexane and HCl solution, varying the concentration of Im, 2MIm and His at constant HD and acid concentrations. When the total concentration of ligand is smaller than that of acid, $[HL]_{total} < [HCl]$ (the pH values are 1.05–1.50 for Im and 2MIm and 1.30–1.70 for His solutions, respectively), D decreases

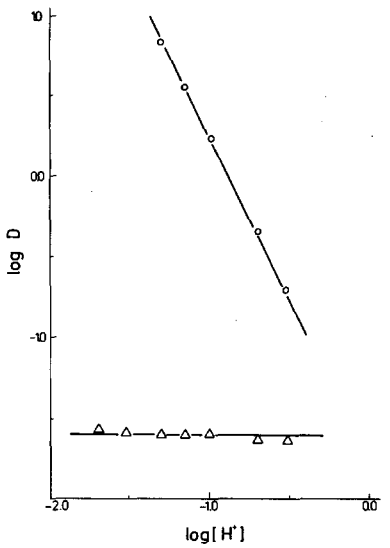

Fig. 1. Acid concentration dependency of D at [HD] = 1.05×10^{-2} F. (○) Zn(II), (△) Hg(II).

gradually with increase in ligand concentration, while it increases rapidly to reach the maximum value when the total concentration of ligand exceeds the acid concentration, $[HL]_{total} > [HCl]$ (the pH values are 7.10–7.70 for Im, 8.00–8.50 for 2MIm, and 5.60–6.00 for His solutions, respectively).

For Im, 2MIm and His in acidic solution, the following protonation reaction occurs:

$$HL + H_3O^+ = H_2L^+ + H_2O. \quad (5)$$

The values of the protonation constant (K_H) were reported to be 1.29×10^7 at $\mu = 0.16$ for Im,[6] 1.35×10^8 at $\mu = 1.0$ for 2MIm,[7] and 1.00×10^6 for His.[8] The concentration of free ligand ([HL]) can be estimated using the values of K_H and the measured values of pH of the solution.

When $[HL]_{total} < [HCl]$, Zn^{2+} forms complexes with the ligand in acidic solution and the concentration of free Zn^{2+} ion extracted into the HD phase decreases. Figure 3 shows plots of log $[HD]/D[H^+]^2[HL]$ vs log [HL], and it is seen that slopes of the plot become zero when $[Im] < 5 \times 10^{-7}$ M, $[2MIm] < 10^{-8}$ M, and $[His] < 5 \times 10^{-6}$ M, which implies that only the second term becomes important in eqn (4). This in turn indicates that only the 1 : 1 complex exists under the experimental conditions. Thus at constant [HD] and $[H^+]$, eqn (4) can be simplified as:

$$\frac{1}{D} = \frac{1}{D_0} + \frac{K_1}{D_0}[L], \quad (6)$$

where D_0 is the distribution ratio of Zn(II) in the absence of ligand.

Plots of $1/D$ vs [HL] gave straight lines, and from the slopes and intercepts the values of K_1 were calculated to be 4.32×10^7, 3.46×10^8 and 1.56×10^8 for Im, 2MIm and His, respectively. It is of interest to note that at constant concentrations of HD and ligand under the experimental conditions, $[HL]_{total} < [HCl]$, plots of log D vs log $[H^+]$ gave straight lines with a slope of -2, which indicated that the only species Zn^{2+} was extracted into the organic phase.

When $[HL]_{total} > [HCl]$, because of the larger values of protonation constant for Im, 2MIm and His, concentration of protonated species becomes approximately the same as that of the acid, and the free-ligand concentration in the solution would be $[HL] = [HL]_{total} - [HCl]_{total}$. Accordingly the pH of

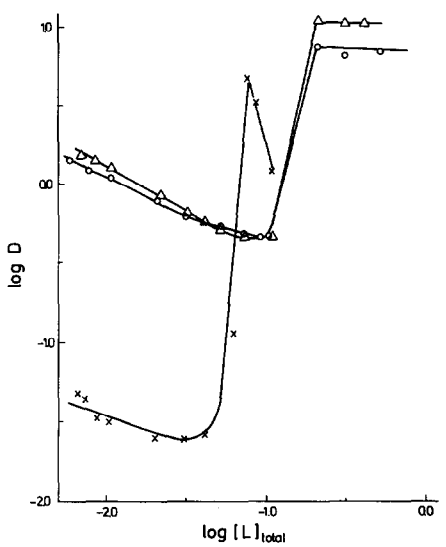

Fig. 2. D of Zn(II) vs total ligand concentration at [HD] = 1.05×10^{-2} F. (○) Im, [HCl] = 0.10 M; (△) 2MIm, [HCl] = 0.10 M; (×) His, [HCl] = 0.05 M.

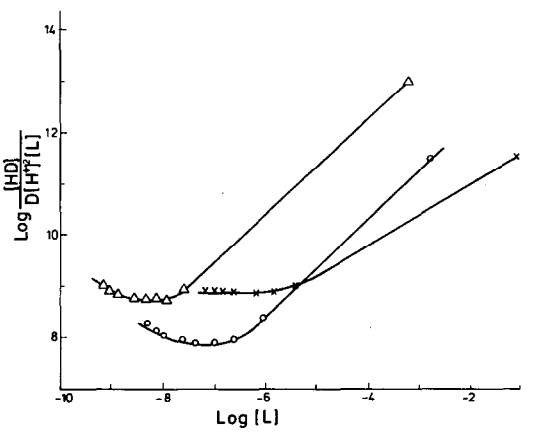

Fig. 3. Extraction of Zn(II) in the presence of ligand with [HL] < [HCl], [HD] = 1.05×10^{-2} F. (○) Im, [HCl] = 0.10 M; (△) 2MIm, [HCl] = 0.10 M; (×) His, [HCl] = 0.05 M.

the solution rises and the mixture behaves as a buffer solution. Edsall *et al.*[6] reported by a pH titration method that Zn(II) forms stable complexes with log $K_1 = 1.98$, log $K_2 = 2.19$, log $K_3 = 2.41$ and log $K_4 = 2.62$ for Im, and Li and Manning[9] found the log K_1 and log K_2 for His to be 6.67 and 5.11, respectively. Thus it is believed that, when $[HL]_{total} > [HCl]$, Zn(II) forms predominantly complex ions, $Zn(HL)_n^{2+}$, which would then be solubilized in the micelle of HD in *n*-hexane by the following reaction:

$$Zn(HL)_n^{2+} + (HD)_{x,0} = [Zn(HL)_n H_{x-2} D_x]_0 + 2H^+. \quad (7)$$

Plots of log D vs log [HD] as shown in Fig. 4 with slopes of +1 indicate that HD exists as micelle with aggregation number x as expected from eqn (7).

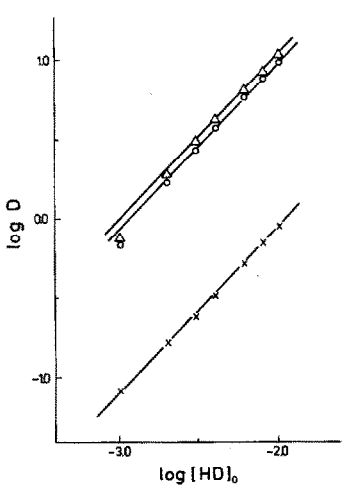

Fig. 4. HD concentration dependency of the D of Zn(II). (○) [Im] = 0.20 M, [HCl] = 0.10 M; (△) [2MIm] = 0.20 M, [HCl] = 0.10 M; (×) [His] = 0.12 M, [HCl] = 0.06 M.

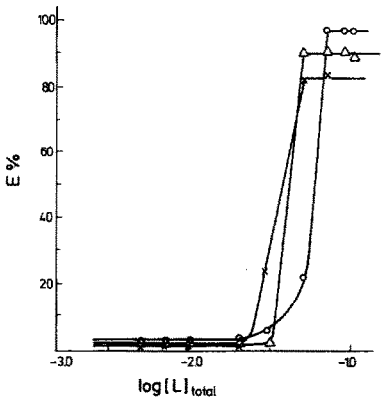

Fig. 5. Extraction of Hg(II) as function of ligand concentrations at [HD] = 1.05×10^{-2} F, [HCl] = 0.03 M. (○) Im, (△) 2MIm, (×) His.

Extraction of Hg(II) *from* HCl *solution in the presence of Im, 2MIm and His*

Figure 5 shows the results of distribution measurements in terms of percent extracted for Hg(II) between HD in hexane and HCl solution, varying the concentration of Im, 2MIm and His at constant HD and acid concentrations. When $[HL]_{total} < [HCl]$, Hg(II) exists predominantly as $HgCl_4^{2-}$ and is not extracted at all by HD into the organic phase. It was found, however, that when the concentration of the added ligand became larger than that of the acid D increased rapidly as observed for the extraction of Zn(II).

When $[HL]_{total} > [HCl]$, the pH of the solution rises to 7.0–7.5, and because of the strong affinity of Hg(II) to nitrogen ligand, the $HgCl_4^{2-}$ ion would react with added ligand to form $Hg(HL)_n^{2+}$ which would then be solubilized in HD:

$$HgCl_4^{2-} + nHL = Hg(HL)_n^{2+} + 4Cl^-, \quad (8)$$

$$Hg(HL)_n^{2+} + (HD)_{x,0} = [Hg(HL)_n H_{x-2} D_x]_0 + 2H^+. \quad (9)$$

When $[HL]_{total} > [HCl]$, keeping the concentrations of HL and acid constant, a plot of log D vs log [HD] gave a slope of +1. Figure 6 shows plots of log D vs log [HCl] at constant concentrations of HD and HL, and varying the concentration of HCl with $[HCl]_{total} < [HL]$. The slope of −2 was obtained for each ligand as expected from eqn (9).

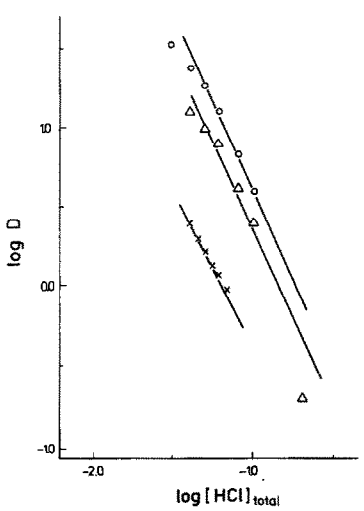

Fig. 6. Acid concentration dependency of the D of Hg(II) at [HL] > [HCl], [HD] = 1.05×10^{-2} F. (○) [Im] = 0.25 M; (△) [2MIm] = 0.25 M; (×) [His] = 0.12 M.

Table 1. Elemental analysis of Hg(II) complexes

Compound	wt% found[a]					
	Hg	C	H	N	Cl	O
Hg(II)–imidazole $Hg(C_3H_3N_2)Cl$	63.3 (66.2)	13.4 (11.9)	1.4 (1.0)	10.1 (9.2)	11.9 (11.7)	
Hg(II)–2-methyl imidazole $Hg(C_4H_5N_2)Cl$	62.1 (63.2)	15.8 (15.2)	2.0 (1.6)	8.8 (8.8)	11.3 (11.2)	
Hg(II)–histidine $Hg(C_6H_8N_3O_2)Cl\cdot 2H_2O$	47.1 (47.1)	15.4 (16.9)	2.3 (2.8)	8.8 (9.9)	9.8 (8.3)	16.6 (15.0)

[a] Calculated values are given in parentheses.

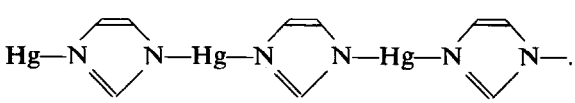
Hg(II) *complexes of Im, 2MIm and His in solvent extraction*

On addition of Im, 2MIm or His (e.g. 0.02 M) to an HCl solution (e.g. 0.01 M) containing a macroamount of $HgCl_2$ (e.g. 2×10^{-3} M), white precipitates formed. When these mixtures were shaken with an equal volume of HD in hexane (e.g. 0.05 F), the white precipitate disappeared immediately.

These precipitates were isolated and analyzed. The results are shown in Table 1.

Brooks and Davidson[10] studied the Hg(II) complexes of Im and His by a potentiometric method and reported that Hg(II) forms $Hg(Im)_2^{2+}$ predominantly at pH 2–4 and a solid substance, $Hg(C_3H_3N_2)ClO_4\cdot H_2O$, precipitates from solutions at pH > 4. They also calculated the formation constant for $Hg(Im)_2^{2+}$ to be $10^{16.74}$ M^{-2} and for $Hg(His)_2^{2+}$ to be $10^{21.22}$ M^{-2}.

The Im, 2MIm and His complexes with Hg(II) becomes insoluble as the pH is raised. The Im complexes precipitate copiously at pH values greater than 4.5, but the His complex is more soluble. Brooks and Davidson[10] presumed that the insoluble mercury compound, obtained from perchlorate solution, $Hg(C_3H_3N_2)ClO_4\cdot H_2O$, contains a linear polymer with one positive charge per polymer unit. A similar structure, $Hg(C_3H_3N_2)Cl$, has been reported by Bottcher.[11]



When the aqueous solution (pH > 4) containing insoluble Hg(II) complexes is shaken with HD, the solid substance, $(HgL\cdot Cl)_n$, may react with acid

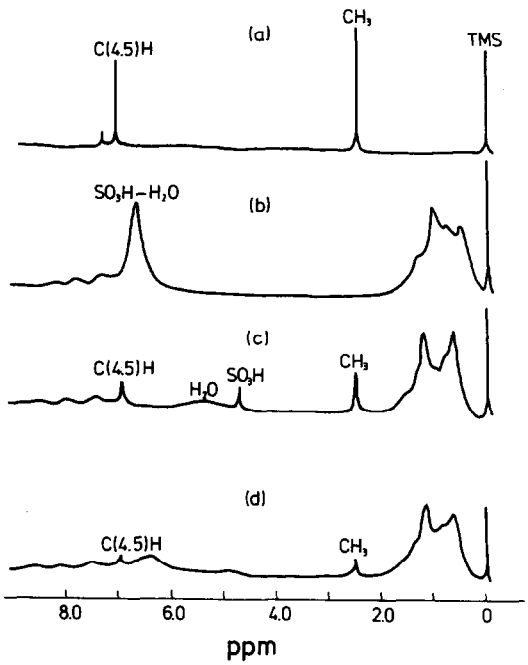


Fig. 7. NMR spectra. (a) 2MIm in $CDCl_3$, (b) HD in CCl_4, (c) organic phase after 2MIm in aqueous solution was extracted into HD in CCl_4, (d) organic phase after 2MIm with $HgCl_2$ in aqueous solution was extracted into HD in CCl_4.

from HD and dissociate to $Hg(HL)_2^{2+}$:

$$2(HgL\cdot Cl)_n + 2nH^+ = nHg(HL)_2^{2+} + nHg^{2+} + 2nCl^- \quad (10)$$

or

$$2[Hg(C_3H_3N_2)]^+ + 2H^+ = [Hg(C_3H_4N_2)_2]^{2+} + Hg^{2+}. \quad (11)$$

Then, the $Hg(HL)_2^{2+}$ complex would be extracted into the organic phase with HD following eqn (9).

In order to investigate whether the Im ligand was extracted into the organic phase, we carried out the following experiments: 2MIm is insoluble in CCl_4, but it becomes soluble in the presence of HD, and this is shown in Fig. 7. Figure 7(a) is the ^1H NMR spectrum of 2MIm in $CDCl_3$ and Fig. 7(b) is that of HD in CCl_4. When an aqueous solution of 2MIm was shaken with CCl_4, no signal of 2MIm was observed. However, when it is shaken with HD in CCl_4 solution, the signals of 2MIm appear as shown in Fig. 7(c). The SO_3H–H_2O proton signal of HD, which solubilized H_2O at 6.78 ppm [Fig. 7(c)] disappears, and new SO_3H and free H_2O signals appear at δ 4.75 and 5.4 ppm, respectively, when 2MIm is solubilized into HD micelles.

On addition of 2MIm into $HgCl_2$ aqueous solution a white precipitate formed, and it disappeared when the mixture in the aqueous phase was shaken with HD in CCl_4. The NMR spectrum of the organic phase was taken, and is shown in Fig. 7(d). The appearance of CH_3 and 4,5C—H signals of 2MIm at δ 2.5 and 6.9 ppm indicates that 2MIm could also be solubilized into the HD micelles in the extraction of Hg(II).

(*Received* 5 *August* 1986; *accepted* 27 *October* 1986)

Abstract—An extended CNDO/2 method has been developed for the calculation of stability constants of organic transition-metal complexes. An atom parameterization scheme is described for Mn to Zn using Slater exponents which is found to give a reasonable correlation with the ionization potential of the respective metal. The corresponding bonding parameters have been evaluated by initially deriving the best correlation between the calculated and experimental stability constants of a series of substituted copper bis(salicylaldehydes) and then relating these values to the other transition metals using the bond dissociation energies of simple diatomics as the essential criteria.

A considerable number of molecular-orbital calculations have been carried out on organic transition-metal complexes over the past few years. Most of these studies, however, have been restricted to valence electron semi-empirical methods such as CNDO/2[1] because the very large number of basis functions on the metal coupled with those of the organic ligand usually preclude studies with the more accurate *ab initio* methods. For example, CNDO/2 calculations have been reported recently on complexes of the transition metals with dimethyldithiocarbamic acid and diformylmethane,[2] maleinonitrilodithiolate,[3] phthalocyanines,[4] ammonia[5] and carbon monoxide cluster systems.[6]

In contrast to these studies which deal with the physical properties of the metal complexes themselves, the work described here relates to the development of an extended CNDO/2 method[7] which would be useful in conjunction with molecular graphics for the design of organic ligands for the selective extraction of transition metals from solutions which may contain high concentrations of other metals. In the design of ligands for this purpose, both the stability constants and conformations of the derived metal complexes have been considered. Clearly, the transition-metal parameterization adopted within the CNDO/2 framework must reproduce:

(1) the known effects of substituents on the stability constant;

(2) the Irving–Williams Order;

(3) the known crystallographic conformation of a given complex.

APPROXIMATIONS

The proton ionization constant (K_H) and stability constant (K_S) for a simple stoichiometric reaction

* Author to whom correspondence should be addressed.

of type:

$$LH = L^- + H^+,$$

$$M^{2+} + 2L^- = ML_2,$$

where LH is a selected organic ligand (such as salicylaldoxime or 8-hydroxyquinoline), M^{2+} is a given transition-metal cation, and ML_2 is the resulting complex, are given by:

$$K_H = \frac{[L^-][H^+]}{[LH]},$$

$$K_S = \frac{[ML_2]}{[M^{2+}][L^-]^2}.$$

The free-energy change (ΔG) for these processes is related to the appropriate constant by the equation:

$$\Delta G = -RT \ln K.$$

The calculation of ΔG from first principles is difficult even for gas-phase reactions of the above type because it is dependent on both enthalpy (ΔH) and entropy (ΔS) terms, i.e.:

$$\Delta G = \Delta H - T\Delta S.$$

However, the successful calculation of the proton ionization and stability constants for a series of structurally related complexes by theoretical methods can be accomplished, in principle, if either of the following conditions hold:

(1) the entropy is constant throughout the series,

(2) the entropy is linearly related to the enthalpy.

Provided one of these conditions is met then the calculation of the free energy and hence the stability constant can be achieved by calculating the energy of the reaction using the expression:

$$\Delta E = E(ML_2) - E(M^{2+} + 2L^-),$$

where E is the calculated energy of the molecular components.

Fortunately this relation can be demonstrated in some cases though it is clear that this concept is fraught with difficulties, not the least being that the enthalpy change is often positive and the driving force of the reaction is dependent, therefore, on a large positive entropy. For example, while the high stability of nickel and copper 5-nitro- and 3,5-dinitro-salicylates[8] in water arises from a large positive entropy term, the free-energy change for the formation of substituted silver phenylthioacetates[9] and the formation of copper and nickel complexes of catechol[10] is due mainly to changes in enthalpy. However, in the formation of five or six co-ordinated copper complexes, prepared from Schiff bases of salicylaldehyde and either aliphatic or aromatic amines with pyridine, the entropy of the process shows a linear correlation with the enthalpy over a wide range of substituents.[11] Similar results have been reported for the addition of heterocyclic bases both to a series of transition-metal complexes of salicylaldimines[12] and nickel complexes of diacetylbisbenzoylhydrazones.[13]

Because the enthalpy term appears to be dominant in many reactions of the type described, correlations have been sought between the calculated energy changes (ΔE) and the experimentally observed stability constant. In the present studies, both the parameterization of the extended CNDO/2 method (CINDO54)[7] and the influence of electron-withdrawing and electron-donating substituents on the calculated stability constants of substituted copper bis(salicylaldehydes) are described.

RESULTS AND DISCUSSION

Parameterization and calibration of the extended CNDO/2 method

Various CNDO/2 parameterization schemes have been proposed for the transition metal in these complexes,[14] but the most widely used parameters are those described by Clack *et al.*[15] which are based on the exponents devised by Zerner and Gouterman.[16] These values have been criticized, however, because in a number of cases the effective charge on the metal atom in the complex is found to be negative, the delocalization of spin density in the ligands is too low, and the energies of removal of the ligands are several times too high.[14] Recently Bohm and Gleiter have described an alternative MO formalism for the transition metals which has been used to interpret the photoelectron spectra of transition-metal complexes.[17]

The theoretical requirements for the transition elements at the CNDO/2 level are different from those previously encountered in the original scheme for elements of the second row of the periodic table (sodium to chlorine) since two shells are now involved. In the calculations described here Slater-type orbitals[18] are used for the 3*d*, 4*s* and 4*p* valence shells, and all inner electrons (including the 3*s* and 3*p* electrons) are treated as part of the non-polarizable core. The approximations arising from the complete neglect of, *inter alia*, a large number of two-centre electron repulsion terms are clearly greater than those for second-row elements, and accordingly the calculated results can only be approximate. In the evaluation of integrals for the valence orbitals, the radial part is given by $r^{2.7}e^{-\zeta r}$ when n is 4 which is not suitable for integration by parts.[18] Following Hase and Schweig[19] we have

adopted a radial exponent of 3 for such cases rather than introduce the averaging technique proposed by Jaffé and Doak.[20] When Burns orbitals[21] are used, such a correction is not required, but these orbitals have generally given unsatisfactory results in our hands.

Because the 3*d* orbitals are partially occupied in the transition elements and are heavily involved in bonding, the local core potential (U^A_{kk}) has been modified to take account of the differences in the one-centre repulsion integrals (γ_{AA}) for the 3*d*, 4*s* and 4*p* orbitals using the relation:[6]

$$U_{ss} = -\tfrac{1}{2}(I_s + A_s) - Z_A\gamma_{ds} + \tfrac{3}{2}\gamma_{ds} - \gamma_{ss},$$

$$U_{pp} = -\tfrac{1}{2}(I_p + A_p) - Z_A\gamma_{dp} + \tfrac{5}{2}\gamma_{dp} - \gamma_{sp},$$

$$U_{dd} = -\tfrac{1}{2}(I_d + A_d) - Z_A\gamma_{dd} + \tfrac{5}{2}\gamma_{dp} - \gamma_{sp},$$

where *s*, *p* and *d* represent the 4*s*, 4*p* and 3*d* orbitals only.

The off-diagonal elements of both the extended Huckel matrix and the core Hamiltonian are modified for second-row atoms such that:

$$H^{\text{core}}_{k1} = K(\beta^o_A + \beta^o_B) * S_{k1}/2.$$

K is empirically given the value of 0.75 if either atom A or B is a second-row element. While this modification is found to improve the overall performance of the theory[1] no calibration studies have been reported for the transition elements. In the studies reported here, *K* has been set at unity for all interactions between the transition element and other elements irrespective of whether the latter is a first-, second- or indeed third-row element such as bromine.

Selection of Mulliken electronegativities

The reported values for elements of the first transition series (used as the on-diagonal elements of the Huckel matrix) were adopted for manganese to copper.[15] The values for zinc, however, have not been determined although extrapolated values have been used recently for the calculation of zinc phthalocyanine.[4] Because the electronegativity of zinc is less than that of either cobalt, nickel or copper on either the Allred–Rochow[22] or Pauling[23] scales, the extrapolated values are almost certainly in error.

The orbital electronegativities increase linearly with increasing atomic number along the first row of transition elements with the exception of the 4*s* value for copper which is higher than that expected.[15] A similar trend is observed for the general electronegativities on the Allred–Rochow scale, but the copper value is less than that expected.[22] Because of these apparent anomalies, the zinc value has been derived from the average value of the two preceding elements of the transition elements representing both an open- and closed-shell electronic configuration (cobalt and nickel) using the relation:

$$(I_k + A_k)_{Zn} = \tfrac{1}{2}(I_k + A_k)_{Ni}X_{Zn}/X_{Ni} + \tfrac{1}{2}(I_k + A_k)_{Co}X_{Zn}/X_{Co},$$

where *X* is the Allred–Rochow electronegativity, and *k* represents the 4*s*, 4*p* or 3*d* orbital as appropriate.

An alternative derivation from the Pauling scale is equally valid but the non-linearity of this scale in comparison with the Mulliken scale makes it less attractive.

Electronic configuration of the first transition series

The average configuration energies of the first-row transition elements (M) determined spectroscopically are given by:[6,24]

(1) $3d^{n-2}4s^2$ for the elements Sc to Mn and Zn,

(2) $3d^{n-1}4s^1$ for the elements Fe to Cu.

While these configurations have given satisfactory results for the calculation of cobalt and manganese carbonyl clusters,[6] very poor correlations were obtained in the present work between the calculated ionization $M \rightarrow M^{2+}$, which is required for the calculation of ΔE, and the known ionization potentials of the transition elements Mn to Zn; as a result, subsequent calculations were carried out with the $3d^{n-2}4s^2$ configuration.

The multiplicity of copper(II) in most of its complexes is well established because of its single unpaired electron. The multiplicity of other transition elements is less clearly defined since a number of different spin states may arise. For example, nickel(II) may be paramagnetic with two unpaired electrons or diamagnetic with paired electrons (see Table 1). In contrast, cobalt(II) is always paramagnetic with either one or three unpaired electrons with multiplicities of 2 and 4, respectively. However, iron and manganese have a variety of spin states depending on the oxidation state and the nature of the ligand (Table 1). Because of the wide variation of spin states encountered, the energy of each element was calculated using the simplest multiplicity possible and these values then adopted as parameters for subsequent binding-energy calculations on metal complexes.

Despite the drastic nature of these approximations for the metals themselves, the calculated energy of the ionization $M \rightarrow M^{2+}$ shows a reasonable monatomic correlation with the known ionization potentials of the transition elements (see Fig. 1). The Slater orbital exponents used for these

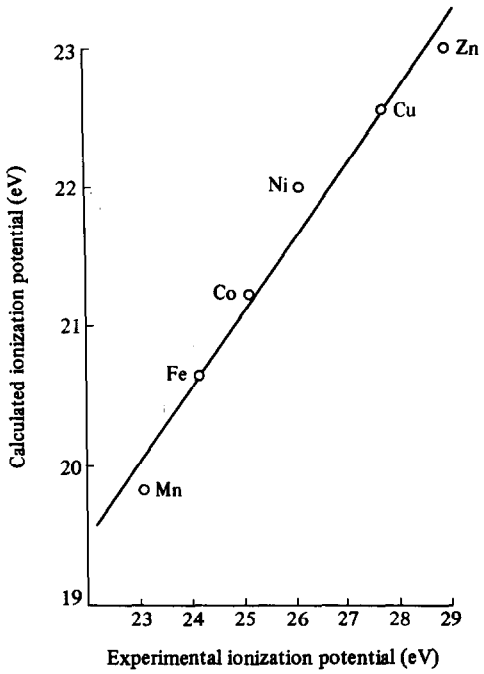

Fig. 1. Plot of calculated vs experimental ionization potentials of transition elements ($M \rightarrow M^{2+}$).

calculations are shown in Table 1 and form the basis for all subsequent calculations reported here.

Selection of bonding parameter values

The values of the bonding parameters (β_k^o) for the transition elements are highly empirical though dependent on the exponents selected. For example, nickel has been assigned the following values:

Metal	$\beta^o(3d)$	$\beta^o(4s, 4p)$	Reference
Ni	19.5	24.6	15
	29.0	32.0	15
	29.0	3.9	14
	10.0	5.0	6

Because of this typically wide variation for the transition elements, calibration studies were carried out with variable β^o values for a series of complexes (see below) so that the resulting binding energies gave the best fit with the experimental stability constants. Salicylaldehyde and its bis complexes with copper(II) were selected for the calibration study for reasons which follow:

(1) Reliable stability constant data are available for a whole range of substituted derivatives which contain both electron-withdrawing and electron-donating groups;

(2) The crystal structure of the copper complex is known[36] (but see below);

(3) The reaction can be represented theoretically by a simple scheme (Scheme 1) which involves a single ionization of the ligand.

However, because the introduction of substituents into a given molecular system usually results in a distortion of the original geometry, standard planar geometries[1] were adopted for calculation purposes except for the angles *a* and *b* which were set at 127.5°, and the metal–oxygen bond length which was set at 1.86 Å, both on the basis of average data from the **A** and **B** forms of copper bis(salicylaldehyde).[36] A wide range of $\beta^o(4s, 4p)$ and $\beta^o(3d)$ values was explored and the binding-energy differences between a given copper complex and the reactants was evaluated and compared with published stability constant data[37,38] using the relation:

$$\Delta E = E_{\text{complex}} - (2E_{\text{anion}} + E_{Cu^{2+}}).$$

Overall, 12 derivatives of salicylaldehyde, its anion, and its copper bis complex were calculated for each β^o value. Selected results from this exercise are shown in Table 2. An analysis of the full data generated (not shown) reveals very complex relationships between the values of β^o adopted and ΔE on the one hand and the correlation coefficients on the other. In summary:

(1) Both the magnitude and the sign of ΔE are determined mainly by the value of $\beta^o(4s, 4p)$ and a linear correlation results at constant $\beta^o(3d)$ values.

(2) Variations in $\beta^o(3d)$ at constant $\beta^o(4s, 4p)$ values cause only small changes in the ΔE values, but the best correlations are obtained at high $\beta^o(3d)$ values.

[b] Values for the unsubstituted complex and anion.

The complex relationships observed in the series reflect the varied interactions between the orbitals of the substituents in their relative molecular positions, and the σ- and π-bonding orbitals of the copper atom. Thus, while high $\beta^o(4s, 4p)$ and low $\beta^o(3d)$ values may adequately represent σ-bonded substituents, such as alkyl groups, the reverse may be required to represent the interactions of π-electron acceptors or donors such as the nitro group or amino group.

Because of the complexity of these relationships, the best fit with experiment was selected (see Fig. 2) with $\beta^o(4s, 4p) = 15$ and $\beta^o(3d) = 30$. The $\beta^o(3d)$ value for copper calculated in this way is the same as that reported by Clack for Gouterman orbitals,[15] and accordingly, the $\beta^o(3d)$ values for the other transition elements have been taken from the published data since they all show a curvilinear relationship with atomic number. The zinc value has been derived by extrapolation. However, because the $\beta^o(4s, 4p)$ value for copper differs considerably from that published, the values for the other transition

[a] Orbital configurations adopted given by $3d^{n-2}4s^2$.

elements have been derived by relating the bond dissociation energies of a series of simple diatomics (MX) to the corresponding value of the copper system.[39] The resultant energy ratio varies widely over the series depending on whether the atom (X) attached to the transition element (M) possesses:

(1) an *s*-orbital (X = H),
(2) *s*- and *p*-orbitals (X = O or F),
(3) *s*-, *p*- and *d*-orbitals (X = Cl, Br, I or S).

In the last two cases it is evident that the bond dissociation energies will reflect an increasing degree of *d*-orbital interaction associated with increasing atomic number. While the relative value for MH alone should be related to the $\beta^o(4s)$ value (only σ-orbitals are involved), the proportionality does not extend to $\beta^o(4p)$. The full data obtained by this procedure for the elements Mn–Ni and for Zn are shown in Table 3 along with the orbital electronegativities and Slater exponents.

COMPUTER PROGRAM CINDO54

The program used for these calculations was based on the standard CNDO/2 version of Pople *et al.*,[1] but with extensive modifications. These were introduced to deal with problems of portability between different machines, to permit the use of smaller or larger basis sets, and to facilitate the incorporation of third-row (or later) elements so that calculations can be carried out on any element, in principle, up to xenon. While overlap integrals are calculated directly by the method of Mulliken,[40] an option of using Burns atomic functions[21] in place of the more usual Slater ones[18] has been included. Slater functions for orbitals with $n = 4$ have a radial part of the form $r^{2.7}e^{-\zeta r}$ for which the normal process of integration by parts fails. This problem is eliminated by the use of Burns orbitals. However, like Clack *et al.*,[15] we have found Burns orbitals to give less than satisfactory results. Accordingly the calculations involving Slater (or quasi-Slater) coefficients have been performed taking the exponent as 3, rather than introduce the additional complication of Jaffé's device.[20]

Output options include the possible suppression of the printing of various of the larger arrays, output of localized orbitals, dipole moment analysis over such orbitals[41] and the display or Armstrong–Perkins bond orders and valences.[42] The evaluation of the eigenvalues and eigenvectors is performed by an algorithm based on those of Wilkinson.[43] This has the advantage of requiring less temporary workspace than that in the original program. Some attempt has been made to overcome the occasional problem of failure of the self-consistent field section to converge. This is done by an empirical density matrix weighting procedure which seems frequently to be sufficient to get the process back to a state of monotonic convergence.

Abstract—The reaction of nickel(II) nitrate with bis(diphenylphosphinomethyl)dimethylsilane in ethanol solution gives $Ni(NO_3)_2 \cdot (Ph_2PCH_2)_2SiMe_2$, recrystallized as orange and violet crystals from dichloromethane. Vibrational, electronic spectral and magnetic measurements of the initial product indicate the presence of *allogons*, the first case involving nitrate anions or a ditertiary phosphine ligand. The structure of the orange crystals **1** was determined by single-crystal X-ray diffraction analysis. The crystals are monoclinic, space group $P2_1/c$ with four molecules in a unit cell of dimensions $a = 10.512(2)$, $b = 15.821(5)$, $c = 18.948(8)$ Å, $\beta = 104.87(4)°$. The structure was solved by the heavy-atom method and refined by full-matrix least-squares calculations to $R = 0.029$ for 2563 observed data. In the monomeric molecule the Ni atoms are square planar, with monodentate nitrate groups [Ni—O = 1.926(2) and 1.933(2) Å]. The bidentate phosphine ligand has a bite angle of 94.81(3)° and the Ni—P bond distances are 2.166(1) and 2.170(1) Å. The six-membered NiP_2C_2Si ring adopts a boat conformation.

The coordination chemistry of nickel(II) complexes of phosphine ligands is well-developed, with much interest focusing on the factors influencing the stereochemistry of $NiX_2(PR_3)_2$ complexes.[1,2] The square planar $\rightleftharpoons$ tetrahedral equilibrium observed for many examples [especially for X = Br and $PR_3 = PPh_2R'$ (R′ = alkyl)] are reasonably predictable in that larger phosphines or halide ions, weaker ligand field strength of the phosphine or halide, and more polar solvents favour the adoption of tetrahedral nickel(II) geometry. The actual isolation of both geometric forms, called *allogons*,[3] has however only been possible for a few specific cases. X-ray crystallographic data are available for the interallogon compounds $NiBr_2[PPh_2(CH_2Ph)]_2$[3] and $NiCl_2(PPh_3)_2$,[4] whereas synthetic and spectroscopic characterization data are reported for some isolable isomeric cases involving $PPh_{3-n}Cy_n$ ($n = 0$–3),[5] $PPh_{3-n}Bu_n$ ($n = 1$ or 2)[6] and other PPh_2R' ligands.[7,8]

All known interallogon compounds of nickel(II) involve halide and monodentate phosphines as ligands. With other anions, the complexes with various phosphines are reported to be either square planar (e.g. NCS^-) or tetrahedral (e.g. NO_3^-) only.[2] With ditertiary phosphines, square planar $\rightleftharpoons$ tetrahedral equilibria were observed for nickel(II) halide complexes of bis(diphenylphosphino)propane (dppp), but *allogons* were not isolated.[9] Similarly, electronic spectral data indicated a related isomeric phenomenon for bis(dicyclohexylphosphino)ethane (dcpe), involving diamagnetic square pyramidal $[Ni(NO_3)_2(dcpe)(H_2O)]$ and square planar $[Ni(NO_3)(dcpe)(H_2O)](NO_3)$; in contrast the ligands dmpe and dppe (R = Me and Ph, respectively, instead of Cy) gave only the yellow square planar $[Ni(L\text{–}L)_2](NO_3)_2$ complexes.[10]

* Authors to whom correspondence should be addressed.

As part of the investigation[11] of the coordinating ability of the related silicon-backbone phosphine ligands, $Me_2Si(CH_2PPh_2)(CH{=}CH_2)$($L^1$) and $Me_2Si(CH_2PPh_2)_2$(L^2) we have observed that $NiX_2 \cdot L^2$ complexes are on the square planar $\rightleftharpoons$ tetrahedral threshold.[12] The orange and violet interallogon compounds $Ni(NO_3)_2 \cdot L^2$ are the subject of this report, which includes synthetic, spectral and (for the orange isomer) X-ray crystallographic data. These *allogons* are the first known for Ni(II) with nitrate as the anion and with a ditertiary phosphine ligand.

EXPERIMENTAL

Preparation of bis(diphenylphosphinomethyl)dimethylsilanedinitratonickel(II), $Ni(NO_3)_2 \cdot L^2$

Equimolar amounts of nickel(II) nitrate dissolved in ethanol and dimethoxypropane (1.5 cm^3) and the ligand L^2 dissolved in methylene chloride were mixed, giving a deep purple precipitate. After stirring the reaction mixture for 20 min, the solid was collected by filtration, washed with ethanol and ether, and dried *in vacuo* at room temperature overnight. Found (calc.): C, 52.5 (52.6); H, 4.8 (4.7); N, 4.4 (4.4). Decomposition temperature, 218°C. Recrystallization of the violet product by slow evaporation from a methylene chloride solution gave both violet (major) and orange (minor) crystals. Repeated attempts at recrystallization failed to give either isomer as a pure product or suitable crystals of the violet isomer for an X-ray analysis. The orange crystals were readily separated (though in small quantity) in suitable form on several occasions, with their relative quantity being favoured by faster evaporation of the dichloromethane solvent.

Physical methods

IR spectra were recorded in the range 4000–200 cm^{-1} using a Perkin–Elmer Model 180 double-beam spectrometer and Nujol or halocarbon mulls between KBr or polythene plates. Electronic spectra were recorded on a Cary 14 spectrophotometer with solid transmission spectra being obtained by the filter paper technique. Magnetic-moment measurements were performed on a Varian EM 360 (60 MHz, CW) NMR spectrometer by the Evans method.

Crystal data. $C_{28}H_{30}NiSiN_2O_6P_2$, $M_r = 639.31$, monoclinic, $a = 10.512(2)$, $b = 15.821(5)$, $c = 18.948(8)$ Å, $\beta = 104.87(1)°$, $V = 3045$ Å^3, $D_c = 1.39\,g\,cm^{-3}$, $Z = 4$, $F(000) = 1328$, Mo-K_{α_1} radiation, $\lambda = 0.70926$ Å, μ(Mo-K_α) = 8.2 cm^{-1}. Space group $P2_1/c$ uniquely from the systematic absences.

Structure solution and refinement. Data were collected to a maximum 2θ of 44.0° on an Enraf–Nonius CAD-4 diffractometer by the ω–2θ scan technique using monochromatized Mo-K_α radiation. Following machine location and centering of 25 reflections with θ in the range $10 < \theta < 15°$, accurate cell constants and the orientation matrix were obtained by a least-squares refinement. A total of 4249 reflections were collected of which 3472 were unique (R factor on averaging 0.015). Of these, the 2563 with $I > 3\sigma(I)$ were used in structure solution and refinement. The intensities of three standard reflections monitored at regular intervals did not change significantly over the period of data collection. The data were corrected for Lorentz and polarization factors and for absorption (maximum and minimum transmission coefficients 0.888 and 0.772).

The structure was solved by the heavy-atom method. Initial refinement* was by full-matrix least-squares calculations with isotropic temperature factors for the non-hydrogen atoms. Difference maps calculated at various stages revealed maxima corresponding to the hydrogen atoms; these were then included (but not refined) in the subsequent calculations in geometrically idealized positions (C—H = 0.95 Å) with an overall isotropic thermal parameter ($U = 0.085$ Å^2). In the final cycles of refinement, weights were derived from counting statistics, and the non-hydrogen atoms were allowed anisotropic motion. Scattering factors used in the structure factor calculations were taken from Ref. 13 for non-hydrogen atoms and Ref. 14 for hydrogen atoms, and allowance made for anomalous dispersion.[15] Refinement converged with $R = 0.029$ and $R_w = [\Sigma w\Delta^2/\Sigma wF_o^2]^{1/2} = 0.039$. A difference map calculated at the conclusion of the refinement had maxima less than 0.22 e Å^{-3} and no significant features. Tables of atomic positional parameters and anisotropic thermal vibrational parameters, each with estimated standard deviations, calculated hydrogen coordinates, molecular dimensions and observed structure amplitudes and calculated structure factors have been deposited.†

* All calculations were done on our PDP11/73 computer using the SDP-Plus system, B. Frenz and Associates Inc. (1983), SDP-Plus, College Station, TX 77840, and Enraf–Nonius, Delft, Holland.

† Copies are available from the Editor. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The phenomenon of interallogony, involving the occurrence of two different stereochemical arrangements of the same number of bonds, is well established for nickel(II) phosphine complexes, though the examples are limited to those involving halide anions and monodentate phosphines.[1-9] X-ray structural determinations are only available for the four *allogon* complexes, $NiBr_2[PPh_2(CH_2Ph)]_2$[3] and $NiCl_2(PPh_3)_2$.[4] Our discovery that the complexes $NiX_2 \cdot L^2$ (X = halide)[12] were on the tetrahedral side of the square planar $\rightleftharpoons$ tetrahedral equilibria, as compared to the analogous $NiX_2 \cdot$ dppp complexes previously reported by Van Hecke and DeW. Horrocks,[9] led us to react $Ni(NO_3)_2$ with our new silicon-backbone ligand. The initial product formed in ethanol was a violet powder, but various recrystallizations from dichloromethane solution gave mixtures of orange and violet crystals. Rapid evaporation of the solvent favoured formation of a larger quantity of the orange crystals. Manual separation of a few crystals of the latter allowed their X-ray analysis and verification as the square planar isomer. Numerous attempts to obtain suitable crystals of the violet form for a single-crystal determination were not successful, although it was possible to isolate a product virtually free of the orange crystals by slow evaporation.

Physical measurements on the violet product initially isolated from the ethanol reaction mixture indicated the presence of four-coordinate Ni(II) species having both square planar and tetrahedral geometries. The complex $Ni(NO_3)_2 \cdot L^2$, which is non-conducting in nitromethane ($\Lambda_M = 25.0\ \Omega^{-1}\ cm^2\ mol^{-1}$ for a 10^{-3} M solution, indicating some solvolysis), showed IR bands attributable to monodentate nitrato groups.[16,17] Bands at 1435 and 1350 cm^{-1} (ν_3 splitting of 85 cm^{-1}), 1000 cm^{-1} (ν_1), 820 cm^{-1} (ν_2), and at 760 and 740 cm^{-1} (ν_4), are absent in the corresponding halide complexes.[12] Weak bands in the far IR at 298 and 267 cm^{-1} can tentatively be assigned to ν(Ni—O) and ν(Ni—P) modes, respectively. An attempt to observe the relative intensities of the three highest-frequency Raman shifts attributable to nitrate fundamentals[18] was unsuccessful due to sample decomposition in the laser beam.

In contrast to the $NiX_2 \cdot$ dppp complexes,[9] for which the square planar $\rightleftharpoons$ tetrahedral equilibria lie considerably toward the square planar side (totally in the solid state), our results[12] for $NiX_2 \cdot L^2$ complexes show that formation of the tetrahedral isomer is favoured. For the present $Ni(NO_3)_2 \cdot L^2$ case, the magnetic moment, measured at 303 K in CH_2Cl_2 solution, is 3.4 BM. Assuming that a value of $\mu_{eff} = 3.5$ BM corresponds to the totally tetrahedral value (as found for $NiI_2 \cdot L^2$),[12] this magnetic moment represents a per cent paramagnetism of 94, or alternatively, $K_{eq} = 17.0$ in favour of the tetrahedral isomer. We have determined that $Ni(NO_3)_2 \cdot$ dppp, not previously reported,[9] is diamagnetic, with no indication of formation in solution of the tetrahedral isomer. By comparison, electronic spectroscopy of $Ni(NO_3)_2 \cdot L^2$ shows that the tetrahedral isomer is predominant, both in the solid state (12,200- and 18,000-cm^{-1} bands) and in CH_2Cl_2 solution [bands occur at 9400 (30), 11,100 (40), 16,800 (70) and 22,200 cm^{-1} (200)]. Electronic spectral parameters for several $NiX_2 \cdot L^2$ complexes and comparisons to reported spectral data for the analogous dppp complexes will be discussed in a future paper. This report verifies that the expectedly larger bite of L^2 than dppp as a chelating ditertiary phosphine ligand leads to the existence of *allogons* for the $Ni(NO_3)_2 \cdot L^2$ case.

The molecular structure of the orange isomer of $Ni(NO_3)_2 \cdot L^2$ is shown in Fig. 1. The Ni coordination, with *cis* P and O atoms in the coordination sphere, is slightly distorted from square planar towards square pyramidal [deviations from the NiO_2P_2 plane (Fig. 1) are: Ni, 0.029(1); O(11), −0.028(2); O(21), 0.014(2); P(1), 0.009(1); P(2), −0.024(1) Å]. Selected bond distances and angles are summarized in Table 1. The six-membered NiP_2C_2Si ring adopts a boat conformation with atoms Ni, P(2), Si and C(1) forming a plane to within ±0.09 Å and with P(1)+0.814(1) and C(2)+0.633(4) Å from the plane. This conformation results in the non-equivalence of substituents on P and Si.

The Ni—P bond distances [2.166(1) and 2.170(1) Å] are considerably shorter than the corresponding

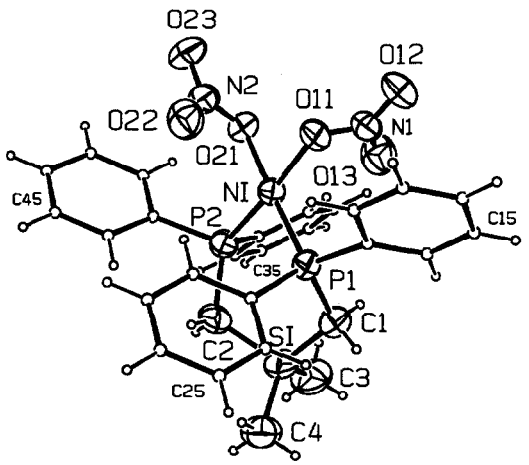

Fig. 1.

[a] For more detailed information, see supplementary data.

distances in the square planar isomers of $NiCl_2(PPh_3)_2$(2.242(3))[4] and $NiBr_2[PPh_2(CH_2Ph)]_2$ (2.263(7) Å).[3] Ni—P bond distances in the tetrahedral isomers of the latter two interallogon examples are longer still by 0.05 Å. The shortening of Ni—P bond distances for the present square planar *allogon*, compared to the monodentate phosphine cases, can perhaps be attributed to the presence of O (of weaker *trans* influence[19]) rather than P atoms in the *trans* positions. The shorter Ni—P bond length also suggests that a stronger bond than normal results from the chelate ring formation. A shortened Ni—P bond length [2.175(4) Å] in *trans*-$Ni(C{\equiv}CPh)_2(PEt_3)_2$ was explained by electronic effects.[20]

The Ni—O bond distances [1.926(2) and 1.933(2) Å] are shorter than previously reported for the Ni—O monodentate nitrato interaction in octahedral dinitrato[2,6 - diacetylpyridinebis(anil)] nickel(II) [2.027(5) vs 2.104(5) ave. for the bidentate nitrato group in the same molecule].[21] The shorter Ni—O bond in a square planar environment is as expected. In the square planar complex bis-(*N*-isopropyl - 3 - methylsalicylaldiminato)nickel(II), Ni—O equals 1.837(2) Å (ave.).[22] The effect of coordination of the nitrato groups is discernible in the differences of the N—O distances, i.e. N—O (bonded), 1.293(4) and 1.303(4) Å, compared to N—O (terminal), 1.217–1.227(4) Å. Similarly, the O—N—O bond angles are considerably larger to the terminal O atoms, 124.3(3)° ave. compared to 116.7–119.2(3)° when both terminal and bound O are involved.

The P—Ni—O angles [172.70(7) and 178.08(7)°] depart significantly from idealized square planar expectations; consistent with the small square pyramidal distortion noted above. Similarly, the P—Ni—O and O—Ni—O angles are less than the theoretical 90° [86.58(9) and 86.80(7)°]. The P—Ni—P angle of 94.81(3)° shows that the bite angle of L^2 is enhanced by the incorporation of a Si atom in the backbone. For comparison, the bite angle of dppp in $Pd(NCS)_2 \cdot$dppp is 89.3°, while that of dppe in Pd(NCS)(SCN)·dppe is 85°.[23]

The C—P—C angles [103.0–107.8(2)°] are less than the ideal tetrahedral value (109.5°) and the Ni—P—C angles [107.0–121.0(1)°] are larger, as expected for metal–phosphine complexes. Other bond distances, such as P—C(CH_2) [1.795 and 1.803(3)Å] and P—C(phenyl) [1.804–1.818(4) Å], are similar to those in other phosphine complexes. The range of C—Si—C angles [107.3–111.5(2)°] reflects the flexibility of the ligand backbone; the 107.3° angle for C(1)—Si—C(2) compares to 116.7° for the C—C—C backbone angle of dppp in $Pd(NCS)_2 \cdot$dppp.[23] The conformationally flexible nature of the L^2 ligand probably contributes to its coordinating ability with several metal centres,[12] and allows interallogon compounds in the case of $Ni(NO_3)_2 \cdot L^2$.

THE REACTIVITIES OF AMINOARSINES TOWARD DIARSINES

V. K. GUPTA, L. K. KRANNICH and C. L. WATKINS*

Department of Chemistry, University of Alabama at Birmingham, Birmingham, AL 35294, U.S.A.

(*Received* 28 *August* 1986; *accepted after revision* 30 *October* 1986)

Abstract—The reactions of Me_2AsNR_2 with $Et_2AsAsEt_2$, and of Et_2AsNR_2 with $Me_2AsAsMe_2$ (R = Me or Et), were investigated over the temperature range 24–75°C by using ^1H and ^{13}C NMR spectroscopy. The NMR data indicate the initial formation of the unsymmetrical diarsine, $Me_2AsAsEt_2$, and the respective dialkylaminodialkylarsine, Et_2AsNR_2 or Me_2AsNR_2. The $Me_2AsAsEt_2$ then undergoes symmetrization to yield $Me_2AsAsMe_2$ and $Et_2AsAsEt_2$. Additional competitive reactions involving  and  systems also occur in the reaction mixture. In each case, the percentage distribution of products and reactants in the studied systems at equilibrium is independent of temperature within experimental measurement. The reaction rates are dependent upon the nature of R and the alkyl group in the diarsine. In addition, equilibrium constants for several competitive reactions have been determined.

The chemistry of P—P-, As—As-, P—N-, As—N- and As—P-bonded compounds has been of continued interest[1–4] with most of the attention being directed toward the reactivity of P—N-bonded systems.[5–13] During the last 20 years, several studies have focused on the reactivity of the more labile As—N bond.[14–19] This literature establishes the fact that As—As and As—N bonds are more labile than the P—P and P—N bonds, respectively. Recently the synthesis and reactivity of heteroatomic group 15 compounds, which contain multiple bonds, i.e., P═N, P═As and P═Sb, have been reported.[20,21]

Our multinuclear NMR investigations of the Me_2AsNMe_2–Me_2AsH[22] and Me_2AsNMe_2–$MeAsH_2$[23] reaction systems demonstrate that the lability of the As—As and As—N bonds leads to reactions involving the exchange of H—,  , Me_2As— and Me_2N— units in solution. These exchange processes directly influence the rate of reaction and/or the distribution of products at equilibrium.

There are no reports in the literature on the reactivities of aminoarsines toward As—As-bonded compounds, except our recent observations[22] while studying the reactivity of Me_2AsNMe_2 toward Me_2AsH. Thus, we have undertaken a systematic study of reactions involving the  system to elucidate the mechanism of reaction, understand the effect that various substituents have on As—N and As—As bond lability, and characterize and establish the relative importance of competing reactions. In this paper, we report a ^1H and ^{13}C NMR study of the reactions of four dialkylaminodialkylarsines with tetramethyl- and tetraethyl-diarsine in toluene-d_8 solution as a function of temperature and time. Some competing reactions have also been studied to establish their relative significance in the  reaction system.

EXPERIMENTAL

Standard high vacuum line techniques and a Vacuum Atmospheres Model HE-43-Dri lab equipped with a Model HE-493 Dri-Train were used for storing and handling of all compounds. Me_2NH

* Author to whom correspondence should be addressed.

(Matheson Gas Products) was dried over sodium metal and was distilled in the vacuum line prior to use. Toluene-d_8 and Me_4Si were purchased from Aldrich Chemical Co. and stored over molecular sieves. Me_2AsNEt_2 (b.p. 80.5°C/90 torr),[15] Et_2AsNEt_2 (58°C/8 torr),[19] Me_2AsNMe_2 (108°C),[24] and $Me_2AsAsMe_2$ (60°C/25 torr)[25] were synthesized by previously reported methods. $Et_2AsAsEt_2$ (185°C) was synthesized[25] by the reaction of Et_2AsCl with Zn dust. Et_2AsNMe_2 (132°C/549 torr) was obtained by the reaction of Et_2AsI with Me_2NH using the procedure[24] analogous to that reported for Me_2AsNMe_2. The purity of all compounds was checked by NMR spectroscopy prior to use.

^1H and ^{13}C NMR spectra were recorded on a Nicolet 300 MHz multinuclear FT NMR spectrometer operating at 300.1 and 75.4 MHz, respectively. The chemical shifts were measured with respect to tetramethylsilane as an internal reference. The reaction mixtures were protected from exposure to light and care was also taken to ensure that the exchange processes were not acid-catalyzed by carrying out reactions in NMR tubes that were not acid washed.

Reactions of $Me_2AsAsMe_2$ *with* Et_2AsNMe_2 *or* Et_2AsNEt_2, *and of* $Et_2AsAsEt_2$ *with* Me_2AsNMe_2 *or* Me_2AsNEt_2

The reactions of $Me_2AsAsMe_2$ (1.0 mmol) with equimolar amounts of Et_2AsNMe_2 or Et_2AsNEt_2, and of $Et_2AsAsEt_2$ (1.0 mmol) with Me_2AsNMe_2 or Me_2AsNEt_2 in a 1:1 mole ratio, were carried out in toluene-d_8 using the following procedure. A stoichiometric amount of the less volatile compound dissolved in toluene-d_8 and a drop of TMS were added to a NMR tube (10 mm × 22.5 cm, pyrex) equipped with a greaseless vacuum stopcock. The tube was degassed using standard vacuum line techniques. An equimolar amount of the more volatile compound was transferred at −196°C into the NMR tube. The total volume of the solution was maintained at 3.0 cm^3. The tube was sealed, agitated gently at −78°C (dry ice–acetone slush), and inserted into the precooled (−60°C) probe of the NMR spectrometer. The reaction was then monitored at the selected temperature by ^1H and ^{13}C NMR spectroscopy as a function of time.

Reactions of Me_2AsNMe_2 *with* Et_2AsNEt_2, Me_2AsNEt_2 *with* Et_2AsNMe_2, *and* $Me_2AsAsMe_2$ *with* $Et_2AsAsEt_2$

Equimolar amounts (1.0 mmol) of the reactants dissolved in toluene-d_8 were mixed to give a total solution volume of 3.0 cm^3 in an NMR tube at room temperature. The progress of the reaction mixture was monitored by ^1H and ^{13}C NMR spectroscopy until equilibrium was attained.

The following is a list of NMR spectral data (values in ppm) independently determined in our laboratory at room temperature in toluene-d_8 solution on synthesized compounds that are identified in the reaction mixture.

^1H *spectral data*

$Me_2AsAsMe_2$: 0.95 (MeAs). $Et_2AsAsEt_2$: 1.17 (CH_3CH_2As, t, $^3J_{HH} = 7.7$ Hz), and 1.56 (CH_3CH_2As, m). $Me_2AsAsEt_2$: 1.02 (MeAs), 1.16 (CH_3CH_2As, t, $^3J_{HH} = 7.7$ Hz), and 1.53 (CH_3CH_2As, m). Me_2AsNMe_2: 0.82 (MeAs), and 2.43 (MeN). Me_2AsNEt_2: 0.87 (MeAs), 0.99 (CH_3CH_2N, t, $^3J_{HH} = 7.0$ Hz), and 2.81 (CH_3CH_2N, q). Et_2AsNEt_2: 1.00 (CH_3CH_2N, t, $^3J_{HH} = 7.1$ Hz), 2.88 (CH_3CH_2N, q), and 1.04–1.50 (Et_2As, m). Et_2AsNMe_2: 1.02–1.54 (Et_2As, m), and 2.56 (MeN).

^{13}C *spectral data*

$Me_2AsAsMe_2$: 5.96 (MeAs, $^1J_{CH} = 132.6$ Hz). $Et_2AsAsEt_2$: 12.78 (CH_3CH_2As, $^1J_{CH} = 125.8$ Hz), and 14.81 (CH_3CH_2As, $^1J_{CH} = 132.4$ Hz). $Me_2AsAsEt_2$: 6.16 (MeAs, $^1J_{CH} = 132.7$ Hz), 12.61 (CH_3CH_2As, $^1J_{CH} = 125.6$ Hz), and 15.28 (CH_3CH_2As, $^1J_{CH} = 132.3$ Hz). Me_2AsNMe_2: 9.92 (MeAs, $^1J_{CH} = 130.6$ Hz), and 41.91 (MeN, $^1J_{CH} = 132.7$ Hz). Me_2AsNEt_2: 12.12 (MeAs, $^1J_{CH} = 130.3$ Hz), 15.73 (CH_3CH_2N, $^1J_{CH} = 125.1$ Hz), and 44.31 (CH_3CH_2N, $^1J_{CH} = 132.2$ Hz). Et_2AsNEt_2: 10.44 (CH_3CH_2As, $^1J_{CH} = 126.4$ Hz), 20.92 (CH_3CH_2As, $^1J_{CH} = 130.6$ Hz), 16.32 (CH_3CH_2N, $^1J_{CH} = 124.9$ Hz), and 44.88 (CH_3CH_2N, $^1J_{CH} = 132.2$ Hz). Et_2AsNMe_2: 10.38 (CH_3CH_2As, $^1J_{CH} = 126.6$ Hz), 19.59 (CH_3CH_2As, $^1J_{CH} = 130.6$ Hz), and 42.61 (MeN, $^1J_{CH} = 132.6$ Hz).

RESULTS AND DISCUSSION

Reaction of Me_2AsNR_2 *with* $Et_2AsAsEt_2$ (R = Me *or* Et)

The ^1H and ^{13}C NMR spectra of a 1:1 mole ratio of Me_2AsNR_2 and $Et_2AsAsEt_2$ in toluene-d_8 solution showed no reaction had occurred at −60°C. As the temperature was raised to 24°C, a reaction occurred to give a mixture of $Me_2AsAsEt_2$, $Me_2AsAsMe_2$, $Et_2AsAsEt_2$, Et_2AsNR_2 and Me_2AsNR_2. Equilibrium was reached within 1 h. No temperature effect was noted on the equilibrium

when the mixture was monitored at 50°C (15 days), 75°C (13 days) and then again at 24°C (10 days). The ^{1}H NMR intensity data gave the following percent distributions at equilibrium for the indicated Me_2AsNR_2–$Et_2AsAsEt_2$ systems: Me_2AsNMe_2–$Et_2AsAsEt_2$ system = 31% $Me_2AsAsEt_2$, 6% $Me_2AsAsMe_2$, 30% Et_2AsNMe_2, 19% Me_2AsNMe_2, and 14% $Et_2AsAsEt_2$; Me_2AsNEt_2–$Et_2AsAsEt_2$ system = 32% $Me_2AsAsEt_2$, 5% $Me_2AsAsMe_2$, 31% Et_2AsNEt_2, 19% Me_2AsNEt_2, and 13% $Et_2AsAsEt_2$.

These results indicate that Me_2AsNR_2 readily reacts with $Et_2AsAsEt_2$ to give the unsymmetrical $Me_2AsAsEt_2$ and Et_2AsNR_2 [eqn (1)]:

$$Me_2AsNR_2 + Et_2AsAsEt_2 \rightleftarrows Me_2AsAsEt_2 + Et_2AsNR_2. \quad (1)$$

The unsymmetrical diarsine, $Me_2AsAsEt_2$, then undergoes symmetrization [eqn (2)]:[22]

$$2Me_2AsAsEt_2 \rightleftarrows Me_2AsAsMe_2 + Et_2AsAsEt_2. \quad (2)$$

This reaction is very facile, with equilibrium being reached within 30 min. Interestingly, the distribution of diarsines is independent of temperature (see discussion below).

Owing to the lability of the As—As and As—N bonds, $Me_2AsAsMe_2$ then reacts with Et_2AsNR_2 according to eqn (3) (see discussion below):

$$Me_2AsAsMe_2 + Et_2AsNR_2 \rightarrow Me_2AsAsEt_2 + Me_2AsNR_2. \quad (3)$$

All other reactions involving the very labile As—N and As—As bonds undoubtedly occur in solution. For example, $Me_2AsAsMe_2$ in eqn (2) would be expected to react with Me_2AsNR_2 [eqn (1)]. However, due to the indistinguishability of reactants and products in these other systems, they could not be studied independently using our NMR techniques.

Since establishment of equilibrium is so fast at 24°C, rate data were collected at −10°C. These data indicate that substitution of an Et for a Me group in the amino moiety of Me_2AsNR_2 does not affect the final equilibrium distribution of species in the reaction mixture. However, the graphs of % Et_2AsNR_2 produced with respect to Me_2AsNR_2 vs time for the Me_2AsNR_2–$Et_2AsAsEt_2$ system [Fig. 1(A)] indicate that substitution of an Et for a Me group in Me_2AsNR_2 does affect the rate of reaction. The Me_2AsNMe_2–$Et_2AsAsEt_2$ reaction is slower than the Me_2AsNEt_2—$EtAsAsEt_2$ reaction. Since these reactions appear to proceed through formation of a concerted four-centered activated intermediate,[26,27] these data suggest that substitution of an Et for a Me group lowers the energy barrier for As—N bond dissociation and leads to a faster reaction.

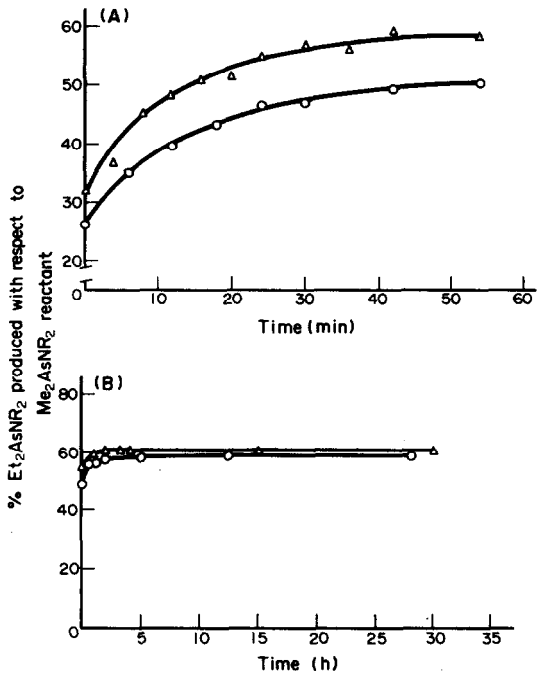

Fig. 1. Percentage of Et_2AsNR_2 formed as a function of time: (A) at −10°C, (B) at 24°C. (△) $Et_2AsAsEt_2$–Me_2AsNEt_2 system, (○) $Et_2AsAsEt_2$–Me_2AsNMe_2 system.

Reaction of Et_2AsNR_2 *with* $Me_2AsAsMe_2$ (R = Me *or* Et)

The ^{1}H and ^{13}C NMR spectra of an equimolar mixture of Et_2AsNR_2 and $Me_2AsAsMe_2$ in toluene-d_8 solution also indicated no reaction at −60°C. At 24°C, resonances assignable to $Me_2AsAsEt_2$, $Et_2AsAsEt_2$, $Me_2AsAsMe_2$, Et_2AsNR_2 and Me_2AsNR_2 were observed. Equilibrium was attained in 29 h for the Et_2AsNMe_2–$Me_2AsAsMe_2$ system and in 6 h for the Et_2AsNEt_2–$Me_2AsAsMe_2$ system. No effect of temperature on the equilibrium was noted when the reaction mixtures were monitored at 50, 75 and then again at 24°C. The ^{1}H NMR intensity data gave the following percent distributions at equilibrium for the indicated Et_2AsNR_2–$Me_2AsAsMe_2$ systems. Et_2AsNMe_2–$Me_2AsAsMe_2$ system: 26% $Me_2AsAsEt_2$, 7% $Et_2AsAsEt_2$, 35% Me_2AsNMe_2, 14% Et_2AsNMe_2, and 18% $Me_2AsAsMe_2$; Et_2AsNEt_2–$Me_2AsAsMe_2$ system: 24% $Me_2AsAsEt_2$, 6% $Et_2AsAsEt_2$, 35% Me_2AsNEt_2, 15% Et_2AsNEt_2, and 20% $Me_2AsAsMe_2$.

These results suggest that Et_2AsNR_2 readily reacts with $Me_2AsAsMe_2$ to yield $Me_2AsAsEt_2$ and Me_2AsNR_2 [eqn (3)]. This reaction, in comparison to that represented by eqn (1), appears to be irreversible, since the reaction of $Me_2AsAsEt_2$ with Me_2AsNR_2 gives indistinguishable reactants and products. $Me_2AsAsEt_2$ undergoes symmetrization via eqn (2) and can also react with Et_2AsNR_2 according to eqn (4):

$$Me_2AsAsEt_2 + Et_2AsNR_2 \rightleftarrows Me_2AsNR_2 + Et_2AsAsEt_2. \quad (4)$$

The $Et_2AsAsEt_2$ produced from the reactions described by eqns (2) and (4) further reacts with the Me_2AsNR_2 [see eqn (1)] formed during the reaction described by eqn (3). Because of the lability of the As—N and As—As bonds, several other reactions involving $\rangle AsAs\langle - \rangle AsAs\langle$,[22] $\rangle AsAs\langle - \rangle AsN\langle$ and $\rangle AsN\langle - \rangle AsN\langle$ systems undoubtedly occur in solution. Due to the indistinguishability of reactants and products in these other systems, they could not be studied independently using our NMR techniques.

The graph of % Me_2AsNR_2 produced with respect to Et_2AsNR_2 vs time for the Et_2AsNR_2–$Me_2AsAsMe_2$ system (Fig. 2) also suggests that substitution of an Et for a Me group in the amino moiety of Et_2AsNR_2 has no effect on the final equilibrium distribution of species. However, the rate of the Et_2AsNEt_2–$Me_2AsAsMe_2$ reaction is much faster than that of the Et_2AsNMe_2–$Me_2AsAsMe_2$ reaction. Also, in this case, substitution of an Et for a Me group appears to lower the energy barrier for As—N bond dissociation.

A comparison of Figs 1(B) and 2 indicates that the rate of reaction for the $Et_2AsAsEt_2$–Me_2AsNR_2 systems is considerably greater than for the analogous $Me_2AsAsMe_2$–Et_2AsNR_2 systems. Thus substitution of an Et for a Me group in the diarsines has a greater influence on the reaction rates than does the substitution in the aminoarsines. This probably is due to the lower As—As bond strength[28] in $Et_2AsAsEt_2$ relative to that in $Me_2AsAsMe_2$, which should lower the energy barrier to As—As bond dissociation in the four-centered intermediate.

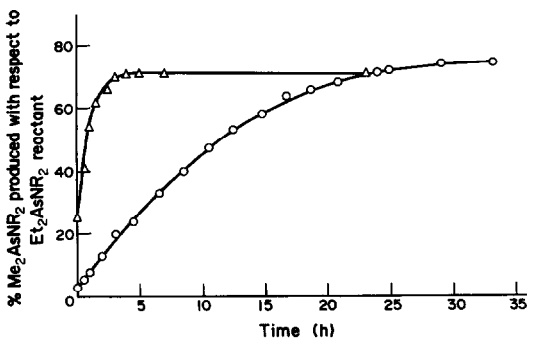

Fig. 2. Percentage of Me_2AsNR_2 formed as a function of time at 24°C: (○) $Me_2AsAsMe_2$–Et_2AsNMe_2 system, (Δ) $Me_2AsAsMe_2$–Et_2AsNEt_2 system.

Reactions of Me_2AsNMe_2 *with* Et_2AsNEt_2, *and of* Me_2AsNEt_2 *with* Et_2AsNMe_2

In both the Me_2AsNR_2–$Et_2AsAsEt_2$ and the Et_2AsNR_2–$Me_2AsAsMe_2$ systems described above, Me_2AsNR_2 and Et_2AsNR_2 are simultaneously present in solution as reactant and/or product. Because the products and the reactants from an exchange reaction represented by eqn (5):

$$Me_2AsNR_2 + Et_2AsNR_2 \rightleftarrows Me_2AsNR_2 + Et_2AsNR_2 \quad (5)$$

are indistinguishable, we could not study this reaction using available NMR techniques. Instead, we established the occurrence of such an exchange by reacting Me_2AsNMe_2 with Et_2AsNEt_2. Within 15 h of mixing a 1:1 stoichiometric ratio of the reactants at 24°C, the ^1H NMR spectrum indicated establishment of an equilibrium to give a mixture containing 24% each of the Me_2AsNEt_2 and Et_2AsNMe_2, and 26% each of Me_2AsNMe_2 and Et_2AsNEt_2:

$$Me_2AsNMe_2 + Et_2AsNEt_2 \rightleftarrows Me_2AsNEt_2 + Et_2AsNMe_2. \quad (6)$$

The calculated equilibrium constant for the reaction represented by eqn (6) is 0.90. The reversibility of this reaction was substantiated by reacting Me_2AsNEt_2 with Et_2AsNMe_2, forming Et_2AsNEt_2 and Me_2AsNMe_2. The calculated equilibrium constant for this reaction is 1.1 at 24°C. These exchange reactions have a low enthalpy of reaction, as evidenced by our findings that the equilibrium constants are invariant with temperature within experimental measurement.

Reaction of $Me_2AsAsMe_2$ *with* $Et_2AsAsEt_2$

The ^1H spectra of a 1:1 mole ratio of $Me_2AsAsMe_2$ and $Et_2AsAsEt_2$ in toluene-d_8 were obtained at 24 and 50°C. The spectra indicate a rapid exchange reaction. The relative concentration of parent and mixed compounds was determined from the integration of the ^1H signals. An equilibrium constant of 1.0 was obtained at each tem-

perature by using the following expression:

$$K = \frac{[Et_2AsAsMe_2]^2}{[Me_4As_2][Et_4As_2]}.$$

These data are consistent with those reported for exchange reactions involving P—As and As—Sb systems. Equilibrium constants of 0.26 and 0.37 were obtained for the Me_2PPMe_2–$Me_2AsAsMe_2$[4] and Ph_2PPPh_2–$Ph_2AsAsPh_2$[3] systems, respectively, in benzene-d_6. In the Ph_2PPPh_2–$Ph_2AsAsPh_2$ system, ΔH^o was very low ($+1.3 \pm 0.3$ kcal mol^{-1}) with a positive entropy contribution ($\Delta S^o = +3.5 \pm 1.0$ eu) and the reaction was rather fast. An equilibrium constant of 0.9 was obtained for the $Me_2SbSbMe_2$–$Me_2AsAsMe_2$ system.[4]

The results of our current study indicate that reactions between As—As- and As—N-bonded compounds occur readily. For the systems studied, the overall reactions involve numerous competing equilibria that are very facile. Preliminary investigations of analogous reactions involving P—P- and As—N-bonded compounds indicate high reactivity, while those involving As—As- and P—N-bonded compounds indicate no reactivity. The reaction of Et_2PPEt_2 and Me_2AsNMe_2 goes to completion within 30 min to yield Et_2PAsMe_2 and Et_2PNMe_2 in solution. Et_2PAsMe_2 then undergoes a slow exchange to give an equilibrium mixture of Et_2PAsMe_2, Et_2PPEt_2 and $Me_2AsAsMe_2$. The  systems are currently being studied to obtain kinetic and thermodynamic data, and to relate these data with those obtained from the  systems.

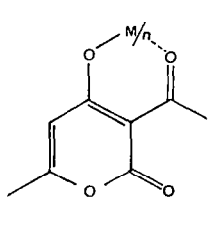
(*Received* 10 *June* 1986; *accepted after revision* 4 *November* 1986)

Abstract—Co(II), Ni(II), Cu(II) and Cr(III) complexes with monoprotic dehydroacetic acid (3 - acetyl - 4 - hydroxy - 6 - methyl - 2 - pyrone) are described. The Co, Ni and Cu compounds present 1 : 2 metal : ligand ratios and the Cr compound a 1 : 3 ratio. All of these compounds are soluble in dimethylformamide and formed adducts with this solvent. One of these solvates, bis(3 - acetyl - 4 - hydroxy - 6 - methyl - 2 - pyrone)cobalt(II) bis(dimethylformamide), afforded crystals suitable for X-ray diffraction analysis, and its crystalline and molecular structures are reported. The crystals are triclinic, space group $P\bar{1}$, with $a = 8.290(1)$, $b = 9.570(2)$, $c = 7.731(1)$ Å, $\alpha = 94.16(2)$, $\beta = 101.52(2)$, $\gamma = 85.15(2)°$, $V = 597.9(2)$ Å^3, $Z = 1$. Least-squares refinement of the structure based on 3088 observations led to final discrepancy indices of $R = 0.075$ and $R_w = 0.049$. The Co atoms lies on a inversion center having distorted octahedral coordination through four O atoms of two 3 - acetyl - 4 - hydroxy - 6 - methyl - 2 - pyrone groups and two O atoms of two dimethylformamide molecules. The 3 - acetyl - 4 - hydroxy - 6 - methyl - 2 - pyrone group is practically planar.

Dehydroacetic acid (3 - acetyl - 4 - hydroxy - 6 - methyl - 2 - pyrone) (**Ia**) is an industrially available product used as a fungicide, a bactericide and also as an important intermediate in organic synthesis. However, little is known on its metal complexes. The Cu and Zn complexes have been reported to be, respectively, a fungicide[1] and a heat stabilizer for vinyl chloride resins.[2] There are some other reports in the patent literature,[3] and also the stability constants of some complexes have been measured.[4,5]

Some of us,[6,7] have described the use of the Co(II) complex (**Ib**) as a substrate to achieve one of the few reactions known to occur at C5 in the dehydroacetic acid. However, nothing was known about **Ib** apart from the most simple spectroscopic characteristics. Therefore, it was considered that a structural study of **Ib** and its congeners **Ic–e**, also prepared for synthetic purposes, could be of interest.



Ia M = H, $n = 1$
Ib M = Co, $n = 2$
Ic M = Ni $n = 2$
Id M = Cu, $n = 2$
Ie M = Cr, $n = 3$

As far as we know the most related molecule studied by X-ray diffraction is the Ni(II) dehydroacetic acid monoimide complex.[8]

EXPERIMENTAL

Synthesis of the complexes

Co(II) *complex*. Co(II) chloride hexahydrate (2.3 g, 9.7 mmol) in water (15 cm^3) was added under stirring to a mixture of dehydroacetic acid (3.27 g, 19.4 mmol) in acetone (40 cm^3) and sodium acetate trihydrate (2.63 g, 19.4 mmol) in water (15 cm^3). The stirring was continued for 1 h, after which the solid pink purple precipitate was filtered, washed with water and acetone, mixed with toluene, and evaporated again to afford 3.5 g of the complex. Found: C, 48.9; H, 3.5. Calc. for $C_{16}H_{14}O_8Co$: C, 48.9; H, 3.6%.

Co(II) complex-dimethylformamide solvate. Crystals suitable for X-ray diffraction with formula $C_{16}H_{14}O_8Co \cdot 2$ dmf were obtained by slow diffusion of ethanol in a dmf solution of the aforementioned Co(II) complex.

Cu(II) *complex*. A mixture of copper acetate monohydrate (3.15 g, 16.0 mmol) and sodium acetate trihydrate (4.35 g, 32 mmol) in water (20 cm^3) was added dropwise with stirring to a solution of dehydroacetic acid (5.50 g, 32 mmol) in acetone (80 cm^3). The blue precipitate formed was filtered, washed with water and acetone, and dried to afford 3.97 g of the complex. Yield 65%, m.p. 322°C. Found: C, 48.3; H, 3.6. Calc. for $C_{16}H_{14}O_8Cu$: C, 48.3; H, 3.6%.

Ni(II) *complex*. A mixture of nickel chloride hexahydrate (10.58 g, 45 mmol) and sodium acetate trihydrate (12.11 g, 89 mmol) in water (90 cm^3) was added dropwise with stirring to a solution of dehydroacetic acid (15.0 g, 89 mmol) in acetone (250 cm^3). The stirring was maintained for 1 h, and the green precipitate filtered, washed with water and acetone, and dried to afford 14.1 g of the complex. Yield 72%, m.p. 190°C. Found C, 44.3; H, 4.4. Calc. for $C_{16}H_{14}O_8Ni \cdot 2H_2O$: C, 44.8; H, 4.2%.

Cr(III) *complex*. A mixture of urea (20.0 g, 0.33 mol), chromium trichloride hexahydrate (3.0 g, 11 mmol), dehydroacetic acid (4.54 g, 27 mmol), water (50 cm^3), and acetone (100 cm^3) was refluxed for 20 h. The mixture was then cooled at room temperature and poured into water (100 cm^3). The formed precipitate was filtered, washed with water and acetone, and dried to afford 2.5 g of the complex. Yield 41%, m.p. 172–174°C. Found C, 52.3; H, 4.1. Calc. for $C_{24}H_{21}O_{12}Cr$: C, 52.1; H, 3.8%.

X-ray structure determination

A prismatic crystal of 0.2 × 0.2 × 0.3 mm was used to determine the cell parameters on a Nonius CAD-4 four-circle diffractometer. Intensity data were collected using the same diffractometer from the same crystal with graphite monochromated Mo-K_α radiation for $2 \leqslant \theta \leqslant 30°$ and the ω–2θ scan technique. Two reflections were used as standard and remeasured every 100 reflections. No decomposition was observed. Of the 3485 independent reflections measured, 3088 were considered as observed with $I > 2\sigma(I)$, σ being determined from counting statistics. Lorentz and polarization corrections were applied but no correction was made for absorption.

The structure was solved by direct methods with MULTAN 80[9] program and subsequent difference Fourier synthesis.

Further least-squares refinements, first with isotropic and later with anisotropic temperature factor coefficients for non-H atoms and isotropic for H atoms (located on a difference Fourier synthesis) reduced R to 0.075 and R_w to 0.049.

The final-difference Fourier map had all residual peaks less than 0.15 e $Å^{-3}$. Figure 1 shows a view of the molecule and Co octahedron. The final bond lengths and bond angles involving the non-H atoms are given in Table 1. Atomic positional parameters and thermal coefficients and lists of F_o/F_c values have been deposited as supplementary material with the Editor from which copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

The scattering factors were taken from *International Tables for X-ray Crystallography* (1974). The computation was made with programs of the X-ray 80 systems,[10] PARST[11] and PESOS[12] on a Vax 11/750 computer.

Physical measurements

Elemental analyses of the newly prepared complexes were performed in our microanalytical laboratory using a Perkin–Elmer 240 microanalyzer. IR spectra were recorded in a Beckman IR-20A spectrophotometer as KBr pellets. Magnetic measurements were made in a Faraday type equipment in the 300–77 K temperature range. The balance was calibrated with standard $Hg[Co(SCN)_4]$. Pascal tables were used for diamagnetic corrections but no attempts were made to introduce TIP corrections.

RESULTS AND DISCUSSION

Structural description of the Co(II) *complex*

The Co atom lies on a inversion center and it has a distorted octahedral coordination with O1 and O2 atoms in equatorial positions, and the O3 atom from the dimethylformamide molecule occupying the most electronegative elongated axial position (Fig. 1).

The Co—O3 distance [2.171(2) Å], is similar to the value of 2.161(3) Å suggested by Castiñeiras *et al.*,[13] but the Co—O1 [2.027(2) Å] and Co—O2 [2.002(2) Å] distances are shorter. However the dimensions are in good agreement with the value of the Co octahedron found by Florencio *et al.*[14] in a Co(II) benzenesulphonate–ethanol complex and in hexahydrated Co(II) benzenesulphonate.

The asymmetric molecular group forms a planar

six-membered ring. All the exocyclic atoms are practically situated in the same plane (Table 1). The Co atom is situated out of this plane by 0.4779 Å. C8—C9 [1.329(4) Å] has a double-bond character and the other molecule bonds display a conjugation effect. The dimethylformamide molecule shows a normal geometry.

Magnetic and spectroscopic properties

All these compounds are very insoluble in the common solvents but they are slightly soluble in dimethylformamide. From this solvent it is possible to isolate different solvates as in the case of the Co complex. The coordination about the Co(II) ion is octahedral in the disolvated complex as shown by X-ray diffraction, but the geometry for the non-solvated compound is not obvious. Magnetic measurements down to liquid-nitrogen temperature gave us evidence for a tetrahedral coordination in this compound.

The complex follows the Curie–Weiss law in the temperature range tested. The plot of the inverse of the magnetic susceptibility vs temperature is a straight line with a very good approximation (correlation coefficient = 0.9996, slope = 0.337, intercept with the X-axis = -7.2 K).

The magnetic moments are temperature-independent in the range 300–77 K, and their average value is 4.77 BM. This value is characteristic for tetrahedral Co(II) complexes[15] with no orbital contribution in the $^4A_2$ ground state. The g value for the Co(II) ion calculated from the Curie constant assuming a spin value of $\frac{3}{2}$ is 2.5. The negative value of the Weiss constant (θ) could be explained assuming intermolecular antiferromagnetic interactions in the crystalline structure. Orbital contributions to the ground state through the mixing in the $^4T_2$-state by a second-order spin–orbit coupling perturbation or effects due to zero field splitting could also contribute to the θ constant.

Magnetic measurements at room temperature of the other compounds also give information for the geometries about the Ni(II), Cu(II) and Cr(III) ions. The dihydrated Ni compound exhibits a magnetic moment of 3.2 BM, which is characteristic for Ni(II) octahedral complexes, and a similar structure to that found in the Co(II) complex should be assumed. The Cu compound has a magnetic moment of 1.8 BM at room temperature and its coordination geometry could be tetrahedral. On the other hand, the Cr compound is a 1 : 3 complex and its magnetic moment is 3.5 BM, so that an octahedral coordination should be expected.

IR spectra show the coordination of the dehydroacetic acid through the hydroxylic and carbonylic groups. The frequency of the C=O band decreases in the complexes with respect to the free ligand (**Ia**, 1750 cm^{-1}; **Ib**, 1680 cm^{-1}; **Ic**, 1680 cm^{-1}; **Id**, 1700 cm^{-1}; **Ie**, 1715 cm^{-1}).

NEW PATHWAY TO TRIAMMINE COMPLEXES OF CHROMIUM(III): CRYSTAL STRUCTURE OF 1-CHLORO-2,3-DIAQUO-4,5,6-TRIAMMINECHROMIUM(III) CHLORIDE

J. PONS and J. CASABÓ*

(*Received* 15 *July* 1986; *accepted after revision* 4 *November* 1986)

Abstract—A new synthetic method to triammine complexes of Cr(III) is reported, via a hydrolytic process from tetrammine complexes. The crystal and molecular structure of 1 - chloro - 2,3 - diaquo - 4,5,6 - triamminchromium(III) chloride are described. The crystals are orthorombic, space group *Pnma*, with $a = 13.230(2)$, $b = 10.545(1)$, $c = 6.754(1)$ Å, $V = 942.3(3)$, $Z = 4$. Least-squares refinement of the structure based on 529 observations led to final discrepancy indices of $R = 0.047$ and $R_w = 0.056$. The Cr atom is bonded to two water molecules, three ammonia molecules and one chlorine atom in a distorted octahedral coordination showing a *trans* chloro–aquo configuration.

While the hexaamine, pentammine and tetrammine complexes of Cr(III) are very well known in their synthetic, structural and reactivity aspects, the chemistry of the triammine species are not so well documented.

Four types of triammine complexes are known: triaquo complexes, $[Cr(NH_3)_3(H_2O)_3]X_3$; monoacidodiaquo complexes, $[Cr(NH_3)_3(H_2O)_2X]X_2$; diacidoaquo complexes, $[Cr(NH_3)_3(H_2O)X_2]X$; and triacido complexes, $[Cr(NH_3)_3X_3]$.[1]

The classical synthetic pathway to triammine complexes starts with the peroxo Cr(IV) species $[Cr(NH_3)_3(O_2)_2]$.[2] This compound affords different triammine Cr(III) complexes by hydrolytic decomposition, depending on the experimental conditions.[1,2]

As part of our thermomagnetic research plan involving double complexed salts[3] we tried to synthesize *cis*-$[Cr(NH_3)_4(H_2O)_2][FeCl_6]$ by mixing a solution of *cis*-$[Cr(NH_3)_4(H_2O)_2](ClO_4)_3$ in water with a solution of $FeCl_3$ in concentrated HCl. After a few days well-formed red crystals appeared which were shown by analysis and spectrophotometric measurements to be a triammine complex of Cr(III).

There are no examples of triamminecomplexes of Cr(III) fully characterized, so we have undertaken its complete characterization by X-ray analysis. To the best of our knowledge this is the first crystal structure of a triammine complex of Cr(III) reported in the literature. Furthermore we think our synthetic method is an easier pathway to triammine complexes than those already reported.

EXPERIMENTAL

Preparation

$[Cr(NH_3)_3(H_2O)_2Cl]Cl_2$ was prepared by dissolving the compound *cis*-$[Cr(NH_3)_4(H_2O)_2](ClO_4)_3$ (1.5 g) in H_2O (10 cm^3). The solution was filtered, poured on hot concentrated HCl and left to stand at room temperature for 2 days in the

* Author to whom correspondence should be addressed.

dark. The red crystals which formed were filtered, washed with EtOH and dried.

A few crystals suitable for X-ray analysis were collected from the main portion of the product. Chemical analyses were in agreement with the formula proposed.

X-ray crystallography

$[Cr(NH_3)_3(H_2O)_2Cl]Cl_2$, $Mw = 245.5$, orthorhombic, $a = 13.230(2)$, $b = 10.545(1)$, $c = 6.754(1)$ Å, $V = 942.3(3)$ Å^3, *Pnma*, $D_x = 1.730$ g cm^{-3}, $Z = 4$, $F(000) = 500$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu(\text{Mo-}K_\alpha) = 20.5$ cm^{-1}. Room temperature.

A red prismatic crystal ($0.07 \times 0.07 \times 0.12$ mm) was selected and mounted on a Philips PW-1100 four-circle diffractometer, and the unit-cell parameters were determined from 25 reflections and refined by least squares. Intensities were collected with graphite-monochromatized Mo-K_α radiation, using the ω-scan technique, (scan width 0.8°, scan speed 0.03 s^{-1}). 529 independent reflections were measured in the range $2 \leqslant \theta \leqslant 25$, 520 of which were assumed as observed by applying the condition $I > 2.5\sigma(I)$: three reflections were measured every 2 h as orientation and intensity control, no significant intensity decay was observed, and Lorentz-polarization corrections were made, but not absorption corrections.

The Cr atom was located from a Patterson synthesis, and the remaining non-hydrogen atoms from a weighted Fourier synthesis. The structure was isotropically and anisotropically refined by a full-matrix least-squares method using SHELX76.[4] The function minimized was $\Sigma w \|F_o| - |F_c\|^2$, where $w = [\sigma^2(F_o) + 0.0046|F_o|^2]^{-1}$. f, f' and f'' were taken from *International Tables of X-ray Crystallography*.[5] The final R factor was 0.047 ($R_w = 0.056$) for all observed reflections.

A diagram of the crystal structure and the numbering scheme used is shown in Fig. 1. Bond distances and bond angles are given in Table 1. Tables of atomic coordinates, anisotropic thermal parameters and the observed and calculated structure factors have been deposited with the Editors. Atomic coordinates and thermal parameters have also been deposited with the Institut für Anorganische Chemie, Bonn, F.R.G.

Electronic spectra

Electronic spectra were recorded in aqueous solution on a Shimadzu UV-240 spectrophotometer.

RESULTS AND DISCUSSION

The structure consists of discrete ions. The Cr atom is bonded to two water molecules, three ammonia molecules and one chlorine atom in a distorted octahedral coordination polyhedron, showing a *mer* configuration (Fig. 1). The Cr, Cl1, O1, O2 and N2 atoms lie on the crystallographic plane, the N and N1′ atoms being located symmetrically with reference to this mirror plane, but not on the axis of the ideal octahedron; their projection is inside the Cr, N2, O1 triangle. The largest deviations from an ideal octahedron are in the N1—Cr—N1′ and O1—Cr—O2 bond angles. The Cr—N distances are essentially equal, bu Cr—O1, *trans* to one chlorine atom, is slightly larger than Cr—O2, *trans* to one nitrogen atom.

There is only one isomer for the complex having a *fac* configuration of the triammine moiety, but two isomers for the *mer* configuration. On the basis

of spectrophotometric and ion-exchange studies Caldwell and House[2] assigned a *mer* configuration to all triammine complexes discussed in their paper: $[Cr(NH_3)_3(H_2O)_3]Cl_3$, $[Cr(NH_3)_3(H_2O)_2Cl]Cl_2$ and $[Cr(NH_3)_3(H_2O)Cl_2]Cl$. In addition a *trans*-chloroaquo and *trans*-dichloro configuration were assigned for the second and third aforementioned complexes, respectively, all of them basically synthesized from the peroxo species $[Cr(NH_3)_3(O_2)_2]$. Our results confirm these predictions, although we have obtained the triammine complex by a very different method, via a hydrolytic process from a tetrammine complex.

SYNTHESIS AND COMPLEXATION OF A NEW 1,1′-DISUBSTITUTED FERROCENE WITH TWO PENDANT CHELATING SITES OF AN α,β-UNSATURATED β-KETO AMINE SUBUNIT

MASAYOSHI ONISHI,* KATSUMA HIRAKI, SHUNJI WADA and YUSHICHIRO OHAMA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852, Japan

(*Received* 29 *July* 1986; *accepted* 4 *November* 1986)

Abstract—Condensation of 1,1′-bis(aminomethyl)ferrocene with acetylacetone gave 1,1′-bis(3 - methyl - 5 - oxo - 2 - aza - 3 - hexenyl)ferrocene in a 56% yield. In chloro-bridge splitting reactions of dinuclear cyclopalladated complexes of benzo[*h*]quinoline and *N*,*N*-dimethylbenzylamine, the condensed compound served as a binucleating ligand of an α,β-unsaturated β-keto aminate subunit. These new compounds formed were characterized by means of ^{1}H and ^{13}C NMR and IR spectroscopy. Their electrochemical properties were discussed also.

With the concept of using functionally substituted metallocenes as ligands in coordination compounds, a few ferrocenyl β-diketones were prepared, such as mono- and 1,1′-bis(benzoylacetyl)ferrocenes by Hauser and Cain[1] and (acetoacetyl)ferrocene by Imai and his coworkers,[2] and their coordination properties were examined towards some transition-metal ions. In this paper, we wish to report on the synthesis of a new 1,1′-disubstituted ferrocene with two pendant chelating sites of an α,β-unsaturated β-keto amine subunit, and its complexation as a bridging ligand between two metal centers.

RESULTS AND DISCUSSION

Condensation of 1,1′-bis(aminomethyl)ferrocene with acetylacetone† gave brown microcrystals of 1,1′ - bis(3 - methyl - 5 - oxo - 2 - aza - 3 - hexenyl)ferrocene (**I**) in a 56% yield. Although the solid material was stable in air, it decomposed slowly in halogenated organic solvents on exposure to air. In the mass spectrum of **I**, the parent ion was observed at *m*/*z* 408 in accordance with the proposed structure. The ^{1}H NMR spectrum in CD_2Cl_2 showed a broad singlet at δ *ca* 11.0 for the NH proton and a doublet ($^{3}J = 5.7$ Hz) at δ 4.14 for protons of the ferrocenyl-bonded methylene group on the nitrogen. In the ^{13}C NMR spectrum in CD_2Cl_2, there were signals at δ 194.8 and 162.5, assigned to the α,β-unsaturated carbonyl carbon (5-C) and the olefinic carbon (3-C) bonded to the nitrogen, respectively.‡ These findings indicated the α,β-unsaturated β-keto amine form of **I** in CD_2Cl_2, rather than the β-keto imine and β-imino enol ones. The indicated form was consistent with the IR data of **I** in CH_2Cl_2, showing bands at 1605, 1565, and 1510 cm^{-1}, and similar sets of IR bands were reported previously for some 4 - amino - 3 - penten - 2 - ones[4] with intramolecular hydrogen bonding.

A mixture of **I** and NaOEt in THF–EtOH was treated with chloro-bridged dinuclear cyclopalladated complexes prepared from benzo[*h*]quinoline[5] and *N*,*N*-dimethylbenzylamine,[6] affording complexes **II** and **III**, respectively, where compound **I** served as a binucleating bridging ligand via two pendant chelating sites of an α,β-unsaturated β-keto

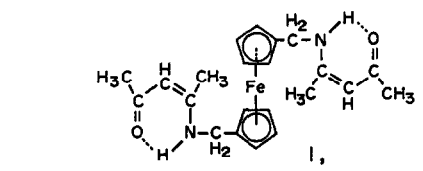
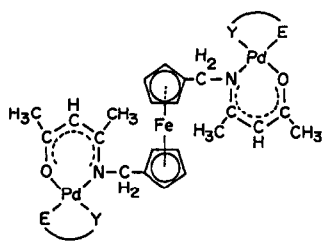
† Acetylacetone = 2,4-pentanedione.

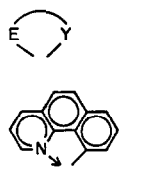
‡ Carbonyl carbons in alkyl methyl ketones resonate at δ more than 200, whereas those in planar α,β-unsaturated ketones resonate usually at around δ 196. Olefinic carbons bonded to amines are expected to show signals in the *ca* δ 148–165 region.[3]



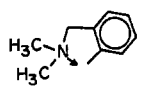
I,



2,



3,



aminate subunit towards two palladium centers. As for **III**, an analytically pure sample was not isolated owing to contamination of **I** in less than a tenth molar amount of **III**. Some decomposition of **III** was observed in the attempt to purify the crude product by column chromatography on silica gel.

Upon complexation with palladium, the NH proton resonance disappeared and the proton signal of the methylene group on the nitrogen turned into a singlet. In addition, the ^{13}C NMR spectrum of **II** showed an up-field shift of the carbonyl carbon resonance by *ca* 16 ppm from that of the free ligand **I**, and the resonance of the methylene carbon on the nitrogen moved down-field by *ca* 14 ppm. These ^{13}C-resonance shifts were due to increased contribution of the β-imino enolate form on chelate complexation with palladium.

Electrochemical experiments using platinum working electrodes were performed with CH_3CN solutions of test compounds containing 0.1 M $(Et_4N)PF_6$ as a supporting electrolyte. The reference electrode was a platinum wire immersed in an CH_3CN solution of 0.01 M $[Fe(C_5H_5)_2]$ and $[Fe(C_5H_5)_2]PF_6$ besides the supporting electrolyte. In the cyclic voltammogram of **I**, we observed an electrochemically reversible redox couple at *ca* 75 mV with a diffusion-controlled one-electron transfer, and attributed it to the Fe(II) ⇄ Fe(III) process

in the ferrocenyl moiety. A similar redox couple was found at *ca* 20 mV for **II**, and showed the decrease in electron density at the Fe redox center upon complexation with palladium.

EXPERIMENTAL

General procedures and materials

^1H and ^{13}C NMR spectra were run on JEOL model MH-100 and FX-90-Q spectrometers with tetramethylsilane as an internal standard. IR spectra were obtained using a JASCO IRA-1 spectrometer. Melting points were determined on a Yanagimoto MP-S3 microstage apparatus in capillary tubes sealed *in vacuo*, and are uncorrected.

The hydrochloride salt of 1,1′-bis(aminomethyl)ferrocene[7] and chloro-bridged cyclopalladated complexes[5,6] were prepared according to the reported methods. All the experiments were performed under dry nitrogen.

Preparation of 1,1′ - *bis*(3 - *methyl* - 5 - *oxo* - 2 - *aza* - 3 - *hexenyl*)*ferrocene* (**I**)

The hydrochloride salt (1.4 g, 4.4 mmol) of 1,1′-bis(aminomethyl)ferrocene in benzene (50 cm^3) was treated with NaOH in a small quantity of H_2O. The aqueous layer was removed with a separatory funnel, and its pH value was around 12. After drying the benzene layer over anhydrous $MgSO_4$, acetylacetone (4.4 cm^3) was added to the layer and the mixture was heated under reflux for 8 h, at which time the H_2O liberated was removed azeotropically by use of a Dean–Stark trap. Benzene and unreacted acetylacetone were evaporated *in vacuo* at room temperature. After washing the residue with hexane 3 times, recrystallization from diethyl ether and hexane gave a brown powder (1.0 g) (**I**) in a 56% yield. M.p. 85–86°C; IR (CH_2Cl_2) 1605(m), 1565(m), and 1510(w) cm^{-1}.

Found: C, 64.4; H, 7.0; N, 7.0. Calc. for $C_{22}H_{28}N_2FeO_2$: C, 64.7; H, 6.9: N, 6.9%.

Reaction of **I** *with chloro-bridged cyclopalladated complexes*

An EtOH solution (6 cm^3) of NaOEt (1.7 mmol) was added slowly to a THF suspension (50 cm^3) of material **I** (300 mg, 0.73 mmol) and the cyclopalladated complex (470 mg, 0.73 mmol) prepared from benzo[*h*]quinoline. After stirring overnight at room temperature and evaporation to dryness *in vacuo*, the residue was recrystallized from diethyl ether and hexane, affording a yellow powder (420 mg) (**II**) in a 59% yield. M.p. 136–139°C; IR (KBr) 1615(w), 1570(m), and 1503(m) cm^{-1}.

Found: C, 59.2; H, 4.5; N, 5.5. Calc. for $C_{48}H_{42}N_4FeO_2Pd_2$: C, 59.1; H, 4.3; N, 5.7%.

A similar reaction of **I** was performed with another cyclopalladated complex prepared from *N*,*N*-dimethylbenzylamine, and the corresponding complex **III** was obtained as a brown powder in a *ca* 70% yield. M.p. 90°C; IR (KBr) 1608(w), 1570(m), and 1500(m) cm^{-1}.

Electrochemistry

Electrochemical experiments were performed on millimolar concentrations of the ferrocenyl compounds in CH_3CN solutions (20 cm^3) of 0.1 M $(Et_4N)PF_6$ as the supporting electrolyte, using a conventional three-compartment electrochemical cell with a Hokuto Denko HA-301 potentiostat and a HB-104 function generater. The cell involved a Pt-disc or Pt-gauze working electrode, a Pt-wire auxiliary electrode, and a $[Fe(C_5H_5)_2]$–$[Fe(C_5H_5)_2]PF_6$ reference electrode. Scan rate was 100 mV s^{-1}.

COMPLEXING PROPERTIES OF NITRILOTRI(METHYLENEPHOSPHONIC) ACID WITH VARIOUS TRANSITION AND HEAVY METALS IN A 10:90 ETHANOL–WATER MEDIUM

B. SPIESS,* E. HARRAKA, D. WENCKER and P. LAUGEL

Laboratoire de Chimie Analytique, Faculté de Pharmacie 74, route du Rhin, 67048 Strasbourg Cedex, France

(*Received* 23 *September* 1986; *accepted* 4 *November* 1986)

Abstract—The nature and stability of some transition- and heavy-metal cation complexes of nitrilotri(methylenephosphonic) acid have been determined in 0.1 M $NaClO_4$ 10:90 ethanol–water solutions by means of pH metric measurements. In this medium stable 1:1 complexes and protonated species were found.

Among the numerous applications found for nitrilotri(methylenephosphonic) acid (NTP) and its salts is one that is concerned with the demetalization of wines, in particular the elimination of iron and copper.[1–7] Indeed such cations can lead to precipitations which make the wine unsuitable for selling as well as for consumption. These wines have then to be treated and the process recommended in Eastern European Countries uses NTP. An important feature of such a treatment is that all the compound has to be removed at the end of the process. It is therefore interesting to know if complexation can occur with the cations present in the wine, and if soluble complexes can remain in solution.

The purpose of the present work is to study at 25°C in a (10:90) ethanol–water medium ($I = 0.1$ M $NaClO_4$), the complex formation between NTP and some transition- and heavy-metal cations such as Fe^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} in order to determine their stability constants.

In the past several authors[8–12] have studied the complexation ability of NTP with some of these cations in aqueous solution. Their results are also reported here and compared with ours.

The nature of the protonated or complexed species and their stability constants are referred to in the following stepwise equilibria:

$$H_{(i-1)}L^{(7-i)-} + H^+ \rightleftharpoons H_iL^{(6-i)-},$$

$$K_{i1} = \frac{[H_iL^{(6-i)-}]}{[H_{(i-1)}L^{(7-i)-}][H^+]};$$

$$MH_{(i-1)}L^{(5-i)-} + H^+ \rightleftharpoons MH_iL^{(4-i)-},$$

$$K_{1i1} = \frac{[MH_iL^{(4-i)-}]}{[MH_{(i-1)}L^{(5-i)-}][H^+]};$$

$$i = 1, 2, 3, \ldots, 6.$$

These constants have been obtained by potentiometric titrations where solutions of the ligand NTP and metallic perchlorates of various stoichiometries have been titrated with NaOH. Details of the experimental procedure, the glass electrode conditioning and the calculation methods using the numerical program SCOGS[13] have been previously reported.[14]

Tables 1 and 2 contain our values of $\log K_{i1}$ and $\log K_{1i1}$, respectively, and those previously determined by several other authors in different media.

As shown in Table 1 only small differences can be observed between our values and those of Hendrickson[8] and Nikitina *et al.*[9] for $\log K_{21}$–$\log K_{51}$. The lower values determined by Carter *et al.*[10] could be due to the ionic strength they used ($I = 1$ M instead of 0.1 M used in the other experiments). Greater differences appear for the first and last con-

stants which are in general more difficult to determine. In our case only upper and lower limits are given.

The values of the logarithms of the stability constants were obtained from a minimum of two experiments for which the ratio of the metal to the ligand concentration was generally about 1 and 0.5. In the calculations the values of the protonation constants were kept constant and $\log \beta_{11}$ was fixed at 12.00. The results show that only the formation of 1:1 complexes and protonated species occur in the pH range studied. Although the determinations were performed in different media, the results are in good agreement with the previous studies of Morozova *et al.*,[11] with the exception of the ZnL complex. On the other hand we were not able to find any evidence of the CuH_4L and ZnH_4L species.

Other results (Table 2) concerning the complexation of transition cations such as Co^{2+}, Ni^{2+} and Fe^{2+} have been collected from the literature.[8,11,12] It would appear, if one considers the whole set of constants, that, except for Ni^{2+}, the cations of the first transition row follow for the ML complexes the Irving–Williams rule.[15] This states that there is an increase in stability from Mn^{2+} to Cu^{2+}, then a decrease for Zn^{2+}. By contrast the complexes of the MH_iL type do not follow this same rule and, moreover, the values of the constants are close together. It seems possible that the selectivity which is observed for the ML complexes is determined by the bonding of the metallic cations and the lone pair on the nitrogen group. Taking into account the high value of $\log K_{11}$ which is related to the protonation of the amine, it is possible that the formation of monoprotonated complexes arises from the fixation of H^+ on the

nitrogen atom. This would mask a coordination site and at the same time introduce a positive charge. The only available coordination sites would then be the oxygen atoms of the phosphonic groups for which the transition-metal cations show lower affinities as pointed out in Pearson's HSAB principle.[16]

Concluding our study, it clearly appears that NTP can form stable soluble complexes with some cations present in the wine. It is likely that the same can occur in this medium when it is treated with NTP.

(*Received* 29 *September* 1986; *accepted* 4 *November* 1986)

Abstract—The extraction of Ni(II) from nitrate media of ionic strength 1.0 mol dm^{-3} by di-*n*-octylphosphinic acid (HR) in toluene solution has been studied over a range of pH and reagent concentrations. The data have been analysed both graphically and numerically to determine the stoichiometry of the extracted complexes and their extraction constants. Evidence was found for the formation of both $NiR_2(HR)_4$ ($\log K_{24} = -9.14 \pm 0.06$) and $NiR_2(HR)_2$ ($\log K_{22} = -7.35 \pm 0.10$), the former being the predominant species although the latter is important at low reagent concentrations and high pH values.

Interest in the extraction of nickel by organophosphorus extractants has recently increased with the introduction of the commercial reagents based on di-(2-ethylhexyl)phosphonic acid (PC88A Daihatchi Chemical Co.) and bis-2,4,4-trimethylpentylphosphinic acid (Cyanex 272 American Cyanamid Inc.). These reagents have found particular application in the separation of cobalt from nickel in sulphate media.[1,2] Fundamental studies of nickel extraction by organophosphorus acids have largely been confined to di-(2-ethylhexyl)phosphoric acid where the stoichiometries $NiR_2(HR)_2$ and NiR_2, $(HR)_2$ representing the dimer of the organophosphorus acid, have been proposed.[3–5] Extraction experiments with the commercial phosphonic acid ester have also indicated from slope analysis the formation of nickel complexes of type $NiR_2(H_2R_2)_{2+x}(H_2O)_{2-x}$, with $x = o$, 1 or 2 depending on the reagent concentration.[1] Recently, Danesi *et al.*[6] studied the extraction equilibria of Ni(II) and Co(II) by purified Cyanex 272 in toluene and postulated the formation of $NiR_2(HR)_4$ species.

However, because of the presence of impurities of unknown composition and concentration in these industrial reagents it is essential to use pure synthesized reagents in any fundamental studies of metal extraction. This paper is therefore concerned with the complexes involved in the extraction of nickel by di-*n*-octylphosphinic acid (HR) and represents an intermediate step in the interpretation of the distribution data in the Ni(II)–LIX 63–HR system. The object of the work is to determine the composition of the metallic species extracted as well as their extraction constants.

EXPERIMENTAL

Reagents

HR was prepared according to Peppard *et al.*[7] by the reaction of octene-1 and hypophosphorous acid using benzoyl peroxide as catalyst. The product after extraction from the reaction mixture was recrystallized several times from hexane as white crystals, m.p. 84°C (literature 84°C[7]). Nickel nitrate, $Ni(NO_3)_2 \cdot 6H_2O$ (Carlo Erba p.a.), was from twice distilled water. Sodium nitrate, toluene, sodium hydroxide and nitric acid (Merck, p.a.) were used as supplied.

Experimental procedure

Experimental data of the distribution coefficient were collected for several total HR concentrations as a function of pH. Organic solutions of HR in toluene in the concentration range 0.020 up to 0.200 mol dm^{-3} were mixed with aqueous phases consisting of 0.5×10^{-3} mol dm^{-3} Ni(II), 1.0 mol dm^{-3} $NaNO_3$ and pH varied from 4 to approximately 7.

Equal volumes (10 cm^3) of organic and aqueous phases were mechanically shaken in special stoppered tubes until equilibrium had been attained (less than 15 min). The pH was measured using a Radio-

* Author to whom correspondence should be addressed.

meter pHM 64 meter, fitted with a GK2322C Radiometer combined glass electrode, standardized with buffer solutions of pH 4.00 and 7.00 at 293 K. Nickel concentration in both phases was measured by atomic absorption spectroscopy (Perkin–Elmer 560). In order to determine the organic metal concentration the nickel was first stripped from organic phases with 1.0 mol dm^{-3} nitric acid solutions.

GRAPHICAL TREATMENT OF THE DATA

The extraction of NI(II) by HR dissolved in toluene may be described by the following general equation:

$$Ni^{2+} + \tfrac{1}{2}(p+q)(HR)_{2org} \rightleftharpoons NiR_p(HR)_{q\,org} + pH^+, \quad (1)$$

where HR stands for the organic acid which behaves as a dimer in aromatic solvents.[7]

K_{pq} being the stoichiometric equilibrium constant for reaction (1), the distribution coefficient of Ni(II) can be expressed as:

$$D = \sum_p \sum_q K_{pq} \alpha_{Ni}^{-1} [(HR)_2]_{org}^{(p+q)/2} [H^+]^{-p}, \quad (2)$$

where α_{Ni} represents the side-reaction coefficient due to the formation of nitrate complexes in the aqueous phase.[8] Taking into account the experimental conditions used, the formation of hydroxo complexes of Ni(II) can be considered as negligible.

Experimental data in the form $\log D$ vs pH at several HR concentrations are illustrated in Fig. 1, where straight lines of slope value 2.0 are obtained. If the extraction of a single species is assumed, eqn (2) becomes:

$$\log D = \log K_{pq} \alpha_{Ni}^{-1} + \tfrac{1}{2}(p+q) \log [(HR)_2]_{org} + p\text{pH}. \quad (3)$$

Experimental functions, $\log D = f(\text{pH})$, defined by eqn (3) have been compared with the theoretical model function:

$$\log D = -p \log V = f(\log V) \quad (4)$$

for different values of the parameter p, V being a normalized variable defined by:

$$V = (K_{pq} \alpha_{Ni}^{-1} [(HR)_2]_{org}^{(p+q)/2})^{-1/p} [H^+]. \quad (5)$$

The best fit between both functions was obtained for $p = 2$, as can be seen in Fig. 1. The differences on the X-axis are functions of $\log [(HR)_2]_{org}$ according to:

$$\log V + \text{pH} = -\frac{1}{p} \log K_{pq} \alpha_{Ni}^{-1} - \frac{p+q}{2p} \log [(HR)_2]_{org}, \quad (6)$$

which are represented in Fig. 2. The value of the slope of the straight line obtained, -1.5, indicates that $q = 4$. From the intercept on Y-axis the value $\log K_{24} = -7.33$ was determined for the extraction of the species $NiR_2(HR)_4$.

As it can be noticed in Fig. 2, it seems that the experimental points at the lowest HR concentrations deviate from the straight line. This can be interpreted in terms of the formation of metallic species with a different solvation number in the organic phase. In order to determine if q can take values other than 4, a curve-fitting analysis has been

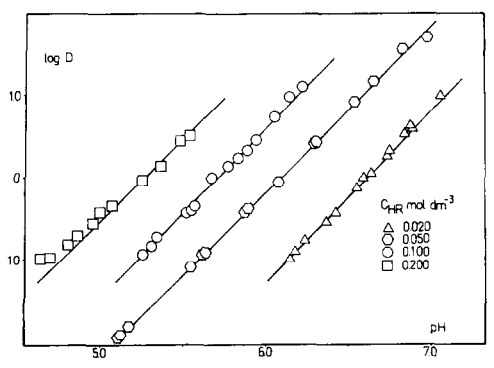

Fig. 1. Variation of the distribution coefficient of Ni(II) with pH at several total concentrations of di-*n*-octylphosphinic acid (HR). Continuous lines represent the normalized function $\log D = f(\log V)_p$ in the best-fit position ($p = 2$).

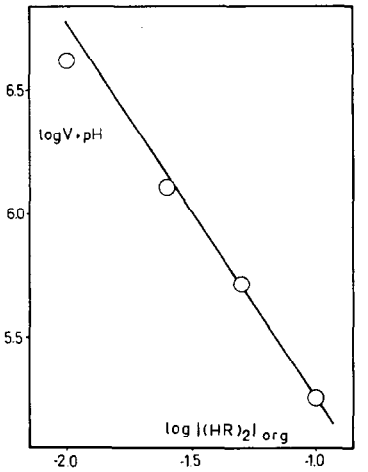

Fig. 2. Differences on X-axis from Fig. 1 as a function of $\log [(HR)_2]_{org}$.

made assuming the formation of species $NiR_2(HR)_n$ as well as the main species $NiR_2(HR)_4$.

With K_{24} and K_{2n} being the respective extraction constants of the above species, the distribution coefficient of Ni(II) can be expressed as:

$$D = K_{24}\alpha_{Ni}^{-1}[(HR)_2]_{org}^3[H^+]^{-2} + K_{2n}\alpha_{Ni}^{-1}[(HR)_2]_{org}^{(n+2)/2}[H^+]^{-2}, \quad (7)$$

which can be rearranged to give:

$$D[H^+]^2\alpha_{Ni}^{-1}K_{24}^{-1}[(HR)_2]_{org}^{-3} = 1 + K_{2n}K_{24}^{-1}[(HR)_2]_{org}^{(n-4)/2}. \quad (8)$$

Defining the new normalized variables:

$$Y = D[H^+]^2\alpha_{Ni}^{-1}K_{24}^{-1}[(HR)_2]_{org}^{-3}, \quad (9)$$

$$X = (K_{2n}K_{24}^{-1})^{(n-4)/2}[(HR)_2]_{org}, \quad (10)$$

and the parameter:

$$i = (n-4)/2, \quad (11)$$

the experimental functions $\log D - 2pH - 3\log[(HR)_2]_{org} = f(\log[(HR)_2]_{org})$ have been compared with the model function:

$$\log Y = \log(1+X^i) = f(\log X) \quad (12)$$

for different values of the parameter i. The experimental functions were obtained from Fig. 1 at different constant values corresponding to 25, 50 and 75% extraction at the different total reagent concentrations. Figure 3 shows the comparison of the experimental functions (it can be noticed that data for each concentration coincide) and the theoretical ones at different i values. The best fit was obtained for $i = -1$; that means, according to eqn (11), $n = 2$.

From the position of best fit in Fig. 3, differences on both axes, according to eqns (9) and (10), let us determine the values of the extraction constants, yielding the values $\log K_{24} = -7.37$ and $\log K_{22} = -9.22$.

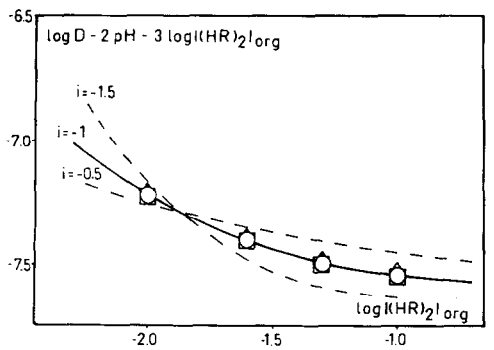

Fig. 3. Comparison of the experimental function defined by eqn (8) and the theoretical functions defined by eqn (12) for different values of the parameter i.

NUMERICAL TREATMENT OF THE DATA

In order to refine the equilibrium constant values graphically obtained and to search for a new combination of species which could improve the fit to the experimental data, a numerical treatment was carried out using the LETAGROP-DISTR program.[9] In this treatment the function to be minimized was the error square sum (U) defined by:

$$U = \sum_{N_p}(\log D_{calc} - \log D_{exp})^2, \quad (13)$$

where D_{exp} represents the experimental distribution coefficient, D_{calc} the corresponding magnitude calculated by the program assuming a certain set of species and constants, and N_p the number of experimental data. For each combination of species tried the program calculates both U_{min} and the mean standard deviation $[\sigma(\log D)]$.

Table 1 summarizes the results of the numerical calculations, being the best fit obtained with the model of species graphically ascertained. In Table 2 values of the stoichiometric extraction constants are given and the uncertainties in the constants refer to $\pm 3\sigma(\log K)$. The fit to the data is illustrated in Fig. 4, where the standard deviation for each experimental point is plotted as a function of pH, showing the absence of systematic deviations.

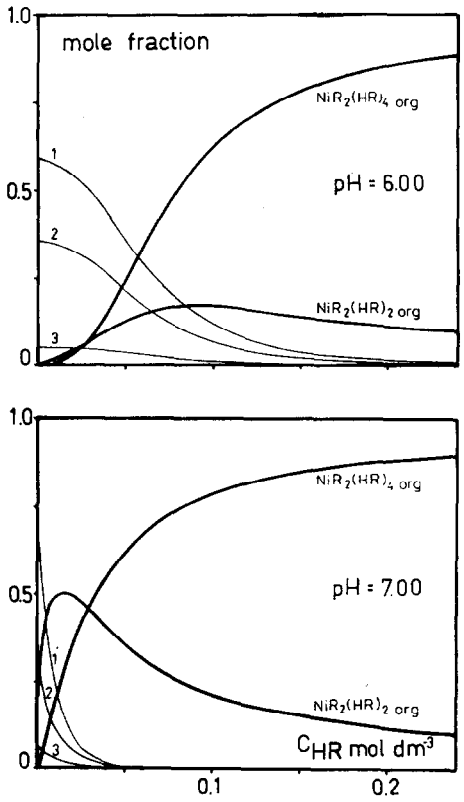

Fig. 5. Nickel distribution diagrams as a function of the total concentration of di-*n*-octylphosphinic acid (HR) at two selected pH values. Lines 1, 2 and 3 represent, respectively, Ni^{2+}, $NiNO_3^+$ and $Ni(NO_3)_2$ species in the aqueous phase.

CONCLUSIONS

The results of the work indicate that the extraction of Ni(II) from nitrate medium by HR dissolved in toluene can be explained assuming the formation of the species $NiR_2(HR)_4$ and $NiR_2(HR)_2$. If compared with the extraction of Ni(II) by di-(2-ethylhexyl)phosphoric acid (DEHPA)[5] it must be pointed out that the extractant ability of HR is lower than that from DEHPA since the extraction occurs at higher pH values under the same conditions. On the other hand, the composition of the extracted species is similar in both cases although there is a difference in the solvation number, HR having more solvating ability than DEHPA.

Figure 5 shows the distribution diagram of Ni(II) species as a function of the total reagent concentration at selected pH levels. It can be seen that $NiR_2(HR)_4$ is the predominant species extracted, but the contribution of the species $NiR_2(HR)_2$ is important at high pH levels and low HR concentration.

SULPHUR–ARSENIC LIGANDS: SYNTHESIS AND CHARACTERIZATION OF SOME RHENIUM(I), RUTHENIUM(II), RHODIUM(III) AND GOLD(I) COMPLEXES OF BIS(DIMETHYLARSINO)SULPHIDE($Me_2AsSAsMe_2$) AND DIMETHYL(METHYLTHIO)ARSINE(Me_2AsSMe)

EDWARD W. ABEL* and MICHAEL A. BECKETT

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 23 *October* 1986; *accepted* 4 *November* 1986)

Abstract—The complexes $[\{RuCl_2(CO)_3\}_2(Me_2AsSAsMe_2)]$, $[RuCl_2(CO)_2(Me_2AsSAsMe_2)_2]$, $[RuCl_2(CO)_2(Me_2AsSMe)_2]$, $[ReX(CO)_3(Me_2AsSAsMe_2)]$ (X = Cl, Br or I), $[RhCl_2(C_5Me_5)(Me_2AsSMe)]$, $[AuCl(Me_2AsSMe)]$ and $[(AuCl)_2(Me_2AsSAsMe_2)]$ have been synthesized from the electron-rich ligands $Me_2AsSAsMe_2$ and Me_2AsSMe. IR and NMR spectrometry along with mass spectra have given sufficient data to indicate structures for all of these products. In all complexes of both ligands, binding to metal is invariably via arsenic and not sulphur. $Me_2AsSAsMe_2$ has now been shown to be capable of monodentate, bridging and chelating modes of complexation.

The use of bis(dimethylarsino)sulphide, $Me_2AsSAsMe_2$ (dmas) and dimethyl(methylthio) arsine, Me_2AsSMe (dmmta) as ligands has received little reported attention. Earlier work on both $Me_2AsSAsMe_2$[1] and Me_2AsSMe[2–5] was restricted to group VI metal pentacarbonyl derivatives, and we have recently investigated reactions with Pt(IV)[6] and Re(I)[6,7] compounds. Despite the availability of potential ligand electrons on both arsenic and sulphur atoms, all products characterized to date have been exclusively arsenic-bound. Herein we have extended our investigation of these two arsenic ligands to report the action of $Me_2AsSAsMe_2$ and Me_2AsSMe upon $[\{RuCl_2(CO)_3\}_2]$, $[\{RhCl_2(C_5Me_5)\}_2]$ and $[AuCl(SMe_2)]$, and the action of $Me_2AsSAsMe_2$ upon the $[ReX(CO)_5]$ halides.

EXPERIMENTAL

General

Reactions were carried out using standard Schlenk conditions under nitrogen, with solvents distilled under nitrogen from an appropriate drying agent. Dmas and dmmta were prepared by reported methods.[7–9] $[AuCl(SMe_2)]$,[10] $[ReX(CO)_5]$[11] and $[\{RhCl_2(C_5Me_5)\}_2]$[12] were also prepared by standard techniques and $[\{RuCl_2(CO)_3\}_2]$ was used as supplied by Johnson–Matthey. The methods used in the syntheses of the metal complexes were very similar and are typified by the examples below. Reaction times, yields, m.ps and analytical data for the products are summarized in Table 1.

Preparation of $[RuCl_2(CO)_2(Me_2AsSAsMe_2)_2]$

To a solution of $[\{RuCl_2(CO)_3\}_2]$ (200 mg, 0.39 mmol) in thf (5 cm^3) was added $Me_2AsSAsMe_2$ (430 mg, 1.78 mmol). After *ca* 1 min a white precipitate had formed (this was the binuclear $[\{RuCl_2(CO)_3\}_2(Me_2AsSAsMe_2)]$ which could be isolated by rapid filtration at this stage and characterized), but subsequent heating under reflux (2 h) produced a clear yellow solution. Low-pressure removal of solvent left a yellow deposit which was extracted at 40°C with 60–80°C light petroleum. Cooling of the filtered extract overnight to −20°C gave pale yellow crystals of the product $[RuCl_2(CO)_2(Me_2AsSAsMe_2)_2]$ (110 mg, 20%).

Preparation of $[ReBr(CO)_3(Me_2AsSAsMe_2)]$

To a solution of $[ReBr(CO)_5]$ (250 mg, 0.61 mmol) in thf (5 cm^3) was added $Me_2AsSAsMe_2$

(170 mg, 0.70 mmol), and the reaction mixture placed under reflux for 24 h. Solvent was removed at low pressure and the residue redissolved in chloroform (2 cm^3). Subsequent addition of 60–80°C light petroleum (5 cm^3) produced a precipitate of the crude product, which was then redissolved in $CHCl_3$ 60–80°C petrol and cooled to −20°C overnight to yield yellow crystals (180 mg, 51%).

NMR studies

^1H and ^{13}C experiments were performed on a Bruker AM 250 instrument at 250 and 62.8 MHz, respectively. All samples were dissolved in $CDCl_3$ and spectra were recorded at ambient temperature.

RESULTS AND DISCUSSION

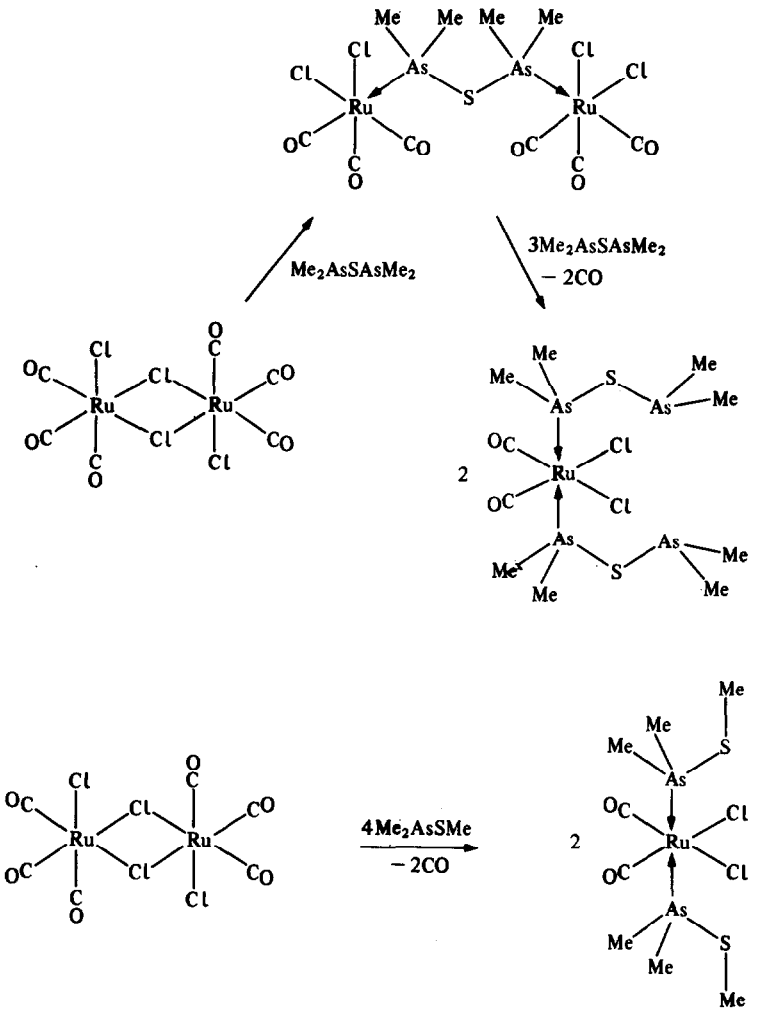
Reactions and syntheses

The ruthenium(II) dimer $[\{RuCl_2(CO)_3\}_2]$ undergoes reaction with $Me_2AsSAsMe_2$ at room temperature without evolution of carbon monoxide to break the halogen bridges and, in effect, become inserted between the two halves of the dimer. The IR spectrum of this product in the metal carbonyl region shows three distinct bands suggesting a *fac* orientation of the three carbonyl groups about the ruthenium(II) centres. If the binuclear product is not isolated from the cold reaction mixture, heating under reflux causes the precipitate to redissolve with evolution of carbon monoxide. From the resulting yellow solution *cis, cis, trans*-$[RuCl_2(CO)_2(Me_2AsSAsMe_2)_2]$ may be isolated. The metal carbonyl stretching region now shows two bands, indicating the mutually *cis* nature of the carbonyl groups, and the ^1H NMR spectrum is consistent with two arsenic-bonded monodentate $Me_2AsSAsMe_2$ ligands mutually *trans* on the ruthenium(II) centre (*vide infra*). When $[RuCl_2(CO)_2(Me_2AsSAsMe_2)_2]$ was heated under reflux in thf further carbon monoxide was evolved. This was presumably due to carbon monoxide displacement by non-bonding arsenic atoms. The hope that what would be formed was the bis chelate complex, $[RuCl_2(Me_2AsSAsMe_2)_2]$, was not realized. The product was polymeric, presumably with $Me_2AsSAsMe_2$ linkages between $RuCl_2$ units.

$[\{RuCl_2(CO)_3\}_2]$ and Me_2AsSMe in thf undergo reaction in 4 days at room temperature to produce $[RuCl_2(CO)_2(Me_2AsSMe)_2]$ in good yield. The reaction is complete in 2 h under reflux and no other product was isolated.

The configuration of the product as *cis, cis, trans*-$[RuCl_2(CO)_2(Me_2AsSMe)_2]$ is evident from IR and ^1H NMR data. This *trans*-Me_2AsSMe complex underwent no decomposition or rearrangement upon prolonged heating under reflux in thf. ^1H NMR measurements indicated bonding of the ligand via arsenic, with no indication that the sulphur could be brought into coordination.

Me_2AsSMe has already been reported to displace carbon monoxide from rhenium pentacarbonyl halides[7] with the formation of *fac*-$[ReX(CO)_3$



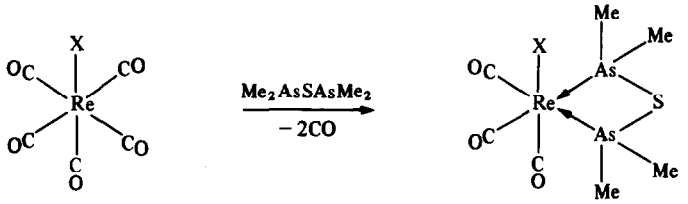
$(Me_2AsSMe)_2$] complexes. We have now reacted the rhenium carbonyl halides with $Me_2AsSAsMe_2$ in thf to produce crystalline air-stable products with stoichiometry $[ReX(CO)_3(Me_2AsSAsMe_2)]$. IR spectra indicate a *fac* configuration about rhenium, and the mass spectrum of $[ReCl(CO)_3(Me_2AsSAsMe_2)]$ shows a strong M^+ at *m/z* 550 (^{37}Cl, ^{187}Re) with a total absence of any signal at *m/z ca* 1100. This along with ^1H NMR evidence points to a *fac* mononuclear type of complex.

The halogen bridge in $[\{RhCl_2(C_5Me_5)\}_2]$ undergoes rapid fission at room temperature upon treatment with Me_2AsSMe in chloroform.

The $[RhCl_2(C_5Me_5)(Me_2AsSMe)]$ produced is again characterized as having arsenic coordinated to the rhodium centre.

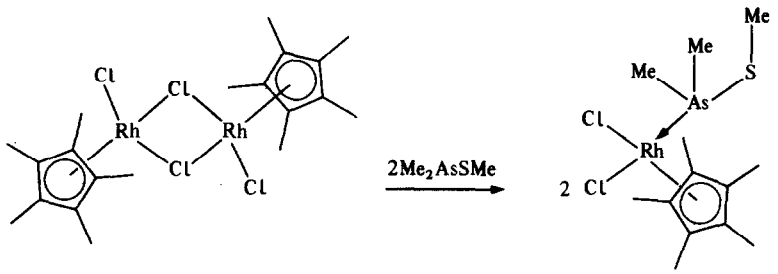
$Me_2AsSAsMe_2$ also underwent rapid reaction at room temperature in chloroform, but we have been unable to isolate and purify a stable product.

Monometallic and bimetallic gold(I) complexes



To date transition-metal complexes of $Me_2AsSAsMe_2$ have been reported in which the ligand has either a monodentate or a bridging role. These rhenium complexes are the first to demonstrate that $Me_2AsSAsMe_2$ is capable of chelation at a metal centre.

of formulae [ClAuL] and [ClAuL–LAuCl] are conveniently prepared[10] by the reaction of a monodentate or bidentate ligand, respectively, upon $[AuCl(SMe_2)]$. Accordingly, we have investigated the reactions of both $Me_2AsSAsMe_2$ and Me_2AsSMe upon the gold compound. In both reac-



tions there was rapid production of air- and light-sensitive white insoluble precipitates. Persistent washing and vacuum drying gave complexes whose analyses (Table 1) corresponded closely to [AuCl(Me_2AsSMe)] and [ClAu($Me_2AsSAsMe_2$)AuCl]. The insoluble and amorphous nature of the products prevented further characterization, and suggested that they were polymers.

NMR studies

The ^1H NMR data for the rhenium(I), ruthenium(II) and rhodium(III) complexes of Me_2AsSMe and $Me_2AsSAsMe_2$ are listed in Table 2. The use of this information for the ascertainment of product structures is outlined below.

The mononuclear complexes [$RuCl_2(CO)_2(Me_2AsSMe)_2$] and [$RuCl_2(CO)_2(Me_2AsSAsMe_2)_2$] have *cis* carbonyl groups and one sharp resonance for the coordinated arsenic-methyl protons. This is inconsistent with the arsenic and chlorine ligands being in the *cis*, *cis* configuration. Either two halogens or two arsines are mutually *trans*. The problem is analogous to the corresponding dimethylphenylphosphine complex [$RuCl_2(CO)_2(PMe_2Ph)_2$] where the assignment *cis* dichloro, *cis* dicarbonyl and *trans* diphosphine was arrived at[13] by virtual coupling arguments. On this basis we favour the analogous configuration for both of our arsenic complexes.

These arsine complexes both show a single ^1H signal for the coordinated arsenic-methyl protons and one signal for the free $AsMe_2$ or SMe protons. The coordinated arsenic-methyl protons resonate *ca* 0.5 ppm downfield from the free-ligand values, whilst the uncoordinated $AsMe_2$/SMe protons are deshielding by only *ca* 0.1 ppm. This behaviour has been noted previously,[6,7] and does enable the ligand bonding mode via arsenic to be clearly defined. The binuclear complex [$Cl_2(CO)_3Ru(Me_2AsSAsMe_2)Ru(CO)_3Cl_2$] has extremely low solubility, but did give one ^1H signal only at δ 2.37 ppm. This was assignable to the protons of the four identical methyl groups where the presence of two metal atoms causes a larger deshielding than observed in the mononuclear complexes, an observation already noted[1] for analogous binuclear metal pentacarbonyl derivatives.

The ^1H NMR spectra of the *fac*-[$ReX(CO)_3(Me_2AsSAsMe_2)$] complexes all show a doublet centred at *ca* 0.5 ppm downfield from the free ligand, suggesting that both arsenic centres are co-ordinated to rhenium in a chelate structure. The two different methyl environments of the doublet lie, respectively, on the halogen and carbonyl sides of the ReAsSAs plane of the molecule. There is a

Table 2. IR and NMR data for metal complexes of Me_2AsSMe and $Me_2AsSAsMe_2$

Complex	ν_{CO}[a] (cm^{-1})	^1H (ppm)		
		Coordinated Me_2As	Free Me_2As	MeS
[{$RuCl_2(CO)_3$}$_2(Me_2AsSAsMe_2)$]	2142, 2088, 2045[b]	2.37		
[$RuCl_2(CO)_2(Me_2AsSAsMe_2)_2$]	2057, 1992	2.05	1.52	
[$RuCl_2(CO)_2(Me_2AsSMe)_2$]	2058, 1992	2.00		2.44
[$ReCl(CO)_3(Me_2AsSAsMe_2)$]	2032, 1950, 1905	2.09, 1.96		
[$ReBr(CO)_3(Me_2AsSAsMe_2)$]	2030, 1952, 1905	2.10, 2.02		
[$ReI(CO)_3(Me_2AsSAsMe_2)$]	2030, 1953, 1906	2.15, 2.14		
[$RhCl_2(C_5Me_2)(Me_2AsSMe)$][c]		1.81		2.32

[a] In chloroform solution unless otherwise stated.

[b] Nujol mull.

[c] ^1H: C_5Me_5, δ 1.74; $\delta(^{13}C)$: +97.4 [^1J(Rh–C) 7.5 Hz], C_5Me_5; +9.1, C_5Me_5; +12.9 [^2J(Rh–As–C), 1.5 Hz], $AsMe_2$; +12.0, SMe.

notable *cis* effect in these complexes, where the methyl protons are shifted increasingly downfield on progressing along the series Cl, Br, I. This trend has been similarly noted for the corresponding *fac*-$[ReX(CO)_3(Me_2AsSMe)_2]$ complexes.[7]

The ^1H NMR spectrum of $[RhCl_2(C_5Me_5)(Me_2AsSMe)]$ consists of the three expected singlets of relative intensity 15 : 6 : 3 from high to low field, respectively. The arsenic-methyl protons are shifted by coordination further downfield (relative to the free ligand than are the sulphur-methyl protons suggesting an arsenic–rhodium-bound ligand. Further, whilst ^{103}Rh coupling is not observed to any of the protons in the molecule, our $^{13}C-\{^1H\}_{sel}$ experiments correlate the arsenic-methyl protons with a carbon resonance coupled to ^{103}Rh (^2J *ca* 1.5 Hz), in the absence of a comparable (^3J) coupling to the sulphur-methyl carbon.

Abstract—The complexes [M(dppe)(μ_2-SMe)$_2$PtXMe$_3$] [M = Pd or Pt; X = Cl, Br or I; dppe = 1,2-bis(diphenylphosphino)ethane] have been synthesized, and by means of ^{1}H and ^{31}P variable-temperature NMR studies are shown to have several different fluxional modes. Where possible, accurate activation parameters for the processes have been determined. The unexpected trends of these values demonstrate the consequences of the presence of the four-membered Pt(IV)—S—M(II)—S ring. The structure of a representative member of this novel range of complexes, [Pt(dppe)(μ_2-SMe)$_2$PtClMe$_3$], has been determined by X-ray diffraction methods.

Since the earliest observations[1] of fluxionality in transition-metal complexes the field has greatly proliferated.[2–4] In many cases the occurrence of stereochemical non-rigidity is facilitated by or dependent upon the presence of the transition metal(s). Large numbers of these species exhibit transitions with values of activation free energy change $\Delta G^{\ddagger}$ in the range 35–100 kJ mol^{-1}, which enables them to be conveniently studied by DNMR techniques. The organochalcogen complexes of the trimethylplatinum halides fall into this category and have been studied extensively.[4] Pyramidal chalcogen atom inversion is commonly observed in such compounds, along with, in many cases, higher-energy processes which involve very considerable bond reorganization. As a further step in our investigation of the factors influencing the stereodynamics and energetics of such systems we have prepared and studied the thiolato complexes [M(dppe)(μ_2-SMe)$_2$PtXMe$_3$], (M = Pd or Pt; X = Cl, Br or I).

Mononuclear metal thiolato complexes have been utilized in the preparation of a range of heteronuclear transition-metal complexes,[5] and in some of these species stereochemical non-rigidity has been observed, and comparisons made between thiolato complex metalloligands and thioethers.[6] Quantitative studies of fluxionality of these thiolato-bridged species are to date rare, and we have now examined them by full DNMR bandshape analysis.

EXPERIMENTAL

Materials

The following were prepared using previously reported procedures: [M(dppe)(SMe)$_2$] (M = Pd or Pt),[6] [{PtXMe$_3$}$_4$][7,8] (X = Cl, Br or I), [Pd(dppe)Cl$_2$],[9] and [Pt(PPh$_3$)$_4$].[10]

Complexes

$[M(dppe)(\mu_2\text{-}SMe)_2PtXMe_3]$ (M = Pd *or* Pt; X = Cl, Br *or* I). All of these complexes were prepared in a similar manner and a representative example is described.

A benzene (10 cm^3) suspension of $[Pt(dppe)(SMe)_2]$ (0.11 g, 0.16 mmol) was treated with $[\{PtClMe_3\}_4]$ (0.47 g, 0.042 mmol). The mixture was stirred for 4 h until the solution lost all trace of the yellow $[Pt(dppe)(SMe)_2]$. The resulting white precipitate was collected by decantation. This crude product was recrystallized from chloroform (14 cm^3) and hexane (20 cm^3) by layer diffusion at −10°C, giving colourless prisms of $[Pt(dppe)(\mu_2\text{-}SMe)_2PtClMe_3]$ (**1**) (0.13 g, 84%).

Complexes **2**–**6** were prepared by the same procedure, with the following reaction times and yields:

Complex	Reaction time (h)	Yield (%)
$[Pt(dppe)(\mu_2\text{-}SMe)_2PtBrMe_3]$ (**2**)	5	89
$[Pt(dppe)(\mu_2\text{-}SMe)_2PtIMe_3]$ (**3**)	8	94
$[Pd(dppe)(\mu_2\text{-}SMe)_2PtClMe_3]$ (**4**)	3	91
$[Pd(dppe)(\mu_2\text{-}SMe)_2PtBrMe_3]$ (**5**)	10	63
$[Pd(dppe)(\mu_2\text{-}SMe)_2PtIMe_3]$ (**6**)	16	36

All of the complexes were isolated as air-stable crystals. The compounds were only moderately soluble in benzene and toluene, but were very soluble in dichloromethane, chloroform and nitrobenzene. Solutions of the compounds in chlorohydrocarbon solvents tended to react over a period of days to produce $[\{PtMe_3(SMe)\}_4]$ and $[M(dppe)Cl_2]$.

Characterization data for complexes **1**–**6** are given in Table 1.

Preparation of [PdS—CH(Me)—CH_2—S(dppe)]. A suspension of $[Pd(dppe)Cl_2]$ (0.50 g, 0.87 mmol) in toluene (50 cm^3) was stirred with 1,2-propanedithiol (2 cm^3) and triethylamine (4 cm^3) for 3 h. Diethylether (200 cm^3) was added to this mixture and the precipitated triethylamine hydrochloride was removed by filtration. The resulting yellow solution was cooled to −5°C yielding large yellow needles of [PdS—CH(Me)—CH_2—S(dppe)] (**7**) (0.48 g, 98%) ^{31}P NMR ($CDCl_3$): δ (ppm) = 49.7 and 50.1, relative to 85% H_3PO_4 (ext.), J(P–P) (Hz) = 32.1.
