HARRY IRVING: A TRIBUTE

R. J. P. WILLIAMS and R. D. GILLARD

Harry Irving was born on 19 November 1905, and has recently, close to his eightieth birthday, retired from the Chair of Analytical Science (which he founded in 1979) at the University of Cape Town. He spent much of the earlier part of his career in Oxford, until he moved to Leeds in 1961 as Professor of Inorganic and Structural Chemistry.

He was initially an organic chemist, becoming later active in analytical and coordination chemistry, but his interests have always remained unusually wide, ranging over the whole field of solution and structural chemistry. It is intriguing that the second and the penultimate paper (separated by 55 years!) in his remarkably varied list of work both deal with a chloral hydrate.

Irving's seminal contributions are chiefly in the area of the relations between the stability of metal complexes of ligands and their structures (both of the ligands and of the complexes). A few of these classes of ligands (such as dithizones, amino-alcohols and complexones: he was of course the translator of Schwarzenbach's book in 1957) are represented in this collection of papers in his honour.

Professor Irving was remarkably percipient in introducing new ideas: quite apart from the Irving–Williams series, he commented very early on steric hindrance influencing stability constants, on kinetic properties of metal ions, on conformations of chelate rings, on solvent extraction in inorganic analysis, and on synergic effects in equilibria. It is salutary to realize that his first doctoral student was R. J. P. Williams (from 1948 when Professor Irving was already aged 43).

Involvement under his tutelage with ideas of stability, reactivity and structure has led Professor Irving's students and collaborators in many new directions. Several are represented in this volume (bio-inorganic chemistry, optical resolutions and stereochemical isomerism, vibrational spectra as a means of studying speciation in solution, and X-ray crystallography for the establishment and confirmation of isomeric structure).

Harry Irving has been, in three universities, a moving spirit for many chemists. While he was one of those who helped to revitalize inorganic chemistry, he also gave to his colleagues and students a wider perspective of a cultured life based on music and dance. He is truly a balanced man. This tribute is dedicated to a many-faceted man of great culture as a mark of affection and respect by his students and associates.

PROFESSOR H. M. N. H. IRVING: LIST OF PUBLISHED WORKS

1929

The action of potassium cyanide on chloroaldehydes. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1929, 1038.

1930

The interaction of butyl chloral hydrate and 2:4-dihalogen-substituted phenylhydrazines. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1930, 87.

1931

The condensation of butyl chloral hydrate with aryl hydrazines. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1931, 751.

The 4-hydroxy-1-aryl-5-methylpyrazoles. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1931, 786.

2:4:6-Trichlorophenylhydrazine. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1931, 1740.

1:3-Benzdioxin. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1931, 2492.

1932

The condensation of butyl chloral hydrate with aryl hydrazines. F. D. Chattaway and H. Irving, *J. Am. Chem. Soc.* 1932, **54**, 263.

1933

2:4:6-Trichloroaniline. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1933, 142.

The $\alpha\alpha\beta$-trihalogenated butaldehydes. F. D. Chattaway, H. Irving and G. H. Outhwaite, *J. Chem. Soc.* 1933, 993.

1934

The action of alkalis on substituted benzdioxins. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1934, 325.

1935

An historical account of Pharaoh's serpents. H. Irving, *Sci. Prog. (London)* 1935, **30**, 62.

The action of halogens upon the arylhydrazones of unsaturated aldehydes. F. D. Chattaway and H. Irving, *J. Chem. Soc.* 1935, 90.

1936

The action of amines upon esters. Part I. H. Irving, *J. Chem. Soc.* 1936, 797.

1937

The applications of floating equilibrium to the determination of density. H. Irving, *Sci. Prog. (London)* 1937, **31**, 654.

1940

The interaction of arylhydrazines and halogenated aldehydes. H. Irving, *J. Chem. Soc.* 1940, 813.

The alleged reduction of the phenylurethane of trichlorolactic ester and nitrile by dilute aqueous alkali. H. Irving and H. Marston, *J. Chem. Soc.* 1940, 1512.

1941

Bunsen's salt. H. Irving and G. W. Cherry, *J. Chem. Soc.* 1941, 25.

1943

The action of alkalis on substituted benzdioxins. H. Irving and (in part) E. G. Curtis, *J. Chem. Soc.* 1943, 319.

1948

The action of amines on esters, Part II. H. Irving and H. I. Fuller, *J. Chem. Soc.* 1948, 1989.

The order of stability of metal complexes. H. Irving and R. J. P. Williams, *Nature (London)* 1948, **162**, 746.

Reversion: a new procedure in absorptiometry. H. Irving, G. Andrew and E. J. Risdon, *Nature (London)* 1948, **161**, 805.

Analytical chemistry. H. Irving, *Annu. Rep. Prog. Chem.* 1948, **45**, 316.

1949

The absorptiometric determination of traces of metals. Reversion: a new procedure. H. Irving, E. J. Risdon and G. Andrew, *J. Chem. Soc.* 1949, 537.

Studies with dithizone. Part I. The determination of traces of mercury. H. Irving, G. Andrew and E. J. Risdon, *J. Chem. Soc.* 1949, 541.

Steric hindrance in analytical chemistry. Part I. H. Irving, E. J. Butler and M. F. Ring, *J. Chem. Soc.* 1949, 1489.

Metal complexes and partition equilibria. H. Irving and R. J. P. Williams, *J. Chem. Soc.* 1949, 1841.

Studies with dithizone. Part II. Dithizone as a monobasic acid. H. Irving, S. J. H. Cooke, S. C. Woodger and R. J. P. Williams, *J. Chem. Soc.* 1949, 1847.

The dissociation constant of 8-hydroxyquinoline. H. Irving, J. A. D. Ewart and J. T. Wilson, *J. Chem. Soc.* 1949, 2672.

Analytical chemistry. H. Irving, *Annu. Rep. Prog. Chem.* 1949, **46**, 268.

1950

The effect of time and temperature on potentials measured with the glass electrode. H. Irving and R. J. P. Williams, *J. Chem. Soc.* 1950, 2890.

1951

The centenary of Penny's process: A landmark in the history of analytical chemistry. H. Irving, *Sci. Prog. (London)* 1951, **39**, 63.

The stability of co-ordination compounds in aqueous solution. H. Irving, In *Proceedings of the First Conference on Coordination Chemistry*, I.C.I. Report No. BRL/146 (1951).

Solvent extraction and its applications to inorganic analysis. H. M. Irving, *Q. Rev.* 1951, **5**, 200.

The valencies of the transition elements in the metallic

state. W. Hume-Rothery, H. M. Irving and R. J. P. Williams, *Proc. R. Soc.* (*London*) 1951, **208A**, 431.

1952

Studies with dithizone. Part III. The extraction constant of zinc dithizonate. H. Irving, C. F. Bell and R. J. P. Williams, *J. Chem. Soc.* 1952, 357.

Studies with dithizone. Part IV. The dissociation constant of dithizone. H. Irving and C. F. Bell, *J. Chem. Soc.* 1952, 1261.

Cinnolines, Part XXIX. E. J. Alford, H. Irving, (Miss) H. S. Marsh and K. Schofield, *J. Chem. Soc.* 1952, 3009.

Some factors controlling the selectivity of organic reagents. H. Irving and R. J. P. Williams, *Analyst* (*London*) 1952, **77**, 813.

The solvent extraction of Group IIIB metal halides. H. Irving and F. J. C. Rossotti, *Analyst* (*London*) 1952, **77**, 801.

The solvent extraction of indium. H. Irving, F. J. C. Rossotti and J. G. Drysdale, *Nature* (*London*) 1952, **162**, 619.

S-methyl dithizone and the structure of the metal dithizonates. H. Irving and C. F. Bell, *Nature* (*London*) 1952, **169**, 756.

1953

Partition chromatography. H. Irving and R. J. P. Williams, *Sci. Prog.* (*London*) 1953, **163**, 418.

The stability of transition metal complexes. H. Irving and R. J. P. Williams, *J. Chem. Soc.* 1953, 3192.

Methods for computing successive stability constants from experimental formation curves. H. Irving and (Mrs) H. S. Rossotti, *J. Chem. Soc.* 1953, 3397.

Steric hindrance in analytical chemistry, Part II. The interaction of ferrous salts with 2-substituted 1:10-phenanthrolines. H. Irving, M. J. Cabel and D. Mellor, *J. Chem. Soc.* 1953, 3417.

Studies with dithizone. Part V. A comparison of routes for the synthesis of [^{35}S]dithizones. H. Irving and C. F. Bell, *J. Chem. Soc.* 1953, 3538.

A reversion method for the absorptiometric determination of traces of lead with dithizone. H. Irving and E. J. Butler, *Analyst* (*London*) 1953, **78**, 571.

1954

The stabilities of complexes formed by some bivalent metals with *N*-alkylated substituted ethylenediamines. H. Irving and J. M. M. Griffiths, *J. Chem. Soc.* 1954, 213.

Inorganic chemical kinetics and reactions. H. Irving, *Nature* (*London*) 1954, **173**, 670.

The calculation of formation curves of metal complexes from pH-titration curves in mixed solvents. H. Irving and (Mrs) H. S. Rossotti, *J. Chem. Soc.* 1954, 2904.

The stabilities of some metal complexes of 8-hydroxyquiniline and related substances. H. Irving and (Mrs) H. S. Rossotti, *J. Chem. Soc.* 1954, 2910.

The influence of ring-size on the stability of metal chelates. H. Irving, R. J. P. Williams, D. J. Ferrett and A. E. Williams, *J. Chem. Soc.* 1954, 3494.

8-Hydroxyquinaldinic acid. H. Irving and A. R. Pinnington, *J. Chem. Soc.* 1954, 3782.

The stability constants of the indium halides. H. Irving and B. G. F. Carleson, *J. Chem. Soc.* 1954, 4390

Studies with dithizone. Part VI. *S*-alkyl dithizone. H. Irving and C. F. Bell, *J. Chem. Soc.* 1954, 4253.

The kinetics and mechanism of inorganic reactions in solution. Introductory survey. H. Irving, *Chem. Soc., Spec. Publ.* 1954, **1**, 1.

1955

Steric hindrance in analytical chemistry. Part III. 1,2′-Pyridylisoquinoline and the ferroin reaction. H. Irving and A. Hampton, *J. Chem. Soc.* 1955, 430.

The determination of the dissociation constants of dibasic acids. H. Irving, (Mrs) H. S. Rossotti and G. Harris, *Analyst* (*London*) 1955, **80**, 83.

The theoretical basis of "sensitivity tests" and their application to some potential organic reagents for metals. H. Irving and (Mrs) H. S. Rossotti, *Analyst* (*London*) 1955, **80**, 245.

An investigation of 5-nitroso-oxine as an analytical reagent. H. Irving, R. G. W. Hollingshead and G. Harris, *Analyst* (*London*) 1955, **80**, 260.

A general treatment of the solvent extraction of inorganic compounds. H. Irving, F. J. C. Rossotti and R. J. P. Williams, *J. Chem. Soc.* 1955, 1906.

The extraction of indium at tracer concentrations from acid bromide solutions into methylisobutyl ketone. H. Irving and F. J. C. Rossotti, *J. Chem. Soc.* 1955, 1927.

The extraction of indium at macro concentrations from hydrobromic acid into methylisobutyl ketone and diethyl ether. H. Irving and F. J. C. Rossotti, *J. Chem. Soc.* 1955, 1938.

The extraction of indium halides into organic solvents. H. Irving and F. J. C. Rossotti, *J. Chem. Soc.* 1955, 1946.

A new application of the theory of corresponding solutions to measurements of the stabilities of some metal complexes. H. Irving and D. H. Mellor, *J. Chem. Soc.* 1955, 3457.

1956

The extraction of indium from hydrobromic acid into mixed organic solvents. H. Irving and F. J. C. Rossotti, *J. Chem. Soc.* 1956, 2475.

Some relationships among the stabilities of metal complexes. H. Irving and H. Rossotti, *Acta Chem. Scand.* 1956, **10**, 72.

1957

The bromination of 8-hydroxyquinaldine. H. Irving and A. R. Pinnington, *J. Chem. Soc.* 1957, 285.

Some bromine-substituted derivatives of 8-hydroxyquinoline. H. Irving and A. R. Pinnington, *J. Chem. Soc.* 1957, 290.

The determination of indium in rocks and minerals by radioactivation. A. A. Smales, J. van R. Smit and H. Irving, *Analyst* (*London*) 1957, **82**, 539.

The determination of indium in cylindrite by neutron-activation analysis and by other methods. H. Irving, J. van R. Smit and (in part) L. Salmon, *Analyst* (*London*) 1957, **82**, 549.

G. Schwarzenbach, *Complexometric Titrations* (Translated by H. Irving). Methuen, London (1957).

1958

The indium content of rocks and minerals from the Skaergaard intrusion. L. R. Wager, J. van R. Smit and H. Irving, *Geochim. Cosmochim. Acta* 1958, **13**, 81.

Diamagnetism in a quasi-tetrahedral nickel(II) complex. H. Irving and J. B. Gill, *Proc. Chem. Soc., London* 1958, 168.

Steric hindrance in analytical chemistry. Part IV. Some sterically hindered complexones. H. Irving, R. Shelton and (in part) R. Evans, *J. Chem. Soc.* 1958, 3540.

The preparation of metal-free acids, alkalis, and buffer solutions of high purity. H. Irving and J. J. Cox, *Analyst (London)* 1958, **83**, 526.

Opredelenie indiya radioaktivatsionym metodom. H. Irving, *Tr. Kom. Anal. Khim., Akad. Nauk SSSR* 1958, **9**, 249.

A versatile electronic device for counting drops of eluant in chromatography or operating ancillary apparatus after pre-set counts or pre-set times. G. L. Reed and H. Irving, *Analyst (London)* 1958, **84**, 317.

1959

Steric hindrance in analytical chemistry. Part V. A new 2-substituted 8-hydroxyquinoline (oxine). H. Irving and D. J. Clifton, *J. Chem. Soc.* 1959, 288.

Some potential chelating agents derived from benziminazole. H. Irving and O. Weber, *J. Chem. Soc.* 1959, 2296.

Some observations on Job's method of continuous variations and its extension to two-phase systems. H. Irving and T. B. Pierce, *J. Chem. Soc.* 1959, 2565.

Metal complexes of 2-aminomethylbenzimidazole. H. Irving and O. Weber, *J. Chem. Soc.* 1959, 2560.

An automatic titrimeter for plotting true-scale titration curves. H. Irving and L. D. Pettit, *Analyst (London)* 1959, **84**, 641.

The stability of metal complexes, Plenary Lecture to the Fourth International Congress on Co-ordination Chemistry. H. Irving, *Chem. Soc., Spec. Publ.* 1959, **13**, 13.

A novel relationship between the stability of certain metal halides and the absorption spectra of their complexes with dithizone. H. Irving and J. J. Cox, *Proc. Chem. Soc., London* 1959, 324.

Synergic effects in the solvent extraction of uranium. H. Irving and D. N. Edgington, *Proc. Chem. Soc., London* 1959, 360.

1960

The structure of some di-(3-methyl-1,5-diarylformazyl)-nickel(II) complexes. H. Irving, J. B. Gill and (in part) W. R. Cross, *J. Chem. Soc.* 1960, 2087.

The photochemical decomposition of diphenyliodonium iodide. H. Irving and R. W. Reid, *J. Chem. Soc.* 1960, 2078.

The electronic absorption spectra of some diaryliodonium salts. H. Irving, G. P. A. Turner and R. W. Reid, *J. Chem. Soc.* 1960, 2082.

(Methyl isocyanide)copper(I) iodide. H. Irving and M. Jonason, *J. Chem. Soc.* 1960, 2095.

Synergic effects in the solvent extraction of the actinides. Part I. Uranium(VI). H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.* 1960, **15**, 158.

The determination of trace quantities of silver in trade effluents. T. B. Pierce and H. Irving, *Analyst (London)* 1960, **85**, 166.

Solubilities of metal chelates of α-amino acids. H. Irving and L. D. Pettit, *Chem. Ind. (London)* 1960, 1268.

The solvent extraction of solvated ion-pairs: a theoretical approach. H. Irving and D. C. Lewis, *Proc. Chem. Soc., London* 1960, 222.

A procedure for determining the molar extinction coefficients of metal dithizonates. H. Irving and R. S. Ramakrishna, *Analyst (London)* 1960, **85**, 860.

The resolution of (±)-propylenediamine by a stereospecific reaction. H. Irving and R. D. Gillard, *J. Chem. Soc.* 1960, 5266.

Stability of metal complexes and their measurement polarographically, Plenary Lecture to the 2nd International Congress on Polarography, Cambridge, 1959. H. Irving, In *Advances in Polarography, Proceedings of the 2nd International Conference, Cambridge, England,* 1959, Vol. 1, p. 42. Pergamon Press, Oxford (1960).

1961

Synergic effects in solvent extraction. H. Irving and D. N. Edgington, *Chem. Ind. (London)* 1961, 77.

Studies with dithizone. Part VII. The action of halogens on dithizone and its analogues. H. Irving and R. S. Ramakrishna, *J. Chem. Soc.* 1961, 1272.

Studies with dithizone. Part VIII. Reactions with organometallic compounds. H. Irving and J. J. Cox, *J. Chem. Soc.* 1961, 1470.

Metal complexes of bis-[3-di(carboxymethyl)aminopropyl] ether. The computation of stability constants with the aid of a high-speed digital computer. H. Irving and M. H. Stacey, *J. Chem. Soc.* 1961, 2019.

Studies with dithizone. Part IX. The absorption spectra of mono- and di-*p*-bromosubstituted dithizones and of their metal complexes. H. Irving and R. S. Ramakrishna, *J. Chem. Soc.* 1961, 2118.

A new stereospecific reaction. H. Irving and R. D. Gillard, *J. Chem. Soc.* 1961, 2249.

A comparison of the stabilities of metal chelates containing N, P, and As as donor atoms. H. Irving and L. D. Pettit, In *Advances in the Chemistry of the Coordination Compounds* (Edited by S. Kirschner), p. 412. Macmillan, New York (1961).

Liquid–liquid extraction. H. Irving, In *Treatise on Analytical Chemistry* (Edited by I. M. Kolthoff and P. J. Elving), Chap. 31, p. 1309. Interscience, New York (1961).

Synergic effects in the solvent extraction of the actinides. Part II. Plutonium(VI) and neptunium(V). H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.* 1961, **20**, 314.

Synergic effects in the solvent extraction of the actinides. Part III. Tetravalent actinides. H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.* 1961, **20**, 321.

Synergic effects in the solvent extraction of the actinides. Part IV. Trivalent plutonium, americium and europium. H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.* 1961, **21**, 169.

1962

The contributions of π-bonding to the stabilities of metal complexes in solution, and a correlation with Hammett's σ-factor. H. Irving and J. J. R. F. da Silva, *Proc. Chem. Soc., London* 1962, 250.

Observations on the computation of stability constants by Olerup's graphical procedure. H. Irving, *J. Chem. Soc.* 1962, 4056.

Steric hindrance in analytical chemistry. Part VI. 1-Methyl- and 1,6-dimethyl-3,4,5-triazaphenanthrene as reagents for iron and copper. E. A. Hobday, M. Tomlinson and H. Irving, *J. Chem. Soc.* 1962, 4914.

The stability of metal complexes of 1,10-phenanthroline and its analogues. Part I. 1,10-Phenanthroline and 2,2′-bipyridyl. H. Irving and D. H. Mellor, *J. Chem. Soc.* 1962, 5222.

The stability of metal complexes of 1,10-phenanthroline and its analogues. Part II. 2-Methyl- and 2,9-dimethylphenanthroline. H. Irving and D. H. Mellor, *J. Chem. Soc.* 1962, 5237.

The stability of metal complexes of 1,10-phenanthroline and its analogues. Part III. 5-Methyl-1,10-phenanthroline. W. A. E. McBryde, (Mrs) D. A. Brisbin and H. Irving, *J. Chem. Soc.* 1962, 5245.

The complexes formed by thallium(I), the alkali metals, and other monovalent ions. H. Irving and J. J. R. F. da Silva, In *Proceedings of the 7th International Congress on Coordination Chemistry, Stockholm* 1962, p. 108.

1963

The stabilities of complexes of thallium(I) and the alkali metals with uramildiacetic acid. H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.* 1963, 448.

The stabilities of complexes of uramildiacetic acid and its homologues. H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.* 1963, 458.

Studies with dithizone. Part X. Reactions with organomercury(II) compounds. H. Irving and J. J. Cox, *J. Chem. Soc.* 1963, 466.

The adsorption of some anionic complexes on a cation-exchange resin. H. Irving and G. T. Woods, *J. Chem. Soc.* 1963, 939.

Metal complexes of *N*-(2-pyridylmethyl)iminodiacetic acid. H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.* 1963, 945.

Complexones containing heterocyclic donor oxygen atoms. H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.* 1963, 1144.

The stabilities of metal complexes of some *C*-substituted derivatives of glycine. H. Irving and L. D. Pettit, *J. Chem. Soc.* 1963, 1546.

The stabilities of metal complexes of 1,4-piperazinediacetic acid. H. Irving and L. D. Pettit, *J. Chem. Soc.* 1963, 3051.

Steric hindrance in analytical chemistry with special reference to the reactions of analogs of 8-hydroxyquinoline. H. Irving and L. D. Pettit, In *Analytical Chemistry, Proceedings of the International Symposium, Birmingham University, England,* 1962, p. 122 (1963).

The stabilities of metal complexes of some derivatives of iminodiacetic acid. H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.* 1963, 3308.

Studies with dithizone. Part XI. Reactions with *p*-fluorophenyl- and *p*-iodophenyl-mercury(II) compounds. H. Irving and A. M. Kiwan, *J. Chem. Soc.* 1963, 4288.

The Three Cultures, Inaugural Lecture. H. Irving, Leeds University Press, Leeds (1963).

1964

Infra-red absorption spectra of complexes of thiourea. K. Swaminathan and H. M. N. H. Irving, *J. Inorg. Nucl. Chem.* 1964, **26**, 1291.

The purification of hydrobromic and hydriodic acids by ion-exchange. H. Irving and P. D. Wilson, *Chem. Ind. (London)* 1964, 653.

An absorptiometric determination of perchlorate by means of a novel coloured liquid anion exchanger. W. E. Clifford and H. Irving, *Anal. Chim. Acta* 1964, **31**, 1.

The stability of the chloride complexes of europium. H. M. N. H. Irving and P. K. Khopkar, *J. Inorg. Nucl. Chem.* 1964, **26**, 1561.

The stabilities of complexes of the rare earths with propylenediaminetetraacetic acid. H. M. N. H. Irving and J. P. Conesa, *J. Inorg. Nucl. Chem.* 1964, **26**, 1945.

The absorption of polybromide ions on an anion exchange resin. H. M. N. H. Irving and P. D. Wilson, *J. Inorg. Nucl. Chem.* 1964, **26**, 2235.

Studies of ligands containing elements of Group V. Part I. L. D. Pettit and H. M. N. H. Irving, *J. Chem. Soc.* 1964, 5336.

H. Irving and R. J. P. Williams, *Separation Methods in Analytical Chemistry. Liquid–Liquid Extraction*, p. 1309. Wiley Interscience, New York (1964).

1965

A simple preparation of meso-stilbenediamine. H. M. N. H. Irving and (Miss) R. M. Parkins, *J. Inorg. Nucl. Chem.* 1965, **27**, 270.

1,1′-Diaminobicyclohexyl and the stability of its metal complexes. M. L. Tomlinson, M. L. H. Sharp and H. M. N. H. Irving, *J. Chem. Soc.* 1965, 603.

The extraction of copper(II) from acetate buffers by solutions of acetylacetone in benzene. H. M. N. H. Irving and N. S. Al-Niaimi, *J. Inorg. Nucl. Chem.* 1965, **27**, 419.

Synergic effects in solvent extraction. Part VI. The solvent extraction of copper(II) from acetate buffers by mixtures of acetylacetone and 4-methylpyridine. H. M. N. H. Irving and N. S. Al-Niaimi, *J. Inorg. Nucl. Chem.* 1965, **27**, 717.

The stabilities of the metal complexes of optically active amino-acids. R. D. Gillard, H. M. Irving, R. Parkins, N. C. Payne and L. D. Pettit, *Proc. Chem. Soc., London* 1965, 81.

Determination of small amounts of long-chain alkylamines in aqueous solution. H. M. N. H. Irving and A. D. Damodaran, *Analyst (London)* 1965, **90**, 180.

Synergistische Wirkingen bei der flüssig–flüssig Extraktion (Synergic effects in liquid–liquid extraction). H. M. N. H. Irving, *Angew. Chem.* 1965, **77**, 57; *Angew. Chem., Int. Ed. Engl.* 1965, **4**, 95.

Synergic effects in solvent extraction. Part VII. Divalent transition metals. H. M. N. H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.* 1965, **27**, 1359.

Synergic effects in solvent extraction. Part VIII. The solvent extraction of copper(II) from acetate buffers by mixtures of acetylacetone with quinoline or isoquinoline. H. M. N. H. Irving and N. S. Al-Niaimi, *J. Inorg. Nucl. Chem.* 1965, **27**, 1671.

A new method for the determination of perchlorate by means of a coloured anion exchanger. H. M. N. H. Irving and A. D. Damodaran, *Analyst* (*London*) 1965, **90**, 443.

Synergic effects in solvent extraction. Part IX. The effect of isoquinoline and 4-methylpyridine on the distribution of diacetylbisbenzoylhydrazone nickel(II) between benzene and aqueous buffers. H. M. N. H. Irving and N. S. Al-Niaimi, *J. Inorg. Nucl. Chem.* 1965, **27**, 2231.

The synthesis of some new complexones and a discussion of the problems that arose in the determination of their acid dissociation constants. H. M. N. H. Irving, L. D. Pettit and M. G. Miles, *Proc. Soc. Anal. Chem.* 1965, **2**, 139.

Conformational aspects of chelate rings. R. D. Gillard and H. M. N. H. Irving, *Chem. Rev.* 1965, **65**, 603.

The solvent extraction of mixed complexes. H. Irving, In *Proceedings of the Symposium on Coordination Chemistry, Tihany, Hungary*, 1964, p. 219. Akademiai Kiado, Budapest (1965).

1966

Stability constants of complexes of thiourea with nickel, cobalt, and bismuth. K. Swaminathan and H. M. N. H. Irving, *J. Inorg. Nucl. Chem.* 1966, **28**, 171.

Electron exchange catalysis in the formation of the EDTA complex of chromium(III) and its photometric determination. H. M. N. H. Irving and W. R. Tomlinson, *Chemist–Analyst* 1966, **55**, 14.

Aryl derivatives of nitrilotriacetic acid, and the stability of their proton and metal complexes. H. M. N. H. Irving and M. G. Miles, *J. Chem. Soc. A* 1966, 727.

Meso- and *dl*-2,3-diaminobutane-*NNN'N'*-tetraacetic acid and their metal complexes. H. M. N. H. Irving and (Miss) R. Parkins, *J. Inorg. Nucl. Chem.* 1966, **28**, 1629.

The isomers of complexes of L-aminoacids with copper(II). R. D. Gillard, H. M. Irving, R. M. Parkins, N. C. Payne and L. D. Pettit, *J. Chem. Soc. A* 1966, 1159.

Analogues of nitrilotriacetic acid and the stabilities of their proton and metal complexes. H. M. N. H. Irving and M. G. Miles, *J. Chem. Soc. A* 1966, 1268.

A new method for determining the activity of concentrated solutions of hydrobromic acid. H. M. N. H. Irving and P. D. Wilson, *J. Inorg. Nucl. Chem.* 1966, **28**, 2033.

1967

The interaction of dithizone with allegedly "purified" dioxan. H. M. N. H. Irving and U. S. Mahnot, *Chem. Ind.* (*London*) 1967, 193.

A study of some problems in determining the stoicheiometric proton dissociation constants of complexes by potentiometric titrations using a glass electrode. H. M. N. H. Irving, M. G. Miles and L. D. Pettit, *Anal. Chim. Acta* 1967, **38**, 475.

The determination of small amounts of long-chain tertiary alkylamines and quaternary ammonium salts. H. M. N. H. Irving and J. J. Markham, *Anal. Chim. Acta* 1967, **39**, 7.

Synergism in the solvent extraction of metal chelates. H. M. N. H. Irving, In *Solvent Extraction Chemistry* (Edited by D. Dyrssen, J. O. Liljenzin and J. Rydberg), p. 91. North-Holland, Amsterdam (1967).

William Skey (1835–1900); a centenary in the history of solvent extraction. H. M. N. H. Irving, *Chem. Ind.* (*London*) 1967, 1780.

The extraction of indium halides into organic solvents. Part VII. The distribution of indium between hydrochloric acid and binary solvent mixtures containing isobutyl methyl ketone. H. M. N. H. Irving and D. Lewis, *Ark. Kemi* 1967, **28**, 131.

1968

Stability constants of copper(II) complexes of optically active α-aminoacids. R. D. Gillard, H. M. N. H. Irving and L. D. Pettit, *J. Chem. Soc. A* 1968, 673.

A general graphical method for evaluating experimental results which should fit a linear equation. H. M. N. H. Irving, *Analyst* (*London*) 1968, **93**, 273.

Complexes of hydroxyacids containing two different metals. H. M. N. H. Irving and W. R. Tomlinson, *Chem. Commun.* 1968, 497.

The extraction of copper(I), lead(II) and tin(IV) from hydrochloric acid by solutions of tetra-*n*-hexylammonium chloride in ethylene dichloride. H. M. N. H. Irving and A. H. Nabilsi, *Anal. Chim. Acta* 1968, **41**, 505.

The extraction of copper(II) from hydrochloric acid by solutions of tetra-*n*-hexylammonium chloride in ethylene dichloride. H. M. N. H. Irving and A. H. Nabilsi, *Anal. Chim. Acta* 1968, **42**, 79.

pH-Meter corrections for titrations in mixtures of water and dioxan. H. M. N. H. Irving and U. S. Mahnot, *J. Inorg. Nucl. Chem.* 1968, **30**, 1215.

The effect of chromium(III) and other ions on the absorptiometric determination of copper using 2,2'-biquinolyl. H. M. N. H. Irving and W. R. Tomlinson, *Talanta* 1968, **15**, 1267.

Studies with dithizone. Part XII. Formation of thiadiazolines by condensation with aldehydes and ketones. H. M. N. H. Irving and U. S. Mahnot, *Talanta* 1968, **15**, 811.

The theory of regular solutions applied to the viscosity of dilute solutions of chromium(III) acetylacetonate in organic solvents. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1968, **30**, 1873.

1969

Selenium analogue of dithizone. R. S. Ramakrishna and H. M. N. H. Irving, *Chem. Ind.* (*London*) 1969, 325.

A novel viscometric method for determining the stability constants of a compound of two uncharged species. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1969, **31**, 159.

A viscometric study of possible adduct formation between solutions of chromium(III) acetylacetonate and thiourea in methanol. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1969, **31**, 169.

Addendum to paper entitled "The theory of regular solutions applied to the viscosity of dilute solutions of chromium(III) acetylacetonate in organic solvents. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1969, **31**, 1212.

Studies with dithizone. Part XIII. The extraction of methyl-, benzyl- and *p*-bromophenyl-mercury(II) dithizonates. H. M. N. H. Irving and A. M. Kiwan, *Anal. Chim. Acta* 1969, **45**, 243.

Studies with dithizone. Part XIV. A new oxidation product of dithizone. H. M. N. H. Irving, D. C. Rupainwar and S. S. Sahota, *Anal. Chim. Acta* 1969, **45**, 249.

Studies with dithizone. Part XV. Further reactions with organomercury compounds. H. M. N. H. Irving and A. M. Kiwan, *Anal. Chim. Acta* 1969, **45**, 255.

Studies with dithizone. Part XVI. Water-soluble arylmercury(II) dithizonates and secondary arylmercury(II) dithizonates. H. M. N. H. Irving and A. M. Kiwan, *Anal. Chim. Acta* 1969, **45**, 271.

Studies with dithizone. Part XVII. The extraction constants of organomercury(II) dithizonates. H. M. N. H. Irving and A. M. Kiwan, *Anal. Chim. Acta* 1969, **45**, 447.

A viscometric study of interactions in solutions of bis-(*N*-methylsalicylaldimine)nickel(II). H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1969, **31**, 2895.

An unusual bicyclic oxidation product of dithizone. W. S. McDonald, H. M. N. H. Irving, G. Raper and D. C. Rupainwar, *Chem. Commun.* 1969, 392.

The non-existence of selenium dithizonate. R. S. Ramakrishna and H. M. N. H. Irving, *Chem. Commun.* 1969, 1356.

Vibrational spectra and force-constant computations of *cis*- and *trans*-dicyanotetrakis(methylisocyanide)-iron(II). R. R. Berrett, B. W. Fitzsimmons, P. Gans, H. M. N. H. Irving and P. Stratton, *J. Chem. Soc. A* 1969, 904.

A viscometric study of iodine–solvent interactions. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1969, **31**, 3163.

Studies with dithizone. Part XIX. A photochemical oxidation product of dithizone. H. M. N. H. Irving and D. C. Rupainwar, *Anal. Chim. Acta* 1969, **48**, 187.

Selenazone: the selenium analogue of dithizone. R. S. Ramakrishna and H. M. N. H. Irving, *Anal. Chim. Acta* 1969, **48**, 251.

G. Schwarzenbach and H. Flaschka, *Complexometric Titrations* (2nd English Edition translated and revised by H. M. N. H. Irving). Methuen, London (1969).

The extraction of silver(I) from hydrochloric acid by solutions of tri-*N*-hexylammonium and tetra-*N*-hexylammonium chloride in organic solvents. H. M. N. H. Irving and A. D. Damodaran, *Anal. Chim. Acta* 1969, **48**, 267.

Liquid–liquid extraction. H. M. N. H. Irving, *Minerals Science and Engineering* 1969, **1**, 15.

1970

Selenium dithizonate. H. M. N. H. Irving, *Chem. Commun.* 1970, 519.

The viscosities of dilute solutions of naphthalene in organic solvents and their interpretation in terms of the theory of regular solutions. H. M. N. H. Irving and J. S. Smith, *J. Inorg. Nucl. Chem.* 1970, **32**, 901.

An examination by viscometry of possible stereospecific interaction between chromium(III) acetylacetonate and an optically active ester in benzene solution. H. M. N. H. Irving, R. B. Simpson and J. S. Smith, *J. Inorg. Nucl. Chem.* 1970, **32**, 2275.

Studies with dithizone. Part XX. On the non-existence of selenium dithizonate. R. S. Ramakrishna and H. M. N. H. Irving, *Anal. Chim. Acta* 1970, **49**, 9.

Studies with dithizone. Part XXI. A novel bicyclic oxidation product of dithizone. H. M. N. H. Irving, U. S. Mahnot and D. C. Rupainwar, *Anal. Chim. Acta* 1970, **49**, 261.

Formation constants of europium(III) salicylate complexes and their extraction into isoamyl alcohol. H. M. N. H. Irving and S. P. Sinha, *Anal. Chim. Acta* 1970, **49**, 449.

The extraction of indium from aqueous halide and thiocyanate media by solutions of liquid anion exchangers in organic solvents. H. M. N. H. Irving and A. D. Damodaran, *Anal. Chim. Acta* 1970, **50**, 277.

The synergic extraction of ternary complexes of europium(III). H. M. N. H. Irving and S. P. Sinha, *Anal. Chim. Acta* 1970, **51**, 39.

A novel unimolecular heterolytic fission of the sulphur–sulphur bond in a symmetrical disulphide. A. M. Kiwan and H. M. N. H. Irving, *Chem. Commun.* 1970, 928.

An automatic capillary viscometer. J. S. Smith, H. M. N. H. Irving and R. B. Simpson, *Analyst (London)* 1970, **95**, 743.

The extraction of indium halides into organic solvents. Part VIII. A theoretical approach to the partition of solvated ion-pairs. H. M. N. H. Irving and D. Lewis, *Ark. Kemi* 1970, **32**, 121.

The extraction of indium halides into organic solvents. Part IX. The relative efficiencies of different organic solvents. H. M. N. H. Irving and D. Lewis, *Ark. Kemi* 1970, **32**, 131.

The synergic extraction of the europium(III)–bis-phenanthroline–tris-salicylate complex and the preparation and properties of analogous ternary rare earth complexes. S. P. Sinha and H. M. N. H. Irving, *Anal. Chim. Acta* 1970, **52**, 193.

Formation constants of bis- and tris-complexes of optically active bidentate ligands. A. T. Advani, H. M. N. H. Irving and L. D. Pettit, *J. Chem. Soc. A* 1970, 2649.

Recommended nomenclature for liquid–liquid distribution. H. M. N. H. Irving, *Pure Appl. Chem.* 1970, **21**, 109.

The determination of microgram quantities of mercury(II) and silver(I) by thermometric titration. K. C. Burton and H. M. N. H. Irving, *Anal. Chim. Acta* 1970, **52**, 441.

1971

Divalent metal complexes of *meso*- and *dl*-2,3-diaminobutane-*NNN'N'*-tetraacetic acid. H. M. N. H. Irving and K. Sharpe, *J. Inorg. Nucl. Chem.* 1971, **33**, 203.

Complexes of *meso*- and *dl*-2,3-diaminobutane-*NNN'N'*-tetraacetic acid with rare-earth cations. H. M. N. H. Irving and K. Sharpe, *J. Inorg. Nucl. Chem.* 1971, **33**, 217.

Stabilities of complexes formed by *dl*- and *meso*-2,3-diaminobutane-*NNN'N'*-tetraacetic acid with iron(II) and iron(III). H. M. N. H. Irving and K. Sharpe, *J. Inorg. Nucl. Chem.* 1971, **33**, 233.

The effect of solvent on the electronic absorption spectra of the mesoionic compounds 2,3-diphenyl-2*H*-tetrazolium-5-thiolate and 4-phenyl-1,3,4-thiadiazolium-2-thiolate. A. M. Kiwan and H. M. N. H. Irving, *J. Chem. Soc. B* 1971, 898.

Kinetics of the decomposition of bis-1,5-diphenylformazan-3-yl disulphide and bis-4-phenyl-Δ^2-1,3,4-thiadiazolin-2-yl disulphide in organic solvents. A. M. Kiwan and H. M. N. H. Irving, *J. Chem. Soc. B* 1971, 901.

The extraction of complex cyanides by liquid ion-exchangers. H. M. N. H. Irving and A. D. Damodaran, *Anal. Chim. Acta* 1971, **53**, 267.

The extraction of mercury(II) as cyanide complexes by solutions of long-chain quaternary amines. H. M. N. H. Irving and A. D. Damodaran, *Anal. Chim. Acta* 1971, **53**, 277.

A secondary dithizone complex containing both silver and mercury. H. M. N. H. Irving and T. Nowicka-Jankowska, *Anal. Chim. Acta* 1971, **54**, 55.

Mixed secondary complexes of silver(I) and phenylmercury(II) cations with dithizone. A. M. Kiwan and H. M. N. H. Irving, *Anal. Chim. Acta* 1971, **54**, 351.

Studies with dithizone. Part XXIII. Some observations on secondary mercury(II) dithizonate. T. Nowicka-Jankowska and H. M. N. H. Irving, *Anal. Chim. Acta* 1971, **54**, 489.

Stereoselectivity in the reactions of cobalt(III) complexes of *meso*- and *dl*-2,3-diaminobutanetetraacetic acid with aliphatic diamines. H. M. N. H. Irving and R. Countryman, *J. Inorg. Nucl. Chem.* 1971, **33**, 1819.

The extraction of chromium(III) from aqueous EDTA by solutions of tetrahexylammonium chloride in dichloroethane. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1971, **55**, 135.

An automatic capillary viscometer. Part II. Apparatus for viscometric titrations. R. B. Simpson, J. S. Smith and H. M. N. H. Irving, *Analyst* (*London*) 1971, **96**, 550.

Viscometric titrations. A new technique applied to acidimetry and alkalimetry. R. B. Simpson, H. M. N. H. Irving and J. S. Smith, *Anal. Chim. Acta* 1971, **55**, 169.

Studies with dithizone. Part XXV. The deterioration of stock solutions and the identification of two oxidation products. H. M. N. H. Irving, A. M. Kiwan, D. C. Rupainwar and S. S. Sahota, *Anal. Chim. Acta* 1971, **56**, 205.

Steric hindrance to the formation of metal complexes of 2-chloro-1,10-phenanthroline. H. M. N. H. Irving and P. J. Gee, *Anal. Chim. Acta* 1971, **55**, 315.

The crystal structure of primary zinc(II) dithizonate and its relevance to the structures of its *ortho*- and *para*-methyl derivatives. A. Mawby and H. M. N. H. Irving, *Anal. Chim. Acta* 1971, **55**, 269.

Studies with dithizone. Part XXVI. Secondary copper(II) dithizonate. H. M. N. H. Irving and A. M. Kiwan, *Anal. Chim. Acta* 1971, **56**, 435.

Studies with dithizone. Part XXVII. Primary copper(I) dithizonate. A. M. Kiwan and H. M. N. H. Irving, *Anal. Chim. Acta* 1971, **57**, 59.

1972

The crystal structure of primary zinc(II) dithizonate. A. Mawby and H. M. N. H. Irving, *J. Inorg. Nucl. Chem.* 1972, **34**, 109.

The calculation of stability constants of weak complexes from spectrophotometric data. P. Gans and H. M. N. H. Irving, *J. Inorg. Nucl. Chem.* 1972, **34**, 1885.

The viscosity of mixtures of benzene and methanol. H. M. N. H. Irving and R. B. Simpson, *J. Inorg. Nucl. Chem.* 1972, **34**, 2241.

Complexes of chromium(III) with nitrilotriacetic acid and their extraction by solutions of Aliquat-336 in dichloroethane. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1972, **60**, 345.

Useful effects of steric hindrance in analytical chemistry. H. M. N. H. Irving, *Proc. Soc. Anal. Chem.* 1972, **9**, 242.

The complexometric determination of cobalt, chromium, and mixtures of bismuth and lead using extractive end-points. H. M. N. H. Irving and R. H. Al-Jarrah, *Chem. Anal.* (*Warsaw*) 1972, **17**, 779.

Observations on the determination of metal–ligand stability constants when the salt background includes potentially complexing anions. H. M. N. H. Irving and M. H. Stacey, *K. Tek. Högskolans Handl.* 1972, **263**, 209.

1973

The extraction of the chromium(III)–EDTA complex by solutions of Aliquat-336 in various organic solvents. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1973, **63**, 79.

The extraction of EDTA by solutions of Aliquat-336 in 1,2-dichloroethane. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1973, **65**, 77.

The mass spectra of dithizone and some related compounds. P. A. Alsop and H. M. N. H. Irving, *Anal. Chim. Acta* 1973, **65**, 202.

Studies with dithizone. Part XXX. Complexes of metals with *S*-methyldithizone and the methylation of metal dithizonates. H. M. N. H. Irving, A. H. Nabilsi and S. S. Sahota, *Anal. Chim. Acta* 1973, **67**, 135.

The crystal structure of diphenylthiocarbazide. M. Harding, M. J. Adams, P. A. Alsop and H. M. N. H. Irving, *Anal. Chim. Acta* 1973, **67**, 204.

Separation and preconcentration. H. Irving, *Fresenius' Z. Anal. Chem.* 1973, **263**, 264.

1974

A new procedure for determining the metal content of colourless complexonates. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1974, **68**, 473.

The extraction of indium halides into organic solvents. X. Synergic effects with solvent mixtures containing alcohols. H. M. N. H. Irving and D. Lewis, *Chem. Scr.* 1974, **5**, 202.

The extraction of indium halides into organic solvents. XI. Synergic effects with solvents containing diethyl ether. H. M. N. H. Irving and D. Lewis, *Chem. Scr.* 1974, **5**, 208.

Application of the solubility parameter concept in liquid–liquid extraction. H. M. N. H. Irving, In *Ion Exchange and Solvent Extraction* (Edited by J. A. Marinsky and Y. Marcus), Vol. 6, Chap. 3, p. 139. Marcel Dekker, New York (1974).

Current uses of liquid–liquid extraction in analytical chemistry. H. Irving, *Chem. Ind. (London)* 1974, **16**, 639.

H. M. N. H. Irving, *The Techniques of Analytical Chemistry, a Short Historical Survey*. H.M. Stationery Office, London (1974).

One hundred years of development in analytical chemistry. Centenary lecture of the Society for Analytical Chemistry. H. M. N. H. Irving, *Analyst (London)* 1974, **99**, 787.

Recommendations on the usage of the terms "equivalent" and "normal". H. M. N. H. Irving, *IUPAC Inf. Bull.* 1974, **26**, 1.

XVth Procter memorial lecture, Fact or fiction? How much do we really know about the chemistry of chromium today? H. M. N. H. Irving, *J. Soc. Leather Technol. Chem.* 1974, **58**, 51.

1975

Fakta, nebo fikce? Co dnes skutečne vime o chemii chromitých sloučenin? H. M. N. H. Irving, *Kožarštvi* 1975, **25**, 59 and 83.

List of trivial names and synonyms (for substances used in analytical chemistry). H. Irving, *IUPAC Inf. Bull.* 1975, **45**, 1.

Preconcentration and separation. H. Irving, *Cron. Chim.* 1975, **46**, 1.

The extraction of various metals as their anionic complexes with EDTA by solutions of Aliquat-336 chloride in 1,2-dichloroethane. H. M. N. H. Irving and R. H. Al-Jarrah, *Anal. Chim. Acta* 1975, **74**, 321.

1976

Separation techniques used in radiochemical procedures. H. M. N. H. Irving, *J. Radioanal. Chem.* 1976, **33**, 287.

1977

Classical methods of analysis. H. M. N. H. Irving, *Pure Appl. Chem.* 1977, **49**, 1575.

The development of analytical techniques. H. M. N. H. Irving, In *Essays on Analytical Chemistry: In Memory of Professor Anders Ringbom* (Edited by E. Wanninen), p. 591. Pergamon Press, Oxford (1977).

Acid strengths of various substituted formazans in ethanolic solution. J. B. Gill, H. M. N. H. Irving and A. Prescott, *J. Chem. Soc., Perkin Trans.* 2 1977, 1683.

H. M. N. H. Irving, *Dithizone*. Analytical Sciences Monographs No. 5, The Chemical Society, London (1977).

1978

The viscosities of isomorphous salts. H. M. N. H. Irving and S. A. Karmali, *J. Inorg. Nucl. Chem.* 1978, **40**, 1401.

Studies with dithizone. Part XXXI. The relationship between $pH_{1/2}$ and molar solubility. H. M. N. H. Irving, N. F. Naqvi and C. G. Tilley, *Anal. Chim. Acta* 1978, **100**, 597.

Recommendations on the usage of the terms "equivalent" and "normal". H. M. N. H. Irving, T. S. West and D. H. Whiffen, *Pure Appl. Chem.* 1978, **50**, 325.

Guide to trivial names, trade names and synonyms for substances used in analytical nomenclature. H. M. N. H. Irving, *Pure Appl. Chem.* 1978, **50**, 339.

Coordination compounds in analytical chemistry. Plenary Lecture, 18th International Conference on Coordination Chemistry, Sao Paulo, Brazil, 1977. H. M. N. H. Irving, *Pure Appl. Chem.* 1978, **50**, 1129.

H. M. N. H. Irving, H. Freiser and T. S. West, *Compendium of Analytical Nomenclature*. Pergamon Press, Oxford (1978).

1979

Crystal structure of bis(2-methyl-8-hydroxyquinolinato)beryllium(II) dihydrate. J. C. van Niekerk, H. M. N. H. Irving and L. R. Nassimbeni, *S. Afr. J. Chem.* 1979, **32**, 85.

Novel intramolecular hydrogen bond to a quasi-aromatic formazan ring: solution conformation and X-ray crystal structure of 3-carboxymethylthio-1,5-diphenylformazan. A. T. Hutton, H. M. N. H. Irving, K. R. Koch, L. R. Nassimbeni and G. Gafner, *J. Chem. Soc., Chem. Commun.* 1979, 57.

Three-coordinate mercury complex: photochromism and molecular structure of phenylmercury(II) dithizonate. A. T. Hutton and H. M. N. H. Irving, *J. Chem. Soc., Chem. Commun.* 1979, 1113.

The crystal and molecular structure of 3-carboxymethylthio-1,5-diphenylformazan. A. T. Hutton, H. M. N. H. Irving, L. R. Nassimbeni and G. Gafner, *Acta Cryst.* 1979, **B35**, 1354.

1980

3-Carboxymethylthio-1,5-diphenylformazan: a potential terdentate ligand with unusual properties. A. T. Hutton and H. M. N. H. Irving, *J. Chem. Soc., Perkin Trans.* 2 1980, 139.

X-Ray crystallographic and spectroscopic study of the configurations of isomeric 3-methylthio-1,5-diarylformazans and their interconversion in solution. A. T. Hutton and H. M. N. H. Irving, *J. Chem. Soc., Chem. Commun.* 1980, 763.

STUDIES ON THE EXISTENCE OF A TAUTOMERIC EQUILIBRIUM IN SOLUTIONS OF THE ANALYTICAL REAGENT DITHIZONE

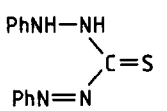
ALAN T. HUTTON*

Department of Analytical Science, University of Cape Town, Rondebosch 7700, South Africa

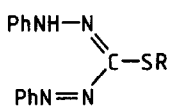
(*Received* 3 *July* 1986)

Abstract—The traditional view that solutions of dithizone in organic solvents comprise equilibrium mixtures of thiol and thione forms which are individually responsible for the characteristic strong visible absorption bands around 440 and 620 nm is examined critically. Fourier transform ^{1}H and ^{13}C NMR spectroscopic measurements on dithizone, seven of its alkyl-substituted homologues, and on its ^{13}C- and ^{15}N-labelled analogues point to the existence of only a single molecular species in chloroform, benzene or acetone. The marked solvatochromism, however, has yet to be explained. Modifications to established synthetic routes are reported which are especially suitable for the small-scale preparation of isotopically-labelled dithizone analogues.

The analytical reagent dithizone (also known as 1,5-diphenylthiocarbazone or 3-thio-1,5-diphenylformazan and abbreviated here as H_2Dz) was first synthetized just over a century ago in 1878 by Emil Fischer from carbon disulphide and phenylhydrazine,[1] and its structure as the thione (**1**) was established by Corwin and Jackson.[2] The same substance was prepared nearly 50 years after Fischer by the reduction of 3-nitro-1,5-diphenylformazan with ammonium hydrosulphide, and Bamberger *et al.*[3] formulated it as the thiol (**2**). The thiol formulation (**2**) is supported by its ease of oxidation to a disulphide,[4] its acidity ($pK_1 \sim 4.5$) and ready solubility in aqueous alkali, and the formation of the strongly coloured, water-insoluble metal *N,S*-chelate complexes $M(HDz)_n$ which have been used so extensively in absorptiometric trace-metal analysis following liquid–liquid extraction procedures.[5,6] Preparations of dithizone by different synthetic routes [i.e. Fischer's[1] or Bamberger's[3] methods (see Scheme 1)] do not distinguish between the alternative structures **1** and **2**: the thione and thiol forms are clearly tautomers. Since the visible spectra of dithizone in solutions of organic solvents always show two strong absorption bands (cf. Table 1) it has long been assumed that these could be attributed to the individual tautomers, and that dithizone in solution thus exhibited the tautomeric equilibrium **1** ⇋ **2**.[7] It should be noted that each of these tautomers could exist in a considerable number of conformations (viz. 16 stereochemical modifications with a further 48 if charge-separated species are included),[8] though many of these possibilities can be excluded on steric or other grounds.[7]



(1)

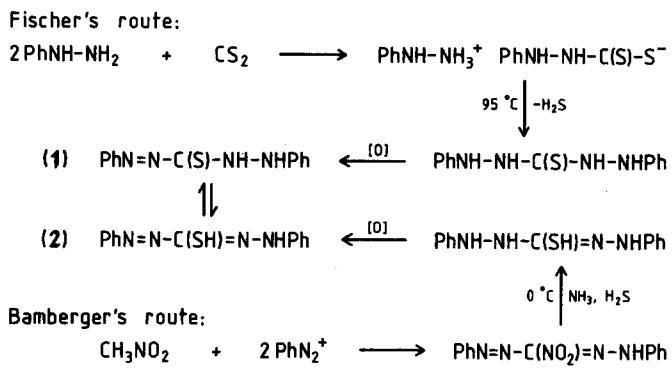


(2) R = H

(3) R = CH_3

Formazans of general formula ArN=N—C(R)=N—NHAr (R = Cl or alkyl) have their main visible absorption band at *ca* 420 nm, and the dithizonate anion, presumably PhN=N—C(S^-)=N—NHPh, absorbs at 470 nm. Since there is commonly a bathochromic shift when chelating agents such as acetylacetone, thenoyltrifluoracetone, 8-quinol-

* M.Sc. and Ph.D. student of Professor H. M. N. H. Irving at the University of Cape Town, 1977–1980; presently "new blood" lecturer in inorganic chemistry at the Department of Pure and Applied Chemistry, The Queen's University, Belfast BT9 5AG, U.K.



Scheme 1.

inol and 8-mercaptoquinoline form their metal complexes, and since metal complexes of dithizone show a single strong absorption band in the region 450–550 nm, it seems reasonable to assume that the band in dithizone at the lower wavelength (*ca* 440 nm) is due to the thiol form (**2**) and that the change in spectrum when a metal complex is formed is due to the disappearance of the thione band at *ca* 620 nm and a bathochromic shift of the thiol band. The assignment of the band at *ca* 620 nm to the thione form is supported by the data for thiobenzophenone and other thioketones (which absorb near 600 nm) and from studies on the spectra of 2-mercaptobenzothiazoles and thioquinolines and their *S*- and *N*-methyl derivatives.[7]

The classical method of assigning structures to potentially tautomeric systems such as dithizone is to compare the spectra of the parent substance with that of derivatives in which the structure has been locked unambiguously in the thiol or thione form by *S*- or *N*-methylation.[9] This fails in the case

Table 1. The visible absorption spectrum of dithizone in different solvents[a]

of dithizone: for while authentic *S*-methyldithizone (**3**) has been synthetized by Irving and Bell,[10] its initially permanganate pink solution in chloroform (λ_{max} 270 and 550 nm, ε_{550} 1225 m^2 mol^{-1}) isomerizes rapidly by first-order kinetics to a yellow isomer (λ_{max} 280, 420 and 540 nm; ε_{420} 1775 m^2 mol^{-1}), the band at 550 nm becoming less intense as that at 420 nm increases. The configurational changes in this system, which are strikingly catalysed by both acids and bases, have recently been elucidated by NMR, IR and visible absorption spectroscopy on **3** and its methyl-substituted homologues and ^{13}C- and ^{15}N-labelled analogues,[11] as well as by X-ray crystallography.[12]

Many of the doubts concerning the existence and structures of thiol and thione forms of dithizone would be resolved if *N*-methylated derivatives such as ArNH—N(Me)—C(S)—N=NAr′, ArN(Me)—NH—C(S)—N=NAr′ and ArN(Me)—N(Me)—C(S)—N=NAr′ could be obtained. Many authors have attempted such syntheses but without success;[2,13,14] in Carlin's Ph.D. dissertation[8] it is stated that these important compounds had been prepared by Barak and Corwin (Ar = Ph, Ar′ = *p*-BrC_6H_4) and various spectra are reported and discussed. No details of these syntheses have ever been published or could be obtained by correspondence. Incidentally, the experimentally verified fact[13] that solutions of dithizone conform strictly with Beer's law enables us to reject Carlin's suggestion[8] that a dimeric form of dithizone (two intermolecularly hydrogen-bonded molecules in the thione form) is one of the species in equilibrium in solution.

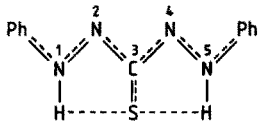
The visible absorption spectrum of dithizone is very sensitive to the organic solvent in which it is dissolved. Although changes in the maxima of the two absorption bands are comparatively small [generally ±4% (cf. Table 1)] the magnitudes of the extinction coefficients may vary by as much as 60% and increases in $\varepsilon_{max,1}$ are commonly associated with decreases in $\varepsilon_{max,2}$ so that the "peak ratio" R ($A_{max,1}/A_{max,2}$) can vary from 1.09 in *n*-hexane to 2.72 in tetrachloroethane. (The subscripts 1 and 2 are used to distinguish the longer and shorter wavelengths, respectively.) There appears to be no simple relationship between shifts in λ_1, λ_2, ε_1 or ε_2, or R values with any of the empirical solvent polarity scales Z, E_T or S (which are linearly related),[15] or with Taft's π^* scale,[16] although there is a tendency for R to increase with solvent polarity. There is, however, quite a striking correlation between the R for dithizone and the values (measured in the same solvent) of the concentration ratio [keto]/[enol] for ethylacetoacetate, or the R for 1-(4-methoxy-3,5-dimethyl)phenylazo-2-naphthol, where an equilibrium between azo and hydrazo tautomers has been postulated.[17] This would seem to favour the hypothesis that solutions of dithizone comprise an equilibrium mixture of thione and thiol tautomers.

It must not be overlooked that the value of R is not a simple measure of the relative amounts of the two postulated tautomers in solution and thence of the equilibrium constant of the reaction **1** ⇌ **2**. Specifically, $R = A_{thione}/A_{thiol} = \varepsilon_{thione}[thione]_o l/\varepsilon_{thiol}[thiol]_o l = K_{T,o}(\varepsilon_{thione}/\varepsilon_{thiol})$, where $K_{T,o} = [thione]_o/[thiol]_o$ is the equilibrium constant for the two tautomers present in the organic solvent. There will only be a linear relationship between R and $K_{T,o}$ if $\varepsilon_{thione} = \varepsilon_{thiol}$ or if the ratio $\varepsilon_{thione}/\varepsilon_{thiol}$ is a constant for all solvents. Admittedly Pel'kis and Dubenko[18] deduced that $\varepsilon_{thione} = \varepsilon_{thiol} = 5745$ m^2 mol^{-1} for chloroform, 5768 m^2 mol^{-1} for benzene, and 5745 m^2 mol^{-1} for carbon tetrachloride solutions, but the basis of their argument is unsound.[19]

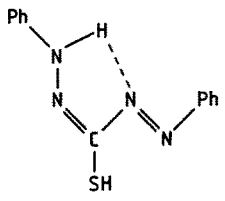
The application of ^1H NMR spectroscopy to dithizone chemistry has hitherto been indecisive owing to the low solubility of dithizone, although in 1970 Coleman *et al.*,[20] using the more soluble homologue 1,5-di(*o*-ethylphenyl)thiocarbazone in $CDCl_3$, observed δ 1.4 (6H, triplet, CH_3), 3.0 (4H, quartet, CH_2), 7.3, 8.1 (8H, multiplet, Ar*H*), and 12.0 ppm (1.6H, singlet, N*H*). The latter resonance, which disappeared on addition of MeOD, showed no signs of splitting over the range +50 to −45°C, and the authors ruled out the hypothesis of tautomeric equilibrium in favour of a single symmetrical species (as **4**), essentially that subsequently established for the solid-state structure by X-ray crystallography,[21] which shows a nearly planar molecule with extensive delocalization of π-electrons, the C—S distance [1.71(1) Å] corresponding to a thioketone rather than a thiol structure. The same extended *anti,s-trans* structure has recently been reported for the dithizone moiety in the crystal structures of the neutral charge-transfer molecular compounds (H_2Dz)–I_2 and $2(H_2Dz)$–$7I_2$, though the location of the hydrogen atoms was not established.[22]

Although Coleman *et al.*[20] noted the effects on the visible spectrum of changes in solvent they suggest that these "appear to be complicated by acid–base equilibria, trace metal effects and even oxidative decomposition of the dithizone".[20] In our experience none of these factors is involved in the solvatochromism. It is noteworthy that Coleman *et al.*[20] observed only 1.6 protons (instead of 2.0), and when Nabilsi examined the ^1H NMR spectrum of dithizone itself[23] he found signals at δ 0.97 as well as at δ 12.61 ppm of integrated intensity 1:3 and

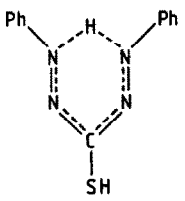
fully accounting for 2.0 protons. The signal at δ 0.97 ppm was attributed to a non-hydrogen-bonded SH group and Nabilsi suggested that dithizone in $CDCl_3$ solution exhibited a tautomeric equilibrium comprising 25% of the thiol form which might be formulated as **5** or the mesomeric form **6**, together with 75% of a thione form formulated as **4** or **7**.[23]



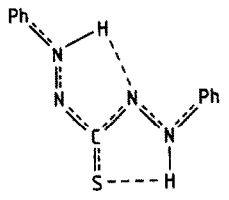
(4)



(5)



(6)



(7)

In view of these and many other discrepancies[7] it was decided to re-examine the solution spectra (particularly by NMR) of dithizone, its alkyl-substituted homologues, and its ^{13}C- and ^{15}N-labelled analogues in search of fresh and possibly decisive data.[24]

RESULTS AND DISCUSSION

Although the use of Fourier transform NMR spectroscopy facilitates measurements on sparingly soluble solutes, to the extent that for the first time good ^1H NMR spectra of dithizone itself were obtained here, it must not be overlooked that residual protons in deuteriated solvents can give rise to spurious signals; a residual line from adventitious $CHCl_3$ enhances the integrated value for aromatic protons so that the intensity of other lines relative to this will be underestimated. In the present work dithizones substituted in their phenyl rings with alkyl groups were used to provide well-defined lines for integration reference and to examine the equivalence or otherwise of the two aryl groups. Using highly purified dithizone Nabilsi's alleged[23] S*H* peak at δ 0.97 ppm could not be reproduced, and this must have originated from solvent or solute impurity or even as a spinning side-band of an intense Me_4Si resonance. Seven alkyl-substituted homologues of dithizone (Table 2) were prepared by Bamberger's method[3] from the corresponding nitroformazans. There were no differences between

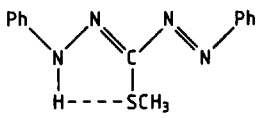
[a] 90-MHz spectra at ambient temperature. Chemical shifts [δ (ppm)] are given for $CDCl_3$, $(CD_3)_2CO$ and C_6D_6 solutions, in that order, relative to $(CH_3)_4Si$. Coupling constants in Hz. Abbreviations used: s, singlet; d, doublet; t, triplet; q, quartet; h, heptet; m, multiplet.

[b] All singlets: all integrate for 2H except in $(CD_3)_2CO$ solutions where the integrals vary from 0.7 to 1.5H due to trace D_2O in the deuterioacetone (see text). All disappear on addition of D_2O.

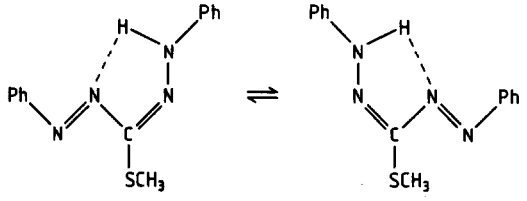
[c] Obscured by solvent resonance.

the visible absorption spectra of individual compounds measured in $CHCl_3$ or $CDCl_3$; all the compounds show two peaks, one close to 445 nm and one at 620 nm. Their ^1H NMR spectra were measured in each of three solvents, viz. $CDCl_3$, $(CD_3)_2CO$ and C_6D_6, with the results shown in Table 2. In every case the substituent alkyl groups (and hence the two aromatic rings) are found to be exactly equivalent on the NMR time-scale, and spectra at $-50°C$ differed from those at $+60°C$ only by the expected slight narrowing of peaks. The same equivalence follows from examination of the aromatic resonances themselves, and it must be concluded that on the NMR time-scale there is only one (symmetrical) molecule in solution. Furthermore, the singlet due to N*H* at *ca* δ 12.5 ppm always integrates for *exactly* two protons in $CDCl_3$ and C_6D_6, and disappears immediately and completely upon washing with D_2O. In $(CD_3)_2CO$ and N*H* singlets integrate for something less than 2.0 protons but no new peaks arise to account for the missing fractions of protons, and we believe that traces of D_2O in the incompletely dry solvent have exchanged with the imino hydrogens to reduce the intensity of the signals. The effect of traces of D_2O in the NMR solvent is accentuated by the dilute solutions afforded by even the substituted thiocarbazones.

That the two non-aromatic protons in dithizone must be bound to equivalent nitrogen sites, viz. N-1 and N-5 (as **4**), was confirmed by preparing dithizone labelled with ^{15}N at N-1 and N-5 from a sample of 3-nitro-1,5-diphenylformazan, itself prepared by coupling nitromethane in alkaline solution with a diazonium solution prepared from 96 atom-% ^{15}N-enriched aniline, following a modification[24] of Bamberger's general procedure[3] (see Experimental). In the ^1H NMR spectrum of this compound in $CDCl_3$ the N*H* signal at δ 12.60 ppm is split into a doublet with a normal[25] coupling constant value of 90.8 Hz (unchanged at $-50°C$). This value excludes the possibility of a rapid thiol–thione tautomeric equilibrium. In such a tautomeric system the observed spin coupling, J(obs), would be given by a weighted average of the various coupling constants involved,[26] in that case ^1J(S–H) and $^1J(^{15}N–H)$. If P(S) and P(N) represent the mole fractions of the two tautomeric species, then $J(\text{obs}) = {}^1J(\text{S–H})P(\text{S}) + {}^1J(^{15}\text{N–H})P(\text{N})$, and if $^1J(^{15}N–H)$ for an unperturbed N—H bond is assumed to be *ca* 90 Hz,[25] then, since ^1J(S–H) is zero, we find that P(N) = 1 and the protons must be bonded to the N-1 and N-5 atoms of a single species. Thus we have previously found a value for $^1J(^{15}N–H)$ of 92.2 Hz in the yellow *anti,s-trans* form of *S*-methyldithizone (**8**), where tautomerism is impossible, while in the pink *syn,s-cis* form **9a** ⇌ **9b**, where a rapid tautomeric equilibrium does exist, $^1J(^{15}N–H)$ is approximately halved (47.6 Hz).[11]

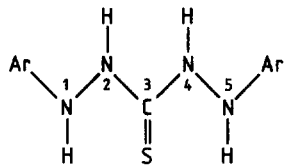


(8)



(9a) (9b)

The diphenylthiocarbazide, which is known to have structure **10** (Ar = Ph) in the solid state,[27] is obtained in the course of the synthesis of dithizone. Its ^1H NMR spectrum in $CDCl_3$ shows two N*H* resonances (at δ 6.18 and 8.08 ppm), each integrating for two protons and both disappearing on washing with D_2O. The spectrum of the compound labelled with ^{15}N at N-1 and N-5 shows the signal at δ 6.18 ppm to be split into a doublet with $^1J(^{15}N–H) = 85.2$ Hz. Clearly the N-1 and N-5 protons are not involved in intramolecular exchange, whereas nothing can be said about the protons attached to N-2 and N-4 until the appropriate labelling studies have been carried out. No success attended efforts to obtain ^{15}N NMR signals from the above ^{15}N-labelled compounds whether using broad-band or inverse-gated ^1H-decoupling.[24]



(10)

Further evidence was obtained when dithizone labelled at C-3 with ^{13}C was synthetized from phenylhydrazine and 91 atom-% ^{13}C-enriched carbon disulphide using modifications[24] of Fischer's original synthesis[1,28] suitable for very small scale working (see Experimental). Had $CDCl_3$ solutions of this compound contained thiol and thione forms in slow-enough dynamic equilibrium, the ^{13}C-3

NMR signal from each form might have been individually observable. In fact there is a single peak in the ^{1}H-decoupled spectrum at δ 171.4 ppm downfield from Me_4Si which does not shift or split at $-50°C$. For comparison, the thiocarbonyl resonances in EtNH—C(S)—NHEt and H_2N—C(S)—NH_2 are at 182.8 and 176.7 ppm, respectively.[29] More conclusive, however, is the ^{1}H-coupled spectrum in which the ^{13}C-3 signal splits into a perfectly symmetrical 1:2:1 triplet with $^3J(^{13}C–N–N–H) = 6.0$ Hz (unchanged at $-50°C$) and which collapses to a singlet on washing with D_2O. The same coupling $^3J(H–N–N–^{13}C) = 6.0$ Hz is also found in the ^{1}H NMR spectrum of the ^{13}C-labelled dithizone, where the N*H* peak is split into a doublet, unchanged at $-50°C$ apart from a slight narrowing of the lines. An earlier ^{13}C NMR study of dithizone was inconclusive.[30]

These data, along with the demonstrated magnetic equivalence of the two imino protons and the two aromatic residues, point to the symmetrical structure **4**, as already established by X-ray crystallography for dithizone in the solid state.[21,22] The view that only a single species (as **4**) is present in solution is consistent with the fact that the visible absorption spectrum of dithizone in chloroform does not vary over the temperature range -50 to $+60°C$: in particular, *R* does not change as it would if there were two species in equilibrium. Thus either the two absorption peaks cannot be ascribed to two discrete species (thiol and thione tautomers), or it becomes necessary to accept the surprising conclusion that their interconversion proceeds with no change in enthalpy.[31] Bag and Freiser[32] recently observed that the molar absorptivity of dithizone in cyclohexane is dramatically enhanced by the addition of small quantities of chloroform, and they attributed this to the formation of a 1:2 dithizone–chloroform complex (formation constant $10^{4.0}$). However, the ratio of the two peak heights did not change significantly, indicating that the observed enhancement was not the result of shifting a thiol–thione equilibrium.

The conclusions drawn from these new NMR data, which extend the early measurements of Coleman *et al.*,[20] agree with those drawn from IR measurements.[33] These show a broad band in the region 3100–2800 cm^{-1} with several absorption maxima. On deuteriation this band disappears and is replaced by one at *ca* 2200 cm^{-1} assigned to ν(N—D), while in the region 3100–3000 cm^{-1} only maxima corresponding to aromatic ν(C—H) remain. There are no traces of ν(S—H) bands (expected at *ca* 2600 cm^{-1}). The close similarity between the IR spectrum of dithizone in solution and in the solid state appears to deny the possibility of tautomerism, and it is perhaps significant that the diffuse-reflectance spectrum of solid dithizone shows a clearly defined band at 450 nm (situated similarly to $\lambda_{max,2}$ in organic solutions) with a broad shoulder covering the region 580–610 nm, which roughly corresponds with the location of $\lambda_{max,1}$ in the solution spectra. A recent and thorough Raman vibrational spectroscopic investigation[34] of the acid–base forms of dithizone has indicated that significant structural changes occur when a proton is added to or lost from neutral dithizone (H_2Dz) to form the corresponding conjugate acid of dithizone (H_3Dz^+) or dithizonate anion (HDz^-). Exploitation of resonance intensity enhancement in these systems allowed the Raman spectra of necessarily dilute solutions of the acid–base forms of dithizone to be acquired: the vibrational data[34] obtained from CS_2 solutions of H_2Dz are clearly consistent with the dithizone molecules existing in the single form shown as structure **4**.

There is no reason why a single species in solution, such as **4**, should not give rise to a visible spectrum with two intense visible absorption bands. Indeed, theoretical calculations of the energy and intensity of the electronic transitions in different forms of dithizone have been made (using LCAO MO SCF LCI methods),[35] with some success for the protonated species H_3Dz^+ and the anion HDz^-. For dithizone itself a spectrum with two prominent bands is predicted, the model used being basically the same as **4** (save that one hydrogen atom is bound to sulphur as a thiol). One of these bands is predicted at *ca* 430 nm corresponding to the $\lambda_{max,2}$ found experimentally; the other is located at *ca* 800 nm, which is well away from the experimental values of $\lambda_{max,1}$ (600–640 nm). Moreover, the intensity of this longer-wavelength band is predicted to be less than that at the shorter wavelength, which is never the case [*R* is always > 1 (see Table 1)]. However, it is clear that the simultaneous presence of thione and thiol forms in solutions of dithizone cannot be inferred from the existence of these two visible bands alone.

Of course, such calculations do not take into account the effect of solvent on the spectra and the pronounced solvatochromism remains to be explained, along with the curious relationships which have been noted between the experimental *R* and the equilibrium constant [keto]/[enol] for ethylacetoacetate in the same solvent, or between values of *R* for a series of structurally modified dithizones and the Hammett factors of the substituents.[7] Nevertheless, the new evidence reported here lends overwhelming support to the hypothesis that solutions of dithizone in organic solvents comprise only a single, highly symmetrical, and planar

species, as **4**. A very recent argument[36] in favour of a thiol–thione equilibrium, in which, *inter alia*, the visible absorption spectra of individual thiol and thione forms were calculated by mathematical analysis of the spectra of dithizone in four organic solvents (the assignment of a single band to each tautomer being rejected), fails to explain away the experimental evidence for a single structure provided by the present work. It has been shown in earlier papers that experimental values of $pH_{1/2}$, pK and R can legitimately be used in calculations, although they are compounded of parameters (partition coefficients, acid dissociation constants, molar solubilities etc.) relating to each of the alleged tautomeric forms, and to the equilibrium constant (K_T) governing the interconversion.[37] Thus none of these solvent effects nor, indeed, the existence of a single species (**4**) rather than the equilibrium **1** ⇋ **2**, has any influence on the reliability of the many applications of dithizone in the selective and quantitative spectrophotometric determination of microgram amounts of various metals using the numerous monocolour, mixed-colour or reversion procedures that have been developed over the years.[5,6] A preliminary communication on the work reported here has been published.[38]

EXPERIMENTAL

General and spectroscopic

Special care was taken in cleaning the optical cells, the NMR tubes, and the glassware in which solutions of the thiocarbazones were handled. The cleaning was done by soaking the apparatus in a chromic acid bath, washing with hot water, and then soaking in a strong ammoniacal solution of the disodium salt of ethylenediaminetetraacetic acid. Finally the apparatus was thoroughly rinsed with glass-distilled water and dried in an oven at 130°C. This provided metal-free glassware as tested by a very dilute solution of dithizone in chloroform, which remained pale green when used to rinse the apparatus.

Visible absorption spectra were recorded on a Varian Superscan 3 instrument using 1.00-cm matched quartz cells. Diffuse-reflectance spectra were taken as Nujol mulls on filter paper using a Beckman DK-2A ratio-recording spectrophotometer in the reflectance mode. ^{1}H NMR spectra were measured at 90 MHz on a Bruker WH-90DS Fourier transform spectrometer at ambient temperature (*ca* 32°C) and at −50°C. Chemical shifts are quoted relative to Me_4Si and are accurate to ±0.04 ppm, while coupling constants are estimated to ±0.02 Hz. ^{13}C NMR spectra with broad-band ^{1}H decoupling were measured at ambient temperature and at −50°C on the same spectrometer operating at 22.63 MHz. The ^{1}H-coupled spectra were obtained in the gated proton irradiation mode.[39] Chemical shifts were recorded relative to the $CDCl_3$ signal and related to the standard Me_4Si using the conversion $\delta(Me_4Si) = \delta(CDCl_3) + 76.9$ ppm;[40] they are accurate to an estimated 0.1 ppm. Shiftless relaxation agents were not used. All solvents used for spectroscopic work were of spectroscopic grade, and were purified and dried. Care was taken to ensure no traces of acid were present and to run the $(CD_3)_2CO$ spectra immediately after making up the samples so as to avoid the reported[41] condensation of acetone with dithizones in acid conditions to form the corresponding thiadiazolines.

A comparison of the visible spectrum of dithizone in $CHCl_3$ and $CDCl_3$ was made by purifying a small quantity of dithizone by paper chromatography and extracting the pure dithizone spot into $CHCl_3$ in an optical cell (1.00-cm) and filling with $CHCl_3$ to a mark. After recording this spectrum the solvent was carefully evaporated from the optical cell under reduced pressure and the cell was refilled to the mark with $CDCl_3$. The resulting spectrum was identical to the first.

Preparative work

Glass-distilled water and purified solvents were used throughout the preparative work.

3-*Nitro*-1,5-*diarylformazans*. Sodium hydroxide pellets (4.0 g, 0.10 mol) were dissolved in water (15 cm^3) and cooled in an ice–salt bath to 0°C. A solution of nitromethane (6.4 g, 0.10 mol) in ethanol (35 cm^3) was added slowly with constant mechanical stirring and keeping the temperature below 0°C. Ice water and crushed ice (*ca* 500 g) were added to dissolve the white precipitate and the solution was kept at 0°C until used. The arylamine (0.20 mol), freshly distilled over zinc dust, was added to a mixture of concentrated hydrochloric acid (60 cm^3) and distilled water (100 cm^3) in a 2-l beaker. The resultant clear solution was cooled to 0°C in an ice–salt bath and diazotized by adding dropwise and with mechanical stirring a solution of sodium nitrite (16.6 g, 0.24 mol) in distilled water (30 cm^3). Filtration of the clear yellow solution was not usually necessary and sodium acetate (41 g, 0.5 mol) dissolved in distilled water (120 cm^3) was added dropwise, keeping the temperature at 0°C, to buffer the solution at pH *ca* 4.5. The alkaline nitromethane solution was placed in a separating funnel containing crushed ice and dropped slowly, with vigorous mechanical stirring, into the diazotized

solution. The required 3-nitro-1,5-diarylformazan separated at once as a bright red precipitate, oil or tar. The solution was stirred for a further 1–6 h after which time any tars had turned solid. The solids were collected on a large Buchner funnel by suction and washed with copious quantities of water, while oils were extracted into chloroform, washed with water, dried with $MgSO_4$, and evaporated to dryness. After drying overnight *in vacuo* over silica gel all of these solids recrystallized easily from ethanol to give well-formed maroon or dark-red needles or plates with the characteristics listed in Table 3.

Any tendency to form a tar was minimized by keeping the temperature well below 0°C, by waiting long enough for the nitrogen oxides to escape after diazotization, and by employing pure nitromethane and freshly-distilled arylamines.

A small-scale adaptation of the above procedure[24] was used to synthetize the 3-nitro-1,5-diphenylformazan labelled at N-1 and N-5 with ^{15}N, starting from 0.63 g of 96 atom-% ^{15}N-aniline supplied by BOC Prochem.

1,5-*Diarylthiocarbazones.* 3-Nitro-1,5-diarylformazan (8.0 g) was suspended in absolute ethanol (60 cm^3) in a 100-cm^3 round-bottomed flask and cooled to 0°C in an ice–salt bath. Dry ammonia gas was bubbled through the mixture until it was saturated (10 min) and then hydrogen sulphide gas was passed into the solution until the thiocarbazide (**10**) separated. When reduction was complete as indicated by a change of colour from maroon to yellow, and by the disappearance of unreduced particles of the nitroformazan, the suspension was added in a thin stream to distilled water (200 cm^3) with mechanical stirring, and immediately filtered off by suction. The thiocarbazides were washed with water and dried over silica gel *in vacuo* to give yields of 86–93%. The surface of the dry powders slowly turned from cream to grey-green as oxidation took place. The unstable thiocarbazide compounds (**10**) were oxidized at once to the thiocarbazones by treating with a 5% methanolic potassium hydroxide solution (30 cm^3) at room temperature. After mixing well and breaking up lumps with a stirring rod, a clear dark-red solution was obtained which was immediately neutralized by pouring slowly into ice-cold dilute 0.5 M sulphuric acid (1 l) with vigorous mechanical stirring. After stirring for 1 h the crude 1,5-diarylthiocarbazone was filtered off, washed with water, and dried over silica gel *in vacuo*.

Purification of this product is necessary as oxidation of the thiocarbazone results in small quantities of the corresponding 2,3-diaryl-2*H*-tetrazolium-5-thiolate contaminating the product. Spectroscopically pure dithizonates are usually prepared[42] by an extensive series of extractions from chloroform into a dilute aqueous base, washing the aqueous layer with more chloroform, and re-extraction into chloroform or precipitation from the aqueous phase by acidification. In this work it was found that column chromatography provided a cleaner, quicker method of purification with a greatly enhanced yield.

The crude material (1.0 g) was dissolved in the minimum amount of benzene and added to a chromatographic column (30 × 2.5 cm) of neutral alumina slurried in benzene. Elution with benzene produced a red fore-run. Once this was visibly separated from the dark band at the origin, elution was continued with solutions of acetone in benzene, increasing the acetone concentration rapidly so that pure acetone was used to wash off the last of the red fore-run. The thiocarbazone fraction was collected by adding a 1% solution of sodium bicar-

Table 3. Yield, melting point and microanalytical data[a] for the 3-nitro-1,5-diarylformazans

Aryl group	Yield (%)	M.p. (°C)	% C	% H	% N
Phenyl	57	159–161	58.05 (58.0)	4.1 (4.1)	25.65 (26.0)
Phenyl[b]	68	159–161	58.0 (57.6)	4.0 (4.1)	26.2 (26.55)
p-Tolyl	31	159–162	60.55 (60.6)	5.15 (5.05)	23.2 (23.6)
m-Tolyl	15	155–157	60.65 (60.6)	5.2 (5.05)	23.4 (23.6)
o-Tolyl	13	151–154	60.65 (60.6)	5.1 (5.05)	23.6 (23.6)
3,5-Dimethylphenyl	41	143–145	62.3 (62.8)	5.95 (5.85)	21.3 (21.5)
p-Isopropylphenyl	16	130–133	64.7 (64.6)	6.7 (6.6)	19.35 (19.8)
p-*n*-Butylphenyl	28	126–127	66.2 (66.1)	7.3 (7.1)	18.35 (18.4)

[a] Calculated values are in parentheses.
[b] Labelled at N-1 and N-5 with 96 atom-% ^{15}N.

bonate in water to the column, and the resulting orange eluent was then slowly poured with stirring into dilute aqueous sulphuric acid (0.1 M). After stirring for a further 1 h the fine blue-black precipitate of pure thiocarbazone was collected by filtration, washed with water, and dried over silica gel *in vacuo*. The analyses, melting points, and yields of the thiocarbazones synthetized are given in Table 4.

Smooth oxidation procedure. In the above synthesis the final oxidation of the thiocarbazide to the corresponding thiocarbazone was carried out with methanolic potassium hydroxide: this is actually a disproportionation reaction and the maximum yield of thiocarbazone can be only 50%. It was found[24] that yields of 80–95% of the thiocarbazone could be obtained by smooth oxidation of the thiocarbazide. The thiocarbazide is dissolved or suspended in an organic solvent (*vide infra*) and air is slowly bubbled through the solution until the production of a very deep green colour indicates complete oxidation. Recalcitrant thiocarbazides may require reflux temperatures for acceptably rapid oxidation. Purification is necessary as oxidation of the thiocarbazone again results in small amounts of the corresponding 2,3-diaryl-2*H*-tetrazolium-5-thiolate in the product. This smooth oxidation procedure was applied to the synthesis of dithizone labelled at N-1 and N-5 with ^{15}N.

^{15}N-*labelled dithizone.* 3-Nitro-1,5-diphenylformazan labelled at N-1 and N-5 with 96 atom-% ^{15}N obtained as above (0.60 g) was suspended in ethanol (15 cm^3) and treated with ammonia gas and hydrogen sulphide as described before. Isolation as above gave the ^{15}N-labelled 1,5-diphenylthiocarbazide (0.52 g, 91%). After setting some product aside for NMR spectroscopy, the remainder (0.46 g) was suspended in carbon tetrachloride (300 cm^3) in a 2-l, two-necked round-bottomed flask placed on a heating mantle. A stream of air was bubbled through the solution which was brought to boiling temperature. A long condenser fitted to the flask reduced evaporation of the solvent, but it was necessary to add further portions of solvent periodically. The colour of the solution changed to an intense dark green over *ca* 2 h. Additional solvent (100 cm^3) was then added to dissolve some unoxidized thiocarbazide and after a total of $2\frac{1}{2}$ h of bubbling the carbon tetrachloride was removed on a rotary evaporator. The residue was taken up in the minimum amount of benzene and purified by column chromatography as described above to yield the ^{15}N-labelled dithizone [0.39 g (85% based on thiocarbazide)].

The use of carbon tetrachloride as solvent in this smooth oxidation of the thiocarbazide was found in trial experiments with unlabelled compounds to give a better yield than diethyl ether (72%) or benzene (76%), presumably because of the greater solubility of dithizone in CCl_4.

Reaction of NaHS *with* 3-*chloro*-1,5-*diphenylformazan.* A second route to obtain the ^{15}N-

Table 4. Yield, melting point and microanalytical data[a] for the 1,5-diarylthiocarbazones

Aryl group	Yield[b] (%)	M.p.[c] (°C)	% C	% H	% N
Phenyl[d]	85	166–169	60.15 (60.4)	4.7 (4.7)	22.4 (22.5)
Phenyl[e]	26	167–170	60.9 (61.05)	4.6 (4.7)	21.6 (21.8)
p-Tolyl	28	161–163	63.15 (63.6)	5.55 (5.3)	19.75 (19.8)
m-Tolyl	17	154–158	63.3 (63.6)	5.4 (5.3)	19.75 (19.8)
o-Tolyl	22	135–138	63.2 (63.6)	5.45 (5.3)	19.7 (19.8)
3,5-Dimethylphenyl	28	137–140	65.2 (65.6)	6.1 (6.15)	18.2 (18.0)
p-Isopropylphenyl	14	142–145	67.0 (67.2)	6.5 (6.8)	16.7 (16.5)

[b] Based on 1,5-diarylthiocarbazide; synthetized using a methanolic KOH oxidation procedure.

[c] All with decomposition.

[d] Labelled at N-1 and N-5 with 96 atom-% ^{15}N; synthetized using a smooth oxidation procedure.

[e] Labelled at C-3 with 91 atom-% ^{13}C; synthetized in one-pot reaction from phenylhydrazine and carbon disulphide.

[f] Sample provided by Prof. H. M. N. H. Irving.

labelled dithizone was investigated which avoids the reduction and low-yield oxidation steps of Bamberger's synthesis.[3] In this route[43] the reactivity of the halogen atom in 3-chloro-1,5-diphenylformazan, PhN=N—C(Cl)=N—NHPh, was exploited in the reaction with sodium hydrogen sulphide to obtain the dithizone directly, either by mechanical shaking at room temperature or by heating under reflux with NaHS. The 3-chloro-1,5-diphenylformazan was obtained by coupling a benzenediazonium solution with dipotassium chloromalonate, itself prepared by the following reaction sequence:

$$CH_2(CO_2Et)_2 \xrightarrow{SO_2Cl_2} ClCH(CO_2Et)_2$$

$$\xrightarrow[EtOH,\,0°C]{KOH} ClCH(CO_2K)_2.$$

This method, however, gave an overall poorer yield in trial runs (*ca* 15% based on aniline) than the route from the nitroformazan, especially if the smooth oxidation procedure was used in the latter route (>50% based on aniline), and so was discarded as a suitable route to the isotopically-labelled dithizone. Further experimental details will be found in Ref. 24.

^{13}C-*labelled dithizone*. This was prepared by a modification of Fischer's original synthesis,[1,28] so adapted that the entire reaction sequence could be carried out in a single vessel with a view to conserving valuable labelled material.[24] Phenylhydrazine (1.42 g, 13.2 mmol) was dissolved in benzene (20 cm^3) in a 50-cm^3 two-necked flask equipped with a magnetic stirrer and a condenser. Carbon disulphide (91 atom-% ^{13}C from BOC Prochem, 0.50 g, 6.6 mmol) was dropped into the solution with constant stirring when the phenylhydrazine salt of the acid PhNH—NH—^{13}C(S)—SH separated as a light-yellow, practically solid sludge. The temperature was gradually raised to 65°C (water bath) when the precipitate gradually dissolved and H_2S was evolved. After *ca* 20 min evolution of H_2S ceased and the thiocarbazide which remained was oxidized by drawing air through the solution while the temperature was increased to 75°C. Additional benzene (20 cm^3) was added, and after 1 h of bubbling the deep green solution was evaporated to dryness and the crude product was purified by column chromatography as described above to give pure ^{13}C-labelled dithizone (0.44 g, 26%).

Acknowledgement—I would like to thank Professor H. M. N. H. Irving for all his help, guidance and friendship over the years, and for passing on and sharing his enthusiasm for the dithizone saga.

CRYSTAL AND MOLECULAR STRUCTURE OF ISOPRENALINE

JOHN F. MALONE* and MASOOD PARVEZ

Department of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, U.K.

(*Received* 3 *July* 1986)

Abstract—Unlike the related sympathomimetic catecholamines adrenaline and noradrenaline, which exist as zwitterions in the solid state, the β-adrenoreceptor stimulant isoprenaline is shown by crystal structure analysis to contain only neutral atoms. Crystals are monoclinic, space group $P2_1/c$, with $a = 9.93(2)$ Å, $b = 13.56(3)$ Å, $c = 8.13(1)$ Å, and $\beta = 101.6°$. The structure was determined by direct methods and refined to $R = 0.087$ for 1154 independent data. The side chain has the fully extended *anti* conformation.

Inorganic acids form chelates with di- and polyphenols, and with the related catecholamines. For a range of protonated catecholamines in aqueous solution, including isoprenaline (**1**), it has been shown that the first phenolic group is more acidic than the protonated amino group.[1] This has been supported by crystal structure analyses of the catecholamines adrenaline[2] (**2a**) and noradrenaline[3] (**2b**), which possess α- and β-adrenergic activity, and of the structurally-related α-adrenoreceptor stimulant phenylephrine[4] (**3**), which show these compounds to exist as zwitterions in the solid state. In each case it is the *meta*-OH group which donates a proton to the nitrogen atom.

Isoprenaline {isoproterenol [1-(3′,4′-dihydroxyphenyl-2-isopropylaminoethanol]} is the most active of those sympathomimetic amines which act almost exclusively on β-receptors, stimulating the heart muscle as well as dilating the bronchioles. The (−)-isomer (**1**) is 50 times as powerful as the (+)-isomer in circulatory activity in man. On the basis of acid ionization constants in solution an analogous zwitterionic structure would be expected for the solid-state free amine. An earlier crystallographic examination of (±)-isoprenaline in the form of its dihydrated sulphate has been performed,[5] but does not, of course, give any information concerning the ionic state of the free base. The

present study was undertaken in order to establish the molecular characteristics of the free base (±)-isoprenaline and to compare the conformation of this drug with other catecholamines.

EXPERIMENTAL

Crystal data

$C_{11}H_{17}NO_3$, $M = 211.2$, space group $P2_1/c$ (No. 14), $a = 9.93(2)$ Å, $b = 13.56(3)$ Å, $c = 8.13(1)$ Å, $\beta = 101.6°$, $U = 1072.5$ Å^3, $Z = 4$, $D_x = 1.32$ g cm^{-3}, $D_m = 1.32$ g cm^{-3} (by flotation in $CHCl_3$–petroleum ether), λ(Cu-K_α) = 1.5418 Å, $\mu = 7.95$ cm^{-1}, $F(000) = 456$.

Crystals of the free base were obtained from its sulphate by treating with aqueous ammonia under nitrogen. The crystals of (±)-isoprenaline were thin colourless plates. Data were recorded on multiple-film equi-inclination Weissenberg photographs (layers *hk*0–*hk*7) and intensities were measured by a densitometer.* Correction for Lorentz and polarization factors yielded 1154 independent structure factors. The non-hydrogen atoms were located in the E-map with the highest absolute figure of merit obtained via the direct phasing methods of MULTAN.[6] After initial least-squares refinement all 17 hydrogen atoms were located in a difference Fourier synthesis, and were included in the refinement with individual isotropic temperature factors. Non-hydrogen atoms were refined anisotropically. At convergence, R was 0.087. The final weighting scheme was $W = (10 + |F_o| + 0.01|F_o|^3)^{-1}$. A final-difference Fourier showed no significant features.

RESULTS AND DISCUSSION

A projection of the molecule is shown in Fig. 1 and the unit-cell contents in Fig. 2. Table 1 lists the principal bond lengths and angles. A full list of results comprising atomic coordinates, anisotropic temperature factors for non-hydrogen atoms, and bond lengths and angles involving hydrogens has been deposited with the Cambridge Crystallographic Data Centre.†

Although a zwitterionic structure was to be expected on the basis of the solution acid ionization constants this analysis shows the isoprenaline molecule to exist in a non-ionized form in the solid state. All hydrogen atoms were located and successfully refined. As the critical hydrogen atom, namely the *m*-hydroxy atom H(O2), is not hydrogen-bonded to the nitrogen of any adjacent molecule the molecule is clearly present in the neutral form. To confirm this phenolic C—O distances, 1.375(6) and 1.380(5) Å, are normal for phenols, unlike the C—O^- distances of 1.346(5) Å in adrenaline,[2] 1.338(3) Å in noradrenaline[3] and 1.341(3) Å in phenylephrine.[4] The molecular dimensions are normal. The catechol is planar, the maximum deviation of any atom from the benzene ring being 0.009 Å. The deviations of the two H atoms on the phenolic groups from the mean plane of the catechol group are 0.002 and 0.018 Å. The side chain, comprising C(1), C(7), C(8) and N(1), is fully extended (*anti* conformation) as found in (±)-isoprenaline sulphate dihydrate.[5] The side chain is approximately perpendicular (77.4°) to the plane of

METAL COMPLEXES OF 1,4,10-TRIOXA-7,13-DIAZACYCLOPENTADECANE-*N*,*N*′-DIACETIC ACID

RITA DELGADO, J. J. R. FRAÚSTO DA SILVA*† and M. CÂNDIDA T. A. VAZ

Centro de Química Estrutural, Instituto Superior Técnico, Lisbon, Portugal

(*Received* 3 *July* 1986)

Abstract—The cyclic diaza-crown ether complexone cTOPDA (1,4,10-trioxa-7,13-diazacyclopentadecane-*N*,*N*′-diacetic acid) has been synthesized and characterized by elemental analysis, titration and NMR spectroscopy. Its ionization constants and the stability constants of its ML and M_2L complexes formed with alkali, alkaline-earth and some transition and representative metals were determined at 25.0±0.1°C and ionic strength 0.10 M (Me_4NNO_3). This ligand forms considerably more stable complexes with the transition metals than the analogous tetraoxa-diaza crown ether complexone cTOODA (1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-*N*,*N*′-diacetic acid), but this last ligand favours ions with larger size, particularly K^+. The cobalt(II) complex of cTOPDA is more stable than the nickel(II) complex, hence the Irving–Williams' order of stability is not obeyed for its transition-metal complexes. These effects are discussed in terms of the size of the cavity of the ligand and of the stereochemical constraints that it may impose.

Macrocyclic polyethers ("crown ethers") are well known for their complexation properties towards alkali and alkaline-earth metal ions: a quite remarkable selection can be achieved by changing the number of oxygen donors and the size of the internal cavity of the ligands.[1]

The inclusion in the ring of other types of donor atoms was a logical further step, since it may introduce a range of different effects by changing the affinity towards some metal ions while maintaining the selectivity associated with the relative dimensions of the ions and the cavity of the ligands.

Nitrogen and sulphur, naturally, are particularly interesting heterodonor atoms to investigate, and various studies were indeed carried out with a series of oligo-oxa–oligoaza or oligosulphur macrocycles in the last decade.[2–4]

The properties of such macrocycles as ionophores, models for catalytical centres, solubilizing agents etc. have been extensively discussed, but their analytical applications are limited by their sometimes reduced solubility in water, and by the fact that the stability of their metal complexes in aqueous solution is only moderate. These difficulties may be overcome by synthesizing macrocycles with hydrophylic pendant arms containing extra potential donors, e.g. —NH_2 or —COOH groups. Again, the stereochemical constraints imposed by these new donors may cause variations in the metal-complexing ability of the resulting ligand, which may or may not be of interest for the objectives envisaged.

The polyaza rings, with or without other donor atoms, afford some practical advantages for the introduction of pendant arms since the hydrogen atoms bonded to nitrogen in these ligands can easily be substituted by convenient groups using appropriate reactions; for example, the introduction of —CH_2COOH groups is normally achieved by reaction with chloroacetate or bromoacetate in a basic medium.

These *N*-acetate derivatives of oligoaza macrocycles are, of course, a cyclic version of the well-known polyamino carboxylic acids ("complexones"), widely used in analytical chemistry, adding now the versatility of these complexing agents to the selective character derived from the constraints imposed by the ring that contains several potential donor atoms.

We have previously studied a series of cyclic tetraaza complexones which have indeed some remarkable properties useful for analytical applications,[5]

Fig. 1. *N*-acetate derivatives of a group of oligo-oxa–oligoaza macrocycles. (a) $m = 2$, $n = 1$: 1,4,10-trioxa-7,13-diazacyclopentadecane-*N*,*N*′-diacetic acid (cTOPDA); (b) $m = 2$, $n = 2$: 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-*N*,*N*′-diacetic acid (cTOODA); and (c) $m = 1$, $n = 1$: 1,7-dioxa-4,10-diazacyclodecane-*N*,*N*′-diacetic acid (cDODDA).

and in the present work we report the results obtained for a member of a group of *N*-acetate derivatives of oligo-oxa–oligoaza macrocycles—like **Ia** (Fig. 1)—that are expected to display some unusual features due to the combined effects of cavity size, type of donor atoms and stereochemical constraints on the preferred coordination symmetry of some metals.

Compound **Ib** has been studied by other authors,[4,6] and results for **Ic** will be presented in a future paper.

EXPERIMENTAL

Synthesis and characterization of the ligand

cTOPDA dihydrochloride (cTOPDA·2HCl) was prepared by reaction of the corresponding amine [Kryptofix® 21 (Merck–Schuchardt)] with potassium chloroacetate, in aqueous solution at 70°C.

Potassium hydroxide was added at such a rate that the pH was always kept below 10. The reaction was complete after 8 h. The product was precipitated after acidifying the ice-cold solution to pH 0.5, and was recrystallized from a water–ethanol mixture.

cTOPDA·2HCl: m.p. = 205±1°C; *M* (titration) 407. Found: C, 41.0; H, 6.7; N, 6.84%. Required ($C_{14}H_{26}N_2O_7 \cdot 2HCl$): C, 41.3; H, 6.5; N, 6.88%. ^{1}H NMR spectrum [solvent D_2O, reference 2,2,3,3-tetradeutero-3-(trimethylsilyl) propionic acid (DTSS), pD ≅ 2.8]: δ 4.05 (singlet, 4H, acetate groups), 3.84 (triplet, 8H, ring protons), 3.76 (singlet, 4H, ring protons), and 3.68 (triplet, 8H, ring protons).

Reagents

Metal salts. Metal nitrates of analytical-reagent grade were used and solutions were prepared in demineralized water, and standardized by EDTA titrations.

The ionic strength was adjusted with a solution of Me_4NNO_3 (prepared from Me_4NOH and HNO_3 and recrystallized from 80% ethanol).

Carbonate-free Me_4NOH. Carbonate-free solutions of this titrant were prepared directly by dilution of the concentrated product (Merck, 10% aqueous solution) under purified nitrogen. The solutions (*ca* 0.05 M) were standardized by titration with 0.010 M hydrochloric acid. The absence of carbonate was tested regularly, and the solutions were discarded when its concentration reached 0.5% of the concentration of the hydroxide.

Potentiometric titrations

The experimental set-up has been described previously;[5] a Crison Digilab 517 measuring instrument was used together with an Ingold U 1330 glass electrode and a U 1335 saturated calomel reference. The temperature was controlled at 25.0±0.1°C by circulating water through the jacketed titration cell. The ionic strength was kept to 0.10 M by use of tetramethylammonium nitrate as background salt; the ionic product of water in these media was taken as 1.68×10^{-14}.

The glass electrode was calibrated in terms of $[H^+]$ by titrating solutions of hydrochloric acid and potassium hydroxide of known concentrations, and correlating the mV readings with calculated values of $[H^+]$. The $[H^+]$-dependent junction potentials were found to be negligible (from Gran plots), and the correlation between measured e.m.f. and calculated $[H^+]$ was strictly represented by $E = E^{o\prime} + Q \log [H^+]$ for both the acid and alkaline zones, with slightly different values of $E^{o\prime}$. In each zone the relevant value of $E^{o\prime}$, was used; in intermediate pH ranges (4.5–8.5) an average $E^{o\prime}$ value was adopted. With this procedure, experimental and calculated titration curves were completely superimposable. The adequacy of the procedure was tested with ligands for which accurate stability constants of proton and metal complexes are known, e.g. NTA and EDTA.

Other measurements

NMR spectra were recorded with a 100-MHz JEOL JNM 100 PTF spectrometer coupled to a JEOL 980 A computer. Deuterium oxide was the solvent and the reference compound was the sodium salt of DTSS.

Melting points were determined with a Reichert–Thermovar instrument provided with a microscope, and are uncorrected.

Elemental analyses were done with a Perkin–Elmer 240 elemental analyzer.

Calculation of the stability constants

The stability constants of the various species formed were obtained from the experimental data with the aid of the program MINIQUAD[7] and a Data General Eclipse S/140 computer.

Suitable approximate values for the constants were obtained by use of a simpler program, and the values were improved by comparison of the experimental titration curves of the complexones in the presence of the various metal ions with calculated titration curves for values of stability constants close to the estimated values, until a satisfactory superimposition of the curves was achieved. This was done on a 2200 Wang computer coupled to a 2212 plotter. The values for the best superimposition were then refined by the MINIQUAD program. In the present work, the values selected were those for which the calculated relative standard deviation was less than 10%, the "fitting index" was less than 0.003 and the acceptable value of χ^2 at the 95% confidence level for 6 d.f. was less than the value (12.6) obtained following the procedure of other authors.[8,9] The results obtained correspond to a minimum of two experiments for which the ratio C_M/C_L was generally about 1 or 2, except for alkaline-metal ions for which the ratio was 10 or 100.

RESULTS AND DISCUSSION

Titration curves for the ligand studied, alone and in the presence of several metal ions, are shown in Fig. 2.

As it can be seen, the ligand is dibasic with p*k* values of the order of 8–9, corresponding to the ionization from protonated nitrogens. In its di-

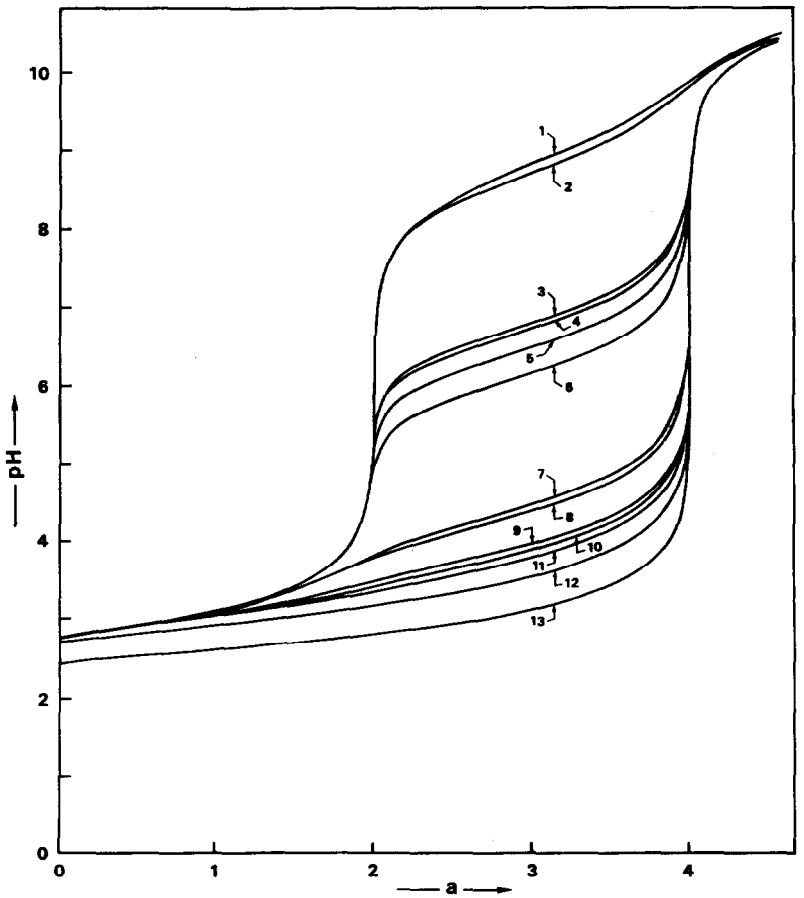

Fig. 2. Titration curves for cTOPDA alone and in the presence of metal ions in 1:1 ratio. $T = 25.0 \pm 0.1$°C, $\mu = 0.1$ M (Me_4NNO_3). (1) cTOPDA alone (10^{-3} M) and with: (2) Na^+ or Li^+, (3) Ba^{2+}, (4) Mg^{2+}, (5) Sr^{2+}, (6) Ca^{2+}, (7) Mn^{2+}, (8) Ni^{2+}, (9) Pb^{2+}, (10) Cd^{2+}, (11) Co^{2+}, (12) Zn^{2+}, and (13) Cu^{2+}.

hydrochloride form, the acetate groups are also protonated and ionize in aqueous solution at low pH; the corresponding pk values are of the order of 2 or lower.

The values of the ionization constants, refined by MINIQUAD, are presented in Table 1, together with those determined by Tazaki *et al.*[6] at 25°C and $\mu = 0.1$ M (KNO_3). Our values were determined at the same temperature and $\mu = 0.10$ M (Me_4NNO_3) both sets of results are presented to allow comparisons. In Table 1 we also include the values of the ionization constants of cTOODA,[4] and of the protonated diaza crown ethers from which cTOODA and cTOPDA were derived, i.e. Kryptofix® 22 and Kryptofix® 21.[10]

The discrepancy between our values and those of Tazaki *et al.*[6] for cTOPDA can be explained easily: the former authors did not taken into account the possibility of formation of K^+ complexes with this ligand and since this does indeed occur ($\log K_{KL} = 1.69$), their pk values are necessarily lower. Compared with the corresponding ionization constants of cTOODA it is seen that cTOPDA is more basic, as expected, since it has less electronegative oxygen atoms in the ring. The pk values for the ionization of these ligands are consistent with those of the corresponding diaza crown ethers from which the ligands were derived.

Concerning the formation of metal complexes, two observations immediately arise from Fig. 1. First, the stability of the complexes of the alkaline-earth metals decreases normally with the increase in the ionic radius of the metal; second, that of the complexes of the transition metals does not follow the "natural" Irving–Williams' order since the cobalt complex is more stable than that of nickel. The zinc complex is also more stable than that of cadmium, but there is no invariant pattern for this pair of metals.

The stability constants of all these complexes were calculated as described in Experimental and are summarized in Table 2, together with the corresponding values for cTOODA, as well as those for EGTA [ethylene bis(oxyethylenenitrilo)tetraacetic acid] and EEDTA [oxy bis(ethylenenitrilo)-tetraacetic acid)],[11] whose linear chains between the substituted nitrogen atoms are similar to the two halves of the structure of cTOPDA. The values of the stability constants of some complexes of cTOPDA obtained by Tazaki *et al.*[6] are also included for comparison, although they are generally incorrect, since they were determined in a complexing medium (KNO_3); furthermore, in the case of the transition metals, only rough approximations were given, due to the slowness of the reactions. In our determinations enough time was given in every case to allow equilibrium to be reached; in the case of iron, manganese, cobalt and nickel this took several hours for each titration, and even in the cases of copper and zinc stable readings were only done several minutes after each addition of titrant. For cadmium and lead, equilibrium was quickly established. Good results were obtained in every case except for iron, probably due to slight oxidation of the metal, even if titrations were carried out under nitrogen.

The correctness of the determinations was checked by carrying out duplicated batch titrations in which several test-tubes containing 1 : 1 and 2 : 1 mixtures of metal and ligand plus variable amounts of titrant Me_4NOH were left for several days in a thermostat, and pH readings were made at regular 1-day intervals. The results obtained in these determinations were very close or identical to those obtained by the normal titrations, but the errors were naturally larger (although less than 0.1 log units).

The excellent results obtained with the demanding MINIQUAD program are also a good indication of the care with which the measurements were made. Two titrations at different metal : ligand ratios (1 : 1 and 2 : 1) were used in each run of the

program and different sets of titrations give results coincident to ±0.05 log units. The values presented in Table 2 correspond to the best outputs of the MINIQUAD program for one set of titrations of each metal–ligand system.

For the other ligands we have used the values available in the literature, and in the cases when more than one set of values are available we have adopted those considered as more reliable (EGTA and EEDTA),[11] or which we considered sufficiently consistent (Kryptofix® 21 and 22).[10]

For the ligand that we have studied we obtained stability constants for the ML and M_2L complexes, and in the cases of Li^+ and Na^+ also for the MHL complexes which are very weak: $\log K_{MHL} = 1.15$ and 0.85, respectively.*

The values quoted for the M_2L complexes are overall constants, i.e. $\log \beta_{ML_2}$; the comparison with the values of $\log K_{ML}$ show that, although the 1 : 1 complexes have a residual affinity to bind a second atom of the metal, this affinity is relatively weak, except in the case of copper, for which the difference $\log \beta_{M_2L} - \log \beta_{ML}$ is 5 log units; for the other metal ions it hardly exceeds 2 log units.

The comparison of our results with those obtained by Chang and Rowland for cTOODA affords interesting results which may also be appreciated in Fig. 3. Hence, whereas the stability constants of the alkaline-earth and Pb^{2+} complexes of cTOODA are approximately equal to those of the corresponding complexes of cTOPDA, but remarkably higher in the case of K^+, the complexes of the first-series transition metals, zinc and cadmium with the first ligand are much less stable than those of the last one, and their stability constants are surprisingly low even in absolute terms, compared with the values for the corresponding complexes of EGTA and EEDTA (Table 2).

This behaviour finds some justification in the degree of fitting of the metal ions to each of the ligands; note that cTOPDA is asymmetric relative

* $K_{MHL} = [MHL]/[M][HL]$.

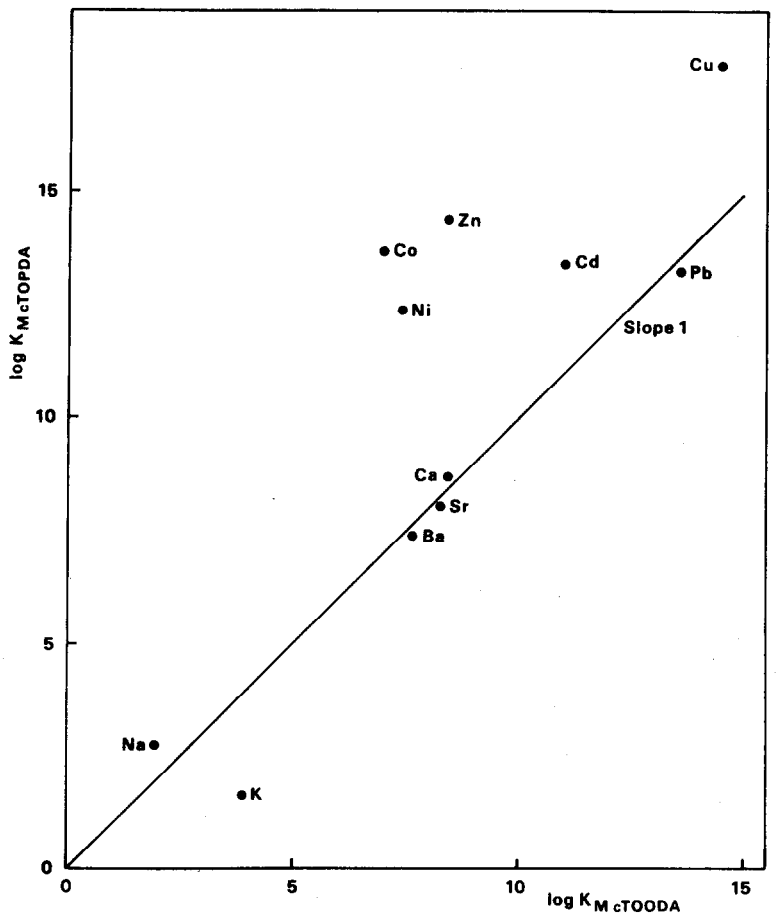

Fig. 3. Correlation of the stability constants ($\log K_{ML}$) of the metal complexes of cTOPDA and cTOODA. A slope 1 straight line would correspond to equal stabilities for the complexes of the two ligands.

to the coordinating nitrogens, hence the metal may be shifted to either side or interact with all atoms, depending on its radius. On this basis we predict that cDODDA will complex the smaller ions even more strongly, and enhance selectivity based on size fitting. This effect becomes clearer when one compares the stability constants of the complexes of cTOPDA on one side and those of the corresponding complexes of EGTA and EEDTA on the other (Fig. 4).

Figure 3 shows that cTOPDA favours the complexation of Cu^{2+}, Zn^{2+}, Co^{2+}, Fe^{2+}, Mn^{2+} and Mg^{2+} relative to EGTA, but when EEDTA is considered instead of EGTA a much better correlation is obtained; the variations in the values of the stability constants on going from EGTA to EEDTA are not substantial for the larger alkaline-earth ions copper and cadmium, but quite considerable for the other transition-metal ions, zinc and magnesium. In both cases, Cd^{2+} is favoured by the non-cyclic ligands.

The behaviour of copper must be considered separately; the structure of its complex with cTOODA has been determined in the solid state by X-ray diffraction[12] and it was found that the metal is tetragonally coordinated with the two nitrogens and the two carboxylate groups in the equatorial plane with two of the ether oxygens of the ligands on opposite sides of the molecule, interacting weakly at longer distances in the axial position. The stability constant of the complex is even smaller than that of the closely similar copper complex of DACODA (1,5-diazacyclooctane-*N*,*N'*-diacetic acid),[13] a ligand that, despite its more basic nitrogen atoms, has no ether oxygen atoms in the ring and, consequently, no other binding interactions besides those of the aminoacetate groups in the equatorial plane. The case of cTOPDA is probably similar, but the axial interaction with the oxygen of the diethyl ether chain seems to be more effective, giving a higher constant than that of Cu(II)cTOODA; this being the case no particular meaning should be attributed

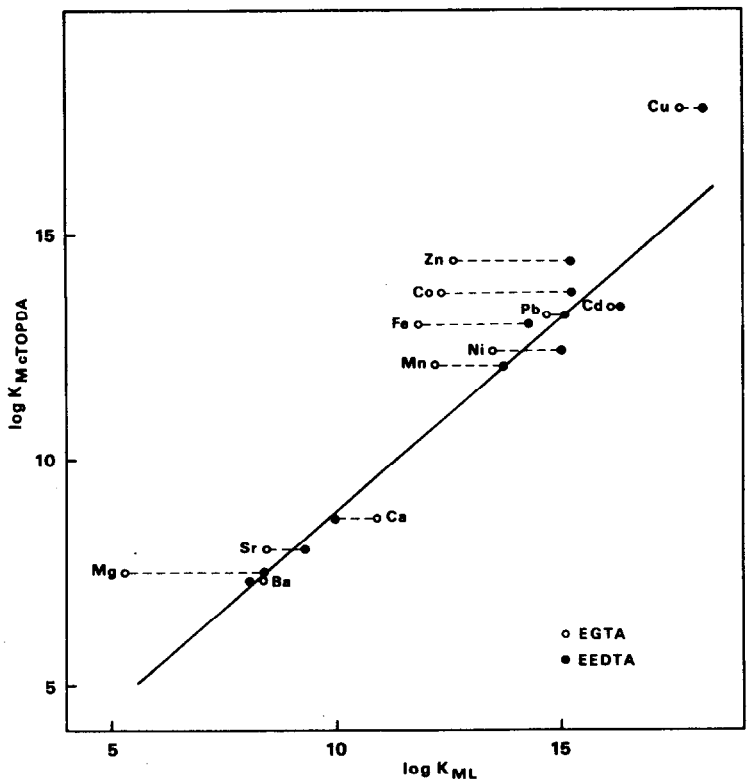

Fig. 4. Correlation of the stability constants ($\log K_{ML}$) of the complexes of cTOPDA and EEDTA (●), showing the shifts when EGTA (○) is considered instead of the latter ligand.

to the location of copper in Fig. 2; it is the type of coordination favoured and not only the size of the ion that is the critical factor in this case.

The conclusions that we derive from these results are that the smaller transition-metal ions tend to bind preferentially to the diaminodiethyl ether *N*,*N'*-diacetate moiety of cTOPDA, similar to EEDTA, whereas the larger alkaline-earth ions, cadmium and lead seem to prefer the other moiety, similar to EGTA.

The larger ligand, cTOODA, naturally prefers the larger ions, and the most favoured is the largest, i.e. K^+. Accordingly, complexes of the smaller metals are destabilized.

These differences of behaviour between cTOPDA and cTOODA must be reflected in the thermodynamic functions for the complexation reactions of each ligand. We expect more favourable enthalpies and entropies of formation of the first-series transition metal, zinc and cadmium complexes of the first ligand (compare thermodynamic data for EEDTA and EGTA complexes), but this idea cannot be confirmed until the relevant data are available (work in progress).

Our final remarks concern the inversion in the normal order of stability of the cobalt and nickel complexes of cTOPDA which is unusual but not specific of this ligand. The effect was already observed in the corresponding amines, i.e. 1,4,10-trioxa-4,13-diazacyclopentadecane or Kryptofix® 21 (denoted by [21]), but not in 1,7-dioxa-4,10-diazacyclododecane (denoted by [11]), neither in 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane nor Kryptofix® 22 (denoted by [22]) (see Table 3).

It therefore seems that the inversion is not directly related to the dimensions of the internal cavity of the ligand—not only cobalt and nickel have similar radii but the inversion is found for a ligand of intermediate cavity size—so we must look into other reasons that may cause this breaking of the normal trend.[14]

Since nickel has a more definite preference for octahedral coordination symmetry than cobalt, it is possible that the inversion is due to a stereochemical constraint of the 15-membered macrocyclic ring, which is asymmetric relative to the two donor-nitrogen atoms, to adopt that favoured configuration. Indeed, the decrease in stability of the complexes of cobalt, nickel and zinc with the increase in the size of the cavity of the ligand from [11] to [21] follows the order Ni > Co, Zn, which is what one would expect from crystal field stabilization energy con-

Table 3. Stability constants of transition-metal complexes of oligo-oxa–oligoaza cyclic amines[a]

Amine	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}	Radius of cavity of ligand (Å)
[11]	5.76±0.1	5.91±0.4	8.16±0.11	6.22±0.07	0.8
[21]	5.22±0.08	4.05±0.16	8.15±0.16	5.34±0.08	1.0
[22]	3.25±0.2	3.43±0.32	7.59±0.18	4.31±0.18	1.40

[a] According to Luboch *et al.*:[10] $T = 25.0°C$, $\mu = 0.1$ M (Et_4NClO_4).

siderations if a tetrahedral coordination geometry was favoured.[14,15] Curiously, with the ligand 1-oxa-7,10-dithia-4,13-diaza cyclopentadecane, the normal order of stability Ni > Co is reestablished,[16] which may be due to the combined effects of the higher polarizability of the sulphur atoms and their larger size, compensating for the less adequate geometry of coordination. Nickel and copper will be preferentially favoured in this case and it was found that $\log K_{NiL} = 7.98$ and $\log K_{CuL} = 11.55$, whereas $\log K_{CoL} = 5.42$ and $\log K_{ZnL} = 5.09$.[16]

When one now considers the *N,N'*-diacetate derivatives of Kryptofix® 21 and 22, it is found that the order of stability observed in their respective complexes is maintained, although the stability constants ($\log K_{ML}$) increase by up to 8–9 log units (a rather remarkable effect, compared to the cases of ethylenediamine and ethylenediamine-*N,N'*-diacetic acid, when the increase is only 5–6 log units; the enhancement certainly is of entropic origin).

This seems to imply that the original coordination symmetry in the complexes of the amines is maintained to a large extent, even if the two carboxylate groups are certainly coordinated (or else the stability constants would not increase by such large values). Since the affinity of carboxylate groups for the transition-metal ions (and zinc) does not vary much (note that $\log K_{ML}$ values for the acetate complexes of these metal ions are all similar, close to $\log K_{ML} \sim 1.5$) one would expect, if our hypothesis is valid, just the "normal" effect of increased stability essentially derived from much more favourable entropy changes. Indeed, water and the carboxylate group have similar ligand fields—they are neighbours in the spectrochemical series—hence substitution of coordinated water molecules by carboxylate groups is insufficient to reverse the observed order of the stability $Co^{2+} > Ni^{2+}$ found for the complexes of Kryptofix® 21.

* $Me_6tren \equiv N[CH_2CH_2N(CH_3)_2]_3$.

It is perhaps worth remembering that the Irving–Williams' stability series is a reflexion of the fact that, in octahedral complexes, nitrogen and sulphur favour Fe^{2+}, Ni^{2+} and Cu^{2+} over the other first-series transition metals and zinc, essentially due to larger CFSE, to which one has to add the effect of tetragonal Jahn–Teller distortion in the case of Cu^{2+}. Carboxylate, sulphate or phosphate donors alone are much less effective and differences in stability are smaller since the ligand field strengths of the corresponding ligands are not much different from that of water.

When, however, the symmetry of the complexes changes from the octahedral aqueous ions to tetrahedral or trigonal bipyramidal, due to constrained ligand structures or steric crowding, the situation is different since the Fe^{2+} (d^6) and particularly Co^{2+} (d^7) will then be more favoured in terms of the crystal field stabilization energy, and the "normal" increase in stability expected from the increase in atomic number may not compensate the loss of CFSE for other ions, namely Ni^{2+}, and one may therefore obtain inversions in the Irving–Williams' order of stabilities. Other inversions can, of course, occur due to different effects, such as a spin-pairing in the Fe^{2+} complexes, and are thoroughly discussed in their original paper,[14] but they are not generally verified with the type of ligands used in the present study.

Current examples of inversions resulting from symmetry changes are those of the tetrachloro and tetrabromo complexes of the first-series transition metals and zinc,[17,18] and of the complexes of hexamethylated amino-triethylamine* of type [M(Me_6tren)X],[18] besides that of Kryptofix® 21 and now of cTOPDA, the first complexone type ligand to clearly exhibit this behaviour (note, however, that in the case of EEDTA the $\log K_{ML}$ values of cobalt and nickel complexes are close, and some authors obtained $\log K_{CoL}$ slightly higher than $\log K_{NiL}$). Other examples may be found in the complexes of some biological ligands with distorted

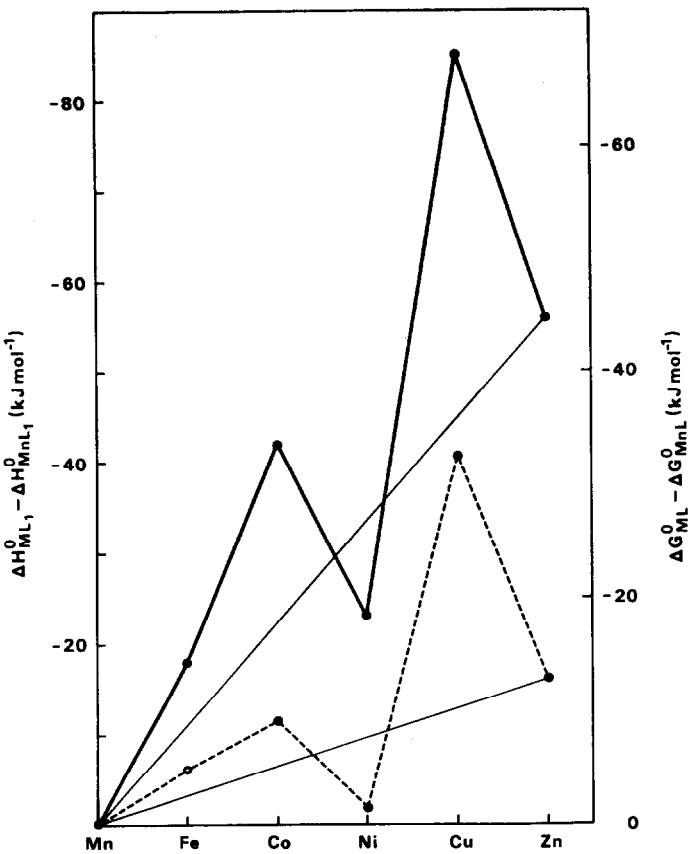

Fig. 5. Relative values of the free-energy and enthalpy changes for the formation of complex compounds from aquo ions. (——) $[M(Me_6tren)Br]^+$: enthalpy changes[18] on the left-hand ordinate; and (– – – –) [McTOPDA]: free-energy changes on the right-hand ordinate.

coordination geometries, which are also a device to increase selectivity. The obvious examples are those of the zinc enzymes with distorted tetrahedral sites in which zinc can be replaced by transition-metal ions, but cobalt is complexed preferentially to nickel.[19]

In the case of the complexes of cTOPDA, the object of the present study, the coordination geometries are not obvious, and electronic spectra do not provide conclusive information because they are not very well-defined. The trend in the free-energy charges on complex formation is similar to that of the enthalpy charges for the complexes $[M(Me_6tren)X]$ (see Fig. 5), and from this one may suggest a trigonal bipyramidal symmetry as a possibility for the transition-metal complexes of cTOPDA, but this will have to be confirmed by other direct experimental evidence and supported by X-ray structure determinations in the solid state.

This paper was submitted in November 1985. Later, a paper by Chang and Ochaya partially on the same subject was published (*Inorg. Chem.* 1986, **25**, 355). The agreement between our values and those obtained by these authors is excellent, with the exception of $\log K_{CuL}$.

COPPER COMPLEXES OF PYRIDINE 2-ALDEHYDE AND 2-ACETYLPYRIDINE THIOSEMICARBAZONES

C. F. BELL,* K. A. K. LOTT and N. HEARN

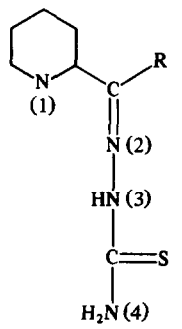
Department of Chemistry, Brunel University, Middlesex UB8 3PH, U.K.

(*Received* 3 *July* 1986)

Abstract—Copper complexes of two heterocyclic thiosemicarbazones were synthesized and characterized by magnetic-moment measurement, and ESR and IR spectroscopy. Implications of the magnetic and spectral data in relation to the structures of the complexes are discussed.

The applications of thiosemicarbazones in the analysis of metals have been well-known for many years. Recent reviews have summarized developments in analytical aspects[1] and structural information on transition-metal complexes of thiosemicarbazones.[2,3] Dithizone (1,5-diphenyldithiocarbazone) is one of the most versatile of all analytical reagents for metals, and our knowledge of its chelating properties and those of the thiosemicarbazone moiety in related ligands owes much to the pioneering work of Professor Harry Irving and co-workers.[4]

Biological activity associated with thiosemicarbazones was first reported[5] in 1946. Their action as antimicrobial and antiviral agents has been reviewed recently by Levinson,[6] and Perrin and Stünzl.[7] In some cases, it is clear that the highest *in vivo* activity is associated with a metal complex rather than the thiosemicarbazone itself.[6] Thus, although the thiosemicarbazone of pyridine 2-carbaldehyde (also known as 2-formylpyridine thiosemicarbazone and abbreviated below as HPATS) has marked anti-tumour activity,[8] its copper complex, $Cu(PATS)^+$, is much more potent, as determined by single-cell survival of Chinese hamster ovary cells.[9] Again, the anti-tumour activity *in vivo* and the cytotoxicity *in vitro* of the agent 3-ethoxy-2-oxobutyraldehyde bisthiosemicarbazone (KTS) is believed to depend on specific and unique properties of its copper(II) chelate, such as its basicity and its interaction with other ligands, rather than on the sequestering action of the ligand itself.[10] There is little information on the structures of transition-metal complexes of HPATS and related ligands in the literature which can be related to their biological properties. We have now studied in some detail the reaction products between copper compounds and HPATS [and of 2-acetylpyridine thiosemicarbazone (MePATS)], and now report on some of their magnetic and spectroscopic properties. Both ligands act as tridentate chelators, via N(1), N(2) and S donors (**I**).



I R = H, HPATS: R = CH_3, MeHPATS

EXPERIMENTAL

Syntheses

HPATS was prepared and purified by the procedure of Hemmerich *et al.*[11] M.p. (after recrystallization from methanol) = 209°C (lit. = 210°C).

* BA (Part II) Oxford (1949–1950) and D.Phil. (1950–1952), both supervised by Professor Irving, and subsequently at Brunel University, Uxbridge. Author to whom correspondence should be addressed.

MePATS was prepared similarly using 2-acetylpyridine. M.p. = 158°C [after recrystallization from 1 : 1 (v/v) ethanol–water] (lit. = 160°C).

(Pyridine-2-carbaldehyde thiosemicarbazone) copper(II) nitrate, $Cu(HPATS)(NO_3)_2$, was made by using the method of Ablov *et al.*[12] for the analogous complex of 8-quinoline aldehyde thiosemicarbazone. It was isolated as a blue-green crystalline solid and purified by solution in water containing a little nitric acid, filtration and then the addition of KNO_3 solution to the filtrate to precipitate the complex. Analysis: Cu, 16.9% [$Cu(HPATS)(NO_3)_2$ requires 17.3%].

(Pyridine 2-carbaldehyde thiosemicarbazone) copper(II) dichloride, $Cu(HPATS)Cl_2$, was prepared by the addition of a hot ethanolic solution of copper(II) chloride (0.0166 mol dm^{-3}) to an equimolar amount of HPATS in solution in *n*-butyl acetate under reflux. An olive-green precipitate formed immediately, which was filtered off after cooling the mixture, and then washed successively with small portions of ethanol and diethylether. M.p. = 220°C. Analysis: C, 26.9; H, 2.8; N, 17.7; Cl, 22.8; Cu, 19.1%. $Cu(HPATS)Cl_2$ requires: C, 26.7; H, 2.5; N, 17.8; Cl, 22.5; Cu, 20.2%.

(Pyridine 2-carbaldehyde thiosemicarbazonato) copper(II) acetate, $Cu(PATS)OCOCH_3$, was prepared by the methods of Hemmerich *et al.*[11] and Antholine *et al.*[13] The first procedure gave the purer product, a dark-green solid with black reflex. M.p. *ca* 228°C (decomp.). It was recrystallized from DMF. Analysis: C, 35.8; H, 3.4; N, 19.2; S, 10.6%. $Cu(PATS)OCOCH_3$ requires: C, 35.8; H, 3.3; N, 18.6; S, 10.6%.

(Pyridine 2-carbaldehyde thiosemicarbazonato) copper(II) chloride, Cu(PATS)Cl, was prepared according to Bhoon[14] by refluxing equimolar solutions in DMF of copper(II) chloride and HPATS. Over a period of 1 h under reflux, a green precipitate formed initially, but slowly dissolved to give a deep-green solution. Excess solvent was distilled off under reduced pressure and water added to the concentrate to precipitate the complex as a dark-brown solid. It was filtered, washed well with water and acetone, and finally dried *in vacuo* over P_2O_5. Although appreciably soluble in DMF and DMSO, it did not prove possible to recover the complex without some decomposition. M.p. = 220–222°C (decomp.). Analysis: C, 30.8; H, 2.5; N, 20.0; Cl, 12.8; Cu, 20.9%. Cu(PATS)Cl requires: C, 30.22; H, 2.52; N, 20.18; Cl, 12.54; Cu, 20.20%.

(Pyridine 2-carbaldehyde thiosemicarbazonato) copper(II) thiocyanate, Cu(PATS)SCN, was precipitated by the addition of an equimolar amount of NH_4SCN in aqueous solution to $Cu(HPATS)(NO_3)_2$ in water. It was isolated as a yellowish-green, paramagnetic solid. Analysis: C, 31.7; H, 2.6; N, 23.9; S, 21.8%. Cu(PATS)SCN requires: C, 31.9; H, 2.3; N, 23.3; S, 21.3%.

(Pyridine 2-carbaldehyde thiosemicarbazone) copper(I) chloride, Cu(PATS)Cl, was prepared by Bhoon's method using copper(I) chloride freshly prepared by the reduction of an aqueous solution of copper sulphate with SO_2 in the presence of dissolved sodium chloride. The complex was isolated as a diamagnetic black solid decomposing at *ca* 240°C. It was not purified further. Analysis: C, 28.5; H, 2.4; N, 18.7; Cu, 22.8%. Cu(HPATS)Cl requires: C, 30.1; H, 2.9; N, 20.1; Cu, 22.5%.

(2-Acetylpyridine thiosemicarbazonato) copper(II) acetate, $Cu(MePATS)OCOCH_3$, and (2-acetylpyridine thiosemicarbazone) copper(II) dichloride, $Cu(MePATS)Cl_2$, were prepared in a similar manner to the HPATS complexes in small quantity for ESR measurements.

ESR spectra of powdered samples and solutions in DMSO at room temperature, and of frozen solutions in DMSO at 77 K, were measured using a Varian E3 ESR spectrometer with DPPH as the reference material. Magnetic-susceptibility measurements were performed by the Gouy method at room temperature. IR spectra were recorded as KBr discs using a Unicam SP2000 IR spectrophotometer. C, H, N, Cl and S analyses were performed by Butterworth Laboratories Ltd, Teddington, Middx. Cu analyses were carried out on aqueous solutions, prepared by dissolving the complexes in dilute nitric acid, using a Perkin–Elmer 2380 atomic absorption spectrometer.

RESULTS AND DISCUSSION

The stoichiometry of the complexes prepared appears to indicate that copper is coordinated by the neutral ligand in $Cu(HPATS)(NO_3)_2$, $Cu(HPATS)Cl_2$ and Cu(I)(HPATS)Cl, and by the singly-charged anion formed by loss of a proton from the thiol form of the ligand in $Cu(PATS)OCOCH_3$, Cu(PATS)Cl and Cu(PATS)(SCN). However, the complex $Cu(PATS)^+$ is known to be very stable ($\log K = 16.90$), and shows[15] no tendency to dissociate at pH values as low as 1.4. Some changes in the electronic spectrum of CuL^+ in aqueous solution from pH 4 to 2[15,16] are associated with protonation of the ligand and indicate that $Cu(HPATS)^{2+}$ is a reasonably strong acid. Complexes containing the neutral ligand therefore only result from reactions in weakly acidic aqueous media or non-aqueous solvents of low polarity.

Magnetic and ESR parameters are given in Table 1. The magneton numbers of $Cu(PATS)OCOCH_3$,

Table 1. Magneton number (X) for Cu complexes (293 K) and ESR data (on solutions in DMSO at 77 K)

Compound	$X_{293\,K}$	$g_\parallel$	$A_\parallel^{Cu}$ (G)	$A_{iso}^{Cu\,a}$ (G)
$Cu(HPATS)Cl_2$	1.51	2.18	155	72
$Cu(PATS)OCOCH_3$	1.83	2.18	175	75
Cu(PATS)Cl	1.89	2.17	163	75
Cu(PATS)SCN		2.18	165	
$Cu(MeHPATS)Cl_2$		2.18	155	75
$Cu(MePATS)OCOCH_3$	1.89	2.16	180	
	$g_\perp$ estimated as ~ 2.03			

[a] Estimated from solution spectra at room temperature.

Cu(PATS)Cl and $Cu(MePATS)OCOCH_3$ all lie close to the spin-only value (1.73) for a d^9-ion, and are consistent with planar or nearly-planar coordination around copper. The ligand is known[2] to coordinate Ni(II) with two sets of coplanar NNS donor atoms to form two chelate rings in $Ni(PATS)_2$, so it is likely that Cu(II) shows four-coordination in these complexes with the last position occupied by an O or Cl donor. There is no magnetic evidence here for any Cu–Cu interaction.

The magneton number of 1.51 recorded for $Cu(HPATS)Cl_2$ is significantly below the spin-only value, perhaps because of metal–metal interaction. The organic ligand should be a tridentate chelator, so it is probable that the Cu(II) ion is in some kind of distorted five-coordinate geometry in this complex.

The ESR spectra (Figs 1 and 2) show similar features to those reported by Antholine *et al.*[15] for solutions containing $Cu(PATS)^+$ ions in 0.1 M KCl and 30% DMSO at 77 K. These workers reported $g_\parallel = 2.204$ and $A_\parallel^{Cu} = 186$ G for this species. For a related complex, CuKTS, doped in Ni, ESR parameters are:[17] $g_\parallel = 2.13$, $g_\perp = 2.035$, and $A_\parallel^{Cu} = 184$ G at 77 K; the value of A_{iso}^{Cu} was estimated to be 87 G. Our values for $g_\parallel$ lie in the range 2.16–2.18, i.e. smaller than reported for $Cu(PATS)^+$. In the case of the four-coordinate complexes, $A_\parallel^{Cu}$ values lie between 163 and 180 G, and the differences probably reflect the different nature of the ligand atom in the fourth coordination position in DMSO solutions. With $Cu(PATS)OCOCH_3$ and $Cu(MePATS)OCOCH_3$, $A_\parallel^{Cu}$ values are close to those reported by Antholine *et al.*[15] for KCl–DMSO solutions of the complex $Cu(PATS)OCOCH_3$. The replacement of acetate by the chloride or thiocyanate ligands produces lower values of $A_\parallel^{Cu}$ because of the greater electronegativity of these ligands. In DMSO solution, it is very likely that solvent molecules coordinate the metal above and below the plane to give a tetragonally-distorted six-

coordination. It is noteworthy that, for Cu(HPATS)Cl_2 and Cu(MeHPATS)Cl_2, $A_{\parallel}^{Cu}$ is lower still (155 G). This may be due to the different coordination number, but Hathaway[18] has cautioned against the use of ESR spectral data to try to develop a firm criterion of the stereochemistry of Cu(II) complexes because of the variety of regular and distorted geometries the metal can show on coordination. In general, our spectra do not show the hyperfine splitting from the two nitrogen donors. In Cu(MeHPATS)Cl_2, the spectrum shows clear evidence for at least a seven-line hyperfine splitting pattern in accordance with the presence of two non-equivalent nitrogens bonded to Cu. If they were equivalent, only a five-line hyperfine structure would be expected.

IR spectral data are summarized in Table 2. In HPATS itself vibrational stretches of the —NH and —NH_2 groups give rise to a multiple absorption band between 3160 and 3440 cm^{-1}. For most complexes studied, these move to lower frequencies as a result of coordination. The ligand shows strong multiple absorption centred at 1530 cm^{-1}, probably a major contributor being a combination of a CN stretch coupled with an N—H deformation mode. This disappears in most complexes, evidence of the loss of the N—H proton upon complexation. The band noted at 1535 cm^{-1} in Cu(PATS)Cl does not have the multiple structure that characterizes the ligand spectrum in this frequency region and its appearance does not necessarily conflict with the belief that the proton must have been lost on complex formation.

Following Campbell and Greszkowiak,[20] we have identified ligand bands at 1470 and 1300 cm^{-1} with a combination of CS and CN stretching and NH_2 deformation modes. The 1470-cm^{-1} band moves to slightly higher frequencies in the complexes.

Thiosemicarbazones typically show a strong absorption around 825 cm^{-1}. With the exception of Cu$(NO_3)_2$(HPATS), other complexes show virtually no band in this region. Other authors have noted the shift of this band to lower frequencies by about 100 cm^{-1} in the ligand complexes, and accordingly have assigned it to a CS stretching mode. This would certainly be strongly affected by S-bonding to a metal atom. If this assignment is correct, then CuS bonding is present in all the complexes reported except Cu(HPATS)$(NO_3)_2$. The nitrate does have atypical properties, being freely water-soluble, and thus possesses salt-like characteristics. At most, it would appear that the ligand is bound only by N(1) and N(3). Possibly, even N(1) is not involved, for it is this heterocyclic N that is protonated in acid solution,[22] i.e. the sort of solvent medium from which this complex is precipitated. Absorption bands arising from pyridine ring vibrations are not tabulated. Those found at 1590 and 1570 cm^{-1} in the ligand HPATS (usually identified as pyI and pyII bands) uniformly move to higher frequencies in all complexes. On this evidence, it appears that the heterocyclic N is bonded to the copper in every case. The IR spectrum of Cu(I)(HPATS)Cl shows very little difference from those of Cu(PATS)Cl and Cu(PATS)SCN with regard to the absorption bands of the organic ligand, indicating that a change in the oxidation state of the metal has little effect on the bonding within the chelate rings. A possible mechanism[9] for the anti-tumour activity of $Cu(PATS)^+$ is reduction to Cu(I) complex by thiols, followed by release of HPATS, and then the binding of this to inhibit ribonucleoside diphosphate reductase action. Alternatively, the complex itself may function by binding donor groups *in vivo* in the fourth coordination position round copper. Further study of copper(I)–HPATS complexes with other ligands would be helpful in the elucidation of the mechanism of biological action.

Abstract—The synthesis of the series of peptides identified in the neuropeptide Nereidine, $(Pro\text{-}Pro\text{-}Gly)_n$ where $n = 1$, 2 or 3, is reported together with a potentiometric and spectroscopic study of their complexes with Cu(II) at 25°C and $I = 0.10$ mol dm^{-3} (KNO_3). All three peptides behave similarly, forming [CuL] species at low pH followed by $[CuL_2]$ and, at higher pH, $[CuH_{-1}L]$. This complex involves co-ordination through the amide nitrogen of the first glycine residue forming an eight-membered chelate ring. Increase in the length of the peptide chain (i.e. increasing n from 1 to 2 or 3) does not affect the complexed species formed. The results of a potentiometric study of the Cu(II) complexes of the series of tetrapeptides Pro-Ala-Ala-Ala, Ala-Pro-Ala-Ala, Ala-Ala-Pro-Ala and Ala-Ala-Ala-Pro are also reported. The behave similarly to complexes of the analogous ligands based on glycine, showing an even clearer "break-point" effect in Cu(II) co-ordination.

Cu(II) forms very stable complexes with simple oligopeptides such as tetraglycine. Below pH 5 it co-ordinates through the terminal amino group and neighbouring carbonyl oxygen to give a [CuL] complex with one nitrogen co-ordinated (charges omitted for clarity). Above this pH it is able to deprotonate the amide nitrogens of peptide linkages successively to form N^-—Cu bonds, and give the planar species $[CuH_{-1}L]$ (an NN complex) up to $[CuH_{-3}L]$ (an NNNN complex).[1] The peptide is now locked into a tightly bent conformation. Inclusion of a proline (Pro) residue into the peptide sequence prevents this mode of co-ordination since Pro does not possess an ionizable amide proton; hence it acts as a "break-point" to the co-ordination of Cu(II). This encourages the formation of large chelate rings of up to 17 atoms with the peptides locked in a bent or folded conformation.[2,3] In proteins β-turns (regions where the peptide chain folds back on itself) give the globular structure necessary for biological activity, and it has been shown that Pro is the amino acid residue most frequently responsible for these β-turns.[4] Recent ^{13}C NMR studies of tetrapeptides containing three alanine (Ala) residues with one Pro have confirmed the importance of Pro in the second position of the sequence in the formation of bent or folded conformations.[5] Potentiometric and spectroscopic studies of Cu(II) complexes of the corresponding

Since 1961 he has been at Leeds University, where he is now a Reader and where Professor Irving was his Head of Department from 1961 to 1971.

tetrapeptides containing glycine (Gly) in place of Ala have shown quantitatively how the Cu(II) ion can lock the peptide in this folded conformation.[2,3] Peptides which can act as neurotransmitters frequently contain one or more Pro residues,[6] and it has been suggested that Cu(II) ions could activate these molecules by locking them in biologically active conformations.[7]

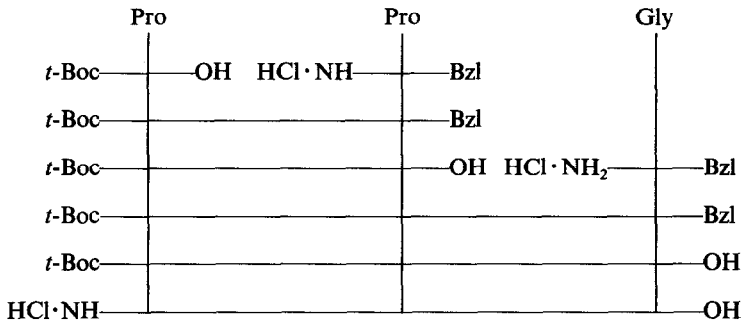
To pursue these suggestions we have extended the study of tetrapeptides containing Pro with three Gly residues to cover peptides containing paired Pro residues. The series of peptides of general formula (Pro-Pro-Gly)$_n$ where $n = 1$, 2 or 3, has been synthesized and their Cu(II) complexes studied potentiometrically and spectroscopically. A number of biologically active peptides contain the subunit -Pro-Pro-Gly, e.g. bradykinin, a smooth muscle stimulant, starts with the sequence Arg-Pro-Pro-Gly-···, and the head activator neuropeptide of hydra starts with *p*-Glu-Pro-Pro-Gly-···.[8] One of the simplest sequences containing this subunit is found in the neuropeptide Nereidine which has been isolated from the cerebral ganglion of the polychaete annelid (marine worm) *Nereis*.[9] This peptide shows specific physiological activity in the inhibition of sexual differentiation, and in the somatic changes associated with the epitoky of the worm, and tests are available to examine the activity of model peptide fragments *in vitro* for hormonal activity.[10] The study of the peptide Nereidine gave a fraction which showed a high hormonal activity, and which contained the hexapeptide Pro-Pro-Gly-Pro-Pro-Gly, and the sequence -Gly-Pro-Pro-Gly- appeared to be the active portion.[11] Hence, the peptides selected should be good model compounds.

In addition we have studied the analogues of the tetrapeptides based on Pro-Gly-Gly-Gly but which contain Ala residues instead of the Gly residues.[2] These were chosen because the tetrapeptides are based on optically active amino acids (i.e. L-Ala) rather than the inactive Gly, and so should show a more organized conformation. In addition they have been studied by ^{13}C NMR.[5] Complexes formed between Cu(II) and the tetrapeptides with Pro in positions 1, 3 and 4 (but not in position 2) have previously been studied spectroscopically.[12]

EXPERIMENTAL

Organic syntheses

The peptides based on Pro-Pro-Gly were synthesized by standard liquid-phase methods using Bu^t-OCO-L-Pro (*t*-Boc-Pro), L-Pro-CH_2-Ph·HCl (Pro-Bzl·HCl) and Gly-CH_2-Ph·HCl (Gly-Bzl·HCl) as starting materials. The syntheses are outlined below:



C-protected derivatives (in chloroform solution) were neutralized with triethylamine before coupling. Coupling reagents were dicyclohexylcarbodiimide (Merck) and 1-hydroxybenzotriazole (Aldrich). Benzyl groups were removed by hydrogenolysis using 10% Pd on charcoal as catalyst and *t*-Boc was cleaved using HCl (4 mol dm^{-3}) in dioxan. The tripeptide was purified by gel filtration (Sephadex G 15, eluant, water) and lyophylized. Percentages of amino acid residues (Pro : Gly = 2 : 1) were confirmed by amino acid analysis.

Oligomers of this tripeptide, (Pro-Pro-Gly)$_2$ and (Pro-Pro-Gly)$_3$, were obtained by the same procedure.

The tetrapeptides Pro-Ala-Ala-Ala, Ala-Pro-Ala-Ala, Ala-Ala-Pro-Ala and Ala-Ala-Ala-Pro were prepared as described previously.[5]

Potentiometric studies

Stability constants for H^+ and Cu^{2+} complexes were calculated from titration curves carried out at 25°C using total volumes of 1.5–2 cm^3. Alkali was added from a 0.1- or a 0.25-cm^3 micrometer syringe which had been calibrated by both weight titration and the titration of standardized materials. Changes in pH were followed using a glass electrode calibrated in H^+ concentrations with $HClO_4$.[13] All solutions were of ionic strength 0.10 mol dm^{-3} (KNO_3) and peptide concentrations of 0.003 mol dm^{-3}. Cal-

culations were made with the aid of the SUPERQUAD computer program.[14] This allows for the refinement of total ligand concentrations, and was able to confirm the agreement between calculated values and those found from Gran plots.[15] A further advantage of this technique is that the concentration of free acetate, a frequent impurity in peptide samples, could be measured and allowance made for this in the calculations.[3] The only peptide containing a significant concentration of acetate ions was Pro-Pro-Gly. The validity of the technique is confirmed by the observation that the stability constants calculated for this ligand are entirely compatible with those found for the comparable ligands. In all cases duplicate or triplicate titrations were carried out at Cu : L ratios of 1 : 1 and 1 : 2. The standard deviations quoted were computed by SUPERQUAD and refer to random errors only. They give, however, a good indication of the importance of the particular species in the equilibrium.

Spectroscopic studies

Solutions were of the same concentrations as those used in the potentiometric studies. Absorption spectra were recorded on a Beckman UV5240 spectrophotometer and circular dichroism (CD) spectra were measured on an automatic recording spectropolarimeter, JASCO-J-20. All CD spectra are expressed in terms of $\Delta\varepsilon$ ($\varepsilon_l - \varepsilon_r$). Electron paramagnetic resonance spectra were obtained on a JEOL JES-ME-3X spectrometer at liquid-nitrogen temperature and 9.13 GHz.

RESULTS AND DISCUSSION

Peptides with two Pro residues: the Pro-Pro-Gly series

The series of three peptides Pro-Pro-Gly, (Pro-Pro-Gly)$_2$ and (Pro-Pro-Gly)$_3$ was studied since these are the fragments studied in work on Nereidine.[11]

Protonation constants are given in Table 1. Values for the protonation of the amino group are almost independent of chain length, and only a little above that for Pro-Gly, as would be expected. Protonation of the carboxylate is favoured in the longer chains, possibly as a result of conformational differences, but the small differences found cannot influence the stabilities of the copper complexes.

Cu(II) complex stability constants are also given in Table 1, together with those for Pro-Gly,[16] while the species distribution curves for 1 : 1 and 3 : 1 peptide : metal mixtures are given in Fig. 1. Spectroscopic data for 3 : 1 peptide : Cu(II) mixtures are given in Table 2.

With Pro-Pro-Gly at low pH the first complex to form is the [CuL] species. This will be co-ordinated through the terminal amino nitrogen and the oxygen of the neighbouring peptide carbonyl group to give a 1N complex, comparable in structure to that found with, for example, Gly-Gly. However with these ligands containing the Pro-Pro fragment the [CuL] species has a much larger pH range of existence than with Gly-Gly, as demonstrated in Fig. 1. This is a result of the "break-point" effect of the Pro residue in position 2. Since this residue does not possess an ionizable peptide amide proton it cannot form a [CuH$_{-1}$L] complex comparable to that formed by Gly-Gly. Rather the only way to form a chelated complex through a peptide amide nitrogen is to bond to the peptide link of the Gly residue, the third residue in the chain. The species so formed will then be an NN complex spanning the first and third residues to form an eight-membered chelate ring as shown in Fig. 2. Co-ordination through the carbonyl oxygen of the first peptide linkage (as in [CuL]) is impossible on steric ground when both Pro residues are of the same chirality. The species so formed would be expected to be less stable than the [CuH$_{-1}$L] species with Gly-Gly but, as with Ala-Pro-Ala-Ala studied below, the conformation of the Pro residue would bring the co-ordinating centres sufficiently close together to allow easy bonding to the Cu(II). This chelation is represented quantitatively by $\log K_1'$ in Table 1, and is comparable to that with Ala-Pro-Ala-Ala.

Since the [CuH$_{-1}$L] species does not possess any further ionizable peptide protons, the [CuH$_{-2}$L] species which forms above pH 10 must be the result of hydrolysis of a co-ordinated water molecule, and is therefore still an NN complex. This is supported by the value for the protonation constant ($\log K_2' = 9.96$), which is very close to that found for the comparable reaction with Ala-Ala-Ala-Pro (9.83) (see Table 1). As an alternative to the formation of a [CuH$_{-1}$L] species, [CuL] could co-ordinate a second peptide molecule to give the bis complex [CuL$_2$]. This species would be an NN complex but would not contain any Cu—N$^-$ covalent bonds. Such a species formed between pH 6 and 8 in 1 : 1 peptide : Cu(II) mixtures where it was only a minor species in the absence of excess peptide (see Fig. 1), and was similar in importance to the comparable species formed by Ala-Pro-Ala-Ala (see Fig. 3). In the presence of excess peptide (e.g. 3 : 1 mixtures) this bis complex becomes the major species over the pH range 7–9.5, and the [CuH$_{-1}$L] complex is never predominant (see Fig. 1). As a result the spectroscopic data in Table 2 show charge-transfer

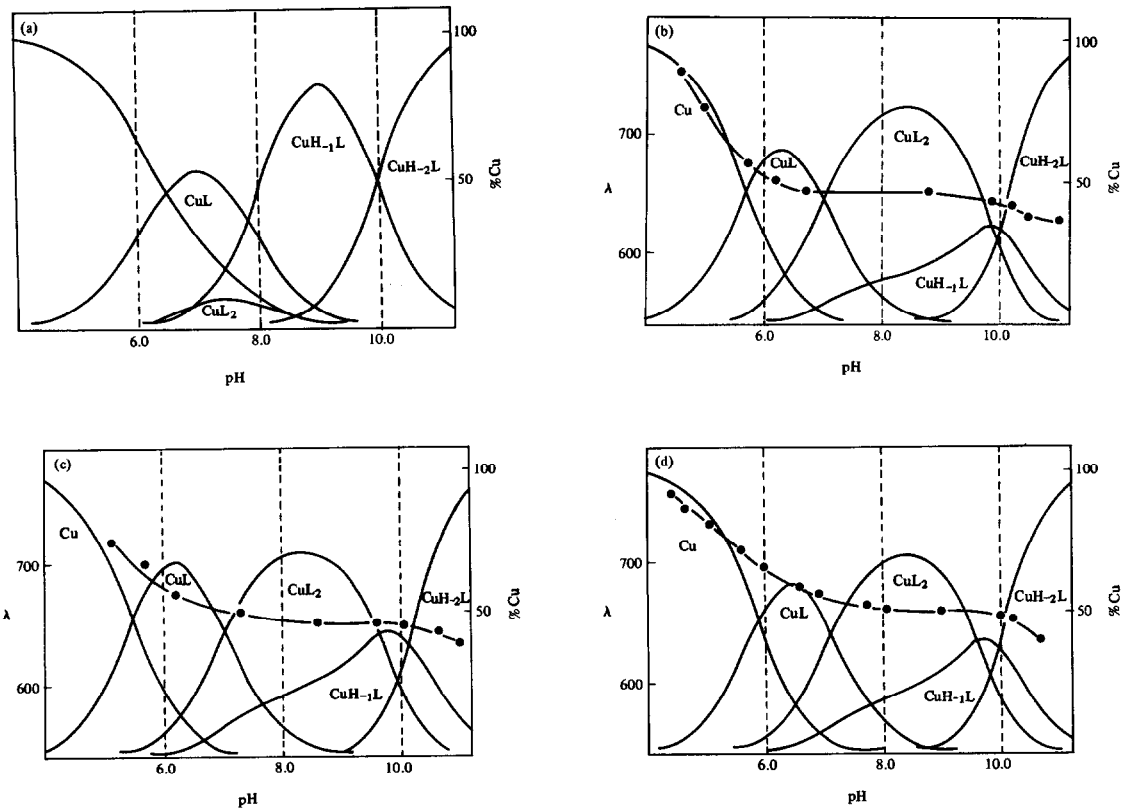

Fig. 1. Species distribution curves for Cu(II) complexes [0.001 mol dm^{-3} Cu(II)]: (a) Pro-Pro-Gly : Cu = 1 : 1, (b) Pro-Pro-Gly : Cu = 3 : 1 with *d–d* band maxima, (c) $(Pro\text{-}Pro\text{-}Gly)_2$: Cu = 3 : 1 with *d–d* band maxima, and (d) $(Pro\text{-}Pro\text{-}Gly)_3$: Cu = 3 : 1 with *d–d* band maxima.

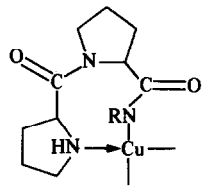
bands characteristic of Cu ← NH= co-ordination only (280–290 nm), although the band in the visible region (630–650 nm) is characteristic of NN co-ordination to Cu(II). It was difficult to gather reliable spectroscopic data above pH 9.5 as a result of solubility problems. The same problem arose at pH 10 in the potentiometric titrations, suggesting that the species $[CuH_{-2}L]$ has a low solubility in water.

The spectroscopic studies therefore confirm the potentiometric results. This is demonstrated for the *d–d* transition energy in Fig. 1, where it is seen that the flat portion of the curve of absorption maximum against pH coincides closely with the range of existence of the NN complexes. This is also supported by the ESR spectra reported in Table 2.

Results for the Cu(II) complexes of the peptides $(Pro\text{-}Pro\text{-}Gly)_2$ and $(Pro\text{-}Pro\text{-}Gly)_3$ are surprisingly similar to those with Pro-Pro-Gly. The spectra are almost completely superimposible, and the stability constants are remarkably similar, giving very similar species distribution curves (see Fig. 1). There are small differences in the magnitudes of the constants, probably as a result of differing chain formations as the peptide chain length increases, but these have only a minor effect on the species actually found. These results suggest that the mode of co-ordination is independent of chain length and that the only co-ordinating centres are the amino-terminal nitrogen atom and the peptide nitrogen of the first Gly residue. At first sight this is surprising since co-ordination through the carboxylate oxygen would



R = $CH_2CO_2^-$

Fig. 2. Donor centres in the $[CuH_{-1}L]$ complex of Pro-Pro-Gly. Co-ordination around the Cu(II) ion may be either *cis* or *trans*, although *trans* co-ordination introduces considerable strain. For conformational reasons co-ordination of the carboxylate oxygen also introduces strain.

be expected in the [$CuH_{-1}L$] complex of Pro-Pro-Gly, but not in those of the hexa- and nonapeptides. However, a study of scale models shows that this carboxylate can co-ordinate only by introducing considerable strain into the chelate ring as a result of the conformation of the two Pro rings which force the Gly terminal away from potential planar co-ordination sites on the copper (see Fig. 2). Hence, the thermodynamic contribution of carboxylate co-ordination would be small. In all cases the proton ionization to give the [$CuH_{-2}L$] species is a result of water hydrolysis, hence the values for this ionization (e.g. K'_2) are very similar.

Peptides with one Pro residue: the Pro-Ala-Ala-Ala series

Protonation constants are presented in Table 1 in addition to those of Ala-Ala-Ala[17] and Ala-Ala-Ala-Ala.[18] The value of $\log K_{HL}$ (i.e. imino or amine protonation) is greatest with the Pro residue in position 1 of the tetrapeptide chain, and gradually falls to a "base" value of $\log K_{HL} = 8.20$ as the Pro residue is moved along the chain. This value is close to that for Ala-Ala-Ala-Ala (8.13).[18] It has been shown by ^{1}H NMR[19] and IR[20] techniques that, in organic solvents, the folded conformation of alanine oligopeptides predominates, and that di- and tripeptides containing alanine in their zwitterionic forms adopt intramolecularly hydrogen bonded folded conformations even in aqueous solution.[21] More recently a combined CD and ^{13}C NMR investigation has shown that the presence of a Pro residue in positions 2 and 4 of a tetrapeptide favours the formation of folded conformations, while Pro in position 3 favours unfolding. Ionization was accompanied by a distinct increase in the amount of folded conformation independently of the position of the Pro residue within the tetrapeptide chain.[5] This could be the source of variations in carboxylate protonation constants, although the value for Pro-Ala-Ala-Ala does seem to be abnormally low. However, with this tetrapeptide the statistics of the computer fit were poor below pH 4, although they were good above this value. Errors in the value for K_{H_2L} would have no influence on stability constants of the copper complexes.

Cu(II) complex stability constants are also given

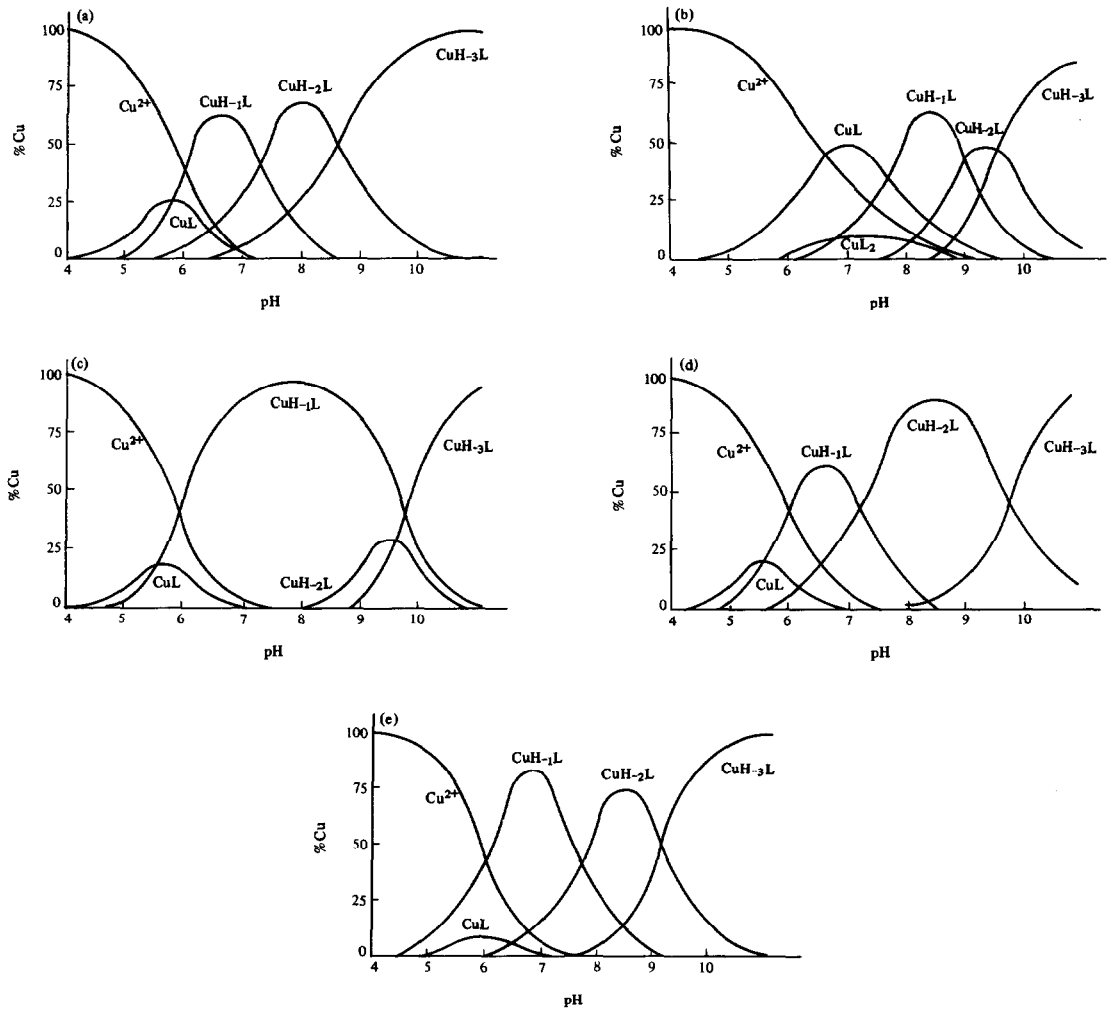

Fig. 3. Species distribution curves for Cu(II) complexes (peptide:Cu = 1:1, 0.001 mol dm^{-3}): (a) Pro-Ala-Ala-Ala, (b) Ala-Pro-Ala-Ala, (c) Ala-Ala-Pro-Ala, (d) Ala-Ala-Ala-Pro, and (e) Ala-Ala-Ala-Ala.[18]

in Table 1, together with stepwise protonation constants. Species distribution curves for 1:1 peptide:copper mixtures are given in Fig. 3, together with those calculated for tetraalanine. In all cases four complexed species were characterized in the pH range 4–10, namely [CuL] (a 1N complex), $[CuH_{-1}L]$ (NN), $[CuH_{-2}L]$ (NNN) and $[CuH_{-3}L]$ (NNNN). In addition a $[CuL_2]$ complex was present with Ala-Pro-Ala-Ala. These species are the same as found with the analogous ligands based on Gly.[2]

The species distribution curves confirm the essentially similar behaviour between peptides based on Gly and those based on Ala. Pro-Ala-Ala-Ala, as expected, behaves similarly to Ala-Ala-Ala-Ala, since it has three secondary peptide nitrogens and, hence, can form an NNNN complex, while Ala-Ala-Ala-Pro resembles Ala-Ala-Ala, having only two successive secondary nitrogens. The most important resemblance is when -Pro- is in the second position, when formation of the $[CuH_{-1}L]$ species is delayed until above pH 7. On the other hand, when it is in the third position this species becomes the predominant complex over the pH range 6–10. Hence, the tetrapeptides containing Ala residues confirm the "break-point" effect identified clearly in the Gly analogues.[2] In fact, comparison of the species distribution curves with those for the Gly analogues shows the effect to be even more marked with the Ala peptides. For example, with Ala-Ala-Pro-Ala the $[CuH_{-1}L]$ complex is more significant than with the Gly analogue, while the $[CuH_{-2}L]$ species is less significant.

The species distribution curves for Cu(II) complexes with Pro-Ala-Ala-Ala and Ala-Ala-Ala-Pro anticipated in the spectroscopic study[12] are shown to be reasonably accurate, but there are significant

differences with Ala-Ala-Pro-Ala. This is probably a result of difficulties in interpreting the spectroscopic data which suggested two different NN co-ordinated species over the pH range of 5–10, and failed to identify an NNN species at high pH. The $[CuH_{-2}L]$ complex (NNN) is never a major species [see Fig. 3(c)], and would be difficult to detect spectroscopically unless the optimum pH (9.5) was selected. This $[CuH_{-2}L]$ complex was detected spectroscopically with Gly-Gly-Pro-Gly,[2] which behaves very similarly to its Ala analogue.

Acknowledgement—We wish to thank Dr K. Sobczyk for providing the samples of Pro-Ala-Ala-Ala, Ala-Pro-Ala-Ala, Ala-Ala-Pro-Ala and Ala-Ala-Ala-Pro.

POTENTIOMETRIC INVESTIGATIONS OF THE EQUILIBRIA BETWEEN CAFFEIC ACID AND COPPER(II), ZINC(II), IRON(II) AND HYDROGEN IONS IN AQUEOUS SOLUTION

PETER WILLIAM LINDER* and ALEXANDER VOYÉ†

Department of Physical Chemistry, University of Cape Town, Rondebosch 7700, South Africa

(*Received* 3 *July* 1986)

Abstract—Interactions in aqueous solution of caffeate with copper(II), zinc(II), iron(II) and iron(III) have been investigated. Virtually instantaneous and complete reduction of iron(III) was observed. Glass electrode potentiometry was used to determine the speciation and corresponding formation constants of caffeate with each of the other three metal ions named. Conditions were: temperature, 25°C; ionic strength, 0.100 mol dm^{-3} with respect to chloride. Values obtained for the logarithms of the stepwise protonation constants of the singly protonated dianion of caffeate (L^{2-}) are 8.72 and 4.41. The titration data carried out in the presence of the three metal(II) ions can be explained by postulating the major complexes: LCu, $\log\beta_{110} = 6.02$; $LCuH^{-}_{-1}$, $\log\beta_{11-1} = 0.25$; $L_3Cu_2H^{5-}_{-3}$, $\log\beta_{32-3} = 0.97$; $LZnH^{-}_{-1}$, $\log\beta_{11-1} = -3.03$; $L_3ZnH^{6-}_{-2}$, $\log\beta_{31-2} = -5.51$; LFe, $\log\beta_{110} = 3.86$; $LFeH^{-}_{-1}$, $\log\beta_{11-1} = -3.83$; $L_3FeH^{6-}_{-2}$, $\log\beta_{31-2} = -6.14$, together with a variety of minor species. Complexation in the major species involves, predominantly, chelation by the catecholic site of caffeate whereas coordination to the carboxylate group together with catechol-type chelation featured amongst the minor species. The tendency of copper(II) to form oligonuclear complexes is evident. A single dinuclear iron(II) complex was also found amongst the minor species.

The bioavailability to plants of metal ions is greatly influenced by coordinating ligands which may be present in the soil or in the synthetic nutrient solutions in which the plants grow.[1] To contribute to the understanding of the role of complexation in the uptake of metals by plants, we are undertaking chemical speciation studies by means of computer simulation of soil and nutrient solutions.[2,3]

Of special interest are phenolic compounds that tend to be exuded by the roots of certain plants when subjected to conditions under which the availability of iron is adversely affected.[4–6] The most important of these phenolic compounds is *trans*-3-(3,4-dihydroxy phenyl)-propenoic acid.[7] Caffeic acid is believed to participate not only in the transport of iron from the surrounding soil solution to the roots but also in the reduction of iron(III) to iron(II).[5] In this regard it has been established that the bioavailable form of iron is the iron(II) aquo ion.[8] Apart from this, caffeic acid can also potentially form complexes with various other metal ions that occur in nutrient and soil solutions. Thus, it forms an essential component for inclusion in our computer-based speciation models. There is however a paucity of data in the literature for caffeate–metal–proton complexes. For this reason we have undertaken the investigation described in this paper.

EXPERIMENTAL

Chemicals

Caffeic acid (Aldrich) was purified by double recrystallization from water. (Found: C, 60.3; H, 4.5%. Calc. for $C_9H_8O_4$: C, 60.0; H, 4.5%.) 0.1 mol dm^{-3} hydrochloric acid was prepared from

Merck Titrisol ampoules and standardized against borax (Merck, G.R.) which had been recrystallized and stored as described by Vogel.[9] Sodium hydroxide solutions were freshly prepared at frequent intervals by dilution of the contents of Merck Titrisol ampoules under nitrogen. These solutions were standardized against potassium hydrogen phthalate (Merck, G.R.) as well as with the standardized hydrochloric acid. Zinc(II) chloride solution was made up by dissolving accurately weighed amounts of granulated zinc metal (Merck, G.R.) in concentrated hydrochloric acid (BDH, "Aristar"). The dissolution process was facilitated by adding a piece of platinum foil to the solution. Copper(II) chloride solution was made up from the dihydrated cupric chloride salt (Merck, G.R.). Iron(III) chloride solution was made up by dilution of a 60% (w/v) ferric chloride solution (BDH, Analar). Both the copper(II) and iron(III) chloride solutions were standardized against EDTA (B. Owen Jones) according to the procedure described by Schwarzenbach.[10] The EDTA was standardized against the aforementioned zinc(II) solution. Iron(II) chloride solutions, free from iron(III) as indicated by the spot test with potassium thiocyanate,[11] were obtained by dissolving accurately weighed quantities of iron powder (Merck, G.R.) which had just previously been reduced at 500°C under hydrogen in freshly degassed, refluxed concentrated hydrochloric acid (BDH, "Aristar"). All of the solutions were prepared using carbonate-free boiled out, glass-distilled water, and were made up to a total chloride concentration of 0.100 mol dm^{-3} using solid sodium chloride (BDH, "Aristar"). The acid content of the metal chloride solutions was determined by titration with standardized sodium hydroxide using the method of Gran.[12] The acid content of the iron(III) chloride solution was determined by difference after passing through a cation exchange column [BDH, Amberlite IR-120(H)].

Potentiometric measurements

Protonation constants for caffeic acid and formation constants for the ligand–metal complexes were determined by potentiometric titrations carried out in Metrohm EA876-20/-50 titration vessels maintained at 25 ± 0.1°C. The electrodes were two Metrohm EA109 glass electrodes used alternately, and a Metrohm EA404 calomel reference electrode containing a saturated sodium chloride solution (BDH, "Aristar") as electrolyte. A nitrogen atmosphere, purified as already described,[13] was maintained in the titration vessel during the titrations. In the protonation constant determinations, solutions containing caffeic acid, sodium hydroxide and chloride were titrated with hydrochloric acid–chloride solution, followed by the reverse titration with sodium hydroxide–chloride solution. This particular sequence was followed owing to the greater ease of dissolving caffeic acid in alkaline compared with acid solutions. The titrants were added from a Metrohm Dosimat E635-20 piston burette controlled by a Metrohm Titroprocessor E636, which also measured and recorded the emf of the cell, together with the corresponding volume of titrant added. The data obtained were used to calibrate the electrodes and determine the protonation constants simultaneously.[14]

For the complexation titrations, caffeic acid in sodium chloride–sodium hydroxide solutions was first titrated with hydrochloric acid–chloride solution as described in the previous paragraph. Immediately following this, accurately measured quantities of metal chloride solutions were added from a Metrohm EA274-50 manual piston burette. The solutions were then titrated "back" towards the basic region with sodium hydroxide–chloride solution. This two stage procedure had the advantage of providing protonation data which were used for calibrating the electrodes *in situ*, specifically for each individual titration.

Computations

The caffeate protonation constants and the electrode calibration parameters were determined by applying the programs MAGEC[14] and MINIQUAD[15] alternately to the relevant titration data, according to the procedure already described.[14]

The complexation data were initially processed by the program ZPLOT[16] in order to obtain experimental formation curves of $\bar{Z}_{obs}$ vs $-\log$ [free ligand], and subsequently by MINIQUAD in order to obtain "best"-fitting chemical models and refined formation constants (β_{pqr}).* To facilitate hypothesis testing, the formation constants corresponding to the finally chosen chemical models were used to generate theoretical formation curves of $\bar{Z}_{calc}$ vs $-\log$ [free ligand] by means of the program PSEUDOPLOT.[17] The degree of matching between the experimental and the theoretical formation curves gave a measure of the validity and the accuracy of the proposed chemical models. Lastly the constants corresponding to the finally proposed

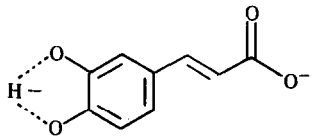
* β_{pqr} refer to the general complex $L_pM_qH_r$, where L = ligand, M = metal ion and H = proton. When $r = -1$, this refers to proton removal from the complex or to hydroxyl ion addition.

chemical models were processed by the program HALTAFALL[18] to give profiles of the distribution of each complex species as a function of pH.

RESULTS AND DISCUSSION

Protonations

Several forward and reverse titrations of caffeic acid were carried out over a pH range of about 2–12, with total initial concentrations of the ligand ranging from 0.0038 to 0.0187 mol dm^{-3}. No attempt was made to determine the first protonation constant of the trianion of caffeic acid [which probably has a pK_1 of *ca* 13 (cf. catechol[19])] because of uncertainties arising from deviations of the glass electrodes from Nernstian behaviour together with a non-constant ionic strength of the solution for pH > 12. Therefore in this paper the ligand species L^{2-} is taken as the dianion (**1**).



1

The very strong basicity of the third dissociable proton has been attributed mainly to electrostatic attraction of the nearby negative charge and, to a smaller extent, to hydrogen bonding between the hydroxyl and phenoxide groups.[20] All the titrations gave superimposable curves of $\bar{Z}_{obs}$ vs $-\log[H^+]$, indicating the formation of solely the monomeric protonated species HL^- and H_2L (i.e. no evidence for any oligomeric species could be found).

Satisfactory statistical fits of the parameters to the data were indicated by reasonable values of the MAGEC objective function (0.012 cm^6), the MINIQUAD *R*-factor (0.0043) and χ^2 (23.9). Values found for the two protonation constants are presented in Table 1 together with literature values for the same and various related ligands. Allowing for variation in ionic strength and background medium the agreement between our protonation constants and those determined by Timberlake[21] is quite acceptable. The sites of protonation were ascertained by comparison of our constants with those for the other ligands included in Table 1. In this respect catechol was an obvious choice for the catecholate site, and acetate was selected as a suitable model of the carboxylate group of caffeate. The values in Table 1 indicate that K_2^H corresponds to protonation of either one of the catecholate oxygen atoms and K_3^H refers to protonation of the carboxylate group. It should also be noted that the catecholic proton of caffeic acid is somewhat more acidic than that of catechol itself, which might suggest some electron-withdrawing effect of the carboxylate moiety being operative across the double bond of the side chain. This does not seem to be the case with 3,4-dihydroxy hydrocinnamic acid, which has a fully saturated side chain, the value for $\log K_2^H$ being close to that for catechol.[22]

Complexations

Meaningful titrations of the iron(III)–caffeate system could not be carried out successfully owing to rapid reduction to iron(II), as indicated by 1,10-phenanthroline spot tests.[11] Even in the initial, very acidic solutions, reduction of the iron(III) was found to be appreciable. On the other hand,

Table 1. Logarithms of the stepwise protonation constants (K_n^H)[a] for caffeate[b]

Ligand	Log K_1^H	Log K_2^H	*d*	Log K_3^H	*d*	Medium (mol dm^{-3})	*T* (°C)	Reference

[a] K_n^H is defined here as the associative constant, i.e. for the reaction:

$$LH_n + H \rightleftharpoons LH_{n+1},$$

with $n = 0$, 1 or 2.

[b] Literature constants for related ligands are included for comparison. *d* = standard deviation of $\log K_n^H$.

titrations with iron(II), copper(II) and zinc(II) presented no problems. A series of replicated titrations of caffeate with the latter three metal ion species were carried out using initial total ligand and total metal concentrations covering the ranges 0.0034–0.0275 and 0.0021–0.0038 mol dm^{-3}, respectively. This resulted in ligand : metal ratios ranging from 1 : 1 to 5 : 1 for iron(II), 7 : 1 for copper(II), and 10 : 1 for zinc(II). In the cases of iron(II) and zinc(II), precipitation occurred early in the 1 : 1 ratio titrations and these data were thus discarded. The pH values ranged from 3.3 to *ca* 7 for copper(II), 6–9 for zinc(II), and 5–8.5 for iron(II). The purpose of using such varying initial concentrations was to facilitate the search for not only binary complexes but also protonated, hydroxo and oligonuclear species. Indeed, although titrations with identical starting conditions gave superimposable formation curves indicating good experimental reproducibility, titrations with different ligand : metal ratios gave non-overlapping formation curves in fact as exemplified by copper(II) in Fig. 1 a large degree of back-fanning was observed for all three systems studied. This feature indicates the presence of not only mononuclear binary complexes but also of hydroxo species. Much of the back-fanning is, however, probably attributable to the loss of the very basic third dissociable proton of the ligand on complexation. This is, of course, indistinguishable from the formation of hydroxo species. Further, because of the existence of two potential coordinating sites on the ligand, the formation of oligonuclear hydroxo complexes was considered to be plausible. Hence, numerous combinations of the stoichiometric coefficients *p*, *q* and *r* were tried for the three metal–caffeate systems in applying MINIQUAD to the potentiometric data. Metal hydrolysis reactions of the sort described by Baes and Mesmer[23] were incorporated into every chemical model tried. The most consistent sets of complexes found for the three metal–caffeate systems, together with their respective formation constants, standard deviations, MINIQUAD *R*-factors and χ^2 values are presented in Table 2. Also given, for the purposes of comparison, are formation constants taken from the literature for the catechol–metal ion and 3,4-dihydroxy hydrocinnamate–metal ion systems. No caffeate–metal ion formation constants have been reported in the literature except for the 21 – 2 complex with copper(II),[21] which was, however, not found, although it was searched for in the present study.

The validity of the three chemical models was illustrated by excellent matching of the experimental $\bar{Z}_{obs}$ vs $-\log[L^{2-}]$ points with the corresponding theoretical formation curves as generated PSEUDOPLOT using the refined formation constants given in Table 2. This can be clearly seen for example in the case of the caffeic acid–copper(II) system presented in Fig. 1. Figures 2–4 show typical species distributions for the

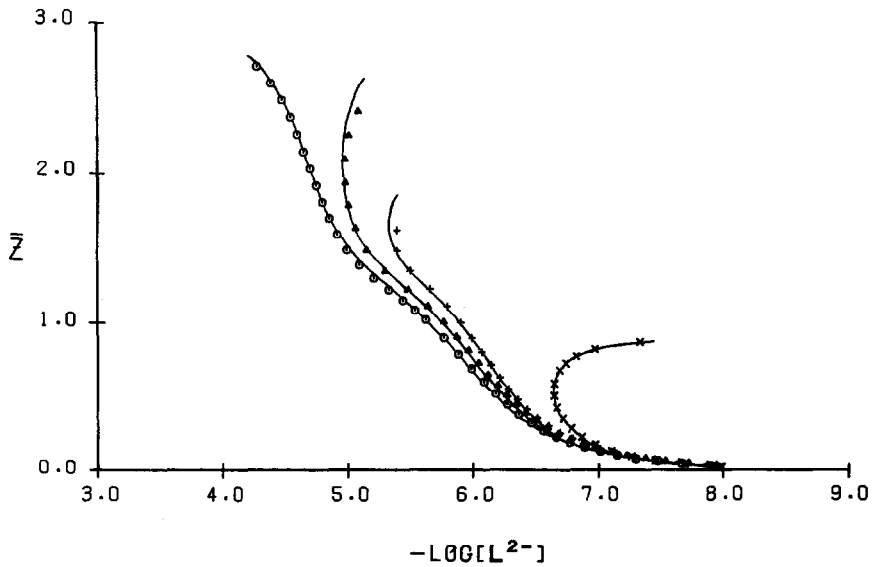

Fig. 1. PSEUDOPLOT formation curves calculated from the caffeate–proton and caffeate–copper(II) formation constants in Tables 1 and 2, plotted together with experimental ZPLOT points. Initial concentrations (10^{-3} mol dm^{-3}) of caffeic acid and copper(II), respectively, are: 3.38 and 3.75 (×), 6.57 and 3.08 (+), 7.81 and 2.75 (▲), and 15.05 and 2.08 (⊙).

copper(II)–, zinc(II)– and iron(II)–caffeate systems as functions of pH.

The complexes suggested in Table 2 are all chemically plausible and may, through reference to Figs 2–4, be roughly divided into major and minor species. As a broad generalization, it is to be expected that major species would tend to involve, predominantly, chelation of the metal ions by the more strongly coordinating catecholate site on the caffeate ligands, whereas coordination to the carboxylate moieties would tend to appear more commmonly and, in some cases, concomitantly with catecholate chelation, amongst the minor species. In the range of lower pH values,the major species formed by all three metals are mono complexes, being 11−1 in the case of zinc(II), 110 in the case of iron(II), and both 110 and 11−1 in the case of copper(II). The iron(II) 11−1 species occurs towards higher pH values and the zinc(II) 110 complex appears as a minor species. Our 11−1 constants for copper(II)–caffeate and zinc(II)–caffeate compare favourably with those reported in the literature for complexation of these metal ions by catechol, indicating chelation of the metal ions by

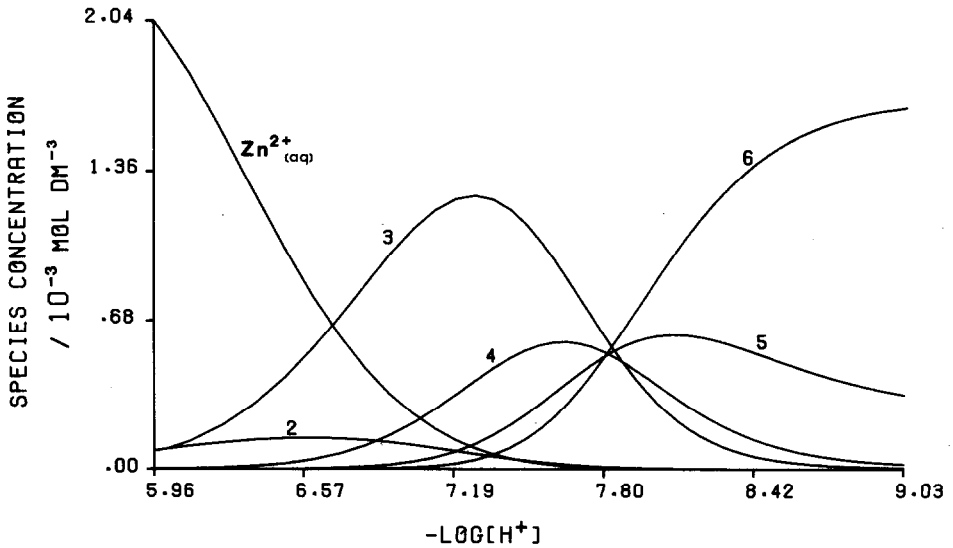

Fig. 3. Distribution of species in the zinc(II)–caffeic acid system. Total concentrations (10^{-3} mol dm^{-3}) are: zinc(II), 2.60; and caffeic acid, 26.1. Species: (2) LM, (3) LMH_{-1}, (4) L_2MH_{-1}, (5) L_2MH_{-2}, and (6) L_3MH_{-2}.

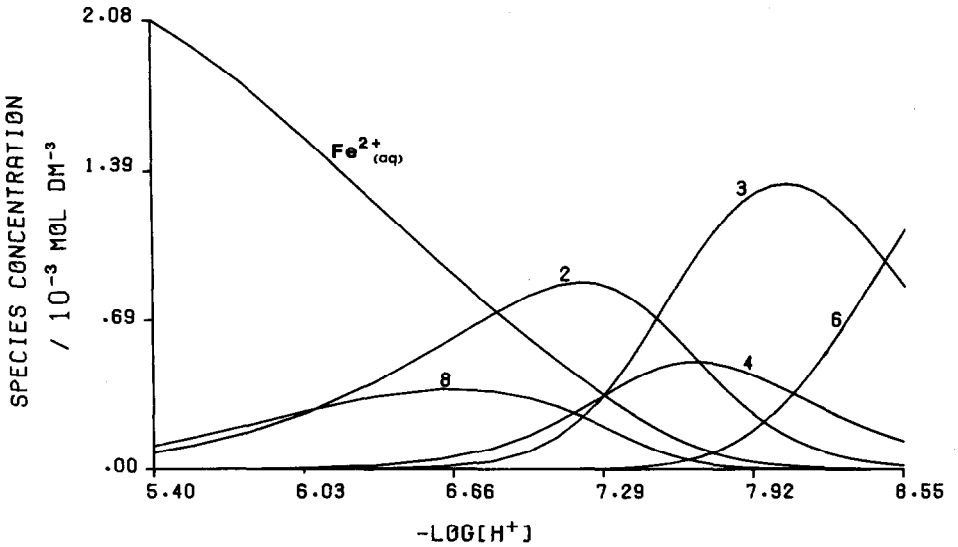

Fig. 4. Distribution of species in the iron(II)–caffeic acid system. Total concentrations (10^{-3} mol dm^{-3}) are: iron(II), 2.98; and caffeic acid, 14.9. Species: (2) LM, (3) LMH_{-1}, (4) L_2MH_{-1}, (6) L_3MH_{-2}, and (8) LM_2.

the fully deprotonated catecholate moiety of caffeate. The alternative of complexation at the carboxylate group of caffeate with a completely deprotonated catecholic site is very unlikely, considering the pH regions ($\ll 12$) in which the complexes occur. Although our constants for the iron(II)–caffeate 11 – 1 complex does not agree closely with the literature value for the corresponding iron(II)–catecholate complex (see Table 2), it is felt that the range of existence of the former complex, namely pH 6–9, approximately, tends to favour catecholate-type chelation over carboxylate complexation, in conformity with the 11 – 1 copper(II)– and zinc(II)–caffeate complexes. As far as the 110 caffeate complexes are concerned, the most likely structure seems to be with chelation at the singly protonated catecholate site and the carboxylate group deprotonated. Although this mode of complexation has not been reported for the copper(II)–catechol system,[13,19] it has been found for the copper(II)–3,5-di-*t*-butylpyrocatechol and iron(II)–catechol systems.[19] Furthermore, our formation constant for the iron(II)–caffeate 110 complex compares quite favourably with that reported in the literature for the corresponding iron(II)–catecholate complex,[19] taking into account the differences in ionic strength and background medium between the two respective investigations. Complexation by the carboxylate group of caffeate, with the catecholate site singly protonated, seems unlikely in view of the significant differences between our 110 metal–caffeate constants and corresponding metal–acetate constants reported in the literature.[24,25] Structures for the 110 metal–caffeate complexes with chelation at the completely deprotonated catecholate site and protonation of the carboxylate group are thought to be unlikely, at least towards higher pH values, for the following reasons. Figures 2–4 indicate the 110 complexes to be present in significant concentrations up to pH values of 7, 7.8 and 8.5 for the copper(II), zinc(II) and iron(II) systems, respectively. In contrast, a protonated carboxylate group is expected to be essentially non-existent at pH values greater than 6.5. At lower pH values a microspecies with protonated carboxylate could contribute towards the 110 macro-stoichiometry, however. The minor species (111), which is unique to copper(II) amongst the caffeate complexes listed in Table 2, could have one of three possible structures. The first, with metal–ion complexation at the fully protonated catecholate site is intuitively unlikely as the corresponding species in the catecholate–copper(II) system was searched for but not found.[13] Furthermore, the carboxylate moiety of caffeate is likely to be protonated in the pH region in which the 111 complex exists. The logarithmic equilibrium constant for the reaction:

$$Cu^{2+} + HL^{-} \rightleftharpoons LCuH^{+},$$

namely, 1.75, is virtually identical to the logarithm of the formation constant of copper(II) with acetate.[24] This agreement lends support to a structure in which complexation occurs at the carboxylate group with a fully protonated catecholate site. A third possible structure with complexation at the singly protonated catecholate site and with the carboxylate group protonated is, however, also

quite likely, because the 111 complex is seen from Fig. 2 to exist over the same pH region in which the 102 protonated ligand species, LH_2, is found. Furthermore, the logarithmic equilibrium constant for the reaction:

$$LCu + H^+ \rightleftharpoons LCuH^+,$$

namely, 4.44, is virtually identical to the $\log K_3^H$, corresponding to protonation of the carboxylate group of caffeate. This lends support to the third alternative because the foregoing considerations of various possible structures for the 110 caffeate complexes of copper(II), zinc(II) and iron(II) tend to favour those with chelation at the singly protonated catecholate site and a deprotonated carboxylate group.

Mononuclear bis(caffeate) complexes appear only as relatively minor species, and of zinc(II) and iron(II) only, not of copper(II). Mononuclear tris-(caffeate) complexes appear in our chemical models as major zinc(II) and iron(II) species. In the light of the foregoing arguments regarding the mono(caffeate) complexes, it is thought that the predominant complexation mode in the bis and tris complexes is metal chelation at the catecholate site, resulting in coordination numbers ranging from 4 to 6.

Towards higher pH values, the only major copper(II) complex of caffeate that we have found, is the dinuclear species (32−3). This, together with the minor copper(II) complexes (23−2 and 12−1), occurring in the lower-pH range, illustrate the tendency of copper(II) to form oligonuclear complexes with ligands possessing two coordination sites.[13,26,27] In these complexes, the copper(II) plays the role of a link between adjoining ligands. Since the caffeic acid molecules in the copper(II) complexes (32−3 and 23−2) are completely deprotonated, it seems likely that all the catecholic sites are involved in the complexation. With regard to the copper(II) complex (12−1) and the analogous minor iron(II) species (120) it seems self-evident that a metal ion is coordinated at each end of the ligand molecule.

THE BIOCHEMISTRY OF ZINC

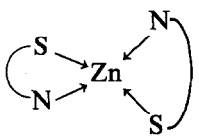
R. J. P. WILLIAMS*

University of Oxford, Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 3 *July* 1986)

Abstract—The biochemistry of zinc is now beginning to be understood. The background to this understanding is a deep knowledge of the chemistry of the element. In this article I shall show some of the ways in which evolution has searched for and found the outstanding potential of zinc in catalysts. As a background an analogy is drawn with man's efforts to evolve analytical methods of high selectivity for the estimation of zinc. The article also illustrates some of my own interests in zinc which started in Professor Irving's laboratory.

The biochemistry of zinc must start from a firm basis in the chemistry of zinc. My first detailed knowledge of that chemistry was during my earliest days as a research student and pupil of Professor Harry Irving. I came to him in 1947 with a determined interest in trace elements and he set me a problem in analysis and the understanding of analytical method. (He had previously been my tutor in inorganic chemistry.) The problem was to be the understanding of the estimation of zinc by the extraction method, followed by colorimetry, using the organic reagent dithizone. The close relationship between analytical chemistry and the selective principles behind trace-element function in biology was soon obvious, and I have never forgotten that lesson. Even if we look at the coordination sphere of the complex between zinc and dithizone



we see two interesting features: (1) the sulphur–nitrogen coordination, and (2) the tetrahedral geometry. We shall refer to both again and again.

There was little known of the structural chemistry of zinc in 1947, nor indeed of its thermodynamics and kinetics. However, earlier work on extraction and analytical methods had demonstrated that zinc was not the element which reacted at the lowest pH with almost any reagent. This distinction belonged to other metals such as mercury, lead, perhaps silver, and, if oxidation could be avoided, copper. Thus, zinc was not a very powerful binding reagent. Curiously (to us at the time) this power of binding was exactly the pattern of the Qualitative Analysis Tables which I had learnt at school and which Dr Irving had taught for some time in undergraduate chemistry. All chemists should know these Tables. Mercury, lead, silver and copper are precipitated before zinc by almost any reagent, e.g. sulphide.

Inspection of the literature showed that, in fact, of all the known analytical organic reagents for metal ions none reacted more readily with zinc than with copper. However, none reacted more readily with manganese than with zinc. With this hint of the appearance of a metal ion series of reactivities we had to stop and think, since there could have been two reasons why metal ions might combine in a preferred order. The first is a matter of affinity (thermodynamics) and the second a matter of speed (kinetics). In 1947 it was not apparent that any of the analytical methods depended on the establishment of equilibrium. In fact it fell to me under Irving's guidance to demonstrate by experiment that the observed series was due to equilibrium not kinetic controls. Dr Irving and I showed this by using a shaking machine working over many hours to produce equilibrium in the extractions of metal ions by dithizone. We showed then that the affinity

* R. J. P. Williams was an undergraduate at Merton College, Oxford (1944–1948), taught inorganic chemistry by Dr Irving, and did his Part II and D.Phil. with Irving. He was a tutor and lecturer at Wadham College, Oxford (1955–1972), before becoming the Napier Royal Society Research Professor at Oxford.

for dithizone at equilibrium with metal ions was in the order of divalent ions:

$$Zn < Cu > Ni > Co > (Fe) > Mn \geqslant Mg = Ca = \text{zero}. \quad (1)$$

Now it was just at this time that Jannick Bjerrum's fine thesis became available to us. In it he demonstrated that equilibrium binding constants could be determined in a single phase, water, for the interaction of metal ions with *neutral* ligands. The order for ethylenediamine was the same as that given above. Thus, we knew that the order did not depend on a phase change (extraction or precipitation) but that there was a fundamental thermodynamic order of interaction energies which was also not dependent on the donor atom, oxygen, nitrogen or sulphur (each shown separately); was not dependent on the anionic character of the ligand; and was not dependent on solvent. Others, especially Mellor and his group in Australia, and Calvin and his group in U.S.A., were approaching the same conclusion. The problem lay in the fact that, although the above order was (almost) universal, any persistent regularity disappeared if data for mercury, lead, cadmium or other ions were included in the series.

Dr Irving and I discovered the reason for the simplicity of the order (1). The metal ions in the order are of very similar size, but their electron affinities change smoothly along the series to a maximum at copper(II) and fall back at zinc. Inclusion of ions of different sizes confuses the description since now readius and ionization energy changes are randomly scattered. In Fig. 1 is plotted the function z/r against the ionization energy from metal ions to the divalent state. The "a"/"b" classification, sometimes unwisely called the hard/soft classification, falls out immediately and so does the Irving–Williams series. Following the evidence of analytical extraction procedures we had uncovered a very simple rule of great general use, i.e. series (1). The rule is almost independent of ligand type, the number of ligands bound, of ligand geometry, and of stereochemistry. The fact that there was a correlation with two central-field parameters, ionization energy and z/r, meant that it was independent of crystal (ligand) field angular polarization, though this adds a term which in octahedral geometry follows the series:

$$Mn < Fe < Co < Ni > Cu > Zn. \quad (2)$$

Just as it is a mistake to use soft and hard as a classification of "a" and "b" metal ions so is it a mistake to overstress the contribution of angular polarization energies to the energy of complex ion formation. It is a fact, as we showed in our very early papers, that series (1) not (2) dominates spectroscopic perturbations of ligand spectra in complexes, i.e. their IR and UV spectra, and the effect

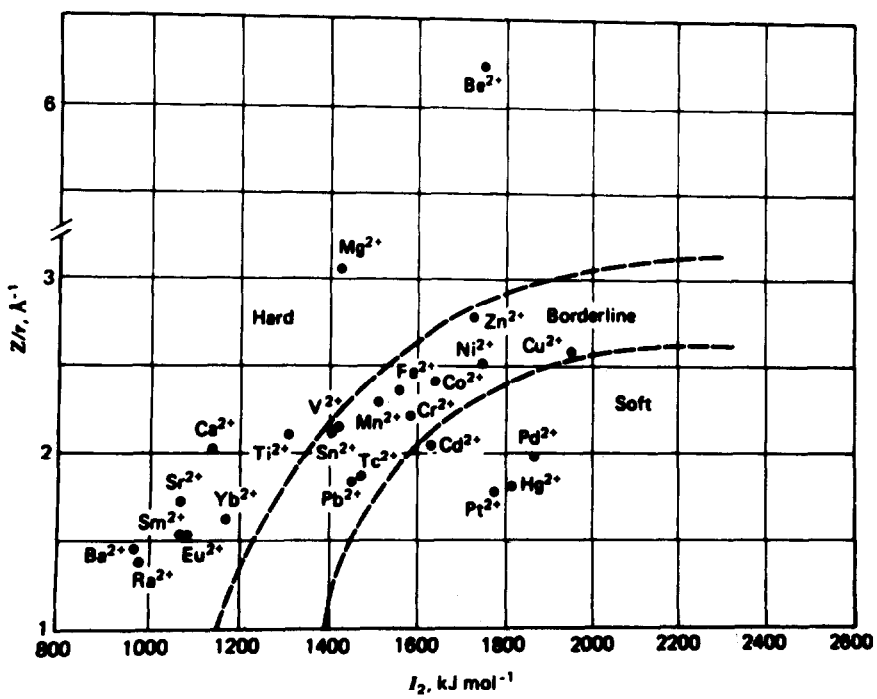


Fig. 1. Plot of z/r against ionization potential for divalent ions showing the classification of metal ions and the Irving–Williams series.

of metal ions as Lewis acids in catalysis. Therefore, the polarization of the ligand by the metal follows order (1). I return to these points later since they must be appreciated if the subtle nature of the use of zinc in biology is to be understood.

Now the background to metal ion–ligand affinity has been given it should also be noticed that the differences in the Irving–Williams order increases as the polarizability of the donor atom increases in the series:

$$O < N < S.$$

This means that there is an increase in selectivity of organic reagents such as dithizone (N,S) over 8-hydroxyquinoline (N,O). Again, this is a lesson of immediate applicability to biological systems. It means that combinations of N- and S-donors can be used to select out powerfully transition metals and B-subgroup metals from A-subgroup metals and that they can also be used to select one transition-metal ion from another. Again, curiously this follows from the way in which the Qualitative Analysis Tables instruct one to proceed. [The classifications in those Tables are in fact of necessity the classifications of elements in biology (Table 1).] The basic idea is the removal of one element, e.g. copper, by one reagent, sulphide, by a phase transfer precipitation before the determination of a second metal, e.g. zinc, in the residual phase. Further metal ions are precipitated as carbonates, an O-ligand. An example is the precipitation of copper as a sulphide at pH < 2 in Group IIA of the Qualitative Analysis Tables followed by filtration. The precipitation of zinc sulphide is at pH = 10 in Group IVA of the same Tables. This shows the large difference between zinc and copper sulphide chemistry. Calcium and magnesium are analysed later by oxygen atom donors. The implication as far as this article is concerned is that biological systems must be able to use a variety of organic ligands to complex metal ions, to control pH in different compartments, and to transfer ions from compartment to compartment in order to keep elements away from one another. In turn, this implies that biological systems have *local* equilibria and use boundaries, membranes, to keep different reaction possibilities under kinetic separation. Biological systems pump ions and compounds across membranes which permits isolation of reactions just as a separation procedure in analyses, e.g. precipitation, uses the removal of one phase, an organic solvent or a precipitate, to carry one set of compounds into a separate set of reaction possibilities. However all these possibilities are preconditioned by binding affinities as revealed in the Irving–Williams series.

Before passing on we note that pumps can be devised and are so devised in biology that they recognize *shape*. The use of the energy of transfer through a membrane depends on a triggering kinetic step. It does not then matter if two compounds bind equally in a thermodynamic sense so long as, for example, the one which is tetrahedral can trigger but the one which is octahedral can not. A tetrahedral zinc complex may traverse the membrane because it is pumped unidirectionally after triggering, but an octahedral nickel complex is unable to pass the membrane at all since it fails to trigger the energy source. In biology the *shape* of complex ions, of ions themselves, of small molecules, of proteins and so on decides the compartment into which they are pumped. We shall see that zinc is readily separated and put in its place by the use of binding energies and the curiosities of its stereochemistry (Fig. 2).

Table 1. Classification of cations in biological systems[a–c]

Na^+, K^+	Mg^{2+}, Ca^{2+}	Zn^{2+}	Fe, Cu, Co, Mo
Charge-carriers	Structure formers and triggers	Super-acid catalysts	Redox catalysts
Mobile	Semi-mobile	Static	Static
Oxygen-anion binding	Oxygen-anion binding	Nitrogen/sulphur ligands	Nitrogen/sulphur ligands
Weak complexes	Moderately strong complexes	Strong complexes	Strong complexes
Very fast exchange	Moderately fast exchange	No exchange	No exchange

THE DISPOSITION OF ZINC IN BIOLOGICAL SPACE

General inspection of the biological systems shows that, whereas copper is rejected by cells from internal compartments especially the cytoplasm, zinc is not. In general zinc is pumped into vesicles in the cytoplasm or is held in the cytoplasm. In general copper is pushed into totally extracellular spaces. Copper becomes the catalyst (in enzymes) for extracellular oxidations while zinc becomes associated with control and triggering reactions in vesicles, e.g. hormonal release, as well as directly with some special enzymes for digestion (see Table 1 and Fig. 2). The observed distribution of high zinc gives a very good clue to its utilization, especially against the background of its chemistry.

KINETIC CONSIDERATIONS

The work Dr Irving and I carried out did not only reveal the thermodynamic order, the Irving–Williams series, and the basis of a wider appreciation of stability constant data in solution such as the introduction of high-spin–low-spin changes within the series, e.g. that of the complexes of the dipyridyls, and the importance of stereochemistry but it nearly gave us a crystal field theory too. We clearly observed that the involvement of the empty orbitals of the *d*-shell at nickel affected the number of ligands taken up equally. It fell to Dr L. E. Orgel to show us the proper theoretical framework for these observations. We did observe another feature of the reactions of complex ions—some were faster than others. It was the work of Eigen and Taube which gave the underlying explanations once again in terms of *d*-shell filling. This gave a quite new order, that of the rates of substitution of ligands around a metal ion:

$$Zn, Mn > Cu > Fe > Co > Ni > \text{low-spin systems.}$$

Notice that zinc is placed in the very fast reacting groups.

Now in any reaction system we can reduce the rate expression to a dependence on several steps: (1) the formation of the appropriate units in a complex, (2) the formation of the correct stereochemistry in that complex, (3) the readiness of the system to pass along a set of reaction intermediates, and (4) the ease of disruption of the final products. We should also add two other considerations: (5) the absence of alternative unwanted paths, and (6) the spatial separation of the reaction system from other such systems could be desirable so that only one set of transformations is carried out in one part of space. Without much mental effort an overview of the value of zinc in a reaction system begins to appear. (1) It binds well though not as well as copper. (2) It has very selective stereochemical possibilities which can be altered easily since it has no strong preferences for a field of given symmetry—no ligand field terms. (3) It exchanges ligands rapidly. (4) It can release rapidly ligands which are chemically changed, i.e. the products. (5) It does not take part in redox reactions. (6) It is readily transferred into special compartments using (1) and (2) together with pumps. Add to this background the fact that zinc is quite soluble in water at pH = 7, and is therefore available to biology, and we have an ion, zinc, which is preferable to almost any other cation to be the favourite choice as an acid–base catalyst in water on grounds of availability, power and absence of redox properties. Biology uses zinc for just these three reasons. Before looking further at the catalytic potential of zinc we must observe that its binding potential and lack of redox properties are extremely valuable in other respects. Because it binds strongly to, say, thiolate groups and does not catalyse their oxidation, it protects them. This is common in the cross-linking of rubbers. Biology will be seen to use this protection of thiolate groups in a number of ways. We discuss catalysis first.

ZINC ENZYMES

Figure 3 shows the pattern of reaction rates for zinc enzymes when the zinc is substituted by other metal ions. The Irving–Williams order of Lewis acid strength has disappeared but not the binding strength to the isolated enzyme. Clearly stereochemical requirements dominate thermodynamics in this enzymic rate series and there is a clear

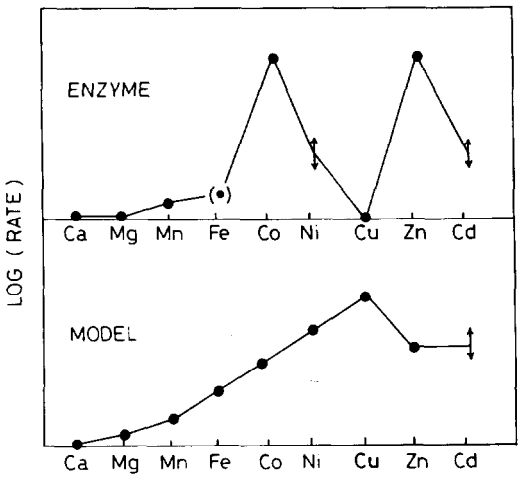

Fig. 3. Plot (below) of the rates of Lewis acid catalysis by free metal ions of model substrates. Shown above is the rate of catalysis by metallo-enzymes in which the native zinc has been replaced by a series of other metal ions.

demand for cations which do not prefer octahedral geometry, i.e. zinc and cobalt. We can draw somewhat convincing reaction pathways, e.g. for carbonic anhydrase (Fig. 4) which show how nicely zinc can aid any catalysis by its fast switches in stereochemistry and by its polarizing power, e.g. in hydroxide generation. I think however that if it had been discovered that copper(II) was at the heart of carbonic anhydrase we could have drawn equally convincing diagrams of its reaction patterns since it has a greater polarizing power and reacts rapidly. After all, it is at the heart of superoxide dismutase. Intrinsically, copper(II) is a better Lewis acid catalyst. The use of zinc to the exclusion of copper in most hydrolytic enzymes has led to the perfecting in a *zinc* enzyme of a pathway peculiar to *zinc* chemistry but zinc was not chosen for its catalytic potential alone. It was selected for the absence of redox reactions. In fact there are no acid–base reactions in biology which are catalysed by copper enzymes. There are a few apparent acid–base transformations where the metal ion in the enzyme is not zinc, but there is the suggestion here that some of these at least go by free-radical paths which zinc can not assist, e.g. diol rearrangements (cobalt in B_{12}), decarboxylations (iron–sulphur), and hydroxy acid rearrangements, aconitase (iron–sulphur). Zinc dominates in all the simple reactions such as ester, amide, ether hydrolyses of biology, and it is here where oxidation must be avoided.

The organic chemist may well ask "but why use zinc at all?" when most hydrolytic enzymes are good catalysts without any metal ion. Here the organic chemist is not observing his own chemical systems closely. The catalysis of reactions in organic chemistry can use extremes of pH so that H^+ and OH^-, even RO^-, are useful free attacking groups. However it is not infrequent for the organic chemist to switch to the use of $AlCl_3$, $ZnCl_2$ etc. as Lewis acid catalysts when he can not control pH, e.g. in organic solvents. Why did he not choose to add organic acids and bases as catalysts? The simple answer is that there are no organic compounds of simple construction which show the high and highly exposed electron affinity of tri- (aluminium) and divalent (zinc) metal ions even in organic solvents. Putting it bluntly, organic chemistry does not supply good attacking groups for either acid or redox reactions at neutral pH. This is the function of metal

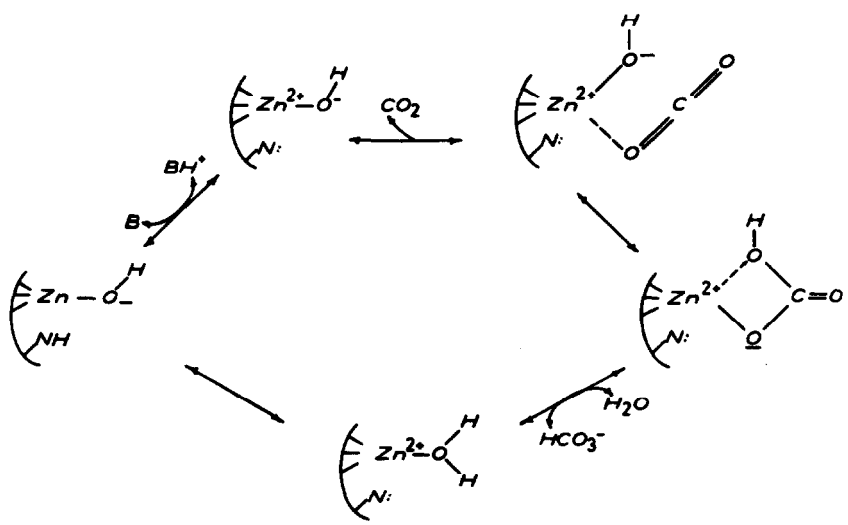

Fig. 4. Proposed outline scheme for the catalysis of the CO_2+H_2O reaction by the zinc enzyme carbonic anhydrase.

Table 2. Comparison between zinc and non-zinc enzymes[a]

Reaction	Zinc-dependent enzyme substrate	Metal-independent enzyme substrate
Hydration	CO_2, levalinic acid	None
Protein hydrolysis	Carboxy-terminal, amino-terminal and dipeptides	Endopeptide None(?)
Phosphate ester hydrolysis	Terminal phosphate	Phosphate transfer
RNA/DNA hydrolysis	Non-specified nucleotides	Ribonucleotides
RNA/DNA polymerase	No specific base	None
β-Lactamase	Penicillins	Penicillins
Aldolase	Several aldols	Several aldols
Phospholipase	(C) Lipid esters	(A) Lipid esters

[a] Generally zinc is employed when the substrate is small, e.g. CO_2, or when the reaction is non-specific, e.g. alkaline phosphatase, RNA polymerase and terminal proteases.

ions or bare H^+ and OH^-. Let us look at acid–base catalysis more closely.

Molecules can be broken rapidly in catalysed steps only by readjusting the bond energies along a pathway. There are two ways of doing this: (1) the bonds can be twisted and stretched, or (2) neighbouring attacking groups can be introduced. Both modes are catalytic. Metal ions are helpful as are any binding modes in (1) but they are unique in (2). Enzymes formed from organic units can only supply very many binding centres for purpose (2) and poorish attacking groups. It follows that if a substrate has many points of attachment to an enzyme it can be twisted and torn apart by an organic template which recognizes the shape of the intermediate better than that of the substrate and, with a little help from friendly disposed but weak organic acids and bases, e.g. in chymotrypsin, which breaks large peptides. However, if the reaction involves a small molecule then the binding must be through very simple attachment, distortion of the substrate is difficult, and catalysis now requires good attacking groups, e.g. zinc. Zinc can activate the smallest of molecules, H_2O, the participant in all hydrolyses. Thus we observe that it is in the hydrolytic reactions of small substrates that zinc is most used (Table 2). (These points are general to the functional use of all metal ions in biological catalyses.)

I do not want to press on with a detailed discussion of the catalytic chemistry of zinc in enzymes. I believe this to be but one area of interest and there are possibly two other areas of zinc action in biology which merit further analysis: (1) protection of thiolates, and (2) triggering. Before passing to these points, however, I would not like three features of the binding of zinc in enzymes and other proteins to be missed (Fig. 5). The zinc is invariably bound to more than one nitrogen or thiolate, and is bound by at least three groups in total to give it *chelate* stability and closely adjusted stereochemistry in the site. If zinc were bound to a smaller number of groups it would not be bound with sufficient strength for permanent (irreversible) attachment. The binding in enzymes is linked to the fold energy of the protein so that the zinc is cooperatively fixed to its site—it does not exchange readily from the enzymes. Note that the zinc enzymes have tight β-sheet folds (Fig. 6). The stereochemistry in the enzymes is carefully tuned to make function optimal—the entatic state tuning of Vallee and Williams, but minor adjustments are permitted to allow flow along a reaction pathway. I shall not elaborate further but I would remind the

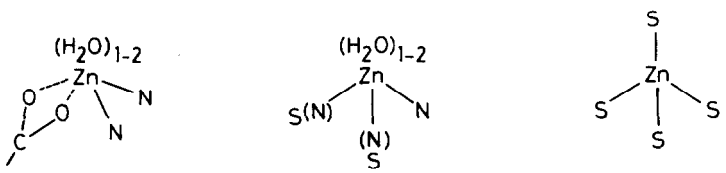

Fig. 5. Different, entatic, geometries of zinc in enzymes. Left: carboxypeptidase, and middle: carbonic anhydrase (N) and alcohol dehydrogenase (S). The right-hand structure shows zinc as a cross-linking agent.

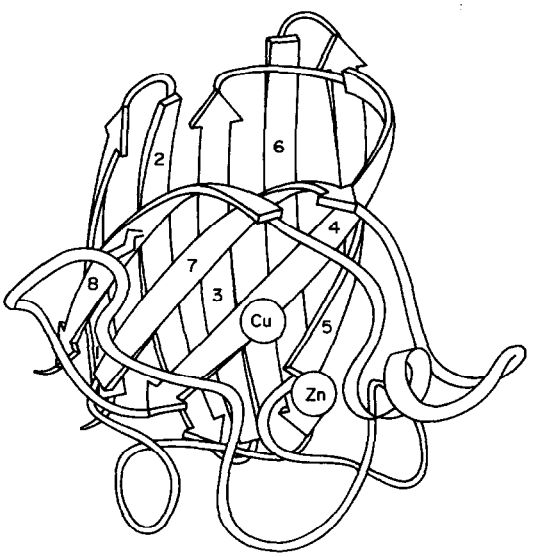

Fig. 6. Outline structure of Cu/Zn superoxide dismutase showing the β-barrel.

reader of the tricks used in analytical chemistry. Dr Irving's favourite, using organic reagents and phase transfer to generate selective determinations of metal ions, is very closely akin to biology's use of organic binding groups not only to control metal ion functions but where they are used and their usefulness.

CROSS-LINKING BY ZINC

Zinc cross-linking is not too unusual in intracellular enzymes. In fact the use of zinc to stabilize a structure is useful in that it can replace the conventional biological cross-links formed from oxidized dithiols, —S—S— bridges, in the extracellular medium. Zinc then provides a centre free from one-electron reactions, which other metals and disulphide could not do, and inside the cell, which is a reducing medium. The cross-links are often now in fact from one RS^- to another through zinc, and the zinc site is frequently in the middle of four such RS^- groups, e.g. in alcohol dehydrogenase and aspartate transcarbamylase (Fig. 5). An alternative cross-link known in one enzyme, the Cu/Zn superoxide dismutase, uses a number of imidazoles, here four again in an approximate tetrahedron. In this last case the zinc is close to the copper at the active site and directly generates the ligand geometry around the copper (Fig. 6). Copper is in a truly entatic condition brought about in part by the zinc. A recent example of unknown importance as yet is the finding of zinc in cytochrome oxidase.

The use of cross-links in enzymes is to be contrasted with the use in other kinds of protein. The best known is the keratin filaments of the tails (flagellae) of such cells as sperm. Here zinc helps to generate a stable yet flexible structure for the motor of this cell. Note that the male reproductive tract is full of zinc—is this to help to keep sperm healthy and moving?

Recently Klug and coworkers have described an impressive example of zinc cross-links in a transcriptase factor. Some 9 or 10 zinc atoms are bound in a repeated domain of a protein which in turn binds to DNA. The on and off reactions of zinc may well be related to the conformations of the protein and its interaction energies with the DNA. Thus zinc could control transcription. We are reminded of two series of experiments. The first showed that zinc is essential for growth of humans and zinc deficiency causes developmental retardation. The second showed that if zinc is replaced by other elements such as cobalt or manganese in *Euglena gracilis* growth media then the genetic machinery suffers some peculiar irregularities.

Finally there are the uses of zinc in some quite peculiar structures such as the tapetum of the eyes of animals with night-vision. Here the zinc is in crystals of zinc cysteinate, it is said. Another use is in the stabilization of the "teeth" of the larvae of insects such as locusts where it is thought the zinc acts as cross-link of phenolate polymers in a form of sclerotin.

ZINC CHEMICAL TRIGGERS

A way of triggering a biological system is to remove an inhibitor. The simplest examples are the breaking of chemical bonds in proenzymes to give enzymes. Thus an inhibitory peptide is broken away from prochymotrypsin, i.e. chymotrypsinogen, to give chymotrypsin. This process is quite sluggish, involving the breakdown of covalent bonds. An alternative mode of triggering of this kind is by the breaking of ionic bonds, and naturally this involves metal ions. Although the following case is not known to be true it looks extremely plausible.

It is now known that many enzymes which breakdown storage proteins to release peptide hormones are thiolate- and zinc-dependent. Such enzymes must be stored ready for use but this has its risks since the thiolates can be readily oxidized. A solution to this problem is to store them with the protein which contains the hormonal peptide in the presence of zinc which both protects the reactive site and inhibits oxidation. The zinc binding must be weak, say two bonds only so that dissociation is fast. In other words a container is needed and a compartment (vesicle) in which there is a somewhat concentrated zinc solution. The zinc is protective

but to be so and readily released it has to be in only moderately strongly held and therefore in fairly high concentration, say 10^{-7} M free zinc ions, in order to function. The situation is unlike that in the above zinc enzymes when the zinc is a catalytic component and is bound almost irreversibly with a constant of 10^{-10} M, although the two modes of action are not mutually exclusive. Now this hypothesis explains immediately the high concentration of zinc in many peptide hormone containing vesicles, e.g. in the brain (endorphins) and the pancreas (insulin). It also explains the presence of high zinc in parts of the sperm and pollen which require proteases to trigger many events—e.g. fertilization. However, the use of zinc in this way needs a mode of concentrating the zinc in the vesicles—a zinc pump.

THE ZINC PUMPS

The way in which zinc is removed from cells to vesicles is unknown. Metallothionine (see Fig. 2) may well be used to export zinc completely from the cell. The same protein is used to expel both copper and to trap cadmium. Thus, metallothionine is one substrate for the pumps. However, zinc goes into compartments where there is no copper. We must suppose that there are special transport pumps for the zinc since we know that zinc is in high concentration in very local biological volumes—vesicles. We have not yet found this pump.

The control of zinc levels in a cell may also be through the protein metallothionine. It is known that this protein has a four metal atom and a three metal atom cluster in two separate domains. All the metal ions are tetrahedrally coordinated to four thiolate groups so that the metals generate a fold. Without the metal ions the protein is in a random coil. The general picture of the function of metallothionine is given in Fig. 3. The zinc-free protein can pass information to DNA. If the zinc concentration rises, or the copper or cadmium concentrations rise, the protein is removed from the DNA and the RNA for production of protein is transcribed. The excess metal is bound. If it is copper or cadmium it is exported probably via lysozymal vesicles. If it is zinc it is pumped into other vesicles for use with proteases for example.

ZINC MECHANICAL TRIGGERS: REMOTE TRIGGERS

The way in which calcium triggers the calmodulin proteins has been outlined in essential detail. It is a very similar mechanism to that for the triggering of hemoglobin allosteric conformations by the iron high-spin–low-spin switch. We have proposed that the triggering of the pumps for ion transfer is similar. In each case the selective binding of, respectively, calcium, oxygen, protons, sodium or calcium, or indeed any channel-opening or pump-regulating molecule, depends upon the rearrangement of helical rods (Fig. 7). These proteins are not built from extended β-sheets as are most enzymes (Fig. 6). The essential difference between an extended sheet and a set of helices is that a sheet provides the more stable long-range two-dimensional order while the rod gives only a one-dimensional long-range order. (Note that a two-stranded sheet is a useful flexible device.) It is easier to rotate rods than sheets and, since the sheets are often closed round in enzymes by loops, it is easier to slide rods. Rods not sheets are the essence of mechanical devices in man's machines, and for very good reason. The mechanical not the catalytic devices of biology are based therefore on helical rods probably

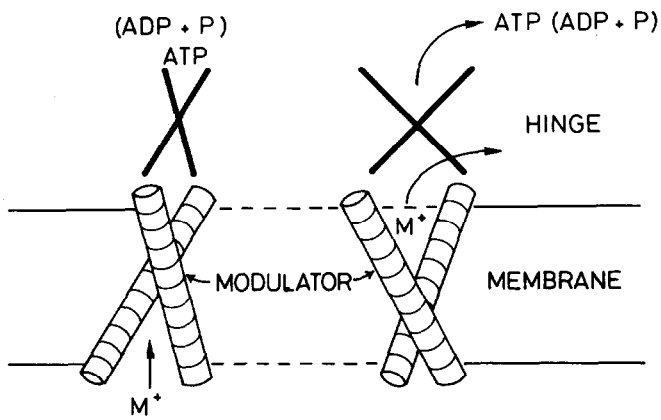

Fig. 7. Proposed scheme for the trigger action of a helical protein. A metal ion such as calcium binds, and by so doing twists and displaces the helices. The displacement drives an enzyme to a new state. The device can be used in reverse to transport ions using the energy of the enzyme reaction.

of necessity. Enzymes can not be so simply based on helices alone since the rods in proteins are weakly cross-linked for the most part by hydrophilic forces of poor directional quality and do not give a framework for selectivity. We shall turn attention away from the enzyme structures which are relatively rigid to the more loosely constructed proteins.

METAL ANTAGONISMS AND REPLACEMENTS

The elements most similar to zinc are cobalt(II) and cadmium. There is no problem from cobalt in living systems since it is rare, but it is an extremely valuable probe atom since its spectroscopic properties and its general chemical similarity with zinc allow it to be functional and observable. This type of isomorphic replacement is very similar to that observed in spinels, being dependent on size and stereochemistry. The easy introduction of the larger cadmium ion into zinc sites is somewhat adjustable. Unfortunately this substitution can lead to major problems *in vivo*. Cadmium poisoning is one of several man-made diseases grouped together under pollution. Metallothionine offers considerable protection, as one would expect from the simple analysis tables, since CdS is precipitated in Group II but not ZnS. Cadmium can be readily determined using dithizone, which brings us back to the beginning of this article and my research work started under Dr H. Irving.

CONCLUSION

I hope, Harry, that you enjoy this article. It has some (probably too much) of the personal provocative approach which you typify. I hope that it contains some of the disciplined constraints which you taught. I think it is thoughtful, reflective and cheeky. The study of chemistry or biochemistry is not dull but full of surprise, and there is the need for flexibility of thought. If my article is to be a compliment to you then I truly hope that it contains these elements. The supervisor is the father of the pupil and inheritable characteristics are inevitably transferred. Apart from my research, I have also tried to see to it through my pupils—your grandchildren—that the inheritance does not die out. They are responsible for much of the work in which I have been involved. As far as the family tree of the chemistry rather than the people is concerned, zinc dithizone was the father of this article.

Acknowledgements—I have not provided references for this article since they can all be obtained from reviews of zinc biochemistry in many review series on bio-inorganic chemistry. I am grateful to the editors of *Endeavour* for permission to reproduce several figures from my article in *Endeavour, New Series*, 1984, **8**, 65, which also has the necessary references.

TIN(II) CHLORIDE IN THE ANALYTICAL CHEMISTRY OF THE PLATINUM METALS: FROM THE "PURPLE OF CASSIUS" TO POLYURETHANE FOAMS

KARIM F. G. BRACKENBURY, LYNN JONES, IRIS NEL, KLAUS R. KOCH* and JEAN M. WYRLEY-BIRCH

Department of Analytical Science, University of Cape Town, P. Bag, Rondesbosch 7700, South Africa

(*Received* 3 *July* 1986)

Abstract—Tin(II) chloride has played a central role in the non-instrumental analytical chemistry of the platinum group metals, the characteristic reaction between tin(II) chloride and platinum(II/IV) chloride having been documented for more than 180 years. The intense colour of hydrochloric acid solutions containing small amounts of Pt(II/IV) and tin(II) chloride constituted one of the first trace colorimetric methods for the determination of Pt in the sub parts per million range. Similar spectrophotometric methods of trace analysis for Rh have been known for more than half a century. Remarkably the detailed nature of the interaction of tin(II) chloride with the platinum group metals has only been elucidated relatively recently, and there is evidence of recent renewed interest in platinum group metal complexes involving the $SnCl_3^-$ moiety as ligand. We wish here to give a brief history of the use of tin(II) chloride in the analytical chemistry of the platinum group metals, highlighted by some of our recent work involving the selective immobilization of chloro(trichlorostannato)platinum/rhodium complex anions by polyurethane foams as a means of separation and pre-concentration of small amounts of Rh and Pt.

HISTORICAL PERSPECTIVE

The characteristic reaction between tin(II) chloride and gold(III) chloride in dilute aqueous solution certainly ranks alongside one of the earliest qualitative colorimetric methods for the detection of small quantities of Au. The discovery of the "purple of Cassius" is attributed to one Dr A. Cassius,[1] at Leyden, in the year 1663.[2] Although the analytical potential of the "purple of Cassius" was probably not initially recognized, nor indeed of interest,[1] the purple-red colouration produced when a solution containing gold(III) chloride is treated with tin(II) chloride had already become well-established as a sensitive method for the detection of traces of Au in mid-nineteenth-century textbooks of qualitative chemical analysis.[3,4] The nature of the precipitated "purple of Cassius" remained poorly understood long after its discovery, although evidence that the purple colour was essentially due to a form of colloidal metallic Au dates to 1780.[1] Nevertheless it was to be more than a century before Schneider[5] and Zsigmondy[6] clearly established the true colloidal nature of the "purple of Cassius" as well as the conditions for its formation. Presently it is generally accepted that the "purple of Cassius" consists mainly of finely dispersed metallic Au, adsorbed onto an insoluble form of hydrous stannic oxide.[1,6] Essentially then, the formation of the "purple of Cassius" by reaction between tin(II) chloride and gold(III) chloride may be described as redox in nature, although this view is probably an oversimplification in the light of recent evidence of the formation of complexes of gold involving Au—Sn bonds,[7] in which the $SnCl_3^-$ moiety behaves as a Lewis acid.

Although we have not been able to establish a definite link between the "purple of Cassius" and the discovery of a similarly characteristic reaction

* KRK was appointed lecturer in the newly established Department of Analytical Science at UCT under the Headship of Professor H. M. N. H. Irving (1979–1984). Author to whom correspondence should be addressed.

between tin(II) chloride and platinum(II/IV) chloride, it seems reasonable to postulate that such a link exists. W. H. Wollaston, one of the early pioneers in the chemistry of Pt,[8] first reported the characteristic red-brown colour produced when an acid solution of platinum(II/IV) chloride is treated with excess tin(II) chloride in 1804.[9] Evidently the intense blood-red colour so produced was rapidly adopted as a sensitive qualitative spot test for the presence of Pt, alongside the "purple of Cassius".[3,4] Indeed, the tin(II) chloride spot test for traces of Pt still enjoys prominence in present-day texts,[10,11] as one of the more sensitive tests available, 25×10^{-9} g Pt being easily detectable.

Early attempts to elucidate the nature of the reaction between Pt salts and tin(II) chloride were undoubtedly influenced by comparison with studies of the "purple of Cassius". Nevertheless, Wöhler and Spengel[12] recognized that the red reaction product was extractable into ether, thus ruling out a possible coloidal suspension of finely divided metallic Pt. On the other hand, the idea of reduction of platinum(II/IV) to a metallic state by tin(II) chloride seems so firmly lodged, that recently revised text-books,[10,11] still regard Pt as being reduced to "colloidal Pt" or "to the elementary state". The extractable nature of the intensely red Pt–Sn compound(s) was later exploited by Wölbing who, in 1934, not only demonstrated a quantitative colorimetric method for the determination of small amounts of Pt, but also utilized an ethylacetate extraction procedure to separate Pt from other noble metals.[13]

Nearly two decades later, Ayres and Meyer undertook a series of detailed spectrophotometric investigations of the reaction between tin(II) chloride and Pt,[14–17] Pd[15] and Rh[15] in HCl. Attempts to understand the nature of these chromogenic reactions[14,15] went in hand with a critical evaluation of these colorimetric methods for the determination of some of the platinum metals.[18,19] Such studies convincingly established the utility of tin(II) chloride as a colorimetric reagent for the microdetermination of Pt(II/IV) by measuring the absorption maximum at $\lambda_{max} = 310$ nm (molar absorptivity 3.95×10^4). The reductive power of tin(II) chloride undoubtedly influenced these early attempts to characterize the red Pt–Sn reaction product(s). Thus, Ayres and Meyer postulated the formation of a tetrapositive $[PtSn_4Cl_4]^{4+}$ cation, in which Pt was thought to be reduced to a zerovalent state.[17] This confusion is understandable, since it has only recently been shown conclusively that some platinum group metals in their highest common oxidation states, viz. Pt(IV), Rh(III) and Ru(IV), are certainly reduced to lower formal oxidation states, Pt(II),[20] Rh(I)[21] and Ru(III/II)[22] by tin(II) chloride in aqueous HCl solution. Although complete reduction of Pt (and Rh) by tin(II) chloride is possible under more forcing conditions in HCl, the circumstances under which this occurs have yet to be clearly demonstrated. On the contrary tin(II) chloride is thought to stabilize Pt(II) to further reduction by molecular hydrogen (see below).[23,24]

The true nature of the highly coloured species formed by reaction of Pt(II) and Rh(III) with tin(II) chloride was first revealed by two independent groups. In the same year, Stolberg and coworkers,[25] as well as Davies *et al.*,[26] showed that complex Pt(II) and Rh(III) *anions* containing $SnCl_3^-$ moieties could be precipitated with bulky cations. Thus Cramer *et al.*[25] isolated compounds such as red $[(C_6H_5)_3PCH_3]_3[Pt(SnCl_3)_5]$ and yellow $[(C_6H_3)_3PCH_3]_2[PtCl_2(SnCl_3)_2]$, along with neutral $[Pt(P(C_6H_5)_3)_2(SnCl_3)Cl]$, while Davies *et al.*[26] reported isolation of $[(CH_3)_4N]_4[Rh_2Sn_4Cl_{14}]$. These preliminary reports were soon followed by a detailed investigation by Young *et al.*,[27] in which the syntheses and properties of a considerable number of neutral and anionic complexes of Pt, Rh, Ir and Ru with tin(II) chloride, were reported. In each of these compounds a direct M—Sn bond was postulated, involving the $SnCl_3^-$ moiety as ligand. An X-ray diffraction study of the unusual $[(C_6H_5)_3PCH_3]_3[Pt(SnCl_3)_5]$ complex confirmed directly the trigonal bipyramidal structure of the pentakis(trichlorostannato)platinum(II) anion, showing discrete Pt—Sn bonds (mean length 2.54 Å).[28] This report was followed shortly by the X-ray crystal structure of a highly unusual trigonal bipyramidal Pt–Sn cluster $(C_8H_{12})_3Pt(SnCl_3)_2$ in which the Pt atoms form a triangle, capped by two Sn atoms (Pt—Sn distances 2.80 Å).[29] The latter structure clearly illustrates the uncertainty in the formal oxidation state of the Pt atoms; a simplistic view yields an oxidation state of +2/3 per Pt atom, assuming Sn(II).

Tin(II) *chloride as reducing agent*

At this point it may be appropriate to emphasize the dual role of tin(II) chloride both as reducing agent as well as ligand in the form of the $SnCl_3^-$ moiety. Although to our knowledge relatively little work has been undertaken concerning redox reactions with the platinum group metals in general, it has been established that Pt(IV) in HCl is certainly rapidly reduced by tin(II) chloride according to an overall rate law: $-d[Pt]/dt = k_{obs}[Pt(IV)][Sn(II)]$, where $k_{obs} = 473 \pm 22$ dm^3 mol^{-1} s^{-1} at 297 K.[20] This reduction is followed by a slower complex formation in which the Pt(II) state appears to be

stabilized to further reduction (see below). In the case of Rh(III), Ir(IV) and Ru(III/IV) reduction to Rh(I),[21] Ir(III)[30] [or Ir(I)][27] and Ru(III/II)[31-33] is also known to occur, but no detailed kinetic studies have appeared. The circumstances under which reduction does occur are in any event not fully understood as it appears for example that Rh(III) is only reduced to Rh(I) in the presence of sufficient excess tin(II) chloride,[21] in order to stabilize the Rh(I) by complex formation with $SnCl_3^-$. The behaviour of Pd(II) on the other hand resembles that of Au(III) most closely, in that the reaction of $PdCl_4^{2-}$ with tin(II) chloride in HCl leads to the formation of transient red-brown and yellow complexes of probable formulation $[PdCl_{4-n}(SnCl_3)_n]^{2-}$ ($n = 1$–4),[34] followed by the formation of an unstable dark green hydrosol, from which ultimately metallic Pd may be recovered. This hydrosol of Pd is not extractable into organic solvents such as 4-methylpentan-2-one (MIBK). Since the chloro(trichlorostannato)platinum(II) complex anions may be readily extracted into MIBK, this difference between Pd(II) and Pt(II) may be conveniently exploited for the quantitative separation of these two metals by extraction with MIBK in the presence of a reasonable excess of tin(II) chloride. Figure 1 shows the distribution of equimolar amounts of Pt(II) and Pd(II) (3×10^{-2} mmol) between 2.4 mol dm^{-3} HCl containing an excess (3×10^{-1} mmol) $SnCl_2$ and various mixtures of MIBK and *n*-hexane [% (v/v)]. Extractions were performed 20 min after mixing of solutions, during which time the Pd hydrosol is fully developed. By controlling the HCl concentration, the amount of tin(II) chloride present, the contact time and the organic-phase composition, quantitative separation of Pt(II) from a 10-fold molar excess of Pd(II) is readily possible.

Trichlorostannato anion as ligand

Interest in Pt(II) complexes involving the trichlorostannato ligands was probably encouraged by the discovery reported in 1963 that solutions containing chloro(trichlorostannato)platinum(II) complex anions readily catalyse homogeneous hydrogenation of ethylene and acetylene at room temperature and low H_2 pressures.[25] Following this early report of the catalytic properties of Pt–Sn complexes, the highly selective hydrogenation of oils such as methyl linolenate to unconjugated dienes has been studied in detail,[23] while homogeneous olefin hydroformylation catalysis by platinum(II) group IVB metal halide complexes has been examined.[24,35] Recently Saito *et al.* proposed a rhodium–tin(II) chloride catalytic system for photo-enhanced dehydrogenation of propan-2-ol.[36,37] The latter system shows promise in the quest to convert solar energy into useful chemical energy, in the form of hydrogen. The role of tin(II) chloride in these catalytic systems is not completely understood, although actively under investigation.[38] It is, however, generally agreed that the $SnCl_3^-$ ligand:

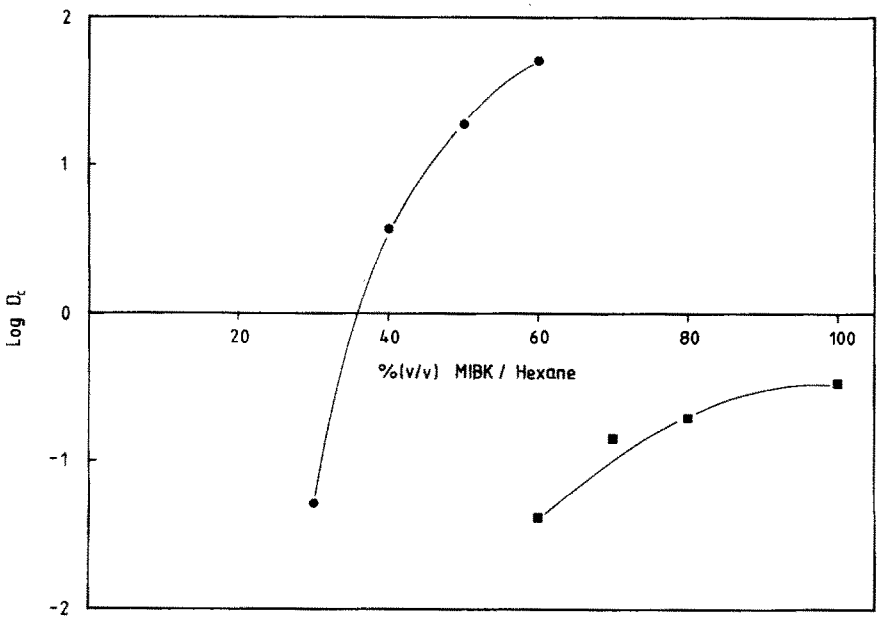

Fig. 1. Distribution coefficients (log D_c) of Pt(II) and Pd(II) between 2.4 mol dm^{-3} HCl and various mixtures of MIBK in *n*-hexane [% (v/v)], in the presence of excess tin(II) chloride at 295 K [Sn(II): $M = 10$ (M = mol Pt+Pd)].

(a) stabilizes Pt(II) to reduction by H_2 to the metallic state with the formation of complex hydride species,[23,24] and (b) the strongly "π-acid" nature of the $SnCl_3^-$ ligand[39] labilizes the often kinetically inert complexes of the platinum group metals to ligand substitution.

A consequence of (a) above is the facile formation of a variety of platinum group metal complex hydrides[40] such as $[Pt(SnCl_3)_4H]^{3-}$ and $H_2Ir(SnCl_3)(PPh_3)_3$. In this context, we have recently observed the formation of a transient complex hydride species of Rh, on simply extracting rhodium(III) chloride from dilute HCl containing excess tin(II) chloride into 4-methylpentan-2-one.[41] This species is best formulated to be $[RhH(SnCl_3)_4Cl]^{3-}$ on the basis of ^{119}Sn NMR evidence. Incidentally, the advent of routine multinuclear Fourier transform (FT) NMR has resulted in great advances in the chemistry of the platinum group metals involving the trichlorostannato ligand, since two naturally occurring isotopes, ^{117}Sn and ^{119}Sn, both have spin $I = \frac{1}{2}$ and, at 7.61 and 8.58% natural abundance, respectively, are easily observed by modern FT NMR spectroscopy.[42] Consequently many authors have used ^{119}Sn–$\{^1H\}$, ^{31}P–$\{^1H\}$ and ^{195}Pt–$\{^1H\}$ NMR spectroscopy to elucidate the fundamental solution chemistry of Pt(II) complexes involving the $SnCl_3^-$ ligand.[38,43–46] Similar studies involving Rh[36,37,41] and Ru[30,47] have been reported.

In the realm of analytical chemistry, the strong *trans* effect of the $SnCl_3^-$ moiety as ligand (comparable to CN^- and CO),[39] has been usefully exploited as a catalyst of ligand substitutions in the usually kinetically inert platinum group metals. Thus a number of solvent extraction schemes for the platinum group metals by a variety of organic extractants have utilized tin(II) chloride as a reducing as well as a "labilizing" agent.[48] The extractive separation of Rh from Ir by diphenylthiourea is catalysed by tin(II) chloride for example, and appears to be quantitative only in the presence of the latter reagent.[49] Similar use of tin(II) chloride was reported by Mojski:[50] the extraction efficiency of Pt, Rh, Ru and Ir by triphenylphosphine from HCl into 1,2-dichloroethane is considerably increased in the presence of tin(II) chloride. Although the role of tin(II) chloride in promoting rapid ligand substitutions of the inert platinum group metals is undisputed, the mechanism of the "labilizing" effect of tin(II) chloride sometimes involves the extraction of complexes containing the $SnCl_3^-$ ligands. In this context we have shown that the extraction of $PtCl_4^{2-}$ by triphenylphosphine in the presence of tin(II) chloride involves the transient formation and extraction of $[Pt(SnCl_3)Cl(PPh_3)_2]$ and $[Pt(SnCl_3)_2(PPh_3)_2]$ into the organic phase, followed by eventual disproportionation of such species, with back extraction of tin(II/IV) chloride into the aqueous phase.[51]

POLYURETHANE FOAM EXTRACTIONS OF THE PLATINUM GROUP METALS

Flexible polyurethane foams are ubiquitous in everyday life, the remarkable versatility of this polymer having prompted the manufacture of a myriad of products for a wide variety of applications. In 1980, about 3×10^6 tons of urethane polymer was consumed worldwide.[52] The versatility of this polymer has recently been extended into the realm of analytical chemistry by the discovery of Bowen[53] that flexible polyurethane foams have the capacity to absorb a large variety of organic and inorganic substances. Amongst the various types of metal complexes that are sorbed by the polyurethane polymer is a group of highly polarizable complex anions such as $AuCl_4^-$ and $FeCl_4^-$, and a host of other transition-metal thiocyanate complexes including those of Rh, Pt and Pd.[54] The continuing interest in the use of polyurethane foams in the separation and pre-concentration of a large range of substances is underscored by the publication of a monograph[55] and a CRC handbook[56] devoted entirely to this subject.

We have recently reported an efficient method for the semi-selective sorption of Pt(II) from dilute hydrochloric acid in the presence of sufficient tin(II) chloride.[57] Detailed studies have been carried out involving the sorption of Pt(II) and Rh(III) from HCl by polyurethane foams in the presence of tin(II) chloride, and it is some of these results we wish to report briefly here.

Chloro(trichlorostannato)platinum(II) complex anions are rapidly and efficiently sorbed by polyurethane foams from 0.5–5.0 mol dm^{-3} HCl solution. The maximum sorptive capacity of the foam with respect to platinum [C(Pt)] depends on the temperature, HCl concentration, the Sn(II):Pt(II) ratio, as well as the presence of alkali earth metal cations, notably K^+. The presence of K^+ ions has a marked depressive effect on the value of C(Pt). Table 1 shows some typical C(Pt) values at 25 and 40°C for a variety of solution conditions. Evidently even at relatively low Sn(II):Pt(II) mole ratios (R_a) in solution, considerable quantities of Pt are sorbed by the foam. Furthermore, we have found that, at 1.0 mol dm^{-3} HCl, the amount of Pt sorbed per unit mass of foam reaches a peak at a value of R_a = 4–5, only to decrease slightly and level off at $R_a > 10$ (Fig. 2). By simultaneous monitoring of the quan-

Table 1. Maximum sorptive capacity of polyurethane foam (cf. Fig. 2) for Pt(II) in 1.0 mol dm^{-3} HCl containing tin(II) chloride, measured for various initial Pt(II) concentrations

[Pt] ($\mu g\ cm^{-3}$)	Sn(II)/Pt	Maximum capacity (mol kg^{-1})			
		$T = 25°C$		$T = 40°C$	
		2	5	2	5
50		0.39	0.50	0.26	0.44
100		0.51	0.59	0.39	0.60
150		0.57	0.58	0.48	0.65
200		0.68	0.66	0.52	0.61

tity of Sn that is coextracted with the Pt, we have determined the average mole Sn : Pt ratio of species sorbed by the foam (R_f). As may be seen from Fig. 2 the value of R_f tends to 5 in the presence of sufficient Sn(II) in solution.

These data suggest that the species preferentially sorbed by the polyurethane foam is the $[Pt(SnCl_3)_5]^{3-}$ complex anion. Nelson and Alcock[58] have recently re-examined the crystal and solution structure of $[(C_6H_5)_3PCH_3]_3[Pt(SnCl_3)_5]$, and found that the $[Pt(SnCl_3)_5]^{3-}$ anion retains its trigonal bipyramidal structure in solution. Furthermore, these authors found no ^{119}Sn and ^{195}Pt NMR evidence of $[Pt(SnCl_3)_5]^{3-}$ dissociating into products such as $[Pt(SnCl_3)_4]^{2-}$ or $[Pt(SnCl_3)_2Cl_2]^{2-}$ in acetone solutions. We have previously examined the solvent extraction of $PtCl_4^{2-}$ in the presence of $SnCl_2$ from HCl into MIBK.[59] Examination of an MIBK extract [obtained from 2 M HCl with Sn(II) : Pt(II) = 10] by means of 186.5-MHz ^{119}Sn NMR showed evidence of only a single set of resonances at 303 K; [$\delta(^{119}Sn) = -127.9$ ppm relative to $(CH_4)_4Sn$, $^1J(^{195}Pt–^{119}Sn) = 16{,}028$ Hz, $^2J(^{117}Sn–^{119}Sn) = 6252$ Hz]. This resonance may be assigned to the $[Pt(SnCl_3)_5]^{3-}$ complex anion on the basis of very similar spin–spin coupling data from the work of Nelson [$^1J(^{195}Pt–^{119}Sn) = 16{,}030$ Hz, $^2J(^{117}Sn–^{119}Sn) = 6230$ Hz].[58]

It is thus reasonable to postulate that, in the case of polyurethane foam extractions, a similar species

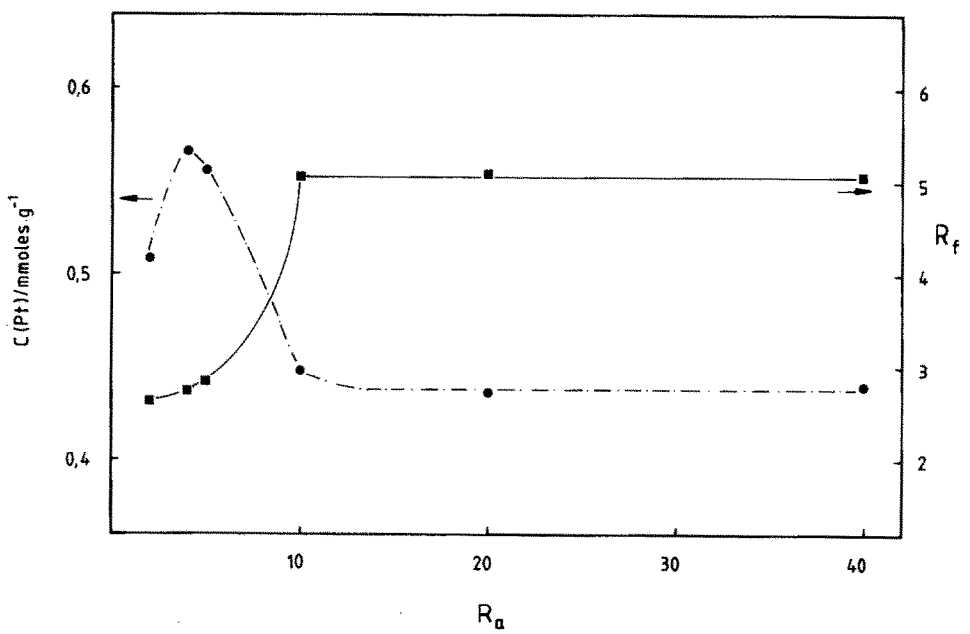

Fig. 2. Variation of the maximum sorptive capacity [C(Pt)] of polyurethane foam [prepared from polypropylene oxide (MW 3400) and an 80 : 20 (v/v) mixture of 2,4- and 2,6-toluene diisocyanate] toward Pt(II) in 1.0 mol dm^{-3} HCl at 298 K as a function of the Sn(II) : Pt mole ratio (R_a). Also shown is the Sn : Pt mole ratio, as observed on the foam (R_f).

[a] Platinum found sorbed by 400-mg block of foam.
[b] Iridium left in solution.
[c] Sn(II) : M mole ratio, M = Pt + Ir.

may be involved, especially in view of the observed Sn : Pt ratios found on the foam.

On a more practical level, we have found that small amounts of Pt can be quantitatively sorbed by polyurethane foams as a means of pre-concentration of this metal. The Pt-loaded foam may then be readily dissolved in hot HNO_3–HCl for subsequent analysis. In this way 250 μg Pt may readily be recovered from a 250-cm^3 solution by a 100-mg block of foam, representing a concentration factor of *ca* 2.5×10^3. Table 2 shows some of the results of Pt separation and recovery experiments. It is clear that, in the presence of sufficient Sn(II), satisfactory recoveries of up to 100 μg Pt per 200 cm^3 solution are achieved even in the presence of a 10^2-fold molar excess of Ir(IV) in 2 mol dm^{-3} HCl.

Rhodium(III) chloride reacts fairly rapidly with tin(II) chloride, and in a similar fashion to Pt(II) in dilute HCl, a variety of Rh(III) and Rh(I) chloro(trichlorostannato)rhodium(III/I) complex anions are formed.[21,26,27] We have examined the extraction of rhodium(III) chloride from dilute HCl containing sufficient tin(II) chloride into MIBK.[60] In this manner, Rh may be readily separated from Ru and Ir, since the formation of correspondingly extractable chloro(trichlorostannato)ruthenium and chloro(trichlorostannato)iridium does not occur at room temperature. On this basis, it might be expected that polyurethane foams should sorb chloro(trichlorostannato)rhodium complex anions. This expectation is amply confirmed by results shown in Fig. 3.

In contrast to the sorption of Pt, it appears that a greater excess of tin(II) chloride results in increasing amount of Rh being sorbed by (cf. Fig. 2). Furthermore, analysis of the of samples loaded foam yields Sn : Rh ratios in the range 3.6–4.5, suggesting that a variety of chloro-(trichlorostannato)rhodium(III/I) species may be simultaneously sorbed by the foam. Such an idea is supported by an ^{119}Sn NMR study of an MIBK extract of an HCl solution containing $RhCl_3 \cdot 3H_2O$ and excess $SnCl_2$. We have found that at least seven sets of ^{119}Sn resonances are observable in MIBK extracts obtained under various conditions:[60] of these, $[Rh(SnCl_3)_5Cl]^{3-}$ [$\delta(^{119}Sn) = -117.5$ ppm, $^1J(^{103}Rh–^{119}Sn) = 558$ Hz, $^2J(^{117}Sn–^{119}Sn) = 1943$ Hz], $[Rh(SnCl_3)_4Cl_2]^{3-}$ [$\delta(^{119}Sn) = -209.6$ ppm; $^1J(^{103}Rh–^{119}Sn) = 587$ Hz, $^2J(^{117}Sn–^{119}Sn) = 2216$ Hz], and $[Rh(SnCl_3)_3Cl_3]^{3-}$ [$\delta(^{119}Sn) = -369.3$ ppm, $^1J(^{103}Rh–^{119}Sn) = 731$ Hz, $^2J(^{117}Sn–^{119}Sn) = 3034$ Hz] have been positively assigned in good agreement with the work of Saito.[21] In addition, as already referred to above, we have also identified a hydrido species $[RhH(SnCl_3)_4Cl]^{3-}$, in the MIBK phase.[41] It is thus reasonable to propose that a qualitatively similar distribution of species may be sorbed by the polyurethane foam, as suggested by the observed trends (Fig. 3). We have carried out a detailed study of the optimum conditions of sorption of chloro(trichlorostannato)-rhodium(I/III) complexes by polyurethane foams, and found that rhodium may quantitatively be separated from iridium and ruthenium by this means. Details of this work are, however, to be published elsewhere.[61]

In conclusion, we have found that small amounts of Pt(II/IV) and Rh(III) are remarkably efficiently removed from dilute HCl containing a reasonable excess of tin(II) chloride by means of polyurethane foams. Neither Ir(IV) nor Ru(III/IV) is appreciably retained by the polyurethane polymer under similar

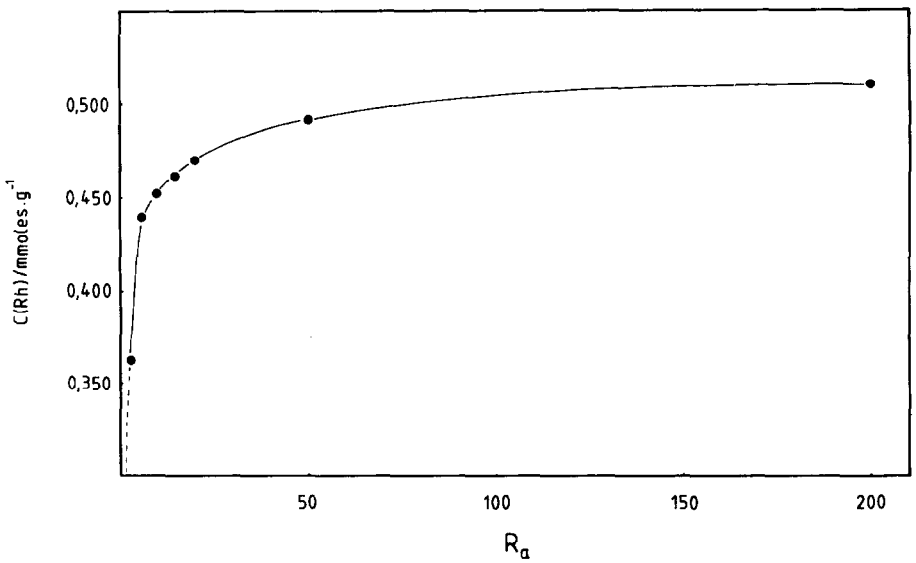

Fig. 3. Sorptive capacity of polyurethane foam toward Rh(III)[C(Rh)] as a function of the Sn(II): Rh(III) mole ratio (R_a) from 2.0 mol dm^{-3} HCl at 313 K.

conditions, hence a clean separation of Pt and Rh from Ir and Ru is possible. Preliminary work indicates that the immobilized Pt and Rh may be conveniently stripped from the polyurethane foam by hot (60°C) 2.5–5.0% (v/v) conc. HCl in ethanol, leading to essentially quantitative recovery of the noble metal. The presence of relatively large amounts of base metals such as Cu, Zn, Ni, Co, Mn and Fe does not significantly affect the immobilization of Pt and Rh in the presence of tin(II) chloride by polyurethane foam. Finally the Sn may be removed from either Pt or Rh by distillation of the volatile $SnBr_4$ at relatively low temperatures.

Acknowledgements—We would like to pay tribute to Professor H. M. N. H. Irving on the occasion of his 81st birthday. We hope that this will be a fitting contribution to mark this occasion. We gratefully acknowledge generous financial assistance from the University of Cape Town, the CSIR (IN and LJ), and MINTEK (KFGB and JMWB), as well as AECI (IN).

SPECTROCHEMISTRY OF SOLUTIONS—XVII.* VIBRATIONAL SPECTRA OF CYANO-PALLADIUM(II) COMPLEXES IN LIQUID-AMMONIA SOLUTIONS

PETER GANS,† J. BERNARD GILL†‡ and DOUGLAS MacINTOSH

Department of Inorganic and Structural Chemistry, The University, Leeds LS2 9JT, U.K.

(*Received* 3 *July* 1986)

Abstract—Complexation of Pd^{2+} by CN^- in liquid ammonia has been studied by means of IR and Raman spectra of the solutions. Stepwise complexation occurs up to the square-planar 4:1 species. In the 2:1 step *trans*-$Pd(CN)_2$ is initially formed at subambient temperatures but slowly equilibrates ($t_{1/2}$ = 6 h) at 293 K into a mixture containing both the *cis* and the *trans* isomers. The 2:1 and 4:1 complexes appear to be thermodynamically very stable. All the 11 C—N stretching modes of vibration of $[(NH_3)_3Pd(CN)]^+$, *cis*- and *trans*-$[(NH_3)_2Pd(CN)_2]$, $[(NH_3)Pd(CN)_3]^-$ and $[Pd(CN)_4]^-$ have been observed and assigned. There is no spectroscopic evidence for multinuclear complexation involving bridging CN^- groups.

We report on the complexation of palladium(II) by cyanide ligands in liquid ammonia. This work forms part of a much wider area of our investigations which encompasses a vibrational spectroscopic, as well as an electrochemical, attack on the problem of identifying the various species which occur when cations and anions or ligands interact in liquid-ammonia solutions.

In most protonic solvents, such as water and the lower alcohols, the cyanide salts of heavy metals are insoluble. In previous papers we have shown how liquid ammonia is particularly useful as a medium for the study of water-insoluble metal cyanides in solution. For instance, the stepwise complexation by CN^- of silver(I)[2] and mercury(II)[1] can be followed in the Raman, usually between 200 and 300 K, by collecting the spectra of a range of solutions at different ligand : metal ratios.

The complexation scheme of silver by cyanide is complicated because it involves both geometry changes on the silver(I) centre and equilibria between linkage isomers. Ligation of mercury(II) by cyanide in ammonia contrasts with that on silver(I) because complexation occurs by the simple stepwise replacement of ammonia molecules in the tetrahedral inner coordination sphere of the Ag^+ ion. Like AgCN and $Hg(CN)_2$, $Pd(CN)_2$ is also soluble in liquid ammonia. A high solubility of these cyanides is favoured because the metal cations possess high energies of solvation in liquid ammonia, much greater than the corresponding values for the aqueous system. All three compounds have high lattice energies, and a consideration of these together with their solvation energies indicates that ammoniation of Ag^+, Hg^{2+} and Pd^{2+} cations is a highly enthalpically favoured process. Thus, ligation of the three metal cations, even by powerful and strong donor ligands, might be expected to be competitively at a disadvantage compared with the solvation process. This is not the case for the ligation of Ag^+ and Hg^{2+} by the CN^- anion in ammonia:[3] in Ag^+–CN^- mixtures, $\log K_1 \sim 7$, $\log K_2 \sim 9$, and $\log K_3 \sim 1.5$. However, it is the case for phosphines, and for thiocyanate, for which further ligation is not detectable either spectroscopically[4] or poten-

tiometrically[3] after the first step: for SCN^-–Pd^{2+} mixtures, $\log K_1 \sim 0.7$.

Our earlier papers have described some of the methods used to identify ion-associated[5] and complexed species[1,2,4] in ammonia solutions from their Raman spectra. To facilitate analysis of the spectra we established our own methods of computer-assisted curve resolution (VIPER),[6,7] and smoothing and derivative convolution processes.[8] These assist in: (i) the identification of the species present, and (ii) a much improved estimation of the positions of the bands which underly the spectral profiles. In the work presented here we have obtained Raman spectra from solutions of cyano-palladium(II) complexes at various $[CN^-]/[Pd^{2+}]$ ratios (S). It should also be noted that for the first time we have been able to bring into use the new techniques which we have been developing to facilitate measurement of IR spectra of liquid-ammonia solutions at ambient temperatures.[9] Principally, it is through the use of IR spectroscopy that we have been able to observe and monitor the kinetically slow process of ligand exchange which occurs in the cyano-palladium(II) system in liquid ammonia.

EXPERIMENTAL

The techniques for examining the Raman spectra of solutions in liquid ammonia have been described previously.[1,2,4] Ammonia solutions of $Pd(NH_3)_4(NO_3)_2$, at concentrations of *ca* $300 = R = (\text{mol } NH_3)/(\text{atoms of Pd})$, and KCN were sealed in round glass tubes at various S. The Raman spectra were recorded within 24 h of the preparation of the mixtures, and thereafter at intervals of time up to about 4 months. All the techniques we normally apply to obtain good spectra with maximm signal: noise ratio and minimum band distortion were used. The spectra, recorded on our modified Coderg RS100 Raman spectrometer, were calibrated against a Hg line at 2187.7 cm^{-1}.

IR spectra were obtained in our new pressure cell. This contains CaF_2 windows in a piston–cylinder assembly constructed within a block of the thermoplastic Kel-F. This material is resistant to attack by ionic solutions in liquid ammonia, though it should be noted that it is destroyed by solutions of alkali metals in ammonia. A full report on the construction and the use of the cell for analytically quantitative IR determinations is presented elsewhere.[9] This includes a description of the method of solvent spectrum subtraction.

Spectra were recorded on a Pye–Unicam ratio-recording SP3-300 IR spectrometer using a cell pathlength of 50 μm. Each spectrum was collected as nine coadded scans on a Hewlett–Packard 9845A computer. The solute spectra were studied in absorbance units after subtraction of the background (solvent spectrum) from the spectra of the solutions. Spectra were recorded at intervals of approximately 0, 1, 2, 4, 8, 12, 24, 36, 48 and 72 h after the preparation of the solutions.

The salts were recrystallized from liquid ammonia.

RESULTS AND DISCUSSION

Following reports in the literature[10] on the coordination of ligands around the Pd^{2+} ion in both the solid state and in aqeuous solutions[11] there is no reason to assume that any coordination arrangement other than a square-planar array of CN^- groups exists around Pd^{2+} in liquid ammonia. All our spectroscopic evidence supports this. The IR and Raman spectra of the CN^-–Pd^{2+} set of complexes in ammonia consists of bands which all lie between 2125 and 2152 cm^{-1}. In those solutions in which the ratio of $S \leqslant 4$ no band due to free cyanide ligand is observed in the region around 2056 cm^{-1}, but immediately the solution composition exceeds $S = 4$ a band appears at this frequency. From this we can conclude that the formation of $[Pd(CN)_4]^{2-}$ is thermodynamically a very favourable process in liquid ammonia, and that no further complexation occurs beyond the 4:1 stage.

Both the Raman and the IR spectra were scanned to 2350 cm^{-1}. The absence of features due to C—N stretching vibrations, in regions other than those indicated above, provides good spectroscopic evidence that no multinuclear species containing bridging CN^- groups form in the system.

The observed spectra are compatible with a stepwise process of addition of CN^- ligands to the Pd^{2+} metal ion. However, this is complicated by a slow exchange reaction which manifests itself in changes observed in the spectra in the course of 2–3 days. We have monitored these changes in the IR spectra, but we have used the Raman data to identify band positions because of the better resolution which can be achieved with the latter. It was impractical to follow spectrum changes with time in the Raman.

All the nine bands listed in Table 1 have been identified in the Raman spectra, but only five bands can be positively identified in the IR spectra. Attempts were made to identify underlying features in the IR spectra by computer-assisted curve fitting, but extensive overlapping of bands, their relatively low absorbances ($\varepsilon \sim 2$ mol^{-1} m^2), and the low resultant signal: noise ratios in the solvent-subtracted spectra led to a high correlation between band parameters.[12] None the less,it was clear from

[a] The numbers indicate approximate relative intensities of component bands.

[b] These samples were made up and stored at −40°C until the first spectrum was recorded. Thereafter they were allowed to stand at ambient temperature.

[c] This band is found only in the one polarized spectrum. It is a weak feature and is lost between bands D and I of the 11 polarized spectra.

these attempts at curve resolution that more than five bands should be used to describe the IR spectra.

Assuming that linkage isomerism may be excluded, it is only at the 2 : 1 stage of complexation that isomerism is possible, i.e. *cis-* and *trans-*$[(NH_3)_2Pd(CN)_2]$. The species formed in the stepwise addition of CN^- to Pd^{2+} should give rise to a possible total of eight Raman and seven IR bands if the system just passes through the *cis* isomer, and seven Raman and six IR bands if complexation involves only the *trans* species. Because nine Raman bands and at least five IR bands can be identified we conclude that both *cis-* and *trans-*$[(NH_3)_2Pd(CN)_2]$ can be found in the solutions with compositions $S \leqslant 2$. To describe this pattern of complexes in the equilibria up to the 4 : 1 stage a total of nine Raman and eight IR bands, representing a total of 11 C—N stretching vibrations, are required. These must include six coincidences, and four mutual exclusions.

Description of the Raman spectra

S = 0.5. Two bands are observed at 2141 cm^{-1} (D/E) and 2134 cm^{-1} (H): both are polarized [E ($\rho = 0.02$), and H ($\rho = 0.1$)]. Because band H, at the lower frequency, is twice as intense as band E we identify it with the A_1 C—N stretching vibration of $[(NH_3)_3Pd(CN)]^+$.

S = 1.0. The same two bands, D/E and H, are observed but the intensity of band D/E is substantially increased relative to band H, and the assignment of band E to a 2 : 1 species is consistent with the attribution of band H to $[(NH_3)_3Pd(CN)]^+$. No significant change is found in this spectrum with the passage of time.

S = 1.12 *and* 1.5. The relative intensity trends observed in the spectra of the solutions at $S = 0.5$ and 1.0 continue in those spectra taken within 24 h of the preparation of the solutions, but a third band at 2145 cm^{-1} (C) appears at a somewhat lower relative intensity. Band C increases in relative intensity as S increases. Spectra taken 7–14 days after the preparation of these solutions change completely to become simple two-band spectra. Although the lower-frequency band H remains a substantive part of these spectra the peak of the feature at 2142 cm^{-1} (D) is shifted slightly with respect to the band at 2141 cm^{-1} (E), and therefore can be identified as a separate feature.

S = 2.0 *and* 2.1. Three peaks, all of which change their relative intensities with time, appear in the spectra. The band of maximum intensity coincides in frequency with band D (observed in the spectrum of a solution at $S = 1.5$ left to stand for several days). The highest-frequency band at 2145 cm^{-1} is in the same position as band C observed soon after an $S = 1.5$ solution has been mixed. After several days band C is reduced in intensity relative to the feature at 2141/2142 cm^{-1}. Band H which is still seen in these spectra is markedly lower in relative intensity that it is in the spectra of the solutions at lower S. It is important to note that the polarization ratio of band H is appreciably higher ($\rho = 0.2$) for these solutions. After a period of 14 days no further changes are observed in the spectra. Four Raman bands are required to be attributed to the vibrations of $[(NH_3)_3Pd(CN)]^+$, and *cis-* and *trans-*$[(NH_3)_2Pd(CN)_2]$. We have already assigned band H to the A_1-vibration of the first of these. On the basis of its polarization ($\rho = 0.02$), and that we might expect the *trans* effect to determine the preferred species, we assign band D (clearly identified in the spectrum of a solution at $S = 1.5$ after several days) to the A_g-vibration of *trans-*$[(NH_3)_2Pd(CN)_2]$, leaving the two bands at 2145 cm^{-1} (C) and 2141 cm^{-1} (E) to be assigned to the *cis-*$[(NH_3)_2Pd(CN)_2]$ isomer. Here assignment poses a problem because the bands at 2142 cm^{-1} and 2141 cm^{-1} severely overlap each other and polarizibility measurements cannot assist. However, we believe that there is some degree of depolarization in this region. Also the band at 2142 cm^{-1} (D) is fairly symmetrical in the spectra taken after several days. Thus it is not unreasonable to infer that band E at 2141 cm^{-1} is a relatively weak feature of the spectra severely masked by band D. Because the band at 2145 cm^{-1} is highly polarized ($\rho = 0.04$) we are inclined to make a tentative assignment of band C to the polarized A_1-vibration of *cis-*$[(NH_3)_2Pd(CN)_2]$ leaving the depolarized (?) band E at 2141 cm^{-1} assigned to its B_1-mode.

S = 2.5 *and* 3.0. The spectrum at $S = 2.5$ exhibits four distinct features at 2148 cm^{-1} (B), 2145 cm^{-1} (C), 2142 cm^{-1} (D and/or E), and 2134 cm^{-1} (H or I). In the perpendicular polarized spectrum bands B, C and D disappear leaving a broad flat-topped region between 2140 and 2132 cm^{-1}. This signifies the existence of two further bands, one at 2136 cm^{-1} (G), the other coincident in frequency with band H at 2134 cm^{-1} (I). Band G does not contribute sufficiently to the parallel polarized spectrum to make itself apparent through the spectral envelope, but its presence in the perpendicularly polarized spectrum indicates that it is a comparatively weak feature with a non-zero polarization ratio. We are fortunate in being able to identify an additional band I at 2134 cm^{-1} by means of the increase in polarization ratio (from $\rho = 0.2$ to $\rho = 0.5$) at this frequency with increase in S from 2.0 to 3.0. At $S = 3$ bands B, C, G and I are observed; these change in relative intensities in the manner which

might be expected as a 2:1 gives is promoted to a 3:1 species. Using the polarization properties we assign band I to the depolarized B_1-vibration of $[(NH_3)Pd(CN)_3]^-$, leaving the bands at 2148 cm^{-1} (B) and 2136 cm^{-1} (G) to be attributed to its two A_1-vibrations.

S = 3.5 *and* 4.0. Two bands, not observed in the spectra described above, appear at 2150 cm^{-1} (A) and 2138 cm^{-1} (F), in an intensity ratio of 6:1. Band A is a highly polarized intense feature ($\rho = 0.01$), whilst band F is depolarized. They are obviously attributable to the symmetrical A_{1g} and the B_{1g} stretching vibrations respectively, of square-planar $[Pd(CN)_4]^{2-}$. The absence of any feature, other than bands A and F, leads us to conclude that complexation to $[Pd(CN)_4]^{2-}$ is complete at $S = 4.0$ and that this complex is thermodynamically very stable.

S = 6.3. No further change occurs in the spectrum when S is increased above 4, but it is to be noted that a band due to free CN^- appears at 2056 cm^{-1} as early as $S = 4.1$, indicating that stepwise complexation is complete at the 4:1 stage.

Description of the IR spectra

IR measurements have enabled us to assign the two Raman-inactive bands. They have also enabled us to monitor the changes in solution composition at ambient temperature during the first 2 days after preparation. At $S \leqslant 2$ the spectra change significantly up to about 50 h; at $S = 3$ changes are complete within 3 h. Five different bands can be clearly discerned and the directions in which they change with time are shown in Table 2.

S = 1 *and* 2. Three features are identifiable at 2141 cm^{-1} (E), 2134 cm^{-1} (H) and 2127 cm^{-1} (K). Relative to the band at 2134 cm^{-1}, which we associate with the C—N stretching frequency of $[(NH_3)_3Pd(CN)]^+$ because of its coincidence with band H of the Raman spectra, the intensities of both the other bands change with time; the band at 2141 cm^{-1} increases and that at 2127 cm^{-1} decreases. No band is observed in the Raman at as low a frequency as 2127 cm^{-1}, and accordingly we can unambiguously assign band K to the Raman-inactive B_{1u} vibration of *trans*-$[(NH_3)_2Pd(CN)_2]$. The highest-frequency band at 2141 cm^{-1} could (on the basis of coincidences with Raman frequencies) be associated with band E (the B_1-vibration of *cis*-$[(NH_3)_2Pd(CN)_2]$. After considering the direction of the changes in the relative intensities of bands E and K we conclude that *trans*-$[(NH_3)_2Pd(CN)_2]$, which forms after the solutions are mixed, reduces in concentration with time giving way to some *cis*-$[(NH_3)_2Pd(CN)_2]$. The overall increase in intensity of the band at *ca* 2141 cm^{-1} (in the Raman) is consistent with an increase in the concentration of the *cis* isomer. Concurrently the band at 2142 cm^{-1} due to the *trans* isomer, in parallel with band K, decreases in relative intensity. The increase in intensity of the feature E compared with the cor-

Table 2. Bands observed in the IR spectra of solutions containing CN^- ligands mixed with Pd^{2+} cations in liquid ammonia at 293 K[a]

Band	B	E	H

$S = 1$		↑	|
$S = 2$		↑	|
$S = 3$	|		
$S = 4$			

Band	I	J	K
Frequency (cm^{-1})	2134	2128	2127
Assignment	$[(NH_3)Pd(CN)_3]^-$	$[Pd(CN)_4]^{2-}$	*trans*-$[(NH_3)_2Pd(CN)_2]$
Symmetry	A_1	E_u	B_{1u}
$S = 1$			↓
$S = 2$			↓
$S = 3$	|		↓
$S = 4$		|	

[a] Arrows indicate the direction of intensity changes of the component bands with time. With solutions at $S = 1$ and 2 there is no detectable change after 50 h; for $S = 3$, it is 4 h.

responding loss of intensity under the K feature is good evidence for slow replacement of the *trans* by the *cis* isomer. Assessments of the changes in the band areas suggests an approximate half-life for the *cis–trans* interconversion of about 6 h. After about 50 h all three bands (E, H and K) are present in the spectra, and we conclude that the system contains an equilibrium which includes $[(NH_3)_3Pd(CN)]^+$ and both *cis*- and *trans*-$[(NH_3)_2Pd(CN)_2]$, and perhaps some $[(NH_3)Pd(CN)_3]^-$.

S = 3. At this composition changes in the spectra are complete within 3 h. A small feature is suggested on some of the profiles at *ca* 2136 cm^{-1} to support the assignment of band G (found in the Raman) to $[(NH_3)Pd(CN)_3]^-$. The most distinctive new feature is the relatively small band at 2146 cm^{-1}. This should be associated with band B seen in the Raman at 2148 cm^{-1} and assigned to the A_1-vibration of $[(NH_3)Pd(CN)_3]^-$. As this band is of relatively low intensity it is tempting to suggest that the proportion of $[(NH_3)Pd(CN)_3]^-$ in a solution of $S = 3$ is relatively low, and, because the principal components of the mixture are the 2 : 1 isomers and $[(NH_3)Pd(CN)_3]^-$, that the third stepwise stability constant K_3 is comparatively low.

S = 4. This spectrum consists of a single symmetrical band at 2128 cm^{-1} (J). Because this is absent from the Raman spectra we can unambiguously assign it to the doubly-degenerate E_u-mode of square-planar $[Pd(CN)_4]^{2-}$.

CONCLUSIONS

(1) The Raman and IR spectra of mixtures of Pd^{2+} and CN^- in liquid-ammonia solutions have enabled frequencies to be assigned to all the 11 C—N stretching vibrations of the five square-planar complexes as follows:

2150 cm^{-1}, A_{1g}, $[Pd(CN)_4]^{2-}$;
2148 cm^{-1}, A_1, $[(NH_3)Pd(CN)_3]^-$;
2145 cm^{-1}, A_1, *cis*-$[(NH_3)_2Pd(CN)_2]$;
2142 cm^{-1}, A_g, *trans*-$[(NH_3)_2Pd(CN)_2]$;
2141 cm^{-1}, B_1, *cis*-$[(NH_3)_2Pd(CN)_2]$;
2138 cm^{-1}, B_{1g}, $[Pd(CN_4)]^{2-}$;
2136 cm^{-1}, B_1, $[(NH_3)Pd(CN)_3]^-$;
2134 cm^{-1}, A_1, $[(NH_3)_3Pd(CN)]^+$;
2134 cm^{-1}, A_1, $[(NH_3)Pd(CN)_3]^-$;
2128 cm^{-1}, E_u, $[Pd(CN)_4]^{2-}$;
2127 cm^{-1}, B_{1u}, *trans*-$[(NH_3)_2Pd(CN)_2]$.

(2) A slow interconversion of *trans*-$[(NH_3)_2Pd(CN)_2]$ and *cis*-$[(NH_3)_2Pd(CN)_2]$ ($t_{1/2} \sim 6$ h) can be followed in the IR spectra. This results in a solution at equilibrium containing $[(NH_3)_3Pd(CN)]^+$ and both the *cis* and *trans* isomers.

(3) Complexation of Pd^{2+} by CN^- in liquid ammonia does not proceed beyond the 4 : 1 stage.

(4) The relative intensities of component bands in the spectra suggest that the formation steps to the 2 : 1 and 4 : 1 species are thermodynamically favoured processes.

(5) There is no spectroscopic evidence for the existence of multinuclear complexes with bridging cyano groups.

(*Received* 3 *July* 1986)

Abstract—IR, ^{1}H NMR and electronic spectra are reported for the complexes *trans*-[$PtX_2(CO)(L)$] (X = Cl or Br; L = NH_3, pyridine, pyridine-*N*-oxide, aniline or imidazole) and *trans*-[$Pt_2X_4(CO)_2$(pyrazine)] (X = Cl or Br). Assignments for the internal ligand modes and metal–ligand vibrations are deduced from the band shifts caused by deuteration of the ligands (L). The simplicity of the IR spectra, particularly in the $\nu(C{\equiv}O)$ region, is consistent with a *trans*-configuration. The ^{1}H NMR data show ^{195}Pt–H coupling at ambient temperature, suggesting a slow exchange, unlike the corresponding ethylene complexes which are highly fluxional at ambient temperatures. Assignments are provided for the UV spectra and the previously reported red shift is observed in the $5d(Pt) \rightarrow \pi^*$ transition which results from the replacement of Cl by Br in the complexes.

Recently, we reported a vibrational study of the complexes *trans*-[$PtX_2(C_2H_4)(L)$], where L represents various oxygen and nitrogen donor ligands.[1] The facile displacement of the ethylene from these complexes[2,3] has enabled us to prepare a large number of platinum carbonyl complexes of the type *trans*-[$PtX_2(CO)(L)$] and *trans*-[$Pt_2X_4(CO)_2$(pyrazine)]. In this paper, IR, ^{1}H NMR, UV and MS have been used to examine the nature of these complexes which differ considerably from their ethylene-containing precursors.

EXPERIMENTAL

The complexes *trans*-[$PtX_2(C_2H_4)(L)$] [X = Cl or Br; L = aniline (an), pyridine *N*-oxide (pyO), pyridine (py), NH_3, imidazole (Him) or pyrazine (pz)] and *trans*-[$Pt_2X_4(C_2H_4)_2$(pz)] were prepared using methods described in the literature.[1,4] Prior to the formation of the new carbonyl analogues of the above complexes, the chloroform and *n*-hexane solvents required were dried and distilled over P_2O_5 and Na, respectively. This is essential to prevent the rapid decomposition of the moisture-sensitive carbonyl complexes and the precipitation of elemental platinum.[5]

(*a*) *Preparation of* trans-[$PtX_2(CO)(L)$] (X = Cl *or* Br; L = an *or* Him)

trans-[$PtX_2(C_2H_4)(L)$] (X = Cl or Br; L = an or Him) (1 mmol) was dissolved in dry chloroform (30 cm^3), and carbon monoxide was bubbled through the solution with stirring, during which time the temperature of the solution was maintained at about 30°C. After several minutes (3–60 min, depending on L) the colour of the solution changed from bright yellow to pale greenish-yellow. At this point the solution was concentrated by evaporation

*In 1976, David Thornton invited Professor Harry Irving to the University of Cape Town as visiting Professor in Inorganic Chemistry. He stayed on to become the University's first Professor of Analytical Science until his retirement in 1984 at the age of 79. Author to whom correspondence should be addressed.

of chloroform using a stream of warm dry air. On addition of dry *n*-hexane (20 cm^3) to the point of cloudiness, the product was precipitated. The products, *trans*-[$PtX_2(CO)(L)$] (X = Cl or Br; L = an or Him) were isolated by vacuum filtration, washed with *n*-hexane and stored over silica gel in a vacuum desiccator (<0.1 mmHg) at −5°C.

(*b*) *Preparation of* trans-[$PtX_2(CO)(py)$] (X = Cl *or* Br)

trans-[$PtX_2(CO)(py)$] (X = Cl or Br) was prepared from *trans*-[$PtX_2(C_2H_4)(py)$] (X = Cl or Br) as described in (a), except that *n*-hexane (10 cm^3) was added before the cloudiness occurred, and the resulting solution was placed over silica gel in a large partly evacuated desiccator and stored at −5°C overnight, during which time the solvent evaporated resulting in the formation of needle-like crystals of *trans*-[$PtX_2(CO)(py)$] (X = Cl or Br) which were collected and stored as described in (a).

(*c*) *Attempted preparation of* trans-[$PtX_2(CO)(pz)$] (X = Cl *or* Br)

(1) Attempts to prepare *trans*-[$PtX_2(CO)(pz)$] (X = Cl or Br) from *trans*-[$PtX_2(C_2H_4)(pz)$] using the method described in (a) resulted in the formation of the bridged complex *trans*-[$Pt_2X_4(CO)_2(pz)$] in quantitative yield.

(2) H[$Pt(CO)X_3$] (X = Cl or Br) (1 mmol), prepared as described by Gribov *et al.*,[6] was dissolved in chloroform. Reaction of this solution with pyrazine in various molar ratios always resulted in the formation of *trans*-[$Pt_2X_4(CO)_2(pz)$], while the addition of a large excess of pyrazine (>10 mmol) resulted in the formation of *trans*-[$PtX_2(pz)_2$].[7]

(3) Crystals of $[PtCl_2(CO)_2]_2$, prepared as described in the literature[8,9] were dissolved in chloroform and allowed to react with pyrazine, in various molar ratios. All attempts resulted either in no reaction or in the formation of either *trans*-[$Pt_2Cl_4(CO)_2(pz)$] or *trans*-[$PtCl_2(pz)_2$].

(4) The salts [NR_4][$PtX_3(CO)$] (X = Cl or Br, R = Pr^n_4 or Bu^n_4) were prepared as described by Browning *et al.*[10] Reaction of these salts with pyrazine, in various molar ratios, resulted either in no reaction or in the formation of *trans*-[$PtX_2(pz)_2$].

(*d*) *Preparation of* trans-[$Pt_2X_4(CO)_2(pz)$] (X = Cl *or* Br)

[$Pt_2X_4(CO)_2(pz)$] was prepared from [$Pt_2X_4(C_2H_4)_2(pz)$] as described in (a), except for the fact that larger volumes of chloroform (~ 70 cm^3) are required to dissolve the ethylene complexes.

The purity and composition of all the compounds were determined by microanalysis (C, H and N) (Table 1). The deuterated complexes were similarly prepared using the following labelled compounds supplied by Merck, Sharp & Dohme (Canada) Ltd (isotopic purity in parentheses): ammonia-d_3 (99%), aniline-d_5 (98%), and imidazole-d_4 (98%); and the following compounds supplied by BOC Prochem Ltd: pyridine-d_5 (99%) and pyridine-d_5 *N*-oxide (98%). The deuteroimine groups of 1,2,4,5-tetradeuteroimidazole (Him-d_4) undergo rapid exchange

in aqueous or ethanolic solution to yield complexes containing 2,4,5-trideuteroimidazole (Him-d_3).

The ^{1}H NMR spectra were run at ambient temperature on a Bruker WH-90 spectrometer using CD_3COCD_3 as the solvent and TMS as reference. The IR spectra were determined as Nujol mulls (4000–1500 and 1300–300 cm^{-1}) or hexachlorobutadiene mulls (4000–1700 and 1500–1300 cm^{-1}) between CsBr plates on a Perkin–Elmer 983 spectrophotometer, and as Nujol mulls between polyethylene plates (500–80 cm^{-1}) on a Digilab FTS-16 B/D interferometer. The UV spectra were determined on a Varian Superscan 3 spectrophotometer using CH_3OH as solvent. Mass spectra were measured on a VG Micromass 16/F instrument operating in the electron impact mode, with electron beam energy = 70 eV, ion-accelerating voltage = 3 kV, and with ion source temperatures in the range 100–195°C. Microanalyses were performed by Mr W. R. T. Hemsted of the University of Cape Town.

RESULTS AND DISCUSSION

IR spectra

The spectrum of each compound was determined twice, firstly in the unlabelled form and secondly with the ligand (L) in the deuterated form. The frequency data and assignments for the internal ligand modes of the complexes are listed in Table 2, while the far-IR frequencies are given in Table 3.

The internal vibrations of the ligands, L, are assigned to those bands which shift significantly on deuteration of L, with more specific assignments made from their ν^D/ν^H ratios.[11] Assignments are made in relation to the analogous ethylene compounds[1] and earlier use of the ν^D/ν^H ratio in complexes of aniline,[11] pyridine[11] and imidazole,[12] while the assignments for the pyridine *N*-oxide complexes follow those reported from a normal coordinate analysis of the free ligand.[13–15]

The ν(C≡O) frequencies were determined in chloroform, as well as in Nujol mulls. The former resulted in a single sharp band, while the latter sometimes resulted in splittings which may arise from rotational fine structure in the solid state.[6] The simplicity of the IR spectrum in the ν(C≡O) region is consistent with *trans* coordination.

The far-IR assignments are in good accord with previous work[10,16,17] on related complexes and the δ(Pt—C≡O) band is at higher frequency than that of ν(Pt—C) as expected in metal carbonyls.[18,19] Only one previous IR study of complexes of this type has been reported,[6] in which Gribov and co-workers reported the IR spectrum of *trans*-$[PtCl_2(CO)(NH_3)]$. Two bands were observed in the skeletal region, at 532 and 477 cm^{-1}, both of which were attributed to δ(Pt—C≡O) deformations. We now attribute these to the deformation δ(Pt—C≡O) and stretching ν(Pt—C), respectively. As expected, the ν(Pt—N) frequency is substantially lower in the complexes *trans*-$[Pt_2X_4(CO)(pz)]$ (where the pyrazine is bridging) than in the complexes where similar ligands are terminal, e.g. *trans*-$[PtX_2(CO)(py)]$.

^{1}H NMR *spectra*

The ^{1}H NMR data for the complexes are given in Table 4. Examination of the data reveals that some of the complexes show ^{195}Pt–H coupling. The complexes *trans*-$[PtX_2(CO)(Him)]$ (X = Cl or Br) and *trans*-$[PtBr_2(CO)(py)]$ exhibit coupling at ambient temperature while *trans*-$[PtCl_2(CO)(py)]$ exhibits coupling at reduced temperatures. This suggests that ligand exchange is relatively slow in the former three complexes, with pyridine being more labile in the latter. The above is in direct contrast to the analogous ethylene complexes,[1,20] *trans*-$[PtX_2(C_2H_4)(L)]$, where exchange is rapid at ambient temperature as indicated by an absence of ^{195}Pt–H coupling. This emphasizes the weaker "*trans* effect" of carbon monoxide relative to C_2H_4.

^{195}Pt–H coupling was not observed in the complexes *trans*-$[PtX_2(CO)(L)]$ (X = Cl or Br, L = pyO or an), probably because the protons are separated by at least four bonds from the platinum atom. The absence of coupling in the complexes *trans*-$[Pt_2X_4(CO)_2(pz)]$ may indicate rapid exchange but this is not easy to verify since all four protons are equivalent when the pyrazine plays a bridging role.

Electronic spectra

The electronic spectral data are listed in Tables 5 and 6. By analogy with similar complexes previously studied[21–23] we expect to observe the $\pi \rightarrow \pi^*$(CO) transition as well as the $5d$Pt $\rightarrow \pi^*$(CO) inverse-charge-transfer and the $X^- \rightarrow Pt^{2+}$ charge-transfer bands. In addition, in complexes where L is a ligand which has π-electrons present, there is the possibility of a $5d$Pt $-\pi^*$(ligand) inverse-charge-transfer transition. Since some of the transitions overlap, giving rise to broad bands, some of the assignments are tentative. We observe the previously reported[23] red shift in the $5d$(Pt) $\rightarrow \pi^*$ transition which results from the replacement of Cl by Br in the complexes.

REDOX REACTION ON TREATING *fac*- OR *mer*-[Mo(CO)$_3$(dppm-*PP'*)(dppm-*P*)] (dppm = $Ph_2PCH_2PPh_2$) WITH Hg(SCN)$_2$ AND CRYSTAL STRUCTURE OF THE SEVEN-COORDINATE PRODUCT [Mo(CO)$_2$(NCS)$_2$(dppm-*PP'*)(dppm-*P*)]

ADRIAN BLAGG, ALAN T. HUTTON* and BERNARD L. SHAW

School of Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

(*Received* 3 *July* 1986)

Abstract—[Mo(CO)$_2$(NCS)$_2$(dppm-*PP'*)(dppm-*P*)] (dppm = $Ph_2PCH_2PPh_2$) is formed in a rapid and clean redox reaction when *fac*- or *mer*-[Mo(CO)$_3$(dppm-*PP'*)(dppm-*P*)] is treated with Hg(SCN)$_2$: dppm-chelate ring-opening with formation of a heterobimetallic species is not observed. The X-ray crystal structure of the product shows the molecule to contain seven-coordinate Mo(II) with "*cis*" CO groups, both monodentate and chelating dppm ligands, and with *N*-bonded NCS groups. The coordination geometry is intermediate between a capped trigonal prism and a capped octahedron. Crystals of [Mo(CO)$_2$(NCS)$_2$(dppm-*PP'*)(dppm-*P*)] are orthorhombic, space group $Pna2_1$, with $a = 21.583(7)$ Å, $b = 12.775(4)$ Å, $c = 18.484(5)$ Å, and $Z = 4$; the final R factor was 0.046 for 3181 observed reflections.

We have described the reactions of Group VI metal carbonyl bis(diphenylphosphino)methane (dppm) derivatives of types *fac*-[M^1(CO)$_3$(dppm-*PP'*)(dppm-*P*)] (M^1 = Mo or W) or *mer*-[M^1(CO)$_3$(dppm-*PP'*)(dppm-*P*)] (M^1 = Cr, Mo or W) with labile Rh(I) or Ir(I) carbonyls to give high yields of heterobimetallic complexes containing the *trans,trans*-[M^1(μ-dppm)$_2$M^2] (M^2 = Rh or Ir) skeleton.[1] Similar dppm-chelate ring-opening reactions are induced by the treatment of [M^1(CO)$_3$(dppm-*PP'*)(dppm-*P*)] with copper(I) chloride or iodide, or with (Ph_3P)AgCN, resulting in stable heterobimetallics of type [M^1(CO)$_3$(μ-dppm)$_2$M^{2}X] (M^1 = Cr, Mo or W; M^2 = Cu, X = Cl or I; M^2 = Ag, X = CN), and preliminary results show that treatment with (Ph_3P)AuCl gives similar heterobimetallic complexes containing a [M^1(μ-dppm)$_2$Au] (M^1 = Mo or W) frame.[2] Mixed Group VI metal–platinum complexes of type [M^1(CO)$_3$(μ-dppm)$_2$PtH(X)] (M^1 = Cr, Mo or W; X = Cl or Br) have also been prepared by treating *mer*-[M^1(CO)$_3$(dppm-*PP'*)(dppm-*P*)] with *trans*-[PtH(X)(PPh_3)$_2$].[3]

RESULTS AND DISCUSSION

We report here on a different and contrasting behaviour when mercury(II) salts are used: these generally oxidize [Mo(CO)$_3$(dppm-*PP'*)(dppm-*P*)] to a mononuclear Mo(II) complex rather than induce ring-opening and formation of a heterobimetallic species. Thus treatment of *fac*- or *mer*-[Mo(CO)$_3$(dppm-*PP'*)(dppm-*P*)] with $HgCl_2$ in dichloromethane at 20°C gives [Mo(CO)$_2$(dppm-*PP'*)$_2$Cl]Cl in good (> 60%) yield, together with metallic mercury. We have also prepared this complex by treating *cis*-[Mo(CO)$_2$(dppm-*PP'*)$_2$] with chlorine; the corresponding bromo and iodo complexes [Mo(CO)$_2$(dppm-*PP'*)$_2$X]X (X = Br or I) have been prepared previously by treating *cis*-[Mo(CO)$_2$(dppm-*PP'*)$_2$] with X_2.[4]

Similarly, treatment of either *fac*- or *mer*-[Mo(CO)$_3$(dppm-*PP'*)(dppm-*P*)] with Hg(SCN)$_2$ in dichloromethane gives mercury metal and golden yellow crystals of the seven-coordinate Mo(II) complex [Mo(CO)$_2$(NCS)$_2$(dppm-*PP'*)(dppm-*P*)] in a

* M.Sc. and Ph.D. student with Professor H. M. N. H. Irving at the University of Cape Town (1977–1980); presently "new blood" lecturer in inorganic chemistry at the Department of Pure and Applied Chemistry, The Queen's University, Belfast BT9 5AG, U.K. Author to whom all correspondence should be addressed.

very rapid and clean reaction. This complex has previously been prepared by treating $[MoCl_2(CO)_4]$ with ammonium thiocyanate followed by dppm, and our IR data (Nujol mull: ν_{CN} 2095 and 2070 cm^{-1}, ν_{CO} 1960 and 1890 cm^{-1}) are very similar to those reported before.[5] The $^{31}P-\{^1H\}$ NMR spectrum of $[Mo(CO)_2(NCS)_2$(dppm-*PP'*)(dppm-*P*)] in CD_2Cl_2 (not previously recorded) showed: a doublet at δ −25.3 ppm, assigned to the non-coordinating phosphorus atom; a multiplet at 34.6 ppm due to the coordinated phosphorus atom of the monodentate dppm ligand; and a broad hump at 5.3 ppm, assigned to the chelating dppm phosphorus atoms. At −50°C this broad resonance was resolved into two 1 : 1 : 1 : 1 quartets at −17.2 and 28.2 ppm, the temperature dependence of the spectrum presumably a result of ligand scrambling about the seven-coordinate molybdenum(II) centre.

It seems likely that the Mo(II) complexes described above are formed *via* Mo–Hg bonded intermediates. Treatment of $[M(CO)_4$(bipy)] (M = Mo or W, bipy = 2,2′-bipyridine) with HgX_2 (X = Cl, Br, I or SCN) has been shown to give complexes of type $[M(CO)_3$(bipy)$(HgX)X]$.[6,7] These M–Hg species were found to be unstable in polar solvents, decomposing to give metallic mercury.[7] Thus we tentatively propose that *fac*- or *mer*-$[Mo(CO)_3$(dppm-*PP'*)(dppm-*P*)] initially reacts with HgX_2 to give $[Mo(CO)_2$(dppm-*PP'*)(dppm-*P*)(HgX)X], which subsequently decomposes to give the observed product and mercury metal.

Single crystals of $[Mo(CO)_2(NCS)_2$(dppm-*PP'*)(dppm-*P*)] suitable for an X-ray diffraction study were obtained as golden yellow prisms from acetone–methanol. The structure (Fig. 1) confirms the seven-coordination around Mo(II) with "*cis*" CO groups, both bi- and monodentate dppm ligands, and with *N*-bonded NCS ligands; all these features were predicted from the IR and ^1H NMR data.[5] The choice of an idealized coordination geometry in a seven-coordinate complex is often not simple and has been the subject of several recent articles.[8–11] One simple procedure is to compare the interbond angles at the metal centre (Table 1) with the values computed for various idealized polyhedra.[8,10–12] This procedure reveals the coordination geometry about the Mo(II) centre to be intermediate between a capped trigonal prism [with N(1) in the unique capping position, P(1), N(2), P(3) and C(4) in the capped quadrilateral face, and P(2) and C(3) in the unique edge] and a capped octahedron [with C(3) in the capping position, P(2), P(3) and C(4) in the capped face, and P(1), N(1) and N(2) in the uncapped face]. This geometry is similar to several other M(II) complexes (M = Cr, Mo or W) containing CO and PR_3 ligands,[8] e.g. $[MoCl_2(CO)_2(PMe_2Ph)_3]$,[13] and in particular the interbond angles at Mo in the present structure are very

close to those reported for the complex [$MoCl_2(CO)_2$(dppm-*PP'*)(dppm-*P*)],[14] in which the introduction of a chelate ring accentuates the distortion more towards the capped trigonal prismatic than the capped octahedral geometry.

The Mo—N bond lengths (see Table 1) differ by *ca* 0.04 Å with the shorter bond [Mo—N(1)] being in the unique capping position of the capped trigonal prismatic structure, and similar differences are found in the corresponding Mo—Cl bond lengths of the two dichloro complexes mentioned above,[13,14] the shorter bond again being in this site. The Mo—P bond lengths (see Table 1) are all different, in the sequence Mo—P(1) > Mo—P(3) > Mo—P(2), and the same pattern is found in several related complexes, e.g. [$MoCl_2(CO)_2$(dppm-*PP'*)(dppm-*P*)].[14] Competition for the metal $d\pi$ electrons presumably lengthens the Mo—P(1) and Mo—P(3) bonds, which are mutually *trans*, whereas the Mo—P(2) bond is the shortest since it is nearly *trans* to an NCS group which does not compete as strongly for metal $d\pi$ electrons. The Mo—P(1) bond may be the longest of the Mo—P bonds because it is additionally somewhat *trans* to the carbonyl group C(3)—O(3) (see Table 1 for angles). The chelate ring angle P(1)—C(5)—P(2) of 96.0(4)° is significantly larger in the present complex than in [$MoCl_2(CO)_2$(dppm-*PP'*)(dppm-*P*)], where it is 90(1)°,[14] though the present value is in the middle of the range reported in a compilation of data for structures containing chelating dppm.[15] As in the homologous dichloro complex,[14] the four-membered chelate ring is puckered with the methylene C(5) displaced towards N(2) and away from the two carbonyl groups, allowing the bulky phenyl rings to avoid unfavourable intramolecular contacts. This puckering can be considered to be quite strong as measured by the relatively small P(1)—Mo—P(2) bite angle of 64.8(1)° and relatively large distance of the methylene C(5) atom from the P(1)—Mo—P(2) plane (0.67 Å) (see Ref. 15 for an analysis of chelating dppm stereochemistry).

It is noticeable that one of the isothiocyanate groups is bonded to the metal centre in a markedly non-linear fashion [Mo—N(2)—C(2) = 159.7(7)°], but the angle falls well within the range defined by other structural determinations of complexes containing *N*-bonded thiocyanate ligands.[16–18] The smaller Mo—N(2)—C(2) angle [159.7(7)° compared to Mo—N(1)—C(1) of 175.8(7)°] within the present structure is probably the result of having a CO ligand virtually *trans* [N(2)—Mo—C(4) = 169.2(3)°] to the isothiocyanate group, the resultant decrease in electron density available for bonding being reflected in predominance of the resonance form $S{=}C{=}N\overset{M}{\diagup}$ rather than $\bar{S}{-}C{\equiv}\overset{+}{N}{-}M$, though the correlation of N–C and C–S distances with the M–N–C angles in this structure is not as distinct as in others.[17,18] Steric or packing effects within the crystal have also been invoked to explain bent M–N–CS angles,[18] but there are no intermolecular contacts significantly less than the sum of van der Waals' radii in the present structure, and the low crystal density (D_c = 1.35 g cm^{-3}) is indicative of the somewhat loose packing of the molecules within the crystal.

EXPERIMENTAL

Reactions were carried out in an atmosphere of dry dinitrogen in deaerated, dried solvents. IR spectra were recorded on a Perkin–Elmer 457 grating spectrometer and ^{31}P–{^1H} NMR spectra were recorded on a JEOL FX100 instrument operating at 40.25 MHz and with positive chemical shifts to high frequency relative to 85% H_3PO_4.

Preparation of [$Mo(CO)_2(NCS)_2$(dppm-*PP'*)(dppm-*P*)]

A stirred solution of *fac*-[$Mo(CO)_3$(dppm-*PP'*)(dppm-*P*)] (0.200 g, 0.21 mmol) in dichloromethane (8 cm^3) was treated with $Hg(SCN)_2$ (0.067 g, 0.21 mmol). The solution turned red almost immediately and carbon monoxide was evolved. After 30 min of stirring a small volume of methanol (*ca* 3 cm^3) was added to aid deposition of metallic mercury. The reaction mixture was filtered and methanol added to precipitate out golden yellow crystals of [$Mo(CO)_2(NCS)_2$(dppm-*PP'*)(dppm-*P*)]. Yield 0.096 g (44%). Analysis found (required): C, 62.4 (62.6); H, 4.2 (4.3); N, 2.6 (2.7)%. A similar yield was obtained when *mer*-[$Mo(CO)_3$(dppm-*PP'*)(dppm-*P*)] was used as the starting material.

Crystal data

$C_{54}H_{44}MoN_2O_2P_4S_2$, $M = 1036.91$, orthorhombic, $a = 21.583(7)$ Å, $b = 12.775(4)$ Å, $c = 18.484(5)$ Å, $U = 5096(2)$ $Å^3$, space group $Pna2_1$ (No. 33), $Z = 4$, $D_c = 1.35$ g cm^{-3}, $F(000) = 2128$, graphite-monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 4.93 cm^{-1}. Golden yellow prisms from acetone–methanol. Crystal dimensions (distance to faces from centre): 0.155 (100, $\bar{1}00$), 0.148 (011, $0\bar{1}\bar{1}$), 0.165 ($0\bar{1}1$, $01\bar{1}$) mm.

Structure determination

Cell dimensions and their standard deviations were obtained by least-squares refinement of diffractometer setting angles for 15 automatically-centred reflections having $34° < 2\theta < 39°$. Intensities of 3405 independent reflections (h, k, l; $4° < 2\theta < 45°$) were measured on a Syntex $P2_1$ diffractometer in the ω–2θ scan mode using scan speeds, according to a prescan intensity, between 2 and 29° min^{-1}, and with the scans running from 1° below $K_{\alpha1}$ to 1° above $K_{\alpha2}$. The structure analysis used the 3181 reflections with $I > 2\sigma(I)$ after correction for Lorentz and polarization factors; absorption effects were corrected numerically (maximum and minimum transmission factors for full data set = 0.89 and 0.83).[19]

Solution by Patterson and difference syntheses was followed by full-matrix least-squares refinement with anisotropic thermal parameters for all atoms except H and the phenyl ring C atoms, using the SHELX program system.[19] The phenyl rings were refined as rigid groups with idealized D_{6h}-geometry, the C atoms having individual isotropic thermal parameters and C—C distances of 1.395 Å. All H atoms, many of which were found in difference maps, were included in the calculation at idealized positions with C—H fixed at 1.08 Å; their isotropic temperature factors were treated as two single parameters (for aromatic or methylene H). The refinement for 251 parameters converged to $R = 0.046$ and $R_w = \Sigma w^{1/2}\Delta/\Sigma w^{1/2}|F_o| = 0.048$, employing the weighting scheme $w = 1/(\sigma^2 F_o + 0.0004F_o^2)$ to give a flat analysis of variance with increasing $\sin\theta$ and $(F_o/F_{max})^{1/2}$. Refinement of the alternative enantiomorphic specification gave larger R-factors (though not significantly so) and the original structure was retained.* A final difference map was featureless. Complex neutral-atom scattering factors were calculated from the analytical approximation and coefficients given in Ref. 20.

(*Received* 3 *July* 1986)

Abstract—Ligand substitution properties of the recently characterized pale-yellow $[Ir(H_2O)_6]^{3+}$ ion in perchlorate solutions, have been investigated. At 120°C in sealed tubes observations on the exchange with $H_2{}^{18}O$ are impaired by a spurious oxidation to purple Ir(IV). Over extended periods at 40°C the ion has been shown to be extremely inert, and the rate constants for substitution of Cl^- into $[Ir(H_2O)_6]^{3+}$ is estimated to be $< 2 \times 10^{-9}$ $M^{-1}\,s^{-1}$.

The aqua ion of Ir(III), first reported in 1976, is now well characterized as $[Ir(H_2O)_6]^{3+}$.[1–3] Studies on hexa-aqua ions remain of fundamental importance in considering the properties of different oxidation states. Of particular interest are the trends in substitution kinetic behaviour of metals in the same group of the Periodic Table. Present findings are discussed in the context of the substitution behaviour of other metal ions, including $[Al(H_2O)_6]^{3+}$ and $[Ga(H_2O)_6]^{3+}$.[4]

EXPERIMENTAL

Materials

Stock solutions of $[Ir(H_2O)_6]^{3+}$ (0.02 M) in 2 M $HClO_4$ were prepared by treatment of $[IrCl_6]^{3-}$ or $[IrCl_6]^{2-}$ (Johnson Matthey) with OH^-, precipitation of $[Ir(OH)_3(H_2O)_3]$, and dissolving this in 0.1 M $HClO_4$ as previously described.[1,2] Final purification was from a Dowex ion-exchange column. The ion was characterized by its UV–visible peaks, λ (nm) [ε ($M^{-1}\,cm^{-1}$)] at 310 (32.5) and 265 (41). Sodium perchlorate, $NaClO_4 \cdot H_2O$, and sodium chloride (both BDH, Analar) were used without further purification. Sodium thiocyanate (BDH, Laboratory Reagent) was recrystallized 3 times from ethanol.

Kinetic studies

Solutions of $[Ir(H_2O)_6]^{3+}$ ($\sim 4 \times 10^{-3}$ M) in 1.0 M $HClO_4$ containing added ^{18}O-enriched H_2O were sealed in glass ampoules and placed in an oven at 120°C (CARE!). Other studies were at 40°C with Cl^- and NCS^- as substituents. The pH of the latter solutions was adjusted to values in the range 1–2 by addition of saturated $NaHCO_3$ (BDH, Analar). The acid dissociation (pK_a) for $[Ir(H_2O)_6]^{3+}$ is 4.37.[3] The spectrum remained unchanged, and it was assumed that no significant amounts of carbonate remained. No information is available on the spectrum of $[Ir(H_2O)_5Cl]^{2+}$, but from the trends observed[5] for the formation of $[Rh(H_2O)_5Cl]^{2+}$ from $[Rh(H_2O)_6]^{3+}$ significant changes are expected. Formation of thiocyanato complexes generally give rise to large absorbance changes in the near UV.

*A.G.S. was lecturer/colleague of Professor Irving, University of Leeds (1961–1971), and moved to the University of Newcastle in 1980. Author to whom correspondence should be addressed.

RESULTS

Over intervals of ~ 3 h at 120°C pale-yellow solutions of $[Ir(H_2O)_6]^{3+}$ became purple. The colour obtained is the same as that of the Ir(IV) product, at present of uncertain molecularity (not monomer), obtained in electrochemical studies on $[Ir(H_2O)_6]^{3+}$, peak at 541 nm.[6] The same behaviour was observed when solutions were sealed under N_2, and in a test with Ag^+ no Cl^- was detected. This does not rule out formation of other oxidation states of chlorine. It was concluded that high temperatures are not appropriate for studies over long time intervals of the H_2O exchange on $[Ir(H_2O)_6]^{3+}$.

At 40°C the following experiments were carried out with $[Ir(H_2O)_6]^{3+}$ at 2.3×10^{-3} M. First with [NaCl] = 2.3 M, $[H^+] = 0.010$ M, $I = 3.0$ M ($NaClO_4$), and then with [NaCl] = 3.7 M, $[H^+] = 0.10$ M, $I = 3.9$ M, no absorbance changes in the 250–350-nm range were observed over 10 and 15 days, respectively. With [NaNCS] = 1.0 M, $[H^+] = 0.010$ M, $I = 2.0$ M ($NaClO_4$), absorbance changes matched those for a solution with no $[Ir(H_2O)_6]^{3+}$ added, and can be attributed to side reactions of NCS^-.[7] Even with the generous allowance that the time the Cl^- runs were monitored for is equal to the half-life of the reaction, a rate constant of 1.4×10^{-8} M^{-1} s^{-1}, comparable to that for $[Rh(H_2O)_6]^{3+}$, is obtained. More realistically assuming that < 10% reaction occurs in this time we fix the rate constant limit for the reaction of $[Ir(H_2O)_6]^{3+}$ with Cl^- at $< 2 \times 10^{-9}$ M^{-1} s^{-1}. In arriving at this estimate an allowance has been made for the conjugate-base $[H^+]^{-1}$ pathway, which it is assumed contributes to the same extent as in the reaction with $[Rh(H_2O)_6]^{3+}$.[8] In the latter $[Rh(H_2O)_5OH]^{2+}$ has been shown to be ~ 6000 times more reactive than $[Rh(H_2O)_6]^{3+}$.

DISCUSSION

It is concluded from these studies that $[Ir(H_2O)_6]^{3+}$ is extremely inert, probably more inert than $[Rh(H_2O)_6]^{3+}$, and therefore the most inert of hexa-aqua ions at present known. Substitution studies on the d^6-ions $[Co(H_2O)_6]^{3+}$ and $[Rh(H_2O)_6]^{3+}$ have previously indicated significant rate law contributions from $[H^+]^{-1}$-dependent terms.[8,9] Experiments on $[Ir(H_2O)_6]^{3+}$ were at pH 1–2 to gain maximum benefit from such $[H^+]^{-1}$ terms in the rate law. The increase in inertness in going from $[Co(H_2O)_6]^{3+}$ to $[Rh(H_2O)_6]^{3+}$, and then to $[Ir(H_2O)_6]^{3+}$ (see Table 1), is in keeping with the effect of increasing ligand-field stabilization.[10] A similar overall trend has been observed for H_2O exchange of the aquapentaammine complexes, $[Co(NH_3)_5(H_2O)]^{3+}$, $[Rh(NH_3)_5(H_2O)]^{3+}$ and $[Ir(NH_3)_5(H_2O)]^{3+}$, although here it is interesting that the volumes of activation 1.2, −4.1 and −3.2 cm^3 mol^{-1}, respectively, indicate a possible change in mechanism from I_d (for Co) towards I_a (for Rh and Ir).[11–13] Participation of some high-spin $[Co(H_2O)_6]^{3+}$ cannot be ruled out as a contributing factor to the faster rate constants observed for this ion.

In sharp contrast the rate constant (25°C) for 1 : 1 Cl^- anation of $[Mo(H_2O)_6]^{3+}$ (4.6×10^{-3} M^{-1} s^{-1}) is some 10^5 times bigger than for $[Cr(H_2O)_6]^{3+}$ (2.9×10^{-8} M^{-1} s^{-1}), and with NCS^- a similar ratio is obtained.[14,15] The low d-electron population, and increase in associative character with increasing size ($4d > 3d$) of the d-orbitals, provides a likely explanation. The associative character of $[Mo(H_2O)_6]^{3+}$ is comparable to that of the more labile $[V(H_2O)_6]^{3+}$ (d^2) and $[Ti(H_2O)_6]^{3+}$ (d^1) ions, which have H_2O exchange rate constants (25°C) of 495 and 1.81×10^5 s^{-1}, respectively.[4]

Reaction	Temperature (°C)	k	Reference
$[Co(H_2O)_6]^{3+} + Cl^-$	25	$\leqslant 2$ M^{-1} s^{-1}	8
$[Rh(H_2O)_6]^{3+} + Cl^-$	40	~ 10^{-8} M^{-1} s^{-1}	9
$[Ir(H_2O)_6]^{3+} + Cl^-$	40	$< 2 \times 10^{-9}$ M^{-1} s^{-1}[b]	This work
$[Co(NH_3)_5(H_2O)]^{3+} + H_2O$	25	5.7×10^{-6} s^{-1}	11
$[Rh(NH_3)_5(H_2O)]^{3+} + H_2O$	25	8.4×10^{-6} s^{-1}	12
$[Ir(NH_3)_5(H_2O)]^{3+} + H_2O$	25	6.1×10^{-8} s^{-1}	13

[a] Contributions from $[H^+]^{-1}$-dependent terms are not included in the first three entries.

[b] An $[H^+]^{-1}$ contribution of similar proportion to that observed for $[Rh(H_2O)_6]^{3+}$ has been allowed for in this estimate.

While it is possible that other hexa-aqua ions of early transition metals may be identified, the availability of an associative route for ligand exchange means that these are unlikely to be very inert. Indeed it is unlikely that there will be a more inert II or III state hexa-aqua ion than $[Ir(H_2O)_6]^{3+}$ in the Periodic Table, and only if $[Pt(H_2O)_6]^{4+}$ is at some time prepared is a more inert ion of this kind likely to be obtained.

A further comparison of interest is that for H_2O exchange (25°C) on $[Al(H_2O)_6]^{3+}$ (1.29 s^{-1}) and $[Ga(H_2O)_6]^{3+}$ (403 s^{-1}), where the size of the metal ion and electrostatics determine the pattern of behaviour observed.[4] Both reactions are assigned an I_d-mechanism from the magnitude of volumes of activation (+5.7 and +5.0 $cm^3\ mol^{-1}$, respectively). This trend also parallels that of characteristic rate constants for water exchange on $[Zn(H_2O)_6]^{2+}$ (3×10^7 s^{-1}), $[Cd(H_2O)_6]^{2+}$ (2×10^8 s^{-1}) and $[Hg(H_2O)_6]^{2+}$ (2×10^9 s^{-1}).[16]

OPTICALLY ACTIVE COORDINATION COMPOUNDS—XLVI.* RESOLUTION OF TRIS-DI-IMINE COMPOUNDS OF CHROMIUM(III) USING *fac*-(+)TRIS[L-CYSTEINESULPHINATO (2−)-*S,N*]COBALTATE(III)

P. S. CARTWRIGHT, R. D. GILLARD† and E. R. J. SILLANPÄÄ‡

Department of Chemistry, University College, Cardiff CF1 1XL, U.K.

(*Received* 3 *July* 1986)

Abstract—The resolving agent $K_3[Co(L\text{-cysu})_3]\cdot nH_2O$ [cysu = cysteinesulphinato(2−)-*S,N*] is further characterized: $n = 3$ or 6 are distinct compounds. A new solid acid of composition $\{H_3(H_2O)_3[Co(L\text{-cysu})_3]\}$ is described. The new cation tris-5,5′-dimethyl-2,2′-bipyridylchromium(III) is described and its resolution [with those of tris-1,10-phenanthrolinechromium(III) and tris-2,2′-bipyridylchromium(III)].

Schubert[2] studied the reaction between cobalt(III) and L-cysteine in basic aqueous solution, and the reaction of the product with hydrogen peroxide. Neville and Gorin[3] further investigated linkage isomerism in the system, showing that bidentate cysteine coordinates to cobalt(III) via the nitrogen and sulphur atoms. Gorin *et al.*[4] confirmed the mode of coordination, rectified some errors in Neville's earlier paper, and suggested the potential stereoselectivity of the reaction, without further investigating it.

Gillard and Maskill,[5] from chiroptical properties, found stereospecific formation of only one isomer of the tris-cysteinatocobalt(III) complex. Conversion by hydrogen peroxide of thiolate to sulphinate ligand was taken as a chemical correlation of optical configuration. They followed up Schubert's observation[2] that the potassium(+)-tris(L-cysu)cobaltate(III) [cysu = cysteinesulphinato(2−)-*S,N*] forms a precipitate with $[Coen_3]Br_3$ (en = ethylenediamine) by showing that this was a diastereomeric salt, containing the resolved cation, $(+)[Coen_3]^{3+}$. Dollimore and Gillard[6] then used this type of reaction to resolve, for the first time, a series of bis- and tris-chelate bpy and phen derivatives (bpy = 2,2′-bipyridyl, phen = 1,10-phenanthroline), together with the complete series $[Co(en)_x(phen)_{3-x}]^{3+}$ ($x = 0$–3).[7]

More recently, Kane-Maguire and Hallock[8] have used this versatile resolving agent, which lately became available commercially, to resolve the $[Crbpy_3]^{3+}$ cation, previously partially resolved by Mason and Peart,[9] who employed (−)barium tris(catechyl)arsenate(V).

We now report in detail on the synthesis and properties of hydrates of potassium(+)tris(L-cysu)-cobaltate(III) and some derivatives, the resolution of $[Crbpy_3]^{3+}$ (which had already been described[8]), a resolution of $[Crphen_3]^{3+}$ with this resolving agent for the first time,[10] and the preparation and resolution of a new cation, $[Crdmbpy_3]^{3+}$ (dmbpy = 5,5′-dimethyl-2,2′-bipyridyl).

EXPERIMENTAL

Physical measurements

Electronic spectra were measured with Cary 17 and Unicam SP8000 spectrophotometers, calibrated for wavelength and absorbance with holmium oxide and acidified potassium dichromate, respectively.[11] Circular dichroism (CD) spectra were measured using a Jobin Yvon CNRS–Rousel–Jouan Dichrographe III spectrophotometer. IR

spectra were recorded, as Nujol mulls, on a Perkin–Elmer 783. NMR spectra were run on a Bruker WM360 spectrometer. Thermogravimetric analyses were obtained with a Stanton Redcroft thermogravimetric TG 750 balance in a dynamic nitrogen atmosphere at a heating rate of 10°C min^{-1}. Microanalyses (C, H and N) were performed by the microanalytical laboratory, Department of Chemistry, University College, Cardiff.

General

All preparations and reactions involving potassium(+)tris(L-cysu)cobaltate(III) were carried out in vessels shielded from direct light. Solvents were of reagent grade purity.

Preparations

Potassium(+)tris(L-cysu)cobaltate(III). A solution of $[Co(NH_3)_6]Cl_3$ (5.34 g, 0.02 mol) in water (150 cm^3) was deoxygenated (N_2 bubbler, 15–20 min) and L-cysteine (12.12 g, 0.10 mol) and KOH (16.84 g, 0.30 mol) were added. The mixture was heated in the dark at 70°C until ammonia could no longer be detected ($\simeq$ 8 h), then ethanol (150 cm^3) was added. A green precipitate of potassium(+)tris[L-cysteinato-*S,N*]cobaltate(III) formed immediately: the mixture was cooled to 0°C, filtered very rapidly, and the collected solid washed with ethanol (2×50 cm^3). This still-moist precipitate was added slowly ($\simeq$ 1 h) to hydrogen peroxide (100 cm^3, 100 vol), keeping the temperature below 10°C. The resulting mixture was allowed to warm slowly to room temperature during 4 h (to ensure complete oxidation). Ethanol (300 cm^3) was added, and the yellow precipitate of potassium(+)tris(L-cysu)cobaltate(III)·$6H_2O$ filtered off and washed with ethanol (2×50 cm^3). Recrystallization was done in two ways. (a) If ethanol was allowed to diffuse slowly into a concentrated aqueous solution of potassium(+)tris(L-cysu)-cobaltate(III), then long, hair-like yellow crystals of the hexahydrate were obtained (Table 1). (b) If recrystallization was done quickly from water–ethanol (2:1.5 by volume), a more compact material was obtained, analysing again as the hexahydrate. The products were dried for several days *in vacuo* over P_2O_5. The yield typically was 3.1 g (21.0% based on $[Co(NH_3)_6]Cl_3$). The trihydrate was obtained by extended desiccation of the hexahydrate (28 days) *in vacuo* over P_2O_5, the material being fluffier and lighter in colour than the hexahydrate (Table 1).

The yellow, hair-like material is very soluble in water, but insoluble in organic solvents. Attempts to modify the morphology of the crystals, i.e. recrystallizing in the presence of LiBr and urea, failed to give anything but hair-like products.

The complex is formed stereoselectively, the ^{13}C NMR spectrum (Table 2) showing only three lines of equal intensity, indicating formation of the facial isomer, as reported by Dollimore and Gillard.[6,7] Separation of isomers of potassium(+)tris(L-cysu)-

cobaltate(III) was attempted by ion exchange chromatography using QAE Sephadex A-25, but only one band was obtained, the chiroptical properties of samples withdrawn from leading and trailing edges of this band being identical. The CD and UV–visible spectra of potassium(+)tris(L-cysu)-cobaltate(III) compared well with the literature[5,6] (Table 3). The hexahydrate showed IR bands at (cm^{-1}): 3500s, 3250s, 3215s, 1600s, 1305m, 1285w, 1268m, 1208s, 1188s, 1168s, 1110s, 1100s, 1063s, 1050s, 992w, 980w, 936s, 930s, 878m, 871m, 807s, 756m, 730m, 690vw, 555m, 540m, 505w, 470s, 387m, 340m and 290m. The complex is photosensitive, the surface of the solid and a solution becoming dark orange in sunlight over 72 h. The changes in electronic and CD spectra are as those reported by Dollimore and Gillard.[6] The ^{13}C NMR spectrum is much more complex for this photoreduced complex (Table 2), indicating the possible formation of the meridional isomer. However, on standing in bright sunlight for 10 days or more, the resultant pink solution shows a broad, less intense absorption maximum *ca* 525 nm with a much less intense shoulder at 310 nm. The CD spectrum shows a small negative peak at 570 nm, together with positive and negative peaks at 523 and 464 nm, respectively, all with $\Delta\varepsilon$ values much reduced from those of the parent potassium tris(L-cysu)-cobaltate(III) (see Table 3).

Tris-fac-[L-*cysteinesulfinato*(−)-S,N]*cobalt*(III). Typically, sulphuric acid (0.5 M, 2cm^3) was added to potassium(+)tris(L-cysu)cobaltate(III) (100 mg in 5 cm^3 H_2O) to give a yellow solid which was collected and washed with ethanol and ether. This compound is very insoluble in most solvents and analyses as the acid salt (see Table 1) of the (+)tris(L-cysu)cobaltate(III) anion, $\{H_3(H_2O)_3\{Co(L\text{-cysu})_2\}\}$. This acid salt shows IR bands (Nujol mulls) at (cm^{-1}): 3490m, 3280m, 3240s, 3210m, 1730m, 1710s, 1410s, 1378s, 1295w, 1245w, 1222s, 1198s, 1185m, 1168m, 1110s, 1070m, 1060s, 1038m, 980w and 932w. On pH titration of potassium(+)tris(L-cysu)cobaltate(III) vs acid, precipitation began after only 1 mole equivalent of acid was added. The identical CD spectrum of the acid salt redissolved in base to that of the potassium(+)tris(L-cysu)cobaltate(III) showed there was no change in optical configuration on acidification.

Preparation of a Ba^{2+} salt is easy, by simple metathesis, adding an aqueous solution of barium chloride to a concentrated solution of potassium(+)tris(L-cysu)cobaltate(III). However, crystal shape remains very similar. The hair-like, yellow material analyses as the octahydrate, $Ba_3(+)[Co(L\text{-cysu})_3]_2\cdot 8H_2O$ (Table 1).

Tris-di-iminechromium(III)*perchlorate*. These compounds were made by prior isolation of chromium(II) acetate. $HClO_4$ (70 cm^3, 1 M) was allowed to drip onto chromium(II) acetate (3 g) in a nitrogen atmosphere, and the resulting blue solution of Cr(II) filtered through glass wool into a suspension of di-imine (5 g) in water (150 cm^3). The dark precipitate which formed was collected, washed with ethanol, ether and was added to $HClO_4$ (100 cm^3, 1 M), with oxygen bubbled through for several hours. The yellow precipitate of $[Cr(\text{di-imine})_3](ClO_4)_3\cdot nH_2O$ was then collected by filtration and washed with ethanol and ether. The method of recrystallization depended on the di-imine present. For $[Crbpy_3](ClO_4)_3\cdot nH_2O$, recrystallization was

[a] Literature[6] gives λ (ε): 406 (824), and 308 (29,000); λ ($\Delta\varepsilon$): 438 (−3.83), and 274 (−11.9).

[b] Literature[12] gives λ (ε): 455 (260), 398 (900), and 312 (23,000). Literature[8] gives λ ($\Delta\varepsilon$): 460 (+1.1) and 315 (70 ± 10%) read from very small digram of spectrum.

[c] Literature[10] gives λ (ε): 426 (384).

carried out from 0.01 M $HClO_4$, yielding two crystal types. The first-formed crystals were yellow needles, analysing as $n = 2$; orange crystals began to form thereafter, with $n = \frac{1}{2}$ (see Table 1). The electronic spectra of both forms compared with the literature[12] (Table 3).

$[Crphen_3](ClO_4)_3 \cdot 2H_2O$ was quite insoluble in 0.01 M $HClO_4$, and was therefore recrystallized from water, giving small, golden yellow crystals. Only the dihydrate was formed (Table 1). The electronic spectrum (Table 3) compared well with the literature,[10] but the molar extinction coefficients measured here were considerably higher.

The new compound $[Crdmbpy_3](ClO_4)_3 \cdot nH_2O$ was first recrystallized from 0.01 M $HClO_4$ to give flaky yellow plates, analysing as the hexahydrate (Table 1). Cubic yellow crystals of composition $[Crdmbpy_3](ClO_4)_3 \cdot 5H_2O \cdot \frac{1}{2}MeCN$ were obtained by dissolving in the minimum amount of water–acetonitrile (50 : 50 by volume) and allowing slow evaporation of solvents. The complex compound is soluble in acetonitrile, nitromethane, acetone, DMF and DMSO, quite soluble in water and insoluble in ethanol, THF, dichloromethane and ether. $[Crdmbpy_3](ClO_4)_3 \cdot 5H_2O \cdot \frac{1}{2}MeCN$ shows IR bands at (cm^{-1}): 3500mbr, 2250mw, 1606m, 1580m, 1508m, 1320m, 1280w, 1235m, 1148w, 1160m, 1190sbr, 930mw, 835m, 700w, 665m, 654w, 621s, 538w, 508w, 440wsh, 422m, 390w and 366m. The electronic spectrum is shown in Table 3 and Fig. 1.

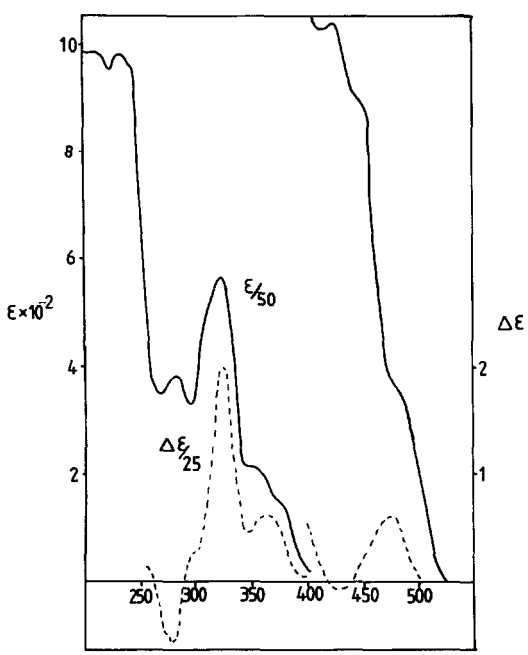

Fig. 1. Electronic absorption (——) and CD (– – – –) spectra of $[Crdmbpy_3]^{3+}$ in water.

Resolution of Δ–Λ$[Cr(di\text{-}imine)_3](ClO_4)_3$. The resolutions were performed in two ways with similar results—the compound was either converted to the chloride salt (Dowex FFIP ion exchange resin, Cl^- form) (cf. Kane-Maguire and Hallock[8]) or a solution of the perchlorate salt was used.

$[Cr(di\text{-}imine)_3]X_3$ (1 mmol) was dissolved in warm water (100 cm^3) and a solution of potassium(+)tris(L-cysu)cobaltate(III)$\cdot 6H_2O$ (0.367 g, 0.5 mmol) in 10 cm^3 water added. For $[Crphen_3]X_3$ and $[Crbpy_3]X_3$, the diastereoisomer (+)$[Cr(di\text{-}imine)_3]$(+)$[Co(L\text{-}cysu)_3]$ was precipitated on cooling in ice for 10 min, and was filtered off, washed with ethanol (25 cm^3) and ether (25 cm^3), and dissolved in 750 cm^3 warm (35°C) water, and ion exchanged for Cl^-. The volume of solution was then reduced to 75 cm^3 and excess $NaClO_4$ added. The (+)$[Cr(di\text{-}imine)_3](ClO_4)_3 \cdot nH_2O$, which separated, was then filtered off, washed with ethanol and ether, and a large excess of $NaClO_4$ added to the filtrate, yielding a more optically active product. The $[Crdmbpy_3]X_3$ gave no diastereomeric precipitate in water. In this case, ethanol was added slowly until precipitation was complete. The same procedure was then adopted, but the more soluble diastereoisomer was dissolved in only 100 cm^3 water.

An excess of $NaClO_4$ was added to the original filtrate, containing (−)$[Cr(di\text{-}imine)_3]^{3+}$, and the resulting precipitate collected and washed with ethanol and ether. An excess of $NaClO_4$ was again added to the filtrate to give a more optically active product. In all cases, the second crop of product, i.e. the more soluble portion, was always the optically pure compound. [$NaClO_4$ could be replaced by $NH_4(PF_6)$ throughout.]

All CD spectral profiles (see Table 3) are consistent with the (+)$[Cr(di\text{-}imine)_3]^{3+}$ cation having the M(C_3) or Λ(C_3) configuration,[13] supported by the fact[6,14] that each (+)$[Cr(di\text{-}imine)_3]^{3+}$ cation forms the less soluble diastereoisomer with the (+)$[Co(L\text{-}cysu)_3]^{3-}$ anion.

It appears also from the CD spectra[6] that (+)$[Mbpy_3]^{3+}$ (M = Cr, Rh or Co) all have related configurations as do (+)$[Mphen_3]^{3+}$.

DISCUSSION

The usefulness of potassium(+)tris(L-cysu)-cobaltate(III) as a means of resolving triply charged cations has been further extended, providing a comparison of configuration within the resolved $[Mbpy_3]^{3+}$ series (M = Cr, Co or Rh), together with a similar comparison within the analogous $[Mphen_3]^{3+}$ series.

Schubert[2] in his original paper, isolated the tri-

hydrate of potassium(+)tris(L-cysu)cobaltate(III) whereas Dollimore and Gillard[6] obtained the hexahydrate. We have obtained both compositions, the trihydrate made from the initially formed hexahydrate by prolonged desiccation *in vacuo*. The structure of potassium(+)tris(L-cysu)colbatate(III) and its photoreduction product have been probed by ^{13}C NMR spectroscopy, and there seems to be a change from facial to meridional geometry on photolysis. The solid trihydrated tribasic acid containing (+)tris(L-cysu)cobaltate(III) has been characterized, the IR spectrum showing a shift of the carboxyl stretching frequency from 1600 to 1700 cm^{-1} on protonation, a process which was found to be reversible, with no loss of optical activity.

A new cation, $[Crdmbpy_3]^{3+}$, has been prepared and resolved, the $(+)[Crdmbpy_3]^{3+}$ having a CD profile consistent with its having the $\Lambda(C_3)$ configuration, as well as forming the less soluble diastereoisomer with potassium(+)tris(L-cysu)-cobaltate(III).

RHODIUM- AND IRIDIUM–MANGANESE CARBONYL COMPLEXES CONTAINING BRIDGING $Ph_2PCH_2PPh_2$ LIGANDS

STUART W. CARR and BERNARD L. SHAW*

School of Chemistry, The University, Leeds LS2 9JT, U.K.

(*Received* 3 *July* 1986)

Abstract—Treatment of *mer,cis*-[$MnCl(CO)_2$(dppm-*PP'*)(dppm-*P*)] with [$Rh_2Cl_2(CO)_4$] in the presence of CO and PF_6^- gives [$Cl(OC)_2Mn(\mu$-dppm$)_2Rh(CO)_2]PF_6$ which might have a bridging chloride ligand. Similar treatment of *mer,cis*-[$MnBr(CO)_2$(dppm-*PP'*)(dppm-*P*)] gave [$Br(OC)_2Mn(\mu$-dppm$)_2Rh(CO)_2]PF_6$ which ^{31}P–{^1H} NMR spectroscopy showed to be a mixture of two closely related species. Treatment of *mer,cis*-[$MnCl(CO)_2$(dppm-*PP'*)(dppm-*P*)] with [$Rh_2Cl_2(CO)_4$] at −30°C probably gave [$Cl(OC)_2Mn(\mu$-dppm$)_2$ $Rh(CO)_2]Cl$ but this decomposes above 0°C: the corresponding dibromide was made similarly and is somewhat more stable than the dichloride. Treatment of *mer,cis*-[$MnX(CO)_2$(dppm-*PP'*)(dppm-*P*)] (X = Cl or Br) with [$IrCl(CO)_2$(*p*-toluidine)] and CO–PF_6^- gave [$X(OC)_2Mn(\mu$-dppm$)_2Ir(CO)_2]PF_6$. Neutral complexes of type [$X(OC)_2Mn(\mu$-dppm$)_2Ir(CO)X'$] (X and X′ = Cl or Br) are very labile and rapidly decompose to give $[Ir(CO)$(dppm-*PP'*$)_2]^+$ and other (unidentified) products. Treatment of *mer,cis*-[$MnX(CO)_2$(dppm-*PP'*)(dppm-*P*)] with [$RhH(CO)(PPh_3)_3$] gave [$X(OC)Mn(\mu$-dppm$)_2(\mu$-H)(μ-CO)Rh(CO)] (X = Cl or Br). These heterobimetallic compounds generally showed broad ^{31}P–{^1H} resonances for the *P* nuclei bonded to Mn at *ca* 20°C due to some coupling with the ^{55}Mn nucleus ($I = \frac{5}{2}$, 100% abundant), but at −30°C these resonances sharpened up due to more rapid quadrupolar relaxation at the lower temperature. NMR and IR data are given.

RESULTS AND DISCUSSION

In a previous paper[1] we showed that manganese(I) complexes of type [$MnX(CO)_2$(dppm-*PP'*)(dppm-*P*)] (dppm ≡ $Ph_2PCH_2PPh_2$) of configurations **1a** (X = Cl) or **1b** (X = Br) underwent ring-opening reactions with platinum complexes, e.g. [$Pt(PPh_3)_4$] or *trans*-[$PtHCl(PPh_3)_2$], to give mixed manganese–platinum complexes containing the moiety $Mn(\mu$-dppm$)_2Pt$. In the present paper we describe similar attempts to effect ring-opening reactions with rhodium(I) or iridium(I) carbonyl derivatives.

In preliminary (NMR) studies we found that treatment of complexes of types **1a** or **b** with [$Rh_2Cl_2(CO)_4$] or [$IrCl(CO)_2$(*p*-toluidine)] gave cationic heterobimetallics but these were labile (see below), and more stable products could be obtained by mixing these reactants in the presence of CO and a large anion, such as PF_6^-. These salts with PF_6^- will be discussed first.

Treatment of a solution of the chloro complex (**1a**) with the equivalent amount of [$Rh_2Cl_2(CO)_4$] in the presence of CO and NH_4PF_6 gave a salt, formulated as [$Cl(OC)_2Mn(\mu$-dppm$)_2Rh(CO)_2$] PF_6. The formulation follows from the elemental analysis (Table 1) and the spectroscopic data. In particular the ^{31}P–{^1H} NMR spectrum, at −30°C, showed a pattern typical of an AA′XX′M spin system (M = ^{103}Rh) with deceptively simple triplets and $|^2J(P_AP_X)+{}^4J(P_AP_{X'})| = 54$ Hz (data in Table 2). There was also a resonance due to PF_6^-. At higher temperatures the resonance pattern of the *P* nuclei bonded to manganese broaden due to a slowing down of the quadrupolar relaxation of the ^{55}Mn nucleus ($I = \frac{5}{2}$, 100% abundant). The ^1H–{^{31}P} NMR spectrum of [$Cl(OC)_2Mn$

[f] Major isomer.
[g] Minor isomer.

(μ-dppm)$_2$Rh(CO)$_2$]PF$_6$ showed an AB pattern due to the CH_2 protons (data in Table 2). The IR spectrum (Nujol mull) of this complex showed bands at 1858w, 1885w, 1942s and 1999s cm^{-1}, indicative of terminal C≡O, with the possibility of a weak bridging interaction associated with the lowest-frequency band. Bridging carbonyls are common in bimetallic-μ-dppm chemistry.[2-6] Sometimes the bridging is strong and of the "ketonic" type as in [ClPd(μ-CO)(μ-dppm)$_2$PdCl],[2] sometimes it is strong and sideways on (σ, π) as in [(OC)$_2$Mn(μ-CO)(μ-dppm)$_2$Mn(CO)$_2$],[3-5] but frequently it is weak, such as in [(OC)$_2$Mn(μ-CO)(μ-dppm)$_2$PdBr][6] and many other complexes. A band at 225 cm^{-1}, absent from the spectrum of the corresponding bromide (see below), is tentatively assigned to a bridging chlorine, i.e. the cation is formulated as [(OC)$_2$Mn(μ-Cl)(μ-dppm)$_2$Rh(CO)$_2$]$^+$. Treatment of the bromo complex (**1b**) with CO–NH$_4$PF$_6$ and [Rh$_2$Cl$_2$(CO)$_4$] or [Rh$_2$Br$_2$(CO)$_4$] gave a corresponding product, [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]PF$_6$.

Elemental analytical data for this complex are given in Table 1 together with IR data [ν(CO)]. The ^{31}P–{^{1}H} NMR spectrum of this product, at −30°C showed it to be a mixture of two closely related complexes (data in Table 2): possibly one isomer has bridging Br and the other bridging (semi-bridging) CO. At higher temperatures the resonance pattern of the phosphorus atoms bonded to manganese broadened due to a slowing down of the quadrupolar relaxation of the manganese nucleus. The spectra at −30 and +21°C are shown in Fig. 1. The ^{1}H–{^{31}P} NMR spectrum of [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]PF$_6$ at +20°C showed a broad AB pattern, which separated into two well-defined AB patterns at −20°C [see Fig. 2 (data in Table 2)]. We find that these products of type [X(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]PF$_6$ (X = Cl or Br) are stable in CH_2Cl_2 solutions at 20°C over a period of a week (^{31}P–{^{1}H} NMR evidence). Also, from NMR evidence, they did not react with NaOPr^i, NaOMe, H$^+$ or Et$_3$BH$^-$ at 20°C. When treated with TlBF$_4$ (1 equivalent) and CNMe or CNBu^t they reacted to give a mixture of products, which we did not separate.

In a ^{31}P–{^{1}H} NMR study we found that [MnCl(CO)$_2$(dppm-*PP'*)(dppm-*P*)] (**1a**), when treated with an equivalent amount of [Rh$_2$Cl$_2$(CO)$_4$] in CD_2Cl_2 at −30°C, gave a heterobimetallic containing an Mn(μ-dppm)$_2$Rh moiety in high yield (data in Table 2). However, when allowed to warm up, e.g. to above 0°C, this product decomposed to give a mixture, and no bimetallic complex was isolated. The corresponding dibromide [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]Br was much more stable and was made by treating [MnBr(CO)$_2$(dppm-*PP'*)(dppm-*P*)] with [Rh$_2$Br$_2$(CO)$_4$] at *ca* 20°C. The product was obtained analytically pure (see Table 1), and was characterized by NMR and IR spectroscopy (Tables 1 and 2). It was stable in dichloromethane solution for about 2 h at 20°C, but then started to decompose. Treatment of **1b** with [Rh$_2$Cl$_2$(CO)$_4$] gave a product, formulated as [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]Cl (characterizing data in Tables 1 and 2). Details of the preparation of both these complexes are given in Experimental. We also converted [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]PF$_6$ into [Br(OC)$_2$Mn(μ-dppm)$_2$Rh(CO)$_2$]Br by treating it with an excess of Me$_4$NBr in a dichloromethane–methanol mixture at 21°C. Details are in Experimental.

We also prepared the manganese-iridium cationic complexes [X(OC)$_2$Mn(μ-dppm)$_2$Ir(CO)$_2$] (X = Cl or Br) as the PF$_6$ salts, by treating [MnX(CO)$_2$(dppm-*PP'*)(dppm-*P*)] with [IrCl(CO)$_2$(*p*-toluidine)] in an atmosphere of CO and in the presence of NH$_4$PF$_6$. Preparative details are in Experimental and characterizing data in Tables 1 and 2. As with the corresponding rhodium complexes, discussed above, the bromide showed the presence of two complexes (isomers), whereas the chloride showed only one.

Neutral species of type [X(OC)$_2$Mn(μ-dppm)$_2$Ir(CO)X'] are very labile, more labile than the rhodium analogues. Treatment of [MnBr(CO)$_2$(dppm-*PP'*)(dppm-*P*)] with [IrCl(CO)$_2$(*p*-toluidine)] gave a solid product, formulated as [Br(OC)$_2$Mn(μ-dppm)$_2$IrCl(CO)], which was not obtained pure, and in CD_2Cl_2 solution decomposed to give [Ir(CO)(dppm-*PP'*)$_2$]$^+$[7], and other (unidentified) products. Considerable amounts of [Ir(CO)(dppm-*PP'*)$_2$]$^+$ were detected by ^{31}P–{^{1}H} NMR spectroscopy *ca* 10 min after dissolution of [Br(OC)$_2$Mn(μ-dppm)$_2$IrCl(CO)] in CD_2Cl_2 at 20°C. Treatment of [X(OC)$_2$Mn(μ-dppm)$_2$Ir(CO)$_2$]$^+$ with LiX or Me$_4$NX (X = Cl or Br), did not give any detectable quantity of [X(OC)$_2$Mn(μ-dppm)$_2$IrX(CO)]: instead [Ir(CO)(dppm-*PP'*)$_2$]$^+$[7] was formed.

We have also treated [RhH(CO)(PPh$_3$)$_3$] with [MnX(CO)$_2$(dppm-*PP'*)(dppm-*P*)] (X = Cl or Br) in hot benzene. This gave heterobimetallics of the expected composition [X(OC)$_2$Mn(μ-dppm)$_2$RhH(CO)] (preparative details are in Experimental and characterizing data in Tables 1 and 2). In particular the ^{31}P–{^{1}H} NMR spectra showed AA'XX'M patterns (Table 2). The ^{1}H–{^{31}P} NMR spectra at 21°C showed AB CH_2 patterns and a hydride resonance at δ *ca* −17, with couplings to ^{103}Rh of 28–29 Hz. Selective decoupling, ^{1}H–{^{31}P},

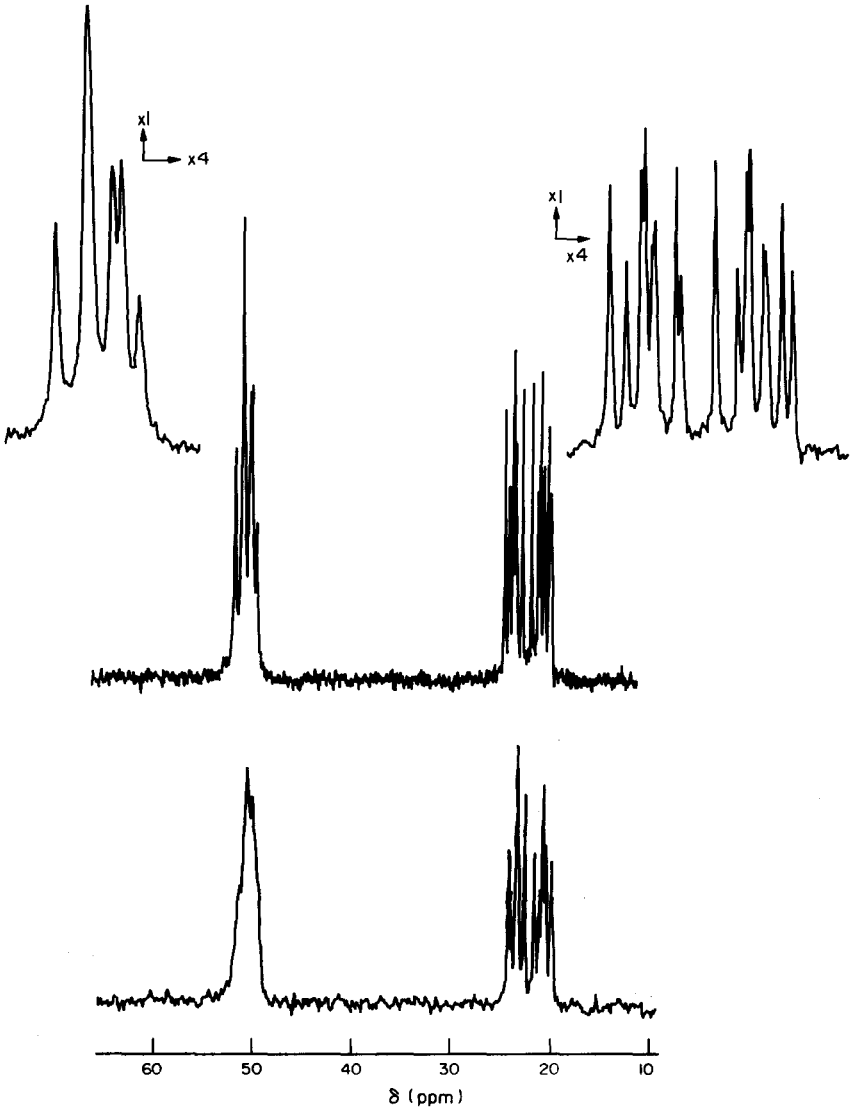

Fig. 1. $^{31}P-\{^1H\}$ NMR spectrum of $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$ (mixture of two isomers) in CD_2Cl_2 at: (a) 21°C, and (b) −30°C.

of each P in turn gave ^1H patterns of the AA′MP and XX′MP types, i.e. the hydride is coupled to all four P nuclei. This result suggests that the hydride is bridging. We tentatively formulate these compounds as $[X(OC)Mn(\mu\text{-H})(\mu\text{-dppm})_2(\mu\text{-CO})Rh(CO)]$: one of the bands due to ν(CO) is at the very low value of 1760 cm^{-1} (Table 2), indicative of bridging CO.

EXPERIMENTAL

All reactions were performed in an atmosphere of dry dinitrogen in degassed solvents. Dichloromethane was dried over molecular sieves (type 4A) and benzene over sodium wire. IR spectra were recorded in either Nujol mulls between KBr plates or in dichloromethane solution on a Perkin–Elmer 257 grating IR spectrometer. Unless otherwise stated, NMR spectra were recorded on a JEOL FX100 instrument at 99.55 MHz (^1H) or 40.25 MHz (^{31}P) using solvent references as internal standards and referenced to TMS or 85% H_3PO_4 as appropriate.

$[Cl(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$

A solution of $[Rh_2(CO)_4Cl_2]$ (0.020 g, 0.055 mmol) in dichloromethane (1 cm^3) was added dropwise to a stirred mixture of *mer,cis*-$[Mn(CO)_2$(dppm-*PP′*)(dppm-*P*)Cl]^1 (0.100 g, 0.11 mmol) dissolved in dichloromethane (10 cm^3) and ammonium hexafluorophosphate (0.18 g, 1.1 mmol) in methanol

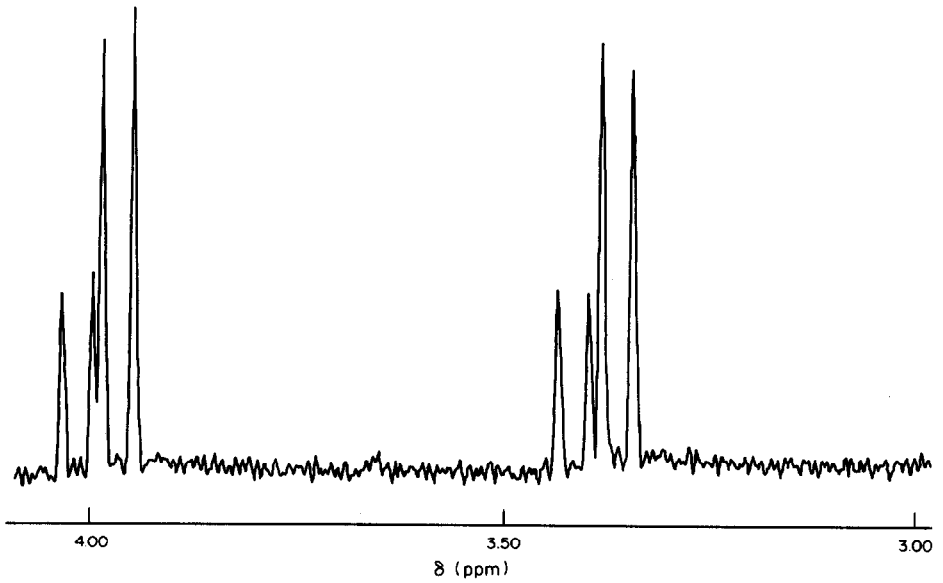

Fig. 2. ^1H–$\{^{31}P\}$ NMR spectrum of the PCH_2P region of $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$ (mixture of two isomers) in CD_2Cl_2 at −30°C.

(10 cm^3) with CO bubbling into the solution. Upon addition of the $[Rh_2(CO)_4Cl_2]$ a bright yellow solution resulted which was stirred under CO for an hour. The resulting mixture was evaporated to dryness under reduced pressure. The required product was extracted into dichloromethane, the solution filtered, and *n*-hexane added until the solution became turbid. This mixture was set aside at −20°C for several hours to give a yellow microcrystalline solid. Yield 0.091 g (68%). The bromo analogue $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$ was prepared by a similar procedure from *mer,cis*-$[Mn(CO)_2$(dppm-*PP'*)(dppm-*P*)Br] and $[Rh_2(CO)_4Cl_2]$ or $[Rh_2(CO)_4Br_2]$ in 78 and 79% yield, respectively.

$[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]Br$

Using $[Rh_2(CO)_4Br_2]$. A solution of $[Rh_2(CO)_4Br_2]$ (0.023 g, 0.047 mmol) in dichloromethane (1 cm^3) was added dropwise to a solution of *mer,cis*-$[Mn(CO)_2$(dppm-*PP'*)(dppm-*P*)Br] (0.100 g, 0.095 mmol) in dichloromethane (5 cm^3) to give a clear yellow solution. *n*-Hexane was then added to precipitate the product which was collected and washed with diethyl ether to give a yellow microcrystalline solid. Yield 0.091 g (81%). The analogous bromide–chloride complex $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]Cl$ was prepared similarly in 83% yield.

From $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$. A solution of $[Br(CO)_2Mn(\mu\text{-dppm})_2Rh(CO)_2]PF_6$ (0.120 g, 0.095 mmol) in dichloromethane (20 cm^3) was added to a degassed solution of tetramethylammonium bromide (0.240 g, 1.56 mmol) in methanol (20 cm^3). The volume of the mixture was reduced slowly to *ca* 20 cm^3 under reduced pressure. The yellow microcrystalline product was collected and washed with water, methanol and diethyl ether. Yield 0.077 g (69%).

$[Cl(CO)_2Mn(\mu\text{-dppm})_2Ir(CO)_2]PF_6$

A solution of $[Ir(CO)_2Cl$(*p*-toluidine)] (0.043 g, 0.11 mmol) in dichloromethane (2 cm^3) was added dropwise to a stirred mixture of *mer,cis*-$[Mn(CO)_2$(dppm-*PP'*)(dppm-*P*)Cl] (0.100 g, 0.11 mmol) dissolved in dichloromethane (15 cm^3), and ammonium hexafluorophosphate (0.087 g, 0.55 mmol) in methanol (10 cm^3), with CO bubbling into the mixture. The resulting yellow solution was stirred under CO for 1 h. The resulting mixture was evaporated to dryness under reduced pressure. The required product was extracted into dichloromethane, the solution filtered, and *n*-hexane added until the solution became turbid. The mixture was then set aside at −20°C for several hours to give a yellow microcrystalline solid. Yield 0.097 g (71%). The bromo analogue $[Br(CO)_2Mn(\mu\text{-dppm})_2Ir(CO)_2]PF_6$ was prepared analogously in 85% yield.

$[Br(CO)_2Mn(\mu\text{-dppm})_2Ir(CO)Cl]$

A solution of $[Ir(CO)_2Cl$(*p*-toluidine)] (0.037 g, 0.095 mmol) in dichloromethane (1 cm^3) was added

to a solution of [Mn(CO)$_2$(dppm-*PP'*)(dppm-*P*)Br] (0.100 g, 0.095 mmol) in dichloromethane (5 cm^3). The resultant orange solution was stirred for 2 min and evaporated to dryness under reduced pressure. The resultant solid was triturated with diethyl ether to give an orange microcrystalline solid. Yield 0.097 g.

[Cl(CO)Mn(μ-dppm)$_2$(μ-H)(μ-CO)Rh(CO)]

A mixture of [MnCl(CO)$_2$(dppm-*PP'*)(dppm-*P*)] (0.100 g, 0.11 mmol) and [RhH(CO)(PPh$_3$)$_3$] (0.100 g, 0.11 mmol) was refluxed in benzene (5 cm^3) for 2 h. The resulting brown solution was cooled to ambient temperature. Light petroleum (b.p. 30–40°C) (10 cm^3) was then added and the mixture set aside at 5°C for *ca* 3 h. A brown microcrystalline solid product was collected. Yield 0.088 g (73%). The bromo analogue [Br(CO)Mn(μ-dppm)$_2$(μ-H)(μ-CO)Rh(CO)] was prepared similarly in 77% yield.

Department of Chemistry, The Pennsylvania State University, University Park, PA 16802, U.S.A.

CONTENTS

I. BACKGROUND

Phosphazene chemistry† is a well-established field that lies at the interface between inorganic and organic chemistry. Its origins can be traced back to the early 1800s when several investigators[1–5]

* Author to whom correspondence should be addressed.

† This field was known as phosphonitrilic chemistry in the early literature.

isolated and studied two unusual heterocyclic compounds with formulae $(NPCl_2)_3$ and $(NPCl_2)_4$ from the reaction of phosphorus pentachloride with ammonia or ammonium chloride.

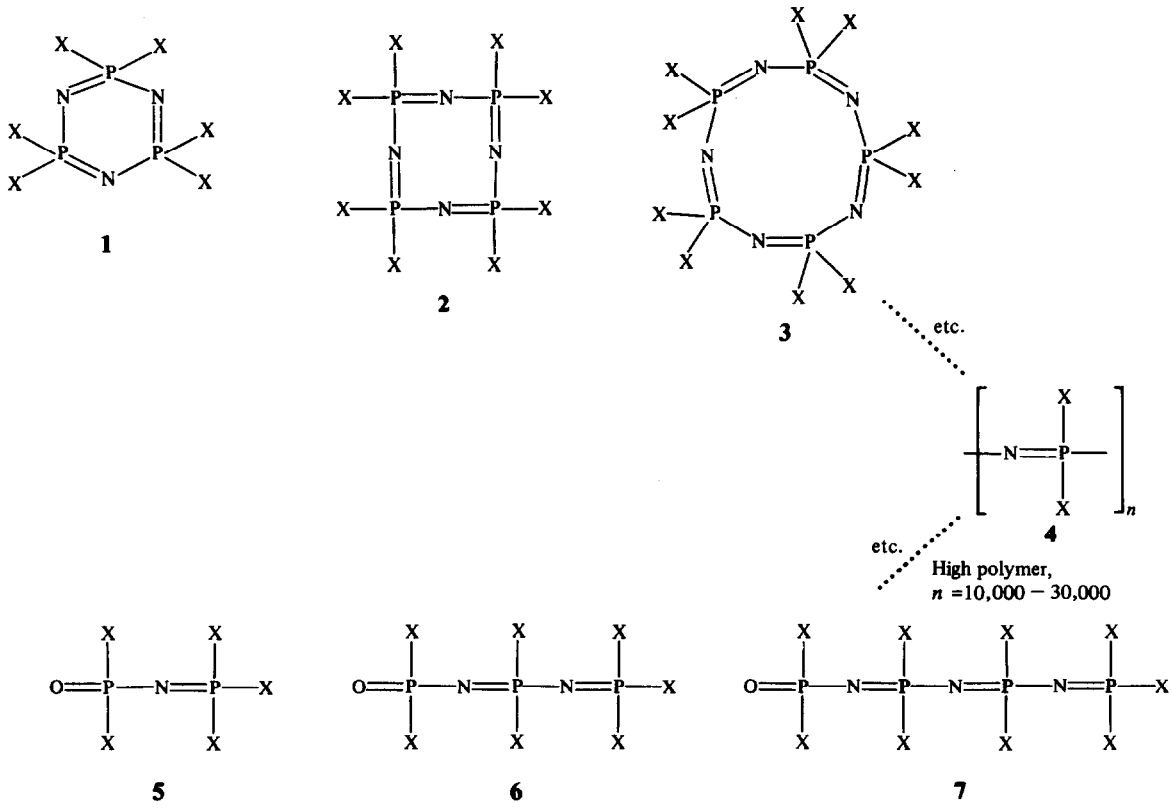
Since that time, a diverse class of ring systems and linear species has been developed,[6] all the members of which are characterized by a cyclic or linear skeleton of alternating phosphorus and nitrogen atoms, with two side groups attached to each phosphorus. Some typical general structures are shown in **1–4** (Scheme 1). In addition, a subclass exists, comprised of short-chain linear phosphazenes (**5–7**) (Scheme 1) with terminal phosphorus atoms that bear three end groups. The side groups in **1–7** can be halogens or a wide variety of organic or organometallic units.

Perhaps the most striking characteristic of phosphazenes is the existence of extensive polymeric series of rings (**1–3**) and linear chains (**5–7**) that culminate in very high molecular weight polymers (**4**).[6,7] Some of these polymers are known to be linear, but the possibility exists that others are giant macrocyclic species. Ring systems that contain up to 40 repeating units have been detected[8] and larger rings are undoubtedly accessible. Short-chain linear species of type **5–7** are known that contain up to six phosphorus atoms, but this class almost certainly extends as a continuous series that culminates in linear high polymers. A resemblance to the organosiloxane polymeric series will be evident.

Of these three classes of phosphazenes (rings, short chains and high polymers), the least is known about the short-chain species. They are generally difficult to synthesize, isolate and study,[6] and only a few of them have been characterized in detail.[9] However, they are valuable because of their role as small-molecule reaction and structural models for the high polymers.[9]

The structural chemistry and organic-reaction chemistry of cyclic phosphazenes comprises by far the most established branch of this area. The organometallic chemistry is still in the developmental stage. An important facet of cyclophosphazene chemistry is its relationship to the high-polymer chemistry, since small-molecule rings are excellent models for exploratory reactions that can be applied subsequently at the high-polymer level.[10]

The linear or macrocyclic high polymers (**4**) have been known for only a few years,[11–14] but already they form the basis of an extensive chemistry and a growing industrial technology.[15] In a



Scheme 1.

practical sense, the high-polymer chemistry provides the driving force for nearly all modern research on phosphazenes.

Historically, the development of phosphazene chemistry can be divided into three phases. Initially, from the 1800s to the 1940s, an emphasis on the Main-Group inorganic chemistry of these compounds was evident.[6] During this period, the synthesis and hydrolysis reactions of halogenophosphazenes [structures **1** and **2** (X = Cl)] were developed.[16]

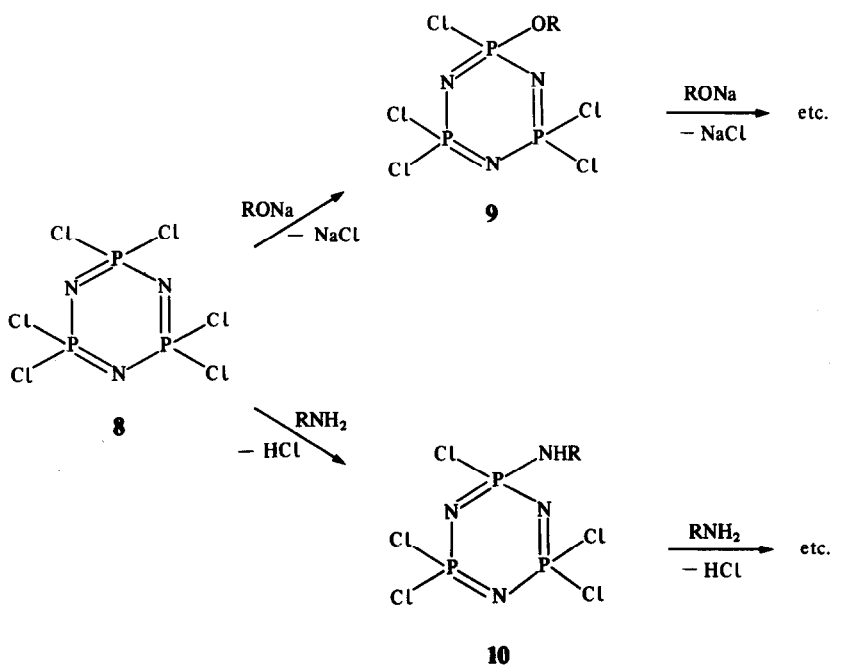
Beginning in the 1950s and extending into the early 1970s, the second phase involved the development of the organic chemistry of cyclophosphazenes.[17–24] Most of this work revolved around the nucleophilic substitution reactions of chlorocyclophosphazenes such as $(NPCl_2)_3$ (**8**) or $(NPCl_2)_4$ with reagents such as simple alkoxides, aryloxides, or primary or secondary amines. Examples of these transformations are shown in the formation of **9** and **10** (Scheme 2). Much of this chemistry involved studies of the substitution mechanisms (S_N1 or S_N2), and the patterns of halogen replacement (*gem* or non*gem*, and *cis* or *trans*), often aided by NMR analysis and, in a few cases, by X-ray diffraction studies.[6,17–24]

The most recent phase, which began in the late 1960s and early 1970s, has been characterized by three main research thrusts: (a) investigation of the detailed structure of phosphazenes, especially by NMR spectroscopy and X-ray diffraction; (b) development of the high-polymer chemistry in both its fundamental and use-oriented aspects; and (c) the emergence of a diverse organometallic chemistry of phosphazenes. This latter topic is the subject of this review.

II. ORGANOMETALLIC CHEMISTRY—OVERVIEW

To understand the present significance of the organometallic chemistry of phosphazenes, it is necessary to consider some of the reasons for the widespread interest in the macromolecular chemistry of these compounds.

High polymers, in general, are the focus of much research because: (a) in the solid state they form fibers, films, glasses and elastomers that are widely used in modern technology; and (b) because, increasingly, macromolecules are being employed as biomedical materials; immobilization carriers for chemotherapeutic agents, enzymes or transition-metal catalysts; as solid electrolytes; and as electronic conductors. Phosphazene high polymers are being developed or considered for use in all these areas.[15,25–34]



8 **9** **10**

Scheme 2.

Phosphazene high-polymer chemistry began with its organic-derivative chemistry. The main synthesis pathways leading to these macromolecules were discovered in our laboratories and are summarized in Scheme 3. Hexachlorocyclotriphosphazene (**8**), prepared from phosphorus pentachloride and ammonium chloride, is polymerized thermally in the molten state to the transparent, rubbery high polymer, poly(dichlorophosphazene) (**11**).[11] Replacement of the chlorine atoms in **11** by organic nucleophiles yields a wide variety of single- and mixed-substituent derivatives of general formulae **12**–**14**.[11–15] Given the wide variety of organic nucleophiles available to chemists, it is clear that an almost infinite variety of different polymer structures and properties are accessible via these reactions. By the beginning of 1986, roughly 300 different organophosphazene polymers had been synthesized and studied.

Interest in the organometallic chemistry of phosphazenes has expanded mainly because it was perceived (at least in our research group) that the use of organometallic reagents instead of organic nucleophiles as substitution reagents might allow the synthesis of two new classes of cyclo- and polyphosphazenes—those with alkyl or aryl groups linked directly to the inorganic skeleton through carbon–phosphorus bonds, and those with transition-metal organometallic units in the side-group structure.

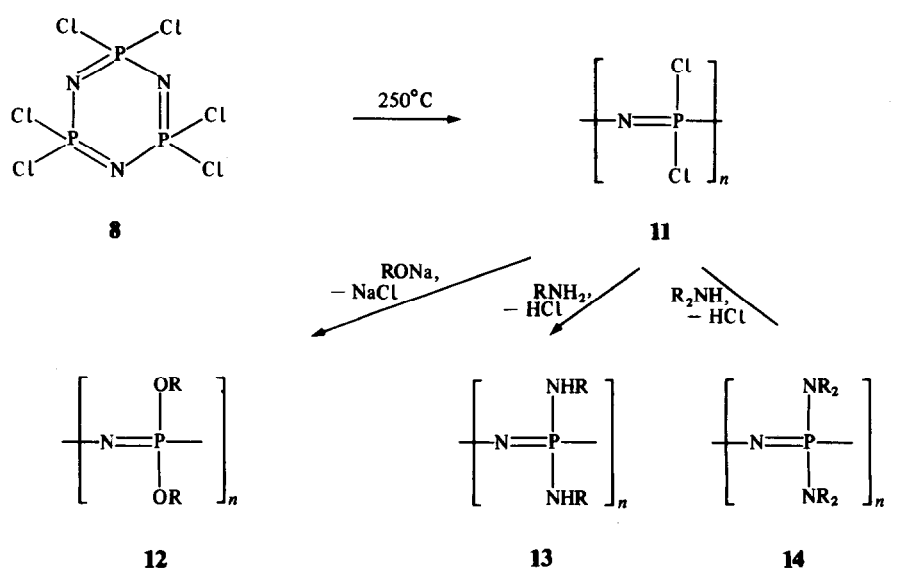
High-polymeric phosphazenes with alkyl or aryl side groups should be chemically unreactive and stable at high temperatures [they would be structural analogues of poly(organosiloxanes)]. The alkyl or aryl groups could be introduced at the cyclic trimer or tetramer level, in which case the resultant organosphophazenes would be candidates for ring-opening polymerization to high polymers. Alternatively, the alkyl or aryl groups could be introduced directly at the macromolecular level by reactions analogous to those shown in Scheme 3. These possibilities are illustrated in Scheme 4. Polyphosphazenes with transition metals in the side-group structure would be valuable molecules for a wide variety of studies related to catalysts, electrode mediators, electronic conductors etc.

In this review, we discuss both types of chemistry, beginning with the reactions of phosphazenes with Main-Group organometallic reagents followed by the transition-metal chemistry. We will mention work from a number of sources, but, in the second half of the review, we will focus mainly on recent work from our own laboratory.

III. REACTIONS WITH MAIN-GROUP ORGANOMETALLIC REAGENTS

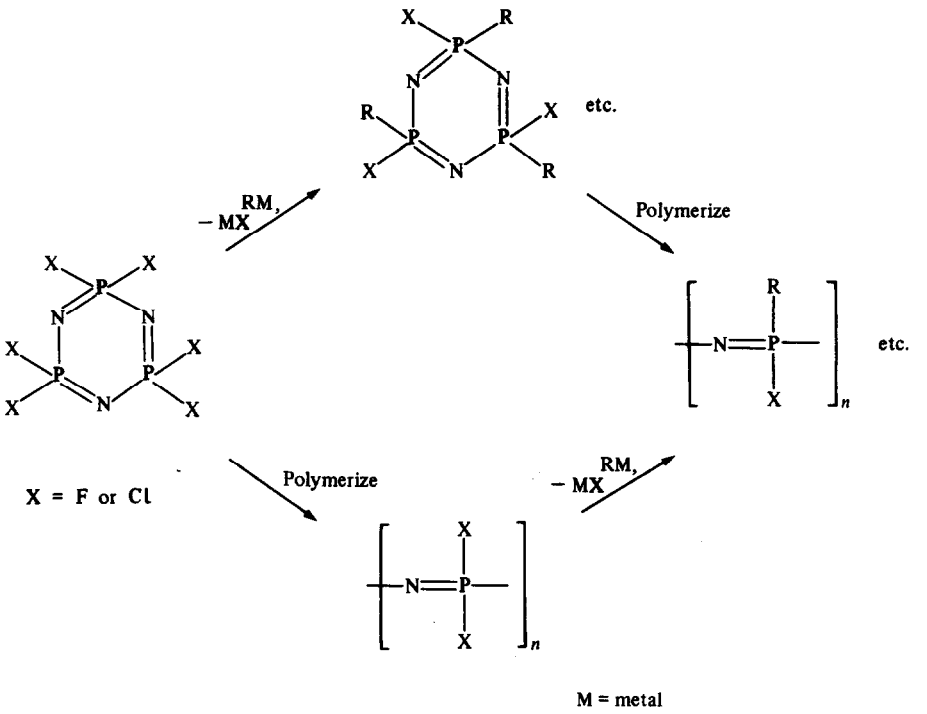
1. *General factors*

The reactions between halogenophosphazenes and Main-Group organometallic reagents have been studied in detail during the past 20 years. These reactions can be complex, and some of the



8 **11** **12** **13** **14**

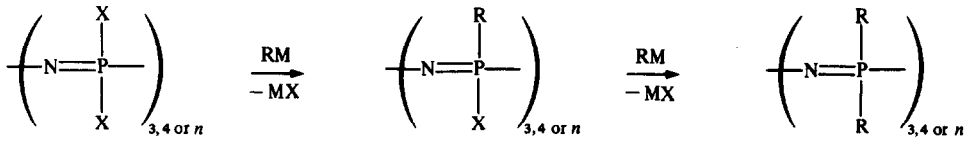
Scheme 3.



Scheme 4.

earlier work in this area has had to be reinterpreted as the degree of complexity has been recognized.

By analogy with the organic substitution chemistry of phosphazenes, it was originally assumed that organometallic compounds, such as Grignard or organolithium reagents, would participate in simple substitution reactions with halogenophosphazenes to yield alkyl or aryl derivatives of general formulae **15** or **16** [eqn (1)]. However, it is now known that nucleophilic substitution is only one of several reactions that can take place; the others include metal–halogen exchange, proton abstraction from organic side groups, and skeletal cleavage reactions.



(1)

15 **16**

The exact course of the reaction depends on the type of organometallic reagent used. However, a more critical influence is exerted by the type of phosphazene. Chlorophosphazenes often generate quite different reaction patterns from fluorophosphazenes. Moreover, the degree of polymerization plays a significant role. Cyclic trimers react in a different manner from cyclic tetramers, and linear high polymers may show striking differences from the cyclic oligomers. For this reason, our discussion of the Main-Group organometallic chemistry is divided into four categories, based on the type of phosphazene substrate that is involved. These categories are: (1) organometallic reactions with cyclic fluorophosphazenes; (2) reactions with cyclic chlorophosphazenes; (3) reactions of high-polymeric, linear fluoro- and chlorophosphazenes; and (4) interactions between organometallic reagents and organophosphazenes, i.e. species that bear organic side groups that are capable of reactions with organometallic compounds.

2. *Reactions of cyclic fluorophosphazenes*

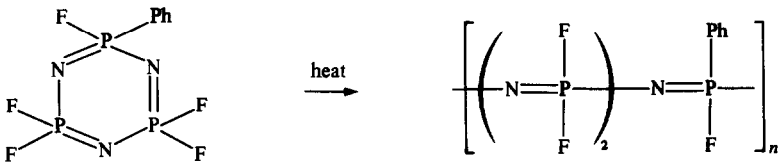
(a) *Aryllithium reagents.* The simplest reactions between halogenophosphazenes and Main-Group organometallic compounds are those between small-molecule cyclic *fluoro*phosphazenes

and aryllithium reagents. The key experiments with this system were performed by Moeller and coworkers,[35–38] starting in 1962, and the topic was subsequently developed by Allen, Paddock and Chivers.[38–44] The overall transformations at the cyclic-trimer level are summarized in eqn (2).

$$\underset{\textbf{17}}{(NPF_2)_3} \xrightarrow[-LiF]{ArLi} \underset{\textbf{18}}{N_3P_3F_{6-n}Ar_n} \qquad (2)$$

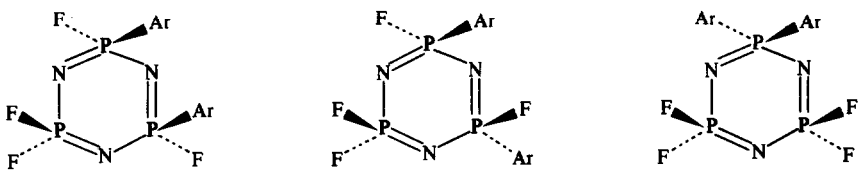
Arylphosphazene derivatives have been isolated in which the aryl side group is C_6H_5, $C_6H_3D_2$, C_6D_5, C_6F_5, *p*-C_6H_4F, *m*-C_6H_4F, *p*-C_6H_4Cl, *p*-$C_6H_4OCH_3$, *o*-$C_6H_4CH_3$, *p*-$C_6H_4CH_3$ and *p*-$C_6H_4N(CH_3)_2$.

The main products are the mono- and disubstituted species, but replacement of the remaining four fluorine atoms is difficult to accomplish by this method. A maximum of four fluorine atoms can be replaced by a combination of aryllithium and Friedel–Crafts reactions,[37–39,42,43] but the reactivity to fluorine replacement clearly declines as additional aryl groups are attached to the phosphazene ring. Species of type **18** have been used to probe the nature of the electronic interactions between the organic and inorganic pi systems.[39,41,44] They are also valuable molecules for polymerization to alkylfluorophosphazene high polymers (**20**) [eqn (3)].[45]



19 **20** $n \approx 1000$ (3)

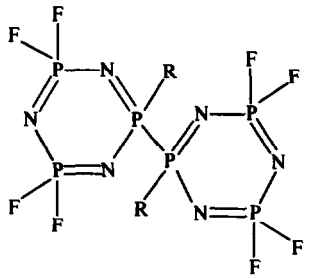
The fluorine replacement pattern that occurs in the conversion of **17** to **18** has been studied in some detail.[46] At the disubstitution stage, three geometrical isomers (excluding enantiomers) are possible (**21–23**). Aryllithium reagents react predominantly via a 1,3-replacement pathway. For example, $(NPF_2)_3$ interacts with two equivalents of phenyllithium to give **21**, **22** and **23** in a 3 : 1 : 0.25 ratio.[36] The more sterically sensitive *o*-$CH_3C_6H_4Li$ reagent gives the 1,3-product only.



21 1,3 - *cis* (non*gem*) **22** 1,3 - *trans* (non*gem*) **23** 1,1- (*gem*)

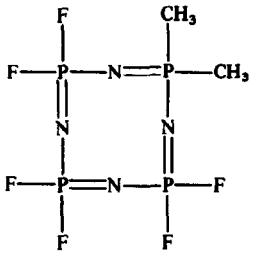
These reactions of $(NPF_2)_3$ with aryllithium reagents are striking in their simplicity when compared to the systems to be discussed. For example, aryl Grignard reagents react with $(NPF_2)_3$ by a more complex pathway,[43,47] since products such as the bi(cyclophosphazene) (**24**)[43] are formed. Species of this structure are normally formed by a metal–halogen exchange process.

(b) *Alkyllithium reagents.* The cyclic trimer $(NPF_2)_3$ reacts with methyl- *n*-butyl-, *t*-butyl or cyclohexyllithium reagents to give mainly monosubstituted products of formula $N_3P_3F_5Alk$.[35,48–52] Small amounts of geminal disubstituted products, $N_3P_3F_4Alk_2$, are also formed when methyl- or *n*-butylithium are used.[48,50,51] *t*-Butyllithium gives the non*gem*–*trans* derivative. Presumably geminal substitution is difficult because of steric hindrance effects. It is believed that methyl- and *n*-butyllithium reagents can not only participate in fluorine substitution processes, but many also induce proton abstraction from the alpha position of alkyl groups already attached to the ring. This reaction can lead to decomposition reactions.

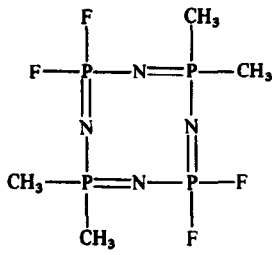


24

Paddock and coworkers[48,53] have made a detailed study of the reactions of methyllithium with octafluorocyclotetraphosphazene, $(NPF_2)_4$. The reaction proceeds predominantly via a 1,1- and 1,1,5,5-fluorine replacement pathway to give species **25** and **26**. Electronic effects within the inorganic ring have been proposed to explain this pattern. However, further fluorine replacement can occur to give the permethyl derivative, $[NP(CH_3)_2]_4$.[48,54] Higher cyclic analogues, such as $(NPF_2)_{6-10}$, react with methylmagnesium bromide to yield $[NP(CH_3)_2]_{6-10}$.[55] *t*-Butyllithium replaces up to two fluorine atoms in $(NPF_2)_4$.[50]



25



26

An appreciable amount of research has been carried out recently by Allen and others on the reactions of unsaturated alkyllithium reagents with $(NPF_2)_3$ and $(NPF_2)_4$.[49,56–60] A motivation for some of this work has been the synthesis of cyclophosphazenes that undergo vinyl- or acetylenic polymerization through the pendent organic reactive site.[46,61,62] Thus, compounds of formula $N_3P_3F_5R$ have been prepared where R is $CH_2{=}CH{-}$, $CH_3CH{=}CH{-}$, $CH_2{=}C(CH_3){-}$, $CH_2{=}C(OC_2H_5){-}$, $CH_2{=}C(OCH_3){-}$, $C_6H_5C{\equiv}C{-}$ or $(CH_3)_3SiC{\equiv}C{-}$. In general, further reaction yields 1,1-disubstituted products.[56–59] Electron donation from the α-CH_3O or α-C_2H_5O substituents favors substitution.[56,57] This electron supply renders the olefinic center less susceptible to anionic attack and subsequent degradation.

2-Lithio-1-methylpyrrole reacts with $(NPF_2)_{3-6}$ to replace one fluorine atom per ring.[60]

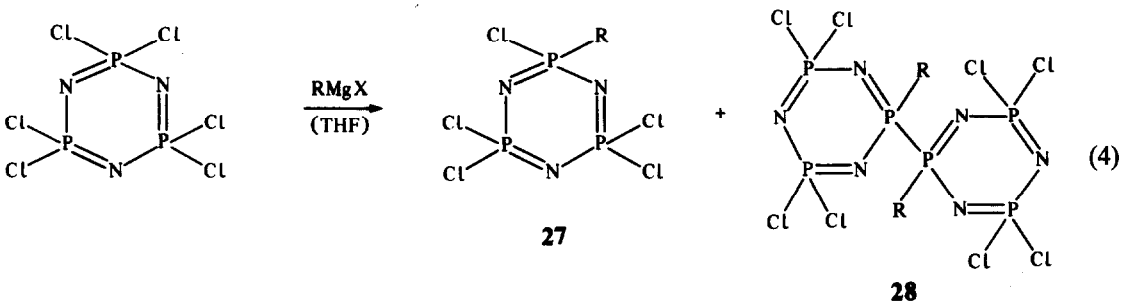
3. *Reactions of cyclic chlorophosphazenes*

(a) *Grignard reagents.* Cyclic *chloro*phosphazenes participate in the widest variety of organometallic reactions. Substitution reactions, skeletal cleavage, metal–halogen exchange, ether cleavage, and ring-contraction processes have all been detected. The preponderance of one reaction over another depends on the type of organometallic reagent, the size of the phosphazene ring, and the solvent used for the reaction. With all these variables, it is perhaps not surprising that different opinions have arisen over the products and mechanisms of particular reactions. Fortunately, enough is now known to allow general principles to be recognized.

Early workers in this field reported that $(NPCl_2)_3$ reacts with phenyl magnesium bromide to give the hexaphenyl derivative, $(NPPh_2)_3$.[63,64] A reinvestigation of this reaction by Biddlestone and Shaw[65–67] yielded the information that, when diethyl ether was used as a solvent, only traces (1–5%) of $(NPPh_2)_3$ were formed, and that this was generated indirectly. The mechanism proposed by these workers involved an initial cleavage of the phosphazene ring, replacement of chlorine atoms in the linear product by phenyl groups, followed by a small amount of recyclization. When diphenyl-

magnesium in dioxane was used in place of phenylmagnesium bromide in ether, a complex mixture was formed which contained linear phosphazenes, a trace of $(NPPh_2)_3$, and a bi(cyclophosphazene). It was proposed that most of these products were formed via phosphazenylmagnesium intermediates.

In our laboratory, Allcock, Desorcie, Harris and Brennan have examined similar reactions in some detail, but with the use of tetrahydrofuran as a reaction solvent.[68–70] Under these conditions, $(NPCl_2)_3$ reacts with a variety of alkyl and aryl Grignard reagents to yield *cyclic* substitution products. No ring-cleavage products were detected. The principal products are the monosubstituted trimer (**27**) and the ring-linked bi(cyclophosphazene) (**28**).



27 **28** (4)

The relative proportions of **27** and **28** are critically dependent on the steric size of the organic group in RMgX. As shown in Table 1, the relative percentage of the monoalkyl product (**27**) in the mixture increases as the size of the alkyl group increases. Phenylmagnesium chloride reacts to give **28** exclusively.

It might be supposed that species **27** would be formed by direct nucleophilic replacement of chlorine by the group R. However, the experimental evidence is in favor of an alternative mechanism in which a metal–halogen exchange pathway is responsible for the fomation of both **27** and **28**.

The initial metal–halogen interaction between $(NPCl_2)_3$ and the Grignard reagent generates a metallophosphazene intermediate (**29**) (Scheme 5). Species **29** contains a trivalent, tricoordinate phosphorus atom which readily participates in chlorine replacement with a molecule of Grignard reagent to yield **30**. At this stage, two possibilities exist. Metal–halogen exchange between **30** and $(NPCl_2)_3$ could generate product **27** and another molecule of **29**. Alternatively, a ring-coupling reaction between **30** and **27** could occur to yield the bi(cyclo) product (**28**). Steric hindrance by bulky alkyl groups inhibits the ring-coupling process. Indirect evidence for the participation of **30** has been obtained by the isolation of **31** from the reaction of $(NPCl_2)_3$ with CH_3MgX or C_6H_5MgX in the presence of iodomethane.

The further reaction of species **27** with Grignard reagents leads to replacement of the geminal chlorine atom by what appears to be a straightforward nucleophilic substitution process to give

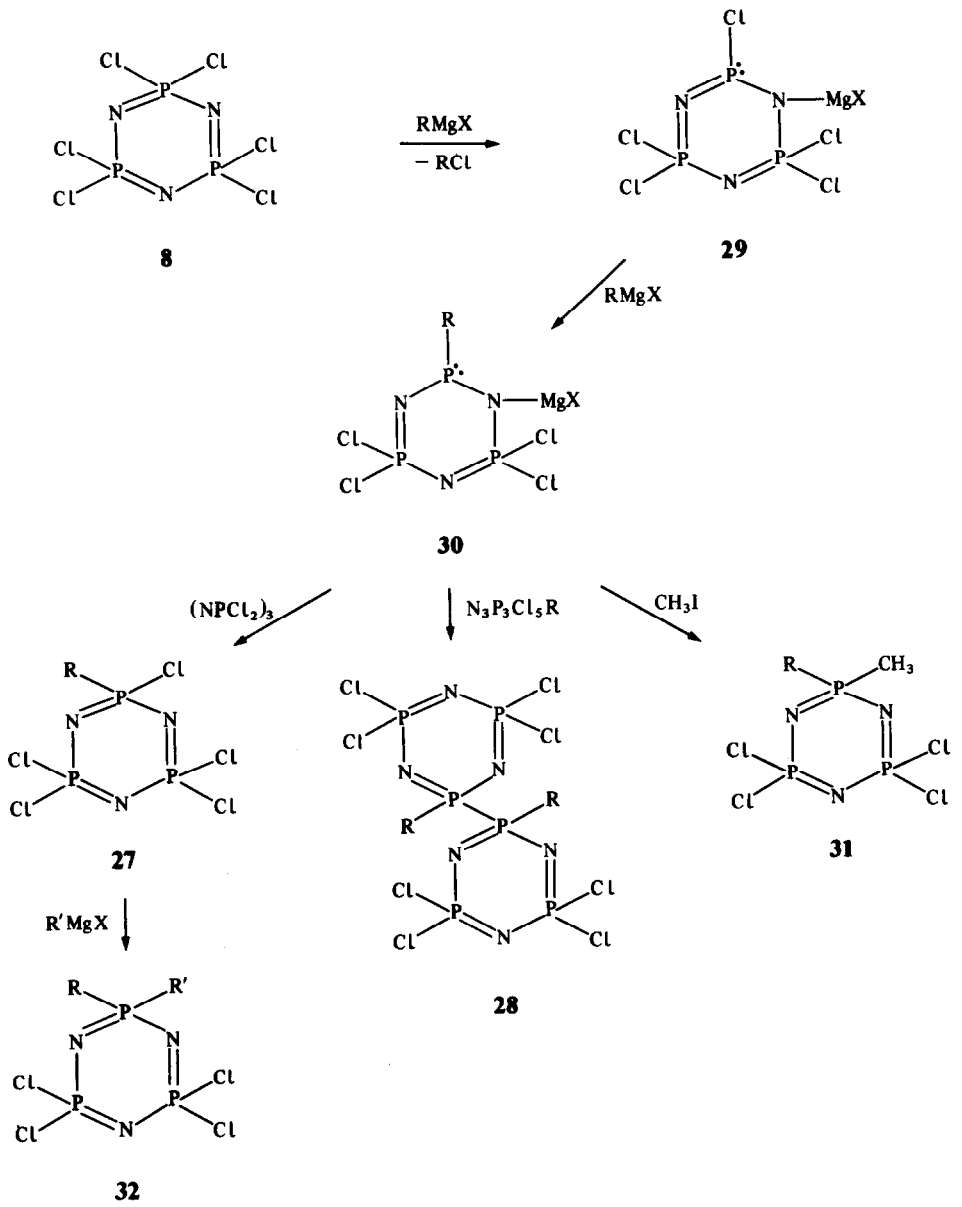

Scheme 5.

species of structure **32**.[69,70] Use of this method has allowed the synthesis of a number of *gem*-alkyl–aryl derivatives by Harris and coworkers.[71]

The reactions of the cyclic tetramer $(NPCl_2)_4$ with Grignard reagents are characterized by both substitution and ring cleavage.[72–74] Thus, the reaction products include cyclic tetrameric species of types **33–35**, and cyclic trimers of type **36–38** formed by skeletal cleavage and ring contraction. The data in Table 2 illustrate how the products vary with changes in group R in RMgX.[72–74]

The mechanism of this ring contraction, first proposed by Shaw,[72,73] is shown in Scheme 6. The initial interaction of $(NPCl_2)_4$ with RMgX results in ring cleavage to form species **39**, which undergoes 1,6-intramolecular nucleophilic displacement to form **40**. Replacement of the chlorine atoms of the pendent unit by reaction with Grignard reagent then yields **36**. This last step seems plausible since the octachloro analogue of **40** has been shown to react with phenylmagnesium bromide to give **36**, with the side-group chlorine atoms reacting first.[75] Species **38** has been isolated from the reaction of $(NPCl_2)_4$ with butylmagnesium halide. (The isopropoxy group is a product of the reaction of a remaining chlorine atom with isopropanol used in the purification process.[74]) A further complication in this type of reaction arises because the ring-contraction process in the

presence of Grignard reagents can also involve cleavage of the ethers used as solvent. Thus, species **37** is formed by reaction with diethyl ether in the presence of methylmagnesium bromide.[74]

This propensity for alkoxyphosphazene formation during Grignard-mediated reactions is especially noticeable when aminophosphazenes react with Grignard reagents.[76,77] A reaction studied recently in our laboratory is shown in eqn (5). Compound **41** reacts with alkylmagnesium halides

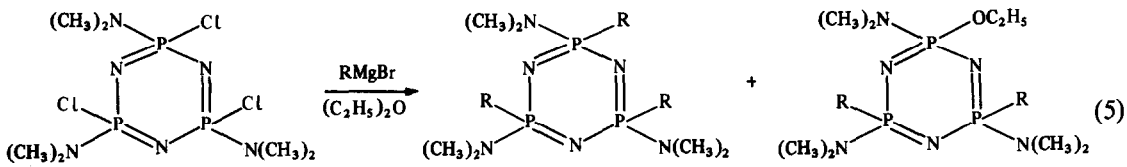
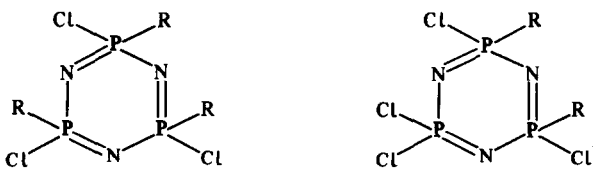
to generate two types of products, depicted as **42** and **43**. Species **43** with an ethoxy side group, is formed by cleavage of the diethyl ether solvent. The mechanism of this ether cleavage is believed to involve a magnesium halide induced removal of chloride ion from phosphorus, followed by an attack by the resultant phosphazenium ion on the oxygen of an ether molecule.[77]



(5)

41 **42** **43**

However, it is possible to maximize the conversion to **42** and discriminate against formation of **43** by the use of a large excess of Grignard reagent in a minimum amount of diethyl ether solvent. Removal of the dimethylamino groups by treatment with hydrogen chloride yields species such as **44** and **45**. These compounds are valuable starting points for further organometallic or organic substitution reactions, because they provide routes to compounds that are not accessible via the direct reaction of $(NPCl_2)_3$ with Grignard reagents. Moreover, compounds such as **44** and **45** can be polymerized to linear macromolecules that contain alkyl groups bonded directly to the skeleton.

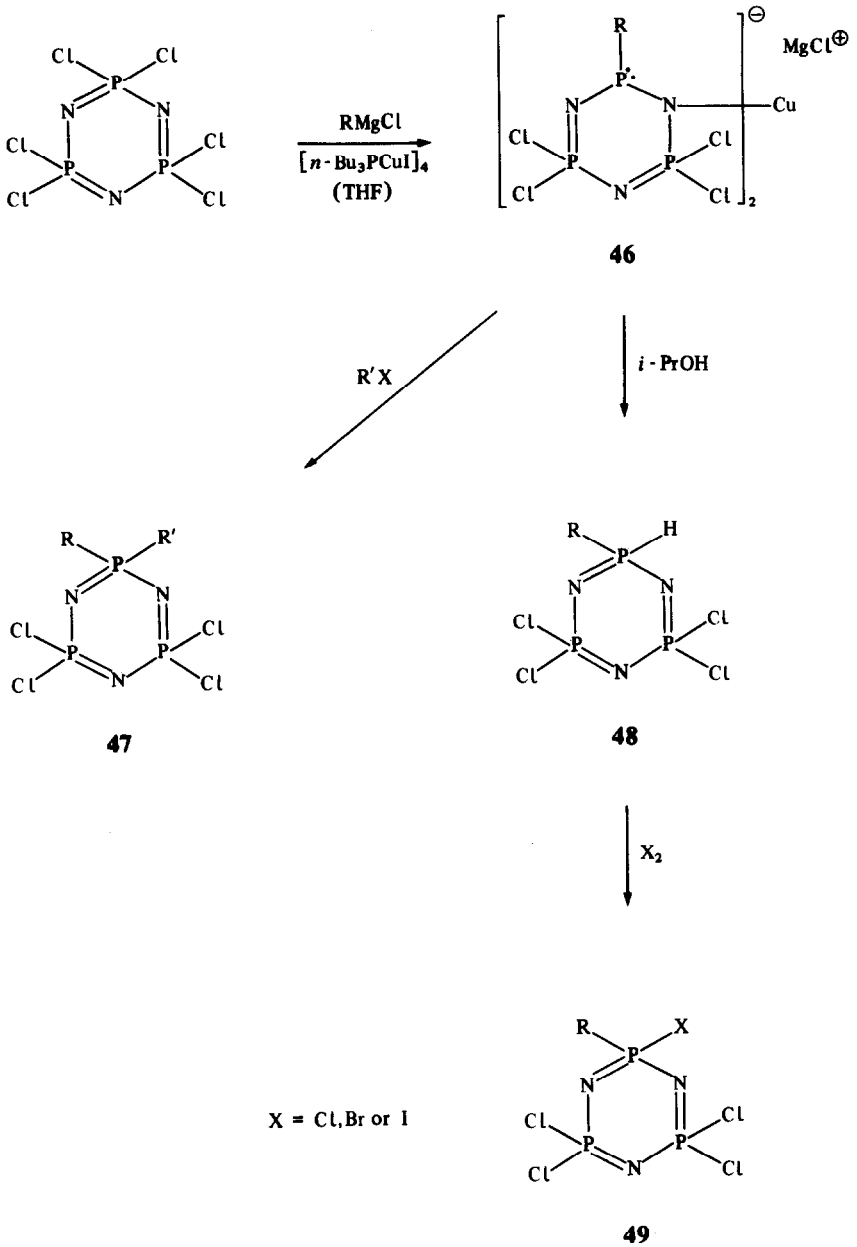


44 **45**

(b) *Organocopper reagents.* In our laboratory, it has been shown that many of the complications inherent in the reaction of chlorophosphazenes with Grignard reagents can be avoided by the use of organocopper reagents.[78–84] Thus, reactions between $(NPCl_2)_3$ and alkyl Grignard reagents in the presence of $[n\text{-}Bu_3PCuI]_4$ lead first to the formation of copper–phosphazene complexes (**46**) (Scheme 7). Reaction of **46** with alkyl halides yields *gem*-dialkyl derivatives (**47**). Treatment of **46** with 2-propanol generates a series of hydridophosphazenes (**48**), which are valuable intermediates for replacement of the hydrogen by chlorine, bromine or iodine to give **49**.

The reactions outlined in Scheme 7 have been explored for systems where R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, i-C_3H_7, i-C_4H_9, t-C_4H_9 or $CH_2{=}CH{-}CH_2{-}$. Arylcopper reagents do not function in the same way. They react with $(NPCl_2)_3$ to give *gem*-diarylcyclotriphosphazenes and ring-cleavage products. The group R′, introduced by treatment of **46** with an alkyl halide, can vary over a very wide range from methyl to allyl, 2-methoxyallyl or propynyl.[81–84] However, the introduction of bulky R′ groups is limited by steric effects.

The key intermediate in all these transformations induced by organocopper reagents is the copper–phosphazene species **46**. It has not been isolated, but it has been studied by ^{31}P NMR spectroscopy and by reaction stoichiometry.[79] It has proved to be one of the most valuable organo-



Scheme 7.

metallic species yet discovered in phosphazene chemistry, since it provides access to a diverse range of products of types **47** and **49**, many of which can be converted readily to linear high polymers.[85–87]

(c) *Lithiophosphazenes.* The hydridophosphazene (**48**) provides an entrée into phosphazene anion chemistry. Treatment of **48** with methyllithium at low temperatures yields the phosphazene anion (**50**) (Scheme 8). Interaction of this with prop-2-ynyl bromide[84] gives the propynyl phosphazene (**51**). In the presence of excess methyllithium, species **52** and **53** are also isolated. Compounds **51** and **53** form pi complexes with cobalt carbonyls, and these will be discussed later.

Phenyl derivatives of the copper–phosphazene intermediate (**46**) have not yet been isolated. Thus, for some time, phenyl analogues of **48** and **49** could not be synthesized. This limitation was removed by the discovery by Connolly in our laboratory that the phenylbi(cyclotriphosphazene) (**54**) undergoes P—P bond cleavage in the presence of lithium triethylborohydride to give the stabilized anion shown as **55**. Species **55** behaves in a similar manner to the copper–phosphazene intermediate[88] when treated with proton sources or alkyl halides. This allows the syntheses of *gem-*

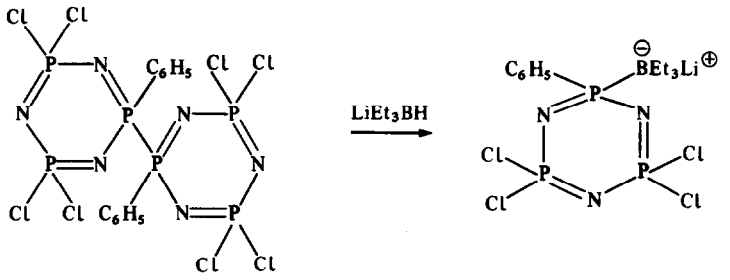
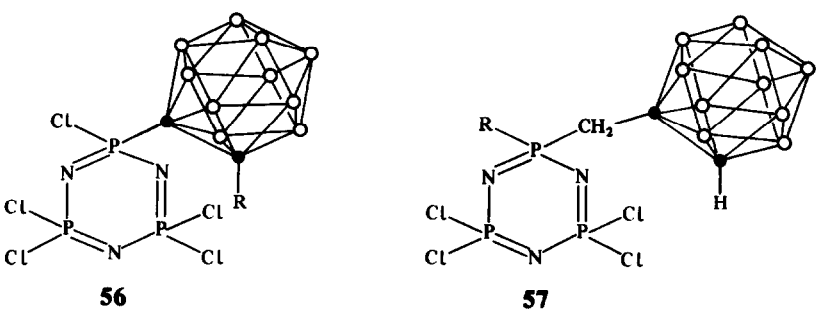
diorganophosphazenes in which one organic unit is an aromatic group. These, too, are valuable precursors to phosphazene high polymers.



54 55 (6)

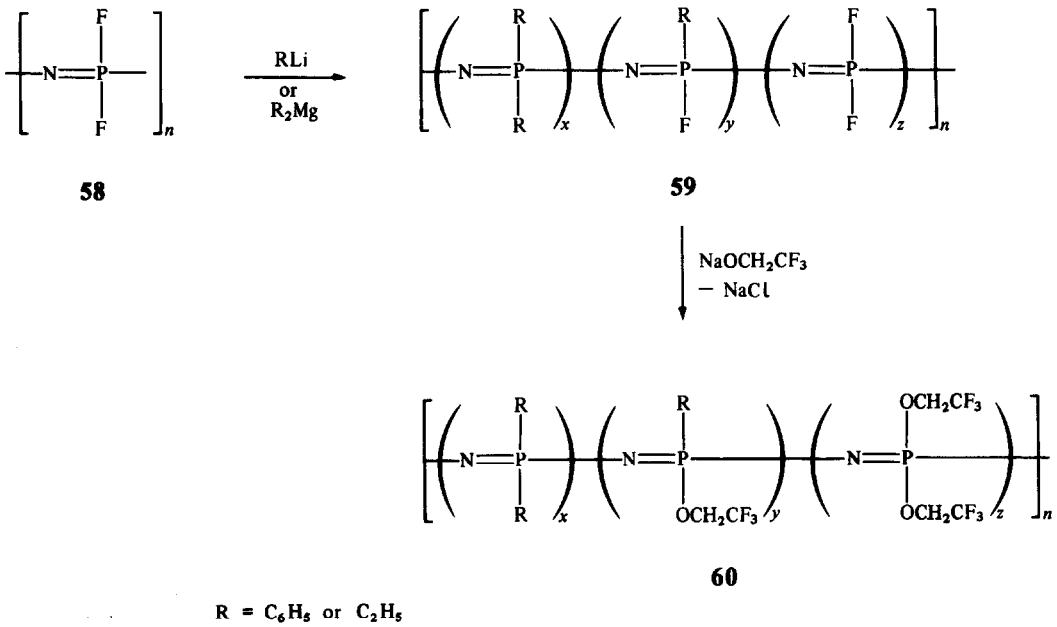
(d) *Organolithium reagents.* Simple organolithium compounds appear to be unsuitable reagents for the replacement of chlorine atoms in $(NPCl_2)_3$ by organic groups. Ring-cleavage reactions predominate when $(NPCl_2)_3$ reacts with methyl- or phenyllithium,[89,90] although traces of methylcyclophosphazene products have been isolated.[90] However, van de Grampel and Winter[91] recently reported that the principal product from the reaction of $(NPCl_2)_3$ with methyllithium in tetrahydrofuran at $-20°C$ is a hydridophosphazene. The formation of this compound suggests a metal–halogen exchange process. The same authors[92] also found that the tetramer $(NPCl_2)_4$ reacts with methyllithium to give ring-linked bi(cyclo) tetramers as well as hydridophosphazenes. These products reinforce the view that metal–halogen exchange reactions can occur with organolithium reagents.

On the other hand, Allcock, Scopelianos and O'Brien have shown[93,94] that lithiocarboranes react with $(NPCl_2)_3$ to give monosubstituted products such as **56**. Similar compounds (**57**) are formed by



56 57

○ = BH, ● = C



Scheme 9.

the reactions of acetylenic phosphazenes (**51**) with decaborane. Such species polymerize to linear macromolecules when heated, and can be converted to *nido*-carboranes and employed as carrier species for transition metals (see later).

(e) *Organoaluminum and organosodium reagents.* Harris and Jackson[95] have shown that trimethylaluminum reacts with $(NPCl_2)_3$ to yield $N_3P_3Cl_2(CH_3)_4$ in good yield. The substitution follows mainly a geminal substitution pathway.

Burg and Caron[96] found many years ago that sodium acetylide reacts with $(NPCl_2)_3$, but the reaction has not been explored in detail.

4. *Reactions of high-polymeric halogenophosphazenes*

As discussed in an earlier section, two alternative organometallic routes exist for the synthesis of phosphazene high polymers that bear alkyl or aryl side groups linked to the chain via C—P bonds.* In the first route, the organic groups are introduced at the cyclic trimer level and the trimer is then polymerized. In the second method, an attempt is made to introduce the organic groups at the high-polymer level by organometallic substitution processes. We have explored this second possibility in some detail, making use of the results from the "model" reactions with cyclic trimers or tetramers.[10]

First, it must be emphasized that the problems involved in carrying out such reactions with high polymers are highly challenging. The complexity of the reaction at the cyclic-oligomer level, as just described, provides a hint of the difficulties to be expected. Moreover, it can be anticipated that skeletal cleavage reactions would be severely detrimental for high polymers, because shortening of the chains would lower the usefulness of the polymers. Nevertheless, some progress has been made.

It can be anticipated from the results described up to this point that *fluoro*phosphazenes are more appealing substrates for most organometallic reactions than are chlorophosphazenes. The fluoro derivatives are less prone to metal–halogen exchange processes and are perhaps less susceptible to skeletal cleavage. Thus, the reactions of poly(difluorophosphazene) (**58**) have been examined as well as those of poly(dichlorophosphazene) (**62**).

Evans and Patterson in our laboratory showed that poly(difluorophosphazene) reacts cleanly with phenyllithium or diethylmagnesium to yield partly substituted macromolecular products (**59**)[97(a)] (Scheme 9). The remaining fluorine atoms can be replaced by treatment with sodium tri-

* An alternative direct-synthesis route also exists, as reported by P. Wisian-Neilson and R. H. Neilson.[97(b)]

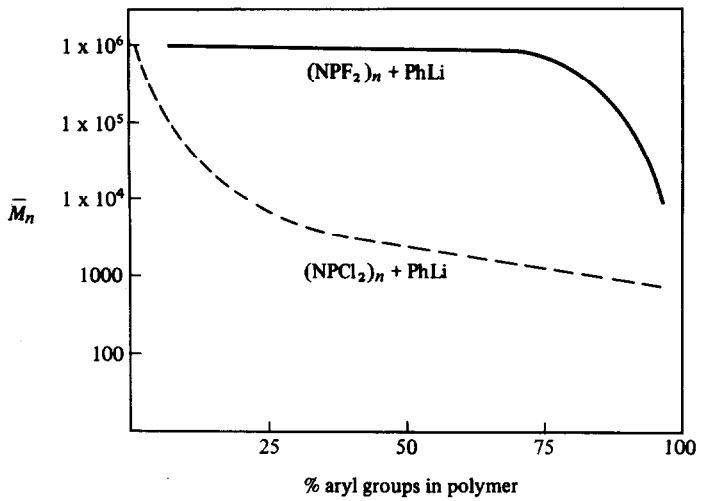


Fig. 1. Comparison of the variation in average molecular weight for $[NP(C_6H_5)_x(OCH_2CF_3)_y]_n$ vs the percentage of phenyl groups attached to the backbone. The broken curve represents the behavior of the system when $(NPCl_2)_n$ is used as a reaction substrate. The solid line illustrates the behavior with $(NPF_2)_n$. From Allcock *et al.*[98]

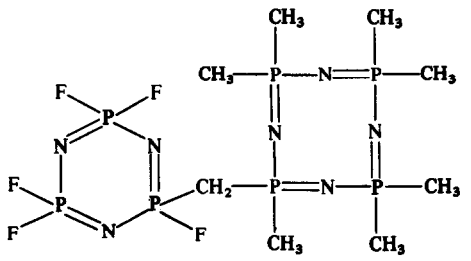
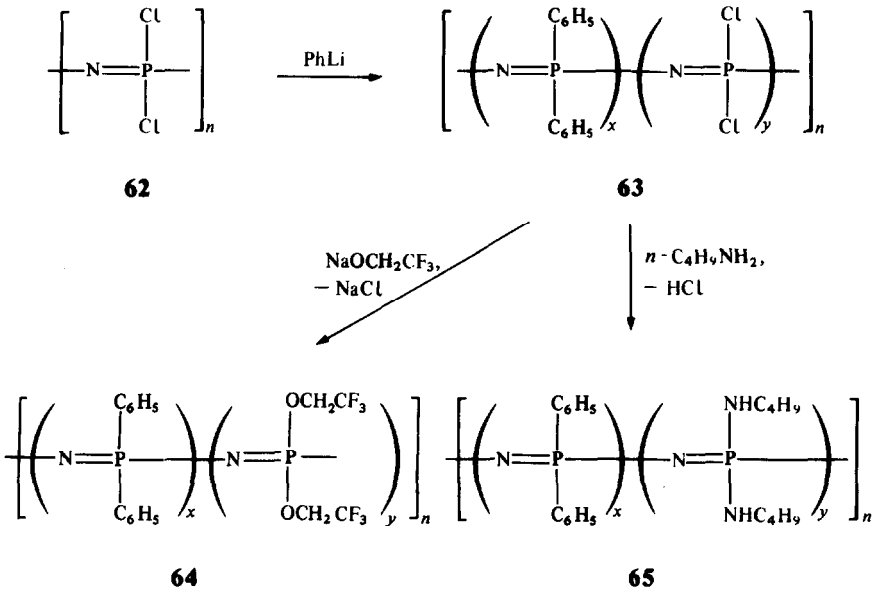
fluoroethoxide to give a hydrolytically stable high polymer (**60**). The phenyltrifluoroethoxy polymers are film-forming materials with molecular weights above 1×10^6.[98] The substitution reaction with phenyllithium appears to be mainly geminal.[98] It proceeds with no evidence of chain cleavage until roughly 70% of the fluorine atoms have been replaced. Beyond this point, the chain length decreases rapidly (Fig. 1). It is speculated that strong electron withdrawal by the fluorine atoms shields the system against chain cleavage by reducing the basicity of the skeletal nitrogen atoms. However, once 70% of the fluorine atoms have been replaced by phenyl, this protection is reduced, and chain cleavage becomes a major contributor to the reaction.[98]

Methyllithium reacts with $(NPF_2)_n$ to replace fluorine atoms by methyl groups and, at the same time, crosslinks the chains.[99] The cross-linking process appears to involve proton abstraction from pendent methyl groups by methyllithium, followed by attack of the resultant anionic site on a P—F bond in another chain. Evidence for this mechanism was provided by a small-molecule simulation in which octamethylcyclotetraphosphazene was treated with methyllithium to generate the carbanion. This species then reacted with $(NPF_2)_3$ to yield compounds **61**.



61

Poly(dichlorophosphazene) (**62**) reacts with a deficiency of phenyllithium[100,101] by a geminal substitution process to yield **63**, and the remaining chlorine atoms can be replaced by treatment with alkoxide or amino nucleophiles to give species such as **64** or **65** (Scheme 10).[100] However, chain shortening occurs almost from the beginning of the organometallic reaction (Fig. 1). A similar molecular-weight decline occurs when $(NPCl_2)_n$ reacts with lithiocarboranes.[94] Organomagnesium, organosodium and organozinc reagents also react with $(NPCl_2)_n$ by a complex mechanism.[102] In this sense, the ring-contraction reactions of $(NPCl_2)_4$ provide a good model for what occurs in the high polymer.



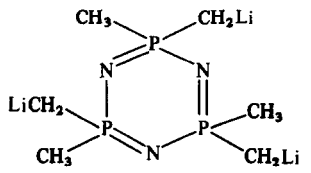
62 **63** **64** **65**

Scheme 10.

5. *Reactions of organophosphazenes*

In principle, the wide array of reactions between Main-Group organometallic reagents and organic compounds can be applied to organic groups that are linked to a phosphazene ring or chain. If conditions are favorable, these side-group reactions may occur without phosphazene skeletal cleavage.[103] Such organic-type reactions offer the prospect of greatly increasing the structures available in phosphazene chemistry. As will be seen later in the section on transition-metal derivatives, this route is of special importance for the synthesis of polymer-bound catalysts.

The possibilities for organometallic transformations at the side groups are so broad that only three examples will be given here. First, Paddock and coworkers have investigated the alkyllithium-induced metal–hydrogen exchange reactions on methyl groups attached to phosphazene rings.[104,105] Compounds such as **66** are formed and can be used as substrates for reactions with electrophiles such as CH_3I, $(CH_3)_3SiCl$, $(CH_3)_3GeCl$, $(CH_3)_3SnCl$, $C_6H_5C(O)C_2H_5$, CO_2, $(CH_3)_2SiCl_2$ and $(CH_3)_2AsI$.[105]



66

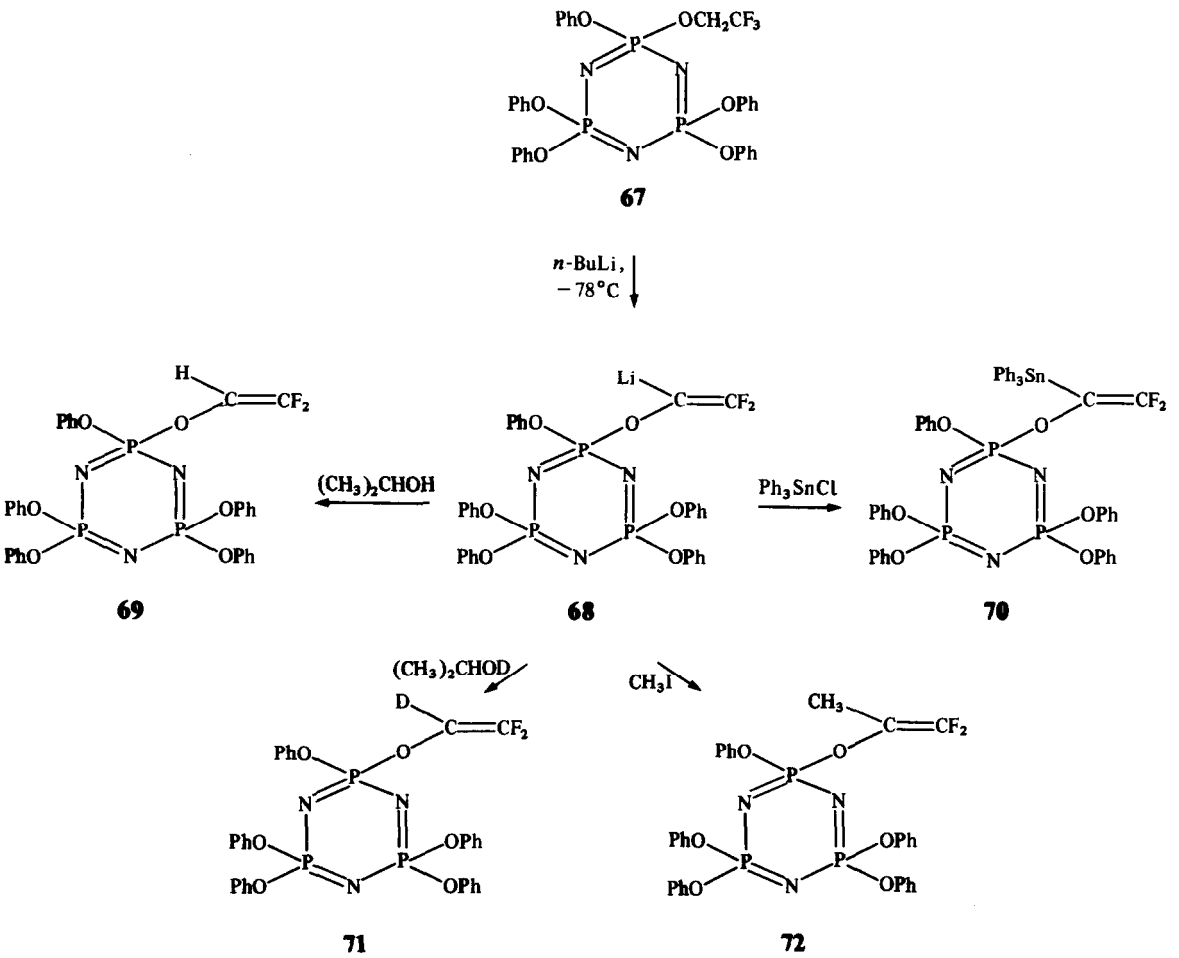
Second, we have shown[106] that trifluoroethoxyphosphazenes such as **67** (Scheme 11) react with organolithium reagents to undergo metal–hydrogen exchange at the α-carbon atoms (**68**). Treatment of **68** with a variety of electrophiles allows access to products such as **69–72**.

Finally, as shown in Scheme 12, metal–halogen exchange reactions can be carried out at aryloxy groups attached to a phosphazene ring or chain.[107–109] Allcock, Evans and Fuller used reactions of this type to prepare a wide range of functionalized aryloxyphosphazenes, some of which (**78**) are good carrier molecules for transition-metal organometallic species.

IV. TRANSITION-METAL CHEMISTRY

1. *General features*

The transition-metal chemistry of phosphazenes is of recent origin but has developed rapidly, particularly during the past 5 years. In the preceding sections, an emphasis was placed on the striking



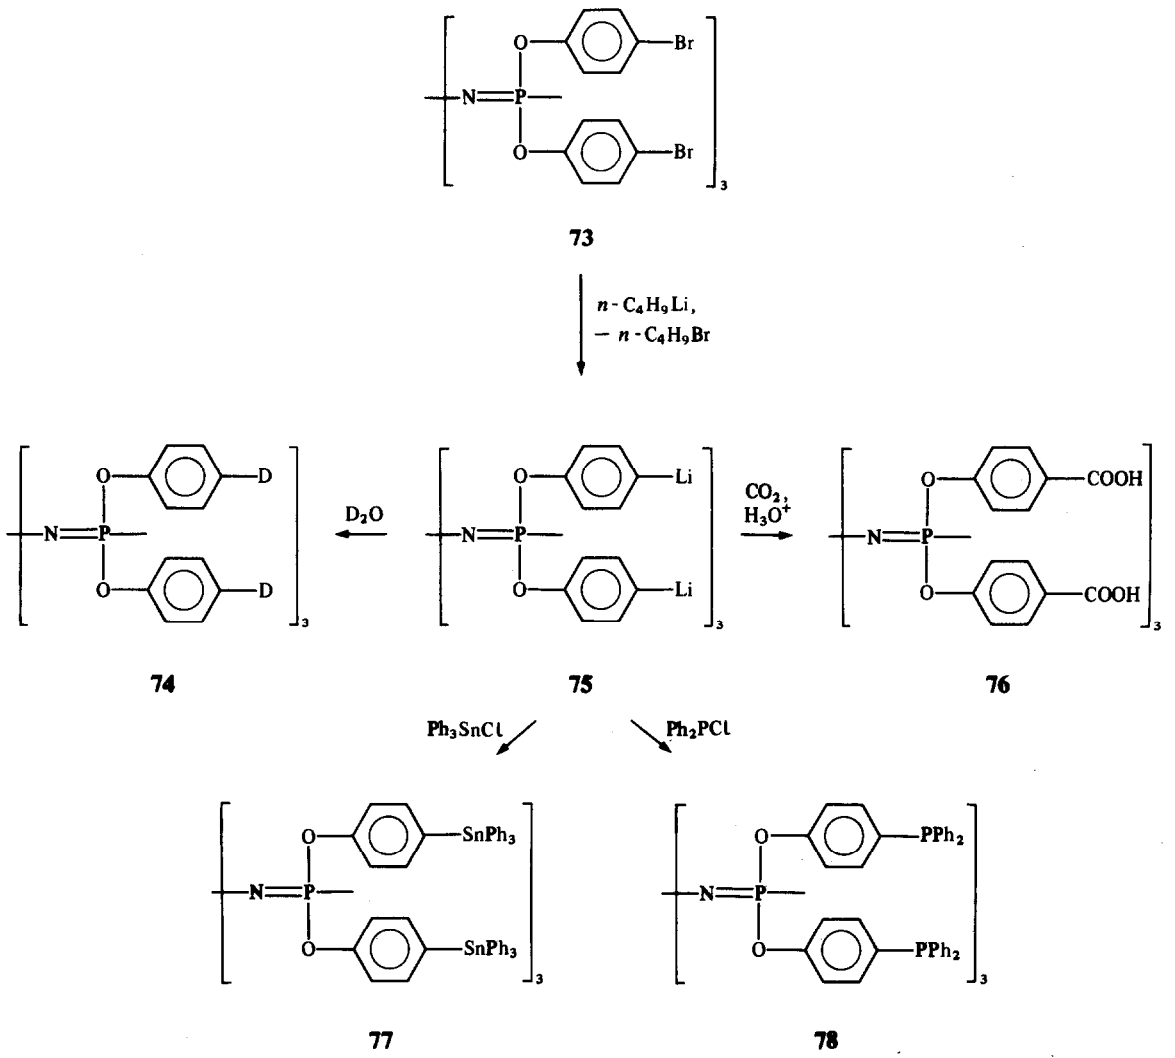
Scheme 11.

differences between the reactions of fluoro-, chloro- and organophosphazenes, and on the role played by skeletal ring or chain size. In transition-metal organometallic chemistry, these differences are still evident, but the most important feature is the nature of the organometallic reagent and the mode of linkage of the transition metal to the phosphazene. The Main-Group organometallic chemistry is valuable in so far as it provides a means for the attachment of organic groups to phosphazenes. The transition-metal organometallic chemistry is important as a method for the linkage of transition metals to phosphazenes.

The mode of attachment of transition metals to cyclic or high-polymeric phosphazenes can be divided into four general categories: (1) use of the electron-donor coordination properties of the skeletal nitrogen atoms of phosphazenes; (2) attachment of the transition metal through ionic, "salt-type" linkages; (3) direct covalent binding between a transition metal and a skeletal phosphorus atom; and (4) attachment of the metal to an organic ligand that is itself connected as a side group to a skeletal phosphorus atom. The first two of these do not fall strictly into the category of organometallic systems, but they are discussed here briefly to provide perspective.

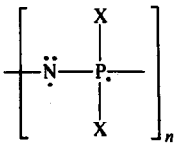
2. *Complexes between metals and skeletal nitrogen atoms*

Each skeletal nitrogen atom of a phosphazene bears a lone pair of electrons (**79**). The remaining nonsigma bonding electrons, one from phosphorus and one from nitrogen, are believed to participate in a d_{π}–p_{π} bond that makes use of a nitrogen $2p_z$ orbital and one of several phosphazene $3d$ orbitals.[110] Delocalization of these pi electrons occurs over three skeletal atoms only[111] in a way that permits



Scheme 12.

an equalization of bond lengths around a ring or along a chain, and gives the superficial appearance of aromaticity without the existence of long-range delocalization effects.[14,15,112]

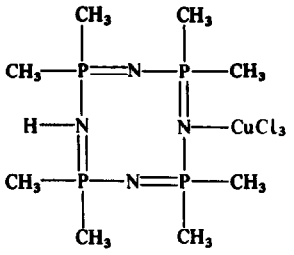


79

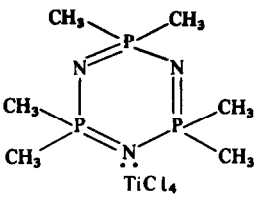
The availability of each lone pair of electrons for coordination to metals depends on the side group X. Electron-withdrawing side groups, such as fluorine or trifluoroethoxy, reduce the basicity of skeletal nitrogen but, at the same time, strengthen the skeletal bonds, probably by causing a contraction of the phosphorus *d*-orbitals and improving their overlap efficiency. Conversely, when the side group is an electron-supplying unit, such as methyl, alkylamino etc., the basicity of the skeletal nitrogen atoms is enhanced and they can now bind protons, alkyl cations, or transition metals.

(a) *Metal halide complexes.* One of the earliest complexes of this type was reported by Dyson[113] who allowed $[NP(CH_3)_2]_4$ to react with anhydrous copper(II) chloride in methyl ethyl ketone as a

solvent. A subsequent X-ray diffraction study of this complex by Trotter and Whitlow[114] showed that the molecule had the structure shown in **80**.

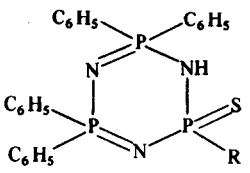


80

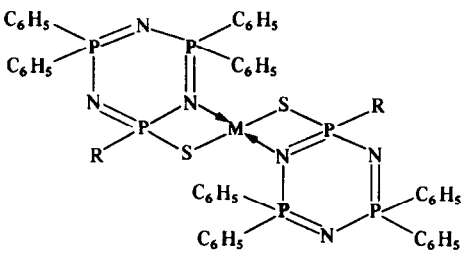


81

Lappert and Srivastava[115] found that $[NP(CH_3)_2]_3$ interacts with titanium tetrachloride in dichloromethane solution to yield the stable crystalline compound shown in **81**. Later, Schmidpeter *et al.*[116] allowed compound **82** to react with nickel, palladium and platinum dichlorides to yield the bis(thionato) metal(II) complexes shown in **83**. An X-ray structure determination by Ahmed[117] of the nickel derivative, where R = CH_3, showed a square planar bischelating geometry that involved a skeletal nitrogen atom and an exocyclic sulfur atom from two phosphazene rings.



82

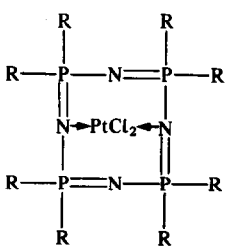


83

R = CH_3, *p*-$C_6H_4OCH_3$ or OC_6H_5
M = Ni, Pd or Pt

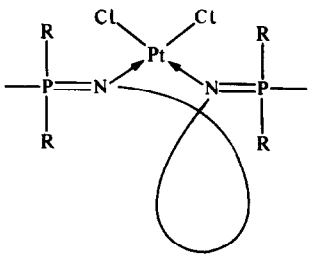
Among the aminophosphazenes reported to form metal halide complexes are species such as $[NP(NHPr^n)_2]_3$ (with Co^{2+}, Ni^{2+} or Cu^{2+} halides) and $[NPNHBu^n)_2]_3$ (with Co^{2+}) in acetonitrile.[118] However, these structures have not yet been studied crystallographically.

More is known about the bidentate platinum complexes formed by $[NP(NHCH_3)_2]_4$ and $[NP(NHCH_3)_2]_n$. Allcock *et al.*[119] found that, in the presence of 18-crown-6-ether, K_2PtCl_4 reacts with these phosphazenes to form the square planar complexes shown in **84** and **85**. In the cyclic tetrameric system, it was shown by X-ray diffraction analysis that the metal is coordinated in a transannular fashion to the 2,6-*skeletal* nitrogen atoms.[120] A similar situation is found when the substrate is $[NP(CH_3)_2]_4$ and the reagent is $PtCl_2$ in benzene.[119] The high-polymeric aminophosphazene similarly forms a $PtCl_2$ complex by means of the skeletal nitrogen atoms.[119] The composition of this complex was $[NP(NHCH_3)_2]_n[PtCl_2]_x$ ($x:n \simeq 1:17$). These platinum complexes are of interest as



84

R = $NHCH_3$ or CH_3

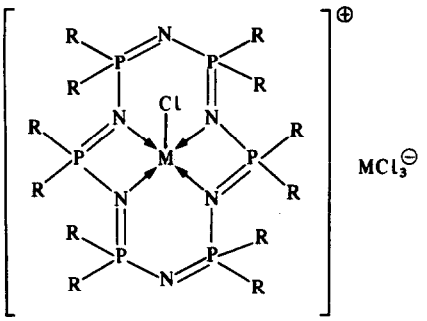


85

R = $NHCH_3$

antitumor drugs. The high polymeric derivative (**85**) has been shown to function as a water-soluble anticancer agent with restricted transmission through semipermeable membranes.

This pattern of transannular linkage with aminophosphazenes extends in higher cyclic species to the formation of macrocyclic chelation systems. For example, Paddock, Trotter and coworkers[121] showed that the cyclic hexamer, $[NP(NMe_2)_2]_6$, reacts with the chlorides of Mn^{2+}, Fe^{2+}, Co^{2+} and Zn^{2+} in methyl ethyl ketone to give macrocyclic chelates of the type shown in **86**.



86

R = $N(CH_3)_2$

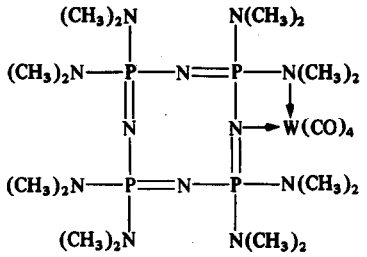
The cobalt complex was examined by X-ray diffraction techniques[122] and was found to possess a structure in which four of the six skeletal nitrogen atoms occupy the basal site of a distorted square pyramid, with a chlorine atom at the apical position. The analogous copper(II) chloride complex, $[(NP(NMe_2)_2)_6CuCl]^+[CuCl_2]^-$, has a similar structure, but with the counterion reduced to the Cu(I) state.[123,124]

(b) *Metal carbonyl complexes.* In principle, aminophosphazenes have three different types of sites for the binding of transition metals—skeletal nitrogen atoms, side-group nitrogen atoms, and ring or chain pi electrons. Which linkage system wins in the competition for the metal atom is a matter of some interest.

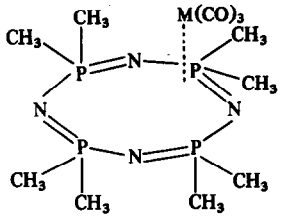
The aminocyclotetraphosphazene, $[NP(NMe_2)_2]_4$, reacts with tungsten carbonyl to give a pale yellow crystalline material that was shown by Paddock, Trotter and their coworkers to have the molecular structure shown in **87**.[125,126]

As indicated in **87**, the phosphazene functions as a bidentate *cis-σ* ligand, with the metal being coordinate by one ring nitrogen and one side-group nitrogen.[126]

A different situation exists when coordination to the side group is impossible. The cyclic tetramer $[NP(CH_3)_2]_4$ reacts with molybdenum or tungsten hexacarbonyl in the melt at 160°C to yield a yellow compound (**88**).[127,128]



87



88

The molybdenum analogue of **88** has also been studied by Cotton *et al.*,[129] but no firm conclusions could be drawn about the mode of metal binding. Related compounds have also been prepared from $[NP(CH_3)_2]_5$ and molybdenum or tungsten carbonyl.[127] It has been reported that $(NPCl_2)_3$ reacts with $Cr(CO)_3(CH_3CN)_3$ to yield a species of formula $(NPCl_2)_3 \cdot Cr(CO)_3$,[130] but the structure of the product has not been determined.

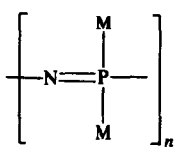
3. *Ionic, salt-type species*

The skeletal nitrogen atoms in aminophosphazenes and alkylphosphazenes can acquire a proton or alkyl cation to generate onium-type sites that function as counterions for metallo anions.

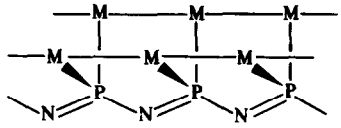
Thus, $[NP(NMe_2)_2]_3$ with $CoCl_2$ gives the salt-type species $[(NP(NMe_2)_2)_3H]_2^+[CoCl_4]^{2-}$; $(NPMe_2)_4$ with the same reagent yields $[(NPMe_2)_4H]_2^+[CoCl_4]^{2-}$;[113,131-133] $[NP(NHMe)_2]_4$ with K_2PtCl_4 in acid gave $[(NP(NHMe_2)_2]_4]^{2+}[PtCl_4]^{2-}$, and $[NPMe_2]_4$ gave $[(NPMe_2)_4H_2]^{2+}[PtCl_4]^{2-}$.[119] A hexamolybdate salt of formula $[(NP(NMe_2))_3H]_2^+$ was also formed when $[NP(NMe_2)_2]_3$ reacted with MoO_3 in water.[134] Similarly, the methyl iodide quaternary salt of $[NPMe_2]_4$, $[N_4P_4Me_9]^+I^-$, reacts with chromium or molybdenum hexacarbonyl to displace one carbon monoxide ligand and generate the species $[N_4P_4Me_9]^+[M(CO)_5I]^-$.[127]

4. *Species with metal–phosphorus covalent bonds*

Compounds that contain phosphazene rings or chains linked directly to transition metals through phosphorus–metal covalent bonds were discovered only recently by Greigger, Wagner, Suszko and Riding[135-142] in our laboratories. These constitute an unusual class of compounds that are true hybrids of Main-Group ring systems with transition-metal carbonyl species. Nearly all the developments in this area have been at the cyclic trimeric or tetrameric level, but very recently, the first high polymeric analogues have been isolated. These are prototypes for yet unsynthesized species of type **89**, which would be hybrids of polymers and metals. It is possible that this chemistry might eventually lead to the synthesis of "outrigger" metallo polymers of type **90**.



89

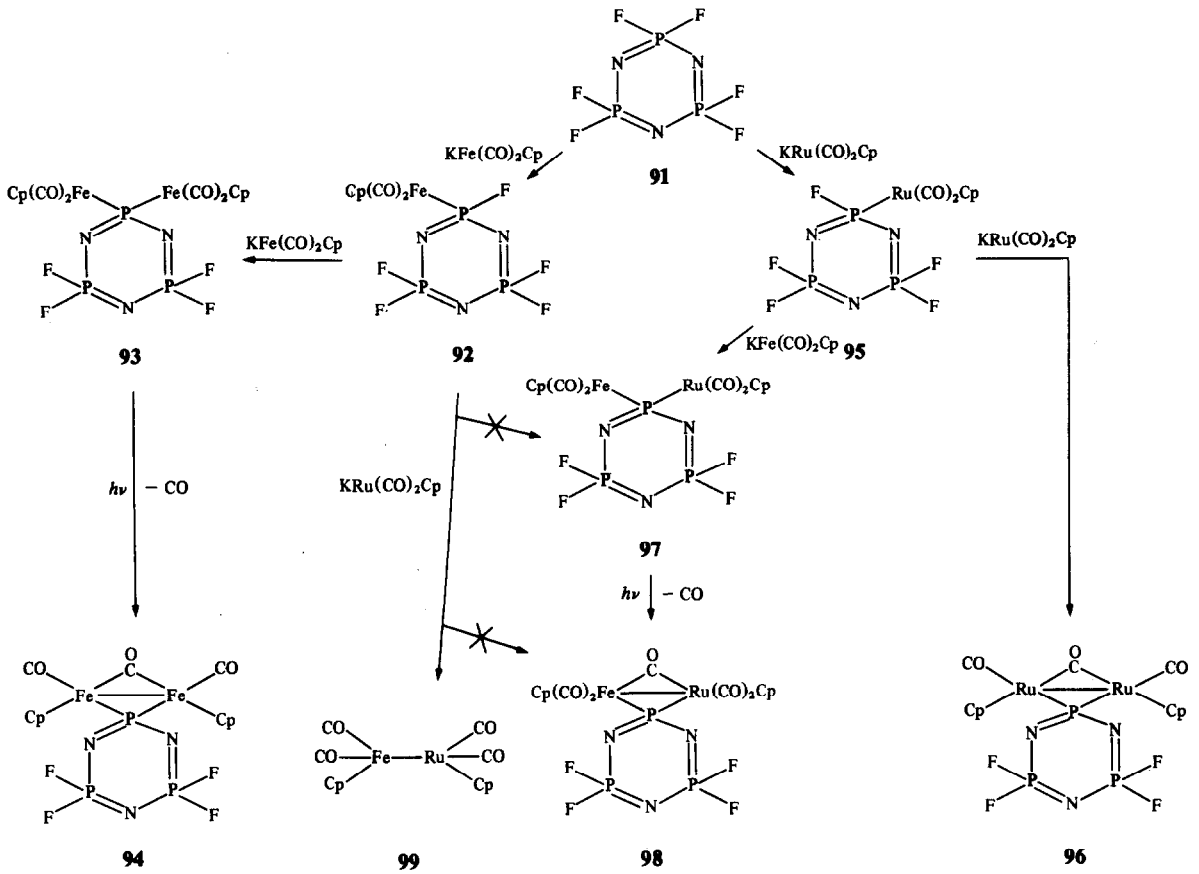


90

Three basic synthetic techniques have been applied to the preparation of small-molecule metallophosphazenes of this type. These are: (a) reaction of transition-metal anions with halogenophosphazenes by a nucleophilic-type substitution process; (b) metal–metal exchange processes to replace one metal already attached to the phosphazene ring by another metal; and (c) the reactions of phosphazene anions with organometallic metal halides which function as electrophiles.

(a) *Reactions of transition-metal nucleophiles with halogenophosphazenes.* These reactions can be viewed as counterparts of the organic and Main-Group organometallic substitution reactions discussed earlier. The first examples of this type of reaction involved the interactions of the most nucleophilic transition-metal carbonyl anions, $[Fe(CO)_2(\eta\text{-}C_5H_5)]^-$ and $[Ru(CO)_2(\eta\text{-}C_5H_5)]^-$, with $(NPF_2)_3$.[135-137] The potassium salts of these anions react with $(NPF_2)_3$ first to give the monosubstituted derivatives (**92** and **95**) in moderate yield (Scheme 13). Further reaction of the iron derivative (**92**) with an excess of $K^+[Fe(CO)_2(\eta\text{-}C_5H_5)]^-$ results in the replacement of the geminal fluorine atom to yield **93** as pale yellow crystals.[136] Exposure of this compound to light results in the loss of one carbon monoxide ligand and the formation of a spirocyclic phosphazene with a metal–metal bond (**94**).[135,136]

The analogous reaction between excess $K^+[Ru(CO)_2(\eta\text{-}C_5H_5)]^-$ and **95** yielded only the spirocyclic compound **96**.[137] The noncyclized, dimetallo intermediate is apparently too prone to decarbonylation to permit its isolation and identification. A mixed-metal derivative (**97**) was prepared by the reaction of $K^+[Fe(CO)_2(\eta\text{-}C_5H_5)]^-$ with the monoruthenium phosphazene (**95**) and this product undergoes facile photolytic decarbonylation to yield the mixed-metal spirocyclic species **98**. However, the converse reaction, that involves treatment of the monoiron phosphazene (**80**) with $K^+[Ru(CO)_2(\eta\text{-}C_5H_5)]^-$, failed to give the same mixed-metal species. Instead, compound **99** was formed,[137] presumably by an attack by the incoming organometallic anion on the phosphorus–metal bond.



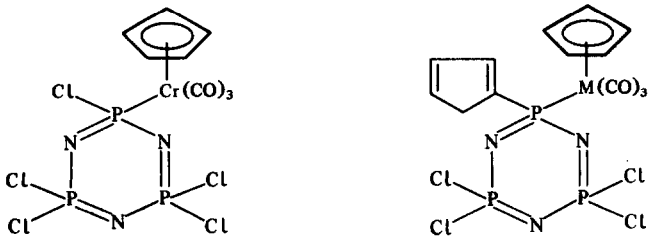
Scheme 13.

No products have yet been isolated in which any of the four remaining fluorine atoms have been replaced by the metallo units. In fact, there appears to be a severe deactivating influence on the nongeminal sites that suggests a strong electron supply from the organometallic moiety into the phosphazene ring.

The structures of **93**, **94** and **98** have been confirmed by X-ray crystallographic studies.[135–137] The influence of the metallo units on the phosphazene ring can be seen in the distortion of ring bond angles and bond lengths.[135–137]

As might be expected from the comparisons between fluoro- and chlorophosphazenes discussed earlier, the reactions between transition-metal anions and $(NPCl_2)_3$ or $(NPCl_2)_4$ are more complex than with $(NPF_2)_3$. Both substitution and cation–halogen exchange are possible with the chlorophosphazenes.

The tetra-*n*-butylammonium salts of the chromium, molybdenum and tungsten anions, $[M(CO)_3(\eta\text{-}C_5H_5)]^-$, react with $(NPCl_2)_3$ in methylene chloride to yield the monometallophosphazenes (**100** and **101**).[138] The structures of **100** and **101** (M = Mo) have been confirmed by

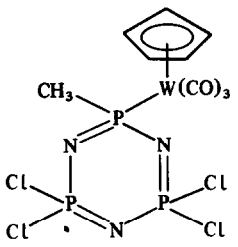


100 **101**

M = Mo or W

X-ray crystal structure analysis.[138] Thus, the chromium derivative (**100**) appears to be the product of a straightforward substitution reaction.

However, the reactions with the molybdenum and tungsten anions are more complex, since a cyclopentadiene unit appears as a substituent at the geminal position. The identification of $MCl(CO)_3(\eta\text{-}C_5H_5)$ from these reactions strongly suggests contributions from a cation–halogen exchange reaction. Further evidence in favor of this interpretation is the isolation of species **102** from reactions in which $(NPCl_2)_3$ reacts with $[W(CO)_3(\eta\text{-}C_5H_5)]^-$ in the presence of methyl iodide.[138]

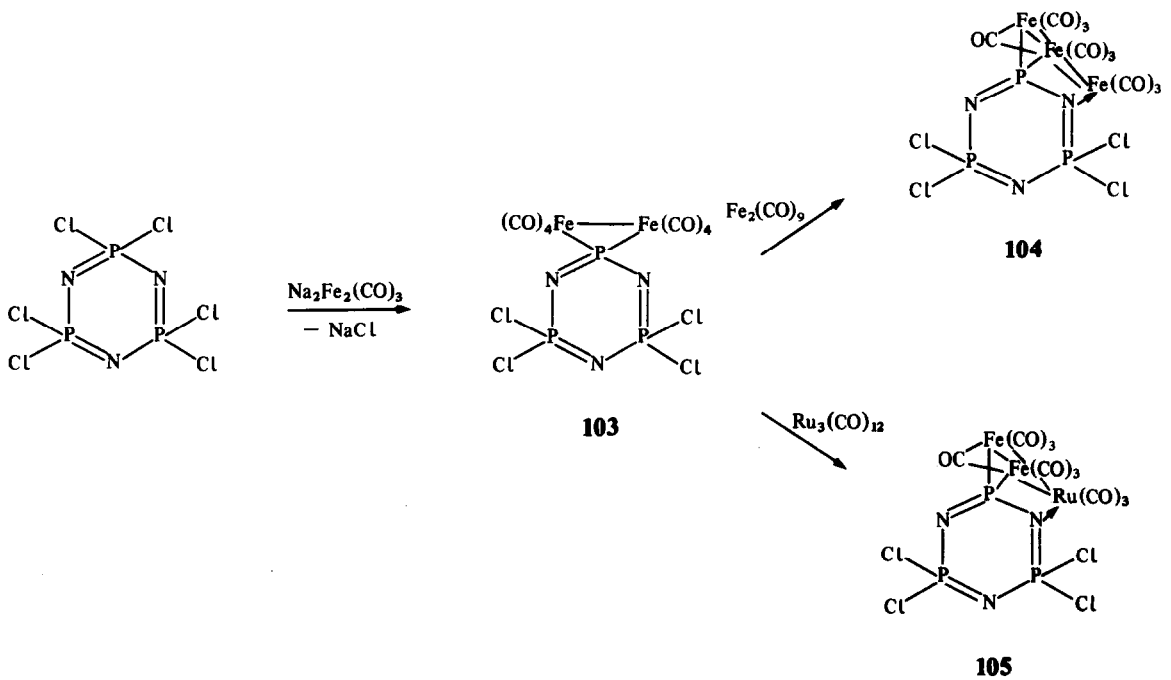


102

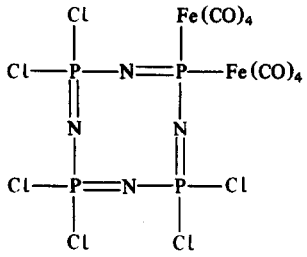
Organometallic dianions also react with chlorophosphazenes.[139,140] Disodium octacarbonyl diferrate, $Na_2Fe_2(CO)_8$, interacts with $(NPCl_2)_3$ in tetrahydrofuran to give the spirocyclic diiron phosphazene shown as **103** in Scheme 14, together with smaller amounts of the triiron cluster phosphazenes (**104**). The source of this latter species is of some interest. It appears to be formed by the reaction of **103** with neutral iron carbonyl species, such as $Fe_2(CO)_9$, which are present in the reaction mixture. Treatment of pure **103** with $Fe_2(CO)_9$ under the same reaction conditions yields **104**. Moreover, treatment of **103** with $Ru_3(CO)_{12}$ gave the diiron–monoruthenium cluster phosphazenes depicted as **105**. X-ray crystal structures have been obtained for compounds **103–105**.[139,140] These confirm that the third metal of the cluster is coordinatively bound to the adjacent ring nitrogen atom. The structures also demonstrate that appreciable phosphazene ring distortion accompanies this interaction.

Similar reactions occur with the chlorophosphazene cyclic tetramer, $(NPCl_2)_4$.[140] The reaction of $Na_2Fe_2(CO)_8$ with $(NPCl_2)_4$ led to the isolation of species **106** and **107**.

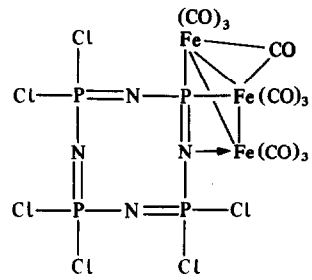
As mentioned earlier, these substitution reactions are of interest not only for their exploratory



Scheme 14.



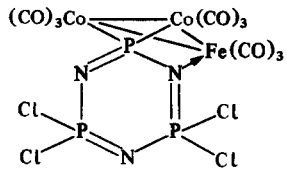
106



107

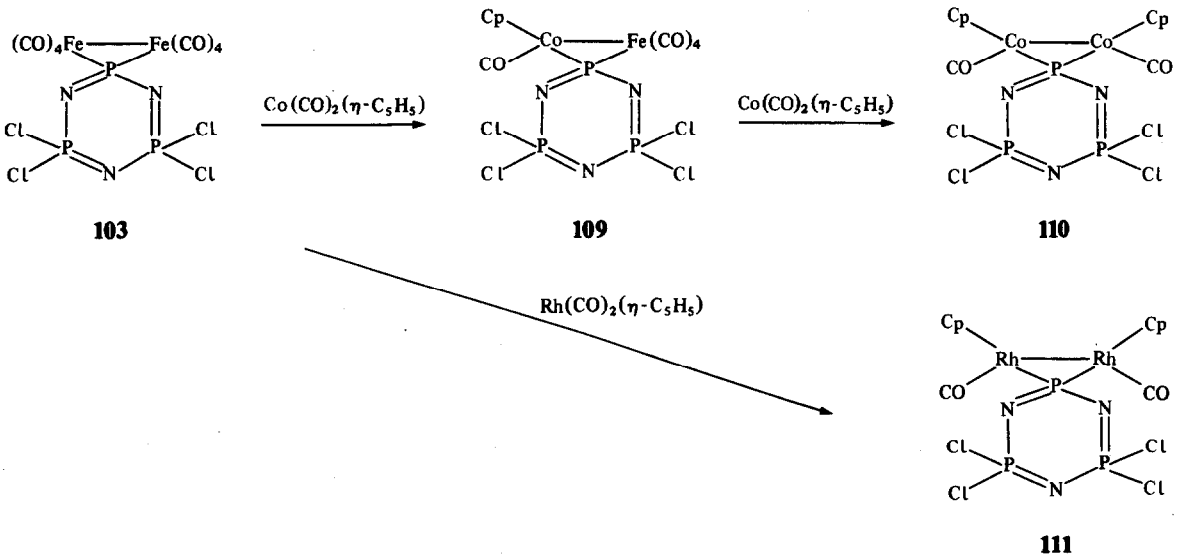
and fundamental value, but also because they offer a means for the incorporation of metals and metallo clusters into phosphazene high polymers. Thus, the long-range significance of these structures may lie eventually in their relationship to electroactive, magnetically-active, or catalytically-active macromolecules.

(b) *Metal–metal exchange reactions.* Species **103** not only adds additional metal atoms to generate trimetallo species, but it can also function as a substrate for replacement of one metal by another. Thus, **103** reacts with $Co_2(CO)_8$ to give the dicobalt–monoiron derivative shown as **108**, in which two $Co(CO)_3$ units are now covalently bound to phosphorus, and the one remaining iron atom is displaced into a peripheral position, and is coordinatively bound to a ring nitrogen atom.[141]



108

Reaction of **103** with the cyclopentadienyl cobalt carbonyl, $Co(CO)_2(\eta\text{-}C_5H_5)$, results first in the replacement of one iron unit to give **109**, while further reaction results in replacement of the second iron to generate **110**[141] (Scheme 15). However, **103** reacts with $Rh(CO)_2(\eta\text{-}C_5H_5)$ to give **111** directly. The structures of **108–110** were confirmed by X-ray diffraction.[141] Species **108** was also examined by Mössbauer spectroscopy.[141]

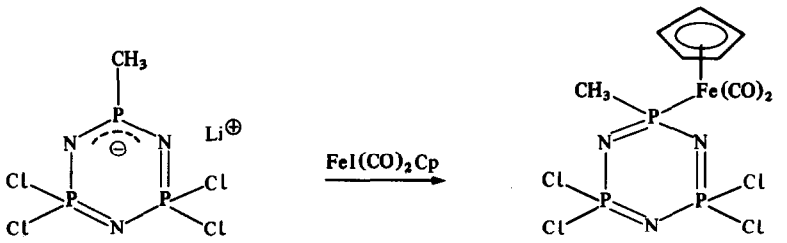


Scheme 15.

(c) *Reactions of phosphazene anions with organometallic electrophiles.* The reactions outlined in the preceding sections yield new compounds that are important from a structural viewpoint. However, when chlorophosphazenes are employed as the reaction substrates, metal–halogen exchange processes are always possible. At the small-molecule level this is not a problem because the products can always be isolated, albeit occasionally, in very low yields.

On the other hand, if such syntheses are to be used at the macromolecular level, the side reactions would impose severe penalties. Thus, two choices remain—either the use of fluorophosphazene high polymers as substrates (and these are soluble only in fluorocarbon solvents) or the development of an alternative method for the formation of phosphorus–metal bonds in these compounds.

As discussed earlier, phosphazene anions are accessible, and these react with organic electrophiles. We have recently shown that they also react with halogeno-transition-metal carbonyl compounds.[122] Thus, the phosphazene anion (**112**) prepared from the hydridophosphazene and methyllithium at −78°C in tetrahydrofuran reacts with $FeI(CO)_2(\eta\text{-}C_5H_5)$ to yield the iron-bound phosphazene (**113**).



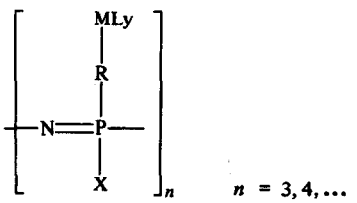
(7)

112 **113**

A similar reaction has been carried out with a phenylphosphazene anion analogous to **112**, but with the anion prepared by P—P bond cleavage of a phenyl bi(cyclophosphazene) with lithium triethylborohydride in the manner discussed earlier. The structure of **113** was confirmed by X-ray diffraction techniques. Ruthenium, chromium, molybdenum and tungsten *gem*-phenyl counterparts of **113** have also been prepared by similar techniques.

5. *Transition metals linked to pendent spacer groups*

A wide variety of methods can be envisaged for the binding of transition-metal organometallic units to organic or inorganic side groups, themselves attached to a phosphazene ring or chain (**114**). In our laboratory, we have examined a number of these possibilities, often making use of the following protocol. First, a phosphazene is synthesized that bears side groups with terminal binding sites for transition metals. Second, a complex is made by interaction of the side group with the metal. Third, the properties of the complex (catalysis, polymerization etc.) are studied. The advantage of this procedure is that it is possible to make use of well-established transition-metal coordination reactions. This has allowed much of the work in this area to be tested first at the small-molecule level, and then extended to the high polymers.

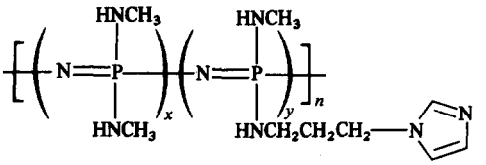


114

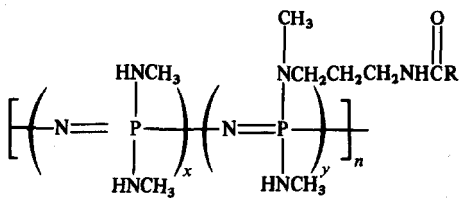
Six areas of chemistry have been developed by the use of this approach: (a) binding of iron porphyrins to phosphazenes either through pendent imidazole units or by covalent binding to the skeleton, (b) linkage of copper phthalocyanines to phosphazenes via organic spacer groups, (c) attachment of phosphine units to aryloxy substituent groups followed by coordination to transition-

metal complexes, (d) conversion of *closo*-carboranylphosphazenes to *nido*-carboranyl derivatives and subsequent reaction with metal complexes, (e) attachment of metallocene units to phosphazenes through P—C bonds, and (f) addition of metal carbonyls to phosphazenes that bear pendent acetylenic side groups. The first two approaches will be mentioned only briefly, because organometallic species are not involved.

(a) *Polyphosphazenes as carrier molecules for iron porphyrins.* Several different systems have been studied,[143,144] and these are depicted schematically as **115–117**. In each case, the Fe(III) porphyrin system was prepared first, and this was reduced to the Fe(II) form by treatment with dithionite.



115



116

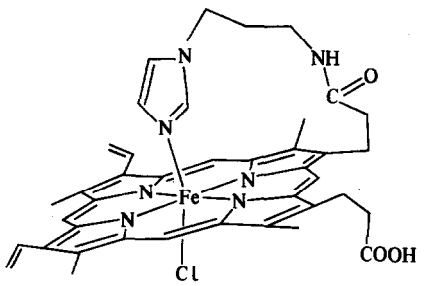
117a



117b

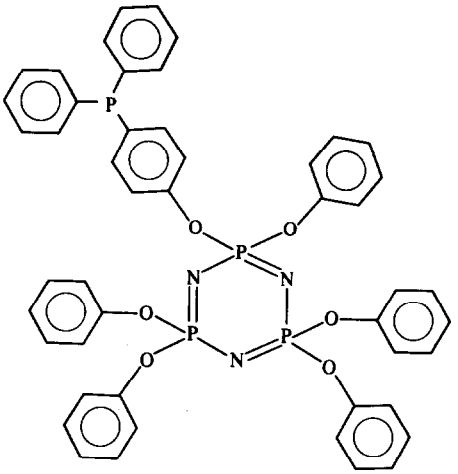
When heme or hemin interacts with the basic, water-soluble control polymer $[NP(NHMe)_2]_n$ in aqueous media, weak (probably acid–base type) adducts are formed that involve pendent carboxylic acid units of the porphyrin ring.[143] The products are bis-aquo-heme or hematin–hemin hydroxide derivatives. By contrast, the polyphosphazene with a pendent imidazole unit (**115**) binds strongly to both heme and hemin via coordination of the imidazole function to the iron atoms to give six-coordinate metal systems. In aqueous media, the heme complex of **115** is irreversibly oxidized to the Fe(III) form in the presence of oxygen. However, the same polymeric complex in the form of thin solid films undergoes cycling between the Fe(II) and Fe(III) forms in the presence or absence of oxygen, with the *polymer* apparently functioning as an internal reducing agent. This is an interesting phenomenon from the viewpoint of potential electrode mediator catalysis.

Covalent binding of Collman-type picket fence and Traylor-type iron porphyrins to a carrier polyphosphazene has also been accomplished (**116** and **117**), and the oxygen-binding behavior and electrochemical characteristics have been studied.[144]

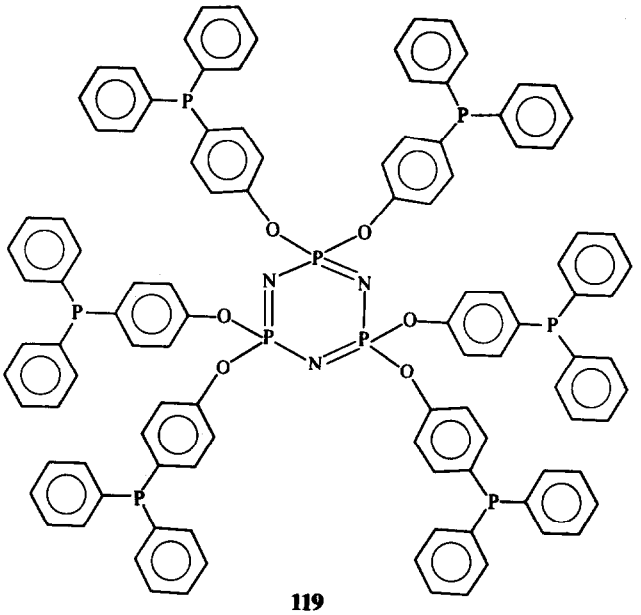
Although not strictly part of the organometallic chemistry of phosphazenes, it should be noted that copper phthalocyanines have been linked to cyclic and high-polymer phosphazenes via organic spacer groups.[145] These generate electrically semiconducting solids when doped with iodine.

(b) *Phosphine-linked phosphazenes.* As mentioned earlier, Main-Group organometallic chemistry

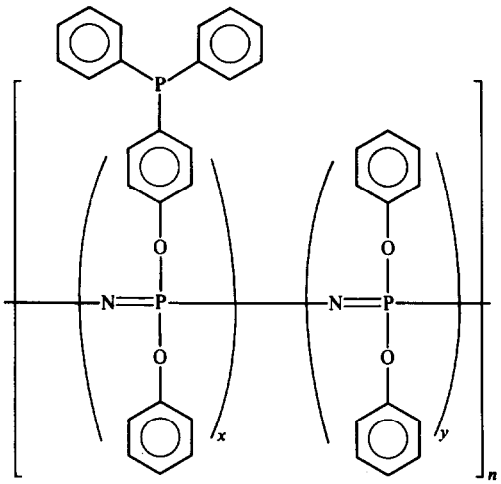
has been used to prepare several cyclic and high-polymeric phosphazenes that bear pendent triarylphosphine groups. Typical compounds of this type are shown as **118–120**.[146]



118



119



120

These compounds are of interest from three points of view. First, the question exists of whether coordination to a metal would take place through the pendent phosphine unit or through the skeletal nitrogen atoms. In fact, for all the cases studied so far {in which the metallo species was AuCl, $H_2Os_3(CO)_{10}$, $Mn(CO)_2THF(\eta\text{-}C_5H_5)$, $Fe(CO)_3(PhCH{=}CHCOCH_3)$ or $[RhCl(CO)_2]_2$}, the coordination has involved the pendent phosphine groups only.[146] This can be attributed to the relatively low basicity of the skeletal nitrogen atoms when weakly electron-withdrawing side groups, such as phenoxy, are present, and to steric shielding of the nitrogen atoms by the aryloxy groups.

The second question bears on the behavior of all species in which a transition metal is linked to a carrier molecule. If the transition metal can form a diphosphine complex, does this lead to the formation of *inter*molecular crosslinks as phosphine units from different carrier molecules bond to the same metal atom or, in the case of species **119** and **120**, is *intra*molecular linkage preferred, to generate a transannular or intrachain coupled system?

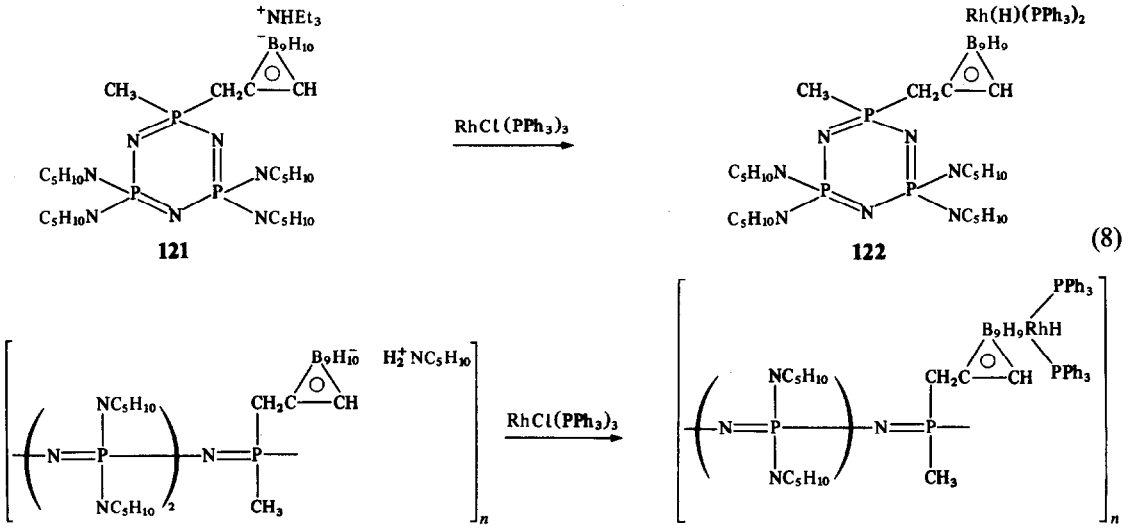
Monophosphine complexes were obtained with the gold, osmium and manganese complexes.[146] However, the iron and rhodium organometallic species formed diphosphine complexes, with both intra- and intermolecular coupling to the phosphines in species **119**. The high polymer **120** underwent

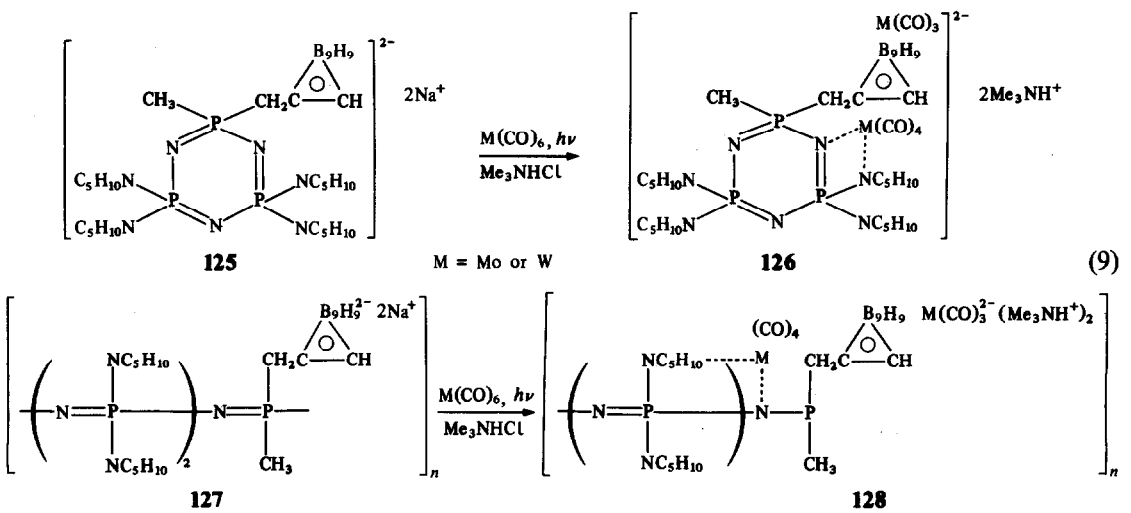
insolubilization through cross-linking in the presence of the same organometallic reagents.[146] A similar cross-linking process was detected when **120** reacted with cobalt carbonyl.[147]

The third question concerns the catalytic activity of transition-metal organometallic species linked to **118–120**. The osmium complexes of **118–120** were catalysts for the isomerization of 1-hexene to 2-hexene.[146] Moreover, the cobalt carbonyl adducts of **118** and **120** were active as hydroformylation catalysts.[147] The main disadvantage of the high-polymer cobalt hydroformylation system is the slow decline in catalytic activity in successive catalytic cycles, which is due to a cobalt-mediated cleavage of the bond that links the pendent phosphorus atom to the supporting aryloxy group. Thus, the phosphino function is lost, and the cobalt escapes with it.[147]

(c) *Metallo-carboranyl-linked phosphazenes.* As discussed in an earlier section, *closo*-carboranyl phosphazenes can be prepared either by the reactions of lithiocarboranes with chlorophosphazenes or by the interaction of propynylphosphazenes with decaborane.[94,148] Such *closo*-carboranyl phosphazenes can be converted to the *nido*-carboranyl anion derivatives by treatment with a base.[148]

When a methylene spacer group separates the carboranyl unit from the phosphazene ring (**121**) or chain (**123**), the *nido*-carboranyl anion units can be induced to form complexes with transition-metal species.[148] For example, compounds **121** and **123** react with $RhCl(PPh_3)_3$ to yield neutral complexes (**122** and **124**) with the transition metal associated with the open face of the carboranyl unit. Similarly, the dianionic derivatives (**125** and **127**) react with $Mo(CO)_6$ or $W(CO)_6$ to form the dianionic complexes depicted as **126** and **128**, in which the metal carbonyl units are bound to the open face of the carborane *and* the phosphazene skeleton.





If the methylene spacer group between the carboranyl function and the phosphazene skeleton is not present as, for example, in species **56** discussed earlier, then although *nido*-carborane anion formation is possible, no transition-metal derivatives could be formed. We presume that steric shielding of the open face of the carborane by the phosphazene ring is responsible for this behavior.[148]

(d) *Metallocene-linked phosphazenes.* The reactions between lithiometallocenes and halogenophosphazenes have been studied intensively in our laboratories by Lavin, Riding and Suszko.[149–153] These reactions have led to the isolation of the first hybrid phosphazene–metallocene compounds, species that have proved to be of considerable interest from a structural point of view[149–151] and as starting materials for the preparation of metallocenylphosphazene high polymers.[152]

The reactions of lithiometallocenes with chloro- and fluorophosphazenes can be understood in terms of the mechanisms discussed earlier for the reactions of organolithium reagents with the same substrates. Specifically, the reactions of lithioferrocene or lithioruthenocene with *fluoro*phosphazenes are cleaner than the corresponding reactions with chlorophosphazenes. With fluorophosphazenes, the main reaction is substitution, i.e. replacement of fluorine atoms by metallocene units. With chlorophosphazenes, the reactions are complex, with substitution being accompanied by metal–halogen exchange and associated side reactions, such as ring coupling, metal–hydrogen exchange, skeletal cleavage and so on. The simpler reactions with fluorophosphazenes will be discussed first.

(i) Reactions of mono- and dilithiometallocenes with $(NPF_2)_3$ or $(NPF_2)_4$. These interactions are summarized in Scheme 16.[149,150] Thus, $(NPF_2)_3$ and $(NPF_2)_4$ react with lithioferrocene or lithioruthenocene first to yield the monosubstituted products (**129** and **131**). Further substitution then takes place at a nongeminal site to give the disubstituted products (**130** and **132**).

Dilithioferrocene or dilithioruthenocene react with the trimer, $(NPF_2)_3$, to give predominantly the transannular-linked (ansa) product (**133**). This reaction also yields a small quantity of an intermolecular-coupled product (**134**) with the ruthenium system. The dilithiometallocenes also react with the cyclic tetramer, $(NPF_2)_4$, in a similar manner to give the isomeric transannular products (**135** and **136**). Most of these structures have been confirmed by X-ray crystallography,[149–151] and all the structures have been verified by NMR analysis.

Of special interest from a structural point of view is the fact that the transannular tetramer **135** (where M = Ru) reacts further with dilithioruthenocene to generate the "double transannular" tetramer shown as **137**.[153] An X-ray study of this compound has shown that, as in the case of all the other transannular metallocenyl phosphazenes, the ring strain is accommodated almost entirely by the phosphazene ring through puckering. Thus, in **137**, the cyclic tetrameric phosphazene ring assumes a highly puckered boat conformation in order to allow two cyclopentadienyl units in each metallocene unit to retain their coplanarity. Moreover, the shape of the molecule **137** is such that the remaining fluorine atoms cannot be replaced by conventional organic nucleophiles such as sodium trifluoroethoxide. Presumably, a S_N2-type backside attack on the phosphorus atom is inhibited by steric shielding.

It should also be noted that dilithio-bis-benzenechromium reacts with $(NPF_2)_3$ to form a transannular derivative.[154]

(ii) Reactions between mono- and dilithiometallocenes and $(NPCl_2)_3$ or $(NPCl_2)_4$. In Scheme 17 we summarize some of the products that are formed when $(NPCl_2)_3$ reacts with the mono- or dilithiometallocenes.[109] Monolithioferrocene or monolithioruthenocene reacts to give the monosubstituted derivative (**138**) together with the asymmetrical bi(cyclophosphazene) (**139**). Product **139** is reminiscent of the species formed when Grignard reagents react with $(NPCl_2)_3$, and is a clear indication that metal–halogen exchange reactions are involved with lithiometallocene reactions also.

Further evidence for the involvement of metal–halogen exchange processes is provided by the reactions of the dilithiometallocenes with $(NPCl_2)_3$. As shown in Scheme 17, the products from these reactions include **140** and **141**, in which a chlorine atom has replaced one of the lithium atoms and, in the case of dilithioferrocene in the presence of TMEDA, species **142**, in which a ferrocenyl unit bridges the P—P bond of a bi(cyclophosphazene) compound.[150] These structures have been confirmed by X-ray crystallography and NMR analysis.[150]

A reaction mechanism has been proposed that explains the formation of all these products (**138–142**).[150] The mechanism most compatible with the data is based on the assumption that the *first* step is probably metal–halogen exchange to give species **143** (Scheme 18). By substitution, this then yields species **144** which, by reaction with $(NPCl_2)_3$, gives **139**. Species **138** could be formed by

abstraction of a chlorine atom from $(NPCl_2)_3$ by **144**. This mechanism appears to be an unnecessarily complex one for the formation of **138**, which could, in principle, be formed directly by a substitution reaction between $(NPCl_2)_3$ and the lithiometallocene. Indeed, the experimental data from the reaction with monolithiometallocenes do not distinguish between these two mechanisms for formation of **138**. However, the data from the reaction with the *di*lithiometallocenes favor a pathway to **138** that proceeds via reactions (c)–(e) (Scheme 18).

In terms of this mechanism, the appearance of a chlorine atom in **140** and **141** in the place previously occupied by lithium, can be explained by metal–halogen exchange. In this context, the overall influence of metal–halogen exchange can be summarized in one reaction, between a mixture of $(NPCl_2)_3$ and $(NPCl_2)_4$ and either mono- or dilithioferrocene.[151] The product (**145**) has both a

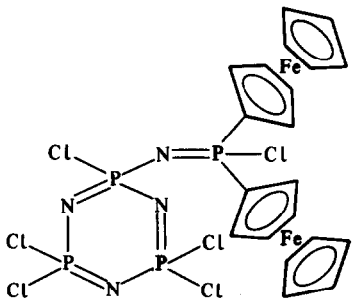
In the absence of the trimer, the tetramer $(NPCl_2)_4$ reacts with monolithioferrocene to yield the ring-contracted species (**146**).[151] The formation of this product can be understood by the mechanism shown in Scheme 19.[151]

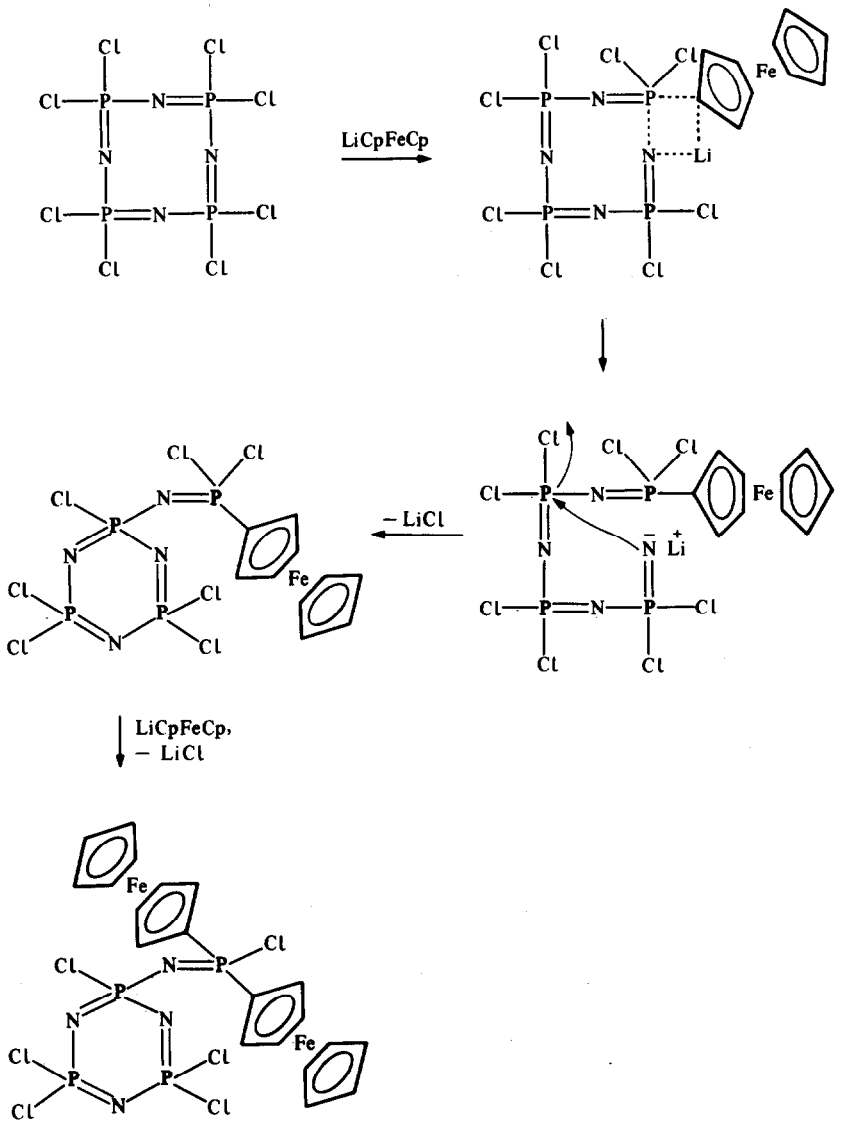


146

(iii) High-polymeric metallocenylphosphazenes. Cyclotriphosphazenes, such as **129** or **138** are of interest not only from a synthetic and structural point of view but also because they can be induced to undergo thermal phosphazene ring-opening polymerization to give linear higher polymers with metallocenyl side groups. Release of phosphazene ring strain in **138** induces a more facile polymerization reaction than in the case of **129**. The fluorine atoms can then be replaced by treatment with organic nucleophiles, such as sodium trifluoroethoxide, to yield water- and heat-stable polymers (**148**, **150** and **152**). The molecular weights of these polymers are in the range of 2×10^6, which corresponds to an average of roughly 5000 repeating units per chain. These reactions are summarized in Schemes 20–22.[152]

The copolymerization reaction shown in Scheme 22 provides a method for the incorporation of two different types of metal centers into the same macromolecule. This is of prospective interest for catalyst, electrode mediator, or electronically-active applications. Polymers of types **148** and **150** are weak semiconductors when doped with iodine.

(e) *Metallo complexes formed by acetylenic phosphazenes.* Finally it is possible through the use of organolithium- or organocopper-mediated reactions to synthesize cyclophosphazenes with phenylacetylenic or propynyl side groups attached to the phosphazene ring.[60,85] It is well-known that acetylenic units form pi complexes with transition metals, especially dicobalt carbonyl species, and that such complexes can serve as catalysts for the cyclotrimerization of acetylenes to benzene derivatives. Chivers[60] first reported a cobalt–phosphazene compound of this type (**153**).



Scheme 19.

We have explored the application of these principles to a broad series of propynyl phosphazenes synthesized in our laboratory.[85] In particular, a number of propynylphosphazenes have been treated with cobalt octacarbonyl to yield the complexes shown as **154** and **155**.[155] Species **154** and **155** induce the cyclotrimerization of diphenylacetylene or phenylacetylene. They also induce the co-oligomerization of propynylphosphazenes with phenylacetylenes to yield benzenoid products with pendent phosphazene rings. Evidence was also obtained that prop-2-ynyl derivatives (but not prop-1-ynyl derivatives) themselves cyclotrimerize to yield benzene rings with three pendent cyclophosphazene rings.

V. CONCLUSIONS

It will be clear that the organometallic chemistry of phosphazenes is a rich and diverse field of study, and one that will form the basis of more extensive explorations in the future.

At the fundamental level, the challenge for the future will be to understand the sometimes complex reaction mechanisms, to expand the chemistry into new areas of transition-metal reactions, to study the novel forms of binding between transition metals and phosphazenes, and to probe the

possibility that metallocene-type sandwich complexes can be prepared with a metal bound to the pi electrons of a phosphazene ring.

The use-oriented prospects for this area of chemistry are also promising. Examples have been given of polymer-bound catalysts that utilize the polyphosphazene chain, and of organometallic

phosphazene high polymers that are actual or prospective semiconductors, electrode mediator catalysts, magnetic disk or tape precursors, or metal-containing preceramic meterials. The organic-type chemistry of phosphazenes has dominated the development of this field until recently. The time now seems ripe for a much increased emphasis on the organometallic aspects.

PREPARATION AND STRUCTURAL PROPERTIES OF A NEW MIXED-METAL BINUCLEAR COMPLEX WITH 4-CYANOPYRIDINE BRIDGING THE PENTAAMMINERUTHENIUM(II) AND THE PENTACYANOFERRATE(II) MOIETIES*

EDGARDO H. CUTIN and NÉSTOR E. KATZ†

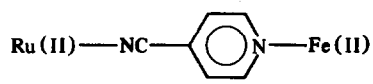
(*Received* 18 *September* 1985; *accepted* 6 *November* 1985)

Abstract—A new binuclear complex, of formula $Na[(NH_3)_5Ru(4\text{-cypy})Fe(CN)_5]\cdot 6H_2O$, with 4-cypy = 4-cyanopyridine, is described. It can be prepared by reaction in aqueous solution, of stoichiometric amounts of $[Ru(NH_3)_5(4\text{-cypy})]Br_2$ and $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ and is insoluble in water and stable in the solid state. Spectral data point to the structure



and the observed hypsochromic shifts of the MLCT bands in the UV–Vis spectrum and the diminished shift to lower frequencies observed in the IR spectrum for the nitrile stretching frequency, when compared to the parent complexes, indicate a reduxed π-backbonding interaction between the metals and the bridging ligand. It is concluded that the asymmetry of 4-cypy causes weak π-resonance interaction between both metallic centers.

Bridged polynuclear complexes are systems of interest in various fields, such as the study of mechanisms of biological redox reactions[1] and the generation of chemical potential energy from solar light absorption.[2] Therefore, important efforts have been made in the synthesis and characterization, by spectroscopic or electrochemical techniques, of new mixed-metal complexes.[3–6] In a recent work,[7] a new complex formed by association of $[Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy (4-cypy = 4-cyanopyridine) at a molar ratio of 2:1 has been described. It was found that the cyanide group gives rise to a bridge between both pentacyanoferrate(II) moieties which is much more stable than that derived from the ambidentate ligand 4-cypy.

In this work, we report the preparation and spectral properties of a new mixed-metal dimer with 4-cypy bridging the pentaammineruthenium(II) and the pentacyanoferrate(II) moieties; both of which are able to interact through strong π-backbonding with aromatic nitrogen heterocycles.[8] This new binuclear species has spectroscopic characteristics that differ from similar dimers bridged by symmetric ligands.[9] By analyzing its UV–Vis and IR spectra, the influence of the asymmetric nature of 4-cypy on the structure of the mixed-metal complex can be assessed.

EXPERIMENTAL

Analytical reagent compounds were used for all preparations described in this work. Doubly distilled water was redistilled from alkaline permanganate in an all-glass apparatus.

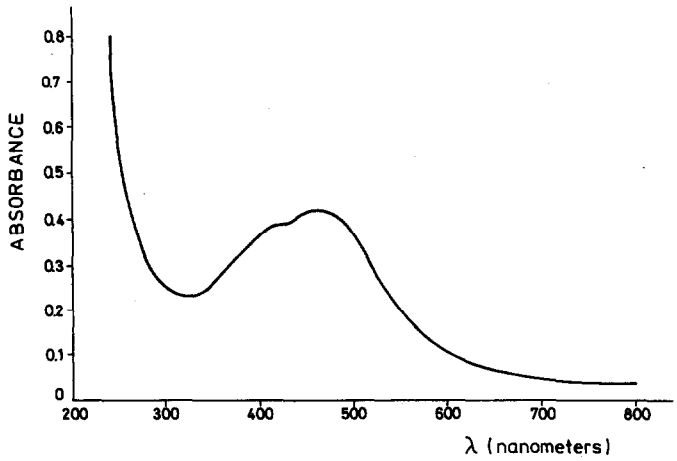

Fig. 1. UV–Vis spectrum of the complex $Na[(NH_3)_5Ru(4\text{-cypy})Fe(CN)_5]\cdot 6H_2O$, as KBr pellet.

4-Cyanopyridinepentaammineruthenium(II) was obtained by a published method.[10] $[Ru(NH_3)_5Cl]Cl_2$ necessary for the previous preparation was synthesized by the method of Allen *et al.*[11] The complexes $Na_5[Fe(CN)_5(SO_3)]\cdot 2H_2O$ and $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ were obtained according to previous works.[12,13]

Forty-three mg of $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ were added to 3 cm^3 of a solution in triply distilled water (at room temperature) containing an equimolar amount (60 mg) of $[Ru(NH_3)_5(4\text{-cypy})]Br_2$. The first complex aquates rapidly,[14] while the latter is substitution inert and insensitive to air oxidation.[10] The dark-red product formed precipitated immediately; after 15 min the solid was collected in a sintered glass filter, washed twice with water, ethanol and ether, and dried under vacuum in a desiccator over KOH. In an alternative preparation, 40 mg of $[Ru(NH_3)_5(4\text{-cypy})]Br_2$ were dissolved in 5 cm^3 of triply distilled water and then an equimolar amount of $Na_5[Fe(CN)_5(SO_3)]\cdot 2H_2O$ was added. The precipitate was treated in the same way as above. Both products gave identical IR spectra.

Carbon, hydrogen and nitrogen analyses were performed at UMYMFOR Laboratories, Buenos Aires, Argentina. Iron analysis was done by atomic absorption spectroscopy on a Varian Techtron AA spectrometer; sodium nitroprusside being the selected standard. Ruthenium analysis was carried out by boiling in peroxydisulfate (in KOH), filtering and recording the absorbance at 415 nm[15] on a Metrolab RC325 spectrophotometer.

Electronic spectra were recorded on a Shimadzu UV-300 spectrophotometer. IR spectra were obtained by using a Perkin–Elmer 580B spectrophotometer. All measurements were carried out with KBr pellets. Different samples gave reproducible results, indicating stability in the solid phase.

RESULTS AND DISCUSSION

Chemical analyses gave the following results. Found: Fe, 10.1; Ru, 16.4; C, 21.1; H, 4.4; N, 25.1%. Calc. for $Na[(NH_3)_5Ru(4\text{-cypy})Fe(CN)_5]\cdot 6H_2O$: Fe, 9.2; Ru, 16.6; C, 21.7; H, 5.1; N, 27.7%. The error observed for nitrogen analysis can be attributed to the exchange of NH_3 by H_2O.[1] Insolubility in water can be related to the hydrophobic periphery of the ion; this fact has already been observed in $[(CN)_5Fe(4\text{-cypy})Rh(NH_3)_5]\cdot 6H_2O$.[3]

Figure 1 shows the UV–Vis spectrum of the complex under study. Formation of a 4-cypy bridge between Fe(II) and Ru(II) is evidenced by the two peaks protruding from the broad asymmetric band, at 418 and 470 nm. The $[Ru(NH_3)_5(4\text{-cypy})]^{2+}$ complex presents a metal-to-ligand charge-transfer (MLCT) absorption at 425 nm, corresponding to coordination of Ru(II) to the nitrile end of 4-cypy.[10] On the other hand, the $[Fe(CN)_5(4\text{-cypy})]^{3-}$ complex has a MLCT band at 476 nm, indicating coordination of Fe(II) to the pyridine N of 4-cypy.[16–18] The bands observed for the dimeric complex at 418 and 470 nm are then shifted to higher frequencies with respect to the monomeric complexes and can be surely assigned, by analogy, to electron transfers $d_\pi(Ru) \rightarrow \pi^*$ (nitrile end of 4-cypy) and $d_\pi(Fe) \rightarrow \pi^*$ (pyridine ring of 4-cypy), respectively. The hypsochromic displacements are similar to those found for the $[(Ru(NH_3)_5)_2(4\text{-cypy})]^{4+}$ complex,[1] and are considered "anomalous" when compared with other structurally related systems.[9] This effect can be explained on the basis of the asymmetrical nature of the bridging ligand. π-Backbonding from Fe(II)

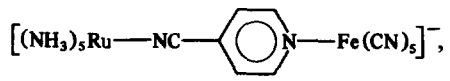
to the pyridine ring must raise the energy of the π^*-orbital of the nitrile end of 4-cypy, while π-backbonding from Ru(II) to NC must increase the energy of the π^*-orbital of the aromatic heterocycle.[19] These charge transfers usually surpass electrostatic effects. Therefore, and because the energy of the MLCT is related to the energy of the ligand LUMO,[1] the energies of both electron transfers increase, resulting in higher absorption frequencies respect to the parent complexes. A weak π-resonance interaction thus seems to be present in the binuclear ion.

Table 1 shows data from IR spectra of the studied complex and the corresponding monomers. The proposed assignments are tentative. The stretching frequency of the nitrile group of 4-cypy is shifted 60 cm^{-1} below the value for the free ligand (2243 cm^{-1}). This lowering, already observed for the $[Ru(NH_3)_5(4\text{-cypy})]^{2+}$ complex,[10] can be attributed to the strong π-backbonding capacity of the $Ru(NH_3)_5^{2+}$ moiety and is another evidence of bonding of Ru(II) to the nitrile end of the bridging ligand. For the monomer complex $[Ru(NH_3)_5(4\text{-cypy})]Br_2$, the decrease is $\Delta\nu(CN) = -64$ cm^{-1},[10] while for the dimer $[(Ru(NH_3)_5)_2(4\text{-cypy})](ClO_4)_4$, $\Delta\nu(CN) = -53$ cm^{-1}.[1] The value observed here is thus intermediate between these species, a fact which can be accounted for—as already stated when discussing the electronic spectrum—by the reduction of π-backbonding from Ru(II) to the NC

group of 4-cypy due to coordination of $Fe(CN)_5^{3-}$ to the pyridine N of 4-cypy, and also by the lower π-backbonding capacity of this latter moiety compared to the $Ru(NH_3)_5^{2+}$ group.[8]

As illustrated in Table 1, the IR band assigned to cyanide stretching frequencies at 2062 cm^{-1} falls in the range expected for cyanoferrate(II) complexes.[9] On the other hand, the band corresponding to the symmetric deformation of NH_3 (1288 cm^{-1}) is characteristic of ammine complexes of Ru(II).[9] Finally, the shifts observed for the pyridine ring vibrations with respect to the monomers confirm bonding of a metal center to pyridine N.[18]

Results from IR studies agree with those from UV–Vis, so that we conclude that the new species, of structure



is stable in the solid state, with localized (II) oxidation states for Fe and Ru. The spectral properties indicate weak π-resonance interaction in the unsymmetrical bridge.

PHENYLIMIDO ETHOXO COMPLEXES OF TUNGSTEN(VI): CRYSTAL AND MOLECULAR STRUCTURE OF DICHLORO-DI-μ-ETHOXOTETRAETHOXOBIS(PHENYLIMIDO)DITUNGSTEN(VI)

PAUL A. BATES, ALASTAIR J. NIELSON* and JOYCE M. WATERS†

Department of Chemistry, University of Auckland, Private Bag, Auckland, New Zealand

(*Received* 28 *October* 1985; *accepted* 11 *March* 1986)

Abstract—Reaction of $[W(NPh)Cl_4]_2$ with various quantities of ethanol and *t*-butylamine leads to $[W(NPh)(\mu\text{-}OEt)(OEt)_3]_2$, $[W(NPh)(\mu\text{-}OEt)(OEt)_2Cl]$ and $[W(NPh)(OEt)Cl_3(NH_2CMe_3)]$. A 1:1 proportionation reaction of $[W(NPh)Cl_4]_2$ and $[W(NPh)(\mu\text{-}OEt)(OEt)_3]$ gives $[W(NPh)(\mu\text{-}OEt)(OEt)Cl_2]_2$, whereas a 3:1 proportionation gives $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$. Bridge-splitting reactions of $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$, with PMe_3 or Et_4NCl give $[W(NPh)(OEt)Cl_3(PMe_3)]$ and $[W(NPh)(OEt)Cl_4][Et_4N]$. $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ reacts with Ph_3CCl to give $[W(NPh)(OEt)Cl_4][Ph_3C]$ and $[W(NPh)Cl_4]_2$ reacts with Ph_3COEt to give $[W(NPh)Cl_4(OEt)][Ph_3C]$. The trityl complexes do not react further to give amido complexes (W—$NCPh_3Ph$). The products were characterized by analytical data, IR, ^1H and ^{13}C NMR spectroscopy. The crystal and molecular structure of $[W(NPh)(\mu\text{-}OEt)(OEt)_2Cl]_2$ was determined from single-crystal X-ray diffractometer data. The crystals are triclinic with $a = 9.637(2)$ Å, $b = 11.135(1)$ Å, $c = 8.016(1)$ Å, $\alpha = 108.47(1)°$, $\beta = 105.51(1)°$, $\gamma = 91.51(1)°$, and space group $P\bar{1}$. The structure was solved by Patterson and Fourier methods and refined to $R = 0.039$ for the 1450 observed data. The molecule is a dimer with the two halves centrosymmetrically related. Both W atoms adopt a distorted octahedral coordination geometry and are linked by two ethoxo bridges. *Trans* to the bridging donors is a linear phenylimido group with a W—N bond length of 1.759(9) Å and a W—N—C bond angle of 172.4(9)°. The remaining octahedral sites are filled by a chloro ligand and two *cis*-orientated alkoxide ligands where the W—O bond distances of 1.835(9) and 1.865(7) Å indicate both ligands participate in π-bonding to the metal.

Many examples of Group VI transition-metal organoimido complexes (M≡NR) are known[1] but few also contain the alkoxide ligand. Those reported to date are the dialkoxides $[(Me_3SiO)_2M(N\text{-}t\text{-}Bu)_2]$[2] (M = Cr or Mo), $[(t\text{-}BuO)_2W(N\text{-}t\text{-}Bu)_2]$[3] and $[WO(NR)(OEt)_2]_n$.[4] Alkoxide ligands are of interest in organoimido chemistry since competitive π-donation from a suitably orientated alkoxide ligand can weaken the very stable, four-electron metal–nitrogen bond, increasing the potential for further reaction at the nitrogen atom.[5–7] In addition, structural features exhibited by the complexes can be affected by the size of the alkoxide R group.[8] We report here the preparation and characterization of mixed chloride–ethoxide phenylimido complexes of tungsten(VI) which complete the series $[W(NPh)(OEt)_xCl_{4-x}]_2$ and demonstrate further relationships between W—OR bonding and structure–reactivity considerations.

RESULTS AND DISCUSSION

In benzene solution phenylimido tungsten tetrachloride $[W(NPh)Cl_4]_2$ reacts with 8 equivalents of EtOH in the presence of excess anhydrous ammonia to give a yellow air- and moisture-sensitive crystalline solid analysing as $[W(NPh)(OEt)_4]_n$, for which the dimeric structure $[W(NPh)(\mu\text{-}OEt)(OEt)_3]_2$ (**1**) is proposed, based on the crystallographically determined methoxo analogue $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$.[8] Using ammonia the

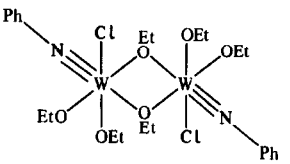
1

yield of **1** is low but with *t*-butylamine and petroleum ether as solvent the yield is increased to over 70%. The reaction produces 8 equivalents of *t*-butylamine hydrochloride after approximately 4 h. If more than 8 equivalents of alcohol and amine are used or the reaction period is shortened, the product reacts with the excess when the solution is concentrated, producing a red gummy contamination product which NMR analysis indicates is a mixture.

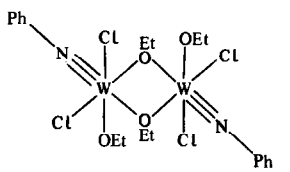
Reaction of 6 equivalents of EtOH and Me_3CNH_2 with phenylimido tungsten tetrachloride failed to give a petroleum ether soluble product, but extraction of the yellow amine hydrochloride residue with toluene gave, after crystallization, a yellow complex which analysed as $[W(NPh)(OEt)_3Cl]_n$. An X-ray crystal structure determination (see later) showed the dimeric ethoxo-bridged structure (**2**). The complex was also obtained in varying



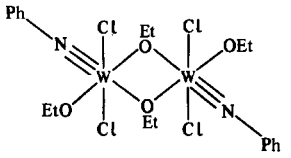
2

yield by toluene extraction of the amine hydrochloride residues produced during formation of the tetraethoxide (**1**) and this complex is the product of further reaction of **2** with 2 equivalents of EtOH and *t*-butylamine.

Four equivalents of EtOH and Me_3CNH_2 reacted with phenylimido tungsten tetrachloride in benzene to give 4 equivalents of amine hydrochloride but the yellow oily product obtained from solution was shown by IR and NMR spectroscopy to be a mixture. However a proportionation reaction between 1 equivalent each of **1** and phenylimido tungsten tetrachloride in benzene gave a yellow crystalline material analysing as $[W(NPh)(OEt)_2Cl_2]_n$ for which an ethoxy-bridged structure (either **3** or **4**) is preferred based on the crystallographically determined ethoxide bridge in **2**.

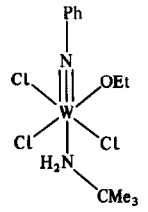


3



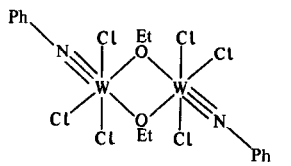
4

Phenylimido tungsten tetrachloride reacted with 2 equivalents of EtOH and Me_3CNH_2, giving a red solution from which the monomeric complex $[W(NPh)(OEt)Cl_3(NH_2CMe_3)]$ (**5**) was obtained.



5

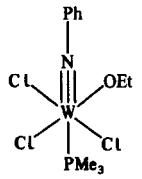
The amino ligand lying *trans* to the imido group is preferred for this complex, based on the X-ray structure of $[W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)]$ where the amine ligates *trans* to the imido function.[8] Proportionation of 1 equivalent of **1** with 3 equivalents of phenylimido tungsten tetrachloride in benzene led to a purple-brown solid analysing as $[W(NPh)(OEt)Cl_3]_n$ for which the dimeric ethoxy-bridged structure (**6**) is assigned on the basis of its



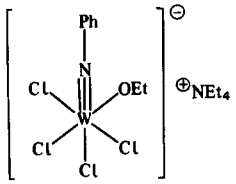
6

IR spectrum. The complex was also obtained by reacting 1 equivalent of $[W(NPh)(OEt)_2Cl_2]_2$ with one of phenylimido tungsten tetrachloride.

Studies carried out on complexes **1–6** to determine the stabilizing effects of the alkoxo ligands and imido ligand reactivity showed the complexes to be surprisingly inert. For example, the ethoxo bridge in complexes **1–3** could not be split with strong σ-donor ligands such as PMe_3, nor was there any tendency to form anionic species by the addition of Ph_4PCl or Et_4NCl. This contrasts with the chemistry of $[W(NPh)Cl_4]_2$ where $[W(NPh)Cl_4(PMe_3)]$[9] and the $[W(NPh)Cl_5]^-$[10] anion are easily formed, and demonstrates the stability of the alkoxo bridge. However, reaction of stoichiometric amounts of PMe_3, Me_3CNH_2 or Et_4NCl with $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ (**6**) gave the monomeric complexes $[W(NPh)(OEt)Cl_3(PMe_3)]$ (**7**), **5** and $[W(NPh)(OEt)Cl_4][Et_4N]$ (**8**), respec-



7



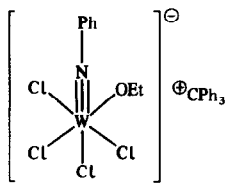
8

tively, suggesting that the bridge in the monoethoxo complex is more easily broken. Further, the room-temperature reaction of excess PMe_3 with **6** in THF did not reduce the complex to tungsten(V) as is the case with $[W(NPh)Cl_4]_2$ which readily reduces to $[W(NPh)Cl_3(PMe_3)_2]$.[9] This complex was, however, obtained after prolonged heating of **6** with the phosphine but no reduced ethoxy complexes could be isolated. Reduction of $[W(NPh)Cl_4]_2$ with sodium–mercury amalgam in the presence of a σ-donor ligand (L) gives rise to the tungsten(IV) complexes $[W(NPh)Cl_2L_3]$[11] but similarly based experiments with the mono- and diethoxo complexes, which are apparently reduced, have so far given intractable products. The tetraethoxide species (**1**) fails to react at all.

For the Group V metals, the imido nitrogen is expected to function as a nucleophile but examples are extremely rare.[12] We have shown that protonation of the W≡NPh bond gives rise to amido complexes (W—NHPh),[6] and bis-imido complexes of molybdenum are known to react with MeBr to produce $PhNMe_2$.[13] We were interested to test the effects of alkyl halide addition to the bridged dimers in the hope of generating amido complexes by the following reaction:

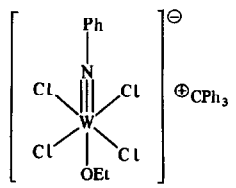
$$[W(NPh)(OEt)_xCl_y]_n + nRX \rightarrow n[W(NPh)(OEt)_xCl_yX^{\ominus}][R^{\oplus}] \rightarrow n[W(NRPh)(OEt)_xCl_yX].$$

All complexes tested failed to react at room temperature with alkyl halides (RX = MeI, MeBr or EtBr) in a variety of solvents and most were resistant to heat. For example, the tetraethoxo complex (**1**) remained unchanged in benzene after heating with MeI to 150°C in a pressure bottle (pressure developed = 700 kPa). However, with Ph_3CCl, $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ was found to react at room temperature to give $[W(NPh)(OEt)Cl_4][Ph_3C]$ (**9**).



9

This complex, which persisted as a non-crystalline material, analysed as a dichloromethane solvate and was a 1 : 1 conductor in acetonitrile. Reaction of phenylimido tungsten tetrachloride with Ph_3COEt gave a similar anionic complex consistent with the formulation $[W(NPh)Cl_4(OEt)][Ph_3C]$ (**10**),



10

whereas $[W(NPh)(OEt)_2Cl_2]_2$ was obtained from the reaction between $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ and Ph_3COEt. The anionic complexes **9** and **10** are apparently stable in solution and we have so far been unable to obtain evidence for any rearrangement to an amido complex.

IR spectra

Organoimido complexes generally show strong absorptions characteristic of the metal–imide vibration between 1100 and 1300 cm^{-1} [11] but in the present complexes this region is obscured by bands arising from the alkoxide ligand. All the compounds do, however, show strong absorptions at approximately 1350 cm^{-1} in KEL-F or as a shoulder of Nujol. For phenylimido rhenium complexes this absorption shifts to a lower wavenumber on ^{15}N-substitution making it a good candidate for $\nu(W{\equiv}NR)$[5] although $\nu(C{-}N)$ bands for aromatic amines also fall in this region but these are usually weak. Raman spectra of **1** and **2**[14] show the 1350-cm^{-1} band to be intense and polarizable, indicating that it arises from multiple bonding where a sufficient electron density is present to give an induced dipole in the Raman effect. In Table 1 the 1350-cm^{-1} bands found in the IR spectrum of the complexes are shown as ν(WNC).

Assignment of C—O and M—O stretching vibrations is straightforward for the complexes since problems of structural complexity and low

[a] t = terminal, b = bridging.

molecular symmetry normally associated with alkoxides are absent. Although the complexes show a series of ν(C—O) bands between 1150 and 850 cm^{-1}, which are characteristic of metal alkoxides in general,[15] only the strongest are shown in Table 1. The monomeric complexes [W(NPh)(OEt)Cl$_3$(L)] (L = NH_2CMe_3 or PMe_3) and [W(NPh)(OEt)Cl$_4$][Et_4N] show a single strong absorption in the ν(C—O) region (1000–960 cm^{-1}) which are from necessity assigned to a terminal mode as also must the M—O band in the region of 600 cm^{-1}.[16] For the parent complex (**6**) both ν(C—O) and ν(M—O) lie at a lower wavelength, which is a characteristic feature of bridging modes in metal alkoxides.[15] The diethoxo complex (**3**) shows absorptions at 1038 and 985 cm^{-1}, suggesting both terminal and bridging modes where the *tri-* and *tetra*ethoxo complexes (**2** and **1**) are similar but show an increasing intensity of the terminal mode with increasing number of terminal ethoxides.

In the far IR **6** shows three W—Cl stretching bands as expected for a *mer* arrangement of three metal chlorides[17] and this is repeated for the monomeric derivatives (**5** and **7**). Comparison of the absorption intensities at 330 and 280 cm^{-1} shows that for the *tri*chloro complex (**6**) the 348-cm^{-1} band dominates, for the dichloro complex, (**3**), the intensities are equal whereas for the monochloro complex (**2**) only one band at 285 cm^{-1} is present. This suggests that the latter absorption may be indicative of a chloro group *trans* to an ethoxide ligand.

NMR spectra

The proton NMR spectra of the complexes (Table 2) show the alkoxide ligand CH_2 resonance in the vicinity of 5 ppm. **6** shows a well-defined quartet as do the other complexes containing only one ethoxide ligand. **2** and **3** exhibit complicated sets of quartets arising from intramolecular exchange of alkoxide ligands but no attempt has been made to obtain frozen-out spectra as it is well established that α-protons of bridging alkoxides absorb upfield of terminal alkoxides.[15] Interestingly, the CH_2 resonances of **1** are less complicated, involving only two sets of quartets in an approximate 2 : 1 ratio, which suggests less intramolecular exchange or a greater magnetic equivalence of the ethoxides in the absence of chloro ligands. For the trityl complexes **9** and **10** the appearance of the CH_2 quartet in the vicinity of 5 ppm confirms the ethoxo group exists as a tungsten alkoxide and not as $EtOCPh_3$. The spectra do not, however, distinguish between a chloro or an ethoxo function lying *trans* to the imido function.

Several of the complexes show well-resolved aromatic resonances which appear to approach first-order spectra. However, as with $[W(NPh)Cl_4(NCEt)]$,[9] the coupling constants are identical indicating deceptive simplicity.[18] In general, anisotropy effects associated with the imido function result in a downfield shift for the *ortho* protons whereas the *para* proton lies upfield.

In the ^{13}C NMR spectra (Table 2) the terminal ethoxide CH_2 resonance of the monoethoxide monomers is observed near 82 ppm as is the case for the trityl complexes (**9** and **10**). $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ is sparingly soluble but what does dissolve shows the CH_2 resonance also at 82 ppm, suggesting that in solution the complex may well exist as a monomer (cf. IR evidence for a bridging ethoxide in the solid). $[W(NPh)(OEt)_2Cl_2]_2$ shows two resonances in this region and a further two near 77 ppm, suggesting two isomeric forms (**3** and **4**). However, the sets of resonances may be a consequence of intramolecular exchange since several resonances appear for both **1** and **2**. With the greater substitution by ethoxide ligands in these complexes the resonances shift upfield until, in the case of the tetraethoxide, all resonances appear in the vicinity of 72 ppm with no strictly terminal CH_2 resonances (82 ppm) apparent at all.

The complexes show strong deshielding of the aromatic ring *ipso* carbons similar to nitrobenzene where electron withdrawal from the ring occurs.[19] Little change occurs for the *meta* carbons, whereas *ortho* and *para* carbons are affected to differing extents. Downfield shifts of α-carbon resonances in *t*-butylimido complexes of Group V metals are associated with a greater electron density in the W≡N bond,[12] hence, assuming that the analogy holds for *ipso* carbons in the phenylimido complexes, comparative W≡N bond strengths should be demonstrable. The $L_xW{\equiv}N$ substituent effects on the ring carbons compared with benzene are shown in Table 2, and show increasingly greater positive *ipso* carbons and more negative *ortho* and *para* carbons as the number of ethoxide ligands increases. Although the shifts are small it would appear that the tetraethoxo complex (**1**) contains the strongest W≡N bond.

Description and discussion of the X-ray crystal structure of **2**

An X-ray crystal structure determination of **2** showed the molecule to be dimeric with the two halves centrosymmetrically related (Fig. 1). Each tungsten atom adopts a distorted octahedral coordination geometry with the oxygen atoms of two ethoxy groups forming bridges between them. The phenylimido ligand lies *trans* to one of these bridges with a terminal ethoxo group lying *trans* to the other. The remaining octahedral sites are filled by a terminal ethoxide and a chloro ligand lying mutu-

ally *trans*. (Bond distances and angles are given in Tables 3 and 4.) There are no unusual intermolecular contacts.

The phenylimido ligand is essentially linear with a W—N(1)—C(1) angle of 172.4(9)°. The distance of 1.759(9) Å for the W—N bond indicates considerable multiple-bond character, the separation lying within the range of values (1.61–1.77 Å)[8,9,11,20] found in other tungsten organoimido complexes. A

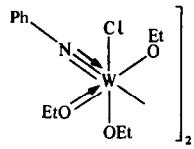
value of 1.71 Å is predicted for a W–N triple bond acting as a four-electron donor.[1]

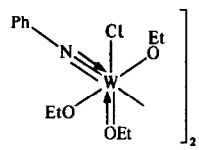
The W—O(1′) bond [2.213(8) Å] is longer than the W—O(1) bond length [2.003(8) Å], resulting in the asymmetric bridging arrangement whereby lone-pair donation from oxygen occurs *trans* to the imido function. The W—O—W′ bond angle of 110.3(3)° is comparable with that found in $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$.[8] The W—O bond lengths of the terminal akoxides at 1.835(9) and 1.865(7) Å are shorter than those forming the bridging structure whereas the W—Cl bond length at 2.454(3) Å lies within the range of values (2.24–2.48 Å) found in other complexes of tungsten.[9,11,21]

The octahedral coordination geometry is distorted away from the ideal with the tungsten atom displaced 0.28 Å above the coordination plane made by the four atoms [O(1), O(2), O(3) and Cl(1)] which lie *cis* to the imido function. This feature is common in other imido complexes and also in those containing the related nitrido ligand.[22] Formation of the ethoxide bridge also contributes to the distortion with the O(1)—W—O(1′) angle being reduced to 69.7(3)°. There are no significant intramolecular contact distances below 3.5 Å in the molecule. Minimal interaction between the phenyl ring and the terminal ethoxide ligands is attained by rotation of the phenyl ring about the N—C(1) bond to a point between the two *cis*-ethoxide groups. As a result the torsion angle, W—N—C(1)—C(2) is 11.0°.

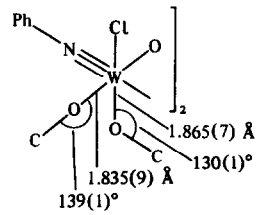
Several implications result from these structural details. Alkoxide ligands formally act as one-electron donors for the purpose of the EAN rule but π-donation involving the oxygen lone pairs allows the ligand to act as a three-electron donor [forming a double bond (M=OR)] or in rare cases as a five-electron donor (M≡OR).[5] The W—O(1) bond length of 2.003(8) Å suggests that this ligand acts as a one-electron donor to W(1).[23] Applying the 18-electron rule with all the alkoxides acting as one-electron donors, the molecule becomes a 16-electron species. Chlorine is a poor π-donor in comparison with an alkoxide and this is reflected by the W—Cl bond length [2.454(3) Å], lying towards the upper limit (2.48 Å) of W—Cl bond lengths.[21] However, the two terminal alkoxide W—O bond lengths [1.835(9) and 1.865(7) Å] are short, lying within the range found for W=OR bonds,[23] so that a measure of π-bonding exists in both. Thus, while an 18-electron configuration may be attained by either **a** or **b**, the structure shows an average of two canonical forms. However, the alkoxide better able to π-bond (shorter bond length and wider W—O—C angle) lies *trans* to the bridging alkoxide. The *cis*-



a



b



alkoxide arrangement allows the two electrons to be more effectively spread than would *trans*-terminal alkoxides as in the former case the *trans* ligands do not compete for π-bonding orbitals.

In $[W(NPh)(\mu\text{-}OMe)(OMe)_3]$ and [W(NPh)(OC-

$Me_3)_3Cl(NH_2CMe_3)]$ where *trans*-alkoxides do exist,[8] the two electrons can be spread over two sets of *cis*-alkoxides, the situation being reflected by similar W—O bond lengths within each molecule. For $[W(NPh)(OEt)_2Cl_2]_2$ either chlorine or alkoxide ligands may orientate *trans* to an alkoxo bridge giving *cis* or *trans* isomers (**3** and **4**) of comparable energy. In the absence of ethoxide acting as a five-electron donor, an ethoxy bridge in $[W(NPh)(\mu\text{-}OEt)Cl_3]_2$ leaves the complex as a 16-electron species which may account for the bridge-splitting reactions giving complexes capable of attaining an 18-electron configuration.

EXPERIMENTAL

$[WOCl_4]_2$ was prepared by reaction of WO_3 with thionyl chloride[24] and $[W(NPh)Cl_4]_2$ by reaction of $[WOCl_4]_2$ with phenyl isocyanate.[11] Trimethylphosphine was prepared by a literature method.[25] Trityl ethoxide was prepared by refluxing trityl chloride with ethanol and triethylamine in benzene and recrystallizing the product from petroleum ether at −20°C. Tetraethyl ammonium chloride was dried at 100°C *in vacuo* for 24 h and stored in a Schlenk tube. Ethanol was dried and fractionally distilled over magnesium ethoxide. *t*-Butylamine was distilled from calcium hydride and stored in a Schlenk flask. Petroleum ether (b.p. range 40–60°C), toluene and benzene were distilled over sodium wire and dichloromethane over calcium hydride. All distillations were carried out under N_2 treated to remove oxygen and water,[26] as were manipulations using bench-top air-sensitive techniques.[26] Infrared spectra were recorded on a Perkin–Elmer 597 spectrometer, ^1H NMR on a Varian T60 Model spectrometer and ^{13}C NMR spectra on a JEOL FX60 spectrometer. Analytical data were obtained by Professor A. D. Campbell and associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under nitrogen on an electro-thermal melting-point apparatus and are uncorrected.

Di - μ - ethoxohexaethoxobis(phenylimido)ditungsten(VI) (**1**)

t-Butylamine (2.7 cm^3, 25.6 mmol) and ethanol (1.5 cm^3, 25.7 mmol) in petroleum ether (50 cm^3) were added to phenylimido tungsten tetrachloride (2.7 g, 3.2 mmol) suspended in petroleum ether (100 cm^3) and the mixture stirred for 6 h. The yellow solution was filtered from the precipitate of *t*-butylamine hydrochloride which was extracted several times with petroleum ether (30 cm^3). The combined filtrates were reduced to *ca* 5 cm^3 and the solution allowed to stand giving the complex as yellow microcrystals. The product was filtered, washed with petroleum ether (2 cm^3 cooled to 0°C), and dried *in vacuo* (1.63 g, 55%) (m.p. 106–110°C). (Found: C, 36.8; H, 5.8; N, 3.0%. $C_{28}H_{50}N_2O_8W_2$ requires: C, 36.9; H, 5.5; N, 3.1%.)

IR (Nujol) bands at 1565w, 1342s, 1275w, 1142m, 1090s, 1050s, 1022s, 986w, 908s, 982m, 760m, 720w, 690m, 620m, 586s, 542m, 508s, 460m, 395w and 325w cm^{-1}.

The product, sufficiently pure for further reaction, was obtained by stripping the solvent completely from the combined filtrates and washing the product with a small quantity of cold petroleum ether (2 cm^3) to remove an orange gummy material also present. Using this method the yield of complex increases to 2.13 g (72%).

Dichloro - di - μ - ethoxotetraethoxobis(phenylimido)ditungsten(VI) (**2**)

t-Butylamine (1.1 cm^3, 15 mmol) and ethanol (0.7 cm^3, 12 mmol) in petroleum ether (50 cm^3) were added to phenylimido tungsten tetrachloride (1.2 g, 1.5 mmol) suspended in petroleum ether (60 cm^3), and the mixture was stirred for 4 h, after which the solution was filtered and the solvent discarded. The pale yellow residue was extracted with warm toluene (2 × 30 cm^3) and the combined extracts filtered. Reduction of the volume to *ca* 5 cm^3 and standing the solution at −20°C gave the complex as yellow crystals (0.82 g, 64%) [m.p. 148–152°C (dec.)]. (Found: C, 32.5; H, 4.6; N, 3.1%. $C_{24}H_{40}Cl_2N_2O_6W_2$ requires: C, 32.3; H, 4.5; N, 3.1%.)

IR (Nujol) bands at 1580w, 1430s, 1355s, 1272m, 1090s, 1030s, 920s, 882s, 805w, 760s, 688s, 640s, 600m, 555s, 528s, 480s, 382m, 326m, 320m and 284 cm^{-1}.

Bulk quantities of the complex may be obtained by extracting the reaction residue with benzene (50 cm^3), filtering the solution, removing the solvent and washing the crystalline solid with petroleum ether (30 cm^3). Analytical data are similar to the recrystallized product. (Found: C, 32.1; H, 4.7; N, 3.1%.)

Tetrachloro - di - μ - ethoxodiethoxobis(phenylimido)ditungsten(VI) (**3**)

1 (0.6 g, 0.66 mmol) in benzene (25 cm^3) was added to phenylimido tungsten tetrachloride (0.55 g, 0.66 mmol) in benzene (30 cm^3) and the mixture stirred for 6 h. The orange-yellow solution was filtered and the solvent removed, to give a yellow crystalline solid which was dissolved in hot toluene (25

cm^3). The solution was filtered, the volume reduced to *ca* 5 cm^3 and the solution allowed to stand at −20°C, giving the complex as yellow crystals which were filtered, washed with petroleum ether (20 cm^3) and dried *in vacuo* (0.38 g, 66%) [m.p. 168–170°C (melts with decomposition)]. (Found: C, 27.9; H, 3.7; N, 3.2%. $C_{20}H_{30}Cl_4N_2O_4W_2$ requires: C, 27.5; H, 3.7; N, 3.2%.)

IR (Nujol) bands at 1440s, 1400w, 1350w, 1080m, 1040s, 1020s, 986s, 920s, 862s, 825m, 755s, 718m, 680m, 624s, 615s, 550s, 535s, 575s, 390w, 330s, 305m and 280 cm^{-1}.

The complex may be obtained sufficiently pure for further reaction by filtering the reaction mixture, stripping the solvent, washing the crystalline residue with petroleum ether (30 cm^3), and drying the product *in vacuo*.

(b) Trityl ethoxide (0.35 g, 1.2 mmol) in dichloromethane (30 cm^3) was added to a suspension of hexachloro - di - μ - ethoxobis(phenylimido)ditungsten(VI) (**6**) (0.52 g, 0.6 mmol) in dichloromethane (40 cm^3) and the mixture stirred for 4 h. The orange-yellow solution was filtered and the solvent removed *in vacuo* to give an orange gum which was washed with petroleum ether (2 × 25 cm^3) followed by acetonitrile (1 cm^3). The yellow residue was filtered, washed further with acetonitrile (0.5 cm^3), filtered again and dried *in vacuo* (0.3 g, 57%). Physical and spectroscopic properties were identical to the product prepared under (a).

t - *Butylaminetrichloroethoxo(phenylimido)tungsten*(VI) (**5**)

(a) *t*-Butylamine (0.628 cm^3, 6 mmol) was added to phenylimido tungsten tetrachloride (1.25 g, 1.5 mmol) in benzene (30 cm^3) and the mixture was stirred for 4 h. The orange-red solution was filtered and the solvent removed to give an orange-yellow crystalline solid. The product was dissolved in toluene (30 cm^3), the volume reduced to *ca* 15 cm^3 and the solution allowed to stand at −5°C, giving the complex as red-brown crystals which were filtered off and dried *in vacuo* (1.1 g, 73%) (m.p. 62–65°C). {Found: C, 30.1; H, 4.9; N, 4.8%. $C_{12}H_{22}Cl_3N_2OW$ [i.e. $W(NPh)Cl_3(OEt)(NH_2CMe_3)\cdot\frac{1}{2}PhMe$] requires: C, 30.4; H, 4.4; N, 5.4%.}

IR (Nujol) bands at 3125m, 3100m, 1558m, 1505w, 1390w, 1343m, 1295m, 1202m, 1150m, 1020s, 990m, 912s, 885m, 823w, 760s, 738m, 678m, 650m, 630s, 620m, 544m, 445m, 418m, 392w, 335s, 318s and 280s cm^{-1}

(b) *t*-Butylamine (0.6 cm^3, 5.7 mmol) in petroleum ether (40 cm^3) was added to **6** (1.2 g, 1.4 mmol) in petroleum ether (50 cm^3) and the mixture was stirred for 15 h. The orange solid was filtered off, extracted with benzene (30 cm^3), and the solvent removed to give the complex as a red-brown crystalline solid which was washed with petroleum ether (30 cm^3), filtered and dried *in vacuo* (0.8 g, 87%). Physical and spectroscopic properties were identical to the product prepared under (a).

Hexachloro - di - μ - ethoxobis(phenylimido)ditungsten(VI) (**6**)

(a) **1** (1.2 g, 1.3 mmol) in benzene (40 cm^3) was added to a suspension of phenylimido tungsten tetrachloride (3.31 g, 3.9 mmol) in benzene (40 cm^3) and the mixture stirred for 4 h to give a purple-brown precipitate. The solution volume was reduced to *ca* 20 cm^3, whereupon further solid was deposited. The product was filtered, washed twice with benzene (2 cm^3) and dried *in vacuo* giving the complex as purple-brown microcrystals (4.05 g, 90%) (slow decomposition above 100°C). (Found: C, 22.9; H, 2.6; N, 2.9%. $C_{16}H_{20}Cl_6N_2O_2W_2$ requires: C, 22.5; H, 2.4; N, 3.3%.)

IR (Nujol) bands at 1280w, 1150w, 1080w, 1058w, 1020w, 975s, 915w, 840s, 755, 618m, 574m, 618m, 550s, 544s, 470m, 384w, 350s, 324m and 292w cm^{-1}.

(b) Tetrachloro - di - μ - ethoxodiethoxobis(phenylimido)ditungsten(VI) (**3**) (0.1 g, 0.1 mmol) in benzene (10 cm^3) was added to a suspension of phenylimido tungsten tetrachloride (0.1 g, 0.1 mmol) in benzene (5 cm^3) and the mixture stirred for 3 h. The volume of the red-brown solution was reduced to *ca* 5 cm^3, whereupon purple-brown microcrystals of the complex were deposited. These were filtered off, washed with petroleum ether and dried *in vacuo*. Physical and spectroscopic properties were identical to the product prepared under (a).

Trichloroethoxo(phenylimido)trimethylphosphinetungsten(VI) (**7**)

Trimethylphosphine (0.13 cm^3, 1.2 mmol) in petroleum ether (30 cm^3) was added to **6** (0.5 g, 0.6 mmol) suspended in petroleum ether (50 cm^3), and the mixture was stirred for 15 h. The solid was filtered, washed with petroleum ether, and dried *in vacuo* leaving the complex as yellow microcrystals (0.54 g, 93%) [m.p. > 140°C (dec.)]. (Found: C, 25.6; H, 4.1; N, 2.6%. $C_{11}H_{19}Cl_3NOPW$ requires: C, 26.3; H, 3.8; N, 2.8%.)

IR (Nujol) bands at 1240m, 1305w, 1285m, 1280w, 1235w, 1278m, 1005s, 990s, 950s, 908s, 850w, 775s, 750m, 720w, 686s, 590m, 555m, 430w, 400w, 338s, 310m, 280s and 250 cm^{-1}.

Tetraethylammonium tetrachloroethoxophenylimidotungstate(VI) (**8**)

Tetraethylammonium chloride (0.175 g, 1.05 mmol) in dichloromethane (30 cm^3) was added to **6** (0.45 g, 0.5 mmol) suspended in dichloromethane (30 cm^3), and the mixture stirred for 2 h. The orange-red solution was filtered and the solvent removed giving a red oil from which crystalline material slowly formed on standing. The product was continually washed, with petroleum ether, filtered, and ground up until the complex was obtained as an orange powder after drying *in vacuo* (0.6 g, 96%). (Found: C, 32.9; H, 5.4; N, 4.6%. $C_{16}H_{30}Cl_4N_2OW$ requires: C, 32.5; H, 5.1; N, 4.7%.) Λ_m(MeCN) = 100.5 Ω^{-1} cm^2 mol^{-1}.

IR (Nujol) bands at 1345s, 1297m, 1250w, 1170m, 1080m, 1020s, 985m, 904s, 984m, 762s, 718w, 684m, 618m, 558m, 474w, 440w, 395w, 330s, 302s and 268s cm^{-1}.

Triphenylcarbonium tetrachloroethoxo(phenylimido)tungstate(VI) (**9** *and* **10**)

(a) Trityl chloride (0.67 g, 2.4 mmol) in dichloromethane (30 cm^3) was added to **6** (1.0 g, 1.2 mmol) in dichloromethane (40 cm^3), and the mixture was stirred for 3 h. The yellow-brown solution was filtered and the solvent removed to give a gummy material which slowly solidified after continual washing with petroleum ether and drying *in vacuo* (1.6 g, 96%). (Found: C, 41.5; H, 3.7; N, 1.5%. $C_{57}H_{56}Cl_{14}N_2O_2W_2$ {i.e. $([W(NPh)Cl_4(O\text{-}Et)][CPh_3]\cdot 1.5CH_2Cl_2$} requires: C, 41.1; H, 3.4; N, 1.7%.) Λ_m(MeCN) = 76.8 Ω^{-1} cm^2 mol^{-1}.

IR (smear) 3100m, 3025m, 2958s, 2925m, 1625m, 1575s, 1560m, 1475s, 1445s, 1370w, 1350s, 1290m, 1260m, 1180m, 1160w, 1080m, 1060m, 1020s, 990s, 910m, 860m, 795s, 758s, 735s, 695s, 680m, 618m, 600m, 550w, 520w, 465m, 400m, 318s, 280s and 250m cm^{-1}.

(b) Trityl ethoxide (0.62 g, 2.2 mmol) in dichloromethane (30 cm^3) was added to phenylimido tungsten tetrachloride dimer (0.9 g, 1.1 mmol) in dichloromethane (40 cm^3), and the mixture was stirred for 4 h. The yellow-brown solution was filtered and the solvent removed to give a gummy material which produced a non-crystalline brown solid after extensive washing with petroleum ether and drying *in vacuo*. (Found: C, 42.6; H, 3.7; N, 1.4%. $C_{28}H_{27}Cl_6NOW$ {i.e. $[W(NPh)Cl_4(O\text{-}Et)][CPh_3]\cdot CH_2Cl_2$} requires: C, 42.6; H, 3.5; N, 1.8%.) Λ_m(MeCN) = 81.7 Ω^{-1} cm^2 mol^{-1}.

IR (smear) identical to that prepared under (a).

X-ray data collection and structure solution

A single crystal of **2** was sealed under nitrogen in a glass capillary and mounted on an Enraf–Nonius CAD4 diffractometer. Cell constants were determined from a least-squares refinement of the setting angles of 25 reflections.

Crystal data. $C_{24}H_{40}Cl_2N_2O_6W_2$, $M = 891.2$, triclinic, space group $P\bar{1}$, $a = 9.637(2)$ Å, $b = 11.135(1)$ Å, $c = 8.016(1)$ Å, $\alpha = 108.47(1)°$, $\beta = 105.51(1)°$, $\gamma = 91.51(1)°$, $U = 780.4(4)$ Å^3, $Z = 1$, $d_c = 1.90$ g cm^{-3}, μ(Mo-K_α) = 80.1 cm^{-1}. A total of 1915 independent data was collected ($\theta_{max} = 22°$) with Mo-K_α radiation using the ω–2θ scan mode. A variable ω-scan width of $(0.8+0.347\tan\theta)°$ was calculated for each reflection as well as a variable horizontal aperture width of $(1.80+1.20\tan\theta)$ mm. A maximum scan time of 50 s was set for each reflection where $\theta \leqslant 18°$ but this was decreased to 40 s for the remainder of the data to speed up the collection. A marked drop in intensity of the three standards monitored was noted during data collection (final intensities had fallen to 65% of their starting value) and the data were scaled to take account of this. An empirical absorption correction was applied[27] with maximum and minimum transmission factors of 0.999 and 0.783, respectively.

The structure was solved by the heavy-atom method and refined by a full-matrix least-squares technique with anisotropic thermal parameters assumed for all non-hydrogen atoms. Final R and R_w values of 0.039 and 0.038, respectively, were calculated for the 167 variables and 1450 data for which $F^2 > 3\sigma(F^2)$. In the refinement the atoms of the phenyl ring were treated as a rigid group (C—C = 1.395 Å and C—H = 1.08 Å). Hydrogen atoms were included in the calculations riding on the carbon atoms to which they were attached (C—H = 1.08 Å) and with group temperature factors determined for each of their various types. Atomic scattering factors were taken from the tabulations of Cromer and Mann,[28] and anomalous dispersion corrections from Cromer and Liberman.[29] The function minimized was $\Sigma W(|F_o|-|F_c|)^2$ with the weight, W, being defined as $0.9316/[\sigma^2(F)+0.001898F^2]$. Final atomic co-ordinates with anisotropic thermal parameters, tables of calculated hydrogen sites and lists of F_o/F_c values have been deposited with the Editor as supplementary material.*

* Atomic co-ordinates for the structure have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their Data Base. Copies are also available on request from the Editor.

COMPLEXES OF 2,2′-BIPYRIMIDINE WITH SOME LANTHANIDES

QASSEM JARADAT and TALAL AKASHEH*

Chemistry Department, Yarmouk University, Irbid, Jordan

(*Received* 20 *August* 1985; *accepted after revision* 13 *May* 1986)

Abstract—Complexes of the lanthanide ions, La^{3+}, Eu^{3+}, Ce^{3+}, Yb^{3+} and Ho^{3+} as well as that of Y^{3+} with the ligand 2,2′-bipyrimidine have been prepared and their physico-chemical properties studied.

Complexes of lanthanides with nitrogen-donor ligands of weak basicity have been known for some time.[1–3] However, 2,2′-bipyridine,[4,5] 1,10-phenanthroline,[6–8] terpyridine[9] and 1,3,5-tri(2-pyridil)-2,4,6-triazine[10] yield complexes whose thermal stability is high, but were found to be unstable in aqueous solution.[8] Water often displaces the ligands to an extent that conventional physical methods in solution often fail to give information about the complexes. Nevertheless, phenanthroline has been shown to change the UV–vis spectra in water. Furthermore, the idea that oxygen donor ligands are more competitive towards the lanthanides has been shown to be erroneous provided the right solvent is chosen.[12,13]

Lanthanide complexes show exceptionally high coordination numbers and this was best established by X-ray crystallography.[4,5]

2,2′-Bipyrimidine (bpm) has recently become a popular substitute for 2,2′-bipyridine in many metal complexes.[14,15] Bpm also acts as a bridging ligand forming bimetallic complexes.[14,15] In this work we report the preparation and characterization of bpm complexes with Y^{3+} and the lanthanides La^{3+}, Ho^{3+}, Ce^{3+}, Eu^{3+} and Yb^{3+}

EXPERIMENTAL

2,2′-Bipyrimidine (Lancaster Synthesis) was recrystallised from benzene. All metal salts were purchased from Laborat and used without further purification. All solvents were AR grade.

UV–vis and IR spectra were recorded using Pye–Unicam SP8-100 and SP-300 spectrophotometers, respectively. NMR spectra were recorded on a Bruker WP80SY instrument. A Harris meter was used for conductivity measurements. Elemental analysis was done by Butterworths Laboratories, England.

The ligand 2,2′-bipyrimidine was reacted with the lanthanide salts listed in Table 1 under the given conditions. The pale yellow Ce^{3+} complex melts and resolidifies at 330°C, while all other complexes do not melt or decompose below 350°C.

$LaCl_3 \cdot 6H_2O$

To a stirred solution of $LaCl_3 \cdot 6H_2O$ (0.23 g, 0.6 mmole) in 20 cm^3 of hot ethanol, was added a hot solution of bipyrimidine (0.19 g, 1.2 mmole) in ethanol (15 cm^3). A white precipitate appeared almost immediately. After 2 min of stirring, the mixture was cooled and filtered. The solid was washed with hot ethanol (twice), ether, and dried by suction. The yield was 0.25 g (66%). The complex does not melt or decompose up to 350°C.

RESULTS AND DISCUSSION

The elemental analysis for the complexes is shown in Table 2. Although the exact coordination number and structure cannot be determined from any of the physical measurements done in this work, it can be safely assumed that Y^{3+} and Eu^{3+} complexes have a bridging bipyrimidine with two metal centres. These were the only bimetallic species we

could obtain. Attempts to prepare pure bimetallic species from the other five salts failed. The tendency to form bimetallic species could be explained by weak σ-bonding and favourable π-bonding. When a metal atom is attached on one side of the ligand, strong σ-bonding withdraws the charge density from the ligands thus making the non-bonding electrons on the other side less available for complexation. π-back donation would have the opposite effect. Thus weak σ-bonding and/or stronger π-bonding (and favourable mole ratios) seem to favour the bimetallic Eu^{3+} species over the other lanthanides studied. Y^{3+} has a noble gas configuration with no *f* or *d* orbitals capable of exhibiting ligand field stabilisation. Hence an overall weak bonding tends to retain the charge density on the ligand allowing formation of a bridge between the two Y^{3+} centres.

Table 3 shows UV bands for the complexes. Since the complexes show the free (bpm) spectrum in water, DMF was used as the solvent. The bands in bpm are assigned as π,π^* (266 nm) and n,π^* (288 nm) based on experimental[14,15] and theoretical results.[16] The intensity of the bands increases and only small shifts in the n,π^* transition are observed. This indicates that the metal–ligand bonds, though existent in DMF, are probably weak (and of course non-existent in water). This result is also consistent with the NMR chemical shifts (Table 4) which differ only slightly from bpm except for the fact that Yb^{3+} and Ho^{3+} give broader and less-resolved spectra.

The best evidence for the existence of the complex species in DMF comes from conductivity (Table 3). La^{3+}, Ho^{3+} and Yb^{3+} yield results indicating a 1 : 1 electrolyte ratio, with two chlorines within the coordination sphere. Europium, cerium and yttrium give results consistent with a 2 : 1 electrolyte ratio, thus confirming the complexed species and the number of coordinated anions (four for Cl^- in Eu and Y; one NO_3^- for Ce). By contrast the conductivity in water is much higher due to free salts (for example, the europium complex yields a molar conductivity of 897 $ohm^{-1}\ cm^2\ mol^{-1}$ indicating the dissociation into two Eu^{3+} (hydrated) and six Cl^- ions).

The high thermal stability of the solids and the lability of the complexes in water is consistent with bpy and phen results.[1–6,12,13]

The IR results are shown in Table 5 for the solids in KBr discs. By comparison with bpm the ν(C=N) band in the ring increases in frequency except for Ce (decreases by 1 cm^{-1}). The effect varies from a shift of 2 cm^{-1} in La and Ho to a maximum of 12 cm^{-1} in Yb. The rise in this frequency is due to complexation.[17–19] Sigma bonding (as in protonation) causes a rise in the frequency while π-bonding causes a decrease.[17] The small effect in the present complexes compared to those of Pt, Pd, Os and Rh[15,20,21] is ascribed to weaker bonding. The CN band is broadened in the complexes and therefore masks the C=C band (1547 cm^{-1} in bpm). Other bands in the table show varying degrees of shifts, the biggest being in the ring breathing mode (1029 cm^{-1} in bpm). Bands in the regions 3300–3500 cm^{-1} and 1625–1640 cm^{-1} are due to lattice and coordinated water. A band in the range 500–750 cm^{-1} is usually assigned to coordinated water.[22] In our case such a band might very well be the band around 685 cm^{-1} (of varying strength) which appears in all complexes except that of yttrium. The cerium complex shows an γ(N—O—N) at 1320 cm^{-1} indicating uncoordinated NO_3^- and γ(N—O—N) at 1546 cm^{-1}(s) indicating a mono-coordinated NO_3^-.[14]

In conclusion, we have been able to extend the behaviour of 2,2′-bipyridine towards lanthanides to the ligand 2,2′-bipyrimidine. The latter's bridging properties have also been made use of in the case of two complexes. X-ray analysis of the solid complexes should determine the high coordination number expected by comparison to those of 2,2′-bipyridine.[4,5,12,13]

(*Received* 3 *March* 1986; *accepted* 19 *May* 1986)

Abstract—The preparation and structure of two so-called aqua-hydroxo double salts of cobalt(III) are reported. X-ray structural analysis showed the compounds not to be double salts of two distinct mononuclear cations but to contain one binuclear cation in which the two equivalent cobalt atoms are bridged by a hydrogen oxide ligand (μ-H_3O_2).

Compound **1**, *trans*-$\{[Co(en)_2NO_2]_2(H_3O_2)\}(ClO_4)_3 \cdot 2H_2O$ forms monoclinic crystals, space group $P2_1/n$, with $a = 12.098(2)$ Å, $b = 8.981(1)$ Å, $c = 14.415(2)$ Å, $\beta = 93.39(2)°$, $V = 1563(1)$ Å^3 and $Z = 2$. Compound **2**, *trans*-$\{[Co(en)_2NCS]_2(H_3O_2)\}(CF_3SO_3)_3 \cdot H_2O$ forms triclinic crystals, space group $P\bar{1}$ with $a = 12.864(2)$ Å, $b = 14.429(2)$ Å, $c = 11.177(1)$ Å, $\alpha = 105.21(3)°$, $\beta = 100.33(2)°$, $\gamma = 65.96(2)°$, $V = 1822(1)$ Å^3 and $Z = 2$.

The two structures were refined by least-squares methods to residuals of $R = 0.077$, $R_w = 0.087$ and $R = 0.063$, $R_w = 0.069$, respectively. In **1**, the dimer resides on a crystallographic inversion center and the O···O separation in the H_3O_2 bridge is 2.412(9) Å. In **2** there is no crystallographic symmetry imposed upon the dimer but the two Co—O(H_3O_2) distances are identical within the experimental error. The O···O length in the H_3O_2 unit is 2.415(6) Å.

The structural features of classical hydroxoaqua ions $[ML_4(H_2O)OH]^{(n-1)+}$ were reported recently.[1] These ions, which may be obtained by neutralization of the diaqua ion $[ML_4(H_2O)_2]^{n+}$ with one equivalent of OH^- ions, are not mononuclear in the crystalline state, but binuclear or polynuclear. Each metal atom in these species is bridged by two *hydrogen oxide* ligands (H_3O_2) to neighboring metal atoms: *cis*-hydroxoaqua ions are doubly bridged dimers, $[L_4M(H_3O_2)_2ML_4]^{2(n-1)+}$, while *trans*-hydroxoaqua ions form chains of metal atoms linked by single H_3O_2 bridges $\cdots M(L_4)(H_3O_2)M(L_4)(H_3O_2)\cdots$.[1] The centered hydrogen bond between the two oxygen atoms of the H_3O_2 ligand is short[1,2] and very strong.[3] Hydrogen oxide bridging between the metal atoms persists in concentrated aqueous solutions.[4]

Neutralization of a *monoaqua* ion such as $[ML_5(H_2O)]^{n+}$ by one equivalent of OH^- produces the classical, mononuclear hydroxo ion $[ML_5(OH)]^{(n-1)+}$. If less than one equivalent of OH^- is added, a mixture of monoaqua and monohydroxo ions is obtained, and at pH = pK_a the ratio of these two species is, of course, 1:1. When such a 1:1 solution is concentrated, either the salt of the aqua ion or that of the hydroxo ion will crystallize, depending on their relative solubilities. However, in some cases neither the aqua salt nor the hydroxo salt but an 'aqua hydroxo double salt' such as $[Co(en)_2(OH_2)N_3][Co(en)_2(OH)N_3](ClO_4)_3$ will precipitate.[5] The results of our earlier work[1] raised the

* Author to whom correspondence should be addressed.

possibility that these so called double salts were symmetric binuclear ions bridged by a single H_3O_2 ligand. The present investigation was undertaken to test this assumption. Herein, the preparation and structure of two typical 'double salts' *trans*-$\{[Co(en)_2(NO_2)]_2(H_3O_2)\}(ClO_4)_3 \cdot 2H_2O$, **1** and *trans*-$\{[Co(en)_2(NCS)]_2(H_3O_2)\}(CF_3SO_3)_3 \cdot H_2O$, **2** are reported.

EXPERIMENTAL

Preparations

trans-$\{[Co(en)_2NO_2]_2(H_3O_2)\}(ClO_4)_3 \cdot 2H_2O$, **1**. To *trans*-$[Co(en)_2(NO_2)(NO_3)]NO_3$[6] (5.9 g) in H_2O (30 cm^3) were added NaOH (1.35 g) and $NaClO_4$ (10 g). After 10 min, 2.13 cm^3 of $HClO_4$ 70.0% were added. The golden crystalline precipitate, which began to form immediately, was filtered after 1 h and washed with ethanol and ether. Suitable crystals for the X-ray study were obtained from the filtrate at 0°C after 24 h.

trans-$\{[Co(en)_2NCS]_2(H_3O_2)\}(CF_3SO_3)_3 \cdot H_2O$, **2**. A solution of *trans*-$[Co(en)_2(NCS)OH]NCS \cdot H_2O$[7] (5.0 g) in $HClO_4$ (4 M, 15 cm^3) was neutralized to pH $\approx$ 7 with NaOH (4 M, 17 cm^3), whereupon *trans*-$\{[Co(en)_2(NCS)]_2(H_3O_2)\}(ClO_3)_3 \cdot H_2O$ (5.3 g, 85%) crystallized. The product was washed with ethanol and ether, and air-dried. Recrystallization from a saturated aqueous solution using $NaClO_4$ (5 M) precipitant and cooling yielded red prisms. Found: C, 14.5; H, 4.4; N, 16.8; S, 7.8; Cl, 13.0%. Calc. for $Co_2C_{10}H_{37}N_{10}Cl_3O_{15}S_2$: C, 15.54; H, 4.52; N, 16.97; S, 7.77; Cl, 12.88%. Its visible absorption spectrum in water (self-buffered) was exactly intermediate between those in 0.01 M $HClO_4$ [$\varepsilon_{max}(538) = 184.6$] and 0.01 M NaOH [$\varepsilon_{max}(508) = 99.0$] indicating that the solution consisted of a 1:1 mixture of the hydroxo and the aqua ions with no evident interaction between them (see discussion section). Crystals of the ClO_4^- salt were found to be unsuitable for an X-ray study. A small sample (0.05 g) was dissolved in 10 cm^3 of $NaCF_3SO_3$ (2.5 M) and the solution was kept at 4°C. Red prisms of **2** were obtained after 24 h.

Two other complexes of the same group $[Co(en)_2A]_2(H_3O_2)(ClO_4)_3$ were prepared, A = N_3^-,[5a] CN^-,[5b] but suitable crystals for X-ray studies could not be obtained.

X-ray crystallography

Crystallographic data and other pertinent information are given in Table 1. Data were measured by using a ω–2θ motion. The scan width, $\Delta\omega$, for each reflection was 1° with a scan time of 20 s. Background measurements were made for another 20 s at both limits of each scan. Three standard reflections were monitored every 60 min. No systematic variations in intensities were found for either compound. For each crystal, Lorentz and polarization corrections were applied. For **1** and **2**, ψ-scans of several reflections indicated that no absorption corrections were necessary. The heavy atom positions in **1** and **2** were obtained from a three-dimensional Patterson function.[8]

In **1**, anisotropic thermal parameters were used for all non-hydrogen atoms of the complex and for the perchlorate chlorine atoms. All the perchlorate oxygens were refined isotropically. There are two kinds of perchlorate ions in the asymmetric unit, both exhibit twofold disorder. The first, Cl(1), is disordered about the crystallographic inversion center at 0, $\frac{1}{2}$, 0. The two disordered tetrahedra share one edge [O(11)—O(11′)]. The chlorine and two of the oxygen atoms, O(12) and O(13) were refined with a half occupancy factor and O(11) with a full one. The difference Fourier map showed that the central chlorine atom, Cl(2), of the second perchlorate ion was surrounding by eight peaks, indicating a twofold disorder of the oxygen atoms. Each of the two disordered ClO_4^- units at this location was treated as a rigid body with a fixed Cl—O distance of 1.50 Å. The eight oxygen atoms [O(14) through O(21)] were refined with a half occupancy factor and Cl(2) with a full one.

Hydrogen atoms of the en ligands were introduced at calculated positions as fixed contributions to F. The two hydrogen atoms of the H_3O_2 ligand, H(1) and H(2) were located from the difference Fourier map. H(1) was found to reside on a crystallographic inversion center at 0, $\frac{1}{2}$, $\frac{1}{2}$. H(1) and H(2) were introduced in fixed positions and their thermal parameters were included in the least-squares refinement [$U = 0.05(3)$ and 0.09(5), respectively].

In **2**, anisotropic thermal parameters were used for cobalt, sulfur, fluorine and oxygen atoms and isotropic ones for all carbon atoms and for the oxygen atom of the lattice water molecule, OL. The two terminal hydrogen atoms of the $H_3O_2^-$ unit, H(1) and H(2) and all the amine hydrogen atoms of the en ligands were located from the difference Fourier map and their positional parameters were included in the final cycles using the riding model. The positions of the methylene hydrogen atoms in the en ligands were calculated and were included in the final cycles as fixed contribution to F. The thermal parameter for all the hydrogen atoms was $U = 0.05$. The structure was refined using two blocks, the first included all the atoms of the dimeric

[a] Data were collected at 20 ± 2°C on a PW 1100 Philips four-circle diffractometer using Mo-K_α ($\lambda = 0.71069$ Å) radiation monochromatized by a graphite crystal.

[b] Unit cell dimensions were obtained by a least-squares fit of 25 reflections in the range $12° < \theta < 16°$.

cation and the crystal water oxygen OL and the second included all the atoms of the three $CF_3SO_3^-$ ions. Values of the atomic scattering factors and the anomalous terms were taken from the conventional sources.[9]

The discrepancy indices $R_1 = \sum||F_o|-|F_c||/\sum|F_o|$ and $R_w = [\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}(w = 1/\sigma^2|F|)$ are listed in Table 1. Lists of atomic positional and thermal parameters and observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS

Compound **1**: trans-$[Co(en)_2(NO_2)]_2(H_3O_2)(ClO_4)_3\cdot 2H_2O$

The bond distances and angles are presented in Table 2. Figure 1 shows the numbering scheme of **1**. With $Z = 2$ in space group $P2_1/n$ there is only half a $\{[Co(en)_2(NO_2)]_2(H_3O_2)\}^{3+}$ ion in the asymmetric unit, with the other half related to it by a crystallographic inversion center at 0, $\frac{1}{2}$, $\frac{1}{2}$. This inversion center is located midway between the two oxygen atoms of the hydrogen oxide unit (O1 and O1′). There are six perchlorate ions in the cell. Four occupy general positions and two reside on twofold crystallographic inversion centers. All these perchlorate units are subjected to a twofold disorder as described in the Experimental section.

The O···O separation and other relevant distances and angles concerning the $H_3O_2^-$ units are listed in Table 4.

Compound **2**: trans-$[Co(en)_2(NCS)]_2(H_3O_2)(CF_3SO_3)_3\cdot H_2O$

Table 3 gives the important bond lengths and angles. Figure 2 shows the numbering scheme in the dimer. With $Z = 2$ in the cell of space group $P\bar{1}$ there is no crystallographic symmetry imposed upon the

complex. Structural features concerning the $H_3O_2^-$ bridge are summarized in Table 4. The $CF_3SO_3^-$ ions are hydrogen bonded through the oxygen atoms to en nitrogen atoms with O···N distances in the normal range of 2.90–3.00 Å. The two terminal hydrogen atoms of the $H_3O_2^-$ unit form two hydrogen bonds: O(1)—O(8) (O_3SCF_3) and O(2)—O(3) (O_3SCF_3) with distances of 2.86(1) Å and 2.89(1) Å, respectively.

$2H_2O$, implies the existence of *two* distinct cationic species in the crystal, an aqua ion and a hydroxo ion, having two different Co—O distances. Structures **1** and **2** are not of this kind. They are definitely not double salts, but salts of a single unique, binuclear cation $[(en)_2XCo(H_3O_2)CoX(en)_2]^{3+}$ (X = NO_2, NCS). The two cobalt atoms in this cation have identical coordination spheres. They have the features of neither a hydroxo nor an aqua ion. The Co—$O(H_3O_2)$ distance, is intermediate between those found in hydroxo and aqua ions. In **1** the two M—$O(H_3O_2)$ distances of 1.906(6) Å are symmetry

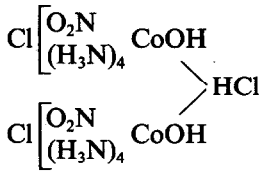
2, *trans*-{[Co(en)$_2$(NCS)]$_2$(H_3O_2)}(CF_3SO_3)$_3$·H_2O	2.415(6)	1.911(5) 1.916(5)	5.77	174.3(4)
trans-[Co(en)$_2$(H_3O_2)](ClO_4)$_2$[1]	2.441(2)	1.916(1)	5.72	180
{[Mo_3O_2(pr)$_6$(H_2O)$_2$]$_2$(H_3O_2)}Br_3·6H_2O[12]	2.52(1)	2.009(7)	5.63	180

related whereas in **2** they are identical within the experimental error—1.911(5) Å and 1.916(5) Å (Table 4). These distances are shorter than the average distance reported for the Co—O(H_2O) bond (1.94 Å)[10] but slightly longer than the Co—O(OH) distance (1.89 Å).[11] Due to the limitation of the X-ray technique, the exact position of the central hydrogen atom in the $H_3O_2^-$ bridge cannot be located. However, the fact that the two M—O(H_3O_2) distances in both structures are identical supports the assumption that the O···H···O bond is symmetrical.

The O···O distances in the $H_3O_2^-$ bridges of **1** and **2**, 2.412(9) Å and 2.415(6) Å, respectively, are significantly shorter than those found in other compounds with $H_3O_2^-$ bridges (2.44–2.54 Å).[1,12] The decrease in the O···O separation is possibly the result of an inductive effect of the electron withdrawing NO_2^- and NCS^- ligands in the *trans* position. From Table 4 it can be seen that the torsional angle of the M—O···O—M system in **1** and **2** is 180° and 174.3(4)°, respectively. This arrangement yields the longest M—M distances and the smallest interactions between the two positively charged metal centers. The same angle was found in other $H_3O_2^-$ bridged complexes of mono- and polynuclear species.[1,12]

Structures **1** and **2** are, as far as we know, the first reported structures of classical aqua-hydroxo 'double salts'. The binuclear $H_3O_2^-$ bridged structure found in these compounds may be expected in other so-called double salts, because the strong H-bond of the $H_3O_2^-$ bridge (~ 100 kJ mol^{-1})[1] makes this structure more stable than a hypothetical species with distinct mononuclear hydroxo and aqua ions. However, before the general role of H_3O_2 bridging in coordination chemistry was outlined,[1] a double salt formulation such as [Co(en)$_2$(NO_2)OH]·[Co(en)$_2$(NO_2)H_2O](ClO_4)$_3$ seemed to be more justified than a symmetric formulation such as [Co(en)$_2$(OH)(NO_2)]$_2$(ClO_4)$_2$·$HClO_4$ which would imply the existence of an acid salt of a hydroxo-complex. The authors were therefore pleasantly surprised to find, while preparing this manuscript, a paper by Alfred Werner (1907)[13] which proposed an essentially correct formulation for this class of compounds, later mistaken for double salts. This paper, bearing the title "Uber anomale anorganische Oxonium Salze, eine neue Klasse basischer Salze" (on anomalous oxonium salts, a new class of basic salts) reports the composition of basic salts of *trans*-[Co(NH_3)$_4$(NO_2)H_2O]$^{2+}$. The structure proposed by Werner for the chloride salt was:



Werner's idea that a hydrogen atom may be bonded to two (or more) oxygen atoms was proposed in an even earlier paper (1902), where the idea of a symmetric hydrogen bond was first used although not explicitly.[14] It is remarkable that Werner applied the idea of hydrogen bonding to structural problems as early as 1902, long before it was first put forward by Latimer and Rodebush as an explanation of the physical properties of water and related liquids.[15]

It was recently shown[4] by Three-Phase Vapor Tensiometry (TPVT) that in moderately concentrated aqueous solutions (~0.1 M) the ion [Cr(bpy)$_2$(H_2O)(OH)]$^{2+}$ is in equilibrium with a significant proportion of the binuclear ion [(bpy)$_2$Cr(H_3O_2)$_2$Cr(bpy)$_2$]$^{4+}$. This doubly bridged dimer is dissociated completely at lower concentrations.[16] Solutions of two other *cis*-hydroxoaqua ions were shown to have the same property.[17] In view of these results, it was of interest to consider the existence of *singly* bridged binuclear ions such as {Co(en)$_2$(NO_2)]$_2$(H_3O_2)}$^{3+}$ in solution. Preliminary results of TPVT measurements of the perchlorate

salt of this ion suggested that at comparable concentration (~0.1 M) such binuclear ions do not exist.[17] This result is supported by the spectrum of the double salt in solution which failed to indicate any interaction between the aqua-ion and the hydroxo-ion (see Experimental section). The higher thermodynamic stability of a doubly bridged dimer in solution, compared to a singly bridged dimer, is the result of two factors: the higher bond energy of the former, which possesses *two* very strong H-bonds (compared to *one* in the latter), and the chelate effect.

(*Received* 3 *March* 1986; *accepted* 19 *May* 1986)

Abstract—The structure of the first U(III) macrocyclic coordinated complex, $[U(III)(BH_4)_2$ dicyclohexyl-(18-crown-6)$]_2U(IV)Cl_5(BH_4)$ (complex **I**), has been determined from three-dimensional X-ray diffraction data. The metal atom in trivalent state is inserted in the crown cavity as a monovalent cation $[U(BH_4)_2]^+$. This compound resulted from a partial oxidation in a dichloromethane solution of $U_3(III)(BH_4)_9$[dicyclohexyl-(18-crown-6)$]_2$ (complex **II**).

EXAFS analysis performed on powdered sample of the homologue of complex **II**, $U_3(BH_4)_9$[18-crown-6$]_2$ (complex **III**) has shown the presence of carbon atoms in the vicinity of the uranium atom and hence has proved that all the oxygen atoms of the crown-ether are directly coordinated to the metal.

In parallel, an EXAFS study on the uranyl complex UO_2(18-crown-6)$(ClO_4)_2$ (complex **IV**) has verified the insertion of the uranyl ion in the solid state, and given evidence for its partial de-insertion in an acetonitrile solution.

Insertion of uranium in macrocyclic crown-ethers has been proved in solution for the valencies VI,[1] V,[2] IV[3] and III.[4] However, insertion in the solid phase has been shown only for VI[5] and IV[3,6] valencies by X-ray crystal structures. A variety of crown-ether complexes of uranium(III) have been studied in the powder state,[4,7–10] but little evidence exists to support the idea that direct coordination of uranium to the oxygen atoms of the crown cavity has been achieved, due to the great difficulty in obtaining and keeping crystals of these very unstable compounds.

From a dichloromethane solution of $U_3(BH_4)_9(dcc)_2$[4] [dcc = dicyclohexyl-(18-crown-6)] (complex **II**), a partially oxidized product, $[U(III)(BH_4)_2dcc]_2[U(IV)Cl_5BH_4]$ has been crystallized (complex **I**). The formula has been established from the single crystal diffraction analysis presented in this paper: two oxidation states, (III) and (IV), coexist in the compound. Coexistence of (IV) and (VI) oxidation states have been observed previously in the oxidized product $[U(IV)Cl_3$(18-crown-6)$]_2$ $[U(VI)O_2Cl_3(OH)(H_2O)]\cdot CH_3NO_2$;[6] in both cases the uranium inserted in the crown-ether has kept its initial oxidation state.

Since no suitable crystal of either of the compounds $U_3(BH_4)_9dcc_2$ or $U_3(BH_4)_9$(18-crown-6$)_2$ could be obtained, we have studied the latter in the powder state with extended X-ray absorption fine structure (EXAFS) analysis at the uranium *L*(III) absorption edge. This technique leads to determination of the radial environment of the uranium atom;[11] consequently it may show the presence of a carbon shell around the absorbing metal[12–14] which would support the idea of the insertion of the uranium(III) into the crown-ether. We have chosen to analyse the compound $U_3(BH_4)_9$(18-crown-6$)_2$ with the unsubstituted crown since it was expected to give a simpler EXAFS spectrum.

To determine the number of neighbours and their

* Author to whom correspondence should be addressed.

distances to the uranium atom, we needed standard compounds with known structures close to those of studied compounds. $U(BH_4)_4$[15] and UO_2(18-crown-6)$(ClO_4)_2$[1] (complex **IV**) were chosen for this purpose, though the latter does not have X-ray determined distances (the direct complexation of uranyl by the 18-crown-6 is known, but twinned crystals have rendered a structure solution to determine the U—O and U—C distances impossible). U—O distances for this complex have been obtained from EXAFS using $UO_2(CH_2COO)_3Na$[11] as a standard compound. We have considered U—C distances as being the same as those found in the insertion complex [UO_2(18-crown-6)(dcc)].[5] The similar configuration of macrocycles (18-crown-6)[6] and dcc,[7] when they are complexed with the cation UCl_3^+, provides a justification for this extrapolation. All EXAFS results refer to the parameters attributed to the solid [UO_2(18-crown-6)$(ClO_4)_2$] (complex **IV**). EXAFS spectra of this complex in the solid phase and in an acetonitrile solution have been compared to test the power of this technique to prove the metal insertion in a macrocyclic ligand in our experimental conditions [in solution UO_2(18-crown-6)$(ClO_4)_2$ is known to be an insertion complex[1]].

EXPERIMENTAL

Complexes **II**, **III** and **IV** were prepared as previously described.[1,4] The solutions studied either in acetonitrile (complex **IV**) or dichloromethane (complex **II**) were saturated. Numerous attempts at recrystallization were performed to obtain suitable single crystals of complex **I**.

Structural X-ray analysis

X-ray data for complex **I**. $U_3(BH_4)Cl_5(O_6C_{20}H_{36})_2$: $M = 1710$, tetragonal $P\bar{4}$, $a = 18.227$ (7), $c = 9.757(2)$ Å, $V = 3241$ Å^3, $Z = 2$; $\rho_{calc} = 1.75$ Mg m^{-3}, μ(Mo-K_α) = 7.34 mm^{-1}; brown single crystal of approximate dimensions $400 \times 250 \times 250$ μm mounted in a capillary in an argon atmosphere. 3250 intensity data were recorded ($1.5° < \theta < 25°$) on a CAD4 diffractometer using graphite-monochromated Mo-K_α radiation with $\omega/2\theta$ scans. Intensities were monitored by three standard reflections every hour and orientation checked every 50 reflections. The large width and weak intensity of most of the reflections showed the crystal imperfection, though the crystal was the best diffracting one. The data were corrected for intensity decay (−23% in 20 h), for absorption (empirical correction ranged from 0.362 to 1.686), and for Lorentz-polarization effects. Direct methods (Multan[16]) and Patterson function led to the choice of space group and location of the two independent uranium atoms. The other atoms were positioned by difference Fourier maps. The structure was refined to $R = 0.097$ for 899 independent reflections with $I > 2.5\sigma(I)$. Only thermal parameters of uranium and chlorine atoms were refined anisotropically. The final difference Fourier map showed residual peaks (height $2e$/Å^3) in the vicinity of the U(III) inserted in the crown-ether. All the parameters were determined with high standard deviations; the poor quality of data did not permit better accuracy. All the calculations were performed with the Enraf–Nonius/SDP program chain.[17]

EXAFS analysis. EXAFS oscillations of complexes **III** and **IV** were recorded at the uranium L(III) absorption edge (room temperature). The data were collected at the EXAFS-I station of LURE (the French synchrotron radiation facility) under the standard operating conditions of the storage-ring DCI.[18] The data reduction was performed as described elsewhere.[11,19] The powder samples were enclosed between several sheets of adhesive tape. The solutions were contained in a cell with mylar windows.

DISCUSSION

X-ray structure of complex **I**

The packing, given in Fig. 1, is built from alternatively negative and positive charged planes along the [001] direction; two new ionic species are present in this structure.

$[U(IV)Cl_5BH_4]^{2-}$ *anion.* The uranium(IV) has a pseudo-octahedral environment (Table 1, Fig. 1). A crystallographic two-fold axis lies along the Cl(22)—U(2)—B(21) line. The U(2)—B(21) distance [2.70(9) Å] corresponds to a bidentate terminal borohydride BH_4^- as in $U(BH_4)_4[OP(C_6H_5)_3]_2 \cdot 2C_6H_6$.[20] The C_2 symmetry is maintained in this type of coordination.

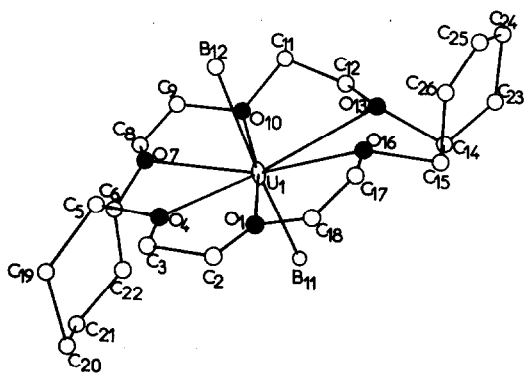

Fig. 2. Atomic numbering in $[U(BH_4)_2dcc]^+$.

$[U(III)(BH_4)_2(dcc)]$ *cation* (Table 1, Figs 1 and 2). The uranium(III) ion is inserted in the crown-ether, and is coordinated to two BH_4^- lying in axial positions on each side of the crown [B(12)—U(1)—B(11) = 173(5)°]. U—B distances have been reported for many U(IV) compounds with BH_4^- or $BH_3CH_3^-$ ligand;[21,22] for U(III) compounds only coordination with $BH_3CH_3^-$ has been published.[23] The distances U(1)—B in the cation (average, 2.57 Å) correspond to tridentate terminal borohydrides. The distances and angles of dcc are severely affected by the weak diffracting power of the crystal; high standard deviations have been usually observed in all described uranium crown-ether compounds.[3,5,6] The mean aliphatic C—C distances are 1.50(17) Å either in the cyclic ether ring or in the cyclohexyl rings; the mean C—O bond length is 1.49(17) Å. The configuration of the dcc is *cis–anti–cis* (isomer B) in the conformation $|^{ax\ eq}_{eq\ ax}|$. This conformation corresponds to a pseudo-symmetry centre located on the centre of gravity of the crown. This pseudo-centre is supported by the cyclic ether ring (Table 3) and by the anions in the packing (Fig. 1) but the U(1) atom does not lie on it: it is located closer to O(7), O(10) and O(13) than to O(4), O(1) and O(16) atoms significantly out of the well-fitted least-square equatorial plane of the ether oxygens (Table 2). This planar configuration may be due to the steric hindrance of the BH_4^- hydrogens. In the $UO_2(dcc)(ClO_4)_2$[5] compound, in which no steric hindrance with UO_2^{2+} oxygen atoms exists, the ether oxygens are more dispersed on both sides of the least-squares equatorial plane. These two structural determinations support the tendency for an inserted linear ion with $D_{\infty h}$ local symmetry to crystallize rather with the B isomer of dcc from a mixture of its A (*cis–syn–cis*) and B isomers. The UCl_3^+ [3,6] ion and $La(III)(NO_3)_3$[23] molecule, having C_2 symmetry, crystallize rather with the A isomer of the dcc.

EXAFS analysis

the U—O_6 equatorial distances; no U—C_3 equatorial peak is detected.

Figure 3(b) gives the FT of complex **IV**. In addition to the two axial and equatorial U–O peaks, a third peak corresponding to U–C is observed. The fit of parameters[19] for this compound is presented in Table 4. An error of about 25% on the atom number of the UO axial shell (uranyl) is obtained when fitting is performed with the standard (method a). The atom number of the equatorial shell is then affected by error. To improve the result we have fitted the equatorial shell with the amplitude and phase parameters of the axial shell of the compound itself[11] (method b). We thus verified the presence of the six oxygen atoms of the crown-ether around the uranyl. Average distances of 1.73 and 2.54 Å have been deduced for U–O axial and U–O equatorial, respectively.

Complex **IV** (*acetonitrile solution*). Figure 3(c) shows the FT of this solution. The presence of the three peaks corresponding to U–O axial, U–O equatorial and U–C, is the proof of the insertion of the uranyl in the crown-ether. The fit with parameters of the solid compound as standard (Table 5) gives too small equatorial oxygen and carbon numbers, although the axial oxygen number is correct. This fact and the short U—O equatorial distance led us to suspect a partial de-insertion of the uranyl. If non-inserted, uranyl, in acetonitrile solution would be coordinated only to five CH_3CN molecules. $UO_2(N_3)_3N(C_2H_5)_4$[11] has been chosen as standard to fit the U–N parameters. We have then fitted the first equatorial shell of the uranyl with oxygen and nitrogen atoms (Table 5). The atom numbers and the U—O and U—N distances obtained confirm a partial de-insertion: 2/3 UO_2 (18-crown-6)$^{2+}$ and 1/3 $UO_2(CH_3CN)_5^{2+}$ (error

sample, the second peak corresponds to the U–B pairs.

Figure 4(b) shows the FT of complex **III**. Three peaks are present: the first one as above is due to a weak oxidation (10%) of the sample, the second and the third peak (U–O, U–B and U–C, respectively) are attributed to the complexation of the uranium(III) with the crown-ether. Table 6 and Fig. 5 give the results of the fit for the second and third shells using the following model: all the crown-ethers contain an axial $U(BH_4)_2^+$ ion like the complex **I** and the non-inserted uranium atoms are surrounded by five BH_4^- ions.[4] This model implies fitting of the U–B_3 and U–O_4 pairs to the second peak and U–C_8 pairs to the third peak, which has been split to improve the fit. The result is excellent for the second shell, but not so good for the third one on account of the high background of experimental filtered spectra. The large distance U—B (2.95 Å) implies the presence of some bidentate

Table 6. Fitted parameters of $U_3(BH_4)_9$(18-crown-6)$_2$ in solid phase with amplitude and phase parameters[19] from the solid compound UO_2(18-crown-6)$(ClO_4)_2$ (UO_6: R = 2.54 Å, UC_{12}: R = 3.44(7) Å) and $U(BH_4)_4$: (UB_6: R = 2.75 Å).[15]

Pairs	N	R (Å)	$\Delta\sigma^2$ (10^3 Å^2)	ΔE_0 (eV)
OU	4.0±0.6	2.51±0.01	4.7±0.4	−8±1
UB	3.0±0.4	2.95±0.04	3.4±0.4	
UC	6.0±0.7	3.47±0.03	0.11±0.03	−6±2
	2.0±0.2	4.14±0.03	0.00	

BH_4^- in the structure. The split of the carbon shell corresponds to an important dispersion around the uranium. This fact and the high σ value of the U–O shell shows that the uranium(III) would not be located on the symmetry center of the crown-ether as in complex **I**.

The FT of the [U_3(III)$(BH_4)_9$(dibenzo 18-crown-6)$_2$] is given on Fig. 4(c). The peak corresponding to U–C pairs is present and proves the insertion of U(III) in the crown, but the strong oxidation (first peak) does not allow quantitative results to be given.

CONCLUSION

The EXAFS technique, which is well-known as a useful tool to obtain structural features which cannot be drawn from X-ray crystal structure analysis, has been shown to be useful in the particular case of uranium, either in powdered solid samples or solutions. The interpretation based on the knowledge of structural information on related compounds of uranyl has given evidence of the partial de-insertion of uranyl in solution and of the insertion of uranium(III) in a series of crown-ethers.

INFLUENCE OF THE STRUCTURE OF ALKYL DERIVATIVES OF SALICYLALDEHYDE OXIME UPON THE EXTRACTION RATE OF COPPER FROM DILUTED ACIDIC SOLUTIONS

(*Received* 17 *January* 1985; *accepted after revision* 28 *May* 1986)

Abstract—Individual pure alkyl derivatives of salicylaldehyde oxime were used for copper extraction using the short-time phase contacting method. The influence of the oxime structure upon the extraction rate and the surface activity was discussed. It was found that the reaction can proceed at the interface and in the bulk of the aqueous phase. The bulk-phase process is dominant for oximes having less than four carbon atoms in the alkyl group, while the interfacial process is dominant for oximes having more than six carbon atoms.

The use of hydroxyoximes as copper extractants has created new possibilities for hydrometallurgy because this extraction technique has been applied to the production of such relatively cheap and large tonnage metals as copper.

However, the slow rate of metal extraction by means of chelating agents is one of the basic drawbacks of this technique. Many papers[1–15] have been published on this subject dealing with physicochemical and mechanistic problems, as well as with its technological aspects. In most of these cases commercial products manufactured by Henkel, Acorga or Shell were used. These products, although carefully purified, contain many components such as different isomers and homologues of the particular active extracting agents and alkylphenol. Some other impurities of the starting materials, especially present in commercial nonylphenol, or formed as by products during the manufacture of the hydroxyoximes, may also be present. All these components can influence the rate of copper extraction, especially if one takes into account the possibility of the surface reaction or the parallel mechanism of the interface and bulk aqueous reactions, which are dependent not only upon the rate of the chemical step but also upon the rates of the diffusion steps and the adsorption of the extracting agent and impurities at the interface. The relative ratio of the interfacial to the bulk reaction may be changed by different extraction conditions, e.g. the method used, and the composition of the aqueous phase, as well as by the structure of the extracting agent, and the type and amount of impurities present in the extractant.

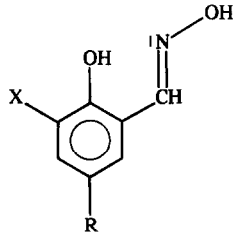
The aim of this work was to determine the extraction rates for different homologues of the alkyl derivatives of salicylaldehyde oxime having from 1 to 12 carbon atoms in the normal or branched alkyl chain, and to discuss the influence of the oxime structure upon the extraction rate and the place of the chemical step.

EXPERIMENTAL

Materials

Ten different pure individual hydroxyoximes (Table 1) of the following structure:

* Author to whom correspondence should be addressed.



were used as copper extractants. Their analytical data have been given in previous papers.[16,17]

Copper solutions were prepared from copper sulphate (AR grade, POCh Gliwice, Poland), Sulphuric acid (AR grade) was used to adjust the pH. Octane and *p*-xylene were used as diluents.

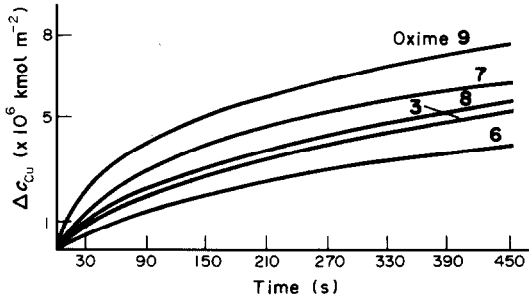


Fig. 1. Influence of the structure of oxime upon the amount of copper transferred into xylene phase (pH = 3.0, $c_{Cu^{2+}} = 0.015$ mol dm^{-3}, $c_{oxime} = 0.025$ mol dm^{-3}).

Kinetic measurements

The short-time phase contacting method described by Yagodin *et al.*[18,19] was used. The conditions for the kinetic measurements were as follows: temperature = 293 K, oxime concentration = 0.003–0.05 mol dm^{-3} copper concentration = 0.015 mol dm^{-3}, pH of the aqueous phase = 3, volume of the aqueous phase = 15.0×10^{-9} m^3, and interface surface = 6.43×10^{-6} m^2.

Additional measurements

Interfacial tensions were determined at 293 K by the drop volume method[20,21] using mutually presaturated organic and aqueous phases. Twice redistilled water was used. The aqueous phase was adjusted by sulphuric acid to pH = 2. The time for the drop to grow was not less than 5 min, and usually 10–15 min.

Distribution coefficients of the oximes at 293 K were determined between 0.05 mol dm^{-3} solutions in xylene and the aqueous phase as adjusted by sulphuric acid to pH 3. The content of the oxime in the aqueous phase was determined spectrophotometrically.[22]

RESULTS

Sample curves showing the amount of copper transferred through the interface during extraction by different hydroxyoximes under the same experimental conditions are presented in Fig. 1. One can observe significant differences for the investigated hydroxyoximes. The extraction rate increases with decrease in the length of the alkyl radical in the 5-position. Oximes having a branched alkyl show a higher extraction rate than their analogues containing a normal alkyl. The introduction of a bulky

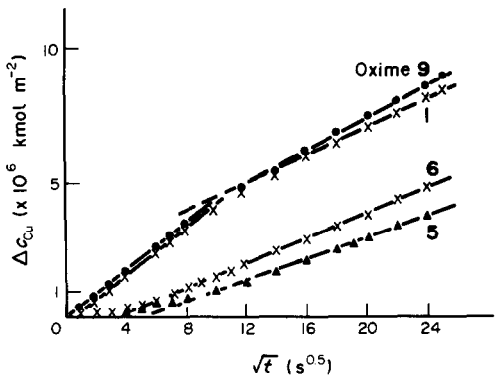

Fig. 2. Relationship between the copper transferred and the square root of the extraction time (xylene, pH = 3.0, $c_{Cu^{2+}} = 0.015$ mol dm^{-3}, $c_{oxime} = 0.025$, 0.05, 0.025 and 0.009 mol dm^{-3}).

t-butyl group in the neighbourhood of the phenolic group (oxime **10**) diminishes the extraction rate so much (about 15 times compared to oxime **7**) that, under the same experimental conditions, the measurement of the extraction rate becomes impossible. However, the electronegative NO_2 group at the 3-position sharply increases the extraction rate. Analogous conclusions can be derived when the results obtained under other experimental conditions, i.e. for different oxime concentrations and octane used as a diluent, are considered.

Figure 2 shows the relationships between the amount of copper transferred to the organic phase and the square root of the extraction time. In most cases the shape of the obtained curves is typical for an interfacial process.[18] At the beginning of the process ($t = 0$) the rate of diffusion is infinitely high or at least very high, and the process rate is determined by the rate of the reaction step. However, after a very short period, usually not exceeding a few tens of seconds, the rates of the diffusion step decrease so significantly that diffusion begins to control the process rate. In this case the considered relationship can be described by the following equations:

$$\Delta c_{Cu} = A + B\sqrt{t},$$

where B is related to the appropriate diffusivities. The extrapolation of the above relation to $\Delta c_{Cu} = 0$ gives the value of the square root of the transient time, which is necessary to convert the process from the kinetic to the diffusion regime.

The value of the transient time (Table 2) increases with the length of the alkyl group of the considered oximes and with the decreasing concentration of the oximes in the organic phase. The direction of the change is similar to the change in the oxime concentration in the aqueous phase, and suggests an increasing role for the interfacial process with the increase in the oxime hydrophobicity and the decrease in the oxime concentration in the organic phase.

Some kinetic curves obtained for an oxime concentration of 0.5 mol dm^{-3}, with the exception of compound **6** (having a long alkyl group), show an atypical shape (Fig. 2). In these cases extraction periods are observed with two different characteristic straight-line slopes and different transient time values. Moreover, for oximes with a lower hydrophobicity, e.g. a shorter-length alkyl or nitro group, this atypical shape of the kinetic curves is also observed in the case of lower oxime concentrations in the organic phase. This suggests a more complex character for the process. Although extraction begins at the interface, the reaction in the bulk of the aqueous phase is also important. The contribution of the bulk reaction increases with the oxime concentration and with the decrease in the alkyl length. For compounds **1** and **9** the first

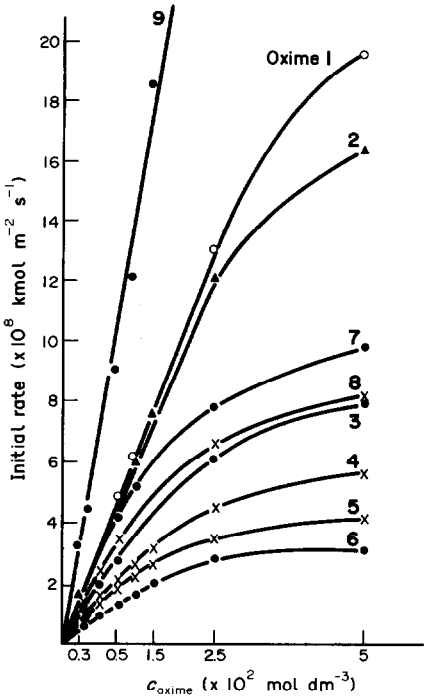

Fig. 3. Influence of the structure of the oxime upon the initial extraction rate (xylene).

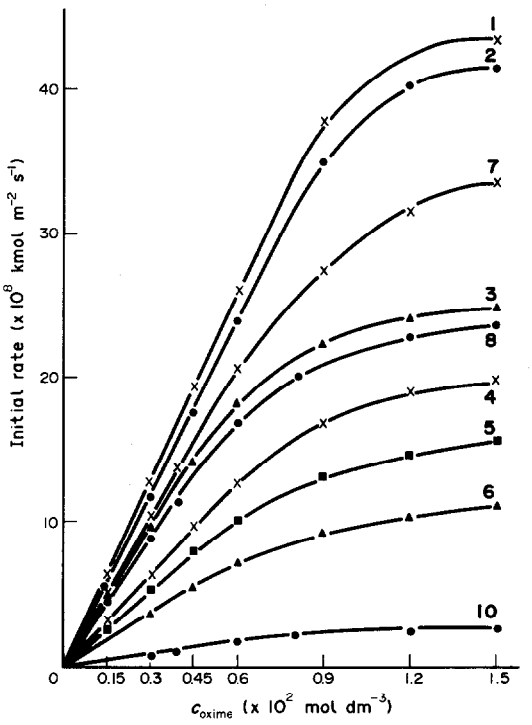

Fig. 4. Influence of the structure of the oxime upon the initial extraction rate (octane).

transient time is equal to zero, which suggests that, even in the first few seconds, the reaction proceeds in the bulk of the aqueous phase and is controlled by diffusional processes. This is in agreement with the independent results of Tarasov *et al.*[13,14] who investigated copper extraction by 2-hydroxy-5-octylbenzophenone oximes using the short-time phase contacting method, and with those of Szymanowski *et al.*,[15,23] who have discussed the influence of the oxime structure upon the extraction rate of copper determined in a Lewis cell, and by the AKUFVE and drop methods.

Figures 3 and 4 show the initial extraction rates obtained by graphical differentiation for $t = 0$ for the oximes considered at different concentrations in the organic phase. Only for compounds **1** and **9** were straight lines obtained for almost the entire range of concentrations considered, which is typical for the bulk reaction. For the other homologues the relationships are not linear and the influence of the oxime concentration decreases as both the concentration and the length of the alkyl increase. For homologues having a higher molecular mass (containing 8–12 carbon atoms in the alkyl group) and higher oxime concentrations (0.025–0.05 mol dm^{-3} for xylene and 0.009–0.015 mol dm^{-3} for octane) the extraction rate is almost constant and independent of oxime concentration. Thus, for oximes with an appropriately long alkyl (more than 12 carbon atoms) the initial extraction rate does not depend upon the length and structure of the alkyl (Fig. 5). This demonstrates the interfacial reaction for oximes having a long alkyl.

The interception points of the asymptotes correspond to four or five carbon atoms in the alkyl. Thus, for the oximes having a normal alkyl the interfacial and bulk reactions dominate for those oximes containing not less than six or not more than three carbon atoms in the alkyl, respectively. This is in agreement with the oxime distribution coefficients (Fig. 6). For oximes containing less than six carbon atoms in the alkyl the extraction rate increases sharply with the decrease in the distribution coefficient (below $\log_{10} P_{RH} = 3$), while for the oximes having more carbon atoms in the alkyl the influence of the distribution coefficient upon the extraction rate is small or almost negligible.

The character of the relationships shown in Fig. 5 is similar to that described in previous work[23] when the results obtained by the Lewis cell method were discussed. In both the methods compared the interface was not renewed and kept constant, which is especially important when the interfacial mechanism is considered.

The influence of the oxime concentration upon interfacial tension is shown in Fig. 7. Relationships typical for surfactants were obtained, i.e. with the increase in the length of the alkyl the interfacial

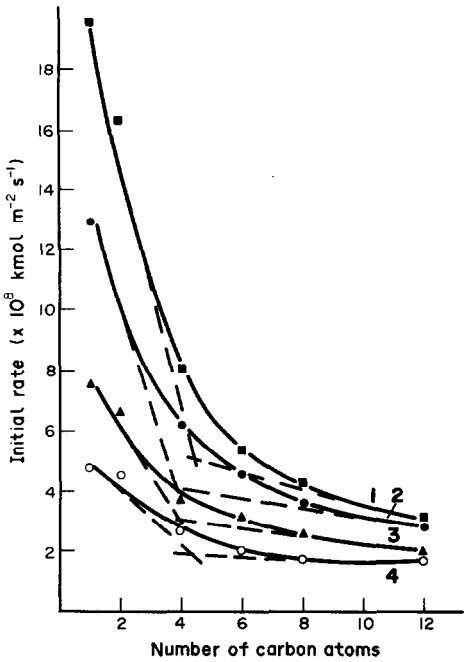

Fig. 5. Influence of the number of carbon atoms in the alkyl upon the initial extraction rate (xylene, curves 1, 2, 3 and 4 = c_{oxime} = 0.05, 0.025, 0.015 and 0.009 mol dm^{-3}, respectively).

tension decreases more efficiently. However, due to the low solubilities the region of critical micelle concentration was not obtained. Only in the case of the oximes having a branched alkyl was the opposite dependence observed. In octane–aqueous systems lower interfacial tensions are observed than in the xylene–aqueous interphase. The values of the excess surface calculated from the Gibbs isotherm:

$$\Gamma = \frac{0.43}{RT}\,\frac{d\gamma}{d(\log c_{oxime})},$$

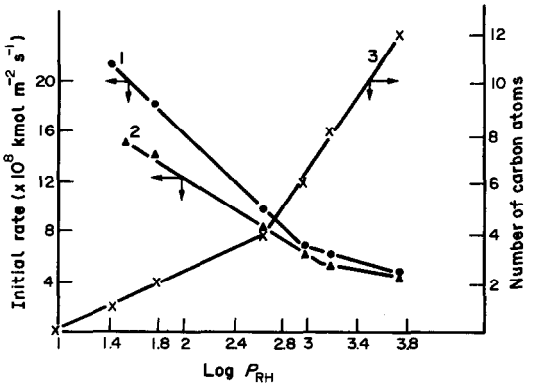

Fig. 6. Relationship between copper extraction rate and the distribution coefficient of the oximes (xylene, curves 1 and 2 = c_{oxime} = 0.05 and 0.025 mol dm^{-3}, respectively; curve 3 = relationship between the distribution coefficient and the number of carbon atoms in the alkyl).

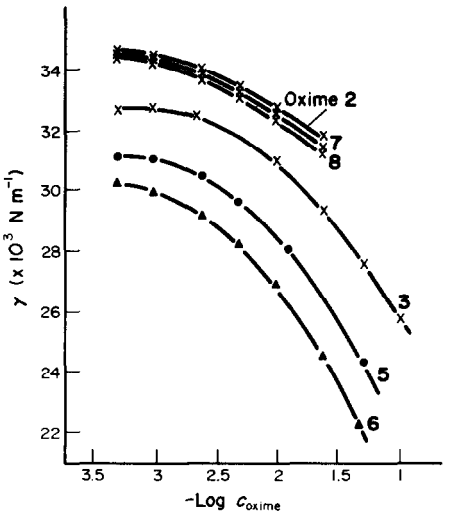

Fig. 7. Interfacial tension isotherms (xylene, 293 K).

are similar for all the oximes considered and vary in the ranges 5–7 × 10^{13} and 16–20 × 10^{13} molecules cm^{-2} for xylene and octane, respectively. This is connected with the similar slopes of the discussed interfacial tension isotherms. Thus the calculated values of the surface excess do not explain the observed differences in the extraction rates. This can be explained by the fact that, in the drop volume method, the equilibrium values of the interfacial tensions are observed after a characteristic time, which depends upon the structure of the considered compounds and the type of system considered. For typical surfactants usually only a few or a few tens of seconds are necessary to achieve equilibrium at the surface of the growing drop. However, in the present case the time for achieving equilibrium is much greater,[8,24] and, therefore, for our oximes dissolved in octane and xylene we estimated it as being equal to about 5 and 10 min, respectively. This means that, although the phases were presaturated, the adsorption or rather the orientation at the interface proceeds so slowly that the extraction rate in such systems should not be correlated with the equilibrium surface activity of the extractant. For extraction systems dynamic methods of measuring the interfacial tension should be elaborated and used. This explains another shape of the kinetic curves obtained by means of AKUFVE method.[23]

For a selected hydroxyoxime the extraction rate and surface activity, measured as a decrease in the interfacial tension, increase as the oxime concentration increases. Thus, in such a case the extraction rate can be proportional to the surface activity.[11,25] However, when different hydroxyoximes are considered quite opposite relationships between the extraction rate and the surface activity

are observed. For constant oxime concentrations the surface activity of the homologous series of oximes considered increases as the length of the alkyl increases, but the extraction rate significantly decreases. This means that under the same conditions the extraction rate does not depend upon the excess surface, but upon the depth of oxime penetration into the aqueous layers near the interface. This further supports our previous conclusions correlating the extraction rate with the hydrophilic–lipophilic balance.[15]

CONCLUSIONS

Our investigations carried out by means of the short-time phase contacting method in which pure individual hydroxyoximes were used showed that copper extraction may proceed both at the interface and in the bulk of the aqueous phase. For oximes having a long alkyl, typical kinetic curves ($\Delta c_{Cu} = A + B\sqrt{t}$) characterized by a relatively short transient time (usually a few or a few tens of seconds) and a constant slope were obtained, which demonstrate that the extraction process occurs at the interface. For hydroxyoximes having a short alkyl or the additional electronegative nitro group atypical curves characterized by two different slope constants were obtained, which suggests a more complex character for the process and the importance of the bulk reaction. The mutual ratios of the interfacial and bulk processes depend not only upon the hydrophobicity of the oximes but also upon the extraction conditions, such as oxime concentration and diluent type. The bulk-phase process dominates for alkyl derivatives of salicylaldehyde oximes having no more than three carbon atoms in the alkyl group, while the surface process dominates for homologues containing not less than six carbon atoms in the alkyl. For compounds containing the electronegative nitro group at the 3-position the bulk-phase process is favoured.

The initial extraction rate depends upon the oxime structure and the length of the alkyl. Higher extraction rates are observed in octane than in xylene. The extraction rate decreases with the increase in the alkyl length in the 5-position. Oximes having a branched alkyl show higher extraction rates than their analogues having a normal alkyl. The nitro group in the 3-position sharply increases the extraction rate while the bulky *t*-butyl group in the 3-position so sharply decreases the extraction rate that it can not even be measured. The oxime structure and extraction conditions also influence the values for the time needed to convert extraction from the kinetic to the diffusion regime. This transient time increases as the oxime concentration decreases and as the length of the alkyl group increases.

The surface activity of the homologous series of oximes increases as the length of the alkyl increases. This suggests that the extraction rate does not depend upon the surface excess under the same extraction conditions but upon the depth of the oxime penetration into the aqueous layers near the interface. This supports the idea correlating the extraction rate with the hydrophile–lipophile balance.

DIAGNOSTIC FEATURES FOR THE LINKAGE ISOMERISM OF THE OXIMATO GROUP: CHARACTERIZATION OF SOME Cu(II), Co(II) AND U(VI) COMPLEXES OF A DIOXIME SCHIFF-BASE LIGAND*

A. O. BAGHLAF, M. M. ALY† and N. S. GANJI

Chemistry Department, Faulty of Science, King Abdulaziz University, Jeddah, Saudi Arabia

(*Received* 18 *April* 1985; *accepted after revision* 28 *May* 1986)

Abstract—The reactions of the dioxime ligand *N,N'*-ethylenebis(isonitrosoacetylacetoneimine) with Cu(II), Co(II) and U(VI) ions produced metal complexes with the oximato groups coordinated through both oxygens, both nitrogens or one oxygen and one nitrogen. Some interconversion of isomers was observed. The U(VI) complexes reacted with Ni(II) acetate to produce the Ni(II) analogue of the Cu(II) complex with the oxygen coordination isomer. The observed linkage isomerism of the oximato group and the suggested formulations of the metal complexes are based on analytical, electronic and vibrational spectra, and magnetic-moment evidence.

Structural studies on the transition-metal complexes of either α-dioxime[1–5] or vicinal oxime–imine ligands[1,6–9] have revealed several interesting aspects. The most interesting one is related to the ability of the oximato group to coordinate to the metal ion through either the oximino oxygen or the oximino nitrogen.[1] However, the possible interconversion of the linkage isomers was not dealt with in most of these reports, although this is considered a deciding factor in the characterization of the coordination mode. We wish to report an investigation on the Cu(II), Co(II) and U(VI) complexes of the Schiff-base *N,N'*-ethylenebis(isonitrosoacetylacetoneimine) (H_2L). This ligand comprises features of both a dioxime and vicinal oxime–imine ligand.[10,11] This study is also related to that of the nitrosation products[12] of the metal complexes of *N,N'*-ethylenebis(acetylacetoneimine).

EXPERIMENTAL

Reagent grade chemicals were used. The ligand (H_2L) was prepared by a published method.[10] The IR spectra of the metal complexes were measured as KBr pellets using a Perkin–Elmer 683 spectrophotometer. The electronic spectra were carried out with a Pye–Unicam S.P. 8000 spectrophotometer. Magnetic susceptibilities were measured at 25°C by the Gouy method where mercuric tetrathiocyanatocobaltate(II) was the magnetic-susceptibility standard. Diamagnetic corrections were effected by employing Pascal's constants.[13] The magnetic moments were calculated from the equation $\mu_{eff} = 2.84\sqrt{\chi_M^{corr}T}$. Carbon, hydrogen and nitrogen analyses were determined at the analytical unit of King Abdulaziz University. Standard methods were used for the determination of the metal ions. All metal complexes were dried *in vacuo* over phosphorus pentoxide.

Preparation of the metal complexes and their reactions

(1) *Reactions of* H_2L *with* Cu(II) *acetate monohydrate in aqueous solution.* (a) Complex **I**: A filtered aqueous solution (100 cm^3) of $(CH_3CO_2)Cu \cdot H_2O$ (1.42 g, 0.0071 mol) was added to a warmed aqueous suspension (100 cm^3) of the equimolar concentration of the ligand (2.0 g). The reaction solution was boiled for 2 h and left for 12 h to precipitate the yellowish-brown complex **I**. This was filtered off, washed with water and dried [2.1 g, 86%

yield)]. This complex was recovered unchanged from either boiling chloroform (2 h) or after digestion in pyridine (4 h) and decomposed when refluxed with piperidine (1 h).

(b) Complex **II**: This complex was prepared as described in (a) by boiling the reaction solution for 1 h and cooling to precipitate the reddish-violet complex which was filtered off, washed with water and dried [1.7 g (70% yield)]. It was found to be stable after refluxing for 1 h in chloroform, piperidine or pyridine.

(2) *Reaction of* H_2L *with* Cu(II) *acetate monohydrate in absolute ethanol.* This reaction was carried out in ethanol, using the procedure described in 1(a) with a 14-h reaction time, to produce complex **I** [1.6 g (66% yield)].

(3) *Conversion of complex* **I** *to complex* **III.** The powdered complex **I** (3.44 g, 0.01 mol) was added to pyridine (15 cm^3). The reaction solution was refluxed for 2 h and diluted with benzene (200 cm^3) to precipitate complex **III.** This was filtered off, washed with benzene and dried [3.0 g (87% yield)].

(4) *Template reaction of isonitrosoacetylacetone with* Cu(II) *acetate monohydrate and ethylenediamine* (2 : 1 : 1 *molar ratio*) *in ethanol.* An ethylenediamine (0.42 g, 0.007 mol) solution in ethanol (50 cm^3) was added to that (200 cm^3) of $(CH_3CO_2)_2Cu \cdot H_2O$ (1.4 g, 0.007 mol). The resulting solution was added to a solution (50 cm^3) of isonitrosoacetylacetone (1.81 g, 0.014 mol). The resulting reaction solution was warmed for 1 h and left for 14 h to precipitate complex **I** which was filtered off, washed with ethanol and dried [1.9 g (79% yield)].

(5) *Complex* **IV.** This complex was prepared in water, as described in 1(a), from the 5 : 1 molar ratio reaction of $CoCl_2 \cdot 6H_2O$ (6.0 g, 0.025 mol) with H_2L (1.42 g, 0.005 mol). The precipitated red complex was filtered off, washed with water and dried [1.5 g (88% yield)].

(6) *Complexes* **V** *and* **VI.** The ethanolic solution (100 cm^3) of the $UO_2X_2 \cdot nH_2O$ [X = acetate, $n = 2$ (4.24 g, 0.01 mol); X = nitrate, $n = 6$ (5.02 g, 0.01 mol)] was added to an equimolar-concentration suspension of the ligand (2.82 g) in ethanol (200 cm^3). The stirred reaction solution was warmed for 4 h. The precipitated complex was filtered off, washed with boiling ethanol and dried [complex **V** = 2.2 g (33% yield); complex **VI** = 1.9 g (28% yield)].

(7) *Reaction of complex* **V** *or* **VI** *with* Ni(II) *acetate tetrahydrate.* An ethanolic solution (100 cm^3) of $(CH_3CO_2)_2Ni \cdot 4H_2O$ (1.0 g, 0.004 mol) was added to a powdered equimolar-concentration suspension of the U(VI) complex (2.69 g of complex **V** or **VI**) in ethanol (50 cm^3). The reaction solution was warmed while stirring for 4 h and left for 14 h. The precipitated complex was filtered off and extracted with chloroform (30 cm^3). The chloroform extract was concentrated to precipitate the yellow Ni(II) complex analogue of complex **I** [0.32 g (24% yield)]. This Ni(II) complex was characterized by elemental analyses, and electronic and vibrational spectra, as well as by comparing with an authentic sample prepared as described earlier.[11]

RESULTS AND DISCUSSION

The analytical (Table 1) and spectral data (Tables 2 and 3) are compatible with regarding the structure of the complexes formed from the 1 : 1 molar ratio

Table 1

reaction of $(CH_3CO_2)_2Cu \cdot H_2O$ with H_2L to be dependent on the solvent used (water or ethanol) and the time of reaction. These reactions are schematically represented in Fig. 1. Thus, the reaction of the ligand with the metal acetate in either water or ethanol led, after a 14-h reaction time, to the formation of the yellowish-brown complex **I** (Fig. 2). However, in the case of a 1-h reaction time the reddish-violet complex **II** was formed in water. The IR spectrum of complex **I** revealed ν(C=O) vibrations at 1688 and 1680 cm^{-1} [compared to ν(C=O) of the dimeric ligand[10] at 1700, 1690, 1678 and 1662 cm^{-1}]. These bands are located in the 1690–1670-cm^{-1} region which was tentatively associated with six-membered chelate ring in the vicinal oxime–imine Ni(II) complexes.[8,9] Furthermore, the ν(C=O) vibrations could be compared in position and intensity with the reported[12] spectrum of the mononitrosation product [ν(C=O) at 1679 cm^{-1})] of *N,N'*-ethylenebis(acetylacetoneimine)copper(II) whose structure (see complex **A** in Fig. 2) was shown,[14] from X-ray structural data, to comprise the six-membered chelate ring with the oximino oxygen coordination to Cu(II). The ν(N—O) vibrations of complex **I**, are located at identical frequencies (1141 and 1135 cm^{-1}) to those of the reported spectrum of the mononitrosation product which is additional evidence for the structure of this complex [ν(N—O) of the ligand[10] appeared at 1062 and 1025 cm^{-1}]. The splitting of ν(N—O) into two bands (separated by 6 cm^{-1}) is attributed to the non-equivalence of the two six-membered chelate rings in the planar structure of the complex rather than to any side coordination by the oximino oxygen. This is because the magnetic moment of complex **I** was found to be 1.81 BM, which is near the spin-only value for one unpaired electron of the d^9 Cu(II) ion, and, therefore, molecular association is unlikely since it would lead to spin–spin interactions and lower the magnetic moment below the spin-only value.

It is noteworthy in this connection that the reported IR spectrum of the complex prepared by Masuda *et al.*[12] from the complete nitrosation of

[a] Saturated solution of the sparingly soluble complex.

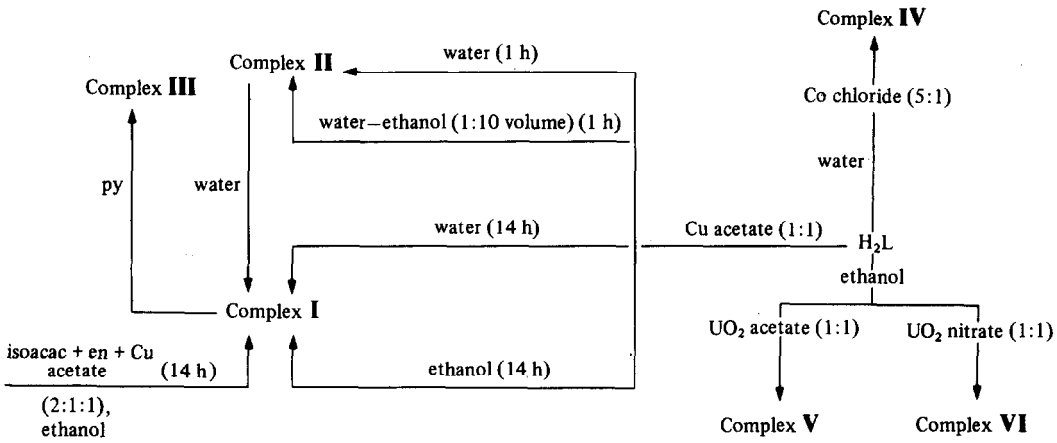

Fig. 1. Schematic representation for the reactions of the ligand with the metal ions and the reactivity of some of the Cu(II) complexes (isoacac, en, py and pip refer to isonitrosoacetylacetone, ethylenediamine, pyridine and piperidine, respectively).

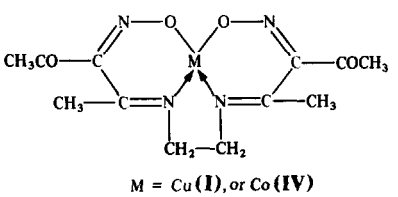
N,N'-ethylenebis(acetylacetoneimine)copper(II) is identical to that of complex **I**. Accordingly, it is believed that its structure is identical to that of our complex **I** and not the reported[12] structure, which suggests coordination of the oximato group through the oximino nitrogen. This conclusion is also applicable to the dark-brown complex reported by Bose and Patel[15] who used the same preparative method of Masuda *et al.*,[12] and proposed a structure based on the *N*-coordination. Moreover, it is in agreement with the structure of the mononitrosation product (*O*-coordination) and, therefore, it should be expected that the nitrosation of the second chelate ring would proceed similarly. This argument is substantiated by the characterization of the red-violet complex **II** (Fig. 2). This complex was prepared from the 1-h reaction of the ligand with $(CH_3CO_2)_2Cu \cdot H_2O$ (1 : 1 molar ratio) in water



M = Cu(**I**), or Co(**IV**)

Fig. 2. Suggested formulations of the metal complexes **I–VI** and their relation to the mononitrosation product complex (**A**).

or water–ethanol (1 : 10) (see Fig. 1). The ν(C=O) of complex **II** was located at a lower frequency (1660 cm^{-1}) than that of complex **I** (Table 2). This vibration is located in the 1660–1630-cm^{-1} region of the carbonyl group[8,9] attached to a five-membered chelate ring in the vicinal oxime–imino complexes of Ni(II). Furthermore, it occurs at a lower frequency than that of complex **I** as well as that of the mononitrosation product (Fig. 2) of *N,N'*-ethylenebis(acetylacetoneimine)copper(II). It is suggested, therefore, that the chelate rings in complex **II** are of the five-membered type which requires the oximato group to be coordinated to the metal ion through the oximino nitrogen. The observed ν(N—O) in complex **II** is located at a higher frequency (1160 cm^{-1}) than that of complex **I** (1142 and 1135 cm^{-1}) (Table 2). This accords with the suggested structures of complexes **I** and **II** since coordination by the oximino nitrogen will produce an N—O bond with a greater double-bond character and consequently a higher ν(N—O) than is the case with oximino-oxygen coordination of less double-bond character for the N—O bond and a lower ν(N—O). The magnetic moment of complex **II** was found to be 1.78 BM, which is comparable with the spin-only value of the unpaired electron of Cu(II). The suggested structures of complexes **I** and **II** represented a new example for the isomeric linkage for the oximato group whereby both the oximato groups are coordinated through the oximino oxygen and the oximino nitrogen, respectively. Complex **II** (*N*-coordination) was converted to complex **I** (*O*-coordination) by allowing the aqueous reaction solution of **II** to stand at room temperature for 14 h. This conversion implied the stability of the *O*-coordination mode of the six-membered chelate ring over the *N*-coordination mode of the five-membered chelate ring.

Complex **I** decomposed in boiling piperidine and was recovered unchanged from boiling chloroform or after stirring in pyridine for 14 h. However, on refluxing its solution in pyridine for 1 h complex **III** was formed, which is formulated as shown in Fig. 2. The vibrational features of this complex regarding the stretching vibrations of the carbonyl and oximato groups are diagnostic for the presence of the isomeric linkage behaviour of the oximato group within the same complex, whereby it exhibits *O*- and N-coordination to produce six- and five-membered chelate rings, respectively. Thus, the IR spectrum of the complex revealed the presence of two distinct ν(C=O) vibrations for the carbonyl groups. The higher-frequency vibrations (1688 and 1680 cm^{-1}) are located in the 1690–1670-cm^{-1} region of the carbonyl group attached to a six-membered chelate ring [in the oxime–imino complexes[8] of Cu(II) and Ni(II)] whereas the lower-frequency band is located in the 1660–1630-cm^{-1} region of the five-membered chelate ring. Similarly, the ν(N—O) vibrations are separated by two distinct and well-resolved bands where the higher frequency (1160 cm^{-1}) is ascribed to the oximino-nitrogen coordination (greater double-bond character for the N—O bond) whereas the lower frequency (1142 cm^{-1}) is associated with the oximino-oxygen coordination (less double-bond character for the N—O bond).

The action of pyridine in the conversion of complex **I** to complex **III** should proceed through dissociation of the metal–oxygen bond of the oximato group. This step could result from the axial ligation of pyridine to the metal atom. Charge redistribution on the oximato group will lead to its coordination through the oximino nitrogen. The magnetic moment of complex **III** (1.82 BM) indicated that molecular association is unlikely as was the case with complexes **I** and **II**. The Ni(II) analogue to complex **III** was prepared from the reaction of H_2L with $(CH_3CO_2)_2Ni \cdot 4H_2O$ in ethanol.[11] The location of the vibrational bands of the carbonyl in the Ni(II) and Cu(II) complexes are identical. However, this similarity does not extend to the ν(N—O) since it is related to the stability of the chelate ring itself which comprises the metal ion.

It is of interest to compare ν(C=N) and the Cu–ligand stretching vibrations of complex **III** (which showed an isomeric linkage of the oximato group in the same complex) with those of complexes **I** (*O*-coordination) and **II** (*N*-coordination) where the oximato groups exhibited one mode of the coordination in the same complex. Thus the ν(C=N) of complex **I** is located[16] at a lower frequency (1585 cm^{-1}) than complex **II** (1604 cm^{-1}). This implied a higher contribution from the imino nitrogen to the strength of the chelate ring in the case of the six-membered chelate ring. Both these vibrations were detected from complex **III** where both five- and six-membered chelate rings are present. The ν(Cu—N) (imino nitrogen) appeared at 592 cm^{-1} in complexes **I–III**, where the ligand had no vibrational bands.[17] In complex **I** with *O*-coordination of the oximato group, a band appeared at 480 cm^{-1}, whereas in complex **II** with *N*-coordination this band was shifted to 465 cm^{-1}. It is therefore safe to assign the 480-cm^{-1} band to ν(Cu—O) (oximino oxygen) and the 465-cm^{-1} band to ν(Cu—N) (oximino nitrogen). These assignments are supported by the presence of those two bands in the case of complex **III** with isomeric coordination.

The electronic spectra of the metal complexes **I–III** are summarized in Table 3. The Nujol mull spectra of complexes **I–III** are indicative of a planar

structure.[18] The chloroform solutions of complexes **I–III** are red, although they have different colours in the solid state (Table 1). The positions of the absorption peaks observed from the Nujol mull spectra are not identical with those of the solution spectra. Moreover, the intensities of these maxima are higher than the usually encountered[18] values. The absorption peak of the ligand at 315 nm is shifted to 282 nm in complexes **I–III**. In view of these observations it is best to consider all these bands as charge-transfer transitions generated from intramolecular electronic interactions.

The reaction of $CoCl_2 \cdot 6H_2O$ with the ligand (5 : 1 molar ratio) led to the formation of the red complex **IV**. The IR spectrum of this complex was identical with that of the Cu(II) complex **I** with regard to ν(C=O), ν(N—O) and ν(metal–ligand) vibrations. It is suggested therefore that the structure of complex **IV** comprises *O*-coordination of the oximato group in a similar manner to that described for complex **I** (Fig. 2). The magnetic moment of complex **IV** (1.71 BM) indicates a low-spin Co(II) complex and its visible spectrum (Table 3) is typical of a square-planer Co(II) complex.[19] The ν(C=N) band in complex **IV** is shifted to a higher frequency (15 cm^{-1}) than the corresponding vibration of the Cu(II) complex **I** of the same structure. This is ascribed to the weaker contribution of the imino nitrogen to the strength of the chelate ring in the case of the Co(II) complex compared to the Cu(II) complex.

The reaction of H_2L with either $(CH_3CO_2)_2UO_2 \cdot 2H_2O$ or $UO_2(NO_3)_2 \cdot 6H_2O$ (1 : 1 molar ratio) led to the formation of the yellowish-brown uranyl complexes **V** and **VI**, respectively. The formulations of these complexes (Fig. 2) are compatible with analytical (Table 1), spectral (Tables 2 and 3) and chemical-reactivity evidence. The formation of complexes **V** and **VI** is explained by the following reactions:

H_2L = (isoacac)$_2$enimine

$$\xrightleftharpoons{C_2H_5OH} 2\text{Hisoacac} + \text{en}, \quad (1)$$

$$H_2L + UO_2X_2 + \text{en} \longrightarrow HLUO_2X \cdot \text{en} + HX, \quad (2)$$

where Hisoacac = isonitrosoacetylacetone, X = acetate (complex **V**) or nitrate (complex **VI**), and en = ethylenediamine. The IR spectra of the complexes **V** and **VI** are almost identical with regard to ν(C=O), ν(C=N) and ν(N—O) vibrations. The presence of two well-resolved ν(C=O) (1693 and 1680 cm^{-1}) is indicative of two non-equivalent carbonyl groups. The higher-frequency band is identical with that observed from the ligand[10] itself whereas the lower-frequency band is located at a comparable frequency to that observed from the carbonyl group attached to the six-membered chelate ring of the vicinal oxime–imine complexes of Ni(II)[8] and Cu(II)[14] as well as from complexes **I** and **IV** [*O*-coordination (see Fig. 2)]. The associated ν(N—O) bands are located at 1073 cm^{-1} for the non-ionized part (shifted from 1062 cm^{-1} in the case of H_2L) and at 1102 cm^{-1} for the six-membered chelate ring. The latter band is located at a lower frequency (30 cm^{-1}) than the comparable ν(N—O) of complexes **I** and **IV** with an identical chelate ring. This observation could be explained by the weaker U—O bond (oxygen of the oximato group in complexes **V** and **VI** compared to the M—O bond in complexes **I** and **IV**. The ν(C=N) vibrations of the chelate ring and the non-ionized part of the ligand were located at 1604 and 1630 cm^{-1}, respectively (shifted from 1635 cm^{-1} in the case of H_2L). The acetato group in complex **V** showed a ν_{as} centred at 1545 cm^{-1}, and the splitting of this band (1555, 1550 and 1540 cm^{-1}) is indicative of coordinate crowding in the equatorial plane of the uranyl ion. Bidentate coordination is suggested for the acetato group by comparing the ν_{as} in this case with other acetato complexes of the metal ion.[20] The $\nu(NH_2)$ of the bidentate ethylenediamine is broad (centred around 3250 cm^{-1}) and mixed with the broad ν(OH) (centred at 3400 cm^{-1}) of the non-ionized part of the ligand. The IR spectrum of complex **VI** did not show any strong band in the 1350–1400-cm^{-1} region of the free nitrate ion but revealed instead a vibrational band at 1485 cm^{-1} which is assigned to ν(N—O) of the coordinated nitrato broup. Other stretching vibrations for nitrato group were observed at 2580, 2495, 1720 and 745 cm^{-1}. These bands are located at comparable locations to those of the known bidentate nitrate[21,22] of the uranyl ion. Accordingly, it is suggested that the U(VI) ion in complexes **V** and **VI** had achieved 6-coordination in the equatorial plane [two from the chelate ring, two from ethylenediamine and two from either the acetato or the nitrato group (see Fig. 2)]. The ν(U—N) (imino nitrogen) is located near 600 cm^{-1} as in complexes **I–IV**. The strong ν(O—U—O) stretching vibration is located at 910 cm^{-1} as in other cases of uranyl complexes of Schiff bases.[21]

The electronic spectra of the sparingly soluble complex **V** (a single peak at 355 nm) and complex **VI** (a single peak at 340 nm) is typical of the uranyl complexes which usually show absorption peaks in the 340–500-nm region related to the UO_2^{2+} entity.[23] The suggested half-ionization of the ligand in complexes **VI** and **VII** is consistent with a similar behaviour of the trivalent lanthanides complexes of Schiff-bases.[24] Moreover, the reaction of

uranyl nitrate with the related H_2L produced the adduct $UO_2(H_2L)(NO_3)_2$ in which the ligand behaved[21] as a neutral bidentate molecule.

Chemical evidence for the suggested formulations of complexes **V** and **VI** is derived from their reaction with $(CH_3CO_2)_2Ni \cdot 4H_2O$ (1 : 1 molar ratio in ethanol). This reaction led to the formation of a Ni(II) complexes which has been characterized, by analytical and spectral evidence, as the previously reported[11] Ni(II) analogue of complex **I**. The formation of the latter complex is explained by the following metal exchange reaction:

$$HLUO_2 \cdot en \cdot X + (CH_3CO_2)_2Ni \xrightarrow{C_2H_5OH} LNi + (CH_3CO_2)_2UO_2 + en + HX. \quad (3)$$

The freed diamine in reaction (3) reacted with the initially formed Ni(II) complex **III** analogue to form that of complex **I**, which is in accordance with our earlier[11] observation regarding the reactivity of the former complex with the diamine.

ANDERSON-TYPE HETEROPOLYANIONS OF MOLYBDENUM(VI) AND TUNGSTEN(VI)

KENJI NOMIYA, TAKEO TAKAHASHI, TAKAHIRO SHIRAI and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 7 *April* 1986; *accepted* 28 *May* 1986)

Abstract—The previously reported preparation of some Anderson-type molybdopolyanions containing divalent metal ions (Zn, Cu, Co or Mn) as a heteroatom has been reinvestigated. The molybdopolyanions of Zn(II) and Cu(II) were confirmed, although the Cu(II) polyanion was not stable and could not be recrystallized. On the other hand, the polyanions of Co(II) and Mn(II) could not be reproduced. Another type of heteropoly compound, $[X(H_2O)_{6-x}(Mo_7O_{24})]^{4-}$ [X = Cu(II), Co(II) or Mn(II)], was isolated as solids, which are not stable thermally. The mixed-type Anderson polyanions, $[Ni(II)Mo_{6-x}W_xO_{24}H_6]^{4-}$, which have been questioned as mixtures of species with different x values, were also reinvestigated using IR, UV absorption and MCD spectra. They are single species, but not mixtures, although some positional isomers may be present for the compounds where $x = 2$–4. The possibility of oxidation of the heteroatom with the Anderson structure maintained was examined. The oxidation of $[Ni(II)Mo_6O_{24}H_6]^{4-}$ by the $S_2O_8^{2-}$ ion in aqueous solution gave the Waugh-type $[Ni(IV)Mo_9O_{32}]^{6-}$ polyanion, whereas the oxidation of $[Ni(II)W_6O_{24}H_6]^{4-}$ gave no heteropoly compound.

Anderson-type heteropolyanions, represented by the general formula $[XM_6O_{24}H_x]^{n-}$, possess a heteroatom (X) in a central octahedral cavity of the crown by edge-sharing six octahedral MO_6 (M = Mo or W).[1] These polyanions become a family for a number of 2+, 3+, 4+, 6+ and 7+ metal ions as the heteroatom. They have been classified into A ($x = 0$) and B ($x = 6$) types by the number of attached protons, although some polyanions with x other than 0 or 6 have been recently reported.[2,3] Most of them have been tabulated in books.[1,4] However, some questionable compounds are also involved there. In this work, we have done three experimental studies. The first is related to members of the family of B-type molybdopolyanions, especially the polyanions containing some divalent metal ions [Zn(II), Cu(II), Co(II) or Mn(II)] other than Ni(II), which have been first reported by LaGinestra *et al.*,[5] and later questioned by Malik *et al.*[6] The second is a reinvestigation by spectroscopic (IR, UV absorption and MCD) methods of the mixed-type Ni(II) molybdotungstopolyanions previously reported by Matijevic *et al.*[7] The last concerns the possibility of the oxidation of Ni(II) molybdo- and tungstopolyanions leading to the corresponding Ni(IV) ones with the polyanion structure maintained.

EXPERIMENTAL

Electronic absorption spectra were measured by a Hitachi 340 spectrophotometer with an attached computer-key board. MCD spectra were recorded by a JASCO J-40AS spectropolarimeter mounted with a 10.0-kG electromagnet. IR spectra were recorded with a JASCO IR-G spectrophotometer. Measurements were made at room temperature.

Preparations

$(NH_4)_3[X(III)Mo_6O_{24}H_6]\cdot 7H_2O$ *and* $(NH_4)_4[X(II)Mo_6O_{24}H_6]\cdot 5H_2O$. B-type molybdopolyanions

* Author to whom correspondence should be addressed.

containing tervalent metal ions (Cr, Al or Fe) and Ni(II) ion were obtained as crystals by the traditional method:[8] adding an aqueous solution of metal sulphates or alums (3.1×10^{-3} mol) in 20 cm^3 water into a boiling aqueous solution of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (5 g, 4.2×10^{-3} mol) dissolved in 80 cm^3 water, further evaporating on a steam-bath, filtering the hot solution and cooling. In the preparation of the Co(III) polyanion, a mixed aqueous solution (30 cm^3) of $CoSO_4 \cdot 7H_2O$ (4.2 g, 0.015 mol) and 30% aqueous H_2O_2 (2 g) was added into the boiling solution of aqueous heptamolybdate (30.9 g, 2.5×10^{-2} mol in 260 cm^3 water). These compounds were recrystallized twice from water. The colour and analytical data are listed in Table 1. Visible absorption spectra of the Co(III), Cr(III) and Ni(II) compounds are in good agreement with the previous data.[9] When the colourless Fe(III) polyanion was dissolved in water, the solution was a wine-red colour due to the dissociation and/or the hydrolysis.

The preparation of B-type Anderson molybdopolyanions containing divalent metal ions (Ni, Zn, Co or Mn) has been reported by LaGinestra *et al.*[5] However, some questionable points were seen. They stated that such polyanions must be prepared without boiling: however, the Ni(II) and Zn(II) compounds were actually obtained from boiling solutions. The Zn(II) compound was obtained as colourless crystals by adding an aqueous solution of $ZnSO_4 \cdot 7H_2O$ (1 g, 3×10^{-3} mol in 20 cm^3 water) into a boiled solution of heptamolybdate (5 g, 4.2×10^{-3} mol in 80 cm^3 water). It was recrystallized twice from water. Analytical data are listed in Table 1. This compound was very soluble in water. Further, the Cu(II) compound was obtained by adding Cu(II) sulphate solution (0.75 g, 3×10^{-3} mol in 20 cm^3 water) into the boiled solution of heptamolybdate (5 g, 4.2×10^{-3} mol in 80 cm^3 water), filtering the yellow insoluble precipitate produced, cooling the filtrate, and adding excess amounts of acetonitrile. The light blue solid obtained was insoluble in water and not stable thermally. The Co(II) and Mn(II) compounds were not obtained from boiling solutions. Any changes in the pH of the initial heptamolybdate solution and in the reaction time gave mixtures of the initial materials and the bluish violet [for Co(II)] or yellow [for Mn(II)] insoluble solids. On the other hand, from the experiments without boiling, the Cu(II), Co(II) and Mn(II) compounds could be obtained, which were insoluble in water and not stable thermally. They were prepared by concentrating the mixed aqueous solutions of the metal sulphates and heptamolybdate without heating and/or adding excess amounts of acetonitrile. However, their spectra were not identical with the characteristic IR spectra of the Anderson molybdopolyanions.

Table 1. Colour and analytical data for $(NH_3)_3[X(III)Mo_6O_{24}H_6] \cdot 7H_2O$ and $(NH_4)_4[X(II)Mo_6O_{24}H_6] \cdot 5H_2O$

X	Colour	Found (%)		Calculated (%)	
		N	H	N	H
Co(III)	Blue-green	2.4	3.6	2.7	3.5
Cr(III)	Reddish-violet	2.4	3.6	2.7	3.5
Fe(III)	Colourless	2.4	3.6	2.7	3.5
Al(III)	Colourless	2.4	3.7	2.7	3.6
Ni(II)	Sky-blue	2.7	4.6	2.7	4.7
Zn(II)	Colourless	2.3	4.5	2.7	4.7

$(NH_4)_4[Ni(II)Mo_{6-x}W_xO_{24}H_6] \cdot 5H_2O$. B-type Ni(II) molybdotungstopolyanions ($x = 1, 3, 5$ or 6) were prepared according to two methods of Matijevic *et al.*[7] Method 1 is based on the dropwise addition of an aqueous solution of Ni(II) sulphate into boiling solutions containing appropriate molar ratios of Mo and W, where the source of Mo is $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ for $x = 0$, $Na_2MoO_4 \cdot 2H_2O$ for $x = 1$, and MoO_3 for $x = 2$–5; and the source of W is $Na_2WO_4 \cdot 2H_2O$ for all x. Method 2 is based on heating above 80°C aqueous solutions containing appropriate molar mixtures of already isolated $x = 0$ or 6 compounds, and cooling spontaneously to room temperature. All compounds, recrystallized twice from water, were obtained as sky-blue crystals. Analytical results for all the compounds were in good agreement within the experimental error. However, they do not lead to direct evidence for these mixed species, because they cannot be discriminated from those of mixtures of species with different compositions.

(Na, K)$_8[Ni(IV)W_6O_{24}] \cdot nH_2O$. An A-type Ni(IV) tungstopolyanion was obtained by the modification of the preparation of the isostructural Mn(IV) tungstopolyanion.[12] A solution of $Na_2WO_4 \cdot 2H_2O$ (20 g, 0.06 mol) in 100 cm^3 water was boiled, into which $NiSO_4 \cdot 6H_2O$ (2.6 g, 0.01 mol) in 10 cm^3 water was slowly added. Further, a fine powder of $K_2S_2O_8$ (5.4 g, 0.02 mol) was added. The boiling was continued for about 15 min, with occasional additions of water. The reaction mixture was poured into an equal amount of hot water and the solution kept at 80°C for about 30 min on the steam-bath. The black crystals formed were filtered, washed with water, and dried (yield 2.5 g). This compound was slightly soluble in water and insoluble in most other solvents.

Oxidation of Ni(II) *molybdo- and tungstopolyanions*

When an aqueous solution of $(NH_4)_4[Ni(II)Mo_6O_{24}H_6]\cdot 5H_2O$ containing $(NH_4)_2S_2O_8$ was heated, a colour change was seen; from sky-blue it turned gradually to black. After the homogeneous black solution was left standing at room temperature, the colourless precipitates produced were filtered off. The black crystals obtained from the filtrate showed IR spectra identical with that of the Waugh-type heteropoly compound $(NH_4)_6[Ni(IV)Mo_9O_{32}]$, which was prepared separately.[13] On the other hand, in the analogous experiments using $(NH_4)_4[Ni(II)W_6O_{24}H_6]\cdot 5H_2O$, no heteropoly compound could be obtained. In this reaction, the solution became blackish via yellowish-brown, but then it turned to green. Further addition of $(NH_4)_2S_2O_8$ showed no more colour change. Only the mixture of decomposed materials was given.

RESULTS AND DISCUSSION

B-type molybdopolyanions with divalent metal ions as a heteroatom

In the Anderson heteropolyanion, each heteroatom forms an octahedral complex of six oxygens for A-type and of six OH groups for B-type. Thus, the visible absorption spectra of B-type polyanions of Co(III), Cr(III) and Ni(II) are comparable with that of the corresponding hexaaqua complexes,[9] although the peak intensities of the polyanions are smaller as shown in Table 2. IR spectra of Anderson-type $[X(III)Mo_6O_{24}H_6]^{3-}$ [X(III) = Co(III), Cr(III), Fe(III) or Al(III)] are presented in Fig. 1. The bands due to the heteroatom are seen only in the region less than 450 cm^{-1}. Since the IR spectra in the 950–900- and 650–550-cm^{-1} regions become independent of the sort of heteroatom, they can be said to be in the pattern common to the B-type Anderson molybdopolyanions. In fact, the Ni(II), Zn(II) and Cu(II) molybdopolyanions show the characteristic IR spectra (Fig. 2). The IR spectrum previously shown for the Mn(II) compound by LaGinestra *et al.*[5] is evidently different from these patterns.

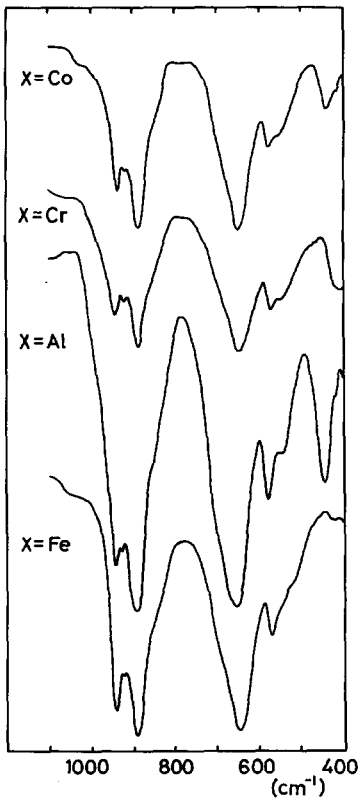

Fig. 1. Solid IR spectra of Anderson-type $[X(III)Mo_6O_{24}H_6]^{3-}$ polyanions.

Table 2. Spectral data of visible and near-IR absorption of Anderson-type molybdopolyanions of Co(III), Cr(III) and Ni(II)

	λ ($\times 10^{-3}$ cm^{-1}) (ε)		
$[Co(III)Mo_6O_{24}H_6]^{3-}$	16.5 (18.6)	24.2 (18.4)	
$[Co(H_2O)_6]^{3+}$ [a]	16.5 (40)	25.0 (50)	
$[Cr(III)Mo_6O_{24}H_6]^{3-}$	18.5 (7.8)	25.3 (9.5)	
$[Cr(H_2O)_6]^{3+}$ [a]	17.4 (13.3)	24.6 (15.3)	
$[Ni(II)Mo_6O_{24}H_6]^{4-}$	9.3 (1.6)	13.7 (1.2)	15.6 (1.8)
$[Ni(H_2O)_6]^{2+}$ [a]	8.5 (2.0)	13.8 (2.1)	15.2 (1.9)
$[SiNiMo_{11}O_{40}H_2]^{6-}$ [b]	8.6 (5.3)	14.5 (6)

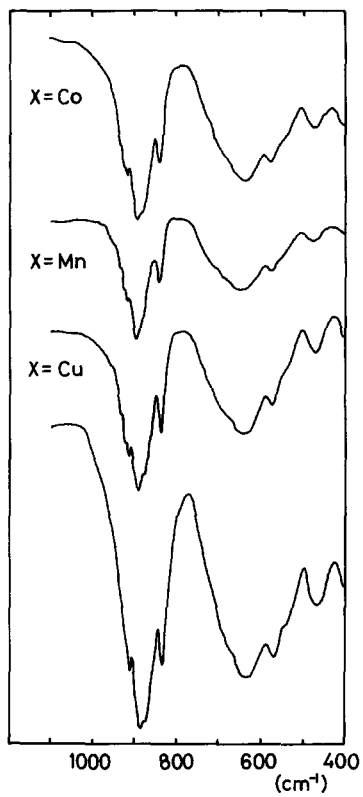

Fig. 3. Solid IR spectra of the 1:1 metal ion (X): $Mo_7O_{24}^{6-}$ complexes and $Mo_7O_{24}^{6-}$ alone (on the bottom).

Although they have attributed the disagreement to the different formulae due to the number of hydrates, it presumably accounted for the compound itself. On the other hand, the IR spectrum presented by them as that of the Co(II) compound is apparently similar to the characteristic patterns. We have occasionally obtained the compound showing such an IR spectrum from the reaction involving boiling with a Co(II) sulphate solution and an aqueous heptamolybdate solution adjusted to pH 4.46. However, such a compound was a minor product.

The Cu(II), Co(II) and Mn(II) compounds obtained from the experiments without boiling were not of the Anderson type, but like the Mo_7O_{24} polyanion. These compounds showed IR spectra very similar to that of the $[Mo_7O_{24}]^{6-}$ polyanion, except for the slightly broad bands in the 650–550-cm^{-1} region and the *ca* 10 cm^{-1} shift to the high-frequency region of the bands at *ca* 900 cm^{-1} (Fig. 3). They were insoluble in water and could not be recrystallized. Heating the aqueous suspension led to decomposition. These compounds are probably the $[X(H_2O)_{6-x}(Mo_7O_{24})]^{4-}$-type 1:1 complex, which was first proposed by Malik *et al.*,[6] from the Job method of continuous variation in an aqueous solution of metal sulphate and heptamolybdate. As a related complex, we have previously isolated the 1:2 Ce(III):Mo_7O_{24} complex as orange-red crystals from an aqueous solution containing ammonium Ce(III) nitrate and ammonium heptamolybdate.[14,15] The preparation was done only at room temperature, and the Ce(III) complex obtained was also insoluble in water, and not stable thermally.

The Anderson heteropolyanion is one of the most well-known polyanions and it constitutes a family with a number of heteroatoms.[1,4] We propose that the Co(II) and Mn(II) ions should be excluded from the Anderson family and entered into another category of polyanion.

Mixed-type $[Ni(II)Mo_{6-x}W_xO_{24}H_6]^{4-}$ *polyanions*

For these mixed polyanions, the possibility has been pointed that they are mixtures of polyanions with different x values.[1] However, it was easily confirmed from the IR spectra that the $x = 3$ compound obtained by method 1 differed from an equimolar mixture of the $x = 0$ and $x = 6$ compounds.

Further, the IR spectra of the $x = 3$ compounds obtained by methods 1 and 2 were identical, as shown in Fig. 4. The IR spectra of each mixed polyanion were subtly different, and all of them resembled that of the $x = 6$ rather than the $x = 0$ compound as a whole.

In aqueous solution, these mixed polyanions showed the behaviour of a single species. Figure 5 shows the UV and MCD spectra of the $x = 0$, 1, 3, 5 and 6 compounds obtained by method 1. MCD spectra evidently indicate that they are single species, but not a mixture of species with different compositions, because the peak positions are quite different.

We can see some implications for the formation of the mixed Anderson cage in the experiments by method 2, and also in the recrystallization process for the $x = 0$ and $x = 6$ compounds. When an aqueous solution containing the Ni(II) Anderson polyanion is heated above 80°C, a colour change of the solution is observed from sky-blue to green. During the cooling process to room temperature, it returns to the original sky-blue. The green solution will be due to the Ni(II) aqua ion produced by dissociation of the polyanion. Therefore, it seems that, during the cooling process, the Anderson cage is formed around the Ni(II) ion as a core. The mixed Anderson cage will be formed on the basis of the reorientation of randomly distributed Mo and W oxo ions at the high temperature. Thus, the experiments by two methods do not exclude the possibility that the $x = 3$ compound, and also the $x = 2$ and $x = 4$ compounds, contain some positional isomers.

Oxidation of Ni(II) *molybdo- and tungstopolyanions*

The oxidation of the $[Ni(II)Mo_6O_{24}H_6]^{4-}$ polyanion by the $S_2O_8^{2-}$ ion in aqueous solution led to the formation of a Waugh-type $[Ni(IV)Mo_9O_{32}]^{6-}$ polyanion, which was isolated separately.[13] The valency of the heteroatom can be changed and the polyanion cage is simultaneously transformed. On the other hand, the oxidation of $[Ni(II)W_6O_{24}H_6]^{4-}$ gave the decomposition mixture, but no heteropoly compound. The same initial materials have been used in the preparations of $[Ni(IV)W_6O_{24}]^{8-}$ and $[Ni(II)W_6O_{24}H_6]^{4-}$ polyanions, except for the

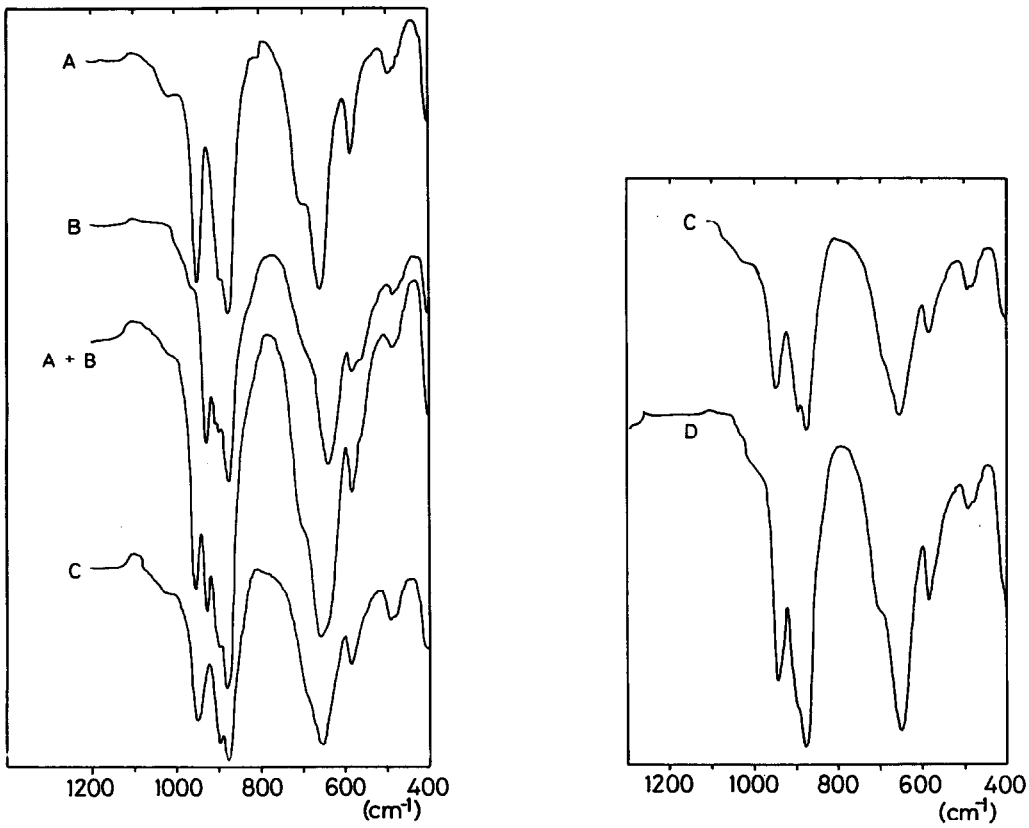

Fig. 4. Solid IR spectra of $[Ni(II)Mo_{6-x}W_xO_{24}H_6]^{4-}$ polyanions; $x = 6$ (A) and 0 (B) compounds, equimolar mixture (A + B) of them, and $x = 3$ compounds obtained by methods 1 (C) and 2 (D).

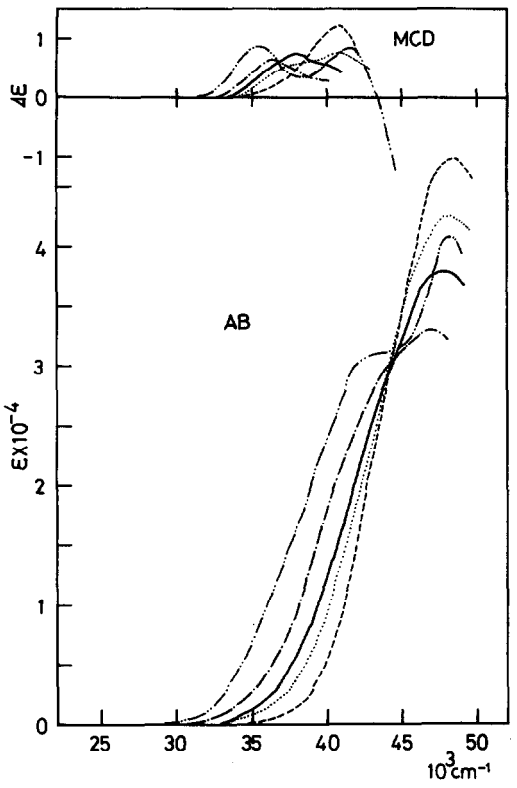

Fig. 5. UV absorption and MCD spectra of $[Ni(II)Mo_{6-x}W_xO_{24}H_6]^{4-}$ polyanions: $x = 0$ (——), $x = 1$ (—·——), $x = 3$ (———), $x = 5$ (·····), and $x = 6$ (– – –).

addition of the $S_2O_8^{2-}$ ion in the former. Thus, this oxidation experiment suggests that the formation of the $[Ni(IV)W_6O_{24}]^{8-}$ polyanion does not proceed through the oxidation of the already formed $[Ni(II)W_6O_{24}H_6]^{4-}$ polyanion. In a Keggin-type polyanion, the valency of the central heteroatom can be changed sometimes by chemical oxidation, with the polyanion structure maintained, such as $[Co(II)W_{12}O_{40}]^{6-} \rightarrow [Co(III)W_{12}O_{40}]^{5-}$ [16,17] and $[Cu(I)W_{12}O_{40}]^{7-} \rightarrow [Cu(II)W_{12}O_{40}]^{6-}$,[18] reactions which proceed by the outer-sphere mechanism of an electron transfer.[18,19] In this case, the Anderson structure may be thermally less stable than the Keggin structure.

PENTACOORDINATED COMPLEXES OF ORGANOTELLURIUM(IV) HALIDES WITH TERTIARY PHOSPHINE SELENIDES

T. N. SRIVASTAVA,* JAI DEO SINGH and SANJAY KUMAR SRIVASTAVA

Chemistry Department, University of Lucknow, Lucknow 226007, India

(*Received* 17 *April* 1986; *accepted* 28 *May* 1986)

Abstract—The pentacoordinated tellurium(IV) complexes [$R_2TeCl_2 \cdot L$] [R = C_6H_5 or *p*-$CH_3OC_6H_4$; L = Ph_3PSe, (*p*-$MeC_6H_4)_3PSe$, Bu_3PSe or $Ph_2P(Se)(CH_2)_2(Se)PPh_2$] were obtained by the reaction of R_2TeCl_2 with L under anhydrous conditions. The complexes have been characterized by spectral (IR, ^1H NMR and ^{31}P NMR) studies. The reaction of $RTeCl_3$ and L, however, yields tellurium/selenium metal. $^1J(^{31}P–^{77}Se)$ coupling constant data suggest complexation. In case of bidentate donor bases only one donor site is used in coordination. The complexes possess distorted octahedral geometry around a central tellurium atom which is surrounded by five groups and one vacant site occupied by a lone pair.

The coordination chemistry of phosphine selenides is little known compared to that of phosphine, phosphine oxides and sulfides.[1] There are only a few reports on the complexes of P=Se bases with some soft acceptors[2–6] such as Pt(II), Pd(II), Ag(I), Zn(II), Cd(II) and Hg(II). A few coordination compounds of the main-group metals Pb(II), Sn(II) and Sn(IV) have also been reported,[7,8] but the corresponding reactions with organometals have not been studied. There is a single paper describing the coordination behaviour of P=Se with (PhTeBr).[9] In continuation of our interest in the synthesis and reactivity of organotellurium(IV) compounds,[10] we report herein the synthesis of such complexes with organotellurium(IV).

EXPERIMENTAL

All manipulations were carried out under dry nitrogen. $TeCl_4$ (BDH) was used as such. Ph_2TeCl_2,[11] (*p*-$MeOC_6H_4)_2TeCl_2$,[12] Me_2TeI_2,[13] (*p*-$MeOC_6H_4)TeCl_3$,[14] and $Ph_2Te(OCOCF_3)_2$ and $Me_2Te(OCOCF_3)_2$[15] were prepared by literature methods. Tertiary phosphine selenides were prepared from the phosphine and KSeCN in CH_3CN[16] or by direct reaction of elemental selenium (red) with phosphines in refluxing toluene.[17] ^1H NMR spectra of the compounds were recorded in $CDCl_3$, using TMS as the internal standard on a Varian 90-D spectrometer. ^{31}P NMR spectra were obtained using a JEOL-PFT 400 Fourier transform spectrometer operating at 40.5 MHz. Samples were contained in spinning 10-mm tubes with $CDCl_3$ as the solvent system with a 1-mm capillary tube containing 85% H_3PO_4 as a reference. The molecular complexes were obtained by the direct interaction of the Lewis acids and bases in dichloromethane.

Reaction of R_2TeCl_2 (R = Ph *or* *p*-$MeOC_6H_4$) *with bases*

In a typical experiment a mixture of Ph_2TeCl_2 (3.52 g, 10 mmol) and Ph_3PSe (3.41 g, 10 mmol) in dichloromethane (~30 cm^3) was refluxed for 4 h, and the excess solvent distilled off. The solution was concentrated to crystallization, yielding [$Ph_2TeCl_2 \cdot SePPh_3$]. Similar products were obtained using $Ph_2P(Se)(CH_2)_2(Se)PPh_2$ as a base and $Me_2Te(OCOCF_3)_2$ as an acceptor.

Reaction of (*p*-$MeOC_6H_4)TeCl_3$ *with bases*

In a representative experiment, a mixture of (*p*-$MeOC_6H_4)TeCl_3$ and Ph_3PSe in a 1:1 molar ratio was stirred in dichloromethane at room temperature. The reaction mixture after a few minutes deposited selenium and tellurium metals. Similarly, Me_2TeI_2 and Me_2TeCl_2 with Ph_3PSe

[a] ν_1 in ligand and ν_2 in complex.

and $Ph_2P(Se)(CH_2)_2(Se)PPh_2$ deposited free metals and failed to yield stable adducts.

RESULTS AND DISCUSSION

The analytical data for the adducts (Table 1) correspond to a 1 : 1 (M : L) stoichiometry except for $[2(p\text{-}MeOC_6H_4)_2TeCl_2 \cdot Ph_2P(Se)(CH_2)_2(Se)PPh_2]$ which has a 2 : 1 (M : L) mole ratio and possesses a bridging ligand. All complexes are white crystalline solids having sharp melting points. They are normally stable but deposit selenium metal on standing for a long time. The complexes possess very offensive odours. They are soluble in common organic solvents such as MeOH, EtOH, CH_2Cl_2, MeCN, Me_2SO, Me_2NCHO and $PhNO_2$. The molar conductances of 10^{-3} M solutions of the complexes in MeOH and MeCN at room temperature indicate their non-electrolytic nature.

All known organoselenophosphorus compounds belong to the P(IV)–Se(II) class. Thus, selenium can be bonded to a phosphorus atom by a single (σ) bond or by a double bond of p_π–d_π (Se $4p_\pi \rightarrow$ P $3d_\pi$) type. P═Se can be considered as essentially a double bond because 3*d* orbitals of phosphorus are available for π-bonding. The p_π–d_π bonding arises from donation of non-bonding $4p_\pi$ electrons of the selenium atom into vacant 3*d* orbitals of phosphorus. This double-bond character in these ligands and the presence of valence *s*-electron density at the nucleus of the selenium atom is more than twice that for phosphorus, which would normally lead to a larger coordinating centre. Depending upon the relative importance of the two resonating hybrid structures the selenium atom will effectively retain from one to two electron lone pairs which have most of the selenium *s*-character, and thus may coordinate to a metal atom in one of the following ways:

$$R_3P{=}Se: \rightarrow M \leftrightarrow R_3P^+\dot{S}e\dot{:}^- \rightarrow M.$$

IR spectra

The IR spectra of the complexes were recorded in the range 4000–400 cm^{-1}. The diagnostic absorptions are discussed below.

Complexes with phosphine selenides

The ν(P═Se) reported in various phosphine selenides lies in the range 511–562 cm^{-1}, and undergoes a negative shift of 8–14 cm^{-1} on coordination. A shift of 10–20 cm^{-1} in ν(P═Se) has been reported for zinc, cadmium, mercury and nickel complexes.[3,18]

The shift is attributed to a weakening of the secondary p_π–d_π bonds between the selenium and the phosphorus atom in the complexes. It is observed that only a small change in the P═Se stretching frequency occurs compared to the corresponding ν(P═O) and ν(P═S) absorptions[18] in the corresponding complexes. This is reasonable since the vibrations involving the relatively heavy selenium atom would be less sensitive to coordination than those with the lighter phosphorus, oxygen or sulphur atoms.

^{1}H *NMR spectral studies*

The ^{1}H NMR values are given in Table 2. The salient features of the spectra are discussed below.

In the ^{1}H NMR spectra of $[(p\text{-}MeOC_6H_4)_2TeCl_2 \cdot Ph_2P(Se)(CH_2)_2(Se)PPh_2]$ (1 : 1 M : L) and $[2(p\text{-}MeOC_6H_4)_2TeCl_2 \cdot Ph_2P(Se)(CH_2)_2(Se)PPh_2]$ (2 : 1 M : L), the —CH_2 protons are doubled due to coupling with the ^{31}P nucleus. The methyl protons of the p-$MeOC_6H_4$ group show a doublet in the 1 : 1 complex. In the 2 : 1 complex the two methyl singlets are separated and are centred at 3.75 and 3.68. However, the two complexes show a single spot in TLC, ruling out the presence of a mixture of the 2 : 1 and 1 : 1 adducts. The structural change may be due to participation of both selenium atoms of the bidentate ligand in coordination, giving rise to a bridging ligand between the two tellurium atoms. The structure of bis(diphenylphosphinoselenide)-ethane favours more a bite and an orientation of the lone pairs for bridging two metals atoms

[a] Free-ligand values.[24]

rather than forming a chelate ring around a single metal.[19] It is concluded that diphosphine selenide acts as a bridging ligand between two tellurium atoms, as reported for diphosphine complexes with other metals.[20–22]

^{31}P *NMR spectra*

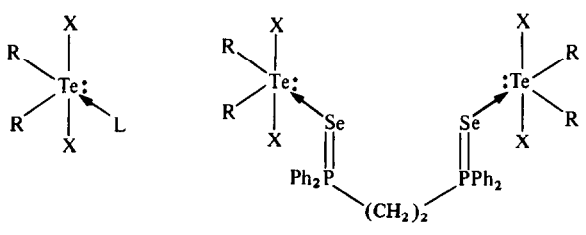
^{31}P NMR spectra of a few complexes were obtained at room temperature and the data are listed in Table 3.

From the ^{31}P NMR data the following facts are deduced:

(i) $J_{P\text{–}Se}(^{31}P\text{–}^{77}Se)$ is sensitive toward coordination and possesses a lower value compared to that for the free ligand. Such a change is attributed to coordination of P=Se to the metal atom through selenium.[23,24]

(ii) In the complex $[(p\text{-}MeOC_6H_4)_2TeCl_2 \cdot SePPh_3]$ the $\delta(P)$ and $^1J(^{31}P\text{–}^{77}Se)$ decrease on coordination, indicating Se → Te bonding.[17,23]

(iii) In the complex $[(p\text{-}MeOC_6H_4)_2TeCl_2 \cdot Ph_2P(Se)(CH_2)_2(Se)PPh_2]$ two sets of ^{77}Se satellites of equal intensity, with $^1J(^{31}P\text{–}^{77}Se) = 635.1$ and 832.2 Hz, are observed. The former coupling constant $[\Delta^1J(^{31}P\text{–}^{77}Se = -100.9$ Hz] is due to coordination from the selenium atom, while the other, being higher ($\Delta^1J = +96.2$ Hz) than that in the free ligand, may be due to an uncoordinated selenium atom.[25] Thus, from spectral data it may be concluded that the complexes possess an octahedral geometry around a tellurium atom with one site being occupied by a lone pair of electrons. The structures of the complexes may be as shown below.



R = CH_3, C_6H_5 or p-$MeOC_6H_4$; X = Cl or $OCOCF_3$

SINGLE-CRYSTAL OPTICAL ABSORPTION SPECTRA FOR MAGNUS-TYPE SALTS OF PALLADIUM AND PLATINUM

MICHAEL L. RODGERS[1] and DON S. MARTIN†

Chemistry Department and Energy and Mineral Resources Research Institute, Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 5 *December* 1985; *accepted after revision* 4 *June* 1986)

Abstract—Polarized single-crystal absorption spectra in the region 800–250 nm were recorded at 300 and 6 K for the 20 possible Magnus-type crystals containing the $PtCl_4^{2-}$, $PtBr_4^{2-}$, $PdCl_4^{2-}$ and $PdBr_4^{2-}$ anions, and the $[Pt(NH_3)_4]^{2+}$, $[Pt(CH_3NH_2)_4]^{2+}$, $[Pt(en)_2]^{2+}$, $[Pd(NH_3)_4]^{2+}$ and $[Pd(en)]^{2+}$ cations. Metal–metal distances were obtained from X-ray diffraction determination of crystal axes. A complete set of X-ray diffraction intensities was collected for 2659 reflections over four octants for crystals of $Pt(en)_2PdCl_4$. Triclinic cell parameters were: $a:b:c = 11.711(7):8.480(6):6.801(2)$ Å; $\alpha:\beta:\gamma = 96.10(4):91.08(4):106.74(8)°$; $V = 642.3(2)$ Å^3; $Z = 2$. However, only 20 very weak reflections occurred that would conflict with a body-centered space group. Refinement in $I\bar{1}$ yielded Pt, Pd, Cl and N positions satisfactory for spectra interpretation. C positions could not be satisfactorily established and refinement in $P1$, $I1$ or $P\bar{1}$ did not converge. The spectra at 6 K provided resolution into components not available at room temperature. The temperature dependence of intensities and in some cases resolution of vibrational structure in the bands was helpful in making transition assignments. For $Pt(NH_3)_4PtCl_4$ a very sharp electric dipole allowed band, not previously observed, was found just above the d–d transitions with x,y polarization (normal to the stacking direction). Similar bands occurred in the $PtCl_4^{2-}$ salts with other Pt cations. The evidence is summarized for assignment of these bands as interionic electron transfers (anion-$d_{xz,yz}$ → cation-p_z). This evidence implies that the very intense absorption at *ca* 35,000 cm^{-1}, z-polarized (along the stacking axis), is also an interionic electron transfer (anion-d_{z^2} → cation-p_z). These results together with shifts of the intraionic $d \rightarrow d$ transitions suggest that the d_{z^2}-orbital in the free MX_4^{2-} ions lies close in energy to the $d_{xz,yz}$-orbitals. Spectra of $PdCl_4^{2-}$ salts with the Pt cations reveal broad dipole-allowed transitions above the intramolecular $d \rightarrow d$ transitions. It appears likely that they are interionic electron transfers. However, their characteristics indicate they cannot be anion-$d \rightarrow$ cation-d nor anion-$d \rightarrow$ cation-p_z transitions. Hence they are most likely anion-$L\pi \rightarrow$ cation-$d\sigma^*$ transitions. The results indicated that Pt was more effective than Pd in shifting d–d transitions in the region of 3.25–3.55 Å. These shifts, except for the $^1A_{1g} \rightarrow {}^1A_{2g}$ transitions, were strongly dependent on the metal–metal distance with cations of the same metal.

The green compound $Pt(NH_3)_4PtCl_4$ first described by Magnus[2] in 1828 is commonly known as Magnus' Green Salt (MGS). Since the compound is formed from the normally colorless $[Pt(NH_3)_4]^{2+}$ cation and the normally red $PtCl_4^{2-}$ anion, it has been the subject of numerous speculations throughout the years. The anomalous color is apparently the result of close face-to-face stacking of alternating cations and anions in one-dimensional arrays with Pt–Pt spacings of 3.24 Å.[3,4] Indeed, a polymorph, Magnus' Pink Salt, without the one-dimensional stacks, has the normally expected color.

The Magnus-type salts consist of similar one-dimensional stacks of MA_4^{2+} cations and $M'X_4^{2-}$

† Author to whom correspondence should be addressed.

anions. In the present work single-crystal polarized absorption spectra have been recorded at room temperature and 6K for the 20 possible Magnus-type salts with M and M′ = Pt or Pd, X = Cl or Br, and A = NH_3, CH_3NH_2 or half the chelating group ethylenediamine (en).

Previously, single-crystal spectra for MGS of very limited quality were reported by Yamada.[5] Day *et al.*[6,7] published single-crystal spectra for MGS, $Pt(CH_3NH_2)_4PtCl_4$ and $Pt(C_2H_5NH_2)_4PtCl_4$ at room temperature while Martin *et al.*[8] presented 300- and 15-K spectra for MGS. The various Magnus-type salts occur with a variety of colors. Miller[9] as well as Day *et al.*[6] have tabulated wave numbers for peaks and some shoulders observed in the diffuse reflectance for a number of the Magnus-type salts. Anex and coworkers[10,11] have used single-crystal polarized specular reflectance spectra to characterize the high-intensity, high-energy transition in a number of Magnus-type salts. Such specular reflection spectra nicely complement the transmission-absorption spectra since they provide polarization information about intense bands that are beyond the capability of absorption measurements. Yamada[5] and Miller[9,12] considered the anomalous color to originate in a band-to-band type of transitions in Magnus-type salts. However, Day[13] has argued that the visible-region spectra were essentially anion spectra in which a number of transitions had been red-shifted. The red shifts for *d–d* transition were attributed to the repulsion interactions between anion electrons and electrons of the adjacent cations. A red shift of an intense *z*-polarized transition was suggested to be the result of transition dipole–dipole interactions. On the other hand Anex and coworkers[10,11] have argued that the intense absorption band for ammonia–chloride Magnus-type salts of Pt and Pd involves a "delocalized" transition without further specification.

The low-temperature spectra in the present study provide resolution into a greater number of bands than can be discerned at room temperature, and also a vibrational structure has appeared in some bands. The temperature dependence of the band intensities is useful since permanent electric dipole allowed transitions will have little temperature dependence, whereas vibronically-enabled transitions (Herzburg–Teller type) decrease significantly in intensity as the temperature falls from room temperature to liquid-helium temperatures. The use of different amines provides some variation in the M–M′ stacking distances which in turn causes a number of band shifts and intensity changes. With the large number of compounds involved, the rather severe testing of any theory or rationalization of orbital and transition energies is now possible.

EXPERIMENTAL

Preparation of crystals

The preparation of the complex anion salts K_2PtCl_4, K_2PtBr_4, K_2PdCl_4 and K_2PdBr_4 has been described previously.[14–16] To prepare the cation complexes, *ca* 50 mg of the potassium salt of the chloride or bromide complex was dissolved in a minimum of water. A concentrated aqueous solution of NH_3 or the indicated amine was added until the Magnus-type salt formed. The reaction mixture was heated until the Magnus-type salt had redissolved and most of the liquid had evaporated. The remaining solution was added to 500 cm^3 of a solution formed from 45% diethyl ether, 45% acetone and 10% ethanol. The white precipitate was stored over a concentrated aqueous solution of the amine to minimize ligand replacement reactions.

Attempts to prepare the compounds $Pd(CH_3NH_2)_4Cl_2$ and $Pd(CH_3NH_2)_4Br_2$ by this technique produced very poor yields of impure products that were unsuitable for use in the Magnus-type salt synthesis. Hence, only 20 Magnus-type salts were prepared of the 24 possible with two metals, two halides and three amines.

Thin crystals were mostly grown in the film of solutions between glass plates by the technique utilized in the earlier study of MGS in our laboratory.[8] Larger crystals were prepared in a crystal grower which consisted of a 25-mm horizontal cyclindrical vessel divided into three compartments by fine sintered-glass discs. The anion salt solution was placed in one end compartment, the cation salt in the other end compartment, and a potassium halide solution in the center compartment. Crystals normally formed on the surfaces of the sintered-disc dividers.

Crystallographic methods

Atoji *et al.*[4] showed that the MGS crystals possess a tetragonal unit cell with the ions stacked face-to-face along the *c*-axis so that the metal atoms are spaced apart by a distance of *c*/2. Miller[12] reported from powder film data that the Magnus-type salts containing methylamine ligands in the cations also formed tetragonal crystals. From the *c*-axis lengths and the optical properties, he concluded that the ions stacked along the tetragonal axis similar to MGS for all the compounds for which he had data. However, the Magnus-type salt with ethylenediamine-complexed cations crystallized as needles with triclinic lattices. Optical examinations of all our ethylenediamine crystals showed that optical extinctions were not appreciably wavelength-dependent, and one extinction was aligned with the

needle axis. The strong dichromism of the crystals indicated that the needle axis, which we have always designated as the *c*-axis, provided essentially the *z*-polarized spectra for the complex. For 16 of the 19 compounds other than MGS itself, we were able to mount suitable crystals on the goniometer head of a four-circle X-ray diffractometer, constructed in the Ames Laboratory of the U.S.D.O.E. This instrument was interfaced with a PDP 15 computer. Automatic indexing was accomplished by an interactive program ALICE of Jacobson.[17] These indexing experiments also provided the indices of the well-developed faces which served for the crystal spectroscopy and the volumes of the unit cells needed for evaluating spectroscopic intensities. These crystallographic axes and angles, determined without any symmetry constraints, are shown in Table 1. The results are in good agreement with tetragonal assignments for the ammine and methylamine salts. Variations in a and b, and between α, β and γ, indicate uncertainties in the axes of about ± 0.02 Å, and in the angles of about 0.1°, in agreement with our experience. Three of the sets of lattice parameters in Table 1 are those of Miller, who collected X-ray powder data for eight of the compounds since we did not index these crystals. For four of the five compounds for which both Miller and we collected data, agreement of axes were within the 0.02-Å uncertainty. However, for $Pt(CH_3NH_2)_4PtBr_4$ our $a:b:c$ axes were 0.16, 0.15 and 0.13 Å larger than Miller's. It should be noted that Miller's values would place $Pt(CH_3NH_2)_4PtBr_4$ unexpectedly in a smaller cell than $Pt(CH_3NH_2)_4PdBr_4$ and would give $Pt(CH_3NH_2)_4PtBr_4$ an unexpectedly smaller *c*-axis than $Pt(NH_3)_4PtBr_4$.

Since no information was available for the triclinic structure of any ethylenediamine compound, a full X-ray diffraction structure determination was attempted for $Pt(en)_2PdCl_4$. Intensity data were collected for 2659 reflections in the four octants hkl, $\bar{h}k\bar{l}$, $\bar{h}kl$ and $h\bar{k}l$. Mo-K_α radiation with a wavelength of 0.70964 Å was utilized. A scintillation counter scanned the peaks in a series of 0.01° steps in ω. The intensities of a set of three standard reflections were measured after each accumulation of intensities for 75 reflections.

From 20 independent reflections with $24° < 2\theta < 40°$ the lattice parameters were determined by the program LATT.[18] The final cell parameters were: $a:b:c = 11.711(7):8.480(6):6.801(2)$ Å, $\alpha:\beta:\gamma = 96.10(4):91.08(4):106.74(8)°$; $V = 642.3(2)$ Å^3. A total of 1244 independent reflections were observed with intensities greater than the limit for statistical significance, viz. $|F_o| > 3\sigma(F_o)$. Data were corrected for both absorption and Lorentz polarization. For all but 20 very weak reflec-

tions $h+k+l$ were even. Thus, although the data indicated a P lattice ($Z = 2$) apparently the heavy atoms, Pt and Pd, were very close to body-centered, I, positions. With the heavy atoms, which dominate the X-ray scattering, in I positions, it appeared expedient to conduct the preliminary refinements in $I\bar{1}$. An initial Patterson map in $I\bar{1}$ clearly indicated the Cl positions. These positions, introduced into the program FOUR,[19] generated an electron density map by a least-squares fitting of the observed and calculated structure factors. The structure refinement was developed stepwise with the Pt and Pd in the fixed positions, initially by block diagonals and finally with full-matrix anisotropic temperature factors for the Pt, Pd, Cl and N atoms in the structure. However, convergence could not be attained with anisotropic temperature factors for the C atoms and isotropic factors were utilized to give R and R_w values of 0.126 and 0.147, respectively.

The positions of the Pt, Pd, Cl and N atoms at this point are included in Table 2, and important interatomic distances and angles are in Table 3. It is to be noted that the Pd—Cl bonds of 2.316(8) and 2.319(8) Å, the Pt—N bonds of 2.04(2) and 2.08(3) Å, and the Cl—Pd—Cl angle of 89.5(3)° meet very reasonable expectations. However, the indicated C—C distance at this stage was 1.43 Å, unreasonably low for a single-bond distance.

A number of refinement procedures to improve the structure were attempted. The introduction of disorder represented by a partial exchange of Pt and Pd atoms did not improve the refinement, and changes in the occupancy factors were toward the nondisordered occupancy. The partial occupancy of two sites for the C atoms, individually as well as together, were tested. The value of R could be reduced only to 0.125 and reasonable C—C bond lengths were still not attained. When the space group $P\bar{1}$ was tried, convergence in the refinement of the metal atom positions was not attained. In addition, improvement by refinement in $P1$, $I1$ starting with the $I\bar{1}$ positions could not be achieved.

Table 2. Indicated atom positions from the partial X-ray diffraction structure of $Pt(en)_2PdCl_4$ refined under $I\bar{1}$

Atom	x	y	z
Pt	0	0	0
Pd	0.5000	0.5000	0
Cl1	0.5238(8)	0.783(1)	0.024(1)
Cl2	0.7054(7)	0.554(1)	0.002(1)
N1	0.007(3)	0.245(3)	0.015(5)
N2	0.818(3)	−0.028(3)	−0.007(5)

Table 3. Some distances and angles in $Pt(en)_2PdCl_4$

Atoms	Distance (Å)	Atoms	Angle (°)
Pt—Pd	3.400(5)	Cl1—Pd—Cl2	89.5(3)
Pd—Cl1	2.319(8)	N1—Pt—N2	81.5(11)
Pd—Cl2	2.316(8)	Cl1—Pd—Pt	87.6(2)
Pt—N1	2.04(2)	Cl2—Pd—Pt	87.9(2)
Pt—N2	2.08(3)	N1—Pt—Pd	86.6(10)
		N2—Pt—Pd	89.4(9)

With these unsatisfactory results the structure determination was abandoned.

It is believed that the positions of Pt, Pd, Cl and N atoms in the crystal are rather accurately established. Apparently, there is disorder in the C positions that is not characterized by X-ray diffraction because of the dominant scattering by the much heavier metal atoms. However, the orientations established for the Pt—N and the Pd—Cl bond are important in identifying some of the electronic transitions in the crystal spectra (see below).

Spectroscopic methods

The procedures we have used for recording polarized crystal spectra at temperatures down to 6 K have been described previously.[20,21]

The crystals were mounted over small holes in a Pt foil. The dimensions of the hole were such that the crystal completely covered the hole so no light which did not pass through the crystal was transmitted. The holes were made by denting the sheet and then abrading the surface with fine emery paper. A sheet might be dented 20 times in order to make a single hole. A fine-point sewing needle was used to make indentations for round holes which could be made as small as 20 μm. However, since many of the crystals were long needles, it was frequently advantageous to use the edge of a new razor blade to make the indentations which would form slits. These slits covered by the crystal could be aligned with the image of the slit in the spectrophotometer sample compartment to provide much greater transmitted light than a round hole.

Generally, from 6 to 10 crystal spectra were measured for each Magnus-type salt; and all of the tabulated bands in the spectra were observed in at least two crystals. It was important to use crystals of widely different thicknesses since weak features would be masked by variations in the base lines for very thin crystals, and more intense bands would not provide sufficient transmitted light in thick crys-

tals. The thickness of at least one crystal for each salt was measured by observing a crystal edge under a microscope equipped with a calibrated reticle. Variations in crystal thickness as well as difficulties in focus limited the uncertainty of such measurements to not less than 20%. For MGS itself, several crystals were found which possessed sufficiently good optical faces that well developed interference waves were developed in the absorbance vs wavelength recording because of multiple internal reflections of the light beam. The thickness of crystals in our previous study[8] of MGS utilized these waves to estimate crystal thickness and indices of refraction. In a subsequent paper[16] it was shown that neglect of dispersion will introduce considerable error into the calculations of crystal thickness and index of refraction. The technique of this latter paper was utilized to calculate the crystal thickness of an MGS crystal which was 4.16(8) μm thick. The indicated index of refraction for a-polarized light was $n_{a\text{-Na-D}} = 1.85$ and $1/n_a(\mathrm{d}n_a/\mathrm{d}\bar{\nu}) = 2.6 \times 10^{-6}$ cm. This compares with the value 1.90 reported earlier and was consistent with the observation that n_a was substantially less than the index of 1.93 for a calibration liquid.

The low-temperature spectra provided better resolution of electronic bands than the room-temperature ones. Even so, it was sometimes found useful to resolve Gaussian components by the damped least-squares procedure of Paponsek and Pliva.[22]

RESULTS AND DISCUSSION

A review of the spectra and excited states of the Pt(II) and Pd(II) square-planar tetrahalide complexes is appropriate since the spectra of the Magnus-type salts have frequently been considered to be just those of the anions perturbed by the close cation neighbors in the solid state. For this discussion we are utilizing the molecular-orbital energy scheme illustrated in Fig. 1. For the "strong-field" d^8-complexes in D_{4h}-symmetry, the lowest unoccupied molecular orbital (LUMO) is the antibonding b_{1g}^*-orbital derived essentially from the $d_{x^2-y^2}$- and the ligand σ-orbitals. All electrons are paired so a ground state of $^1A_{1g}$ is indicated. Our present assignments for the transitions of the four anions are given in the first columns of Tables 4–7. They have been inferred from solution spectra as well as single-crystal spectra of the potassium salts where the distance between the metal atoms along a tetragonal axis is greater than 4.1 Å.[15,23,24]

According to the orbital-energy diagram, the low-energy transitions should be the relatively low-intensity, electric dipole forbidden $d \rightarrow d$ tran-

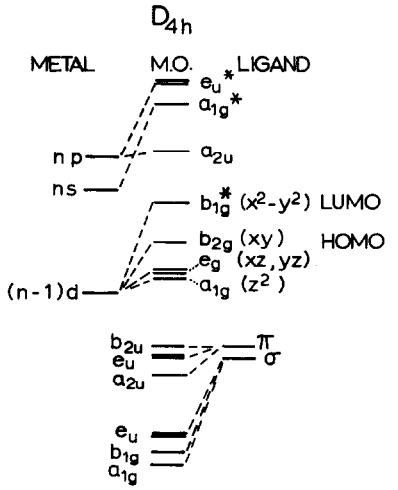

Fig. 1. Ordering of molecular-orbital energies for d^8-ions in D_{4h}-symmetry. The gerade ligand π-orbitals have been omitted for clarity.

sitions, which "borrow" intensity from higher allowed transitions by vibronic perturbations. The lowest electronic transition in this case would be a spin-forbidden singlet–triplet transition which attains intensity as a consequence of spin–orbit coupling in addition to the vibronic perturbations. At higher energies a series of electric dipole allowed transitions can occur due to excited $^1A_{2u}$-states, which will yield z-polarized transitions, and ^1E_u-states, which will give the x,y polarized transitions. Allowed $^1A_{2u}$- and ^1E_u-states can arise from the halide ligand to metal charge transfer (LMCT) $L\pi \rightarrow d^*_{x^2-y^2}$ transitions. At a somewhat higher energy will be another degenerate pair of LMCT $L\sigma \rightarrow d^*_{x^2-y^2}$ transitions to ^1E_u-states. In addition, possible electric dipole allowed $d \rightarrow p$ transitions may be spectroscopically accessible, viz. states $^1A_{2u}$, $nd_{z^2} \rightarrow (n+1)p_z$ and ^1E_u, $nd_{xz,yz} \rightarrow (n+1)p_z$.

There is a striking difference between the intense dipole-allowed transitions of the Pt and Pd complexes. In aqueous solution $PdCl_4^{2-}$ shows two intense bands at 37,400 cm^{-1} (ε = 9300 cm^{-1} M^{-1}) and 45,000 cm^{-1} (ε = 25,800 cm^{-1} M^{-1}).[16] Polarized crystal spectra of K_2PdCl_4 show that both of these bands must be largely x,y-polarized. There is a much weaker peak at 37,400 cm^{-1} in z-polarization. The temperature dependence of the intensity for this weaker peak indicates that it is electric dipole allowed despite its lower intensity. The z-polarized absorption could be followed to 44,000 cm^{-1}, and there was no indication of a peak in the vicinity of 45,000–46,000 cm^{-1} for it. These results justify the assignment of absorption at *ca* 37,500 cm^{-1} to the L-πMCT transitions and the 45,000-cm^{-1} absorption to L-σMCT. Jorgensen[25] indicated that mixing

of the σ- and π-orbital states would greatly enhance the ^1E_u, x,y absorption at 37,500 cm^{-1}. For the $^1A_{2u}$ transition with the electron-orbital designation of $b_{2u} \rightarrow b_{1g}^*$ there is no mixing possible for the σ- and π-orbitals; and, in z-polarization, the transition must be pure L-πMCT.

The spectra for the $PdBr_4^{2-}$ ion support this assignment as well. The LMCT transitions are expected to occur at a lower energy than for the corresponding chloride complexes. Thus an intense x,y-polarized band at 30,700 cm^{-1} corresponds to the L-πMCT, ^1E_u transition; and a still stronger band at 40,400 cm^{-1} corresponds to the L-σMCT, ^1E_u transition. A much weaker electric dipole allowed band in z-polarization at 30,900 cm^{-1} is the L-πMCT, $^1A_{2u}$ transition. There is no z-polarized band near 40,000 cm^{-1}.

In contrast to the Pd complexes there is a very intense peak at 46,000 cm^{-1} in $PtCl_4^{2-}$ with a weaker shoulder at 43,000 cm^{-1}. Polarized-reflectance spectra by Anex and Takeuchi[26] showed that in this region the z-polarized band was more intense than the x,y-polarized absorption. This difference between the Pt and Pd complexes has been attributed to $d \rightarrow p_z$ transitions in this region for the platinum. Recently Isci and Mason[27] have observed A-terms in the magnetic circular dichroism (MCD) spectra of $PtCl_4^{2-}$ in this region, which indicate the presence of two ^1E_u-transitions so that they believe that the L-πMCT as well as the $d \rightarrow p_z$ transitions are in the vicinity of 43,000–46,000 cm^{-1}. The presence of the L-πMCT transition is also supported by the spectra of $PtBr_4^{2-}$ where an intense x,y-polarized band is seen at the lower energy of 37,000 cm^{-1}, where there is only a weak absorption in z-polarization.

Three of the four spin-allowed d–d transitions can be assigned unambiguously for all four of the anions. The transition to the $^1A_{2g}$-state $d_{xy} \rightarrow \sigma^*(d_{x^2-y^2})$ is predicted from consideration of all the molecular vibrations of the square-planar MX_4^{2-} ion to be forbidden in z-polarization. This selection rule is apparently exact since a pure x,y band is observed in each complex (it is at 26,400 cm^{-1} for $PtCl_4^{2-}$).[20] In addition, the ^1E_g [$d_{xz,yz} \rightarrow \sigma^*(d_{x^2-y^2})$] states have been identified in aqueous solution by an A-term in the MCD spectra.[28,29] In $PtCl_4^{2-}$ this ^1E_g-states can be associated with the peak at 30,300 cm^{-1} (aqueous), 29,200-z, 29,800-xy (15-K crystal).

Although there is a consensus in the assignment of these $^1A_{2g}$ and ^1E_g d–d states, the situation is much less clear with respect to the third spin-allowed $d \rightarrow d$ state, the $^1B_{1g}$, $d_{z^2} \rightarrow \sigma^*(d_{x^2-y^2})$. For some time it was assigned to a weak shoulder at 38,000 cm^{-1} in $PtCl_4^{2-}$ solution and at 36,500 cm^{-1} in K_2PtCl_4. Such an assignment was proposed by Chatt *et al.*,[30] Jørgensen[31] and supported by semiempirical MO calculations of Basch and Gray[32] and Cotton and Harris.[33] There is a band at about 21,000 cm^{-1} seen in both c- and x,y polarizations, which although weaker than the $^1A_{2g}$- and ^1E_g-bands does have 20–30% of the intensity of these. There are much weaker features still at 17,000 and 23,000 cm^{-1} which can be logically assigned as spin-forbidden transitions; but the intensity of the 21,000-cm^{-1} band is anomalous. Martin and Lenhardt[34] suggested that the $^1B_{1g}$-state might be associated with the 21,000-cm^{-1} band. However, a ligand field calculation,[35] which included spin–orbit coupling and the electron–electron repulsion Slater–Condon parameters F_2 and F_4, which were considered reasonable at the time, indicated the $^3B_{1g}$-states would fall in the region of 14,000 cm^{-1} where there was no detectable absorption. However, two sets of seemingly satisfactory parameters were obtained which placed calculated $d \rightarrow d$ transitions at observed band energies in the spectra. One set placed the $^1B_{1g}$-state of 35,300 cm^{-1} whereas the alternative placed it at 29,700 cm^{-1}, in close proximity to the ^1E_g-band and impossible to resolve from it. Elding and Olsson[36] indicated that the shift in the 35,500-cm^{-1} band, as Cl^- ligands were replaced by H_2O, was different from $d \rightarrow d$ transitions and favored placing the $^1B_{1g}$-band at about 29,700 cm^{-1}. Tuszynski and Gliemann,[37] on the other hand, have performed ligand field calculations which placed the $^1B_{1g}$ back at the 21,000-cm^{-1} anomalous-intensity peak of $PtCl_4^{2-}$. For this computation they used considerably smaller electron–electron repulsion parameters than have usually been applied to transition-metal complexes. Hence, the spin-forbidden $^3B_{1g}$-transitions were placed no lower than 17,000 cm^{-1}.

A very similar situation occurs for the d–d transitions of $PtBr_4^{2-}$. The $^1A_{2g}$- and ^1E_g-transitions are indicated unambiguously, and there is an anomalous-intensity band at lower energies.[15] For the $PdCl_4^{2-}$ and $PdBr_4^{2-}$ ions again the $^1A_{2g}$- and ^1E_g-transitions are identifiable.[16,38] These states have a much smaller separation than in the Pt anions so the peaks are not separable in x,y-polarization. Spin-forbidden transitions are much weaker with the lighter Pd atom. Such very weak transitions were observed below the $^1A_{2g}$- and ^1E_g-transitions. There is no third, anomalous-intensity band so the $^1B_{1g}$-band must either lie too close to the $^1A_{2g}$- and ^1E_g-bands to be resolved from them or else must be at a considerably higher energy. In the latter case for K_2PdCl_4 the $^1B_{1g}$-band would have to lie at least 8000 cm^{-1} above the $^1A_{2g}$-band and would fall under the tail of the L-πMCT band.

The spectrum of the colorless $[Pt(NH_3)_4]^{2+}$ ion in aqueous solution is available from the work of Isci and Mason.[39] They assigned a broad maximum at 35,000 cm^{-1} ($\varepsilon = 40$ cm^{-1} M^{-1}) to the $^3A_{2g}$- and ^3E_g-states; and an intense peak ($\varepsilon = 10{,}000$ cm^{-1} M^{-1} at 50,950 cm^{-1}) was assigned as the $d \rightarrow p$ transitions. Very weakly defined shoulders on this intense band at 41,000 and 45,000 cm^{-1} were then assigned as $^1A_{1g} \rightarrow {}^1A_{2g}$ ($d_{xy} \rightarrow d^*_{x^2-y^2}$), ^1E_g ($d_{xz,yz} \rightarrow d^*_{x^2-y^2}$) and $^1A_{1g} \rightarrow {}^1B_{1g}$ ($d_{z^2} \rightarrow d^*_{x^2-y^2}$), respectively. Thus, the transitions all have much higher energies then the corresponding ones in the anions. As a consequence simple halide salts of this cation are colorless.

The single-crystal absorption spectra for all the Magnus salts studied are shown in Figs 2–24. Some comments about the site symmetries are relevant before a consideration of the spectra. The anions for the tetraamine and the tetra(methylamine) salts are in tetragonal sites, and the spectra are measured for a $h,k,0$ face. The c-polarization for such faces gives an explicit molecular z-polarization and the polarization normal to c gives an accurate molecular x,y polarization for a degenerate pair of transitions that have been labelled in the figures.

The partially determined structure determination for the $Pt(en)_2PdCl_4$ can serve to assign polarizations for the group of salts with ethylenediamine complexes. From the atom positions and bond angles of $Pt(en)_2PdCl_4$ in Tables 2 and 3 the following inferences may be drawn. The $PdCl_4^{2-}$ ion is very nearly square-planar ion with D_{4h}-symmetry. In $[Pt(en)_2]^{2+}$, the PtN_4 grouping of atoms must be nearly planar, exactly so if there is a $\bar{1}$-symmetry. The angles between the Pt—N bonds in the chelate ring however are only 81.5° so the PtN_4 grouping must be considered to have approximately D_{2h}-symmetry. The ions stack along the c-axis, and it is apparent from the Pt—Pd—Cl and the Pd—Pt—N angles that the normals to the planar groups are within about 3° of the c-axis. The crystals were needles with the c-axis as the needle axis. The needle axes for all the ethylenediamine salts were invariably observed as a polarization (extinction) direction for one of the two waves transmitted by the indicated $h,k,0$ face, although this is not required by crystallographic symmetry for triclinic systems. The two polarizations directions have been labeled as molecular z-polarization for the c-polarization and $\perp z$ polarization for the normal-to-c polarization. We have used this designation rather than x,y polarization since a nearly D_{4h} $PtBr_4^{2-}$ in $K_2PtBr_4 \cdot 2H_2O$ exhibited absorptions differing by a factor of 2 normal to its z-axis in an orthorhombic crystal.[40]

The arrangement of the bonds in the counter cations also need to be considered because of their influence on some possible interionic electron transfer transitions. For MGS itself which is the one tetragonal salt with a complete crystal structure[4] the Pt—N and Pt—Cl bonds can be considered as partially staggered since the $[Pt(NH_3)]^{2+}$ is rotated by 28° about the c-axis from an eclipsed configuration with the $PtCl_4^{2-}$. Both ions occupy a $4/m$ site. From our partial determination of $Pt(en)_2PdCl_4$ the bisector of the N—Pt—N angle in the cation is within 1.7° of being parallel to the bisector of the Cl—Pd—Cl bond angle in the anion. Hence, the ions can be considered as eclipsed as is possible with very approximately mmm (D_{2h}) symmetry.

MGS

Day[13] has maintained that the color and transitions in the visible region of MGS can be explained by the shift of $d \rightarrow d$ transitions of the anions due to the close proximity of the neighboring cations. The d_{xy} and the $d_{x^2-y^2}$ metal orbitals which are concentrated in the plane of the ion are presumably influenced least by the presence of neighbors, and the transition to an $^1A_{2g}$-state, d_{xy} (b_{2g}) $\rightarrow d^*_{x^2-y^2}$ (b_{1g}), is expected to be shifted very little. However, the $d_{xz,yz}$ (e_g) orbitals which place more electron density out of the plane are expected to be influenced more. Repulsions between the $d_{xz,yz}$-electrons and the electrons of the cation are expected to raise the energy of $d_{xz,yz}$-electrons and result in a red shift of the ^1E_g-transition. The transition to the $^1B_{1g}$-state ($d_{z^2} \rightarrow d^*_{x^2-y^2}$) should be red-shifted an even greater amount because of the high electron density placed along the z-axis.

The $^1A_{2g}$-band, which is forbidden in z-polarization, is clearly evident in the potassium salts of the four anions, which also possess a vibrational structure, exhibiting a long Franck–Condon progression. This transition can usually be identified in the Magnus-type salts from its polarization, and in a number of cases a vibrational structure is resolvable as well.

Crystal spectra for $Pt(NH_3)_4PtCl_4$. considerably superior to any recorded previously, are shown in Fig. 2. For x,y polarization there is only a single broad $d \rightarrow d$ band at *ca* 24,800 cm^{-1}, whereas K_2PtCl_4 has two bands at 26,400 and 30,300 cm^{-1}. The very narrow peak at 31,800 cm^{-1} is unlike any d–d transition observed previously for Pt(II) salts and will be discussed later. Hence, it is concluded that the ^1E_g-band, placed by consensus at *ca* 30,000 cm^{-1} in K_2PtCl_4, has been red-shifted by about 5500 cm^{-1} to about 25,300 cm^{-1} in MGS. A faint vibrational structure with maximum amplitude at

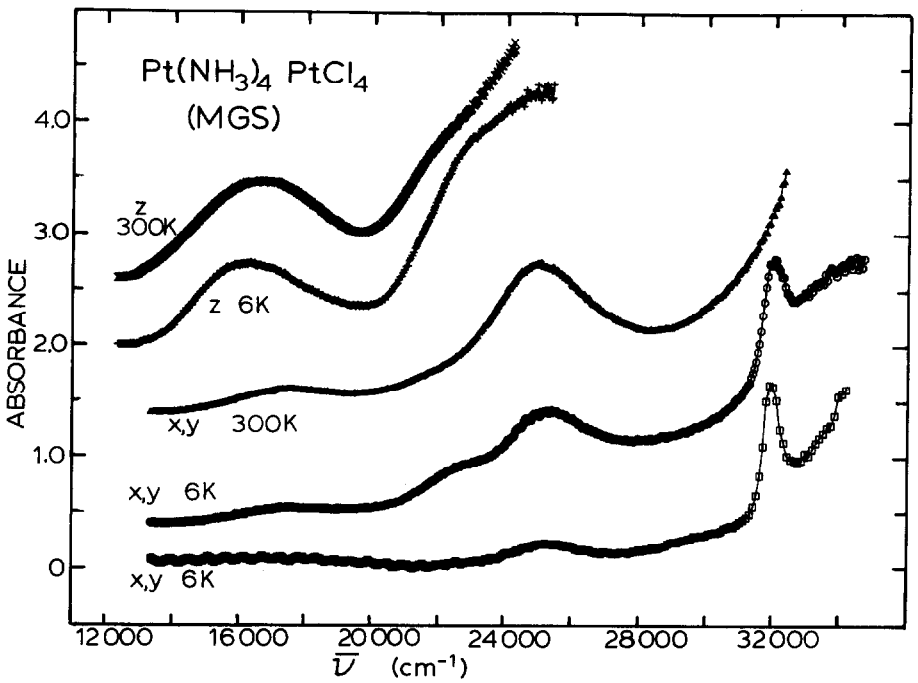

Fig. 2. Polarized single-crystal spectra for $Pt(NH_3)_4PtCl_4$ (MGS). The upper four spectra are for a 12.3-μm-thick crystal. The lowest curve is for a 4-μm-thick crystal.

24,900 cm^{-1} is evident in the 6 K–x,y spectrum of the 12.3-μm crystal in Fig. 2, indicating the presence of the $^1A_{2g}$-band which has been shifted by only 1500 cm^{-1} from K_2PtCl_4. In x,y polarization MGS appears yellow in color. The green color results from the z- or c-polarization of the crystals where there is a low-absorption "window" in the spectrum in the vicinity of 20,000 cm^{-1}. The specular-reflectance spectra[10,11] indicate an intense absorption peak at 35,000 cm^{-1}, some 10,000 cm^{-1} below the highest peak in $PtCl_4^{2-}$ solutions. Although a peak in the vicinity of 25,000 cm^{-1} in z-polarization was at one time reported,[6,7] it has been shown[8] that this was a consequence of either a finite elipticity of the polarizer or depolarization at the surface of the crystal; and the absorption rises rapidly in the vicinity of 25,000 cm^{-1}. However, the low-energy transitions apparently "borrow" z-intensity from the intense band at 35,000 cm^{-1}, and absorption in the vicinity of a maximum at 16,000 cm^{-1} is at least an order of magnitude greater than in the x,y polarization. The peak at 16,000 cm^{-1} is presumably the peak at 21,000 cm^{-1} in K_2PtCl_4 which has been red-shifted by the proximity of the neighboring ions. Since this red shift is only 5000 cm^{-1} and no greater than the shift of the ^1E_g-band, we have concluded that the 21,000-cm^{-1} anomalous-intensity band in K_2PtCl_4 is not the $^1B_{1g}$ ($d_{z^2} \rightarrow d^*_{x^2-y^2}$) band, and must therefore be assigned to spin-forbidden transitions. Such bands become allowed by virtue of spin–orbit coupling, which mix in spin-allowed transitions; their symmetry must be treated by the double rotational group D_4'. Probably, most intensity will be in transition to A_2'-, B_2'- and E_1'-states since the $^1A_{2g}$, $^1B_{1g}$ and ^1E_g wave functions, respectively, are basis functions for these double-group irreducible representations. The assignment of the three resolvable spin-forbidden bands of K_2PtCl_4 to the double groups, based on the ligand field parameter B in ref. 35 are included in Table 4. It is noted that all of the bands contain contributions for transitions from all four orbitals, d_{xy}, d_{xz}, d_{yz} and d_{z^2} so a red shift no greater than that of the ^1E_g-band is reasonable. We are therefore placing the $^1B_{1g}$-transition in the 30,000-cm^{-1} band at $PtCl_4^{2-}$ where it is not resolvable from the ^1E_g-transition. In MGS we assign it to the fairly weak feature, a shoulder at 23,500 cm^{-1}. In this case its red shift is 6500 cm^{-1}, significantly greater than for the $^1B_{1g}$-band. Moncuit[41] has reported a theoretical treatment of the intensities of vibronically allowed d–d transitions of $PtCl_4^{2-}$. His calculations predict that, although the $^1B_{1g}$-band is vibronically allowed in both polarizations, the $z:x,y$ oscillator strength ratio at 0 K is nearly 40 and the x,y oscillator strength of the $^1B_{1g}$-transition is 0.12 times that for the $^1A_{2g}$-transition and 0.08 times that for the x,y-component of the ^1E_g-transition. Hence, this assignment of the relatively weak 23,500-cm^{-1} component appears to be quite consistent with these computations.

A new feature in the MGS spectra of the present

work is the remarkably sharp, narrow band seen at 31,800 cm^{-1} in the 6K–x,y-spectra of Fig. 2. The improved crystal specimens and techniques permitted the observation of this band. In previous reports of this spectrum for MGS the scans were terminated on the rapidly rising portion of this band. The narrow width of this band, not over 200 cm^{-1} at half-height, is unlike any of the other d–d bands in which an electron is excited into the $d^*_{x^2-y^2}$-orbital, and which have half-widths of the order of 2000 cm^{-1}. Even so, the measurements are unquestionably subject to instrumental limitations. For example, this peak for the 4-μm-thick crystal in Fig. 2 with the better resolution appears as high or higher than that for the 12.3-μm crystal. (The waves in the low-absorption region of the 4-μm crystal are due to interference from the multiple reflections in the optical faces of the crystal.) In Fig. 3, scans of this peak at a series of temperatures show that the peak height increases as the peak narrows with lower temperatures and the integrated intensity is relatively temperature independent. This is in contrast to the vibronically allowed bands and indicates that the transition is effectively electric dipole allowed, although it has a relatively low transition moment. An unusual feature is the shift of the peak to longer wavelengths as the crystal is cooled. This is in contrast to most sharp electronic bands in crystal spectra where the shift is to shorter wavelengths as thermal excitation of phonon states are reduced at lower temperature. Since there appears to be no logical molecular transition for this band, we are proposing an anion → cation (A → C) electron transfer. Since all the indicated transitions to the $d^*_{x^2-y^2}$ (σ-antibonding) orbitals are broad, we suggest that this transition must be to an orbital not involved in the σ-bonding. The most reasonable orbital would seem to be the $(p_z)_C$ orbital. A $(d_{xz,yz})_A \rightarrow (p_z)_C$ electron transfer would be dipole-allowed for x,y polarization. The intensity would depend upon the overlap of the cation and anion orbitals which, of course, is not high. It is not possible to predict the energy of such a transition since it would depend upon the ionization energy of the anion, the electron affinity of the cation and the lattice energy changes induced by replacing doubly charged ions by a pair of singly charged ions. The $(p_z)_C$ orbital has a suitable σ-symmetry for forming a bond to adjacent $(d_{z^2})_A$ orbitals and in solid-state parlance would be considered to form a pair of one-dimensional bands. The observed transition would then be a band-to-band transition. However, the energy separation of the bands, indicated by the transition wave numbers together with the narrowness of the optical bands preclude any significant bonding between the ions.

An examination of the spectra of other $PtCl_4^{2-}$ salts shows that similar sharp peaks are clearly evident in the salts with Pt cations. In $Pt(CH_3NH_2)_4PtCl_4$ with nearly the same Pt—Pt distance as MGS the peak is at 31,800 cm^{-1} as well, whereas for $Pt(en)_2PtCl_4$ with significantly higher

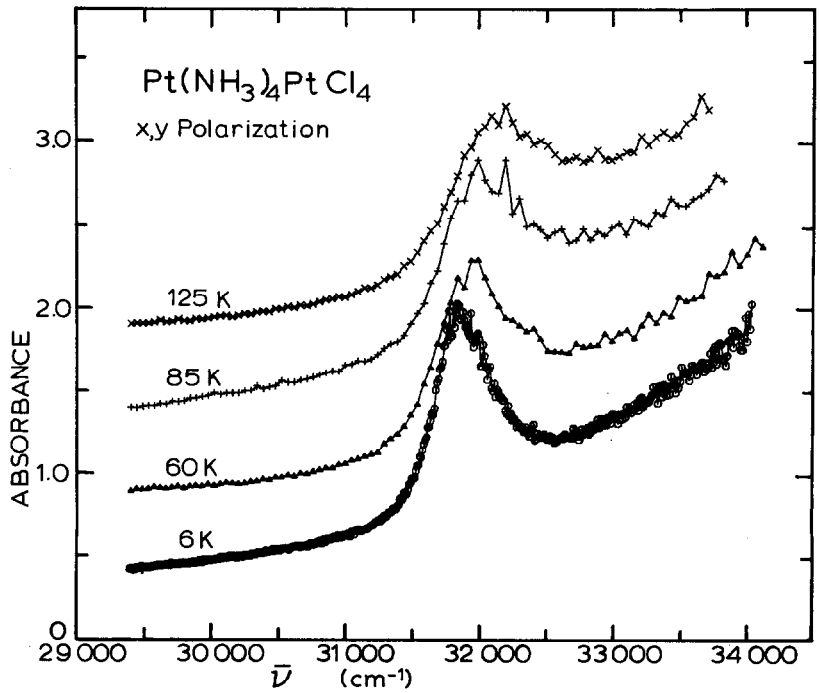

Fig. 3. Temperature dependence of the narrow high-energy band in the 4-μm MGS crystal of Fig. 2 for x,y polarization.

Pt—Pt distances the band is at higher energy (33,600 cm^{-1}). There was no evidence for such a narrow band in the $PtCl_4^{2-}$ with Pd cations. However, the 6-K scans could only be extended to 31,700 cm^{-1} for the $[Pd(en)_2]^{2+}$ compound and to 32,500 cm^{-1} for the $[Pd(NH_3)_4]^{2+}$ compound.

The foregoing information now provides some insights into the assignment of the intense absorption maximum at 35,000 cm^{-1} in z-polarization in MGS. Day[13] attributed this to the $d_{z^2} \rightarrow p_z$ transition in $PtCl_4^{2-}$ which had been shifted to a lower energy by 10,000 cm^{-1}. In the treatment of absorption in crystals as Frenkel excitons, energy shifts are predicted as a consequence of the interactions of transition dipoles which will therefore by intensity-dependent.[42] As Day showed with rather widely separated one-dimensional chains extending in the z-direction, a z-polarized transition is shifted to lower energies and x,y-polarized bands are shifted to high energies by one half as much. The shifts are proportional to the transition moments squared and to a first approximation inversely proportional to the cube of the separation of the moments. According to the theory, the shift for a z-directed 1.0 e Å transition moment with 6.48 Å separation of the moments in a one-dimensional chain is less than 2000 cm^{-1}, much less than the required 10,000 cm^{-1}. In addition, in our spectra for $Pt(CH_3NH_2)_4PdBr_4$ (Fig. 20) a truncated very intense band is seen that must have a maximum at about 28,000 cm^{-1}. This is assigned as the intense L-$\pi \rightarrow$ M charge-transfer band that occurs at about the same energy (30,200 cm^{-1}) in $PdBr_4^{2-}$ solutions. Hence, no significant blue shift of this intense band has occurred in this Magnus-type salt with 3.35-Å spacing between the oppositely charged ions. Therefore, we believe that the 35,000-cm^{-1} band of MGS cannot be the simple molecular $d_{z^2} \rightarrow p_z$ transition.

If the $n-d_{z^2}$ orbital on the anion metal atom is destabilized by the repulsions with the cation electrons, then the $(n+1)p_z$ orbital must be destabilized to an even greater extent. It is our contention that such orbital destabilizations take the transitions involving the anion p_z-orbitals out of the spectroscopic region and to such a high energy that it cannot participate in significant interionic bonding. We therefore prefer to assign this 35,000-cm^{-1} transition to the $(d_{z^2})_A \rightarrow (p_z)_C$ interionic electron transition. If one considers only a linear system of two cation metal atoms about an anion metal there will be a $\Sigma_g^+ \rightarrow \Sigma_u^+$ transition which will be polarized in the z-direction. This is an equivalent interionic transition, except that it involves a d_{z^2}-electron rather than a $d_{xz,yz}$-electron, to the one we assigned to the 31,800-cm^{-1} band in x,y polarization, consistent with our conclusion that the d_{z^2}-orbital lies close in energy to the d_{xz}- and d_{yz}-orbitals. The major problem then is the explanation for the striking difference in intensities in these similar types of transition since the one with polarization in the stacking direction is so much stronger.

For treating the intensities, a one-dimensional array of alternating anion and cation metal atoms will be considered along the z-axis. There are a total of N cells, each contain one anion at $z = \frac{1}{4}$ and one cation at $z = \frac{3}{4}$ in the array. With the usual neglect of end effects, orthogonal and normalized wave functions for the one-dimensional bands will have the form:

$$\psi_{1,n} = (1/\sqrt{N}) \sum_j e^{2\pi inj/N} d_{z^2,A,j}, \quad (1)$$

$$\psi_{2,m} = (1/\sqrt{N}) \sum_j e^{2\pi imj/N} p_{z,C,j}, \quad (2)$$

$$\psi_{3,l} = (1/\sqrt{N}) \sum_j e^{2\pi ilj/N} d_{xz,A,j}, \quad (3)$$

where $1 \leqslant j \leqslant N$ is the index of the cell in the chain, and l, m, n are the quantum numbers 0, 1, ... $N-1$ for the states in the band. Since the d_{z^2}- and p_z-orbitals each have σ-symmetry with respect to the z-axis there may be some interaction between the $\psi_{1,n}$ and $\psi_{2,m}$ wave functions. Only an overlap between adjacent anions and cations will be significant. For a one-electron treatment the matrix elements will be:

$$H_{1,n;1,n} = \langle d_{z^2,A,j}|H|d_{z^2,A,j}\rangle, \quad (4)$$

$$H_{2,m;2,m} = \langle p_{z,C,j}|H|p_{z,C,j}\rangle, \quad (5)$$

$$H_{1,n;2,m} = \frac{1}{N}\sum_j \{e^{2\pi i(m-n)j/N}\langle d_{z^2,A,j}|H|p_{z,C,j}\rangle + e^{-2\pi nj/N} e^{2\pi im(j-1)/N}\langle d_{z^2,A,j}|H|p_{z,C,j-1}\rangle\}. \quad (6)$$

Equation (6) can be rewritten as:

$$H_{1,n;2,m} = \frac{1}{N}\sum e^{2\pi i(m-n)j/N}\{d_{z^2,A,j}|H|p_{z,C,j}\rangle + e^{-2\pi im/N}\langle d_{z^2,A,j}|H|p_{z,C,j-1}\rangle\}. \quad (7)$$

The sum is zero unless $m = n$, and the problem therefore reduces to a set of $N2 \times 2$ secular equations. In addition, since:

$$\langle d_{z^2,A,j}|H|p_{z,C,j}\rangle = -\langle d_{z^2,A,j}|H|p_{z,C,j-1}\rangle, \quad (8)$$

the matrix elements can be reduced to:

$$H_{1,n;2,n} = \langle d_{z^2,A,j}|H|p_{z,C,j}\rangle(1-e^{-2\pi in/N}). \quad (9)$$

The roots of these secular equations will give a band of states, filled with electron pairs below $\langle d_{z^2,A,j}|H|d_{z^2,A,j}\rangle$, and an empty band above $\langle p_{z,C,j}|H|p_{z,C,j}\rangle$. If the interaction integral in equation (9) is small, the bands will be narrow; and a

wave function with neglect of overlap can be written for the filled- and empty-band orbitals, respectively:

$$\Psi_{\mathrm{I},n} = (1-\alpha_n^2)^{1/2}\psi_{1,n} - \alpha_n\psi_{2,n} \tag{10}$$

and

$$\Psi_{\mathrm{II},n} = \alpha_n\psi_{1,n} + (1-\alpha_n^2)^{1/2}\psi_{2,n}.$$

In the present case $|\alpha_n| \ll 1$.

The z-component for a transition moment of a $\psi_{\mathrm{I},m} \rightarrow \psi_{\mathrm{II},n}$ excitation is:

$$\mu_z(m \rightarrow n) = \frac{1}{N}\Big\langle \sum_j e^{2\pi ijm/N} \times [(1-\alpha_m^2)^{1/2} d_{z^2,A,j} - \alpha_m p_{z,C,j}]|ez| \times \sum_j e^{2\pi in/N}[\alpha_n d_{z^2,A,j} + (1-\alpha_n^2)^{1/2} p_{z,C,j}]\Big\rangle. \tag{11}$$

This expression can be rewritten with the assumption of zero overlap between nonadjacent anions and/or cations:

$$\begin{aligned}\mu_z(m \rightarrow n) = \frac{e}{N}\sum_j e^{2\pi i(n-m)j/N} &\times \{(1-\alpha_m^2)^{1/2}\alpha_n\langle d_{z^2,A,j}|z|d_{z^2,A,j}\rangle \\ &- \alpha_m(1-\alpha_n^2)^{1/2}\langle p_{z,C,j}|z|p_{z,C,j}\rangle \\ &+ (1-\alpha_m^2)^{1/2}(1-\alpha_n^2)^{1/2}[\langle d_{z^2,A,j}|z|p_{z,C,j}\rangle \\ &+ e^{-2\pi in/N}\langle d_{z^2,A,j}|z|p_{z,C,j-1}\rangle] \\ &- \alpha_m\alpha_n[\langle p_{z,C,j}|z|d_{z^2,A,j}\rangle \\ &+ e^{2\pi in/N}\langle p_{z,C,j}|z|d_{z^2,A,j+1}\rangle]\}. \end{aligned} \tag{12}$$

If the z-axis origin is placed at the center of the one-dimensional stack of ions then the $|z|$ operator in equation (12) can be replaced by $|Z_j + z_j|$, where Z_j is the z-coordinate of the center of the j cell and z_j is the coordinate measured from Z_j. With this substitution in equation (12) the summation provides nonzero values only for the transitions where $n = m$. Since

$$d_{z^2,A,j}|Z_j + z_j|d_{z^2,A,j} = Z_j - c/4,$$

$$p_{z,C,j}|Z_z + z_j|p_{z,C,j} = Z_j + c/4,$$

and

$$\sum_j Z_j = 0,$$

the final expression for μ_z becomes:

$$\begin{aligned}\mu_z(n \rightarrow n) = e\{&\alpha_n(1-\alpha_n^2)^{1/2}(-c/2) \\ &+ (1-\alpha_n^2)[\langle d_{z^2,A,j}|z_j|p_{z,C,j}\rangle \\ &+ e^{-2\pi in/N}\langle d_{z^2,A,j}|z_j|p_{z,C,j-1}\rangle] \\ &- \alpha^2[\langle p_{z,C,j}|z_j|d_{z^2,A,j}\rangle \\ &+ e^{2\pi in/N}\langle p_{z,C,j}|z_j|d_{z^2,A,j+1}\rangle]\}. \end{aligned} \tag{13}$$

On the other hand the x-component of $\psi_{3,m} \rightarrow \Psi_{\mathrm{II},n}$ is:

$$\mu_x(m \rightarrow n) = \frac{1}{N}\Big\langle \sum_j e^{2\pi ijm/N} d_{xz,A,j}|e\,x| \times \sum e^{2\pi ijn/N}[\alpha_n d_{z^2} - (1-\alpha_n^2)^{1/2} p_{z,C,j}]\Big\rangle. \tag{14}$$

Again, only transitions between states with $m = n$ are allowed. This equation leads to the final expression:

$$\mu_x(n \rightarrow n) = -e\langle d_{xz,A,j}|x|p_{z,C,j}\rangle \times (1-\alpha_n^2)^{1/2}[1 + e^{-2\pi in/N}]. \tag{15}$$

This expression contains a factor dependent on overlap of the d_A- and p_C-orbitals, and a factor in square brackets which describes the variation in intensity across the band. They are expected to be of the same order of magnitude as the overlap terms for $\mu_z(n \rightarrow n)$ in equation (13). The high intensity of the z-polarized intensity then resides in the first term of expression (13) where, although α_n is small, $\alpha_n(c/2)$ is orders of magnitude greater than the integrals involving overlap. This is in essence the same argument utilized by Robin and Day,[43] who used a localized rather than a band description to account for the high intensity of transitions polarized in the stacking (z) direction for mixed-valence compounds, [Pt(II)A_2X_2][Pt(IV)A_2X_4]. In those cases square-planar Pt(II)A_2X_2 complexes stack alternately with octahedral Pt(IV)A_2X_4 complexes. Very intense z-polarized absorption occurs because of mixing of the $d_{z^2,\mathrm{II}}$, $d_{z^2,\mathrm{IV}}$ orbitals whereas dipole-allowed x,y polarization transitions have orders of magnitude lower intensity. This treatment requires that anion $p_{z,A}$-orbitals not be mixed significantly with the $(d_{z^2})_A$–$(p_z)_C$ bands since their presence would enhance the x,y-polarized transitions equally with the z-polarized transition.

One disturbing question is the sharpness of the x,y A → C transfer transition and the high absorption over a wide region in z-polarization in MGS. It is apparent that z-polarized transition "borrow" intensity from the 35,000-cm^{-1} peak and the intensity of the borrowing increases as the distance between transitions decreases. The spin-forbidden $d \rightarrow d$ transitions in the $[Pt(NH_3)_4]^{2+}$ are placed at 35,000 cm^{-1} and with some red shift as occurs in the anion may well be in the vicinity of 30,000 → 32,000 cm^{-1}. Their contribution may broaden the absorption somewhat. It may also be that the reflectance techniques are subject to saturation effects which appear to a broaden a peak so that an accurate picture of the width of the z-polarized absorption is not available.

Spectra of $PtCl_4^{2-}$ *salts*

The shifts of the $d \rightarrow d$ transitions of the other $PtCl_4^{2-}$ salts can be compared with MGS. Although the crystal in Fig. 4 for $Pt(CH_3NH_2)_4PtCl_4$ was too thin for identification of the $^1B_{1g}$-band, the $^1A_{2g}$, ^1E_g and the spin-forbidden band all lie very close to the values in MGS. However, for $Pt(en)_2PtCl_4$ in Fig. 5, the $^1A_{2g}$-band can be assigned from the well-developed vibrational structure which is a maximum on the shoulder at 24,800 cm^{-1}. The peak at 28,00 cm^{-1} is due to the ^1E_g-band that has been shifted only about 2000 cm^{-1} from K_2PtCl_4. Enhancement of intensity in z-polarization is not as great as in MGS, and a peak can be identified at 24,500 cm^{-1} which is assigned to the $^1B_{1g}$-band. Also the spin-forbidden band at 17,000 cm^{-1} has not been shifted as far as with the other two Pt cations. For the Pd salts there is much less intensity enhancement in the z-polarization. For $Pd(NH_3)_4PtCl_4$ in Fig. 6 the x,y peak at 26,000 cm^{-1} is assigned to the ^1E_g-band, and the feeble vibrational structure indicates the $^1A_{2g}$-band is at 25,300 cm^{-1}. The maximum in z-polarization occurs below that in x,y polarization so that the $^1B_{1g}$-band is placed at 25,000 cm^{-1}. For $Pd(en)_2PtCl_4$ in Fig. 7 the $^1A_{2g}$- and ^1E_g-transitions are well resolved in x,y-polarization and the $^1B_{1g}$-transition would be placed at about 26,500 cm^{-1} from the z-polarized absorption of a crystal that was only 15 μm thick. Thus the shift of the spin-allowed d–d bands are perhaps surprisingly similar with the Pt and Pd cations. Although the corresponding Pt and Pd salts give separations that are surprisingly similar, the extension of the d-orbitals in Pd are usually considered considerably less than in Pt. In contrast to the spin-allowed transitions, the shift of the band at 21,000 cm^{-1} in K_2PtCl_4 which we are assigning as spin-forbidden is shifted much less with the Pd cations and appears at 19,600 cm^{-1}.

Spectra for the $PtBr_4^{2-}$ *salts*

The metal–metal separations range from 0.07–0.14 Å higher for the $PtBr_4^{2-}$ salts than with $PtCl_4^{2-}$. For the d–d transitions there is generally a similar but small red shift of the transition energies from K_2PtBr_4 through the salt series. $Pt(NH_3)_4PdBr_4$ in Fig. 8 shows a merged $^1A_{2g}$, ^1E_g peak which requires only a 3300-cm^{-1} shift of the ^1E_g-band from K_2PtBr_4 compared to 4700 cm^{-1} for the Pt–Cl system. The $^1B_{1g}$-band is evident from the z-polarized band. The $Pt(CH_3NH_2)_4PtBr_4$ spectra in Fig. 9 are for a very small thin crystal, and distinct base-line problems are evident. For $Pt(en)_2PtBr_4$ in Fig. 10 there is very little shift of the ^1E_g-band but the z-polarization indicates a distinct shift of 3300 cm^{-1} for the $^1B_{1g}$-band. The spin-forbidden peaks of the $PtBr_4^{2-}$ salts with Pt cations are at very nearly the same wavenumber as for $PtCl_4^{2-}$ which implies

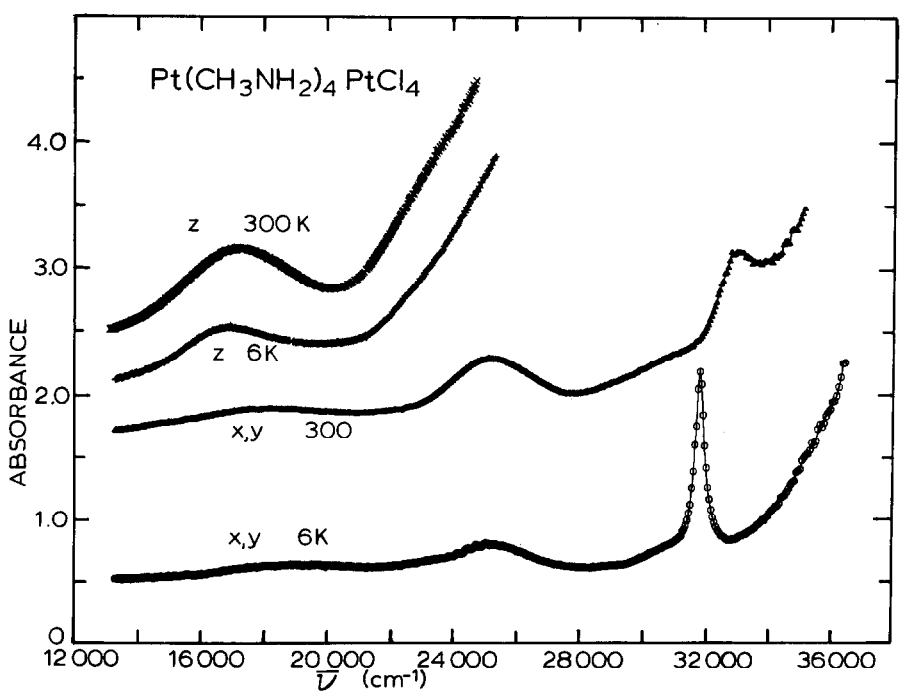

Fig. 4. Polarized spectra for $Pt(CH_3NH_2)_4PtCl_4$ crystal, 6 μm thick.

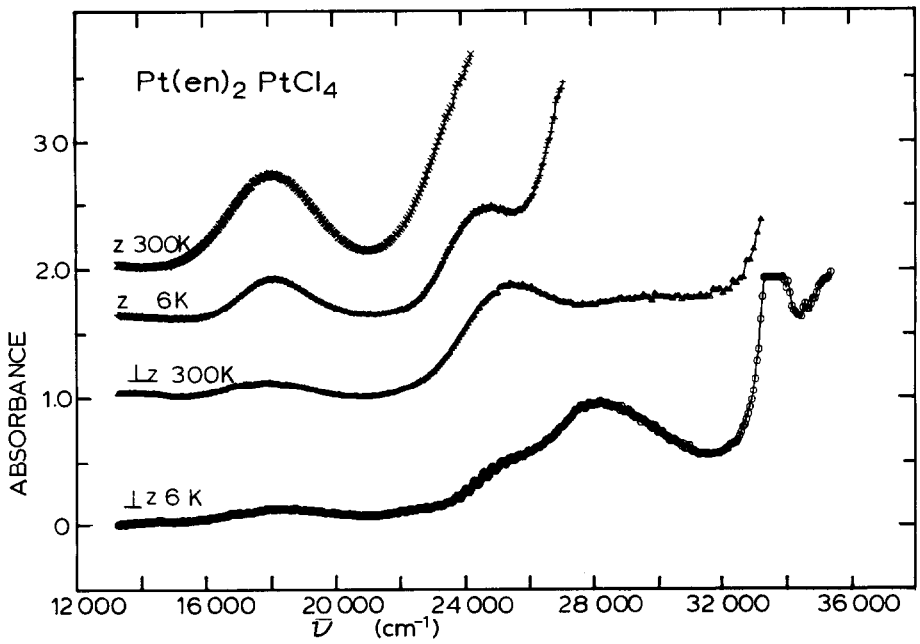

Fig. 5. Polarized single-crystal spectra for $Pt(en)_2PtCl_4$ crystal, 16 μm thick.

that the shifts for the $PtBr_4^{2-}$ transitions are about 2000 cm^{-1} smaller. For $[Pd(NH_3)_4PtBr_4]^{2-}$ (Fig. 11) there appears to be a merged broad peak that contains the $^1A_{2g}$- and ^1E_g-bands. The z-polarized spectrum indicates that the $^1B_{1g}$-transition is very close to the others. For $Pd(en)_2PtBr_4$ in Fig. 12 the appearance of two peaks indicates that the $^1E_{1g}$-band has shifted by no more than 1200 cm^{-1} from K_2PtBr_4 and the z-polarized spectra suggest that the $^1B_{1g}$-band is contained in this band as well. In the Pd salts the one identifiable spin-forbidden band is shifted very little from K_2PtBr_4.

The intense ^1E_u charge-transfer band, at 37,000 cm^{-1} in K_2PtBr_4, conceals any A → C electron-

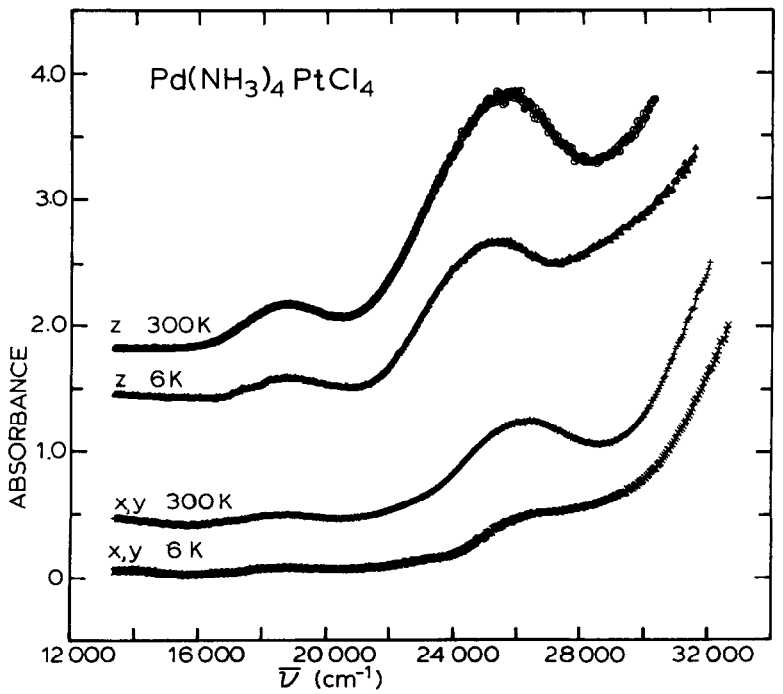

Fig. 6. Polarized spectra for $Pd(NH_3)_4PtCl_4$ crystal, 13 μm thick.

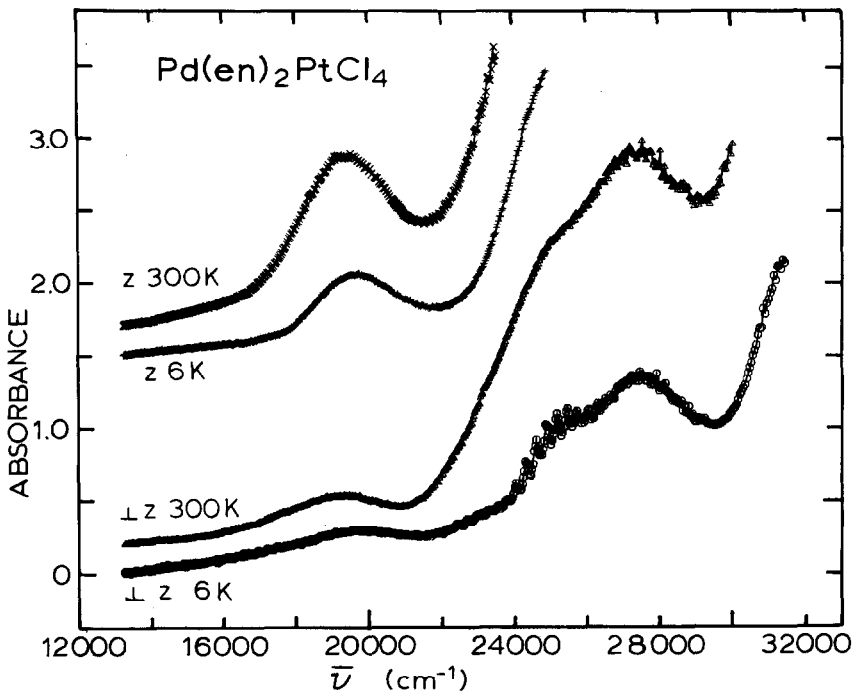

Fig. 7. Polarized spectra for $Pd(en)_2PtCl_4$ crystal, 26 μm thick.

transfer transitions in x,y polarization which might be expected at somewhat higher energies than in $PtCl_4^{2-}$ salts. The z-polarized intensity of the $PtBr_4^{2-}$ salts does not appear to be enhanced as strongly as in the $PtCl_4^{2-}$ salts. In addition, no vibrational structure for the $^1A_{2g}$-band was evident.

Spectra of $PdCl_4^{2-}$ *salts*

For K_2PdCl_4 the $^1A_{2g}$-band exhibits a vibrational structure which is centered at 20,800 cm^{-1}. In the $d \rightarrow d$ transition region the x,y-absorption intensity is significantly greater than the z-absorption inten-

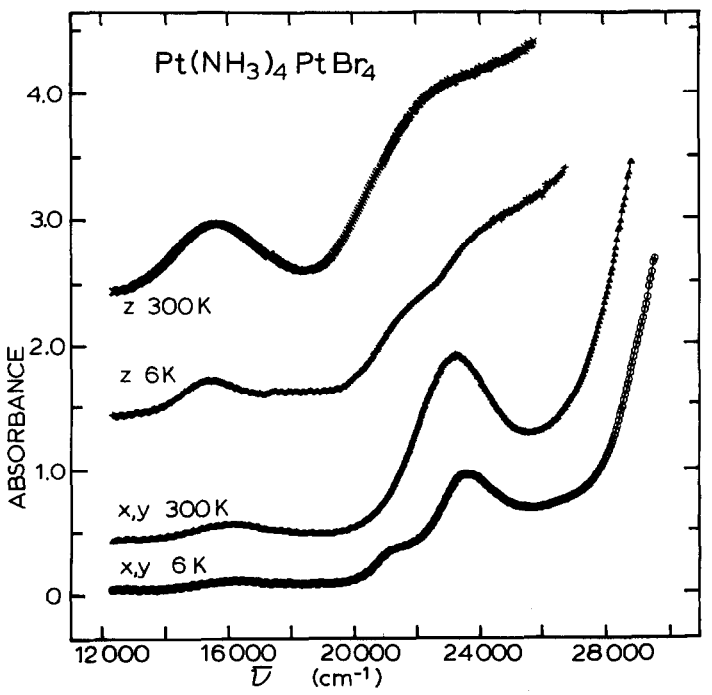

Fig. 8. Polarized spectra for $Pt(NH_3)_4PtBr_4$ crystal, 8 μm thick.

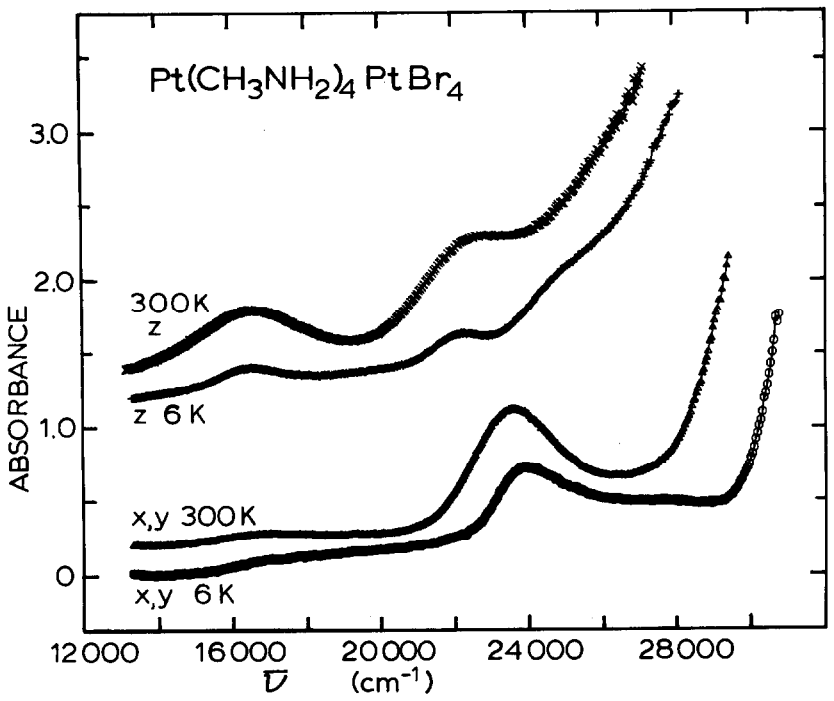

Fig. 9. Polarized spectra for $Pt(CH_3NH_2)_4PtBr_4$ crystal, 4.0 μm thick.

sity. There is only a very low absorption from 24,000 to 30,000 cm^{-1}; consequently the ^1E_g- and $^1B_{1g}$-transitions are assigned at *ca* 22,000 cm^{-1} and are not well resolved from the $^1A_{2g}$-band. All the $PdCl_4^{2-}$ Magnus-type salts show vibrational structure in the x,y or $\perp z$ polarization. The center of this structure is taken as the $^1A_{2g}$-transition energy which ranges only 300–900 cm^{-1} below the K_2PdCl_4 assignment. For $Pt(NH_3)_4PdCl_4$ in Fig. 13 there is some absorption in x,y polarization with no resolvable single peak in the region of 22,000–26,500 cm^{-1}. However, in z-polarization there is a broad-

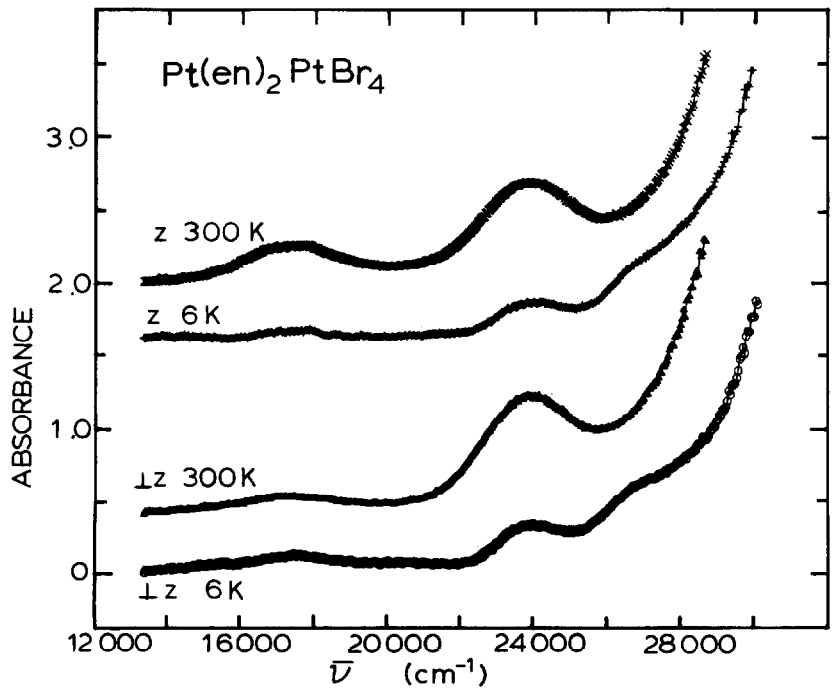

Fig. 10. Polarized spectra for $Pt(en)_2PtBr_4$ crystal, 7 μm thick.

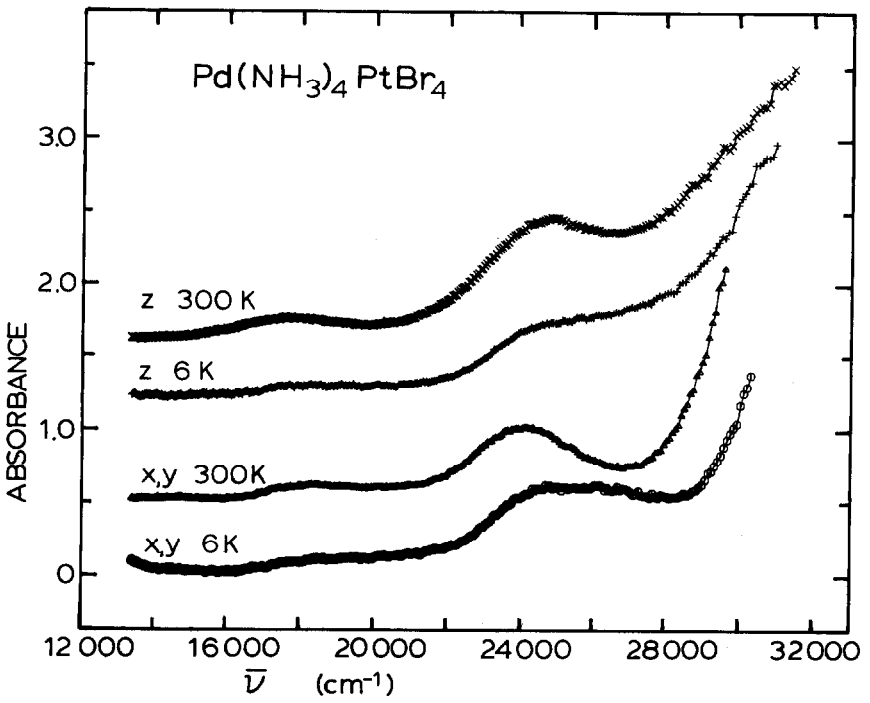

Fig. 11. Polarized spectra for $Pd(NH_3)_4PtBr_4$ crystal, 6 μm thick.

peak maximum at 22,400 cm^{-1} which is more intense than the $^1A_{2g}$-band in x,y polarization. Furthermore, this 22,400-cm^{-1} peak does not decrease in intensity at low temperatures as do the $d \rightarrow d$ transitions. $Pt(CH_3NH_2)_4PdCl_4$ in Fig. 14 shows a similar absorption in this region with the z-polarized peak at 23,000 cm^{-1}. In $Pt(en)_2PdCl_4$ (Fig. 16) the z-polarized peak has moved to still higher energy (25,400 cm^{-1}). In addition, for this salt there is also a well-resolved band in x,y polarization at this energy. There is little absorption from 22,000–25,000 cm^{-1} for the two $PdCl_4^{2-}$ Magnus-type salts

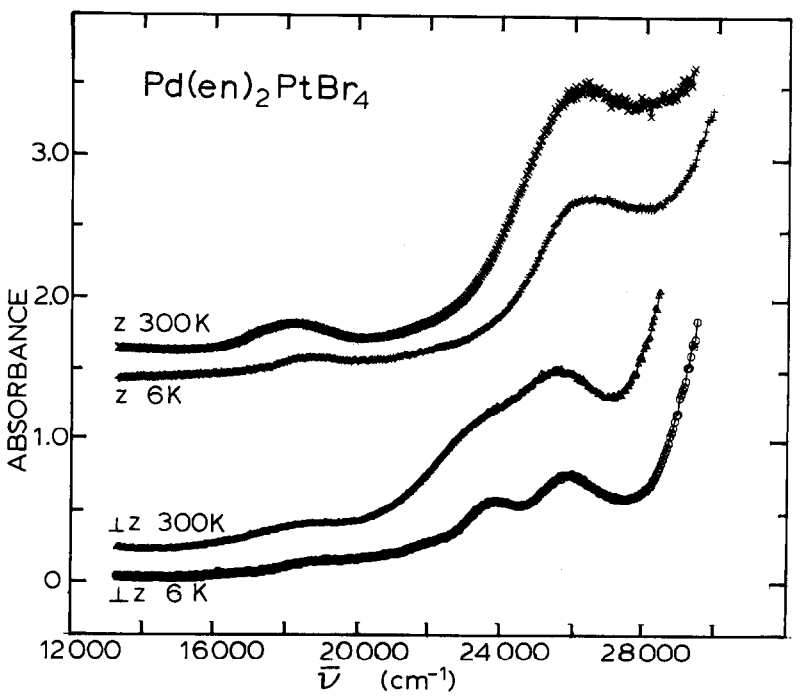

Fig. 12. Polarized spectra for $Pd(en)_2PtBr_4$ crystal, 8 μm thick.

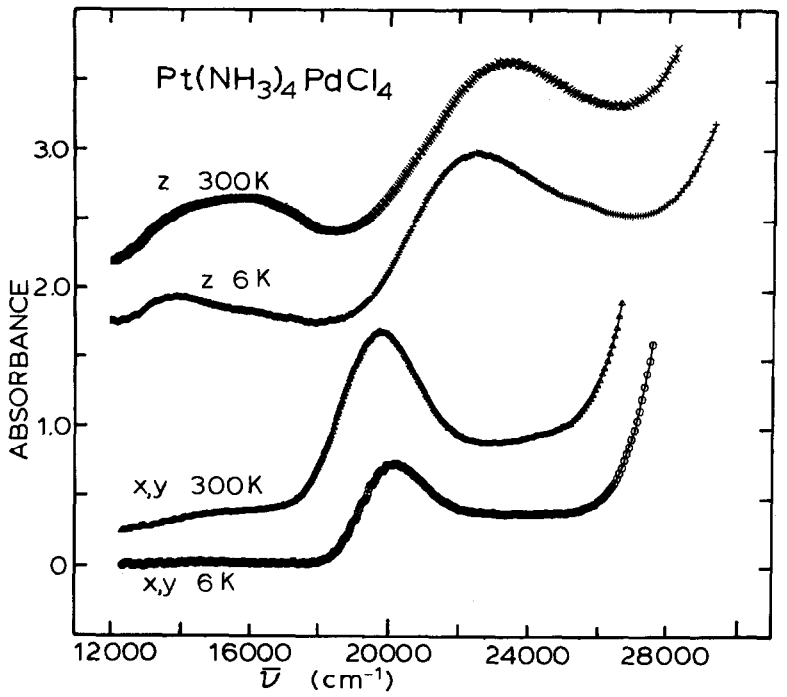

Fig. 13. Polarized spectra for $Pt(NH_3)_4PdCl_4$ crystal, 9 μm thick.

with Pd cations (Figs 17 and 18). We have concluded that the absorption in this region is not due to intraionic $d \rightarrow d$ transitions, but that it must be attributed to some solid-state effects which will be discussed later. In $Pt(NH_3)_4PdCl_4$ there are two components clearly apparent in z-polarizations at energies below the $^1A_{2g}$-transition, viz. at 13,800 and 16,200 cm^{-1}. The peak at 16,200 cm^{-1} is more intense at room temperature than the other but becomes much less intense at 6 K. We assign this

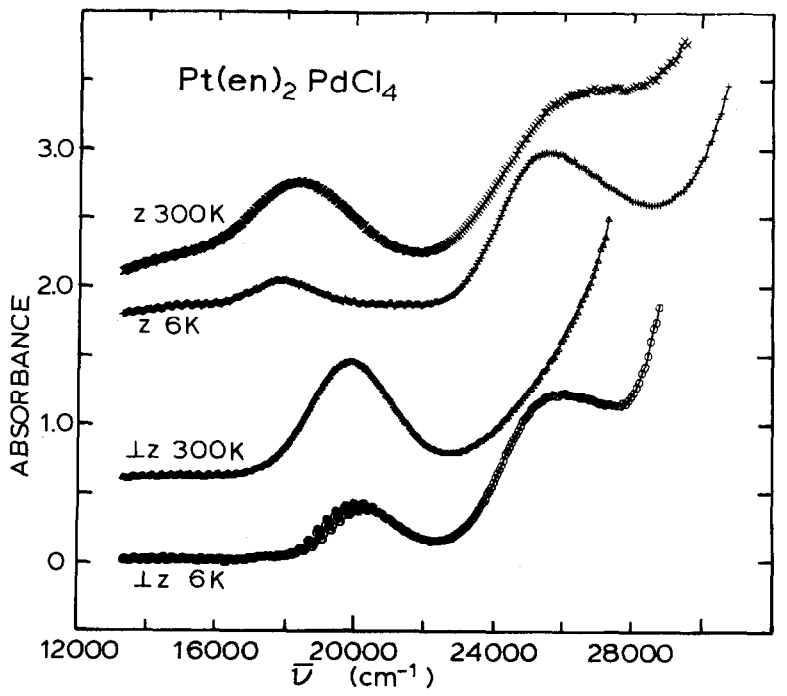

Fig. 14. Polarized spectra for $Pt(en)_2PdCl_4$ crystal, 8 μm thick.

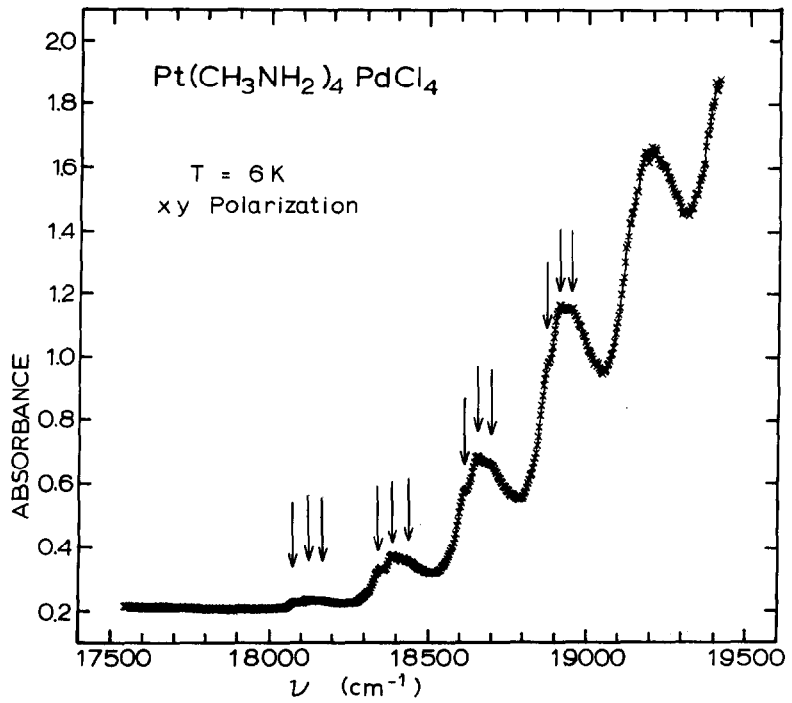

Fig. 15. Spectrum in x,y polarization at 6 K for $Pt(CH_3NH_2)_4PdCl_4$ crystal, 70 μm thick.

16,500-cm^{-1}-transition as $^1B_{1g}$. The z-polarized component of this becomes vibronically allowed by virtue of only a B_{2u} molecular vibration. This vibrational frequency is not accessible in either IR or Raman spectroscopy. However, it is a pure bending mode and is expected to have a lower frequency than a stretching vibration. The temperature dependence of a vibronically enabled transition is expected to increase as the vibrational frequency decreases. Hence, our assignment is based primarily

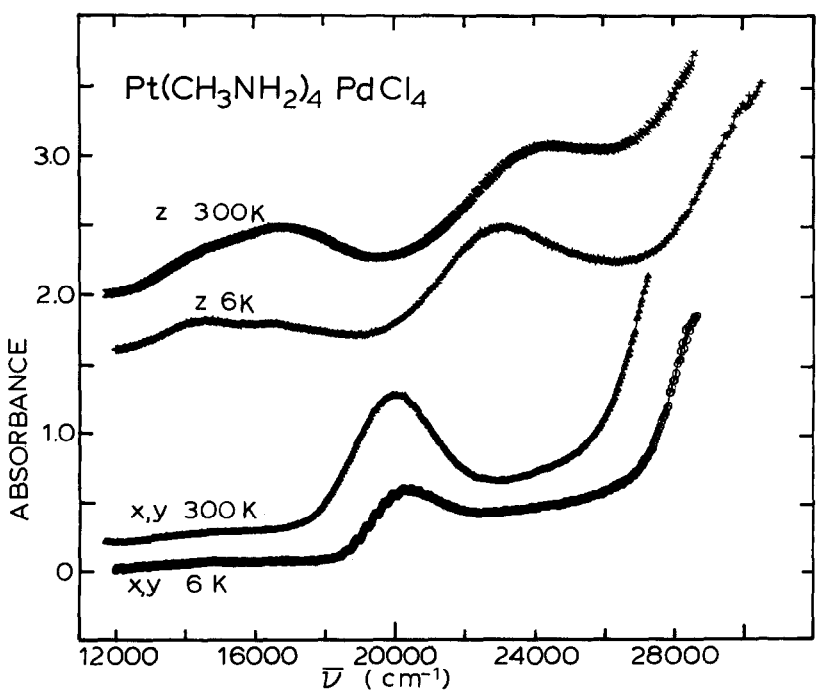

Fig. 16. Polarized spectra for $Pt(CH_3NH_2)_4PdCl_4$ crystal, 11 μm thick.

on this temperature dependence. The 13,800-cm^{-1} component would then be a spin-forbidden band. The assignment of the 16,200-cm^{-1} band as the $^1B_{1g}$-transition appears to be consistent with the theoretical treatment of vibronic intensities of $PdCl_4^{2-}$ by Enry and Moncuit.[44] They predict an oscillator strength ratio $f(z)/f(x, y)$ of 20 for the $^1B_{1g}$-transition of $PdCl_4^{2-}$ with the $^1A_{2g}$-transition in x,y-polarization about 4 times as intense as the z-component of $^1B_{1g}$. However, they placed the $^1B_{1g}$-transition at 30,000 cm^{-1} which would enhance its intensity since at that energy it would be much closer to the allowed transition from which it borrowed intensity.

With $Pt(CH_3NH_2)_4PdCl_4$ the low-energy absorption is very similar to $Pt(NH_3)_4PdCl_4$, and for it the $^1B_{1g}$-band can be placed at 16,800 cm^{-1} and the spin-forbidden band at 14,300 cm^{-1}. With $Pt(en)_2PdCl_4$ in Fig. 16 the $^1B_{1g}$ has not been so strongly red-shifted and a z-polarized band is evident at *ca* 17,800 cm^{-1}. For all of the $PdCl_4^{2-}$ Magnus-type salts with Pt cations the ^1E_g must be placed in the vicinity of the $^1A_{2g}$-band. For the two $PdCl_4^{2-}$ salts with Pd cations, all of the $d \rightarrow d$ transitions must fall under a single band, the transitions appearing somewhat closer together than in K_2PdCl_4.

A number of possibilities were considered for the dipole-allowed bands appearing at 22,000–26,000 cm^{-1} in the $PdCl_4^{2-}$ salts with Pt cations. Could they be spin-forbidden L-πMCT bands that were red-shifted by the proximity of cation neighbors? The $Pd(NH_3)_4PdCl_4$ crystal, whose spectra are shown in Fig. 17, was very thin so the spin-allowed L-πMCT ($b_{2g} \rightarrow b_{1g}^*$) transition can be identified at 34,000 cm^{-1}. This is a red shift of 2900 cm^{-1} from K_2PdCl_4. In this transition the chloride MO is a linear combination of p_z-orbitals with a node in the molecular plane. Electron repulsions with cation electrons might account for the red shift. However, the only spin-forbidden transition which becomes electric dipole allowed by spin–orbit coupling involves transfers from chloride p_x, p_y orbitals which concentrate electron density in the molecular plane so a lower electron repulsion should occur. In the $PdBr_4^{2-}$ salts the repulsion of electrons in the π-orbitals with the neighbors might be expected to be greater, such repulsions together with the lower energy of the LMCT would serve to obscure the $d \rightarrow d$ transitions which clearly does not occur.

It seems necessary therefore to assign these transitions to $A \rightarrow C$ electron transfers and logical assignments must be sought. An assignment of $d_A \rightarrow (p_z)_C$ does not seem likely. First, there is not the high intensity in z-polarization nor the narrow peak in x,y polarization seen for Pt–Pt $A \rightarrow C$ transitions. Besides, Anex[11] and coworkers have seen a high z-intensity at 40,400 cm^{-1} in specular reflectance spectra for $Pt(NH_3)_4PdCl_4$ which they correlated with the $Pt(NH_3)_4PtCl_4$ band at 35,000 cm^{-1}. The possibility of $d_A \rightarrow (d_{x^2-y^2}^*)_C$ was also considered. For a staggered arrangement of metal–ligand bonds, the $(d_{xy})_A$ transition will provide an electric dipole allowed transition. However, in an eclipsed arrangement this transition is forbidden. For $Pt(en)_2PdCl_4$ with very close to anion D_{2h} local symmetry, this transition is forbidden and there seems no way to account for such a strong z-component

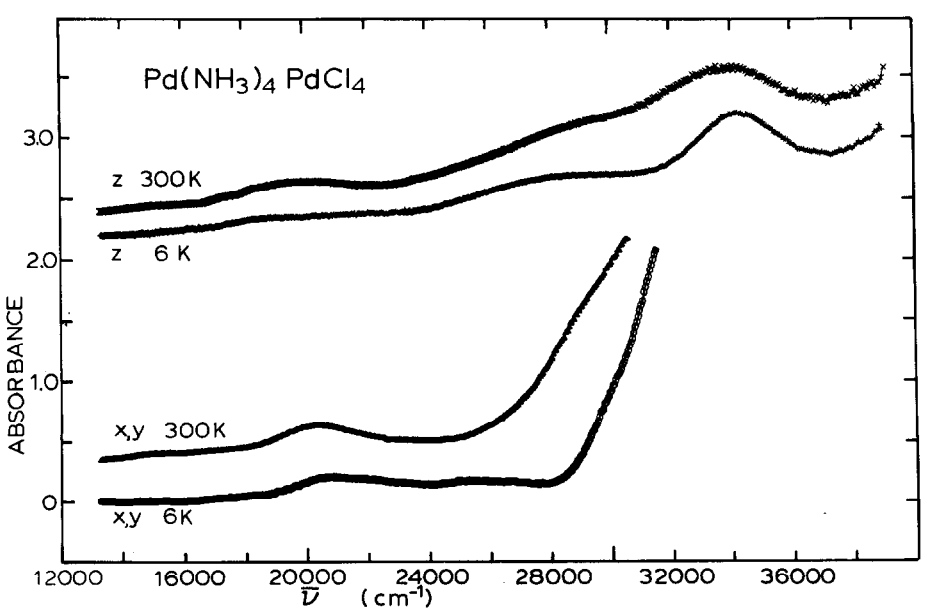

Fig. 17. Polarized spectra for $Pd(NH_3)_4PdCl_4$ crystal, 3.1 μm thick.

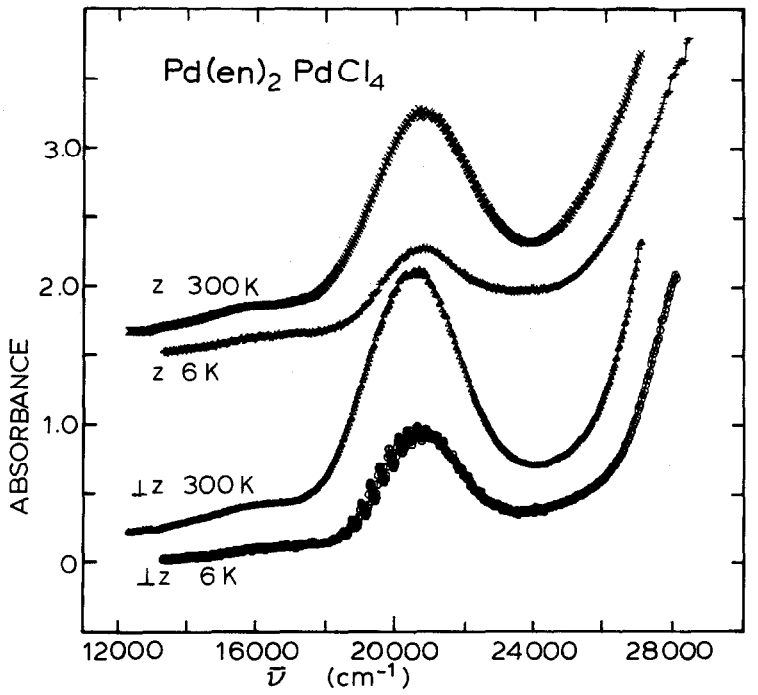

Fig. 18. Polarized spectra for $Pd(en)_2PdCl_4$ crystal, 40 μm thick.

at 25,400 cm^{-1} as an $d_A \rightarrow d_C$ transition. We believe the best assignment to be an $(L\pi)_A \rightarrow [\sigma^*(d_{x^2-y^2})]_C$ transition. There are such transitions with orbital symmetries for an electric dipole allowed character in both polarizations. However, orbital overlap for such transitions would be expected to be very low.

Spectra of $PdBr_4^{2-}$ *salts*

Most $PdBr_4^{2-}$ spectra shown in Figs 19–24 were for such thin crystals that the $^1A_{2u}$ L-πMCT band was evident. It occurred at about the same energy at which it occurs in K_2PdBr_4. As mentioned pre-

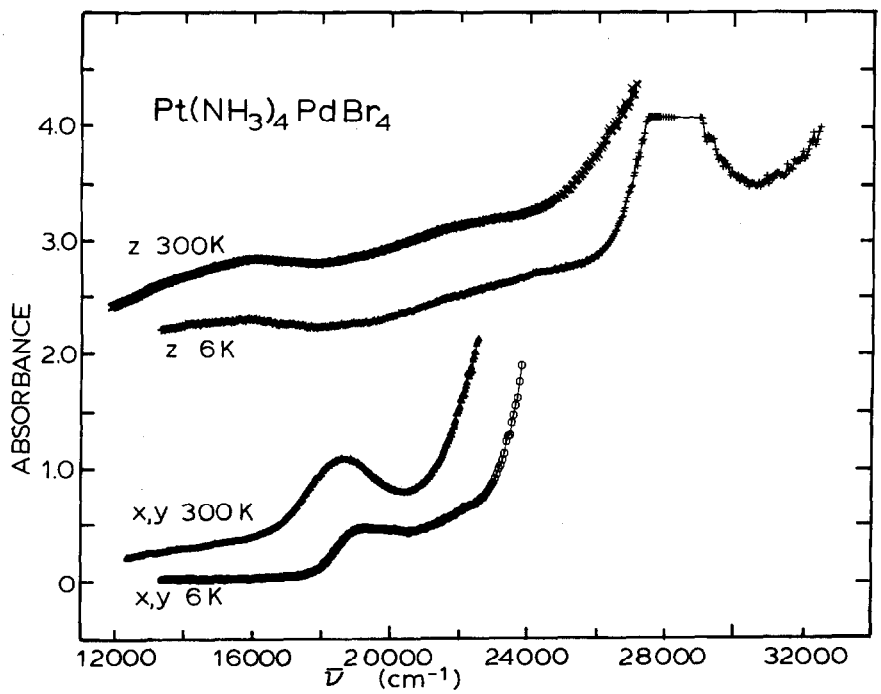

Fig. 19. Polarized spectra for $Pt(NH_3)_4PdBr_4$ crystal, 10 μm thick.

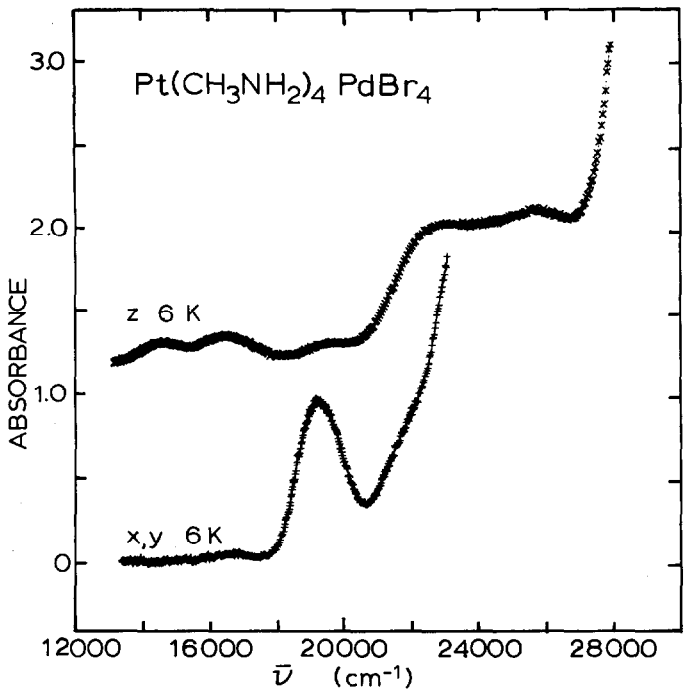

Fig. 20. Polarized spectra for $Pt(CH_3NH_2)_4PdBr_4$ crystal, 13 μm thick.

viously, the truncated ^1E_u L-πMCT band could be observed for the 3-μm crystal to place this transition at *ca* 28,000 cm^{-1}. The proximity of this intense transition enhances x,y intensities among the $d \rightarrow d$ transitions. Each of the $PdBr_4^{2-}$ salts had a moderately strong band with a strong temperature dependence for the intensity in x,y polarization that ranged from 18,700 to 19,200 cm^{-1} which could be associated with the $^1A_{2g}$-transition which is at 20,200 cm^{-1} in K_2PdBr_4. Vibrational structure was not as strongly developed as for the $PdCl_4^{2-}$ salts and indeed was barely evident only in the 13-μm $Pt(CH_3NH_2)_4PdBr_4$. The $^1B_{1g}$-band is generally placed with the z-polarized absorption below the $^1A_{2g}$-region. In the 13-μm $Pt(CH_3NH_2)_4PdBr_4$ crystal (Fig. 20) there are clearly two weak peaks in this region. The $^1B_{1g}$-transition can be associated with the 16,500-cm^{-1} peak which had a higher tem-

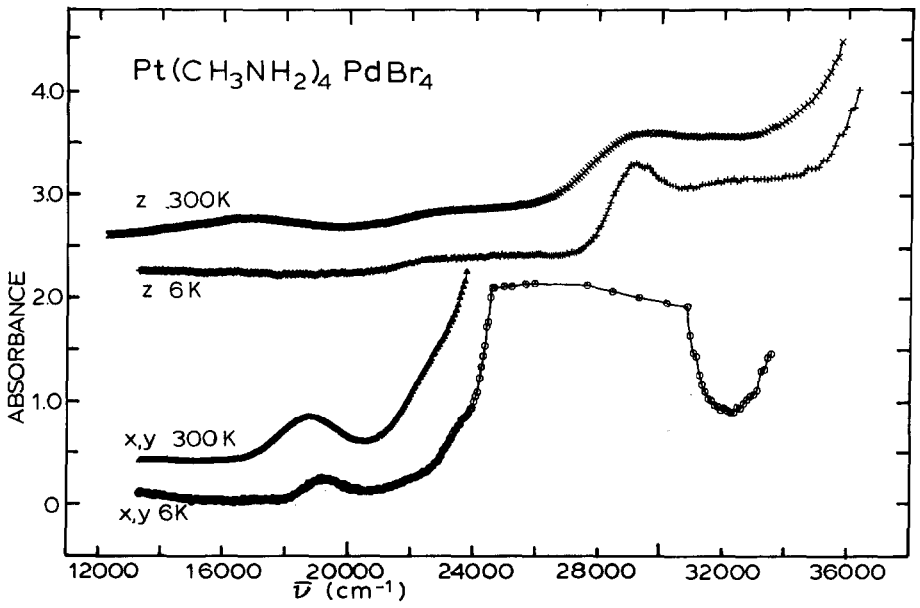

Fig. 21. Polarized spectra for $Pt(CH_3NH_2)_4PdBr_4$ crystal, 3 μm thick.

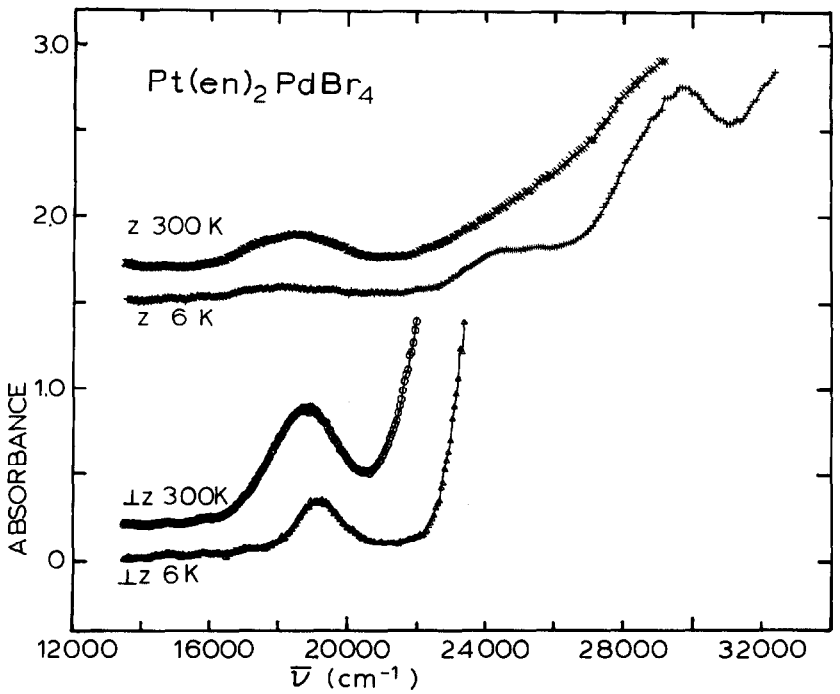

Fig. 22. Polarized spectra for $Pt(en)_2PdBr_4$ crystal, 5 μm thick.

perature dependence, and the 14,500-cm^{-1} band is then a spin-forbidden band. Again, the ^1E_g-transition must be placed close to the $^1A_{2g}$-band. Unfortunately, the relatively low z-polarized absorption does not clearly indicate this transition because of strong x,y enhancement. Absorption above 22,000 cm^{-1} can logically be attributed to molecular L-$\pi \rightarrow$ M charge transfer.

There is no absorption apparent that can be correlated to the $(L\pi)_A \rightarrow [\sigma^*(d_{x^2-y^2})]_C$ bands assigned the $PdCl_4^{2-}$ salts with Pt cations. Since they do involve electron transfers from halides a lower energy might be expected for bromide. However, the increase in interionic spacing will produce a counteracting energy shift and also should serve to reduce the intensity appreciably.

Vibrational structure in the spectra

As was commented earlier, vibrational structure was present in the $^1A_{2g}$-band of the potassium as well as many of the Magnus-type salts of the anions.

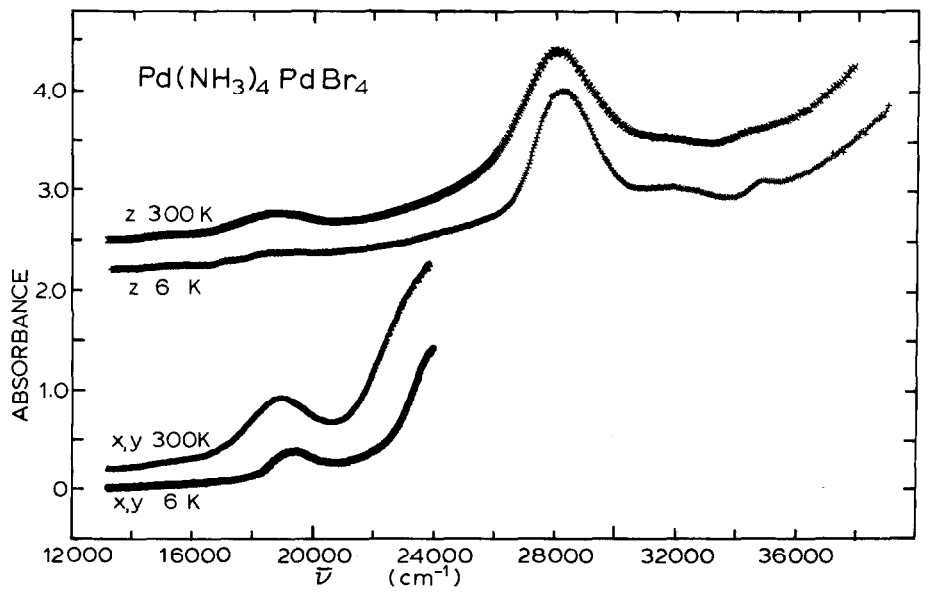

Fig. 23. Polarized spectra for $Pd(NH_3)_4PdBr_4$ crystal, 3.1 μm thick.

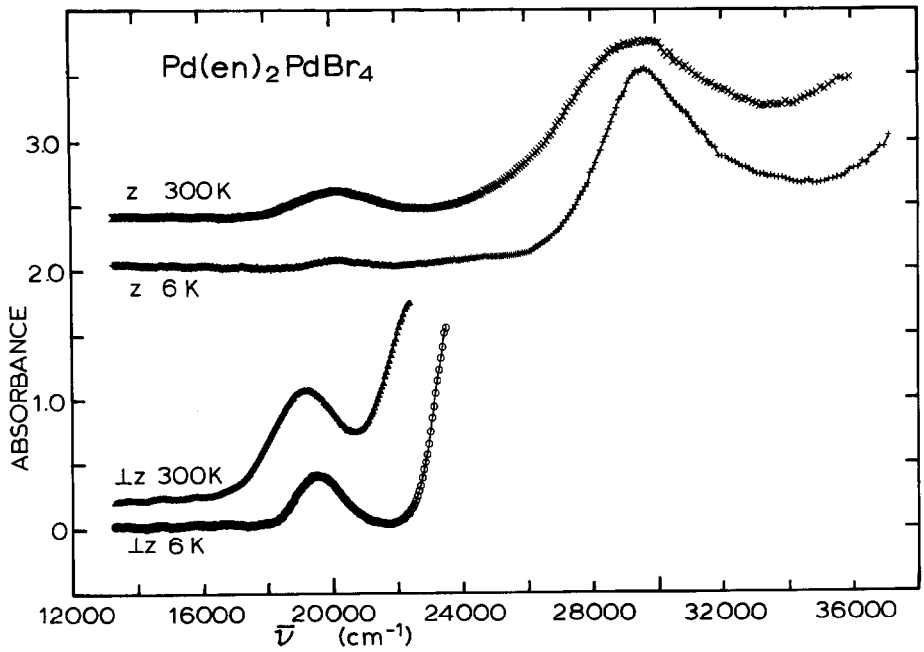

Fig. 24. Polarized spectra for $Pd(en)_2PdBr_4$ crystal, 5 μm thick.

This structure indicated the presence of long Franck–Condon progressions in a totally symmetric vibration of the excited state, which would be the ν_1 stretching vibration for the MX bonds. It is consistent with a relaxation of the bonds in the excited state that would be expected for excitation of an electron into a σ-antibonding orbital. An examination of the spectra in the figures shows that the vibrational structure is generally most highly developed in the ethylenediamine and least developed in the ammonia complex salts. Now vibrational detail will be lost when there are a distribution of sites persisting even at helium temperatures which have transition energies which differ in energy by the order of ν_1. These shifts in transition energies may result from interactions of electrons in the orbitals involved in the transition with neighboring atoms. For the $^1A_{2g}$-transition the two orbitals involved are mostly the d_{xy} and $d_{x^2-y^2}$, concentrated in the plane of the atoms in the ion. Since these two orbitals would be subject less to external influences, it is logical that this transition would have the most highly developed vibrational structure. Rotation of NH_3 groups about the M—N bond can result in site differences being frozen in at low temperatures which compromise the vibrational detail. With the more limited motion imposed by the methyl group in methylamine and especially by the chelate ring with ethylenediamine ligands, the vibrational structure is enhanced. Also the salts with chloride complexes with higher values of ν_1 generally had better developed vibrational structure than those of the bromide complexes.

For cases where five or more vibrational components could be read from the spectra, their wavenumbers were fitted to the component number by linear least squares. The indicated values of $\bar{\nu}_1$ for the $^1A_{2g}$-transition are included in Table 8 together with the indicated standard deviations. Ground state values for $\bar{\nu}_1$, available from the Raman spectra of the potassium salts, are listed in Table 8. The values of $\bar{\nu}_1$ for the excited $^1A_{2g}$-state are quite comparable to those observed in the potassium salts. They are quite generally 12–15% lower than the $\bar{\nu}_1$ for the ground state in the potassium salts. The value for $\bar{\nu}_1$ for the salts with ammonia complexes appear 5–10 cm^{-1} lower than those for salts with methylamine or ethylenediamine complexes. The one exception to this rule may be $Pd(NH_3)_4PdCl_4$; however, the value for this compound does have a large 6-cm^{-1} standard deviation.

For a thick crystal of $Pt(CH_3NH_2)_4PdCl_4$ sufficiently high resolution was attained, as shown in Fig. 15, that clearly each vibrational peak was comprised of three components. This result suggests that three separate vibrations provide vibronic perturbation which induce the necessary transition dipole moment. An E_u vibration symmetry is required for the $^1A_{2g}$-transition and the square-planar ions possess only two E_u-vibrations, ν_6 (an asymmetric stretch) and ν_7 (an in-plane bending mode). From IR spectra these vibrations are set

Table 8. Vibrational structure in Franck–Condon progressions for Magnus-type salts

Compound	$\bar{\nu}^a$ for potassium salts: Ground state Raman spectrum	Excited state

at 335 and 195 cm^{-1}, respectively.[47] It is logical to assign the largest, central component of each peak to the ν_6 stretching vibration $+n\bar{\nu}_1$ vibrations in the Franck–Condon progressions. The second strongest component in each peak is the lowest member that occurs only *ca* 40 cm^{-1} below the ν_6-peak. We would assign this to the ν_7 bending vibration. The weakest feature is quite broad and seems likely due to a lattice or phonon band. Thus in a peak the component would be assigned $\nu_L+(n+1)\nu_1$. This means there would be such a component too weak to be observed below the first peak. The indicated separation of the bending and stretching component of only 40 cm^{-1} is very low in view of the difference of 140 cm^{-1} for ν_6–ν_7 in the ground state from IR spectra. Harrison *et al.*[48] observed a similar arrangement of components in the $^1A_{2g}$-absorption for $PdCl_4^{2-}$ in a Cs_2HfCl_6 host crystal with somewhat greater resolution. In that case the bending, ν_7, components was 70 cm^{-1} below the stretching, ν_6, components. Since the A_{1g} stretching vibration for the $^1A_{2g}$-state is only 44 cm^{-1} lower than in the ground state, it probably indicates that some feature in the ion packing of $Pt(CH_3NH_2)_4PdCl_4$, perhaps hydrogen bonding between Cl and N atoms, serves to raise the bending vibration frequency for ν_7.

For a very thick crystal of $Pd(en)_2PdCl_4$ (105 μm), vibrational structure was resolved for separate low-energy triplet bands in z- as well as x,y polarization. The indicated A_{1g} vibrational frequencies, given in Table 8, were not within the statistical uncertainty different from those for the $^1A_{2g}$ band.

Finally, vibrational structure appears in x,y polarization on a weak component which is below the $^1A_{2g}$-band and the assigned $^1B_{1g}$-peak seen in z-polarization of $Pt(en)_2PtCl_4$, which must be for one of the triplet bands, largely ^3E_u. The indicated A_{1g}-frequency, given in Table 8 is about 5 cm^{-1} higher than for the $^1A_{2g}$-band.

SUMMARY

The collection of single-crystal absorption spectra that are now available permit some important conclusions about this interesting class of compounds. First of all, the planar nature of the ions provides a close contact of the metal atoms as these alternating cations and anions stack in one-dimensional arrays. There is some orbital overlap between the metal atoms in the cations and anions. However, there appears to be negligible covalent bonding or delocalization as occurs in the mixed-valence chains with the planar $Pt(CN)_4$ groups, which have much smaller Pt—Pt distances and metallic conductivity. There is, however, sufficient overlap with the 3.25–3.5-Å metal spacing to permit interionic electron-transfer transitions and these account for a higher absorption of polarized light with the electric vector oriented in stacking direction that has been recognized as a characteristic of a number of these compounds. It is especially important to this assignment that the expected interionic electron transfer with polarization normal to the stacking direction can now be identified in some of the cases.

The energies of a number of *d–d* transitions for the anions are highly sensitive to differences in the metal–metal spacings in the region of 3.25–3.6 Å. These differences in the band frequencies account for the anomalous colors which have drawn attention to these compounds. Controversy over where to place the d_{z^2}-orbital with respect to the other *d*-orbitals has simmered for the past 25 years. Our results provide, we believe, good but perhaps not overwhelming evidence for placing the d_{z^2} and the $d_{xz,yz}$ pair close together in the free MX_4^{2-} ion so the $^1B_{1g}$- and ^1E_g-bands are not resolved in aqueous solution or in the potassium salts. One general conclusion is that the valence shell orbitals of Pd are more compact than the corresponding orbitals of Pt. Thus the Pt cations gave greater shifts of aborption bands and higher interionic electron transfer probabilities for a given anion. The results were also consistent with a much lower $d \rightarrow p$ excitation energy for Pt compared to Pd.

Finally, we believe that the earlier assignment of intermolecular electron-transfer transitions for the molecular compounds of $Pt(en)Cl_2$ and $Pt(en)Br_2$ should be reconsidered.[49,50] These nearly planar molecules stack face to face in one-dimensional arrays in orthorhombic crystals. Metal–metal spacings are 3.39 and 3.50 Å, respectively. Both have an intense absorption band polarized in the stacking direction. Polarized reflectance spectroscopy by Anex and Peltier[51] places the peak at 35,100 cm^{-1}. Diffuse-reflectance spectra on the other hand showed maxima at 37,500 and 36,700 cm^{-1}, respectively, for the chloride and bromide compounds. Thus they each have a strong band similar to those in the $PtCl_4^{2-}$ and $PtBr_4^{2-}$ Magnus-type salts. In view of the present work, it appears logical now to assign this transition as an intermolecular $d_{z^2} \rightarrow p_z$ electron transfer rather than as the red-shifted intramolecular $d_{z^2} \rightarrow p_z$ originally proposed. Although the neutral molecules would be expected to have greater ionization energy and electron affinity than the anion and cation, the formation of an ion-pair would greatly increase the lattice energy. The narrow band, indicated to arise from a dipole-allowed transition, polarized normal to the stacking direction at 33,100 and 33,500 cm^{-1} for the chloride and bromide would then correspond to intermolecular $d_{yz} \rightarrow p_z$ electron transfer rather than the intermolecular $d_{yz} \rightarrow d^*_{xy}$ transition proposed. (In this case the axes were selected so that the d_{xy} was the *d*-orbital involved in the σ-bonds to the ligands[50].) This transition occurred among the normal intramolecular $d \rightarrow d$ transitions. Although for these crystals the metal–metal distances permitted the intermolecular electron transfer transitions, they were sufficiently large that no significant red shift of the spin-forbidden *d–d* bands occurred as in the case of many of the Magnus-type salts with ethylenediamine cations.

^{95}Mo AND ^{183}W NMR STUDIES OF TRIPLY BONDED DINUCLEAR M(III) AND RELATED M≡C (M = Mo OR W) COMPLEXES

CHARLES G. YOUNG, EDWARD M. KOBER and JOHN H. ENEMARK*

Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

(*Received* 27 *May* 1986; *accepted* 4 *June* 1986)

Abstract—^{95}Mo and ^{183}W NMR data are reported for a series of dinuclear triply bonded M(III) (M = Mo or W unless specified) and related $[M{\equiv}CR]^{3+}$ complexes. Complexes of general formulae M_2L_6 (L = $[OCMe_3]^-$ or $[NMe_2]^-$; M = Mo, L = $[CH_2CMe_3]^-$, $[CH_2SiMe_3]^-$, $[OCH_2CMe_3]^-$ or $[OCHMe_2]^-$) and $M_2(OCHMe_2)_6L_2$ (L = C_5H_5N, $\frac{1}{2}Me_2PCH_2CH_2PMe_2$ or $\frac{1}{2}MeNHCH_2CH_2NHMe$) exhibit very deshielded resonances in the δ-2430–3695 (M = Mo) and δ-4196–4736 (M = W) regions. The novel $M_2(O_2CMe)_4(CH_2CMe_3)_2$ complexes exhibit resonances which are shielded relative to the above complexes and related $M_2(O_2CR)_4$ complexes. The $M(CXMe_3)(CH_2XMe_3)_3$ (X = C or Si) complexes, which contain formal M≡C triple bonds, exhibit resonances at δ 1400 and 1845 (M = Mo), and δ 2867 and 3613 (M = W), respectively. The tungsten alkylidyne complexes exhibit septet ^{183}W resonances due to coupling of ^{183}W and $CH_2XMe_3^-$ protons ($^2J_{W-H}$ = 10.5 Hz). The magnitude of the nuclear shielding in these related species increases in the order: $[M{\equiv}M]^{4+}$ $(\sigma^2\pi^4\delta^2)$ < $[M{\equiv}M]^{6+}$ $(\sigma^2\pi^4)$ < $[M{\equiv}M]^{6+}$ $(\pi^4\delta^2)$ ~ $[M{\equiv}C]^{3+}$ < $[M{\equiv}N]^{3+}$. The nuclear deshielding appears to be related to the extreme covalency of the multiple bond in which the metals are involved.

Metal NMR has developed into a powerful probe of the solution structure, reactivity and dynamics of coordination and organometallic compounds. In particular, ^{95}Mo and ^{183}W NMR spectroscopies have experienced sustained development since the first solution studies were reported 10 years ago.[1] Molybdenum complexes of oxidation states 0–VI have now been characterized by ^{95}Mo NMR, and ^{183}W NMR has been applied to tungsten complexes of oxidation states 0, II and VI.[2] While mononuclear complexes of M(0), M(II), M(IV) and M(VI) (M = Mo or W hereafter) generally possess the diamagnetism necessary for NMR observation, the study of M(V), M(III) and M(I) complexes by NMR is restricted to dinuclear or otherwise spin-paired complexes. Interestingly, dinuclear complexes possessing direct metal–metal bonds exhibit unique ^{95}Mo and ^{183}W NMR properties. Quadruply bonded $[M{\equiv}M]^{4+}$ complexes, for example, exhibit the most deshielded resonances known (δ 3225–4150 for Mo,[3,4] and δ 6760 for W[5]). In contrast, mononuclear M(II) complexes exhibit resonances at the other extreme of the chemical-shift range (δ 50 to −2075 for Mo, and δ −2400 to −4037 for W[2]).

The origin of the extreme deshielding in the $[M{\equiv}M]^{4+}$ complexes is unclear. In order to better understand such phenomena we have investigated the metal NMR properties of other complexes containing metal–metal bonds. Here, we report ^{95}Mo and ^{183}W NMR data for a series of dinuclear triply bonded Mo(III) complexes (**A** and **B**), several of their *N*- and *P*-donor ligand adducts (**C**), and related complexes containing triply bonded M≡C fragments (**D** and **E**). This work represents the first study of such complexes by ^{95}Mo and ^{183}W NMR spectroscopies, and provides a basis for the routine characterization of such species by these NMR techniques. A preliminary account of the ^{95}Mo NMR spectra of the $[M{\equiv}Mo]^{6+}$ complexes has appeared.[6]

EXPERIMENTAL

The compounds M_2L_6 (L = alkyl,[7,8] alkoxide[9,10] or amide[11,12]), $M_2(O_2CMe)_4(CH_2CMe_3)_2$,[13] $M(CXMe_3)_3(CH_2XMe_3)_3$ (X = C or Si[14–16]), and $W(CPh)(OCMe_3)_3$,[17] were prepared according to published procedures or adaptions thereof. The $M_2(OCHMe_2)_6L_2$ (L = py, ½dmpe or ½Me_2en[10,18]) were prepared *in situ* from $M_2(NMe_2)_6$, $HOCHMe_2$ and L.* The NMR samples were prepared under anaerobic conditions using dried and deoxygenated solvents.

The NMR spectra were recorded on a Bruker WM250 NMR spectrometer. The ^{95}Mo NMR spectra were measured with a 10-mm molybdenum probe (16.3-MHz). To reduce the effects of probe ringing a Doty Scientific duplexer and preamplifier with a 16-MHz center was inserted between the probe and the Bruker broadband preamplifier. The duplexer was gated off during the pulse and 5 μs after the pulse. With this arrangement the preacquisition delay was reduced to 100 μs. The transmitter output was amplified with a Heathkit SB-201 (1-kW) linear amplifier. The input was attenuated to give a 26-μs 90° pulse. A 2 M $Na_2[MoO_4]$ solution in D_2O, effective pH 11, was used as the external standard. Spectra were run unlocked; no drift of the spectrometer was detected when the external standard was measured between samples. Typically 10^4–10^5 transients were accumulated.

The ^{183}W NMR spectra were measured at 10.28 MHz using a 10-mm broadband (7.6–31.2-MHz) probe. The duplexer and preamplifier described above was inserted between the probe and the broadband preamplifier to reduce the effects of probe ringing. A preacquisition delay of 320 μs was employed. The transmitter output was amplified as described above and the input was attenuated to give a 90-μs 90° pulse. A 40-μs pulse was employed in data acquisition and the spectrometer was locked on the deuterium signal of C_6D_6. The ^{183}W chemical shifts were referenced to an external standard of 2 M $Na_2[WO_4]$ in D_2O, effective pH 11.

RESULTS AND DISCUSSION

Dinuclear triply metal–metal-bonded complexes of type Mo_2L_6 (L = $[CH_2CMe_3]^-$, $[CH_2SiM_3]^-$, $[OCMe_3]^-$, $[OCH_2CMe_3]^-$, $[OCHMe_2]^-$ or $[NMe_2]^-$) exhibit ^{95}Mo NMR resonances over the chemical-shift range δ 2430–3695, a deshielded portion of the known chemical-shift range.[2] The shielding of the ^{95}Mo nuclei in these complexes increases in the order: alkyl < 3° alkoxide < 2° and 1° alkoxide < dialkylamide. The resonances are not as deshielded as those of quadruply bonded Mo(II) complexes,[3,4] but their chemical shifts are almost certainly a consequence of the metal–metal bond. The relatively narrow linewidths of the Mo(III) complexes (120–1320 Hz) contrast with the broad resonances of the Mo(II) dimers (up to 1960 Hz at elevated temperatures).[3] The broader resonance of $Mo_2(NMe_2)_6$ could result from enhanced quadrupolar relaxation of ^{95}Mo bonded to ^{14}N.

The tungsten complexes W_2L_6 (L = $[OCMe_3]^-$ or $[NMe_2]^-$) also exhibit very deshielded resonances (δ 4196 and 4489, respectively) and exhibit the same ligand-dependent order as that found for the molybdenum complexes. The W_2L_6 (L = $[OCHMe_2]^-$ or $[OCH_2CMe_3]^-$) complexes have not been isolated due to their decomposition to the tetrameric hydrido W(IV) complexes, $W_4(OR)_{14}H_2$.[19] We could not detect signals from dilute solutions of the $W_2(CH_2CMe_3)_6$ and $W_2(CH_2SiMe_3)_6$ complexes.

The $M_2(OCHMe_2)_6$ complexes readily react with amine and phosphine ligands to form triply bonded adduct complexes, $M_2(OCHMe_2)_6L_2$ (L = py, ½dmpe or ½Me_2en[10,18]). These adducts exhibit chemical shifts which are slightly deshielded compared to the precursors, $M_2(OCHMe_2)_6$. For the molybdenum complexes the magnitude of the deshielding ranges from 435 ppm for the dmpe adduct to *ca* 280 ppm for the *N*-donor ligand adducts. Similar deshielding is observed in the tungsten complexes which exhibit resonances between δ 4380 and 4736. ^{183}W–^{31}P spin–spin coupling is observed in the phosphine complex $W_2(OCHMe_2)_6$(dmpe). The values of the one- and two-bond ^{183}W–^{31}P couplings, 228 and 19 Hz, respectively, are in good agreement with those derived from the ^{31}P NMR spectrum of the related complex, $W_2(OCH_2CMe_3)_6(PMe_3)_2$ (^1J = 240 Hz, ^2J = 20 Hz).[18] The shielding trend of

*Abbreviations used: Me = methyl, py = pyridine, dmpe = 1,2-bis(dimethylphosphino)ethane, and Me_2en = 1,4-dimethylethylenediamine.

[b] For ^{183}W spectra $W_{1/2} = 10$ Hz.
[c] Not observed.
[d] These complexes are not known.

the *N*- and *P*-donor ligands observed here is the opposite to that observed in a variety of mononuclear $M(S_2CNEt_2)_2(CO)_2L$ adducts.[20] The above triply bonded dinuclear Mo(III) complexes possess a $\sigma^2\pi^4$ triple-bond electron configuration. The deshielded nature of their resonances is clearly reminiscent of the deshielded resonances of the Mo(II) complexes $Mo_2(O_2CR)_4$,[3,4] which possess a $\sigma^2\pi^4\delta^2$ electron configuration.

The novel dinuclear complexes $M_2(O_2CMe)_4(CH_2CMe_3)_2$ are extraordinary in that they possess a formal metal–metal triple bond of $\pi^4\delta^2$ configuration, i.e. there is no σ-bond. Their metal resonances are substantially more shielded than the quadruply bonded $M_2(O_2CR_2)_4$ precursors. For example, $Mo_2(O_2CMe)_4(CH_2CMe_3)_2$ has δ 2040, whereas $Mo_2(O_2CMe)_4$ has δ 3700–3770, depending upon the experimental conditions.[3] The structures and bond lengths of both types of compounds are similar: the $M_2(O_2CMe)_4(CH_2CMe_3)_2$ species have neopentyl ligands in the axial positions, aligned with the metal–metal vector (**B**). The ^{95}Mo NMR data for the related pair of complexes, $Mo_2(O_2CCF_3)_4$ and $Mo_2(O_2CCF_3)_4(py)_2$, also show shielding of the metal resonances (*ca* 200 ppm) upon axial ligation by the pyridine ligands.[4]

As a compliment to the above studies we have also examined the NMR properties of the alkylidyne complexes $L_3M{\equiv}CR$ (L = alkoxide or alkyl). Although these species formally contain a Mo(VI) center, homolytic cleavage of the rather covalent M≡C triple bond would generate half of the $[M{\equiv}M]^{6+}$ ($\sigma^2\pi^4$) core. The alkylidyne–Mo(VI) complexes $Mo(CXMe_3)(CH_2XMe_3)_3$ exhibit resonances at δ 1845 (X = Si) and δ 1400 (X = C), which are toward the deshielded end of the known chemical-shift range of monomeric Mo(VI) complexes.[2] The tungsten analogues also exhibit deshielded ^{183}W resonances (X = Si, δ 3613; X = C, δ 2867) as does the related $W(CPh)(OCMe_3)_3$ complex (δ 2526). Although more shielded than the resonances of the M_2L_6 species, the $L_3M{\equiv}CR$ resonances are significantly deshielded relative to the resonances of complexes containing metal–nitrogen triple bonds, e.g. $MoN(OCMe_3)_3$ (δ 55).[21] The photoelectron spectra of the metal–alkylidyne and metal–nitride complexes reveal that the metal–alkylidyne triple bond is much more covalent than the metal–nitride triple bond.[22] The greater covalency of the M≡C multiple bond may contribute to the deshielding of the metal nuclei. Interestingly, the alkylidyne carbon nuclei are also extremely de-

shielded [$\delta(^{13}C)$ *ca* 330].[15] The metal resonances for the Si-containing complexes are considerably more deshielded than the neopentyl derivatives consistent with a general deshielding influence for β-Si in substituted alkylidyne complexes. In contrast, the metal chemical shifts of the $M_2(CH_2XMe_3)_6$ (X = C or Si) complexes are quite similar. These observations suggest that the deshielding effect of the β-Si atom is mediated through the electronic structure of the metal–alkylidyne fragment, in support of a covalent M≡C bond being associated with the deshielding of the metal nuclei.

Both tungsten–alkylidyne complexes exhibit septet resonances (see Fig. 1) produced by the coupling of ^{183}W to six equivalent $C\underline{H}_2XMe_3$ protons: the magnitude of this two-bond coupling is 10.5 Hz. This is the first reported two-bond ^{183}W–^1H coupling to be derived from a ^{183}W spectrum, and the potential of such a coupling to characterize complexes with mixtures of alkyl, alkylidene and alkylidyne ligands is obvious. The value of the coupling is in close agreement with that derived from the ^1H spectrum of $W(CSiMe_3)(CH_2SiMe_3)_3$.[14] A similar coupling has not been previously reported for $W(CCMe_3)(CH_2CMe_3)_3$.[15,16]

The ^{95}Mo and ^{183}W chemical shifts of analogous pairs of complexes are often related by linear expressions which yield shielding sensitivities[2] [defined as $\Delta\delta(^{183}W)/\Delta\delta(^{95}Mo)$]. Several diverse classes of Mo and W compounds exhibit shielding sensitivities of 1.3–1.7.[20,23–26] For the complexes under discussion a broad correlation with a shielding sensitivity of *ca* 1.5 is observed when all data, except those for the $M_2(O_2CMe)_4(CH_2CMe_3)_2$ complexes, are considered. This correlation may be indicative of a common electronic origin for the deshielding in the $[M{\equiv}M]^{4+}$ ($\sigma^2\pi^4\delta^2$), $[M{\equiv}M]^{6+}$ ($\sigma^2\pi^4$) and $[M{\equiv}CR]^{3+}$ ($\sigma^2\pi^4$) species.

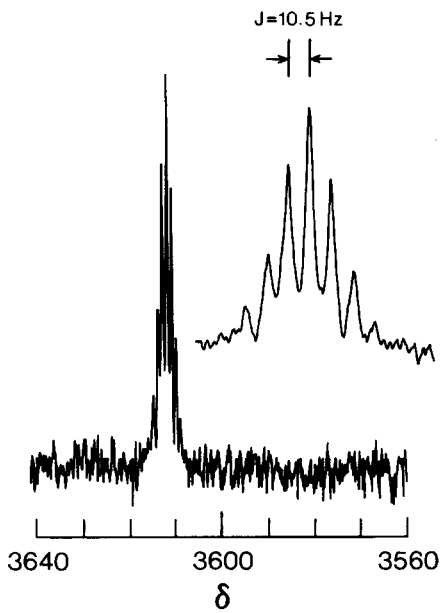

Fig. 1. ^{183}W NMR spectrum of $W(CSiMe_3)(CH_2SiMe_3)_3$ in d^6-benzene. The insert shows an expansion of the septet resonance. Acquisition parameters were: spectral width, 5 kHz; acquisition time, 1.638 s; digital resolution, 0.61 Hz (point)$^{-1}$; number of scans, 17,400.

Detailed theoretical calculations of the nuclear shielding are not yet feasible for large polyelectron atoms such as Mo and W. However, it is generally recognized that the paramagnetic term in the Ramsey equation for nuclear shielding dominates the chemical-shift differences among transition-metal compounds by mixing the angular momentum of appropriate metal excited states into the ground state.[27] For some series of complexes the metal chemical shift is inversely correlated with the energy of the lowest electronic transition of the molecule.[28–30] In other instances there is no correlation between the energy of the first excited state and the metal chemical shift.[2,31] The latter situation applies to the present study. The lowest-energy excited states of the $M_2(O_2CR)_4$ and $M_2(O_2CR)_4(R')_2$ species occur at similar energies,[32] yet their chemical shifts are quite disparate. On the other hand, the lowest-energy excited states of the $M_2(NR_2)_6$, $M_2(OR)_6$ and $M_2(OR)_6L_2$ complexes are rather different,[22,33] yet their chemical shifts span a relatively narrow range. These observations are consistent with the assignments for the lowest-energy electronic transitions in these complexes. For example, the lowest-energy transitions in the $[M{\equiv}M]^{4+}$ ($\sigma^2\pi^4\delta^2$) and $[M{\equiv}M]^{6+}$ ($\pi^4\delta^2$) complexes are $\delta \rightarrow \delta^*$ and $\delta \rightarrow \pi^*$ (O_2CR) (MLCT) in origin. Neither of these transitions should be an important contributor to the nuclear shielding. The $\delta \rightarrow \delta^*$ transition leaves the angular momentum unchanged, and the $\delta \rightarrow \pi^*$ (O_2CR) (MLCT) excitation removes the electron from the metal center. On the other hand, the metal-centered transitions of the $[M{\equiv}M]^{6+}$ unit which occur at higher energies ($\delta \rightarrow \pi^*$, $\delta \rightarrow \sigma^*$, $\pi \rightarrow \delta^*$ and $\pi \rightarrow \sigma^*$) could be very important contributors to the nuclear shielding.[4]

In conclusion, deshielding of the metal nuclei in multiply bonded dinuclear species appears to be related to the strongly covalent nature of the bonding present in such complexes. For the complexes studied herein the magnitude of the nuclear shielding increases in the order: $[M{\equiv}M]^{4+}$ ($\sigma^2\pi^4\delta^2$) < $[M{\equiv}M]^{6+}$ ($\sigma^2\pi^4$) < $[M{\equiv}M]^{6+}$ ($\pi^4\delta^2$) ~ $[M{\equiv}C]^{3+}$ < $[M{\equiv}N]^{3+}$. There is no clear correlation of the chemical shift with the HOMO–LUMO energy gap, which underscores the import-

ance of the entire excited state manifold to the paramagnetic term of the chemical shift.

SYNTHESIS, MOLECULAR STRUCTURE AND SPECTROSCOPIC CHARACTERIZATION OF $Mo(CO)_2I_2(\eta^2\text{-dppm})(\eta^1\text{-dppm})$

F. ALBERT COTTON* and MAREK MATUSZ

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 4 *February* 1986; *accepted* 18 *June* 1986)

Abstract—A new, high-yield method has been developed for the preparation of $Mo(CO)_2I_2(\eta^2\text{-dppm})(\eta^1\text{-dppm})$. The title compound was prepared by the reaction of $[Et_4N][Mo(CO)_4I_3]$ with dppm in benzene in 95% yield. It has been characterized by a single-crystal X-ray study. The crystallographic data are as follows: monoclinic, space group $P2_1/n$, $a = 19.023(4)$ Å, $b = 14.439(3)$ Å, $c = 20.141(5)$ Å, $\beta = 100.45(2)°$, $V = 5440(2)$ Å^3, $Z = 4$. The geometry around the central metal atom could be considered as either a distortion from a capped octahedron with a carbonyl in a capping position or from a trigonal prism with the iodine capping a rectangular face. The solution behavior of $Mo(CO)_2I_2(dppm)_2$ was examined with ^{31}P NMR, which showed it to be fluxional.

Recently we have been investigating the possibility of forming multiply bonded heteroatomic dimers. One of the designed approaches would be to have a bidentate, dangling ligand on one metal atom. The dangling ligand might then coordinate to a second metal atom, bringing it close enough for an M—M′ bond to be formed, with the dangling ligand(s) becoming a bridge spanning the dimetallic core. For such a purpose the starting material would have to meet at least the following criteria:

(1) contain a metal that easily forms multiple bonds, or

(2) have the metal already in a suitable oxidation state.

Of the possible bidentate ligands, phosphines are of the greatest practical interest, with bis(diphenylphosphino)methane (dppm) being one of the best choices.

There are only a few examples in the chemical literature of complexes with dangling diphosphines.[1–7] At first we focused our attention on Mo(II) and Mo(III) compounds, since they fulfill the above requirements. A search of the chemical literature then revealed that a promising candidate for our experiments already existed and has been structurally characterized. $Mo(CO)_2Cl_2(dppm)_2$ was first prepared[3] by Colton *et al.*, and then later structurally characterized[7] as possessing a seven-coordinate molybdenum atom with two carbonyl groups, two chlorine atoms, one chelating diphosphine ligand and one dangling dppm ligand.

The reported synthesis of $Mo(CO)_2Cl_2(dppm)_2$ utilized the following reactions:

$$Mo(CO)_6 + Cl_2 \rightarrow Mo(CO)_4Cl_2,$$

$$Mo(CO)_4Cl_2 + 2dppm \rightarrow Mo(CO)_2Cl_2(dppm)_2.$$

In our hands the first step, i.e. the oxidative halogenation of molybdenum hexacarbonyl, has proved to be unreliable. In view of recent structural characterization of other $M_2(CO)_8X_4$ type dimers[8,9] it is possible that dimeric $Mo_2(CO)_8Cl_4$ instead of monomeric $Mo(CO)_4Cl_2$ is the product of chlorination of $Mo(CO)_6$, and that this may lead to poor yields of $Mo(CO)_2Cl_2(dppm)_2$.

We turned our attention to the corresponding bromo and iodo compounds. We found that $Mo(CO)_2I_2(dppm)_2$ (**1**) had been prepared by the following procedure:[10]

$$Mo(CO)_6 + dppm \rightarrow Mo(CO)_4dppm$$

$$\xrightarrow{I_2} \alpha,\beta Mo(CO)_3I_2dppm$$

$$\xrightarrow{dppm} Mo(CO)_2I_2(dppm)_2.$$

*Author to whom correspondence should be addressed.

This method gives not only the molecular compound $Mo(CO)_2I_2(dppm)_2$, but also the *cis* and *trans* isomers of $[Mo(CO)_2I(dppm)_2]I$, which have to be separated. We therefore searched for an alternative method of preparation of **1**.

After trying several reactions we found that the desired product could be synthesized in 95% yield by the following procedure:

$$[R_4N][Mo(CO)_4I_3] + 2dppm \rightarrow Mo(CO)_2I_2(dppm)_2 + R_4NI.$$

The starting material, $[R_4N][Mo(CO)_4I_3]$, can be easily prepared in a high-yield, one-pot synthesis from $Mo(CO)_6$. Compound **1** had not been structurally characterized, and some unusual stereochemistry might be found in a relatively crowded, presumably seven-coordinate molecule. The molecular structure was therefore determined by single-crystal X-ray studies.

During the routine spectroscopic characterization we discovered that the ^{31}P NMR spectrum was temperature-dependent, indicating fluxional behavior of $Mo(CO)_2I_2(dppm)_2$ in solution. The low-temperature ^{31}P spectrum is in accord with the observed solid-state structure.

EXPERIMENTAL

General

Standard Schlenk tube techniques were employed throughout. All solvents were dried and freshly distilled prior to use. Tetraethylammonium iodide was purchased from Aldrich Chemical Co. and used as received.

Formation of $[Et_4N][Mo(CO)_4I_3]$[11]

Molybdenum hexacarbonyl (9.08 g, 0.0344 mol) and Et_4NI (9.19 g, 0.0359 mol) were charged into a 500-cm^3, round-bottom flask. 100 cm^3 of THF was added and the reaction mixture was refluxed for 1.5 h. After that time the color of the reaction mixture was bright yellow, indicating the formation of $[Et_4N][Mo(CO)_5I]$, which can be isolated by adding ether and refrigerating. If any unreacted $Mo(CO)_6$ is still present, the reaction mixture should be filtered while still hot. The bright yellow solution was cooled and 8.7 g (0.0344 mol) of elemental iodine was added from an addition finger during a period of 5 min. The reaction mixture was stirred vigorously during that time. Addition of each portion of iodine was accompanied by evolution of carbon monoxide. After all the iodine was added, the reaction mixture was stirred for an additional 15 min. It was dark orange at this time. 100 cm^3 of diethyl ether was added to initiate precipitation and the reaction mixture was refrigerated overnight. The crystalline product was filtered, washed with ether and vacuum dried. The yield was 18.1 g (73%) of dark yellow crystals. An additional 2.4 g of the product could be recovered from the mother liquor, bringing the yield to 83%.

$Mo(CO)_2I_2(dppm)_2$ (**1**)

$[Et_4N][Mo(CO)_4I_3]$ (1.0 g, 1.40 mmol), 1.6 g (6.1 mmol) of dppm and 40 cm^3 of benzene were stirred at room temperature. The reaction proceeded with CO evolution and an orange precipitate was deposited. After 6 h of stirring the reaction mixture was brought to a boil and filtered hot. Remaining solids were treated with an additional 40 cm^3 of hot benzene and filtered. A white solid (Et_4NI) remained on the filter stick. The combined filtrates were treated with 100 cm^3 of hexane and refrigerated. The product was filtered, washed with hexane and vacuum dried, to give a yield of 1.55 g (95%) of orange-red crystalline material. The complex is air-stable in the solid state, but it is light-sensitive both in the solid state and in solution. Found: C, 55.5; H, 4.1%. Calc. for $Mo(CO)_2I_2(dppm)_2 \cdot C_6H_6$: C, 55.6; H, 4.0%. IR spectrum (Nujol mull): $\nu(CO) = 1930(s)$ and $1850(s)$ cm^{-1}. Solution spectra (chloroform and toluene) were essentially identical. Electronic spectrum (chloroform solution): $\lambda_{max} = 450$ nm (sh), and 350 nm (sh).

Measurements

Elemental analyses were performed by Galbraith Laboratories Inc. IR spectra were recorded on a Perkin–Elmer 785 spectrophotometer. The electronic spectra were recorded on a chloroform solution using a Cary 17D spectrophotometer. $^{31}P-\{^1H\}$ NMR spectra were recorded on a Varian XL 200 spectrometer at an operating frequency of 80.98 MHz in $CDCl_3$ solutions. 85% H_3PO_4 was used as an external standard. For the variable-temperature measurements the sample was referenced to H_3PO_4 at room temperature.

X-ray crystallographic procedures

Single crystals of **1** were grown by layering hexane on top of a benzene solution of the complex. The diffraction data were collected on a P3 autodiffractometer. Lorentz, polarization and absorption corrections were applied to the data. Standard

$^a R = \Sigma \, ||F_o| - |F_c|| / \Sigma \, |F_o|$.
$^b R_w = [\Sigma \, w(|F_o| - |F_c|)^2 / \Sigma \, w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
^{c} Quality of fit $= [\Sigma \, w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

procedures were used to process the data.[12]* The solution of the structure was initiated by placing the Mo atom at a position obtained from the $Mo(CO)_2Cl_2(dppm)_2 \cdot C_6H_6$ structure[7] (x- and z-coordinates were reversed). Additional atoms were located from the alternating least-squares cycles and difference Fourier maps. All the nonhydrogen atoms with the exception of the benzene molecule present as solvent of crystallization and C(44) were refined anisotropically. The structure converged to a value of $R = 0.0416$. The final difference Fourier map was featureless with a highest peak of 0.60 e Å^{-3}. All the relevant crystallographic data are presented in Table 1.

* Calculations were done on the VAX 11/780 computer at the Department of Chemistry, Texas A&M University, College Station, Texas, with a VAX-SDP software package.

RESULTS AND DISCUSSION

Synthesis

Preparation of **1** proceeds through the following synthetic steps:

$$Mo(CO)_6 + R_4NI \rightarrow [R_4N][Mo(CO)_5I] + CO$$

$$\xrightarrow{I_2} [R_4N][Mo(CO)_4I_3]$$

$$\xrightarrow{dppm} Mo(CO)_2I_2(dppm)_2 + 2CO + R_4NI.$$

The first stage entails thermal CO substitution of $Mo(CO)_6$ by tetraalkylammonium iodide. The reaction is of a general type, and has been widely used with other alkylammonium salts. The product, $[R_4N][Mo(CO_5)I]$, was not routinely isolated, but oxidized *in situ* with elemental iodine. The iodine has the advantage of being a mild oxidiz-

ing agent and it is easy to handle. The oxidation proceeds rapidly, with high yields. Despite the earlier reports of the extreme instability of $[R_4N][Mo(CO)_3I_3]$, we found that it can be isolated and conveniently handled. In the absence of light and air the complex could be stored for several days. The last step in the preparative procedure, the ligand substitution with dppm, gives the desired compound (**1**) with yields over 95%. A variety of tetralkylammonium salts have been tried (ethyl, propyl and butyl), with tetraethylammonium being the most convenient.

The preparation of **1**, by the method of Colton[10] has several disadvantages, namely, lower yields, and, in addition to the desired molecular complex $Mo(CO)_2I_2(dppm)_2$, *cis*- and *trans*-$[Mo(CO)_2I(dppm)_2]I$ are also formed.

Colton and coworkers also investigated reactions of $[Mo(CO)_4X_3]^-$ with dppm,[13] but under their conditions only the ionic complex $[Mo(CO)_2I_2dppm)_2]I$ was formed.

The preparation of **1** via the route employed for the synthesis of $Mo(CO)_2Cl_2(dppm)_2$ is not feasible because diiodotetracarbonyl molybdenum is inaccessible.

Our method of preparation of **1** gives only the molecular complex, uncontaminated by the ionic isomers. $Mo(CO)_2I_2(dppm)_2$ can be recrystallized from dichloromethane–hexane, but refluxing of dichloromethane solutions of **1** or even their prolonged storage leads to the formation of ionic species.

Spectroscopy

The IR spectrum shows two strong C≡O absorptions at 1947 and 1869 cm^{-1} in toluene (1940 and 1865 cm^{-1} in $CHCl_3$).

Figure 1 represents a series of variable-temperature ^{31}P studies of **1** in $CDCl_3$ solution.

At −40°C (Fig. 1a) the spectrum consists of four groups of peaks (integration 1 : 1 : 1 : 1), indicating that all four phosphorus atoms are nonequivalent, which is in accord with the solid-state structure. The assignment of all the lines in the spectrum is given in Fig. 1a. There are four chemical shifts (ppm) (12.64, 7.78, −25.40 and −43.04) and four coupling constants (Hz) (30.50, 84.7, 168 and 22.3). A large coupling constant (J_{AD} = 168 Hz) is probably between P(3) and P(2), since these are the most *trans* phosphorus atoms. The second largest coupling is observed for P(1) and P(2) in the chelating dppm (J_{DB} = 84.7 Hz). Small coupling constants are observed for the two phosphorus atoms in the dangling dppm (J_{AC} = 30.5 Hz) and between P(3) and P(1) (J_{AB} = 22.3 Hz). The doublet at −25.40 ppm is assigned to uncoordinated phosphorus. This value is consistent with that of free dppm. The coupling to the second phosphorus atom in this dppm molecule splits the signal into a doublet. One of the chelating phosphorus atoms is shifted upfield to −43.04 ppm, an unusual chemical shift, since phosphorus atoms in a five-membered ring are usually shifted downfield from the corresponding uncoordinated phosphines.

Upon warming, the resonances due to P(1) and P(2) start broadening. Also the J_{AB} coupling is "lost" in the P(3) resonance. At room temperature (Fig. 1d) the resonances of P(1) and P(2) are broad, and the fine structure of (P3) is very poorly resolved, except for the AC coupling. The dangling phosphorus P(4) is still present as a sharp doublet, suggesting that fluxionality does not involve opening of the chelating ring, and closing with an uncoordinated phosphorus P(4). There are at least two possible exchange mechanisms for **1**. One is a dissociative mechanism, involving dissociation of iodide from the capping position in the trigonal prism. The trigonal prism can then rearrange to an octahedron, rendering the phosphorus atoms equivalent. Another possibility is a simple rearrangement between capped trigonal prisms[14] which can be achieved easily by compressing and elongating bonds (see Fig. 2). As the temperature increases the sharp doublet assigned to the uncoordinated phosphorus atom begins to broaden as well, but it has been observed that **1** is decomposed in boiling dichloromethane or even at room temperature over a period of days.

Molecular structure

Selected bond distances and angles for **1** are listed in Table 2. Figure 3 presents a labelled ORTEP diagram of **1** along with a labelling scheme.* The molecule is seven-coordinate with the molybdenum atom bonded to two carbonyl groups, three phosphorus atoms and two iodine atoms. One of the dppm ligands is bidentate, but the second one is only monodentate. This type of structure has been postulated and observed before. The structure is distorted from a capped octahedron with CO(2) capping the P(1)–P(3)–1C(1) face and a trigonal prism with the I(1) capping the C(1)–P(2)–I(2)–

P(3) rectangular face (see Fig. 2). The principal distances (in Å) in the molecule are: Mo(1)—I(1) = 2.846(1), Mo(1)—I(2) = 2.904(2), Mo(1)—P(1) = 2.491(2), Mo(1)—P(2) = 2.589(2), Mo(1)—P(3) = 2.574(2), Mo(1)—C(1) = 1.957(10), and Mo(1)—C(2) = 1.945(9). All the distances are with the normal range and require no further comment. All the angles are almost identical to those observed in the chloro analogue, Table 3, demonstrating that substitution of chlorides by iodides had almost no effect on the molecular structure.

Concluding remarks

We have developed a new synthetic method for the preparation of $Mo(CO)_2I_2(\eta_2\text{-dppm})(\eta_1\text{-dppm})$. The title complex has been characterized by a single-crystal X-ray diffraction. The central molybdenum atom is seven-coordinate with two iodine atoms, two carbonyl groups and three phosphorus atoms forming the immediate coordination sphere. One of the dppm ligands is chelating, the other one has one dangling phosphorus atom. The geometry around the central molybdenum atom is distorted from a capped octahedron or a capped trigonal prism. Variable-temperature ^{31}P NMR studies revealed that the molecule is fluxional in solution. The reac-

KINETICS OF THE REVERSIBLE PHOTOAQUATION OF THE OCTACYANOMOLYBDATE(IV) ION*

VILMOS GÁSPÁR and MIHÁLY T. BECK†

Department of Physical Chemistry, Institute of Chemistry, Kossuth Lajos University, Debrecen, P.O. Box 7, H-4010, Hungary

(*Received* 4 *June* 1986; *accepted* 23 *June* 1986)

Abstract—The kinetics of the photoaquation of the octacyanomolybdate(IV) ion in aqueous solution were studied by potentiometric and spectrophotometric methods. In an alkaline medium a simple scheme analogous to the photoaquation of the hexacyanoferrate(II) ion describes the process. The values of the constants of the kinetic equation are: $\Phi = 1.0$, $k_8 = (6.55 \pm 0.8) \times 10^{-9}\ s^{-1}$, and $k_{-8} = (7.88 \pm 0.5) \times 10^{-2}\ mol^{-1}\ dm^3\ s^{-1}$ (pH = 10.5). The reversibility of the photoaquation is also explained by the scheme. A simultaneous measurement of free cyanide ion concentration and the absorbance at 512 nm shows that the red coloured transition product is a heptacyano complex.

The kinetics and mechanism of the photoaquation of different cyano complexes have been intensively studied for a long time.[1] Nevertheless, the reversible photoaquation of hexacyanoferrate(II) and octacyanomolybdate(IV) ions remained unsolved. In an earlier paper we dealt with the kinetics of the photoaquation of the hexacyanoferrate(II) ion.[2] It was shown that a simple scheme (see Fig. 3 in Ref. 2) explains all the experimental observations. The success of those experiments is due to the application of a cyanide-selective electrode. This sensor can sensitively monitor both the thermal reactions and the photoreactions without perturbing the system, even if the conversions are very small. Since there are many similarities in the photochemistry of the two cyano complexes, we have tried to investigate the photoaquation of the octacyanomolybdate(IV) ion in an alkaline medium by applying the same experimental and computational methods as in the case of the hexacyanoferrate(II) ion.[2]

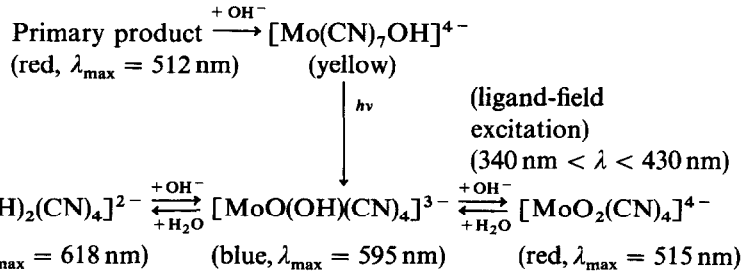
The aqueous solution of the complex ion is stable in the dark. The rate constant of its thermal aquation reaction was determined by Wilson *et al.*[3] Its value is $8.5 \times 10^{-8}\ s^{-1}$. It is well known[1] that on illumination by sunlight or 365-nm monochromatic light the yellow coloured aqueous solution of the complex turns to red and hydrogen cyanide is formed simultaneously. By interrupting the illumination, the solution turns back to its original yellow. The photoreaction is reversible. If, however, the irradiation time is longer, the transient red colour disappears and the solution turns irreversibly green and finally blue. Formation of a blue precipitate can also be observed at a high concentration of the complex.

Mitra and Mohan[4] isolated a yellow complex as a potassium salt by addition of a calculated amount of KOH to the red solution. The composition of this yellow complex was $K_4MO(CN)_7(OH)$. Their experiments suggest that the blue product is formed by *photolysis* of *this* complex ion, rather than, as previously supposed, by a series of thermal reactions. A careful investigation of this blue product showed that it should be a mixture of different

*Dedicated to Professor Viktor Gutmann on the occasion of his 65th birthday.

†Author to whom correspondence should be addressed.

species. Their results can be summarized by the following scheme:



Surprisingly, the composition of the primary product is still a subject of controversy in the literature. A number of investigations[5-8] support the following simple reaction (A) as the primary process:

$$[Mo(CN)_8]^{4-} \overset{h\nu(LF),\,+H_2O}{\rightleftharpoons} [Mo(CN)_7(H_2O)]^{3-} + CN^-. \quad \text{(A)}$$
(yellow) (red)

Jakob *et al.*[9] proposed reaction (B) that results in an increase in the coordination number:

$$[Mo(CN)_8]^{4-} \overset{h\nu(LF),\,+2H_2O}{\rightleftharpoons} [Mo(CN)_8(H_2O)_2]^{4-}. \quad \text{(B)}$$

Reaction (C) was suggested by different authors[10,11] according to spectrophotometric investigations:

$$[Mo(CN)_8]^{4-} \overset{h\nu(LF),\,+OH^-}{\rightleftharpoons} [Mo(CN)_7(OH)]^{3-} + CN^-. \quad \text{(C)}$$

The conductometric and pH titration curves[12] of the photolysed solutions of octacyanomolybdic acid corresponding to the stage of maximum optical density at 512 nm showed a sharp minimum and an inflexion, respectively, at 4 equivalents of KOH per mole of the complex. First the three strong H^+ ions were neutralized and then in a slow reaction 1 equivalent of the base was consumed. This latest process was attributed to a ligand exchange reaction, in which the coordinated water molecule of the product of reaction (A) was replaced by an OH^- ion. According to these observations, reactions (B) and (C) cannot be taken into account as the main photoreactions.

Our esperimental set-up allows us to determine simultaneously the free cyanide ion concentration and the optical density at the characteristic wavelength of the red species. Therefore we can perform a *direct* experimental investigation of the primary process. Only such an experiment can finally resolve the controversy.

We hoped that an exact kinetic investigation of the photoaquation by our method[2] would result in an accurate value of the quantum yield, since rather different values were determined earlier by different methods (Table 1.)

EXPERIMENTAL

Potassium octacyanomolybdate(IV) dihydrate was obtained by the method of Van de Poel and Neumann.[14] The yellow crystals were recrystallized 4 or 5 times from ethanol solutions. Purity was controlled by a spectrophotometric method (ε = 15,540 mol^{-1} dm^3 cm^{-1} at 240 nm).

(A) Investigation of the stoichiometry of the primary photoreaction

120 cm^3 of 2.5 × 10^{-3} mol dm^{-3} potassium octacyanomolybdate(IV) solution was put into a 150 cm^3 beaker. The pH of the solution was adjusted to 10.3 by adding a few drops of 1.0 M

Table 1. Quantum yield (Φ) of the photoaquation of the octacyanomolybdate(IV) ion on the exposure to 365-nm light

Determination of cyanide ion production by spectrophotometric method, pH = 8–12 in borate buffer	0.15	13

carbonate-free sodium hydroxide solution. The solution was kept in the dark and under an argon atmosphere for at least 30 min. The free cyanide concentration was monitored potentiometrically by using an OP-711-D-I ion-selective electrode and a Radiometer Type K401 saturated calomel electrode with an OP-205 Radelkis mV-meter. The pH of the solution was measured by a combined glass electrode (GK 301 B Radiometer) and a PHM-51 Radiometer mV-meter. A Hitachi–Perkin–Elmer 139 single-beam spectrophotometer was used for determination of the absorbance of the red product at 512 nm. The optical length of the flow-cell was 0.51 cm. The solution was stirred with a magnetic stirrer.

After reaching an equilibrium state in the dark, the solution was irradiated by sunlight. (Although sunlight is not monochromatic, its intensity is much more higher than that of the lamp used in our standard photochemical experiments. Therefore, on illumination by sunlight the red state was reached within a few minutes.)

The side of the beaker opposite to the direction of the irradiation was covered with an aluminium foil to maintain nearly the same intensity of irradiation in the whole volume of the solution.

(B) Kinetics of the photoaquation in an alkaline medium

A detailed description of the photochemical device is given in our earlier paper.[2] In these experiments, however, the light source was a TUNGSRAM PRK-2 medium-pressure mercury lamp. The constant intensity of irradiation was measured by the ferrioxalate method.[15] It amounts to $2.1 \pm 0.1 \times 10^{-10}$ mol of photons (365 nm) cm^{-2} s. For monitoring the reaction, the same electrodes and mV-meters were used as described in part (A) of this section.

RESULTS AND DISCUSSION

Figure 1 shows the simultaneous changes in the absorbance at 512 nm and the free cyanide concentration on exposure to sunlight. The cyanide ion concentration increases monotonically to a final value that corresponds to 1.8 mol of free cyanide

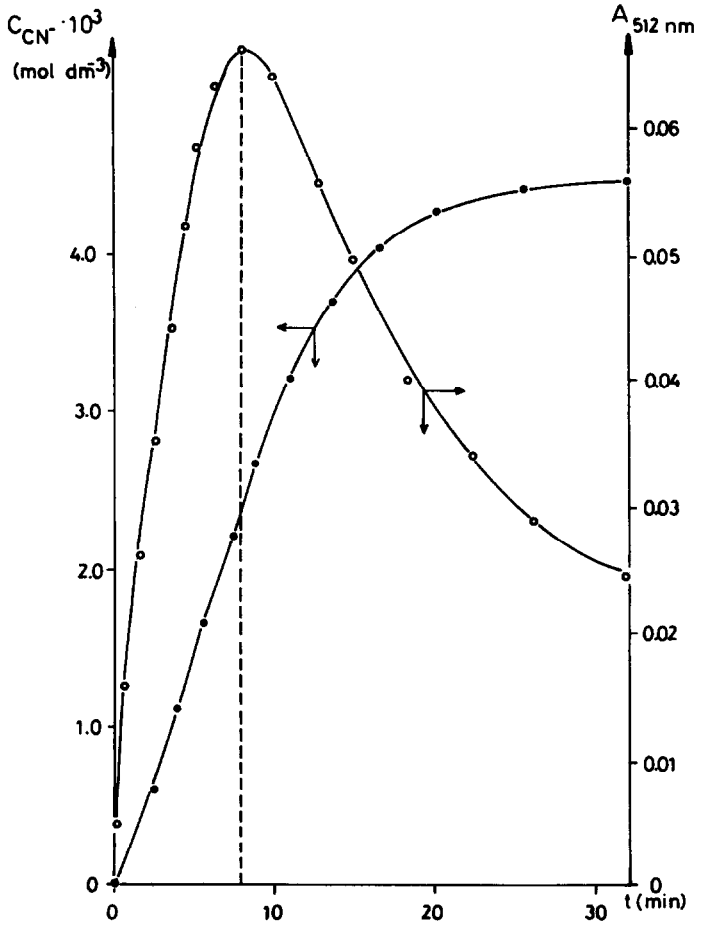

Fig. 1. Simultaneous change in the free cyanide ion concentration (●) and absorbance (○) at 512 nm on exposure to sunlight. $[Mo(CN)]_o^{4-} = 2.5 \times 10^{-3}$ mol dm^{-3}.

ion released by 1 mol of the initial complex ion. The absorbance changes according to a maximum curve. At the maximum value the free cyanide ion concentration is 2.35×10^{-3} mol dm^{-3}. Since in a strongly alkaline solution the amount of hydrogen cyanide formed can be neglected, the kinetic mean coordination number ($\bar{n}_t$) can be calculated by the following equation:

$$\bar{n}_t = \frac{T_{CN} - [CN^-]_t}{T_{Mo}}$$

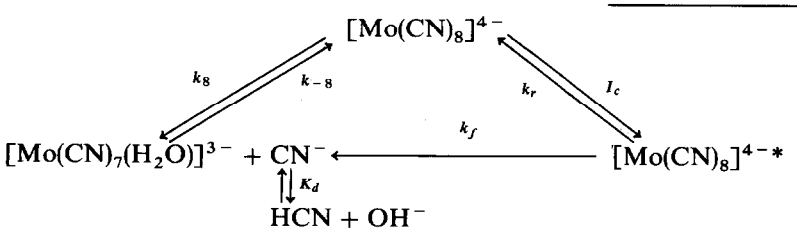
where T_{CN} and T_{Mo} are the analytical concentrations, and $[CN^-]_t$ is the actual concentration of the free cyanide ion. At the maximum value of the absorbance $\bar{n}_{max} = 7.06$. *This value is in good agreement with the stoichiometry proposed by reaction (A).*

The roughly estimated molar absorbance of the red species is about 50 mol^{-1} dm^3 cm^{-1}. Its magnitude is consistent with the fact that the ligand-field transitions are symmetry-forbidden.

The small decrease (0.1–0.2 pH units) in pH during the irradiation confirms the reaction scheme of Mitra and Mohan.[4]

When the intensity of the irradiating light is small as in our kinetic experiments and the time of illumination is not too long, the reaction system remains in the so-called reversible stage. Figure 2 shows a few periods of the alternating increase and decrease in the free cyanide concentration in the subsequent periods of illumination and darkness.

This behaviour of the system can be qualitatively described by scheme (D), neglecting the decomposition and the ligand exchange reaction of the red species:



(D)

This scheme is completely analogous to the scheme applied for the description of the kinetics of the photoaquation of the hexacyanoferrate(II) ion in alkaline solution. (The water molecules are systematically omitted from the scheme.) I_c is the average number of moles of photons (365 nm) absorbed by the complex ion per unit volume and unit time. In our experiments it amounts to 6.3×10^{-8} mol of photons dm^{-3} s^{-1}. $[Mo(CN)_8]^{4-*}$ is the excited state of the complex ion. k_r and k_f are the first-order rate constants of the recombination and decomposition of the excited complex ion, respectively. k_8 and k_{-8} are the rate constants of the thermal reactions. K_d is the dissociation constant of hydrogen cyanide.

Introducing the quantum yield Φ $[= k_f/(k_f + k_r)]$ and applying the steady-state approximation for the concentration of the excited complex ion, the following rate equation can be derived:

$$-\frac{d[Mo(CN)_8]^{4-}}{dt} = \frac{d[Mo(CN)_7(H_2O)]^{3-}}{dt} = \Phi I_c + k_8[Mo(CN)_8]^{4-} - k_{-8}[Mo(CN)_7(H_2O)^{3-}][CN^-].$$

Taking into account that the total amount of cyanide released by the complex ion always equals the concentration of the heptacyano complex ion, the concentration of hydrogen cyanide, cyanide and hydroxide ions can be calculated as the components of an acid–base equilibrium system. The exact values of the constants of the kinetic equation were calculated by a least-squares method from the linear algebraic system of the equations given for the parameters. The calculation of the kinetic curves (full lines in Fig. 2) was based on the required combination of the fourth-order Runge–Kutta and Newton–Raphson numerical methods. The values of the constants are: $\Phi = 1.0$, $k_8 = (6.55 \pm 0.8) \times 10^{-9}$ s^{-1}, and $k_{-8} = (7.88 \pm 0.5) \times 10^{-2}$ mol^{-1} dm^3 s^{-1}. According to these data the photostationary (A^*) and thermal-equilibrium (A) values of free cyanide ion concentration can be calculated. As is shown by Fig. 2, the difference between these values is nearly one order of magnitude only. The reversibility of the photoaquation can be interpreted in the light of the two stable solutions, depending on the conditions.

Applying the definition of the $\bar{n}_t$, its change during the reaction can be easily calculated (see dashed line in Fig. 2). The conversions in both photoreactions and thermal reactions are small (1.98 and 0.11%, respectively). Nevertheless, these very small changes could be exactly determined because of the high sensitivity of the cyanide ion selective electrode.

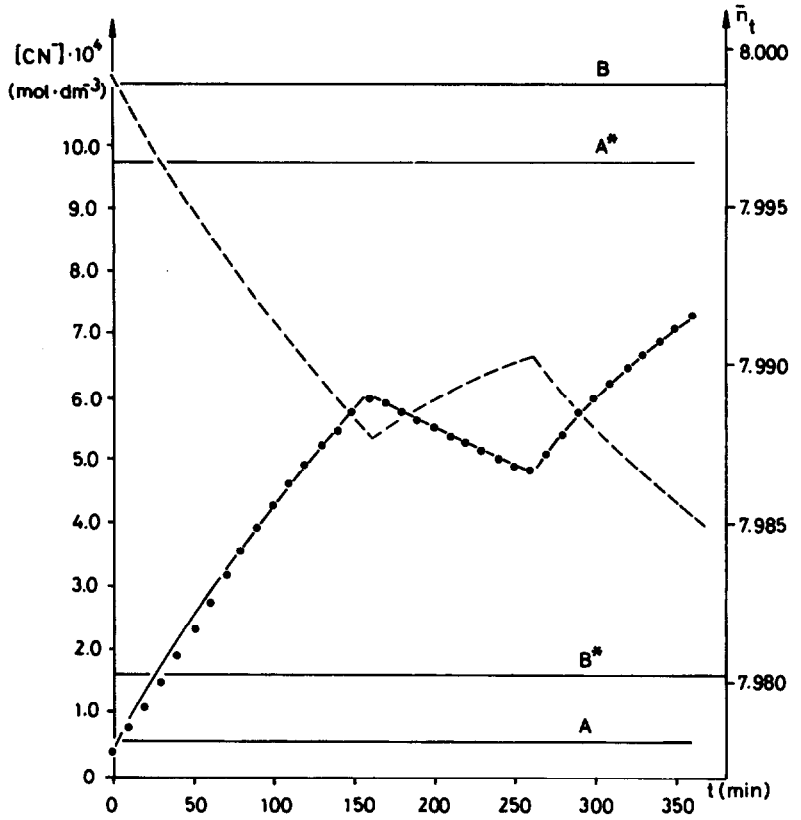


Fig. 2. Experimental (●) and calculated (full line) changes in the free cyanide ion concentration in 5.0×10^{-2} mol dm^{-3} octacyanomolybdate(IV) solution at pH = 10.5. The order of periods is: illumination, darkness, illumination. Dashed line: calculated change in the kinetic mean coordination number ($\bar{n}_t$). *A* and *A** are the thermal and photostationary values of the free cyanide ion concentration, respectively. *B* and *B** are the analogous values of the coordination number.

It follows from the kinetic data that the stability constant of the eighth complex (K_8) ($=k_{-8}/k_8$) is $(1.2 \pm 0.1) \times 10^7$ mol^{-1} dm^3. Unfortunately, no reference *data* are available in the literature on the stability of the complex ion or on the stepwise complex formation reactions. Our result is consistent with the fact that the hexacyanoferrate(II) ion is more stable in alkaline solution and its K_6 value[2] is higher by a factor of 5.

One should take into consideration that scheme (D) is correct only in the case of small conversions. For describing the complete photochemical decomposition of the octacyanomolybdate(IV) ion, scheme (D) should be simply extended by the reaction scheme of Mitra and Mohan.[4]

SOME ORGANOPEROXO COMPLEXES OF MOLYBDENUM AND TUNGSTEN

M. T. H. TARAFDER* and A. R. KHAN

Department of Chemistry, University of Rajshahi, Rajshahi, Bangladesh

(*Received* 17 *April* 1986; *accepted* 23 *June* 1986)

Abstract—Several new peroxo complexes of molybdenum and tungsten containing different organic ligands have been prepared. The complexes have the compositions $[Mo(O)(O_2)L_2]$, $[Mo(O)_2(O_2)L(H_3O)]^+$, $[Mo(O)(O_2)L']$ and $[W(O)(O_2)L_2]$ [L = oxoquinolino, aniline-2-carboxylate, 2-aminophenoxide, picolinato or 2-carboxylatoquinolino ligand; L′ = *N*-(2-oxophenyl)salicylidenimino ligand], respectively. The complexes were found to oxidize allyl alcohol, and also PPh_3 and $AsPh_3$, to their oxides. The IR spectra of the complexes indicate that the frequency of the ν_1-mode of the $M(O_2)$ grouping, which is essentially an O—O stretch, decreases with the increase in atomic number of metals in a particular group.

In recent years, there has been considerable interest in the dioxygen complexes of transition metals because of their coordination chemistry as well as their role in synthetic organic chemistry.[1–10] Dioxygen itself is a reactive entity but, since it has a triplet ground state, its direct combination with organic molecules is a spin-forbidden process.[2] Transition metals having multiple spin and oxidation states can readily interact with dioxygen, and, in some cases, they form isolable oxygen adducts.

Investigations into the fixation and activation of molecular oxygen by transition metals were largely initiated to understand the bondings and structures of such compounds, but later these were found to be both stoichiometric and catalytic reagents for epoxidation of olefins, allyl alcohols etc. We have been interested to extend such a study with new hetero ligand peroxo complexes of molybdenum and tungsten. We report here the synthesis of these complexes and their possible oxygen transfer reactions.

EXPERIMENTAL

Physical measurements

IR spectra (as KBr discs) were recorded with a Pye–Unicam SP3-300 IR spectrophotometer. Conductivities of solutions in nitrobenzene or *N*, *N*′-dimethylformamide (DMF) were measured at 298 K with a conductivity bridge type M.C.3 (Electronic Switchgear Ltd, London). 10^{-3} M solutions of the complexes were used for this purpose.

Reagents

All chemicals used were of reagent grade and were used as supplied by Merck.

Analyses

Molybdenum and tungsten were determined gravimetrically.[11] Methanolic solutions of the peroxo complexes were titrated with Ce(IV) to determine the number of active oxygen atoms present.[11] Carbon and hydrogen analyses were done by Mikroanalytisches Labor Pascher, Germany.

Preparation of the Schiff base (L′)

This was prepared from 2-aminophenol and salicylaldehyde following the published procedure.[6]

Preparation of complexes

General method for the preparation of complexes (**1**, **3**, **4**, **6** *and* **7**): $M(O)(O_2)L_2$ [M = Mo(VI) *or* W(VI), L = *picolinato or 2-carboxylatoquinolino ligands*]. A suspension of MO_3 (0.013 mol) in 30%

*Author to whom correspondence should be addressed.

H_2O_2 (50 cm^3) was stirred overnight at 45–50°C to get a clear solution. This was cooled to 0°C when a solution of organic ligand L (0.026 mol) in acetone (20 cm^3) was added to it. The mixture was stirred while cooling at the same time in an ice–salt bath. A bright yellow precipitate appeared, which was washed successively with water and *n*-hexane, and dried *in vacuo* over P_4O_{10}.

Preparation of $H^+[Mo(O)_2(O_2)(C_6H_4NH_2COO)(H_2O)]$. The same procedure was applied to 2.2 g (0.0153 mol) of molybdic acid and 2.1 g (0.0153 mol) of 2-aminobenzoic acid. Yield 3.0 g (62%) of the complex.

Preparation of $[Mo(O)(O_2)C_{13}H_9NO_2]$. This was prepared from 1.5 g (0.01 mol) of molybdic acid and 2.4 g (0.01 mol) of *N*-(2-hydroxyphenyl)salicylidenimine. Yield 2.5 g (67%) of the complex.

Reaction of **1** *with allyl alcohol (reaction A)*

Compound **1** (6.5 g, 0.015 mol) was suspended in 20 cm^3 of tetrahydrofuran (THF), and a stoichiometric amount of allyl alcohol was added. The mixture was refluxed at 60°C for 24 h. Microdistillation under *ca* 19 mmHg yielded glycidol [0.5 g (57%)] at 145–150°C. The glycidol was identified from its boiling point.

Catalytic reaction of **1** *and* H_2O_2 *with allyl alcohol (reaction B)*

A 25-cm^3 quantity of allyl alcohol (21.3 g, 0.367 mol) was dissolved in 20 cm^3 of dioxane and 1.1 g of **1** was added followed by 25 cm^3 of 30% H_2O_2. The mixture was kept under reflux at 90°C for 24 h. The reaction mixture was filtered and the filtrate distilled at 19 mmHg pressure. The fraction collected at 175–180°C was identified as glycerol [18 g (53% yield)].

Reaction of **3** *with triphenylphosphine (reaction C)*

A solution of triphenylphosphine (0.7 g, 0.0026 mol) in THF (20 cm^3) was added to a solution of **3** (0.94 g, 0.0026 mol) in the same solvent (60 cm^3). The mixture was refluxed for 48 h. TLC indicated that the reaction was complete. The solution was filtered and the residue collected. A yellowish white powder was recovered from the filtrate which was identified as $OPPh_3$ [m.p. 155–157°C (lit. 157°C)].

Reaction of **4** *with triphenylarsine (reaction D)*

A solution of triphenylarsine (0.68 g, 0.0022 mol) in THF (30 cm^3) was added to a solution of **4** (0.86 g, 0.0022 mol) in the same solvent (70 cm^3). The mixture was refluxed for 72 h. TLC indicated that arsine was converted entirely into arsine oxide. The solution was filtered and the residue collected. Evaporation of the filtrate yielded the product [m.p. 187–189°C (lit. 189°C)].

Complexes **6** and **7** were also found to be effective stoichiometric reagents for the oxidation of PPh_3 and $AsPh_3$ to their oxides.

RESULTS AND DISCUSSION

The analytical and molar-conductance data (Table 1) are consistent with a seven-fold coordination of the metal atom. Titrations of methanolic solutions of the peroxo complexes with Ce(IV) indicated that **1**–**7** were monoperoxo complexes. The molar-conductance values indicated that all of the complexes were non-electrolytes in solution except for **2** which exhibited a value characteristic of a 1:1 electrolyte in DMF (Table 1). Literature values[12] for 1:1 electrolytes are comparable to ours. Alkalimetric titration of **2** indicated an inflection point at pH 6.3 which corresponds to the neutralization of the outer-sphere proton.

IR spectral data are shown in Table 2. The ν(O—H) band at 3405 cm^{-1}, observed in the free 8-hydroxyquinoline disappears upon coordination, which indicates deprotonation and coordination at the oxygen site. Further, in compounds **1** and **7**, the decrease in ν(C=N), by 50 and 30 cm^{-1}, respectively, relative to the free-ligand value (1610 cm^{-1}) indicates coordination by the heterocyclic nitrogen.[4,9,13] The shifting of ν(C=N) modes thus suggest that Mo(VI) acts as a stronger acceptor than W(VI). Complexes **2** and **3** show two ν(N—H_2) bands (Table 2) significantly lower than the values for 2-aminobenzoic acid and 2-aminophenol (3390, 3300 and 3414, 3342 cm^{-1}).[6] Complexes **2**, **4** and **6** show a decrease in ν(C=O) by 48, 85 and 77 cm^{-1}, respectively, from the free-ligand values, indicating carboxylate binding in the complexes.[4,6,13] In **4** and **6**, the appearance of ν(C=N) at 1595 and 1590 cm^{-1}, respectively, suggest that the heterocyclic nitrogen is coordinated to the metal atom. The Schiff-base *N*-(2-hydroxyphenyl)-salicylidenimine in complex **5** behaves as a tridentate–dinegative ligand coordinating at the imino nitrogen and two oxygen atoms.[6] In complex **5**, the decrease in ν(C=N) by 25 cm^{-1} relative to the free-ligand value[6] indicates coordination through the imino nitrogen atom.[14,15] The ν(O—H) band

[a]Relative band intensities are denoted by vs, s, m, w, sh and br, meaning very strong, strong, medium, weak, shoulder and broad, respectively.

observed in the free Schiff-base at 3290 cm^{-1} disappears upon coordination, which indicates deprotonation and coordination at the oxygen site. Further support for M—O′ (O′ = oxygen in organic ligand, M = Mo or W) and M—N bondings in **1–7** are evident from the appearance of ν(M—O′) and ν(M—N) modes at 375–405 and 280–312 cm^{-1}, respectively. All of the complexes display ν(M=O modes.[5]

The metal–peroxo grouping gives rise to three IR-active vibrational modes. These are predominantly O—O stretching (ν_1), the symmetric M—O stretch (ν_2), and the antisymmetric M—O stretch (ν_3). The characteristic ν_1(O—O) modes of **1–6** appear at 848–900 cm^{-1}. There is a decrease in ν_1 upon passing from molybdenum complexes to the tungsten complex **7**. The ν_1-mode was found to decrease further in the peroxo complex of uranium.[6] The ν_3 and ν_2-modes in **1–7** appear at 637–680 and 538–612 cm^{-1}, respectively. The assignments shown in Table 2 are based on comparisons with other peroxo complexes of molybdenum and tungsten.[4,5,16,17]

Reactivity

Peroxo complexes of melybdenum and tungsten were not explosive. These were found to liberate iodine on treatment with aqueous iodide. So that the possible reactivity of the present peroxo complexes toward olefinic compounds could be explored, compound **1** was allowed to react stoichiometrically with allyl alcohol (reaction A) which produced glycidol as indicated by an IR band at 1055 cm^{-1} assigned to a C—O—C stretching mode.[7,18] With H_2O_2 and only a catalytic amount of **1** (reaction B), the product isolated was glycerol as indicated by its boiling point. The IR spectrum was identical with that of an authentic sample. A possible reaction path is shown in Scheme 1.

Reactions C and D produced $OPPh_3$ and $OAsPh_3$, respectively. The products showed IR bands at 1190 and 880 cm^{-1}, assigned to ν(P=O) and ν(As=O) modes, respectively.[19,20] IR spectra of the metal residues of reactions C and D showed the disappearance of ν_1(O—O) bands, thereby indicating the transfer of peroxo oxygens to the substrates.

HAVE $Cp^*_2MoOCl_2$ AND $Cp^*_2WOCl_2$ EVER BEEN ISOLATED? ON THE REPRODUCIBILITY OF THE REPORTED SYNTHESES

PIETRO DIVERSI, GIOVANNI INGROSSO, ANTONIO LUCHERINI* and MARCO LANDUCCI

Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via Risorgimento 35, 56100 Pisa, Italy

(*Received* 15 *May* 1986; *accepted* 23 *June* 1986)

Abstract—The literature reports on the syntheses of $Cp^*_2MOCl_2$ (M = Mo or W, Cp* = cyclopentadienyl or indenyl) could not be confirmed, and attempts to prepare $(C_5H_5)_2MoOI_2$ by oxidative addition of I_2 to $(\eta^5\text{-}C_5H_5)_2MoO$ failed.

We were interested in studying the reactivity of the complexes $Cp^*_2MOCl_2$ (M = Mo or W; Cp* = C_5H_5, C_5Me_5 or indenyl) as suitable starting materials in organometallic chemistry and catalysis.

The preparation of the cyclopentadienyl and indenyl complexes, according to the following equation:

$$MOCl_4 + 2Cp^*H\,(\text{or } Cp^*Na) \xrightarrow{THF,\Delta} Cp^*_2MOCl_2 + 2HCl\,(\text{or NaCl})$$

has been reported by Multani *et al.*[1–6] since 1968 without mentioning possible problems in the isolation and crystallization of the products. These syntheses appeared very simple, and suitable to be extended to the preparation of $(C_5Me_5)_2MOCl_2$.

Surprisingly all the attempts to prepare these compounds were unsuccessful. This fact, in addition to the recent reports[7,8] on the failure to confirm the synthesis of $(C_5H_5)_2WOCl_2$ and other preparations by Multani *et al.*, stimulated us to relate our results.

RESULTS AND DISCUSSION

Molybdenum and tungsten oxide tetrachlorides

It has been repeatedly asserted by Multani *et al.*[2,3,5,9] that the $MOCl_4$ oxychlorides, necessary for the synthesis of the title complexes, were prepared from MO_3 in refluxing $SOCl_2$, following the preparation described by Colton and Tomkins.[10]

We have found that only $MoOCl_4$ could be easily obtained by this way, since WO_3 did not react in refluxing $SOCl_2$ even when a long reaction time (48 h) was employed. We succeeded in preparing $WOCl_4$ either by reacting WO_3 with an excess of S_2Cl_2 at 180°C,[11] or from tungstic acid (Fluka) in refluxing $SOCl_2$ for 3 h (yield 75% of sublimed product). This last route, which is analogous to that reported by Colton and Tomkins[10] who prepared $MoOCl_4$ from sodium molybdate and $SOCl_2$, has been independently discovered by Crabtree and Hlatky.[7]

Reaction of molybdenum and tungsten oxychlorides with Cp*H

According to the literature method,[1–6] the $MOCl_4$ oxychlorides were reacted with an excess of Cp*H ($[Cp^*H]/[MOCl_4]$ = 3–4) in refluxing THF for 6–8 h, giving dark-blue or black products insoluble in pentane and diethyl ether, hardly soluble in benzene, chloroform and methylene chloride, and partly soluble in THF. These solubilities were very much different from those reported for the expected complexes, and all attempts to obtain pure crystalline compounds failed. Moreover the raction products were found not to be inert to water, in contrast to the literature report.[4] Although the IR spectra were not well resolved, bands at 950–980 cm^{-1}, attributable to the stretching of M=O, were observed. The ^1H NMR spectra of

*Author to whom correspondence should be addressed.

the $CDCl_3$ or C_6D_6 extracts showed enlarged signals in the region of the Cp* resonances that might be indicative of a mixture of products and/or the presence of paramagnetic impurities. The results of elemental analyses changed from run to run, and in general the carbon and chlorine percentages were markedly lower than those calculated for the expected products.

In the case of the reaction of $WOCl_4$ with indene, the elemental analysis of the residue to the extraction (THF) of the crude reaction product gave a chlorine percentage close to that expected for $(C_9H_7)_2WOCl_2$, but a carbon percentage clearly lower; the elemental analysis of the product recovered from the THF extracts gave results that were consistent with the formulations $(C_9H_7)_3WOCl$ or $(C_9H_7)_3WOCl \cdot THF$ (see Experimental).

On the basis of these results, and of some reports[6,12] on the preparation of complexes of type Cp^*_4MoO on reaction of $Cp^*_2MoOCl_2$ or $MoOCl_4$ with Cp*Na, we repeated the reactions using a [Cp*H]/[$MOCl_4$] molar ratio of 2: we obtained again insoluble dark-blue or black crude products.

The same results were obtained by adding the Cp*H reagent at low temperature (−20°C), or varying the reaction time, or the solvent (benzene, diethyl ether or *n*-hexane), or carrying out the reaction in the presence of diethylamine as HCl trapper.

Since several alkyl complexes of type $(C_5H_5)_2WOR_2$ (R = Me, Et, Ph or CH_2Ph) were prepared[3] by alkylation of $(C_5H_5)_2WOCl_2$, we tried to obtain the methyl derivatives by the treatment of the crude residues with MeMgI in diethyl ether: we could not obtain any pentane-soluble product nor isolate other organometallic compounds.

Reactions of the molybdenum and tungsten oxychlorides with Cp*Na

In spite of many attempts carried out according to the described procedure,[1-6] we failed to obtain $(C_5H_5)_2MOCl_2$ by reacting $MOCl_4$ oxychlorides with two equivalents of C_5H_5Na in refluxing THF for 3–4 h. Instead brown-black precipitates were obtained, which were extracted with THF. Addition of *n*-hexane to these solutions caused the precipitation of blue-black compounds, whose IR analyses were indicative of the presence of C_5H_5 and M=O groups; however elemental analyses gave carbon and chlorine percentages lower by far than those calculated for the desired products (M = Mo, Found: C, 30.4; H, 3.7; Cl, 16.6%. Calc. for $C_{10}H_{10}Cl_2MoO$: C, 38.4; H, 3.2; Cl, 22.7%. M = W, Found: C, 21.6; H, 2.9; Cl, 12.5%. Calc. for $C_{10}H_{10}Cl_2OW$: C, 30.0; H, 2.5; Cl, 17.7%.)

In the case of the reactions of the $MOCl_4$ oxychlorides with C_9H_7Na in refluxing THF no precipitate formed: evaporation of the solvent led to residues insoluble in benzene and diethyl ether. Attempts to eliminate NaCl by washing with H_2O gave insoluble blue-black residues whose elemental analyses were very different (chlorine percentages always lower than 6%) from those calculated for the expected complexes.

Variations in some reaction parameters such as temperature (−20 to +20°C) or medium (*n*-hexane, diethyl ether or benzene) did not cause any improvement.

Since we were interested in the synthesis of Group VI transition metal metallacycles,[13] we treated the crude mixture obtained from the reaction of $MoOCl_4$ and C_5H_5Na with an excess of 1,4-dilithiobutane in diethyl ether. Chromatographic purification of the pentane-soluble materials on a column of neutral alumina yielded a small quantity of orange-red crystals identified as bis(η^5-cyclopentadienyl)molybdenacyclopentane by elemental analysis and by comparison of its ^1H NMR spectrum with that of an authentic sample.[13] We do not know whether $(\eta^5\text{-}C_5H_5)_2Mo(CH_2CH_2CH_2CH_2)$ is derived from the alkylation of the $(\eta^5\text{-}C_5H_5)_2MoCl_2$ compound, or from $(C_5H_5)_2MoOCl_2$, 1,4-dilithiobutane behaving both as a reducing and an alkylating agent.

Alkylation of the other crude mixtures obtained from $MOCl_4$ and Cp*Na with 1,4-dilithiobutane failed to give identifiable organometallic compounds.

Reaction of bis(cyclopentadienyl)molybdenum oxide with I_2

In the attempt to obtain $(C_5H_5)_2MoOI_2$ by an alternative route, we reacted the $(\eta^5\text{-}C_5H_5)_2MoO$ complex[14] with I_2 in THF at room temperature, but the desired oxidative addition of I_2 did not occur, and we recovered a precipitate (59% yield) identified as $(\eta^5\text{-}C_5H_5)_2MoI_2$ by comparison of its IR and ^1H NMR spectra with those of an authentic sample.[15] No organometallic compound was isolated from the THF solution.

In contrast to the literature reports[1-6] the reactions described here failed to give the desired compounds, leading always to mixtures of insoluble, intractable compounds.

We cannot, of course, exclude the possibility that our failure to repeat the described syntheses of the title compounds is due to some unpublished but important experimental detail. However, on the basis of these and other[7] efforts to repeat this

chemistry, we would suggest that one must be careful before choosing $Cp^*_2MOCl_2$ complexes as starting materials.

EXPERIMENTAL

All operations were carried out under dinitrogen or argon by Schlenk techniques. Diethylether and THF were first refluxed and distilled from sodium, and then from lithium aluminum hydride. Pentane and benzene were washed free of olefins or thiophene with concentrated sulphuric acid, dried on calcium chloride, and then distilled from lithium aluminum hydride. Unless otherwise stated, other solvents were reagent grade, and were degassed under reduced pressure and dried on molecular sieves before use.

IR spectra were run on a Perkin–Elmer 283-B instrument. ^1H NMR spectra were run at 60 MHz on a Varian T60 instrument using $SiMe_4$ as the internal standard. Microanalyses were performed by the Laboratorio di Microanalisi of the Istituto di Chimica Organica, Facoltà di Farmacia, Università di Pisa.

$MoOCl_4$,[10] $WOCl_4$,[7] C_5H_5Na,[16] C_9H_7Na,[17] $Li(CH_2)_4Li$[18] and $(\eta^5\text{-}C_5H_5)_2MoO$[14] were prepared as described.

The reactions of $MOCl_4$ with Cp*H (or Cp*Na) were performed as described,[1–6] or with the variations described in Results and Discussion; the resulting solid products were washed with diethyl ether and pentane, and then dried *in vacuo* (0.1 mmHg). The reactions of 1,4-dilithiobutane with the crude products obtained by reacting $MOCl_4$ oxychlorides with Cp*Na were carried out according to the described procedures.[13]

Reaction of $WOCl_4$ *with indene*

$WOCl_4$ (1.20 g, 3.52 mmol) dissolved in benzene (50 cm^3) was treated with freshly distilled indene (1.8 cm^3, 15.4 mmol). The resulting mixture was refluxed for 14 h and then the brown solid formed was separated, washed with diethyl ether (3 × 30 cm^3) and extracted with THF (2 × 50 cm^3). The insoluble black residue was recovered and dried *in vacuo*. (Found: C, 35.3; H, 2.7; Cl, 15.4%. Calc. for $C_{18}H_{14}Cl_2OW$: C, 43.2; H, 2.8; Cl, 14.2%.) Evaporation to dryness of the THF extracts gave a brown solid which was washed with pentane and dried *in vacuo*. (Found: C, 58.3; H, 4.6; Cl, 6.5%. Calc. for $C_{27}H_{21}ClOW$: C, 55.8; H, 3.6; Cl, 6.1%. Calc. for $C_{31}H_{29}ClO_2W$: C, 57.0; H, 4.5; Cl, 5.5%.)

Reaction of $(\eta^5\text{-}C_5H_5)_2MoO$ *with* I_2

$(\eta^5\text{-}C_5H_5)_2MoO$ (0.241 g, 1.0 mmol) dissolved in THF (50 cm^3) was treated with I_2 (1.0 mmol, 4 cm^3 of a 0.25 mol dm^{-3} THF solution). The resulting mixture was stirred at room temperature for 4 h and then the black solid formed was separated, washed with diethyl ether (3 × 10 cm^3), and dried *in vacuo*. $(\eta^5\text{-}C_5H_5)_2MoI_2$ (0.284 g, 59% yield) was obtained. (Found: C, 25.6; H, 2.6; I, 53.1%. Calc. for $C_{10}H_{10}I_2Mo$: C, 25.0; H, 2.4; I, 52.7%.)

COMPLEXES OF 1-(2′-HYDROXYBENZYL)-2-(2′-HYDROXYPHENYL)-BENZIMIDAZOLE WITH U(VI) AND Ce(IV)

K. M. M. S. PRAKASH, L. D. PRABHAKAR* and M. C. CHOWDARY

Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515003, India

(*Received* 9 *December* 1985; *accepted after revision* 27 *June* 1986)

Abstract—Some new U(VI) and Ce(IV) complexes of 1-(2′-hydroxybenzyl)-2-(2′-hydroxyphenyl)-benzimidazole have been prepared and characterized by spectral, magnetic and conductance studies. IR spectral data suggests that the ligand in all the complexes is monodenate through the tertiary nitrogen and that the phenolic oxygen is free from coordination. Conductivity measurements indicate that the nitrate and acetate complexes of U(VI) are non-electrolytes, whereas the nitrate complex of Ce(IV) is a 1:1 electrolyte.

Uranyl complexes with various nitrogen and oxygen donars have been extensively reviewed.[1–7] Recently the Schiff's base compounds have aroused new interest because of their high stability, and they can be used for selective chemical separations.[8,9] Herein we report the synthesis and characterization of the uranyl and cerium complexes.

EXPERIMENTAL

Physico-chemical measurements

Elemental (C, H and N) analyses of the complexes were recorded in the Analytical Division, Regional Research Laboratory, Hyderabad, India. IR spectra were recorded in both Nujol mulls and KBr pellets on a Perkin–Elmer 983 G IR spectrophotometer. Magnetic susceptibilities for the solid compounds were determined by the Guoy method using $Hg[Co(NCS)_4]$ as standard. The molar conductances of the complexes were determined by using Systronics direct reading Conductivity Meter 303.

Synthesis and characteristics of the ligand

1-(2′-Hydroxybenzyl)-2-(2′-hydroxyphenyl)-benzimidazole was prepared according to Subbarao and Ratnam[10] by refluxing 1,2-phenylenediamine with salicylaldehyde (1:3) in glacial acetic acid. The white product that separated was recrystallized from MeOH.

The IR spectra measured in KBr pellets showed a peak at 1480 cm^{-1} which can be assigned to $\nu(C{=}N)$ stretching. A peak at 3500–3700 cm^{-1} corresponding to the free phenolic —OH is not observed; instead a peak at 3300 cm^{-1} confirms the intramolecular hydrogen bonding of the two —OH groups.[11–13] Based on the above observations the structure of the ligand can be represented as

	C	H	N
Calculated	75.9	5.6	8.9
Experimental	75.8	5.8	8.7

Preparation of the compound

The complexes were prepared by refluxing methanolic solutions of ligand and corresponding metal salts at 70–80°C. The solution containing the complex was evaporated *in vacuo* until the solid crystallizes. The precipitates were filtered off and washed with aqueous MeOH. The product was dried *in vacuo* for 24 h.

Physical properties

Uranyl(VI) nitrate, uranyl(VI) acetate and Ce(IV) nitrate complexes are soluble in MeOH, DMSO

and DMF. All the complexes are crystalline powders, decomposed only by strong hot perchloric acid.

Chemical analysis

Uranium was determined by the oxine method as U_3O_8 and cerium was estimated by the Ce(IV) iodate method and subsequent ignition to CeO_2.[14]

RESULTS AND DISCUSSION

Analytical data of the complexes and ligand are shown in Table 1. The ligand has two potential sites for co-ordination, the pyridine nitrogen and the phenolic oxygen atom. Since no change was observed in the pH of the free-ligand solution and its solution after complexation, it can be inferred that the ligand has not been deprotonated. This fact is also supported by the IR spectra where the shift corresponding to the —OH stretching vibration is not observed.

IR spectra

IR spectra of the ligand and its metal chelates* shows a strong IR absorption around 3300 cm^{-1} which is due to —OH stretching vibrations associated with intramolecular hydrogen bonding.[12,13] The hydrated complexes also show a strong absorption in the same region. There is no absorption at 1605 and 900 cm^{-1} corresponding to stretching, and scissoring and rocking modes of vibration of co-ordinated water. Beyond 1600 cm^{-1} the first absorption band in the ligand appears between 1590 and 1450 cm^{-1}, which can be attributed to the C=C of the phenyl ring and the C=N stretching frequency. The ν(C=N) band in the ligand observed at 1480 cm^{-1} is shifted to 1470 cm^{-1} in its complexes. Hence it can be concluded that co-ordination takes place through the pyridine nitrogen and the ligand acts as a neutral one.

The unco-ordinated nitrate (D_{3h}) is expected to exhibit three IR-active fundamentals: $\nu_2(A_2)$, 831 cm^{-1}; $\nu_3(E)$, 1390 cm^{-1}; and $\nu_4(E')$, 790 cm^{-1}; whereas a co-ordinated nitrate (C_{2v}) exhibits six such fundamentals:[15] $\nu_4(B_1)$, 1530–1480 cm^{-1}; $\nu_1(A_1)$, 1290 cm^{-1}; $\nu_2(A_1)$, 1030 cm^{-1}; $\nu_5(B_2)$, 810 cm^{-1}; $\nu_3(A_1)$, 740 cm^{-1}; and $\nu_6(B_1)$, 731 cm^{-1}. In the nitrate complexes of Ce(IV) and U(VI) the $\nu_4(B_1)$ mode falls in the range 1435–1460 cm^{-1} and $\nu_1(A_1)$ in the range 1250–1320 cm^{-1}. The magnitude of $\nu_4 - \nu_1 \neq (140–185\ cm^{-1})$ in these complexes might be considered to be in favour of the bidentate character of the C_{2v} nitrate,[16] though this has not been considered as a good criterion to distinguish between a bidentate and a monodentate nitrate by Kowano and Osokio.[17] A very weak band at 1010–1035 cm^{-1} is assigned to the $\nu_2(A_1)$ mode and those in the region 790–815 cm^{-1} to the $\nu_5(B_2)$ mode of the C_{2v} nitrate. The $\nu_6(B_1)$ mode is

*A table of IR spectral data has been deposited with the Editor as supplementary material.

not observed in both of the nitrate-containing complexes, similar to results of Mishra *et al.*[18] In the sulphate complexes the peaks at 1050, 1160 and 1230 cm^{-1} can be attributed to the bidentate bridging sulphate groups.[16,19] The sharp peak at 1550 cm^{-1} which is absent in the ligand and other complexes is attributed to the ν_{assy}-mode of the monodentate acetate group.[15] The metal–chloride stretching frequency of the uranyl chloride is observed in the range 250–350 cm^{-1} as a weak band, which is absent in the ligand.[20,21]

The uranyl ion exhibits[22,23] three vibrational frequencies: a symmetric (ν_1), asymmetric (ν_3), and stretching and bending (ν_2) frequency. With the linear uranyl ion, only the asymmetric stretching is easily observed in the normal IR spectrum, since the bending frequency is predicted to be around 200 cm^{-1} and the symmetric stretching is IR-inactive. The observed frequencies (890–920 cm^{-1}) lie below that found for an aqueous solution of UO_2^{2+}.

Conductance measurements

The molar conductance of the complexes are shown in Table 1. All the complexes except the Ce(IV) nitrate complex, show a low conductance in DMSO, DMF and MeOH which shows that they behave as non-electrolytes[24] in these solvents. The Ce(IV) nitrate complex shows a conductance attributable to a uni-univalent electrolyte, $[Ce(NO_3)_3L_2]^+NO_3^-$, in all solvents, which indicates that three of the four nitrate groups are in a co-ordination sphere whereas the fourth one is out of the sphere. Thus it can be concluded that only in the Ce(IV) nitrate complex is the nitrate group acting as ionic, monodentate and bidentate. The ability of the nitrate group to function as both a monodentate and a bidentate ligand has been recognized earlier.

Magnetic susceptibilities

All complexes are diamagnetic, as generally expected for $5f^0$U(VI) and $4f^0$Ce(IV) compounds, and it can be concluded that reduction of the metal does not take place under the influence of the ligand.

PREPARATION OF NOVEL PENTAAZA MACROCYCLIC SCHIFF BASE LIGANDS AND APPLICATION OF ONE AS A HIGHLY SELECTIVE EXTRACTANT FOR COPPER(II)

TAKAYUKI MATSUSHITA,* KAZUHIKO TAKAISHI, MANABU FUJIWARA and TOSHIYUKI SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 17 *December* 1985; *accepted after revision* 27 *June* 1986)

Abstract—The novel macrocyclic Schiff base ligands L^1, L^2 and L^3 were prepared by the condensation of *N,N'*-bis(2-formyl-4-nitrophenyl)ethylenediamine with ethylenediamine, bis(3-aminopropyl)amine and *N,N*-bis(3-aminopropyl)methylamine, respectively, under high-dilution conditions. Their complexing abilities and extractabilities for transition-metal ions have been investigated and L^2 has been found to be an excellent extractant for copper(II).

Many macrocyclic ligands, such as crown ethers and polyaza compounds, have been extensively synthesized and their complexation with metal ions investigated. However, the complexation and extractability of unsaturated polyaza macrocycles for transition-metal ions have been little studied so far. Zolotov *et al.* reported several tetraaza macrocyclic Schiff base ligands which can selectively extract copper(II).[1–3]

Recently, we have reported that the dinitro-substituted ligand of 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,5,7,12-tetraene has a much more efficient extraction rate and selectivity for copper(II) than the parent macrocycle.[4] Moreover, we have reported that the polymeric ligands containing a tetraaza macrocyclic Schiff base in the polymer backbone can be applied as effective extractants[5,6] and adsorbents[7] selective for copper(II).

In this paper, we will describe the preparation of novel pentaaza macrocycle Schiff base ligands (Fig. 1) and their extractabilities for transition-metal ions such as copper(II), nickel(II) and cobalt(II).

EXPERIMENTAL

Preparation of macrocyclic Schiff base ligands

N,N'-bis(2-formyl-4-nitrophenyl)ethylenediamine was prepared as yellow crystals, according to the methods described in the literature.[8,9]

L^1, L^2 and L^3 stand for 7,8,15,16,17,18-hexahydro-3,12-dinitrobenzo [*e, m*] [1,4,8,11] tetraazacyclotetradecane, 7,8,9,10,11,12,13,20,21,22,23-undecahydro-3,17-dinitrodibenzo[*e,r*] [1,4,8,12,16] pentaazacyclononadecane and 7,8,9,11,12,13,20,21,22,23-decahydro-*N*(10)-methyl-3,17-dinitro dibenzo[*e,r*][1,4,8,12,16]pentaazacyclononadecane, respectively.

These ligands were obtained as yellow crystals as follows: A solution of the required diamine or triamine in 50 cm^3 of *N,N*-dimethylformamide (DMF) was added slowly with stirring to a solution of 0.358 g (1 mmol) of *N,N'*-bis(2-formyl-4-nitrophenyl)ethylenediamine in 500 cm^3 of DMF which had been warmed at about 65°C. The yellow solution was stirred for 24 h at 65°C, and then the solvent was removed under reduced pressure. The resulting yellow powder was collected on a glass filter, washed with ethanol, and dried *in vacuo*. The yields of the ligands were 70–80%.

L^1: m.p. 299–300°C (decomp.). Found: C, 56.5; H, 4.7; N, 21.9%. Calc. for $C_{18}H_{18}N_6O_4$: C, 56.5; H, 4.7; N, 22.0%. IR (in KBr disc): 1635, 1605,

MS: m/z = 467 (M^+ = 467). ^1H NMR (in $CDCl_3$): δ (ppm) = 1.62–1.90 (m, 6H, CH_2—$C\underline{H}_2$—CH_2 and C_6H_3—N$\underline{H}$); 2.15 (s, 3H, N—$C\underline{H}_3$); 2.42–2.62 (t, 4H, $C\underline{H}_2$—N—CH_3); 3.60–3.78 (m, 8H, CH=N—$C\underline{H}_2$ and C_6H_3—NH—$C\underline{H}_2$); 6.58–8.26 (m, 6H, $C_6\underline{H}_3$); and 8.35 (s, 2H, C$\underline{H}$=N). These assignments were made according to those for the analogous compounds described in the literature.[10,11]

Preparation of copper(II) and nickel(II) complexes with L^1

The copper(II) and nickel(II) complexes with L^1 were prepared according to the literature,[9,12] and confirmed by the elemental analyses.

Preparation of copper(II) and nickel(II) complexes with L^2

To a DMF solution (100 cm^3) of copper(II) acetate monohydrate (0.2 g, 1 mmol) was added L^2 (0.45 g, 1 mmol), the solution was stirred for 2 h at 50°C, and then the solvent was removed to dryness under reduced pressure. The resulting brown powder was collected on a glass filter, washed with ethanol, and recrystallized from DMF. The yield was 79%. Found: C, 50.4; H, 4.9; N, 18.2%. Calc. for $Cu(C_{22}H_{25}N_7O_4)$: C, 51.3; H, 4.9; N, 19.0%. IR (in KBr disc): 1610, 1590, 1535, 1490, 1430, 1275, 1245, 1180, 1150, 1105, 820, 750 and 690 cm^{-1}.

A nickel(II) complex of L^2 was obtained in a similar manner to that described for the copper(II) complex, using nickel(II) acetate tetrahydrate in place of the copper salt. It was recrystallized from DMF. The yield was 76%. Found: C, 50.9; H, 4.9; N, 18.8%. Calc. for $Ni(C_{22}H_{25}N_7O_4)$: C, 51.8; H, 4.9; N, 19.2%. IR (in KBr disc): 1610, 1590, 1535, 1485, 1430, 1285, 1250, 1185, 1155, 1100, 800, 750 and 690 cm^{-1}.

Preparation of copper(II) and nickel(II) complexes with L^3

Both copper(II) and nickel(II) complexes with L^3 were obtained in a similar manner to those described for L^2. These were recrystallized from DMF. The yield of the copper(II) complex was 83%. Found: C, 52.0; H, 5.1; N, 18.5%. Calc. for $Cu(C_{23}H_{27}N_7O_4)$: C, 52.2; H, 5.1; N, 18.5%. IR (in KBr disc): 1605, 1590, 1535, 1490, 1435, 1400, 1285, 1245, 1160, 1105, 805, 750 and 700 cm^{-1}.

The yield of the nickel(II) complex was 78%. Found: C, 52.3; H, 5.2; N, 18.8%. Calc. for $Ni(C_{23}H_{27}N_7O_4)$: C, 52.7; H, 5.2; N, 18.7%. IR (in KBr disc): 1605, 1585, 1535, 1485, 1430, 1395, 1285, 1250, 1200, 1155, 1100, 795, 750 and 700 cm^{-1}.

Procedure for solvent extractions

Solvent extractions were carried out as described previously.[6]

Measurements

All measurements were carried out as described previously.[6]

Materials

All reagents were of reagent grade. DMF was distilled over CaH_2 under reduced pressure prior to use. Other solvents were purified by the usual manner. Water was deionized. Acetate buffer solutions (0.2 M) were used for adjusting pH from pH 3.5 to 5.8. The pH values below 3.5 or above 5.8 were adjusted by the addition of adequate amounts of 1 M hydrochloric acid or sodium hydroxide.

RESULTS AND DISCUSSION

The novel pentaaza macrocyclic Schiff base ligands were obtained in good yields by a high-dilution method. Their copper(II) and nickel(II) complexes were prepared by the reaction of the free ligands with metal ions and characterized by electronic spectroscopy. Moreover, these ligands were applied as extractants for transition-metal ions, and L^2 was found to be a highly selective extractant for copper(II).

Electronic spectra

Figure 2 shows the electronic spectra of the free ligands L^2 [Fig. 2(A)] and L^3 [Fig. 2(B)] and their copper(II) and nickel(II) complexes in DMF. L^2 and L^3 have an intense absorption band at 25.3 and 25.6 $\times 10^3$ cm^{-1}, respectively, which can be assigned to the $\pi \rightarrow \pi^*$ transitions. The spectra of the complexes show the absorption band shifted to lower energies: 21.9 $\times 10^3$ cm^{-1} for $Cu(L^2\text{-}2H)$, 20.4 $\times 10^3$ cm^{-1} for $Ni(L^2\text{-}2H)$, 21.8 $\times 10^3$ cm^{-1} for $Cu(L^3\text{-}2H)$ and 20.2 $\times 10^3$ cm^{-1} for $Ni(L^3\text{-}2H)$. These absorption bands can be assigned to the transitions from the same origin as the ligands. Moreover, in the visible region, the spectra of $Cu(L^2\text{-}2H)$ and $Cu(L^3\text{-}2H)$ exhibit an absorption band at 16.7 and 16.1 $\times 10^3$ cm^{-1}, respectively, which can be assigned to ligand field transitions. As for the nickel(II) complexes, the shoulder band was observed around 16.7 and 16.1 $\times 10^3$ cm^{-1} for $Ni(L^2\text{-}2H)$ and $Ni(L^3\text{-}2H)$, respectively. These bands can also be assigned to ligand field transitions.

The magnetic susceptibilities of $Ni(L^2\text{-}2H)$ and $Ni(L^3\text{-}2H)$ are diamagnetic, suggesting that the nickel(II) ion of these complexes may adopt a four-coordinate planar configuration. On the other hand, for $Cu(L^2\text{-}2H)$ and $Cu(L^3\text{-}2H)$ a coordinate environment about the copper(II) ion, four- or five-coordinate, could not be determined from the available data.

Solvent extractions by L^1, L^2 and L^3

Extractabilities of L^1–L^3 toward transition-metal ions such as copper(II), nickel(II) and cobalt(II) have been studied under various conditions.

Effect of shaking time on extraction

Figure 3 shows plots of percentage of copper(II) extracted by L^1–L^3 against shaking time. The concentrations of the extractants in chloroform and of the metal ion in the aqueous phase were 1 $\times 10^{-3}$ and 1 $\times 10^{-4}$ M, respectively, and the pH of the aqueous phase was adjusted to nearly 6.7 using a 0.2 M acetate buffer solution plus appropriate amounts of an aqueous solution of sodium hydroxide. The extraction rate by L^2 was found to be much faster than those by L^1 and L^2. Moreover, the percentage of copper(II) extracted by L^2 reached nearly 100% within 30 min, whereas with L^1 and L^3 only 20 and 40% of copper(II), respectively, were transferred into the organic phase after shaking for 4 h. The large difference in the extraction rates between L^2 and L^3 may arise from the difference in their hydrophilicity: the former possesses a secondary amino group (—CH_2NHCH_2—) which is more hydrophilic than the tertiary amino group [—$CH_2N(CH_3)CH_2$—] of the latter.

On the other hand, no nickel(II) and cobalt(II) were extracted by these extractants under the same conditions as the copper(II) case after shaking for 8 h.

Effect of pH on extraction by L^2

Figure 4 shows the effect of the pH of the aqueous phase on extractions of copper(II), nickel(II) and cobalt(II) by L^2. The extractions were made under the following conditions. The concentrations of L^2 in chloroform and of the metal ions in the aqueous

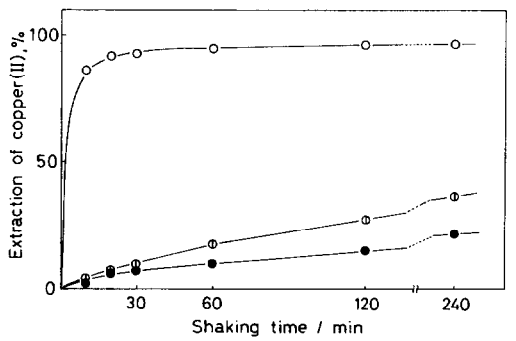

Fig. 3. Effect of shaking time on extraction of copper(II) (1×10^{-4} M) by L^1, L^2 and L^3 (1×10^{-3} M) at pH 6.7. (●)L^1, (○)L^2, and (Φ)L^3.

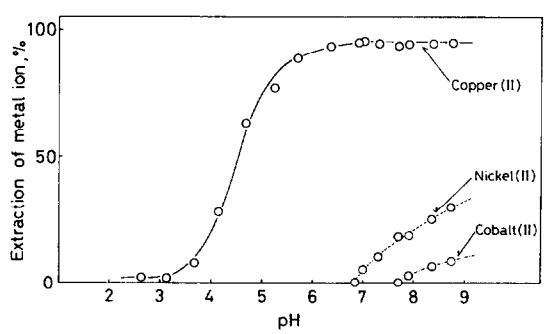

Fig. 4. pH dependence of extraction of metal ions (1×10^{-4} M) by L^2 (1×10^{-3} M). Shaking time 2 h.

phase were 1×10^{-3} and 1×10^{-4} M, respectively. The shaking time was 2 h for all systems. No copper(II) was extracted in the pH region below 3.0. The extraction began to occur at pH 3.5 and its percentage increased with increasing pH of the aqueous phase and reached nearly 100% in the pH region above 6.5. No nickel(II) or cobalt(II) as extracted at a pH lower than 7.0 or 7.8, respectively. Moreover, the percentage extractions of these metal ions were much less than that of copper(II). These results indicate that the selective extraction of copper(II) by L^2 can be achieved by adjusting the pH of the aqueous phase to about 6.7.

From these results L^2 is considered to be a better extractant than the tetraaza macrocyclic Schiff base ligands which were reported previously by us[4,5] in its extraction rate, efficiency and selectivity for copper(II).

Relationship between distribution factor and pH or extractant concentration

In order to identify the species of copper(II) extracted by L^2, the relationship between the distribution factors of copper(II) and the pH or extractant concentration was investigated. The slope of the plot of the logarithm of the copper(II) distribution factor ($\log D$) vs the pH of the aqueous phase is about 2, which indicates that two hydrogen ions of L^2 should be substituted through complexation with copper(II). Moreover, the plot of $\log D$ vs $\log [L^2]$ is linear over the range of L^2 concentration of 1×10^{-3}–1×10^{-4} M, and its slope is nearly unity. This suggests that the ratio of copper(II) to L^2 in the extracted species is 1:1. These results indicate that the copper(II) is extracted by L^2 as the neutral complex Cu(L^2-2H).

Recovery of copper(II) extracted by L^2

The copper(II) extracted by L^2 was recovered by treatment with aqueous solutions of hydrochloric acid as follows. The copper(II) in the aqueous phase was completely extracted into the organic phase of L^2 by shaking for 2 h at pH 6.7 and then the aqueous phase was separated and removed. A dilute hydrochloric acid solution was added to the

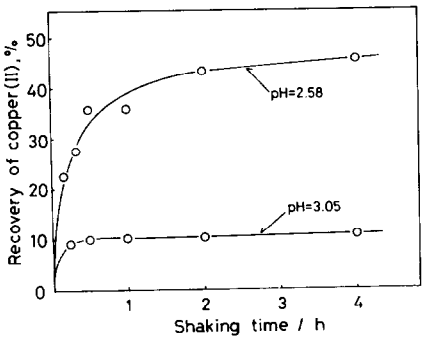

Fig. 5. Back-extraction of copper(II) (1×10^{-4} M) with acidic solutions after complete extraction by L^2 (1×10^{-3} M).

remaining organic phase and it was shaken for an appropriate time. The copper(II) back-extracted into the hydrochloric acid solution was determined by atomic absorption spectrometry. The results are shown in Fig. 5. When an aqueous solution of pH 3.05 was used, the percentage of recovered copper(II) was very low (*ca* 10%) after shaking for 4 h. With an aqueous solution of pH 2.58, it reached *ca* 45% after shaking for 4 h. However, in this case, nearly 20% of the extractant in the organic phase was found to decompose, which was determined spectrophotometrically. Moreover, with an aqueous solution with a pH lower than 1.0, nearly 100% of copper(II) was recovered, but almost all the extractant in the organic phase was found to decompose.

(*Received* 17 *December* 1985; *accepted after revision* 27 *June* 1986)

Abstract—Appreciable changes in effective magnetic moment, isomer shift (I_s) and quadrupole splitting (ΔE_q) (Mössbauer spectra) as well as in the EPR spectra occur upon cooling a sample of the title compound [Fe(salophen)NO] at a temperature of about 180 K. The observed changes are consistent with a $S = 3/2 \rightleftarrows S = 1/2$ spin crossover. At 300 K $I_s = 0.29$ and $\Delta E_q = 0.198\,\text{mm s}^{-1}$, while for a sample temperature of 100 K values are observed of 0.15 and $1.738\,\text{mm s}^{-1}$, respectively. In the EPR spectrum of polycrystalline samples a broad signal is observed. At 100 K two sharp lines corresponding to $g_\perp = 2.108$ and $g_\parallel = 2.211$ are present. The EPR spectrum for 12 K is nearly identical to the spectrum obtained at 100 K. The physicochemical properties of the complex resemble strongly those of the analogue [Fe(salen)NO] and consequently rationalization of the results in terms of the MO diagram for the latter complex can be given. From the magnetic susceptibility and Mössbauer data a separation of the orbitals—involved in the spin-crossover process—of about $300\,\text{cm}^{-1}$ was calculated. Analysis of the magnetic-susceptibility data further reveals, via the large values found for $\Delta S^\ominus$ ($286.2\,\text{J mol}^{-1}\,\text{K}^{-1}$) and $\Delta H^\ominus$ ($28.9\,\text{kJ mol}^{-1}$), that the spin crossover is accompanied by a relative large change in the bonding distances and/or angles. In oxygen- and/or water-containing solutions the complex is rapidly transformed into the μ-oxo-dimer $[\text{Fe(salophen)}]_2\text{O}$.

The pentacyanonitrosylferrate or nitroprusside dianion is very interesting from several points of view. The properties of this anion have been recently reviewed.[1] Nitroprusside is frequently used as a reagent for detection and/or determination of a wide variety of nucleophillic species—generated in (strongly) alkaline medium from compounds such as thiols, ketones, aldehydes, phenols, pyrrols, indols and thioureas—and sulphite. Moreover, nitroprusside is a potent hypotensive drug. Unfortunately, a number of drawbacks limits its therapeutic use. Nitroprusside is administered by (intravenous) infusion (in the clinic), because the drug is not absorbed after oral administration. Secondly, nitroprusside is especially light-sensitive in (infusion) solutions. On the other hand, the drug is toxic due to the *in vivo* loss of the cyanide ligands. Reactivity, and most probably the biological activity as well, are related to the Fe(II)–NO^+ moiety.

Therefore, our ultimate aim was the synthesis of

*Author to whom correspondence should be addressed.

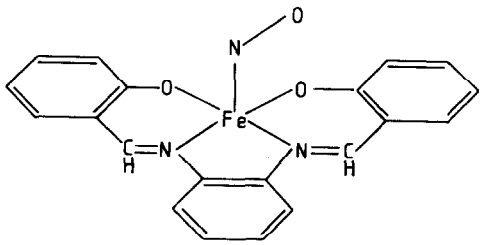

Fig. 1. Structure of [Fe(salophen)NO].

stable and less toxic (mono)nitrosyl analogues of nitroprusside with at least a comparable hypotensive action. In general the separations of the orbitals involved in the ligand coordination in iron nitrosyl complexes are small.[2] As a consequence both the stability of iron mononitrosyl complexes and the character of the nitrosyl group (NO^+, NO^0 or NO^-) are sensitive to subtle changes in the properties of the coordinated ligands. A survey of the literature on mononitrosyl iron complexes reveals that only a minority of these compounds are to a certain extent stable in the solid state and in solution. On the basis of the anionic multidentate ligands present in the relatively stable complexes porphinato,[3] phthalocyanato,[4] dithiolato,[5] dithiocarbamato[6] and Schiff base[7-9] mononitrosyl coordination compounds can be distinguished. Apparently, π-extended systems possess stabilizing properties towards iron nitrosyl complexes. This is not surprising, since cyanide present in the comparatively stable nitroprusside ion is a strong field ligand with an exceptional $d\pi$-accepting ability.

An alternative approach to the preparation of nitroprusside analogues is the replacement of the central metal ion by Ru(II). In this ion the fully occupied t_{2g}^6-orbitals extend far more into space and consequently strong back-bonding interactions with common π-acceptor ligands such as NO^+ occur.[10-13] For this reason Ru(II) nitrosyl complexes can be formally regarded as Ru–NO^+ and are in general relatively stable. Unfortunately, Ru(II) complexes are both mutagenic and carcinogenic.[14]

In order to obtain more insight into the role of conjugation in stabilizing mononitrosyl iron complexes, the phenylene analogue of [*N*,*N*′-ethylenebis(salicylideniminato)]nitrosylferrate, [Fe(salophen)NO] (Fig. 1), was prepared and its physicochemical features were compared to those of [Fe(salen)NO] which was recently characterized by Wells *et al.*[8]

Finally, the stability of [Fe(salophen)NO] was investigated in the solid state and in solution, employing the intensity of the characteristic nitrosyl stretching frequency in the IR spectrum as criterion.

EXPERIMENTAL

Reagents and ligands

Sodium acetate, sodium nitrite, *o*-phenylenediamine and sulfuric acid (Merck analytical grade), ferrous perchlorate hexahydrate (Ventron), salicylaldehyde (Baker reagent grade), methanol and ethanol (Baker analytical grade) were used in the synthetic procedures. The ligands *o*-ethylene- and *o*-phenylenebissalicylideniminato were obtained by condensation of the respective diamines with salicylaldehyde (1:2) in refluxing ethanol. The crop of yellow and orange crystals was subsequently thoroughly washed with ethanol and recrystallized from ethanol.

Preparation of [Fe(salophen)NO]

Earnshaw *et al.*[7] prepared [Fe(salen)NO] via the extremely air-sensitive [Fe(salen)] complex. In our method the desired nitrosyl complex is produced in one step, circumventing the unstable intermediate. 0.32 g powdered ligand was added to 30 cm^3 methanol, which was deoxygenated by purging with nitrogen purified via a BTS tower. Thereafter, a 0.16 g sodium acetate (0.02 M) and 0.36 g ferrous perchlorate (0.01 M) were added. Immediately NO gas, generated from sodium nitrite by dropwise addition of 2 M sulfuric acid and purified by passage through a 30% KOH solution and a column of KOH pellets,[15] was bubbled through the well-stirred reaction medium. The solution turned black and a black product precipitated. After 1.5 h the excess NO gas was removed by purging with nitrogen and the black microcrystalline material was filtered, washed with 30 cm^3 deoxygenated methanol under a stream of nitrogen and finally dried *in vacuo* for 1.5 h.

Found: Fe; 13.7%. Calc. for [Fe(salophen)NO] ($FeC_{20}H_{14}N_3O_3$): Fe, 14.0%. ν_{NO} = 1720 cm^{-1} (KBr, Nujol mull).

Preparation of [Fe(salen)NO] *and* [Co(salophen)NO]

The complex [Fe(salen)NO] was prepared in an analogous way. In the synthesis of [Co(salophen)NO] Co(II) acetate tetrahydrate was used, while sodium acetate was omitted.

[Fe(salen)NO]: ν_{NO} = 1710 cm^{-1} (KBr); [Co(salophen)NO]: ν_{NO} = 1640 cm^{-1} (KBr).

Physical measurements

Powder X-ray diffractograms were recorded by means of a Philips diffractometer, type PW 1025/25 using Cu-K_α radiation (λ = 1.5418 Å).

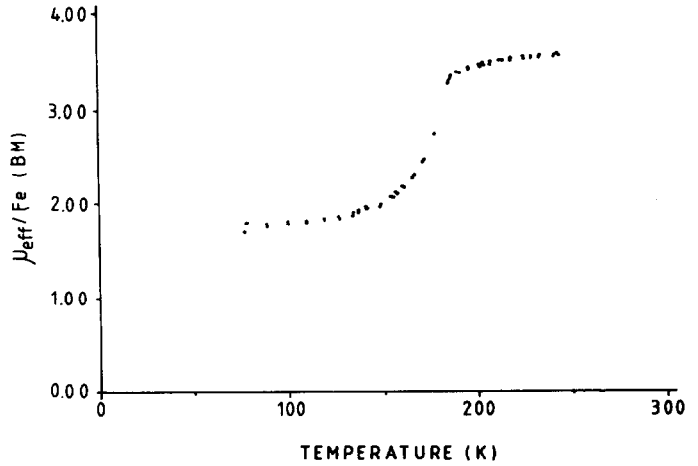

Fig. 2. Effective magnetic moment (μ_{eff}) for [Fe(salophen)NO] in the temperature range 80–300 K.

The magnetic properties of [Fe(salophen)NO] were determined in the temperature range 2–300 K. The high-temperature susceptibility ($T > 77$ K) was measured using a Faraday balance. In the low-temperature range susceptibility and magnetization measurements were performed using a PAR vibrating sample magnetometer. Field-dependent magnetization curves were recorded at liquid-He temperature applying fields up to 5.6 T. All susceptibility data were corrected for diamagnetism of the samples[16] and the sample holder.

The IR spectra were recorded for both the KBr pellet and the Nujol mull by means of a Beckman IR-10 spectrometer in the frequency range 4000–200 cm^{-1}. For the Mössbauer experiments a conventional constant-acceleration type spectrometer was applied. The source was ^{57}Co diffused in rhodium. All isomer shifts (I_s) are relative to sodium nitroprusside.

The EPR spectra for a polycrystalline sample of [Fe(salophen)NO] were recorded at room temperature, and 100 and 12 K on a Varian E 3 at X-band frequencies, employing a 9.22-GHz field modulation.

RESULTS

Magnetic susceptibility

The data for polycrystalline [Fe(salophen)NO] are represented in Fig. 2.

These results closely resemble those for [Fe(salen)NO]. At about 180 K a spin crossover occurs. Above the crossover temperature (T_c) the effective magnetic moment (μ_{eff}) is approximately 3.9, while at temperatures below T_c the effective magnetic moment is about 1.9. These values are very close to the spin-only values for $S = \frac{3}{2}$ (3.88) and $S = \frac{1}{2}$ (1.73), respectively. In addition a magnetic phase transition due to antiferromagnetic coupling of the Fe centres is observed at $T = 6$ K (Fig. 3).

The magnetic-susceptibility data can be treated according to eqn (1):

$$\mu_{eff}^2 = \alpha \cdot \mu_{S=3/2}^2 + (1 - \alpha)\mu_{S=1/2}^2, \qquad (1)$$

in which $\mu_{S=3/2}$ and $\mu_{S=1/2}$ are the theoretical spin-only values of 3.88 and 1.73. The equilibrium constant at various temperatures for the spin crossover (K_{eq}^T) can be calculated by eqn (2):

$$K_{eq}^T = \alpha/(1 - \alpha), \qquad (2)$$

where α denotes the fraction in the high-spin state. Subsequently, eqn (3):

$$\ln K_{eq}^T = \Delta S^{\ominus}/R - \Delta H^{\ominus}/RT \qquad (3)$$

offers the possibility of calculating both enthalpic and entropic changes accompanying the spin transition. In Fig. 4 the plot of $\ln K_{eq}^T$ vs T^{-1} is given. From this plot values of 286.2 J mol^{-1} K^{-1} and 28.9 kJ mol^{-1} were calculated for $\Delta S^{\ominus}$ and $\Delta H^{\ominus}$. The $\Delta S^{\ominus}$ value comprises an electronic entropy change related to a difference in spin multiplicity and state degeneracy for the high- and low-spin states. In theory the electronic entropy change for the present case equals $R \ln(\frac{4}{2}) = 5.8$ J mol^{-1} K^{-1}. Thus the calculated value for $\Delta S^{\ominus}$ may almost entirely be ascribed to changes in bond distances and/or bond angle occurring concomitantly with the spin-crossover process. The value of 286.2 J mol^{-1} K^{-1} is very high. Petty *et al.*[17] found

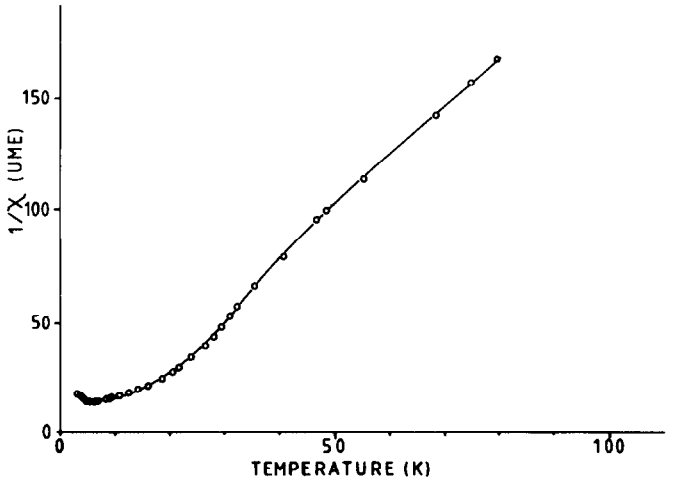

Fig. 3. Reciprocal magnetic susceptibility ($1/\chi$) for [Fe(salophen)NO] in the temperature range 2–80 K.

a value of 112.2 J mol^{-1} K^{-1} for an iron(II) complex. Apparently, large changes in bonding distances and/or angles occur during the spin crossover. A change in bonding distance of 0.1–0.2 Å is reasonable.[16] Assuming a change equal to 0.2 Å, the expected inner coordination sphere reorganization energy is 25.1 kJ mol^{-1}.[18] As a consequence, the estimated electronic contribution to the observed enthalpic change amounts to 28.9 − 25.1 = 3.8 kJ mol^{-1}. This value reflects the separation of the electronic levels involved in the spin transition and is estimated as 300 cm^{-1}.

Mössbauer spectroscopy

In the Mössbauer experiments performed at various temperatures the spin transition is also observed at $T_c = 180$ K. The Mössbauer data are summarized in Table 1. In Fig. 5 the variation in the quadrupole splitting (ΔE_q) and I_s with temperature is depicted. Representative Mössbauer spectra for $T = 293$, 200, 160 and 100 K are given in Fig. 6. The magnetic-susceptibility and Mössbauer data are thus in good agreement. The quadrupole-splitting values at each temperature [$\Delta E_q(T)$] are related to the quadrupole splitting at $T = 0$ K [$\Delta E_q(0)$] via eqn (4):[19]

$$\Delta E_q(T) = \Delta E_q(0) \tanh(\Delta \tfrac{1}{2} kT). \quad (4)$$

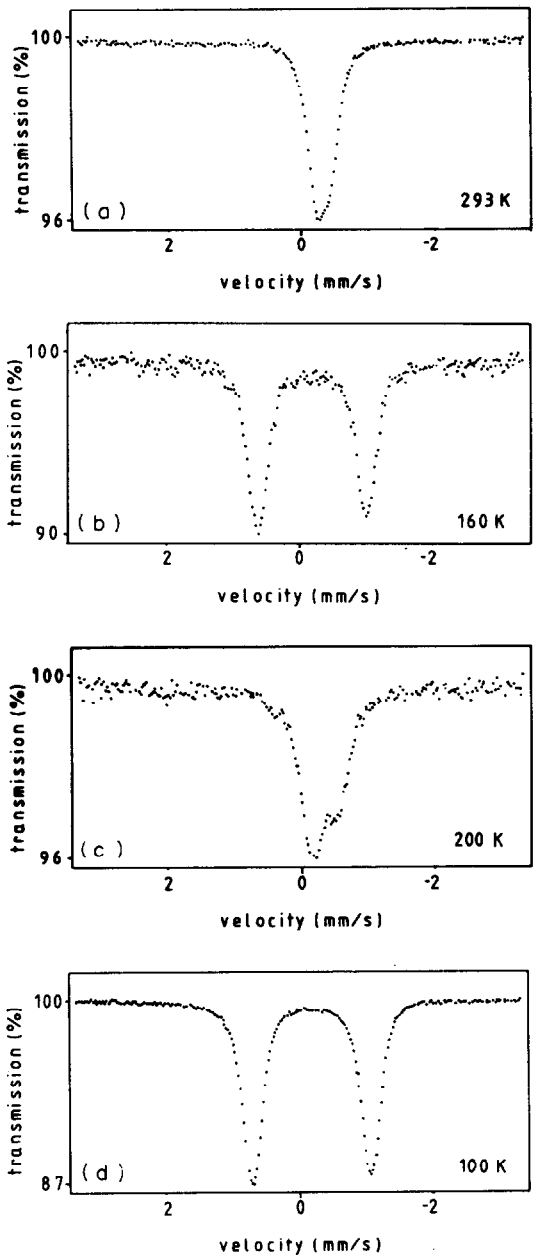

Fig. 6. Mössbauer spectra for [Fe(salophen)NO] at the indicated temperatures.

In eqn (4) Δ represents the separation of the levels playing a role in the spin crossover. Using for $\Delta E_q(0)$ the extrapolated value of $1.83\,\mathrm{mm\,s^{-1}}$ a reasonable fit between experimental and calculated values is obtained for $\Delta = 280\,\mathrm{cm^{-1}}$. This value is relatively close to the value of $300\,\mathrm{cm^{-1}}$ derived from the susceptibility data.

X-ray analysis

The X-ray powder diffraction pattern of [Fe(salophen)NO] can be indexed in an orthorhombic space group. The cell parameters are $a = 16.74$ Å, $b = 17.32$ Å and $c = 10.65$ Å. Systematic absences indicate *P*222 to be the most likely space group. Data for the observed reflections with 2θ between 10 and 25° are presented in Table 2. The results agree qualitatively with the reported structure for one of the modifications of the related Co complex [Co(salophen)].[20] The cell parameters are about the same for both complexes, but in the case of the iron compound the *c*-parameter is doubled with respect to the value for the Co compound. This is probably due to the presence of the NO moiety in the Fe complex and to the larger size of the central Fe ion. Both conditions may give rise to a shift

DISCUSSION

Comparison of the magnetic behaviour, EPR, IR and Mössbauer parameters of [Fe(salen)NO] and [Fe(salophen)NO] leads to the conclusion that only minor changes occur upon extension of the conjugation in the equatorial Schiff base ligand. This is consistent with the observation that μ_{eff} for the $S = \frac{1}{2}$ and $\frac{3}{2}$ spin states approximates the theoretical spin-only values, suggesting a limited admixture of the salophen orbitals and the metal *d*-orbitals. Lack of suitable orbitals on the phenolic oxygen may account for a slight degree of delocalization involving the equatorial ligand. Because of the similarities in the properties of [Fe(salen)NO] and [Fe(salophen)NO] the MO description proposed by Wells *et al.*[8] (Fig. 8) might be used for the explanation of the observed features of [Fe(salophen)NO]. The relatively low nitrosyl stretching frequency of 1720 cm^{-1} is, according to Gaughan *et al.*,[21] indicative either of an Fe(II)–NO^0 or an

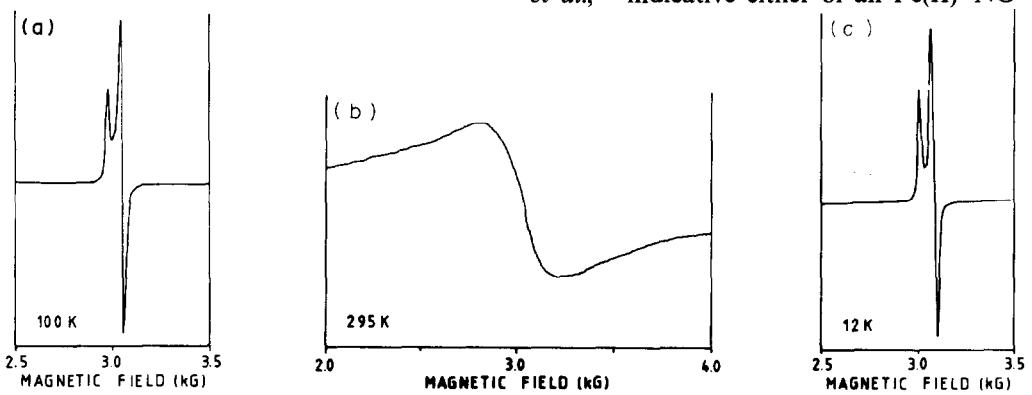

Fig. 7. Polycrystalline EPR spectra for [Fe(salophen)]NO]. The sample temperatures are indicated.

coordination. In the structure of the orthorhombic modification of the Co complex the *c*-axis is perpendicular to the almost planar ligand. Alternation of the assumed out-of-plane shift of the Fe atom in the positive and negative direction will result in a doubling of the translation symmetry along the *c*-axis with respect to the original structure.

EPR spectroscopy

Figure 7 shows the EPR spectra for polycrystalline [Fe(salophen)NO]. At $T = 295$ K a broad polycrystalline EPR signal is observed. Upon lowering the sample temperature the EPR spectrum changes markedly at about 180 K. At $T = 100$ K two sharp lines are observed which correspond to $g_\perp = 2.108$ and $g_\parallel = 2.211$. The EPR spectrum for $T = 12$ K is practically the same with $g_\perp = 2.090$ and $g_\parallel = 2.195$.

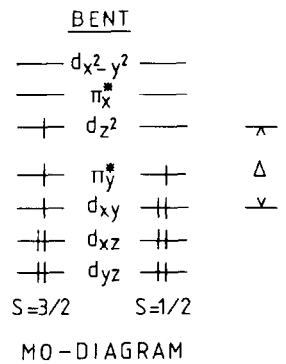

Fig. 8. MO diagram for an $\{FeNO\}^7$ complex with a bent geometry.

Fe(III)–NO^- moiety. In the given MO diagram six *d*-electrons are placed in orbitals with a predominant *d*-character, while one electron resides mainly in the antibonding π_y^*-orbital. Thus, the high-temperature state can be formally regarded as

temperature state can be formally regarded as Fe(II)–NO. Furthermore, the NO stretching frequency for [Co(salophen)NO] is 1640 cm^{-1}. The decline in the NO stretching frequency, going from d^6 [Fe(salophen)NO] to d^8 [CO(salophen)NO] is in agreement with the orbital leveling as given by Wells *et al.*[8] In the Co analogue a second *d*-electron is placed in the π_y^*-orbital leading to substantial weakening of the bond between the *N* and the O atom in the nitrosyl group.

As suggested by the large values found for ΔH^0 and ΔS^0, the spin-crossover process is accompanied by structural changes, i.e. changes in bond distances and/or angles. X-ray analysis of [Fe(salophen)NO] at 293 K suggests that in the high-spin state the Fe ion is displaced out of the plane of the Schiff base ligand. Wells *et al.*[8] derive from their Mössbauer experiments that on going from the $S = \frac{3}{2}$ state to the $S = \frac{1}{2}$ state the recoil-free fraction increases. These authors attribute this phenomenon to the movement of the iron atom from an out-of-plane position to an in-plane position. It is clear that this implies a change in bond distances and angles. Therefore, changes in the bond distances and angles must be taken into account in the interpretation of the Mössbauer parameters. Wells *et al.*,[8] however, neglect these changes in their explanation given for the variation of Mössbauer parameters with temperature. According to the MO diagram, the spin crossover consists in the transfer of electron density from the d_{xy}-orbital to the d_{z^2}-orbital. The d_{z^2}-orbital possesses less *d*-character because of overlap between the d_{z^2}- and the σ^*-orbital. As a consequence the electric field gradient (EFG) and thus the quadrupole splitting is larger for the $S = \frac{1}{2}$ state. At the same time the Fe atom moves into the plane of the equatorial salophen ligand and consequently the bond distances (*r*) become shorter. This effect will also lead to an increase in the EFG, since the EFG is proportional to r^{-3}. As a result of these two cooperative effects the quadrupole splitting will greatly change in the neighbourhood of the spin conversion temperature (180 K). On the other hand a relatively small decrease in I_s is observed. This indicates the effective *s*-electron density as experienced by the iron nucleus in the $S = \frac{1}{2}$ state to be smaller. The spin crossover is apparently associated with an increase in shielding of the *s*-type iron electrons due to transfer of electron density from the σ^*-type d_{z^2}-orbital to the d_{xy}-orbital.

The complex [Fe(salophen)NO] is relatively stable in the solid state. No decrease in the intensity of the nitrosyl stretching frequency (1720 cm^{-1}) was observed over a period of 2 months. By contrast, in oxygen- and/or water-containing solutions a red precipitate is rapidly formed. The observed peak at 820 cm^{-1} in the IR spectrum of the red material points to the formation of the μ-oxo-dimer [Fe(salophen)]$_2$O.[22,23] Gulotti *et al.*[24] have reported that the μ-oxo-dimer [Fe(salen)]$_2$O is cleaved in the presence of excess cyanide, while [Fe(salen)(CN)$_2$] is slowly converted into the oxygen-bridged species. Most probably this type of dimirization can be prevented by a (strong) ligand at the sixth position. Placing a sixth ligand along the *z*-axis will lift the d_{xz}-, d_{yz}- and especially the d_{z^2}-orbital. This may result in an orbital leveling very similar to the orbital configuration in the nitroprusside ion.[25]

In conclusion [Fe(salophen)NO] is not a suitable nitroprusside analogue. Most probably replacement of the four equatorial cyanide ligands in nitroprusside by an anionic multidentate with exceptional $d\pi$-accepting ability may result in a stable Fe(II)–NO^+ complex.

(*Received* 19 *December* 1985; *accepted after revision* 27 *June* 1986)

Abstract—The complex species formed in aqueous solution between Be(II) and iminodiacetic, *N*-methyliminodiacetic, *N*-ethyliminodiacetic and *N*-propyliminodiacetic acids were studied at 25°C and ionic strength 0.5 M in Na ClO_4. The application of the least-squares computer program LETAGROP to the experimental potentiometric data, taking into account hydrolysis of the Be(II) ion, indicates that, upon varying the ligand–metal relationship, only the monohydroxide complex $[Be(OH)C]^-$ (H_2C ligand) is formed in significant amounts for the four systems studied. The formation constants β_{pr} (11, −11 and −21) of the protonated species of the ligands, β_{pq} (−12 and −33) of the hydrolytic species of Be(II), and β_{pqr} (−311) of the complex $[Be(OH)C]^-$ were determined.

The coordinating properties of Be(II) in aqueous solution with polyaminocarboxylic acids have, in general, been very little studied,[1–3] probably because of the strong tendency to hydrolyse displayed by the small Be(II) cation.[4] In some cases where such a study has been carried out, as with iminodiacetic acid (IDA), the results have been contradictory: Dyatlova *et al.*[5–7] found that IDA *did not form complexes with* Be(II). No references to the same are to be found in the tables of stability constants.[1–3] However, more recently, Jain *et al.*[9] and Dubey *et al.*[8] have determined from potentiometric measurements the stability constant of the neutral complex BeC (ligand H_2C). But these authors have not taken into consideration the hydrolysis of Be(II) in their calculations.

In our studies in aqueous solution of the systems Be(II)-EDTA[10,11] (EDTA = ethylenediaminetetraacetic acid) and Be(II)–NTA[12] (NTA = nitrilotriacetic acid) we have found upon analysing the experimental potentionmetric data by means of the NERNST/LETA/GRAFICA[13] version of the LETAGROP[14] program that the species resulting from hydrolysis of Be(II) must be taken into consideration in the calculations in order to determine the complex species really present in the solution and to obtain correct values of the stability constants. Otherwise, the values obtained are higher than the true ones, since the acidity due to hydrolysis of the non-complexed Be(II) is included in the value of the stability constant obtained.

For these reasons we decided to reinvestigate in this work the Be(II)–IDA system in aqueous solution. The analogous Be(II)–MIDA (MIDA = *N*-methyliminodiacetic acid), Be(II)–EIDA (EIDA = *N*-ethyliminodiacetic acid) and Be(II)–PIDA (PIDA = *N*-propyliminodiacetic acid) systems have also been studied, no references to these having been found in the literature.

EXPERIMENTAL

Reagents

IDA was prepared by recrystallization of IDA (Merck, analytical grade). MIDA, EIDA and PIDA were synthesized by reacting methylamine, ethylamine and *n*-propylamine (Merck, products for synthesis), respectively, with previously neutralized chloroactic acid, following the procedure described by Souchay *et al.*[15] The previously obtained barium salts gave the corresponding acid on adding conc. H_2SO_4. The acids were purified by recrystallization in water–isopropanol mixtures, and were identified by their potentiometric equivalents, and NMR and mass spectra.

The solution of $Be(ClO_4)_2$ was prepared by reacting metallic Be (Spex Industries Inc.) with an excess of $HClO_4$ (Merck, analytical grade), its free acidity[16] being determined, as well as the concentration of Be(II) in aqueous solution which was evaluated gravimetrically.[17,18] The carbonate-free sodium hydroxide solution was prepared according to the school of Sillén[19] and standardized against potassium hydrogen phthalate. $NaClO_4$ was prepared by recrystallization of $NaClO_4$ (Merck, analytical grade).

Apparatus and titration procedures

The potentiometric titrations were carried out in an inert argon atmosphere, at 25 ± 0.0.5°C, ionic strength 0.5 M in $NaClO_4$, using a Radiometer Type PHM-64 potentiometer, a Radiometer G 202 B glass electrode and a K 401 calomel electrode. The cell constants were determined according to the method of Biedermann and Sillén,[20] the liquid junction potentials being found to be negligible within the margins of $[H^+]$ studied. It was found that $pK_w = 13.72$, in excellent agreement with reported data.[21]

Measurements were taken of the ligands alone at the following concentrations: IDA, MIDA and EIDA (C_L = 10 and 20 mM); PIDA (C_L = 10 and 5.7 mM). Be(II) was measured alone (C_M = 10 and 20 mM) in order to study hydrolysis, and the ligands in the presence of Be(II) at the following concentrations and ligand: metal ratios: C_M = 10, 20 and 40 mM and 1:1, 2:1, 4:1 and 6:1 ratios for IDA and EIDA; C_M = 10 mM, and 1:1, 2:1 and 4:1 ratios for MIDA; and C_M = 10, 20 and 40 mM, and 1:1 ratio for PIDA.

Data treatment

The experimental potentiometric data were analysed by means of the NERNST/LETA/GRAFICA version[13] of the LEGATROP program,[14] based on a generalized form of the least-squares method that establishes the best model and best values of the β_{pqr} constants, minimizing the function $U = \sum(Z_{exp} - Z_{calc})^2$, Z being the average number of disassociated protons for the total concentration of ligand (Z_C) or for the total concentration of metal (Z_B). The LETAGROP calculations also give the standard deviations $\sigma(Z)$ and $\sigma(\log \beta_{pqr})$.[22] The computations were performed on a Burroughs 6700 computer (Facultad de Ciencias, Universidad Central de Venezuela, Caracas).

RESULTS AND DISCUSSION

Hydrolysis of Be(II)

The aquo cation $Be(H_2(O)_4^{2+}$ only exists in a strongly acid medium.[4] Since the work of Kakihana and Sillén,[23] later confirmed by other authors,[24–29] it has been established that the main product of the hydrolysis of Be^{2+}, in solutions more concentrated than 1 mM, is the trinuclear species $[Be_3(OH)_3]^{3+}$. In a more acidic medium, the dinuclear species $[Be_2(OH)]^{3+}$ has been identified, the percentage of formation of which increases with the concentration of beryllium.[26] The species $Be(OH)_2$ has been proposed before precipitation of the hydroxide[22,25,26,29] in a small proportion because of the very little solubility of $Be(OH)_2$ in water.[4] Mesmer and Baes[4,27] question of the existence of this species at concentrations above 1 mM, and from the studies of Bertin *et al.*[26] it is deduced that neither is it present at concentrations of 10 mM or over.

Prior to our study of the coordinating capacity in aqueous solution of Be(II) with different iminodiacetic ligands, we investigated the hydrolysis of Be(II) under the same conditions of temperature (25°C) and ionic strength (0.5 M in $NaC1O_4$). We also used concentrations of Be(II) of 10 and 20 mM, similar to those employed in the study of the coordinating capacity.

The constants β_{-pq} are defined by means of equilibrium (1):

$$qBe^{2+} + pH_2O \rightleftharpoons [Be_q(OH)_p]^{(2q-p)+} + pH^+. \quad (1)$$

The model that best fits the experimental results is that which considers the presence of the hydroxylated species $Be_2(OH)^{3+}$ and $Be_3(OH)_3^{3+}$ in the range of concentrations and pH values (2.5–5.3) studied. Forty-eight experimental points of the two potentiometric titrations carried out were used for

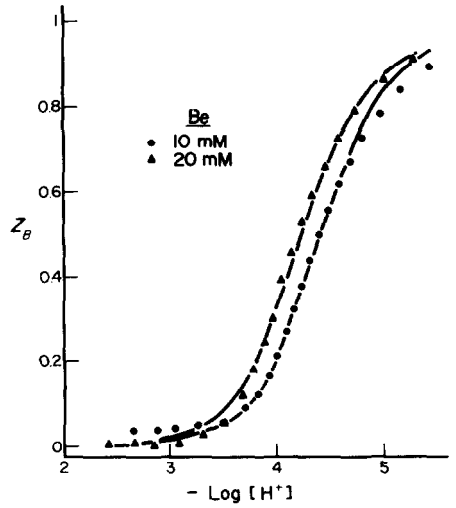

Fig. 1. Z_B vs log[H^+] curves of the hydrolysis of Be(II). Full curves have been calculated using the constants β_{pq} found.

the calculations. It was found that:

$-\text{Log}\,\beta_{-12}$	$\text{Log}\,\beta_{-33}$	Standard deviation [$\sigma(Z)$]	Reference
3.20	8.92 ± 0.08	0.018	Present work
3.20	8.81		26

in good agreement with other authors[4,23-27,29] and especially with Bertin *et al.*[26] who worked at the same ionic strength and temperature. Figure 1 shows the excellent agreement between the experimental curves Z vs $-\log[H^+]$ and those calculated from the values found for β_{-12} and β_{-33}. It should be noted that $Z \to 1$ in accordance with the major formation of the species $(Be_3(OH)_3]^{3+}$.

Ionization constants of the acids

From the values obtained for the constants β_{pr} corresponding to equilibrium (2):

$$pH^+ + rH_2C \rightleftharpoons [H_p(H_2C)_r]^{p+} \qquad (2)$$

the ionization constants of the acids (K_i) given in Table 1 could readily be determined.

The values of pK_i are in good agreement with those found at 25°C and ionic strength 0.1 M in KCl,[30] and with those found for IDA[1,2,31-34] and MIDA[2,35] at 25°C and ionic strength 0.5 M in $NaClO_4$. It is observed that the order of basicity of the N atom[36] (equilibrium HC^-/C^{2-}) is IDA < MIDA < EIDA ≤ PIDA, which order corresponds to the electron donor effect to the corresponding alkyl radical.

Formation constants of the complexes formed

The formation constants β_{pqr} are defined by means of equilibrium (3):

$$pH^+ + qBe^{2+} + rH_2C \rightleftharpoons [H_pBe_q(H_2C)_r]^{(p+2q)+}. \qquad (3)$$

Since, according to Dyatlova *et al.*[5-7] IDA does not form complex with Be(II), we first applied the model FONDO (species $[Be_2(OH)]^{3+}$, $[Be_3(OH)_3]^{3+}$, H_3C^+, HC^- and C^{2-}) to the potentiometric curves of the four systems studied, implying the non-formation of complexes. The Z_c vs $-\text{Log}[H^+]$ experimental curves for the ligand-metal ratios of 1:1 and 2:1 shift slightly to the left with regard to the calculated curves, this effect being most visible at pH ≃ 5 or over. This seems to indicate the presence of a supplementary acidity due to the formation of complex species. Since Jain *et al.*[8] and Dubey *et al.*[9] have affirmed the formation of the complex BeC for IDA acid, and considering the possible formation of the complex $BeHC^+$, the possible presence of these complexes is now analysed, by using the models FONDO + $BeHC^+$, FONDO + BeC and FONDO + $BeHC^+$ + BeC. A shift to the left in the experimental curves Z_C vs $-\log[H^+]$ continues to exist with respect to the calculated curves; therefore the supplementary acidity does not seem to be due to these complexes. A summary of the calculations for the IDA–Be(II) and MIDA–Be(II) systems is given in Table 2 and shows that the constants β_{pqr} are very badly defined for these complexes, so if the complex species $BeHC^+$ and BeC exist in these systems they would be present in a practically negligible amount. The calculation for the PIDA–Be(II) system shows that the species BeC is practically non-existent.

If the complex BeC is only formed in the curves for the ligand: metal ratio of 1:1, $Z \to 2$, but it can be observed from the experimental data in Fig. 2 (the other three systems behave analogously) that at the ratio 1:1 the curves inflect at a value of $Z > 2$. These values are attained shortly before turbidity is reached for all the R–IDA–Be(II) systems. This result is a qualitative proof of the presence of a complex with $p/r > 2$, which could be $[Be(OH)C]^-$.

From Fig. 2 it can also be deduced that the complex species will be formed at $Z > 1$ (pH > 3.5). At these pH values and at the concentration of Be(II) studied, in accordance with Bertin *et al.*[26]

and our results (Fig. 1), the hydrolytic species of Be(II) are mainly present, $[Be_2(OH)]^{3+}$ and especially $[Be_3(OH)_3]^{3+}$. On the other hand, Thomas *et al.*[37–39] have shown that the trimer species $[Be_3(OH)_3(H_2O)_6]^{3+}$ is not destroyed if the ligands are mono- or didentate, since the tetra-coordination of the Be(II) is then maintained, displacing one or two molecules of water for each

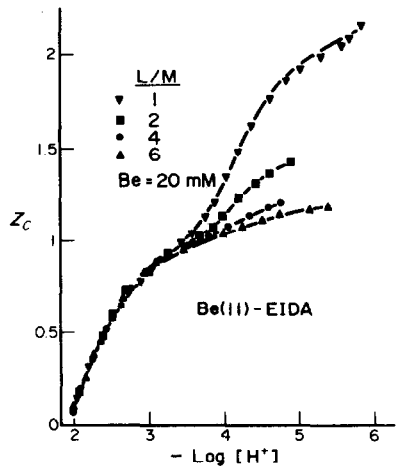

Fig. 2. Z_C vs $-\log[H^+]$ curves of the EIDA–Be(II) system. Full curves = calculated curves (Model "FONDO + $[Be(OH)C]^-$", using β_{-311} in Table 3).

atom of Be(II). Considering the possibility that the R–IDA ligands display a behaviour similar to that of bidentate ligands, we tried the models FONDO + $[Be_2(OH)C_2]^-$, and FONDO + $[Be_3(OH)_3C_3]^{3-}$. The data presented in Table 2 for IDA and PIDA show that good limits of tolerance are not obtained for the constants β_{pqr}, therefore permitting us to discount the presence in significant amounts of the binuclear species $[Be_2(OH)C_2]^-$ and the trinuclear species $[Be_3(OH)_3C_3]^{3-}$.

The presence was then confirmed of the mononuclear species $[Be(OH)C]^-$, by applying the model FONDO + $[Be(OH)C]^-$. The constant β_{-311} is well defined for the four R–IDA–Be(II) systems studied, as manifested in the summary of LETAGROP calculations given in Table 2. The values fit better if the calculations are carried out at $Z > 1$. The best values found are given in Table 3. Figure 2 shows a good fit between the experimental $Z_C$vs $-\log[H^+]$ curves and those calculated from the values of β_{-311} given in Table 3. Analogous curves are obtained for the other three systems. The curves calculated for the model FONDO + $[Be(OH)C]^-$ practically coincides with the curve calculated for the model FONDO up to pH $\simeq$ 5. It is deduced that the complex $[Be(OH)C]^-$ is mainly formed at pH > 5. This result is best observed in the diagram of species distribution presented in Fig. 3 for the IDA–Be(II) system. Analogous distribution diagrams are obtained for the other three systems. The species $[Be(OH)C]^-$ begins to form in small amounts at pH > 4, but mainly at pH > 5. The limited margin of existence of the species $[Be(OH)C]^-$ is conditioned by the great stability of the hydrolytic species $[Be_3(OH)_3]^{3+}$. In Fig. 3 it is

Acid	$-\text{Log}\,\beta_{-311}$	Log K	Log K	Log K	Log K
IDA	11.60 ± 0.06	13.95	16.83[a]		
MIDA	11.31 ± 0.04	14.20	16.15[b]	13.53[c]	
EIDA	11.40 ± 0.10	14.53		13.80[c]	
PIDA	11.54 ± 0.21	14.36		13.48[c]	11.28[d]

[a] Cu(II), 25°C, I = 0.1 M in KCl[1]
[b] Cu(II), 20°C, I = 0.1 M in KCl.[1]
[c] Pb(II),25°C, I = 0.1 M in $NaNO_3$.[41]
[d] Fe(II), 25°C, I = 0.1 M in KCl.[30]

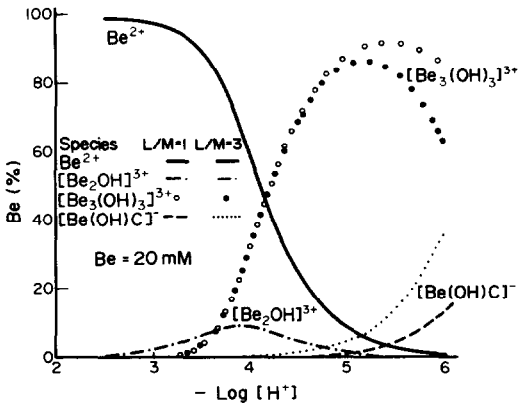

Fig. 3. Species distribution as a function of $-\log[H^+]$ for the IDA–Be(II) system.

observed that as the concentration of the ligand increases, the proportion of the complex $[Be(OH)C]^-$ increases and that of the species $[Be_3(OH)_3]^{3+}$ decreases. That is, the complex $[Be(OH)C]^-$ is fundamentally formed by means of equilibrium (4):

$$\frac{1}{3}[Be_3(OH)_3]^{3+} + HC^- \rightleftharpoons [Be(OH)C]^- + H^+ \quad (4)$$

which accounts for the supplementary acidity observed in Fig. 3 upon formation of the complex $[Be(OH)C]^-$.

The R–IDA ligands act, therefore, as tridentate ligands, destroying the trinuclear species $[Be_3(OH)_3]^{3+}$. The OH^- will occupy fourth place in the tetrahedron of coordination[40] of the Be(II), leading us to propose the structure in Fig. 4 for the complex $[Be(OH)C]^-$. The species $BeC(H_2O)$ is unstable, since if it were formed it would undergo rapid hydrolysis, stabilizing the species $[Be(OH)C]^-$. But the experimental data are more

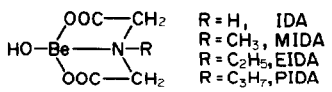

Fig. 4. Structure proposed for the complex $[Be(OH)C]^-$.

in accordance with its formation from the trimer species $[Be_3[OH_3]^{3+}$ (Fig. 3). NTA and such stabilize the neutral complex BeC^- (H_3C ligands),[12] because the ligand is tetradentate and satisfies the coordination necessities of the Be(II).[40]

The values of the constant β_{-311} are practically identical for the four ligands studied (Table 3). The values of the stability constant K of the complex $[Be(OH)C]^-$ are also given in Table 3, according to equilibrium (5):

$$Be^{2+} + C^{2-} + OH^- \rightleftharpoons [Be(OH)C]^-, \quad (5)$$

readily calculated from β_{-311} (Table 3), β_{-21} (Table 1) and K_w, the ionic product of the water. Upon comparison with other values of $\log K$ for $[M(OH)C]^-$ complexes (Table 3), it is found that the complexes of Be(II) are more stable than those of Fe(II), somewhat more stable than those of Pb(II) and less stable than those of Cu(II).

TOPOLOGY AND CHEMISTRY OF POLYOXOMETALATES: INORGANIC POLYMERS FORMED BY CONNECTING OCTAHEDRAL UNITS, HETERO- AND ISOPOLYANIONS, AND THEIR STRUCTURAL STABILITY

KENJI NOMIYA

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 24 *February* 1986; *accepted after revision* 27 *June* 1986)

Abstract—The structure of inorganic polymers such as hetero- and isopolyanions formed by connecting some MO_6 octahedra is topologically discussed on the basis of the mode of connectivity of the octahedral components. The path in the inorganic polymer and the closed loop in the polyanion, which are contours continuously linked by *trans*-located bridging vertices (oxygens) in each constituent octahedron, are discussed. The previously reported three rationalizations of the polyanion structure are standardized; the first is Lipscomb's proposal on the number of terminal vertices within each octahedral unit of actual polyanions, the second is Pope's classification of all polyanions according to Lipscomb's proposal, and the third is our presentation of the structural stability based on the number of closed loops. A topological definition of a polyanion is provided by the Lipscomb–Pope condition; the polyanion is a condensation compound of some octahedral units where each octahedron has one or two mutually *cis*-located terminal oxygens. The structure of the polyanion skeleton is determined by the combination of the structural parameters *A*, *B* and *C*, where *A* is the number of MO_6 octahedral components constituting the polyanion skeleton, *B* the number of MO_6 units constituting the closed loop, and *C* the number of closed loops. The closed loop is directly related to the mode of connectivity of the octahedral units and significantly contributes to the structural stability. The combination of the structural parameters *A*, *B* and *C* represents the topological character of the polyanion. The topological isomer with an identical combination is distinguished from the chemical isomer with an identical composition.

Hetero- and isopolyanions in chemistry are included in an inorganic polymer formed by connecting some MO_6 octahedral units, that is, by repeating their corner and/or edge sharings. They have also been considered as assemblages of metal–oxygen octahedra, or as fragments of metal-oxide lattices and close-packed arrays.[1] Topology has provided us with some tools for classifying geometrical figures as a bounded and closed set, or a compact set, an arcwise connectivity, Euler's characteristics and so on.[2] As shown in elementary topology, these items have a mathematically common property, the topological invariant, which all homeomorphic figures necessarily possess.* However, they are not always a powerful tool for the topology of the polyanion structure as a geometrical aggregate of octahedral units. In this paper, we have discussed the polyanion structure and its stability by using a new idea concerning the connec-

*The theorem for the topological invariant is well-known. Theorem. If two figures (*A* and *B*) are homeomorphic, the following three propositions are presented. (1) If *A* is the compact set, *B* is also the compact set, (2) if *A* is arcwise-connected, *B* is also arcwise-connected, and (3) their Euler's characteristics are equal.

The contraposition of the theorem has been practically used for classification of the figures. For two figures (*A* and *B*): (1) if *A* is the compact set and *B* is not, *A* is not homoemorphic with *B*, (2) if *A* is arcwise-connected and *B* is not, *A* is not homeomorphic with *B*; and (3) if their Euler's characteristics are different from each other, they are not homeomorphic.

tivity of octahedral components, the path and the closed loop, which are contours continuously linked by *trans*-located bridging vertices in each octahedron. The polyanion is topologically defined by the Lipscomb–Pope condition.[3,4]

RESULTS AND DISCUSSION

The path

For instance, in a hypothetical inorganic polymer (I), M_nO_{4n+2}, formed only by edge sharing, and a polymer (II), M_nO_{5n+1}, formed only by corner sharing of n MO_6 octahedral units [Fig. 1(a)], both are arcwise-connected, because they have a continuous linkage of octahedral components. Further, they have an identical Euler's characteristic; $\chi = V$ (vertex) $- E$ (edge) $+ F$ (face) $= n + 1$, because $V = 4n + 2$, $E = 11n + 1$, and $F = 8n$ for polymer **I**; and $V = 5n + 1$, $E = 12n$, and $F = 8n$ for polymer **II**. The topological invariant is a necessary but not a sufficient condition for homeomorphic figures.* Therefore, these two polymers cannot be discriminated in a simple way. In these polymers, six vertices of an octahedron and a connecting mode are essential points. Each octahedron could not be substituted by a spherical ball, although they are homeomorphic with each other. Here we intend to propose that a path becomes a tool classifying the structure of such polymers. The path is defined as the contour continuously linked by *trans*-located bridging vertices (oxygens) in each MO_6 octahedron, O—M—O—·····—M—O. The path starts from a vertex in the terminal octahedron. It should pass through all the octahedral units. In the above example, there exist two paths in polymer **I**, but only one path in **II** [Fig. 1(b)]. The analogous polymer formed only by face sharings, M_nO_{3n+3} ($V = 3n + 3$, $E = 9n + 3$, and $F = 6n + 2$), has three paths. However, this polymer is homeomorphic with a monomeric polyhedron and a spherical ball, because none of the linking octahedra have terminal vertices. In fact, it has an Euler's characteristic of 2, independent of n. It follows, therefore, that this polymer is distinct from polymers **I** and **II**. The path is a stricter condition than the arcwise connectivity. In polymer **I**, if each edge sharing is transformed into corner sharing by "scissoring" the shared edges, many corner-sharing polymers are produced. All of them, of course, have equal Euler's characteristics. Only one of them, polymer **II**, has one path and the others have no path despite the continuous linkage of all the octahedral components. If some edge sharings are transformed into corner sharings by "scissoring", a number of polymers containing both corner and edge sharings are produced. Only limited polymers have one path. Some examples are depicted in Fig. 2.

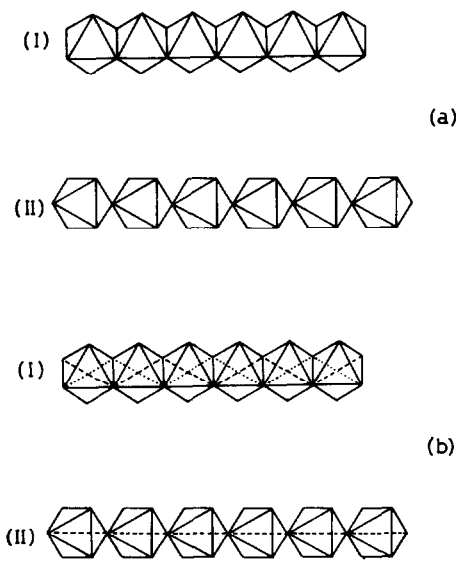

Fig. 1. (a) Hypothetical inorganic polymers formed by edge and corner sharings of n octahedral MO_6 units: **I** with general formula of M_nO_{4n+2}, and **II** with that of M_nO_{5n+1}, respectively. They are drawn as $n = 6$ for convenience. Both have an identical Euler's characteristic: $\chi = V$ (vertex) $- E$ (edge) $+ F$ (face) $= n + 1$. (b) Classification of **I** and **II** by path. There are two paths represented by broken and dotted lines in **I** and one path by a broken line in **II**.

The next examples are the polymers M_3O_{14} (**III**), M_3O_{14} (**IV**) and M_3O_{13} (**V**) formed by the edge sharing of three octahedra (Fig. 3). They are fundamental fragments which frequently appear in many polyanion structures.[1] The difference between polymers **III** and **IV** is an edge-sharing site of a terminal octahedron. Three octahedra in polymer **V** share an edge with each other. These polymers also have an equal Euler's characteristic ($\chi = 4$), as readily confirmed. Polymer **V** can be certainly discriminated from **IV** and **III** by the arcwise connectivity resulting from a removal of one octahedron. However, the path provides a more evident difference; there exist two paths in **III**, one in **IV** and none in **V** (Fig. 3). Since the path is related to the mode of connectivity of each octahedron, it is meaningful in the topology of an inorganic polymer.

In polymers **I** and **II**, a condensation by edge, corner or face sharing between two terminal octahedra leads to cyclization, although it needs an appropriate number of linking octahedra. The

*See footnote on p. 309.

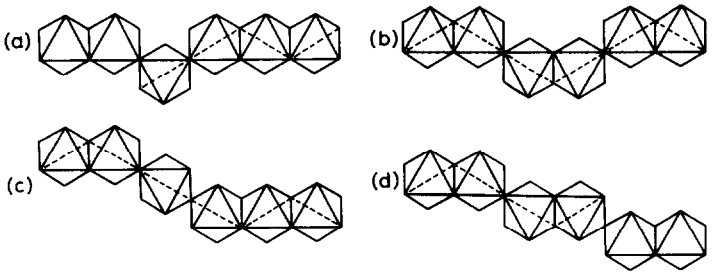

Fig. 2. Inorganic polymers containing both edge and corner sharings produced by "scissoring" of I. There is one path in (b) and (c), but no path in (a) and (d).

propagation of an inorganic polymer by the condensation of some octahedral units ceases on cyclization, because a linear-type condensation is endless. This not only applies to the main chain but also to the side chain or the branch. Evidently, the number of terminal vertices (oxygens) of condensating octahedra decreases on cyclization. The cyclic polymer (I'), M_nO_{4n} ($V = 4n$, $E = 11n$ and $F = 8n$; $\chi = n$), derived from polymer **I**, and the cyclic polymer (II'), M_nO_{5n} ($V = 5n$, $E = 12n$ and $F = 8n$; $\chi = n$), derived from polymer **II**, have two and one path, respectively [Fig. 4(a)]. In these cases, the path forms a closed linkage. Incidentally, polymers **I** and **II** are not homeomorphic with the cyclic polymers **I'** and **II'**, because the Euler's characteristics are different.* The cyclic polymers **I'** and **II'** have two and four terminal vertices in each octahedron, respectively. This implies that polymer **I'** has a higher degree of condensation than **II'**. Here it is noteworthy that the cyclization is independent of the connecting positions between the two condensating octahedra. In the cyclic polymers, closed linkages sometimes exist, but more frequently they do not. This is exemplified in polymer **II'**, where the probability of having a closed linkage is 1/5 [Fig. 4(b)].

The Lipscomb–Pope condition and the polyanions

Although the polyanion is an inorganic polymer, we should discuss them separately. The reason is that the inorganic polymer which is a condensation compound of octahedral units includes the polyanion, but the condensation compound is not always a polyanion. Thus, the definition of the polyanion is required.

Lipscomb[3] has previously proposed that MO_6 octahedra polymerize in aqueous solution to give stable polyanions in which no octahedron terminates in three or more terminal oxygens. In fact, in the actual polyanions hitherto known, the number of terminal oxygens in each octahedral component is less than or equal to two. According to this proposal, Pope[4] has classified the known polyanions into three types; type I comprising each octahedron with a single terminal oxygen, type II comprising each octahedron with two mutually *cis*-located terminal oxygens, and type III containing both sorts of octahedron. Lipscomb's proposal requires that multiple condensations of octahedral units are absolutely necessary for the formation of

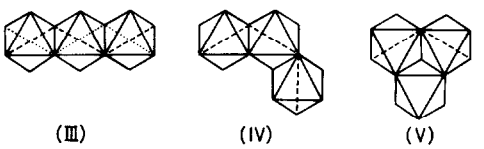

Fig. 3. Polymers formed by edge sharing of three octahedra and classification by path. There are two, one and no path in **III**, **IV** and **V**, respectively.

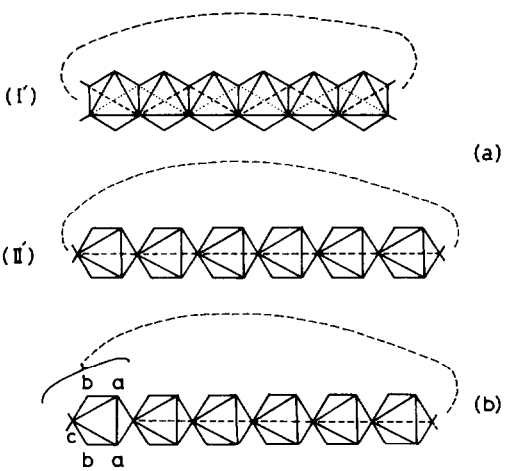

Fig. 4. (a) Cyclic polymers derived from **I** and **II** and path; **I'** with general formula of M_nO_{4n} and **II'** with that of M_nO_{5n}. They have an identical Euler's characteristic; $\chi = n$. (b) Connectivity and path in cyclic polymer **II'**. Only when the cyclization is completed at point *c* does one closed linkage exist.

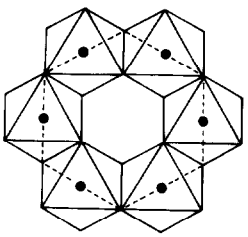
*See footnote on p. 309.

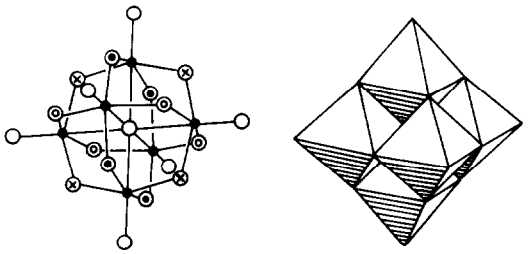
the polyanion, because the number of nonbridging oxygens in the monomeric octahedron, six, should decrease to less than or equal to two. The formation of the polyanion is certainly well described by the proposal. Further this can be considered to be the necessary and sufficient condition for the condensation compound being the polyanion. Thus, the topological definition of the polyanion is given by the Lipscomb–Pope condition; the polyanion is the condensation compound of octahedral units where each octahedron has one or two mutually *cis*-located terminal oxygens.

Here it should be noted that the Lipscomb–Pope condition concerns the number of terminal oxygens in each octahedral unit derived from the already formed polyanions. Coordination by a heteroatom and modification by attaching water, hydroxy and some organic groups can sometimes convert the terminal oxygens into nonterminal ones. Accordingly, it is possible that the Lipscomb–Pope condition can be satisfied by such modifications, even though it is not satisfied by the original skeleton. Furthermore, it is silent about whether the polyanion is stable or not.

As referred to in the definition, none of the examples of inorganic polymers (**I**–**V**) and the cyclic polymer **II**′ are polyanions. The cyclic polymer **I**′ has two terminal oxygens in each octahedron; however, it is also ruled out, because of their *trans* location.



(VI)



(VII)

Fig. 5. Path and closed loop for polyanions formed by edge sharings of six octahedra; one path in **VI** constitutes one closed loop. In **VII**, there is no path through all the octahedra, but three closed loops through four octahedra. In **VI** and **VII**, the filled small circles are metal (M) atoms and in the framework bond model of **VII** the uniformly marked circles (oxygens) identify one closed loop. The polyhedral skeletons of **VI** and **VII** are actually seen in the Anderson polyanion and the $[M_6O_{19}]^{n-}$ isopolyanion, respectively.

The closed loop and structural stability

The path is a convenient tool for distinguishing some inorganic polymers consisting of the same number of octahedral units. This can also be applied to a polyanion. We frequently find that the route along the path forms the closed linkage passing through only bridging vertices. Generally, when the starting vertex of the contour is the same as the end vertex, we have called it a closed loop.[5(a)] The closed loop does not necessarily pass through all octahedral units in the polyanion. There sometimes exist some local closed loops passing through partial octahedral units. This point may be different from the path in the polymer. However, the closed loop also becomes a topological tool for distinguishing some polyanions. When the path is a closed linkage, it is essentially a closed loop. These are shown in Fig. 5.

The formation of a closed loop is directly related to the mode of connectivity of the octahedral components. Further, the combination of the structural parameters *A*, *B* and *C*, where *A* is the number of MO_6 octahedral components constituting the polyanion skeleton, *B* the number of MO_6 units constituting the closed loop, and *C* the number of closed loops, represents a one-to-one correspondence with many actual polyanion structures.[5(a)–(d)] Thus, this combination is representative of the topological character of the polyanion. As a matter of fact, a number of polyanions are more conveniently classified by *A*, *B* and *C* than by the Euler's characteristic. Here it should be noted that in the heteropolyanions the number of heteroatoms themselves, and some elements and groups regarded as the heteroatom, do not contribute to the structural parameters, especially to parameter *A*, and the closed loop is only applied to the polyanion skeleton as an aggregate of octahedra.

If polyanions with different structures have an identical combination of *A*, *B* and *C*, they should be topologically isomeric. Since the topological isomer is not related to a chemical formula or composition, it is not always chemically isomeric. Some mechanisms for the interconversions between α- (**VIII**) and β-$[Mo_8O_{26}]^{4-}$ (**IX**) isopolyanions,

and between Anderson-type $[XMo_6O_{24}H_6]^{n-}$ (X) and Lindqvist-type $[Mo_7O_{24}]^{6-}$ (XI) polyanions, have been previously proposed by some workers (Fig. 6).[6,7] However, α- and β-$[Mo_8O_{26}]^{4-}$ polyanions are chemical isomers, but not topological isomers, because the structural parameters are $A = 6$, $(B, C) = (6, 1)$ in the former, and $A = 8$, $(B, C) = (4, 2)$ in the latter.[5(a)] On the other hand, the Anderson-type $[XMo_6O_{24}H_6]^{n-}$ heteropolyanion, the Lindqvist-type $[Mo_7O_{24}]^{6-}$ and the α-$[Mo_8O_{26}]^{4-}$ isopolyanions are topological isomers, but not chemical isomers, because these polyanions have identical parameters $[A = 6, (B, C) = (6, 1)]$[5(a)] in spite of different chemical compositions. Recently Pope and coworkers[8] have prepared new heteropolytungstoarsonates, $[RAsW_7O_{27}H]^{7-}$ (R = CH_3, C_6H_5 or p-NH_2—C_6H_4) (XII), and discussed the mechanism for the interconversion with the "topologically" related compound, the Lindqvist-type $[W_7O_{24}]^{6-}$ polyanion. The former parameters are $A = 7$, $(B, C) = (6, 1)$, but the latter ones are $A = 6$, $(B, C) = (6, 1)$, because the central nonoxo WO_6 octahedron in the Lindqvist structure has been treated as a heteroatom.[5(a)] Thus, these polyanions are neither chemically nor topologically isomeric. However, the $[(RAs)_2W_6O_{25}H]^{5-}$(XIII) polyanion $[A = 6, (B, C) = (6, 1)]$, which is rapidly induced from XII in aqueous solution, is topologically isomeric with the $[W_7O_{24}]^{6-}$ isopolyanion (Fig. 7).

Apart from the above points, the closed loop is chemically meaningful and it significantly contributes to the stability of the polyanion, since the cyclic π-bonding system along the loop can be considered. The π-bonding character of bridging oxygens has been experimentally confirmed.[6(a)] We[5(a)] have previously proposed the structural stability of the polyanion skeleton on the basis of the number of closed loops and defined the stability index (η) as the number of closed loops per MO_6 octahedral unit. It has been estimated from the

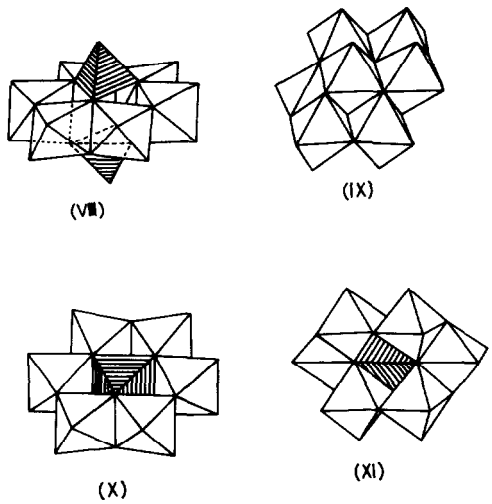


Fig. 6. Polyhedral models of some polyanions; α-$[Mo_8O_{26}]^{4-}$ (VIII), β-$[Mo_8O_{26}]^{4-}$ (IX), Anderson-type $[XM_6O_{24}H_6]^{n-}$ (X) and Lindqvist-type $[M_7O_{24}]^{6-}$ (XI) structures. Shaded polyhedra are the heteroatom or the groups regarded as it.

structural parameters A, B and C as $\eta = (\Sigma BC)/A$. This, in turn, represents the proportion of octahedral components constituting the closed loop to the total number of octahedral units of the polyanion. The product BC shows the number of bridging oxygens on the closed loops. The summation is more than, equal to, or less than the number of actual bridging oxygens according to the multiplicity of the loop passing through the same vertex (bridging oxygen). η has been estimated for a number of actual polyanions[5(a)–(d)] and its properties have been summarized as general rules: (1) polyanions with a larger index are more stabilized; (2) polyanions with an identical index within the same series of constituting elements (M ion and heteroatom) can be interconverted, or converted from one polyanion to another; (3) the index reveals the degree of condensation; (4) when a heteropolyanion decomposes, or degrades, into

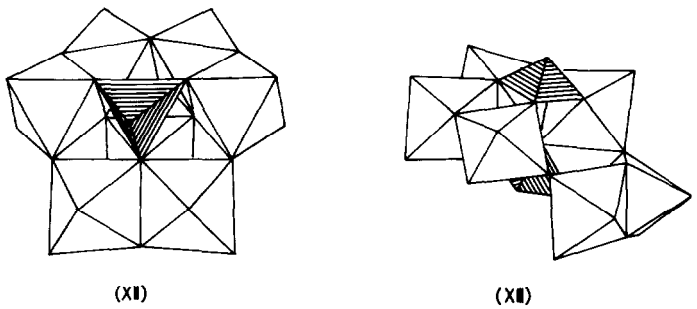

Fig. 7. Polyhedral models of $[RAsW_7O_{27}H]^{7-}$ (XII)[8] and $[(RAs)_2W_6O_{25}H]^{5-}$ (XIII)[1] polyanions. The tetrahedral part of the $RAsO_3$ group is shaded.

some isopolyanions under an appropriate condition, the isopolyanion possessing the largest index is predominantly produced; and (5) the real heteropoly and isopoly compounds with a smaller index are stabilized by some supporting factors other than the structural one.

Acknowledgment—I thank Professor M. Miwa of Seikei University for his helpful advice.

(*Received* 25 *February* 1986; *accepted after revision* 27 *June* 1986)

Abstract—The following compounds, $TlBrI_2(PyO)_2$, $TlBrI_2(2\text{-}PicO)_2$, $TlBrI_2(3\text{-}PicO)_2$, $TlBrI_2(4\text{-}PicO)_2$, $TlBrI_2(4\text{-}Cl\text{-}PyO)_2$, $TlBrI_2(4\text{-}CN\text{-}PyO)_2$, $TlBrI_2(4\text{-}NO_2\text{-}PyO)_2$ and $TlBrI_2(4\text{-}CH_3O\text{-}PyO)_2$, have been prepared and characterized by elemental analysis. The solids behave as non-electrolytes in acetonitrile solution and are monomers in benzene. Vibrational (IR and Raman) spectra suggest that the most probable structure is that of a trigonal bipyramid with the halogen atoms in equatorial positions and the two ligands in axial positions.

Our previous work reported the detailed characterization of $TlI_3 \cdot L_2$[1] and $TlClI_2 \cdot L_2$[2] complexes, following a new and simple synthesis procedure which is an improvement on the one published by Cotton.[3]

We now report the synthesis and structural characterization of interhalogen derivatives of thallium(III) of type $TlBrI_2 \cdot L_2$. The selected ligands are: pyridine *N*-oxide (PyO), 2-, 3- and 4-methylpyridine *N*-oxide (2-PicO, 3-PicO and 4-PicO), 4-chloropyridine *N*-oxide (4-Cl-PyO), 4-cyanopyridine *N*-oxide (4-CN-PyO), 4-nitropyridine *N*-oxide ($4\text{-}NO_2\text{-}PyO$) and 4-methoxypyridine *N*-oxide ($4\text{-}CH_3O\text{-}PyO$). $TlBrI_2 \cdot 2PyO$ has been prepared previously[4] but it is prepared now for comparison.

EXPERIMENTAL

Measurements and material

IR spectra were recorded on a Perkin–Elmer 180 spectrophotometer with a far-IR accessory and the Raman spectra with a Jarrel–Ash spectrophotometer (Ar^+ laser, 5145 Å). The conductivity measurements were carried out with a WTW LF-3 type conductivity bridge and an LTA type electrode using 10^{-3} M solutions in acetonitrile, and the molecular weights of those complexes that were sufficiently soluble were determined in benzene in a Knauer vapour pressure osmometer. Standard procedures were used for determining the elements. All products were of reagent grade and the solvents were dried by standard procedures.

Synthesis of the complexes

They were prepared by the addition of a solution of iodine in acetonitrile, drop by drop, with magnetic stirring, to a TlBr suspension and the donor in the same solvent. As the addition proceeds the TlI can be observed dissolving as a consequence of the formation of the new $TlBrI_2 \cdot 2L$ compounds which are often soluble in the selected solvent. The transparent solution formed is stirred for a few hours and concentrated in the vacuum line. Some solids were recrystallized in acetonitrile.

RESULTS AND DISCUSSION

All the compounds were prepared in a 1:2 molar ratio as coloured solids (some of them crystalline). The compounds are photo- and air-stable, with the exception of $TlBrI_2(4\text{-}NO_2\text{-}PyO)_2$ which is hydrolyzed slowly by air (in acid medium the hydrolysis is very fast). They are soluble in solvents with lower dielectric constants. The molecular weights show that the compounds exist as monomers, at least in benzene, in agreement with data obtained for similar compounds.[1,3-5] The milimolar conductivities in acetonitrile (see Table 1) are lower than the values reported for 1:1 electrolytes,[6] and show their non-electrolytic behaviour in this solvent.

The most significative bands of the IR spectra of the ligands and adducts are shown in Table 2. The ligand bands have been assigned according to Shindo[7] and Karayannis.[8]

The position of the ν(N—O) vibration mode in the compounds is shifted toward lower wavenumbers ($\Delta\nu \simeq 20\text{–}49\,cm^{-1}$), showing that the coordination takes place through the oxygen atom of the N—O group. The strong band, close to $850\,cm^{-1}$ and assigned to δ(N—O), undergoes small shifts which have been ascribed to two competitive effects[9] and have also been detected in other complexes with these aromatic amine oxides.[2,4,8,10]

The ν(Tl—Br), ν(Tl—I), ν(T1—O) and δ(Tl—X) bands that appear between 500 and $50\,cm^{-1}$ contain information concerning the structure of the complexes. The assignments of the ν(Tl—Br) and ν(Tl—I) vibrations has been accomplished by comparing the spectra of our complexes with the assignments made in other thallium halide complexes[1,2,4,5] prepared by us, and taking into account that, according to Carty,[11] the ν(Tl—Br)/ν(Tl—Cl) and ν(Tl—I)/ν(Tl—Cl) ratios must be 0.7 and 0.6, respectively. The bands appearing at 130 and $150\,cm^{-1}$ have been taken as δ(Tl—Br) and δ(Tl—I) modes, respectively, as has been suggested by Walton[12] and McWhinnie.[13] The position of the ν(Tl—O) band has been placed at $300\,cm^{-1}$ according to the assignments of other papers.[1,5] These assignments are listed in Table 2.

X-ray diffraction studies of the complexes $TlCl_3(4\text{-}CN\text{-}PyO)_2$,[14] $TlI_3(2\text{-}PicO)_2$,[15] $TlBr_3(TPPO)_2$,[16] $TlBr_3(PyO)_2$,[17] $TlBr_2I(TPPO)_2$[18] and $TlClBrI(TPPO)_2$,[19] have confirmed the presence in these crystals of slightly distorted trigonal bipyramidal molecules. Recently $TlBrI_2(TPPO)_2$[20] and $TlBrI_2(4\text{-}PicO)_2$[21] have been studied. The unit cell of $TlBrI_2(4\text{-}PicO)_2$ is orthorhombic, space group *Pnna*, and the structure consists of discrete molecules which have distorted trigonal bipyramidal geometry. The thallium atom is coordinated to two iodine atoms and a bromine atom in equatorial positions, and by two ligands in the axial positions.

The small number of bands present in the vibrational spectra of the complexes and their position may exclude the presence of covalent dimeric or polymeric structures and ionic forms.[1,22,23]

For our $TlBrI_2$ compounds the presence of monomer trigonal bipyramidal species must be expected. For this kind of systems there are three different spatial arrangements with thallium C_{2v}, C_s or C_1 local symmetries. All of them originate one ν(Tl—Br), two ν(Tl—I) and two ν(Tl—O), all IR- and Raman-active. The number of bands present in the IR spectra of these compounds is compatible with a *bpt* structure, in spite of us being able to find only a band which can be assigned to a Tl—O stretching mode. However, the Raman spectra show a band at *ca* $270\,cm^{-1}$, which can be assigned to the symmetrical Tl—O stretching mode, which should be stronger in Raman than in IR spectra.

COMPLEXES OF TRIMETHYLPLATINUM(IV) HALIDES WITH OPTICALLY ACTIVE SCHIFF BASE LIGANDS

EDWARD W. ABEL, KENNETH KITE* and PHILLIP S. PERKINS

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 3 *June* 1986; *accepted* 27 *June* 1986)

Abstract—The complexes $[(PtMe_3X)C_6H_4NC(R):NCH(Ph)Me]$ (X = Cl, Br or I; R = H or Me) of the Schiff bases derived from (*S*)-(−)-α-methylbenzylamine and 2-pyridinecarboxaldehyde and 2-acetylpyridine, respectively, have been prepared and characterized by 400-MHz ^1H NMR spectroscopy. The diastereoisomeric mixtures have been separated, but rapid isomerization is observed in solution.

The *fac*-methyl groups in trimethylplatinum(IV) compounds[1] make the octahedrally coordinated metal a chiral centre whenever there are three different *trans* substituents, or multidentate ligands which remove the planes of symmetry. No optically active $PtMe_3^+$ complexes have been reported to date, though in the closely related complex $(\eta^5\text{-}C_5H_5)Pt(CH_3)(C_2H_5)(COCH_3)$ the pseudo-tetrahedral or "piano stool" disposition of ligands confers optical isomerism. The ^{13}C and ^1H NMR signals from all four ligands in this complex are split in the presence of a chiral shift reagent[2,3] but it was not possible to resolve the isomers.

The addition of an optically active ligand of defined chirality (*S*) to a prochiral metal centre will necessarily generate two diastereoisomers during synthesis, with optical configurations (*S*)(*R*) and (*S*)(*S*) at the (ligand)(metal) atoms, respectively. This has been elegantly exploited by Brunner and co-workers,[4] who found that "piano stool" complexes of type $[(\eta^5\text{-}C_5H_5)Mn(NO)(CO)_2]^+$ could be resolved by replacing one of the CO groups with an optically active *t*-phosphine,[5] and the octahedral complexes *fac*-$[(CO)_3M(PPh_3)(L\text{–}L)]$ (M = Cr, Mo or W) by using a chiral Schiff base (L–L).[6] The direct parallels with *fac*-trimethylplatinum(IV) led us to prepare the complexes $[PtMe_3X(L\text{–}L)]$, where X = Cl, Br or I, and (L–L) = the Schiff bases **I** and **II** made from the condensation of 2-pyridinecarboxaldehyde and 2-acetylpyridine, respectively, with the optically active primary amine (*S*)-(−)-α-methylbenzylamine, and to study their optical stability by ^1H NMR spectroscopy. Another feature of interest in these complexes is their similarity to the thioether compounds $[(PtMe_3X)MeS(CH_2)_2SMe]$, which undergo an intramolecular fluxion at high temperatures that causes a coalescence of the ^1H NMR signals from the Pt—Me groups. The most plausible mechanism for this process is a "pancake flip" rotation of the thioether.[7] Such a mechanism applied to the Schiff base complexes would interconvert the two diastereoisomers, and a ligand flip process has been suggested by Brunner to explain the isomerization of diastereoisomers of some square pyramidal Mo(I) complexes of I.[8]

EXPERIMENTAL

Literature methods were used to prepare trimethylplatinum iodide[9] and sulphate,[10] from which the bromide and chloride were obtained by reaction with the appropriate potassium halide.[11] 2-Pyridinecarboxaldehyde, 2-acetylpyridine and (*S*)-(−)-α-methylbenzylamine were commercial samples (Aldrich) whose purity was checked by NMR spectroscopy before use.

The Schiff base ligands $C_6H_4NC(R):NCH(Ph)Me$ (**I**, R = H; **II**, R = Me) were made by the method of Brunner and Herrmann[12] in 82 and 76% yield for **I** and **II**, respectively. They were purified by low-temperature recrystallization from diethyl ether, and characterized by mass spectroscopy, optical rotation and NMR spectroscopy in $CDCl_3$ solution [**I**, *m/z* 210 (210); $[\alpha]^{589\,nm}$ = +7.36°; δ 1.60 d (3H) (*J* = 6.7 Hz); 4.63 q (1H) (*J* = 6.6 Hz); 7.36 m (5H); and 8.46 s (1H): **II**, *m/z* 223–225 (224); $[\alpha]^{589\,nm}$ = +90.4°; δ 1.53 d (3H)

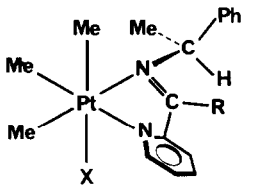

Fig. 1. Structure of the Schiff base complexes [**IA**, R = H, X = Cl; **IB**, R = H, X = Br; **IC**, R = H, X = I; **IIA**, R = Me, X = Cl; **IIB**, R = Me, X = Br; **IIC**, R = Me, X = I].

(J = 6.7 Hz), 2.40 s (3H), 4.89 q (1H) (J = 6.5 Hz), and 7.2–7.4 m (5H)]. Reported NMR data[8] for **I** and **II** are in agreement, allowing for the different solvent system. Optical rotation data are reported for **II** alone, and show that the specific rotation is very wavelength-sensitive, the most comparable value being +101° at 579 nm.

The trimethylplatinum(IV) complexes **IA–C** and **IIA–C** (Fig. 1) were made by the same general method, the following for **IIC** being typical. A mixture of trimethylplatinum(IV) iodide (0.25 g, 0.68 mmol*) and **II** (0.155 g, 0.69 mmol) in chloroform (15 cm^3) was refluxed overnight. The solution was evaporated to dryness, and the solid recrystallized twice from dichloromethane–light petroleum as fine yellow crystals (0.24 g, 59.7%).

^{1}H NMR spectra were recorded at 400 MHz on a Bruker WH-400 spectrometer and at 100 MHz on a JEOL PS/PFT-100 equipped with standard accessories for variable-temperature work. The ^{13}C NMR spectra were recorded on a JEOL GX-270 spectrometer. Band shape analyses were carried out with a version of the DNMR programme of Kleier and Binsch[13] modified to calculate spectral changes based on six initial chemical configurations. Far-IR spectra were run in polythene discs on a Grubb–Parsons/NPL Cube interferometer linked to an Apple II microcomputer. Molecular weights were determined by vapour pressure osmometry, and mass spectra were obtained on a single focussing VG-Micromass MM-30 spectrometer using electron ionization at a potential of 70 eV and probe temperatures of 145 and 200°C.

RESULTS AND DISCUSSION

Complexes **IA–C** and **IIA–C** were prepared from the appropriate trimethylplatinum(IV) halide and an equimolar quantity of the ligand as yellow or orange solids. Analytical and far-IR data (Table 1) are consistent with the mononuclear structure in Fig. 1.

The bromides and iodides crystallized as rhombic or needle-like crystals from CH_2Cl_2–MeOH (1:1 by volume). The chlorides separated as oils, which turned solid on prolonged pumping. The melting ranges indicate isomeric mixtures, the bromides and iodides showing signs of change up to 20°C before the onset of melting. Lower values for the chlorides and their reluctance to crystallize shows a marked change in ease of crystal packing with increase in halide size. Monomeric molecular ions were seen in the mass spectra of all of the complexes. The mononuclear structure in solution was confirmed by vapour pressure osmometry on the iodides in chloroform and the similarity of the NMR data for all three halides. The presence of coordinated X^- was confirmed by the observation of terminal Pt—X stretches in the far IR, these modes being uniformly lower in the complexes of ligand **II**.

^{1}H *NMR spectra*

The 400-MHz ^{1}H NMR spectra of both series of complexes confirm the structures in Fig. 1 and show clear evidence of the presence of two diastereoisomers in every case. For reasons that will be apparent later, it is convenient to discuss the spectra of the two series separately. The spectroscopic data for complexes **IA–C** are recorded in Table 2, aromatic protons (non-first-order multiplets) being omitted as they give no extra structural information.

In the spectra of **IA–C** each diastereoisomer (**a** and **b**) shows six sets of signals (including the aromatic protons) almost all of which are clearly resolved at 400 MHz. The isomers are present in different proportions as expected, and the relative amounts of each are reflected in all six regions of the spectrum, making assignments unambiguous. Relative proportions of one isomer (averaged from all the signals) are 1.34, 1.04 and 0.88 for **IA**, **IB** and **IC**, respectively. Of the three Pt—Me signals for each isomer (Fig. 2), two show $^2J(^{195}Pt–^1H)$ values expected[14] for methyls *trans* to N (68.9–71.7 Hz) and one shows ^2J values for methyls *trans* to halide, with the latter invariably at higher field as is usual in this type of complex.[15] These highest-field signals clearly show that for **IA** and **IB** (X = Cl or Br) the most abundant isomer has its methyl *trans* to X signal at higher field while for **IC** (X = I) the situation is reversed. The more abundant isomer usually has a slightly higher ^2J value for methyls *trans* to N, and in one of the pair of isomers the

[b]Not seen.

two Pt—Me signals for methyls *trans* to N have a much narrower chemical-shift separation.

Each isomer shows the same pattern of signals assignable to the PhC*H(Me) group, viz. a doublet (^3J = 6.7–7.0 Hz, 3H) (Fig. 2), a non-first-order multiplet (1H) with ^3J couplings to both ^{195}Pt and the C—Me protons (Fig. 3), and a low-field multiplet (5H) for the aromatic protons. For *one* of the isomers (the one resonating at lower field in each case) the C*—H(Me) signals show a marked depen-

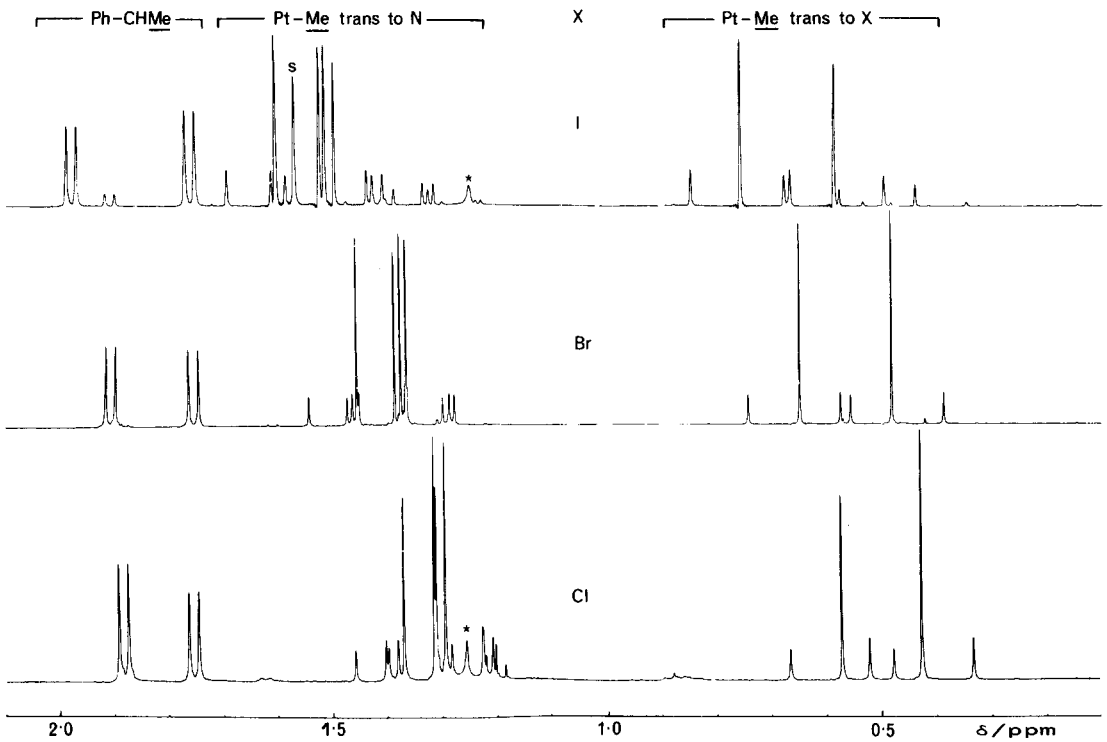

Fig. 2. 400-MHz ^{1}H NMR spectra of complexes IA–C in the region 0–2.0 ppm showing the Pt—Me (right) and Ph—CMe signals and the isomer populations (S = solvent, * = impurity).

dence on halide, moving downfield from chloride to iodide. The proton of the CH=N group appears further downfield, and the signals, split by coupling to ^{195}Pt (^3J = *ca* 28 Hz), also show long-range coupling (J = *ca* 1.3 Hz) to one of the pyridine protons, which implies that the coupled protons are in a planar configuration.

Close examination of the spectra of **IB** and **IC** reveals a second set of low-intensity signals which in relative intensity reflect the proportions of the major pair of isomers. The peak-for-peak correspondence throughout the spectra (where peaks are not overlapped), and the J values for the coupled signals show that each major isomer (**a** and **b**) has a very similar "ghost" (labelled **a′** and **b′**), though the chemical shifts show considerable differences. The variation in abundance of these additional signals with halide ($I^- > Br^- > Cl^-$) leads us to conclude that they may be attributed to *rotamers* arising from restricted rotation about the benzyl–nitrogen bond caused by a steric clash between the phenyl ring and the halide. Molecular models show that this is reasonable, but do not reveal any specially favoured configuration. Assignments of **a′** and **b′** are based on relative signal intensities alone, and do not necessarily imply that they are the rotamers of major isomers **a** and **b**, respectively.

For complexes **IIA–C** very similar spectra resulted, the most prominent difference being the expected replacement of the triplet of doublets at low field by a 1:4:1 triplet at *ca* 2.1 ppm (^4J = ~ 3.6–3.8 Hz) from the N=C(Me) protons coupled to platinum. Spectral data in Table 3 show that two isomers (**a** and **b**) are present, but for this series the relative isomer ratio is barely altered by a change in halide, and there are no additional "ghost" signals. The methyl group probably inhibits the N—C* bond rotation and locks the structure in one rotameric conformation. The ^2J values for Pt—Me groups *trans* to N indicate that for all complexes both Pt—N bonds are stronger[14,15] than in **IA–C**. In a series of $PtMe_3^+$ complexes containing a substituted salicylaldimine and 3,5-lutidine[16] the two Pt—Me signals could be readily distinguished by their ^2J values (65.7–68.1 Hz *trans* to imine N and 71.3–72.3 Hz *trans* to lutidine N), with the former invariably at lower field. In both **IA–C** and **IIA–C** the distinction is more difficult to make as the ^2J values are much closer together, though in **IIA–C** the Pt–Me signal at lowest field (except for **IIBb**) has the smaller ^2J value, so it is likely that this is a methyl *trans* to imine N.

^{13}C *NMR study*

Further characterization of one of the complexes (**IB**) was done by recording a 270-MHz proton-decoupled ^{13}C NMR spectrum. Data are given in

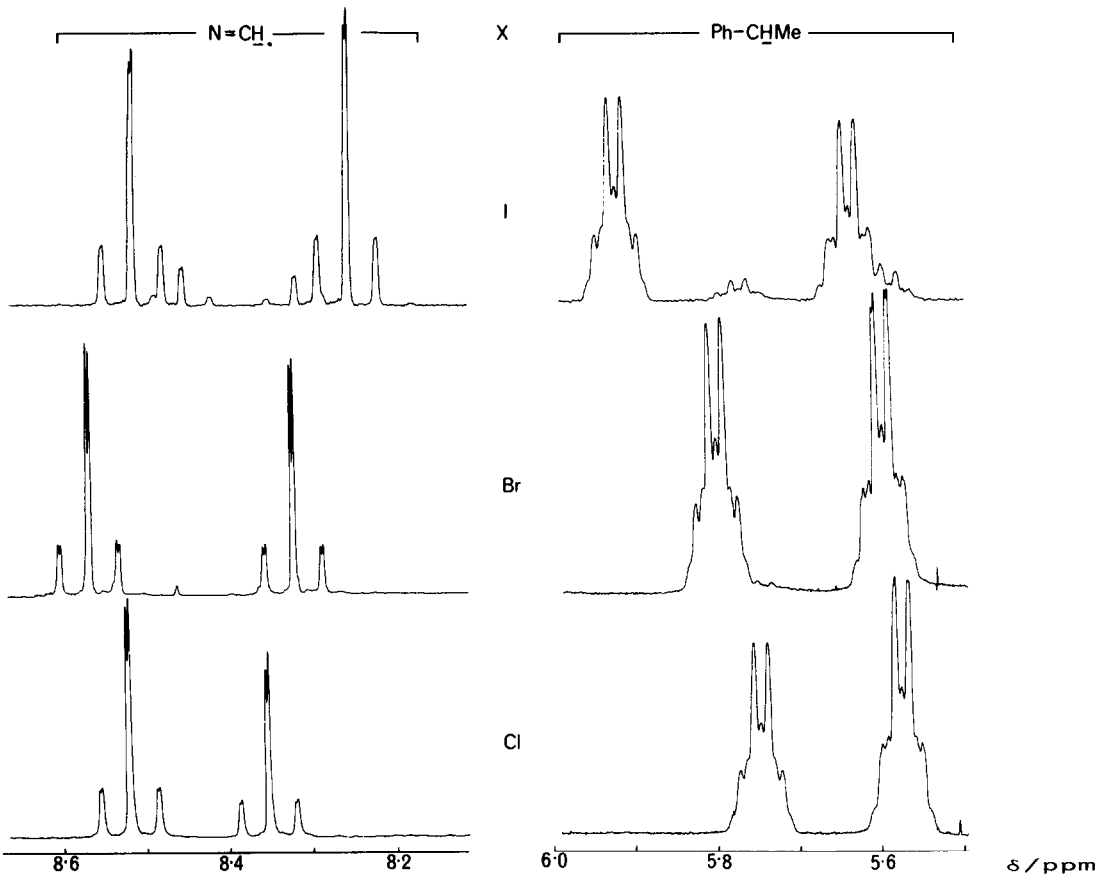

Fig. 3. 400-MHz ^{1}H NMR spectra of complexes IA–C showing the N=CH (left) and Ph—CH (right) proton signals.

Table 4 with assignments shown in Fig. 4. Signal assignments are based on $^1J(^{195}Pt)$ couplings, chemical-shift values, and the fact that signal intensities decrease in the order $CH_3 > CH_2 > CH > C$ due to relaxation effects.[17] Coupling to ^{195}Pt through two or more bonds was also evident, making possible the complete assignment of the pyridine ring carbons. The spectrum was too noisy for

rotamers to be detected, but the relative populations of the two major isomers agree with values from the 400-MHz ^1H spectra. Pt—Me groups *trans* to X^- showed higher ^1J values than those *trans* to N, paralleling the ^2J values from the proton spectra.

Separation of the isomers

Initial attempts were made to separate the isomers of **IB** and **C** and **IIB** and **C** by fractional crystallization from a range of single- and mixed-solvent systems, and by thin-layer chromatography (tlc) on Kieselgel 60F. In every case an ^1H NMR spectrum of the product showed no isomeric enrichment. A sample of **IIC** showed some broadening on the tlc plates, but column chromatography on Kieselgel 60F with CCl_4 followed by CH_2Cl_2 gave head and tail fractions with the same isomer abundance. The reason for this behaviour became apparent when samples of the solids **IIA–C** were washed with small aliquots of CCl_4. The *remaining* solid in each case was enriched with one isomer, the percentage enrichment (determined by 100-MHz NMR spectra) being dependent on the halide (I^- = 90.4%, Br^- = 86.4%, Cl^- = 60.0%). However, on standing in $CDCl_3$ the relative proportions of the isomers gradually changed to the quilibrium populations shown in Table 3, the half-life for the iodide complex **IIC** being 13.6 min at 19°C. Clearly this propensity for the isomers to interconvert in solution at room temperature frustrated attempts to separate them, but enabled the isomerization to be followed kinetically.

Interconversion of the isomers

A time-dependent set of ^1H NMR spectra for complexes **IIA–C** in $CDCl_3$ was obtained at 100 MHz, and the spectral changes in the Pt–Me region for the iodide complex are shown in Fig. 5. Changes in the population of the isomers **a** and **b** are clearly seen in the two highest intensity high-field signals. The first-order rate constant for the intramolecular process **a** = **b** was calculated by plotting $\ln x$ against time, where x is the percentage by which the more abundant isomer exceeds its equilibrium value. For first-order kinetics this prod-

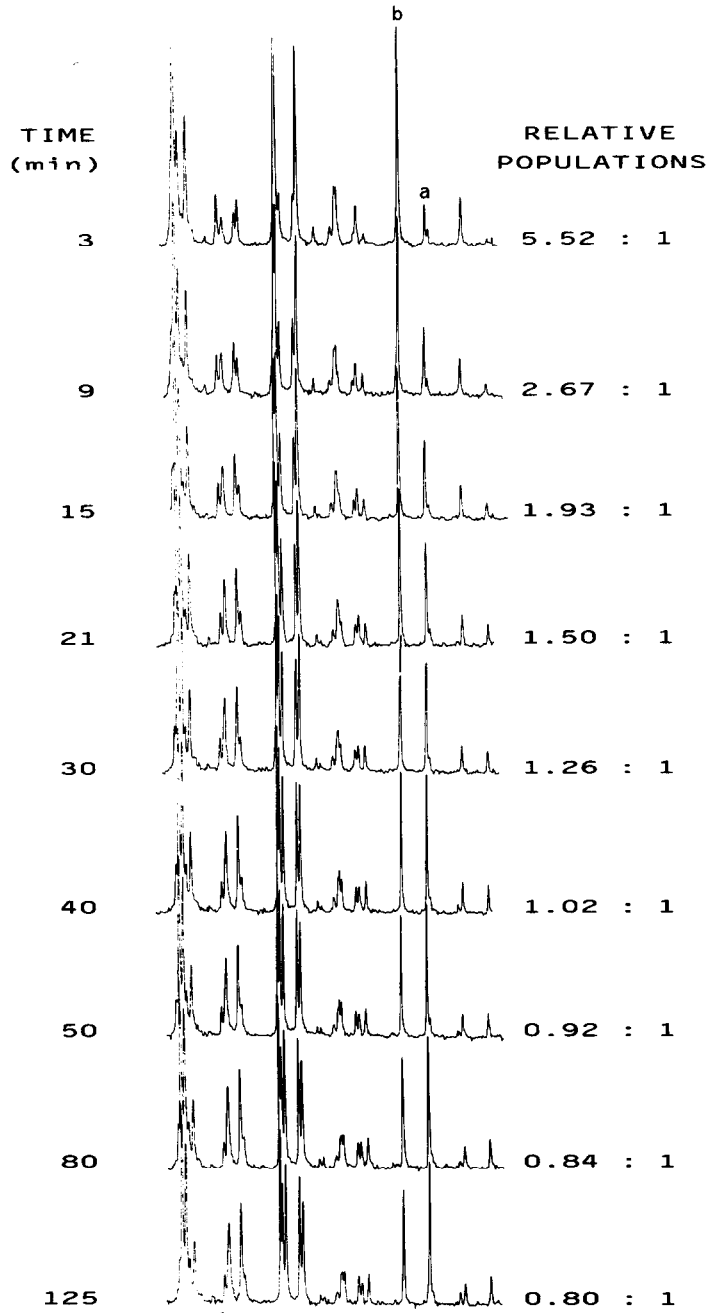

Fig. 5. Time-dependent 100-MHz ^{1}H NMR spectra of **IIC** in $CDCl_3$ at ambient temperature, showing relative populations (**b**:**a**) of isomers **b** and **a**.

uces a straight line with gradient $-k$. Values of x were obtained from the relationship:

$$x = a_t^N - a_\infty^N,$$

where a_t^N is the normalized amount of **a** at time t given by:

$$a_t^N = \frac{a_t}{a_\infty + b_\infty}$$

Data are recorded in Table 5. Owing to the low initial enrichment obtainable for the chloride **IIA**, it was not possible to get accurate rate data, though the interconversion was clearly slower than for the bromide. An additional run on the bromide complex **IIB** using a more dilute solution gave an almost identical rate for the interconversion (Fig. 6), implying that the process is not solvent-dependent. The more than doubling of the rate on raising the temperature by 11°C is as expected for the first-

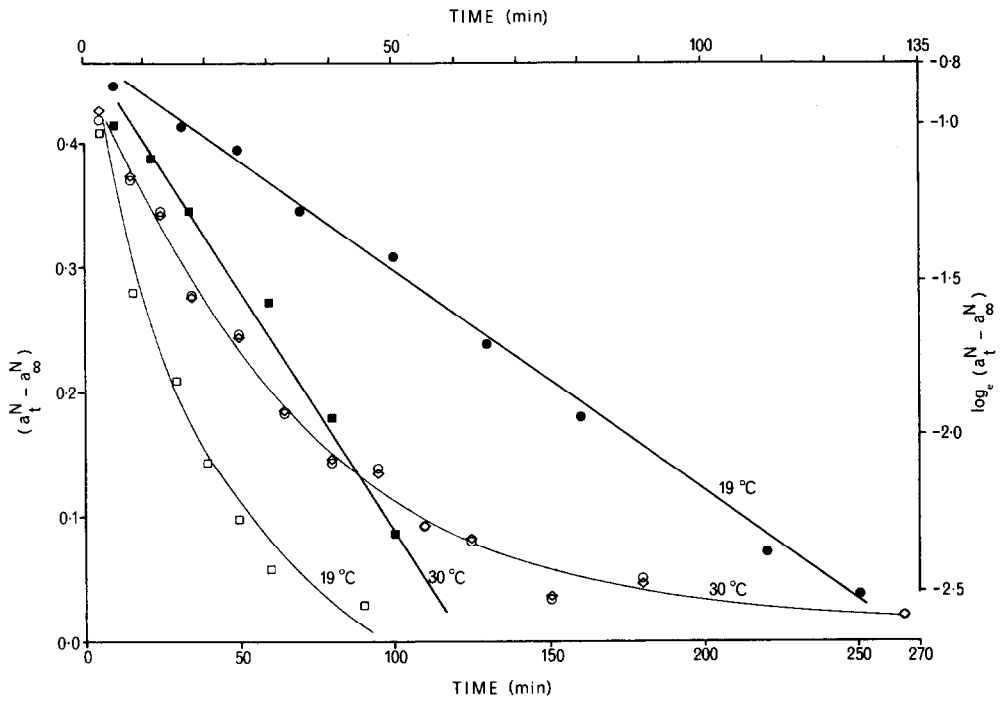

Fig. 6. Isomerization of **IIB** and $CDCl_3$ showing exponential (□ and ○) and $\log_e$ (■ and ●) plots. Curves ○ and ◇ refer to isothermal runs at different concentrations.

Table 5. First-order rate constants for the isomerization of **IIB** and **IIC**

Complex	Halide	Temperature (°C)	$t_{\frac{1}{2}}$ (min)	k $(min)^{-1}$
IIB	Br	19	48.3	0.014
IIB	Br	30	22.0	0.032
IIC	I	19	13.6	0.05

order kinetics, and the process causing the isomerization is therefore intramolecular.

High-temperature NMR spectra

A DNMR study of the thioether complexes mentioned earlier revealed a high-temperature intramolecular fluxion[6] which causes the ^1H NMR signals from the Pt–Me groups to coalesce. As the isomers of the iodide complex **IIC** show the fastest rate of interconversion, the 100-MHz NMR spectra of the iodides were examined at high temperatures to see whether a Pt—Me scrambling process would occur. Complex **IC** showed no spectral changes up to 115°C ($CDCl_3$, sealed tube) so it seems likely that this series does not show high-temperature fluxionality. When complex **IIC** was studied in the same solvent, spectral collapse was seen to begin at 100°C, but as the broadening was not complete at the highest temperature accessible in this solvent (115°C) a different solvent system (CD_3NO_2–$C_6D_5NO_2$, 2:3 by volume, sealed tube) was used. Here spectral collapse began at a much lower temperature (65°C), implying that the process was solvent-dependent. This was confirmed by the failure of attempts to simulate the spectra using a program structured for purely intramolecular mechanisms.[13]

Evidence for a high-temperature fluxional process was seen in the spectral changes of the N=C—Me proton signals of **IIC**. The pair of triplets at room temperature broaden and coalesce to a single sharp triplet at 150°C. However, on raising the temperature by a further 10–20°C this triplet disappeared and was replaced by a low-intensity multiplet. On cooling to room temperature, the final spectrum was identical to the initial one, minus the pair of triplets from the N=C—Me group. A substantial increase in the signal from residual CH_3NO_2 in the solvent region strongly suggests a CD_3 for CH_3 group exchange on the ligand. A repetition of this experiment using free ligand in the same solvent system showed no exchange. We are uncertain whether it is just atom (H–D) or group (CH_3–CD_3) exchange.

General discussion

The $PtMe_3$(IV) complexes are the first reported which contain neutral bidentate Schiff base ligands,

which compared to the ionic salicylaldiminates[16] are poorer donors via the imine N. A parallel was found with the formerly analogous complexes *fac*-$[(CO)_3M(PPh_3)(L\text{–}L)]$ (M = Cr, Mo or W; L–L = **I**)[6] and *fac*-$[(CO)_3MnBr(L\text{–}L)]$ (L–L = **I**)[18] which contain a d^6-metal, in that each compound exists in solution as a mixture of two diastereoisomeric forms (**a** and **b**) having either the (*R*)(*S*) or the (*S*)(*S*) configuration at the metal and benzyl carbon atoms, respectively. The apparent rapid interconversion of **a** and **b** in solution was surprising, in view of the success of the $PtMe_3^+$ ion as a probe to identify the *meso* and racemic forms of some chelating diarsines.[19,20] In particular, the reaction of $[PtMe_3I(diarsine)]$ with $AgPF_6$ in the presence of pyridine to give $[PtMe_3(py)(diarsine)]^+$ with *meso*-$[C_6H_4(AsMePh)_2]$ proceeded stereospecifically for both isomers of the iodide (arsine methyls pointing towards or away from the halide),[19] indicating that the $PtMe_3$ group and the arsine retain the same stereochemical relationship during the reaction. The stronger Pt—As bond (^2J = *ca* 65 Hz) may be responsible. The mechanism by which isomers **a** and **b** interconvert is apparently first-order, and a "ligand flip" of the Schiff base is one possibility.

It is not possible to say which isomer has which configuration, but the ^1H NMR parameters for all the C*(Me)H ligand signals are considerably halide-sensitive, suggesting a difference in conformation with respect to the axial Pt—X bond. It is possible to ascribe the additional isomers of **IA** and **IB** to rotamers, on the basis of the variation in abundance with halide size (greatest in the more sterically crowded iodide), and also the failure to detect them in **IIA–C**, where the additional ligand methyl group presumably favours one rotameric form.

PALLADIUM COMPLEXES WITH BIOLOGICAL LIGANDS—II.* KINETICS AND MECHANISM OF PYRIDOXAL-5′-PHOSPHATE AND PYRIDOXAMINE-5′-PHOSPHATE REACTIONS WITH PD(II)

MOHAMED S. EL-EZABY,† HAYAT M. MARAFIE and HUSAM M. ABU-SOÛD‡

Chemistry Department, Faculty of Science, University of Kuwait, Kuwait

(*Received* 9 *December* 1985; *accepted* 30 *June* 1986)

Abstract—The kinetics of the interaction of either pyridoxal-5′-phosphate (PLP) or pyridoxamine phosphate (PMP) with Pd(II) have been studied in acidic aqueous solution at 37°C and ionic strength 0.15 M (NaCl). The observed dependence of the rate constant k_{obs} on the total ligand concentration (T_L) at a given pH is as follows for each system: $k_{obs}(PLP) = A + BT_{PLP}$ and $k_{obs}(PMP) = C + DT_{PMP}$. The parameters A–D are pH-dependent. It has been suggested that, in the case of the Pd(II)–PLP and Pd(II)–PMP systems, the prior fast formation of a $Pd(H \cdot VB_6P)Cl_3$ (VB_6 = vitamin B_6) complex species has been assumed.

Pd(II) complexes with non-phosphorylated vitamin B_6 (VB_6) compounds have been shown to have inhibitory effects on some cell divisions.[2] The stopped-flow method has been used to study the kinetics of their formation in aqueous solution.[2] It has been concluded that the 1:1 complexes were formed relatively faster than the 2:1 species, specially in the case of the pyridoxal (PL)– and pyridoxamine (PM)–Pd(II) systems. It has been also concluded that possibly $PdCl_4^{2-}$ as well as $[PdCl_3(OH)]^{2-}$ are the Pd(II) reactive species in their complex formation with VB_6. In the present work the interaction of the phosphorylated VB_6 compounds with Pd(II) has been studied under identical conditions to the previous investigation[3] in order to examine the effect of the phosphate group on the complex formation kinetics.

EXPERIMENTAL

A stock solution of Pd(II) chloride (0.1 M) was prepared in 1.0 M HCl. The Pd(II) concentration was checked by a gravimetric method as Pd(dimethylglyoxime)$_2$.[4] Pyridoxal-5′-phosphate (PLP) and pyridoxamine phosphate (PMP) were analytically pure chemicals and were used without purification. Stock solutions (0.1 M) of the ligands were prepared by dissolving the right amount in deionized double distilled water and kept in the dark at 4°C. In all measurements, the ionic strength was kept constant at 0.15 M (NaCl).

Measurements

Kinetic measurements were done using a Durrum stopped-flow apparatus. The optical path length was 20.0 mm. The mixing syringes and cuvette were thermostated at 37°C. The observed pseudo-first-order rate constants were calculated from data for up to 85% completion of the reaction. Measurements of pH were carried out using a Radiometer pH-meter type 62 equipped with a combined glass electrode (GK 2301C). The pH meter was calibrated before use with radiometer buffer solutions (pH 4.00 and 7.00). Spectrophotometric measurements were carried out on a Pye–Unicam SP8-100 spectrophotometer. The concentration range of the ligands used was $(0.25–1.75) \times 10^{-2}$ M. The Pd(II) concentration was kept constant at 2.5×10^{-4} M.

RESULTS AND DISCUSSION

Pd(II)–*PLP system*

The spectral band of Pd(II) in the visible region was lost when a 10 times concentration of PLP was added at pH = 2.00 (Fig. 1). This was taken as an indication of the complex formation between Pd(II) and PLP. In order to determine if the phosphate group was involved in the complex formation or not, a solution of NaH_2PO_4 was added to a Pd(II) solution under identical experimental conditions to the above. The Pd(II) spectra in the visible region and in the pH range 2–6 were the same in the absence and in the presence of the phosphate solution A wavelength (λ) of 470 nm has been selected to carry out the kinetic study in the pH range 2.25–4.50 where PLP has a practically minimum absorption. Figure 2 shows the dependence of the observed rate constant (k_{obs}) (under pseudo-first-order conditions) as a function of the pH. On the other hand, Fig. 3 shows the linear dependence of k_{obs} on the total concentration of PLP (T_{PLP}) at interpolated values of pH. At any particular pH these linear relations can be represented by the following equation:

$$k_{obs}(PLP) = A + BT_{PLP}, \quad (1)$$

where A and B are the intercept and slope values at various pH values. Table 1 depicts the values of A and B at interpolated pH values. In analogy to the PL–Pd(II) system[3] it may be reasonable to assume that the 1:1 complex is formed relatively faster than the 2:1 complex. A mechanism similar to what has been proposed (Scheme 1) for PL–Pd(II) systems may be applied to the PLP–Pd(II) system. In this case, however, we have several species of PLP existing under the experimental

conditions used, namely H_4PLP^+, H_3PLP, H_2PLP^- and $HPLP^{2-}$ (Table 2). There is also the possibility that two species of Pd(II) may exist, $PdCl_4^{2-}$ and $[PdCl_3OH)]^{2-}$. Other chloro and/or hydroxy species of Pd(II) may be ignored since the solutions have a relatively high chloride ion concentration ($\simeq 0.15$ M) and are acidic (pH $\leqslant 4.5$).

$$\begin{array}{l} H_4PLP^+ \\ \downarrow\uparrow \\ H_3PLP \\ \downarrow\uparrow \\ PdCl_4^{2-} + H_2PLP^- \overset{K'_{1C}}{\rightleftarrows} [Pd(H_2PLP)Cl_3]^{2-} + Cl^- \qquad \text{(i)} \\ \downarrow\uparrow K_{OH} \qquad\qquad \downarrow\uparrow K'_{OH} \\ [PdCl_3(OH)]^{2-} + H_2PLP^- \rightleftarrows [Pd(H_2PLP)Cl_2OH]^{2-} + Cl^- \qquad \text{(ii)} \end{array}$$

The integrated rate equation describing the above mechanism is as previously reported:[3]

$$\ln \frac{(C_{\text{IIPLP}})_{eq}}{(C_{\text{IIPLP}})_{eq} - (C_{\text{IIPLP}})_t} = \{Q_8 + Q_7 T_{\text{PLP}}/Q_2([\text{H}^+] + K_{2\text{PLP}})\}t, \quad (2)$$

where:

$$Q_8 = k'_{-1}[\text{H}^+][\text{Cl}^-] + k'_{-2}[\text{Cl}^-] + k'_{-3} + k'_{-4}[\text{OH}^-],$$

$$Q_7 = k'_1[\text{H}^+] + k'_2 K_{2\text{PLP}} + k'_3 K'_{\text{OH}} K_w[\text{Cl}^-]^{-1} + k'_4 K_{2\text{PLP}} K'_{\text{OH}}[\text{OH}^-][\text{Cl}^-]^{-1},$$

$$Q'_2 = 1 + K'_{\text{OH}}[\text{OH}^-][\text{Cl}^-]^{-1} \simeq 1,$$

and

$$k_{\text{obs}} = Q_8 + Q_7 T_{\text{PLP}}/Q'_2([\text{H}^+] + K_{2\text{PLP}}) \quad (3)$$

and

$$A = Q_8,$$

$$B = Q_7/([\text{H}^+] + K_{2\text{PLP}}) \text{ if } Q'_2 = 1.$$

If $A[\text{H}^+]^{-1}$ is plotted vs $[\text{H}^+]^{-1}$ a quadratic curve is produced [Fig. 4(a)] which is represented by the following equation:

$$A[\text{H}^+]^{-1} = a_0 + a_1[\text{H}^+]^{-1} + a_2[\text{H}^+]^{-2}, \quad (4)$$

where $a_0 \simeq 0$, $a_1 = (4.3 \pm 0.1) \times 10^{-2}$ and $a_2 = (3.9 \pm 0.4) \times 10^{-7}$. These coefficients correspond to k'_1, $(k'_{-2}[\text{Cl}^-] + k'_{-3})$ and $k'_{-4}K_w$ (K_w = ionic product of H_2O), respectively. The probable values of the k's are listed in Table 3. On the other hand, the plot of $B([\text{H}^+] + K_{2\text{PLP}})[\text{H}^+]^{-1}$ vs $[\text{H}^+]^{-1}$ is also quadratic [Fig. 4(b)]. The relationship follows the equation:

$$B([\text{H}^+] + K_{2\text{PLP}})[\text{H}^+]^{-1} = b_0 + b_1[\text{H}^+]^{-1} + b_2[\text{H}^+]^{-2}, \quad (5)$$

where b_0, b_1 and b_2 have the values 7.4 ± 1, $(6.6 \pm 0.2) \times 10^{-3}$ and $(3.1 \pm 0.6) \times 10^{-9}$, respectively. These parameters correspond to k'_1, $k'_2 K_{2\text{PLP}} + k'_3 K'_{\text{OH}}$ $K_w[\text{Cl}^-]^{-1}$ and $k'_4 K_{2\text{PLP}} K'_{\text{OH}} K_w[\text{Cl}^-]^{-1}$, respectively. The values of micro-rate constants are listed in Table 3 after the adoption of reasonable assumptions shown in the footnotes to the table.

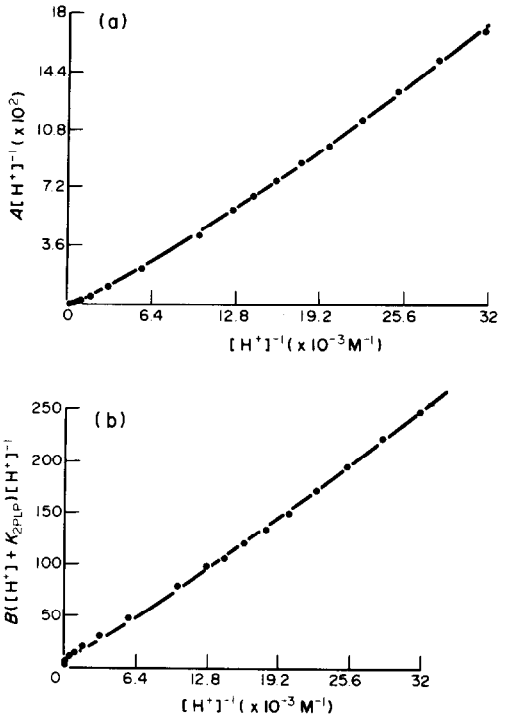

Fig. 4. (a) Dependence of $A[\text{H}^+]^{-1}$ on $[\text{H}^+]^{-1}$. (b) Dependence of $B([\text{H}^+] + K_{2\text{PLP}})[\text{H}^+]^{-1}$ on $[\text{H}^+]^{-1}$.

Pd(II)–*PMP system*

The addition of a solution of PMP to that of Pd(II) in the pH range 2.0–5.0 caused considerable spectral changes in the latter in the visible region as shown in Fig. 5. Similar to the Pd(II)–PLP system no precipitation was observed in the pH range used. The kinetic runs were done at $\lambda = 470$ nm in the pH range 2.5–5.0. Figure 6 shows the dependence of pseudo-first-order rate constants [k_{obs}(PMP)] on the pH and the total PMP concentration (T_{PMP}). Figure 7 shows the dependence of k_{obs}(PMP) on T_{PMP} at interpolated pH values obtained from Fig. 6. The dependence is linear and is expressed by the following equation:

$$k_{\text{obs}}(\text{PMP}) = C + DT_{\text{PMP}}, \quad (6)$$

where C and D are pH-dependent parameters. The values of these parameters are listed in Table 4.

The reaction mechanism describing the data expressed by eqn (6) is similar to that shown in Scheme 1 except that the PMP species are different. In this case we have possibly four species in the pH range 2.5–5.0, namely H_5PMP^{2+}, H_4PMP^+, H_3PMP and H_2PMP^- (Table 2), and the reactive ones are likely H_4PMP^+ and/or H_3PMP, since the phosphate group has been excluded from possible ligation with Pd(II). Now, if H_4PMP^+ is the

Table 3. Summary of the micro-rate constants mentioned in this work

System	k	Magnitude of k	Equilibrium constant (K)
PLP–Pd(II)	k'_1, k'_{-1}	7.4, ~0	$\gg 7.4$
	k'_2, k'_{-2}[a]	25, 0.3	$\geqslant 86$
	k'_3, k'_{-3}[a]	2.4×10^{10}, 4.3×10^{-2}	5.6×10^{11}
	k'_4, k'_{-4}[b]	4×10^7, 9.4×10^6	0.42
PMP–Pd(II)	k''_1, k''_{-1}	~0, 10.9	~0
	k''_2, k''_2[c]	19.4, 0.14	1.4×10^2
	k''_3, k''_{-3}[c]	8.3×10^5, 2.2×10^{-2}	3.8×10^7
	k''_4, k''_{-4}[b]	8.1×10^4, 1.45×10^6	$\geqslant 5.6 \times 10^{-2}$

[a]The assumption was $k_{-2}[Cl^-] \gg k_{-3}$ such that $k_{-2}k_{-3} = a_1$ and vice versa: similarly $k'_2K_{2PLP} \gg k'_3K'_{OH}K_w[Cl^-]^{-1}$ such that $k'_2K_{2PLP} = b_1$ and vice versa.

[b]K'_{OH} was assumed to be equal to $10^{5.7}$.

[c]Similar to the above: either $k''_2K_{2PMP} \gg k''_3K_{OH}K_w[Cl^-]^{-1}$ or vice versa, and either $k''_{-2}[Cl^-]^{-1} > k''_{-3}$ or vice versa.

ligating species PMP may be monodentate and if H_3PMP is the ligating species it will be bidentate. In both cases the metaoxy group is one of the ligation sites and in H_2PMP^- the amino group may act as the second ligating site: in that case a switch in the pK values may occur. If we assume that the formation of a 1:1 species is too fast to be detected by a stopped-flow technique and the kinetics of the reaction are describing the formation of a 2:1 species with H_2PMP^-, then the mechanism may be treated similarly to Scheme 1. The plot of $C[H^+]^{-1}$ vs $[H^+]^{-1}$ is quadratic [Fig. 8(a)] and can be represented by the equation:

$$C[H^+]^{-1} = c_0 + c_1[H^+]^{-1} + c_2[H^+]^{-2}, \quad (7)$$

where $c_0 = k''_{-1} = 10.87 \pm 11.02$, $c_1 = k''_{-2}[Cl^-] + k''_{-3} = (2.18 \pm 0.07) \times 10^{-2}$, and $c_2 = k''_{-4}K_w = (6.04 \pm 0.75) \times 10^{-8}$. The probable values of the k''s are listed in Table 3. The plot of $D([H^+] + K_{2PMP})[H^+]^{-1}$ vs $[H^+]^{-1}$ is quadratic [Fig. 8(b)], i.e.:

$$D([H^+] + K_{2PMP})[H^+]^{-1} = d_0 + d_1[H^+]^{-1} + d_2[H^+]^{-2}. \quad (8)$$

d_0, d_1 and d_2 have the values ~0, $(1.73 \pm 0.06) \times 10^{-2}$ and $(1.01 \pm 0.06) \times 10^{-7}$, respectively. These values stand for k''_1, $k''_2K_{2PMP} + k''_3K'_{OH}K_w[Cl^-]^{-1}$ and $k''_4K_{2PMP}K'_{OH}$

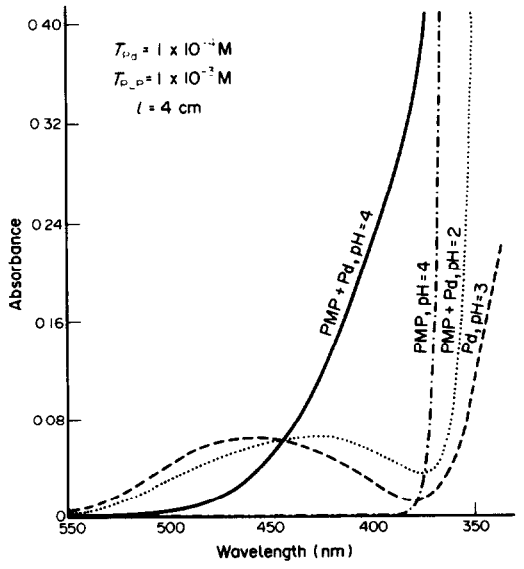

Fig. 5. Absorption spectra of Pd(II)–PMP system at various pH values.

Conclusion

The complexes of Pd(II) with PLP and PMP are different from those with PL and PM in that they are more soluble. Although the phosphate group did not take part in complex formation yet they enhance kinetically the complexation with the other

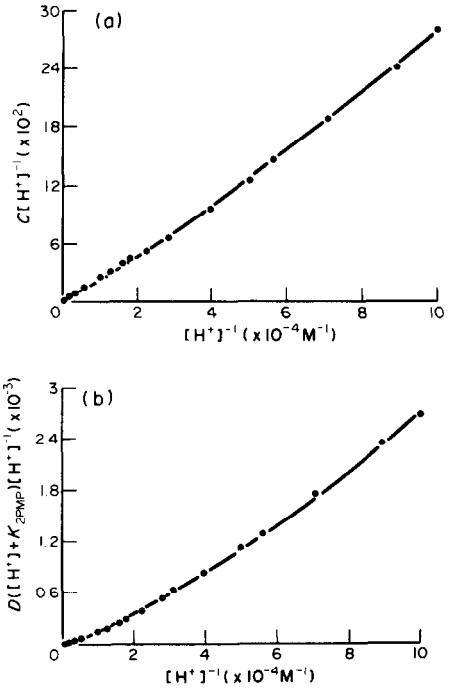

Fig. 8. (a) Dependence of $C[H^+]^{-1}$ on $[H^+]^{-1}$. (b) Dependence of $D([H^+] + K_{2PMP})[H^+]^{-1}$ on $[H^+]^{-1}$.

ligating sites (Table 3). The most interesting feature of the Pd(II) complexes with PLP and PMP is that reaction (c) in Scheme 1 is highly significant in the formation of the products and reaction (d) is the least significant. One should expect that the converse is true since the ligand is less protonated with the free ligating sites available for metal ion complexation. However, this may reflect the fact that OH^- substitution with ligands is favorable with highly protonated species. This conclusion indicates that hydrolyzed species are more reactive than non-hydrolyzed species. The presence of two chloride ions in the product complex formula does not necessarily indicate that they are inner-sphere ligands. If PLP or PMP act as a monodentate ligand the two chloride ions are likely to be of an inner-sphere type. Conversely, if they are bidentate ligands it is likely that the chloride species are not inner-sphere species.

COMMUNICATION

A KINETICS METHOD FOR THE IDENTIFICATION OF COORDINATIVELY-UNSATURATED SUBSTITUTED METAL CARBONYL TRANSIENTS: *CIS*-[(TRIPHENYLPHOSPHINE)TETRACARBONYLTUNGSTEN(0)]*

GERARD R. DOBSON,† KHALIL J. ASALI, STEPHEN S. BASSON and CHARLES B. DOBSON

Center for Organometallic Research and Department of Chemistry, North Texas State University, Denton, TX 76203-5068, U.S.A.

(*Received* 4 *June* 1986; *accepted after revision* 28 *July* 1986)

Abstract—The specifically solvated, five-coordinate intermediate [(triphenylphosphine)-tetracarbonyltungsten(0)] was produced via pulsed laser flash photolysis from *cis*-(piperidine)(triphenylphosphine)tetracarbonyltungsten(0) in chlorobenzene. This five-coordinate species was identified through comparison of the "competition ratio", k_2/k_{-1}, for its interaction with piperidine (governed by k_{-1}) and tri(isopropyl) phosphite (governed by k_2) as determined through parallel flash photometric and thermal studies. This method offers a broadly applicable means of identification of transients generated upon flash photolysis and of obtaining values of all rate constants for ligand-displacement reactions of substituted octahedral metal carbonyls by Lewis bases.

Flash photolysis of metal carbonyls in solution ultimately generates specifically solvated, coordinatively unsaturated transients in their electronic ground-states which are implicated as key intermediates in metal carbonyl substitution reactions or which participate in a variety of homogeneous catalytic pathways;[1,2] UV and/or visible light are most commonly employed in transient detection. For the mononuclear parent carbonyls, identification of the photogenerated transients poses little difficulty since the number of possible primary photoproducts is very limited; thus, for $M(CO)_6$ (M = Cr, Mo or W), $[M(CO)_5]$ is the only reasonable candidate. For *substituted* metal carbonyls, however, e.g. for $LM(CO)_5$ (L = phosphines, phosphites) several possible photogenerated species resulting from M—CO or M—L bond-breaking or isomerization can be envisioned. While UV–vis detection conveniently monitors rates of reaction of the photogenerated species, their spectra are relatively featureless and generally similar.[3] Under usual circumstances the various postulated transients are also expected to exhibit similar (bimolecular) rate behavior; thus it is difficult to distinguish among them.

We report parallel photochemical and thermal rate studies of such species which afford complementary kinetics data of sufficient complexity and congruence to provide unequivocal identification of the photogenerated intermediate. This method, which is broadly applicable, has been employed in the identification of *cis*-$[Ph_3PW(CO)_4]$ (**1**) and the determination of the rate data for the ligand displacement

$$cis\text{-(piperidine)}(Ph_3P)W(CO)_4 + L \rightarrow cis\text{-(L)}(Ph_3P)W(CO)_4{}^4 + \text{piperidine} \quad (1)$$

for which **1** has been found to be both a photochemically and thermally generated intermediate.

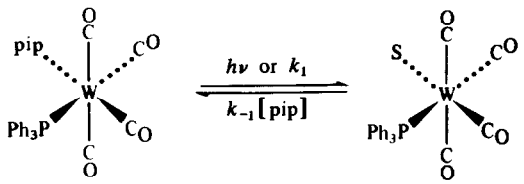
It has been observed that complexes containing chelating rings coordinating through both N and

*Part 59 of the series, Octahedral metal carbonyls. For Part 58, see Ref. 10.

†Author to whom correspondence should be addressed.

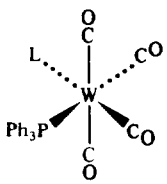
P, e.g. $(NP)Mo(CO)_4$ (NP = 1-diethylamino-2-diphenylphosphinoethane) react both thermally[5,6] and photolytically[7] via metal–nitrogen bond fission to afford largely specifically solvated[8] $[(\eta^1\text{-}NP)Mo(CO)_4]$ intermediates in which the solvated coordination site is *cis* to L. This being the case, *cis*-(pip)$(Ph_3P)W(CO)_4$ [pip = piperidine (**2**)] was selected as a species likely to afford **1** upon photolysis and thermolysis. The relatively inert W complex was selected to avoid competitive thermal reactions during photolysis. The complex was synthesized from $W(CO)_6$ via *cis*-$(pip)_2W(CO)_4$ employing the method of Darensbourg and Kump.[9] Analytical, flash photolysis and thermal kinetics data are consistent with stoichiometry (1) and with mechanism (2).

Pulsed laser flash photolysis reactions of **2** (355 nm photolyzing and 430 nm analyzing wavelengths) were carried out in chlorobenzene over ~20–35°C in the presence of varying flooding concentrations of L (= triethyl phosphite, tri(*iso*-propyl) phosphite and triphenylphosphine) and, separately, of pip, employing equipment and



S = solvent (chlorobenzene)

$$-S \downarrow k_2[L] \quad (2)$$



methods described previously.[7] Plots of absorbance vs time for disappearance of the photogenerated transient exhibited logarithmic decay; from these plots were extracted pseudo-first-order rate constants, k_{obsd}. Plots of k_{obsd} vs [L] obeyed the rate law

$$k_{obsd} = k[L] \quad (3)$$

consistent with loss of pip and bimolecular interaction of (**1**) with L (the step governed by k_2) or with pip (the step governed by k_{-1}) as outlined in eqn (2).

Thermal reactions of **2** in the presence of large excesses of *both* pip and L, also proceeding via the stoichiometry given in eqn (1) were also studied over long periods of time in sealed cells[10] monitoring 425 nm in chlorobenzene at 33.3°C, a temperature at which the flash photolysis studies were also carried out. In terms of the pseudo-first-order rate constants, k'_{obsd}, rate data were consistent with the rate law

$$k'_{obsd} = k'[L]/([pip] + k''[L]). \quad (4)$$

This rate law is consistent with mechanism (2), where $k' = k_1k_2/k_{-1}$ and $k'' = k_2/k_{-1}$, the 'competition ratio' for bimolecular rate constants of interaction of **1** with L and pip, respectively. The rate constant for unimolecular dissociation of pip from **2** [k_1, scheme (2)] may be calculated as k''/k'; all rate constants for both the photochemical and thermal pathways at ~20–35°C are exhibited in Table 1.

It is to be noted that the 'competition ratio', $k'' = k_2/k_{-1}$, determined from the tnermal data may be compared to this same ratio obtained from the *photochemical* data; the values (Table 1) are the same, within experimental error. The adherence of both the thermal and photochemical reactions to both a common stoichiometric expression and rate law, and the agreement between rate constants (the 'competition ratios') obtained through independent thermal and photochemical rate studies carried out under identical reaction conditions provide compelling evidence in support of this mechanism and show that **1** is the thermally and photochemically generated transient. There is no evidence for stereochemical rearrangement in **1** on the timescale of processes governed by k_{-1} or k_2.[11]

Activation parameters for interaction of both $P(OiPr)_3$ and pip with **1** are also given in Table 1. They agree within experimental error, as might be expected given the relatively non-discriminating nature of the intermediate, and exhibit entropies of activation near zero, reasonable for a solvent–L exchange process. Rates of bimolecular interaction of pip and L with solvated **1** vary in the order pip > $P(OEt)_3$ > PPh_3 > $P(OiPr)_3$, which suggests a dominant (but not exclusive) steric influence on reaction rate. A similar conclusion has been drawn through ligand-competition studies of the closely-related *cis*-(amine)(L)$Mo(CO)_4$ complexes.[12]

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF A DINUCLEAR PLATINUM HYDRIDE COMPLEX OF TETRACYANOBIIMIDAZOLE

J. CARLOS BAYÓN

Departament de Química, Universitat Autònoma de Barcelona, Bellaterra, Barcelona, Spain

and

J. BRUCE KOLOWICH and PAUL G. RASMUSSEN*

Department of Chemistry, University of Michigan, Ann Arbor, MI 48109, U.S.A.

(*Received* 19 *June* 1986; *accepted* 15 *August* 1986)

Abstract—Reaction of the diacid form of tetracyanobiimidazole via oxidative addition with two equivalents of $Pt(PPh_3)_4$ produces a dinuclear complex whose structure is solved by X-ray analysis. The presence of dihydride is confirmed by observation of IR shift of a deuterium-labelled compound.

The reaction of protic acids with platinum(0)tetrakisphosphines via oxidative addition to form platinic hydrides has been well documented in the literature. Earlier works have described numerous examples of reaction of Pt(0) with mineral acids[1] and imides[2] to produce such hydride compounds, but reactions with oxyacids do not produce compounds of similar stability.[3] Hydride-containing dinuclear complexes of platinum without bridging hydrides are rare,[4–7] and are not the product of reaction of a diacid with two equivalents of a Pt(0) species.

We now report the synthesis of a symmetrical platinum(II)hydrido dinuclear compound formed by the oxidative addition of a non-oxygen diacid, 4,4′,5,5′-tetracyano-2,2′-biimidazole ($C_{10}N_8H_2$), to two equivalents of tetrakistriphenylphosphineplatinum(0). The white, air-stable reaction product, $HPt(PPh_3)_2(C_{10}N_8)(PPh_3)_2PtH$, precipitates quantitatively on stirring for 1 h in tetrahydrofuran, regardless of the stoichiometric ratios added to the reaction mixture. Crystals of this compound suitable for X-ray analysis were prepared by allowing a mixture of the reactants to stand overnight in a new flask. Once the compound was prepared, it showed no solubility in common laboratory solvents except those which react with the hydride.

Chemical characterization of the dinuclear compound included elemental analysis and IR spectra. Principle characterization of the structure was the result of X-ray analysis (Fig. 1).† From this we find the geometry about the platinum to be a slightly distorted square-planar, with angles P1—Pt—N1 99.8° and P2—Pt—N1 95.0°. The atoms P1, P2, Pt and N1 are coplanar, and this plane is almost exactly perpendicular to that of the central ligand. The bonded distance of 2.125 Å for Pt—N1 compares to the non-bonded distance of 3.027 Å for Pt—N3′. Examination of packing plots from all axes revealed no strong intermolecular association.

†Crystal data: $C_{82}H_{62}N_8P_2Pt_2$, $M = 1611.58$, triclinic, space group $P\bar{1}$, $a = 13.397$ Å, $b = 14.734$ Å, $c = 12.379$ Å, $\alpha = 100.82°$, $\beta = 115.90°$, $\gamma = 64.65°$, $U = 1986$ Å^3, $Z = 1$, $D_{calc} = 1.408$ g cm^{-3}, μ(Mo-K_α) = 36.81 cm^{-1}, λ(Mo-K_α) = 0.71069 Å, $N = 4614$, $NP = 479$, $R = 0.0283$, non-hydrogen atoms anisotropic, hydrogens fixed but not refined. Tables of atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

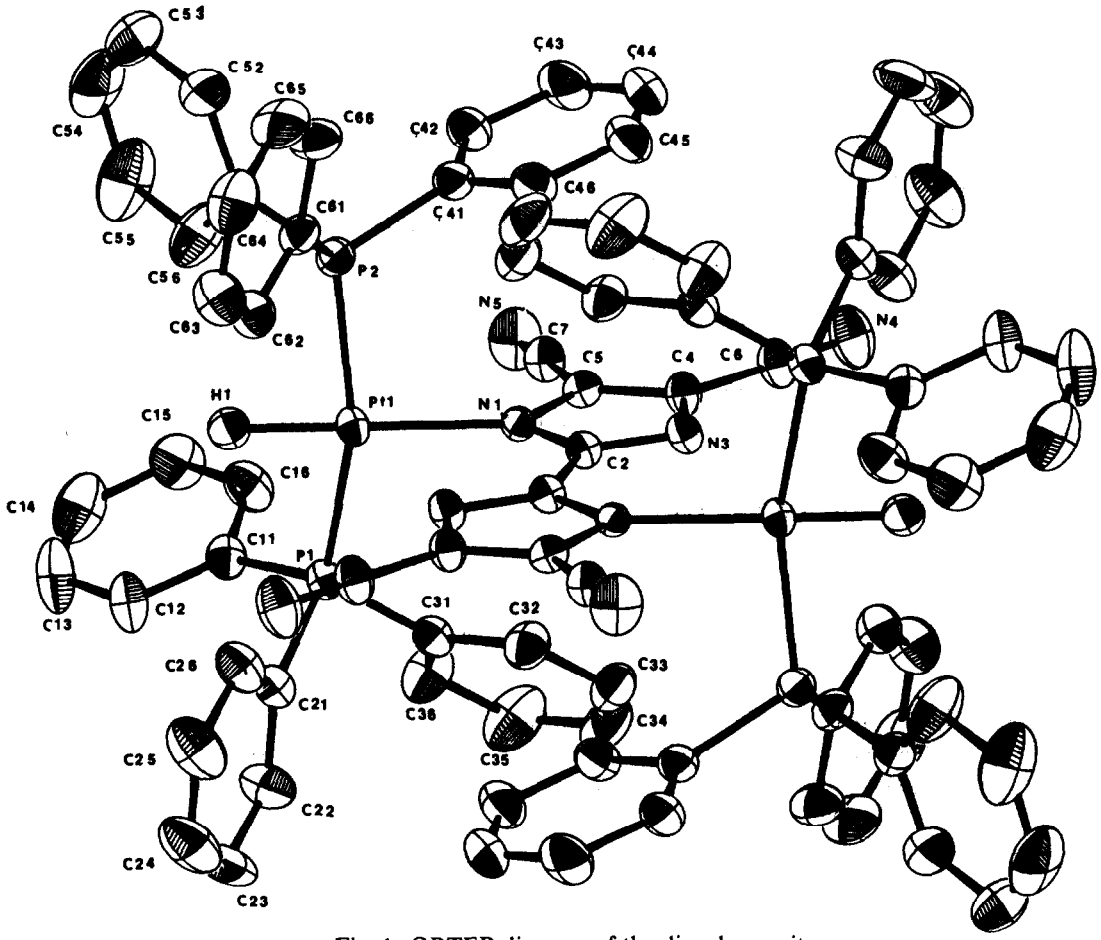

Fig. 1. ORTEP diagram of the dinuclear unit.

Stereoplots of these packings indicated that interaction was mainly confined to the phenyl ring periphery of the molecule. This is the first example of coordination of this type for tetracyanobiimidazole. More commonly expected are dinuclear species with quadridentate binding to the ring nitrogens,[8] or mononuclear bidentate species with the metal atom bound to one side of the ligand.[9]

The hydride was verified via isotopic labeling and observance of the shift in frequency for the IR Pt—H resonance. Labeling was accomplished by stirring the acid form of the ligand in D_2O at 5°C for several hours. This deuterated form of the ligand ($D_2C_{10}N_8$) was then allowed to react with two equivalents of tetrakistriphenylphosphine-platinum(0). The resulting product was identical in appearance and solubility to the protic analog. IR spectra of the two compounds were virtually identical, except for the hydride–deuteride bands. The hydride band at 2196 cm^{-1} was absent in the deuteride spectrum, and as expected, a new resonance had appeared at 1621 cm^{-1}.

Investigations of this unusual molecule are continuing with synthetic attempts to probe the hydride reactivity.

COMMUNICATION

ON THE NATURE OF ACTIVATION OF ANCHORED RHODIUM CATALYSTS BY BOROHYDRIDE

B. VISWANATHAN* and D. RAMESH

Department of Chemistry, Indian Institute of Technology, Madras, India

(*Received* 15 *July* 1986; *accepted* 4 *September* 1986)

Abstract—The nature of the active polymer anchored rhodium catalysts used for hydrogenation has been deduced to be a mono- or dihydridorhodium(III) species.

Rhodium complexes anchored on polymers containing ligands like phosphine[1] and anthranilic acid derivatives[2] have been employed as hydrogenation catalysts. The systems containing polymers with anthranilic acid derivatives were synthesized from $RhCl_3$ and were subsequently treated with $NaBH_4$.[2] In this process,[2] it is considered that Rh(III) is reduced to Rh(I) as evidenced from the colour change observed as well as from XPS results. The purpose of this communication is to examine the nature of activation caused in the catalyst as a result of borohydride treatment.†

Normally, rhodium (III) chloride complexes containing nitrogen ligands on treatment with borohydride yield either mono- or dihydrido species by nucleophilic displacement of chloride or undergoes reduction to Rh(I) or Rh(O).[4] It is also known that a dihydrorhodium(III) complex can be obtained by oxidative addition of molecular hydrogen to Rh(I) species.[5] It is therefore deduced that treatment of Rh(III) complexes with borohydride (which can also act as a source for hydrogen[6]) can result in a di- or monohydridorhodium(III) complex depending upon the nature of the ligands. However, hydrido species could not be formed from Rh(III) complexes by treatment with other reducing agents like sodium amalgam, hypophosphorus acid or molecular hydrogen.[4] It is likely, therefore, that the active hydrogenating polymer-anchored catalysts can contain Rh(III) hydrido species. The reports available in the literature[2] have unfortunately identified this species as Rh(I) on the basis of a low value (~308 eV) of the binding energy of the Rh $3d_{5/2}$ emission. Furlani *et al.*[7] have analysed the XPS data of a number of rhodium compounds and have shown that: (i) the binding energy as well as the FWHM of Rh 3*d* line is strongly dependent on the nature and the number of co-ordinating species, and (ii) the rhodium species on the polymer surfaces are predominantly in the higher oxidation state. The lower binding energy values for Rh $3d_{5/2}$ (~308 eV) observed for these species could arise from: (i) the initial-state chemical shifts resulting from the nature of the ligands, and (ii) the final-state relaxation shifts whose contribution could be significant especially in view of the extended nature of the polymer backbone used.

Borane generated during borohydride treatment[6] could also bind to the polymer (the presence of highly charged boron species is also reported in polymer-bound nickel catalysts[8]) and can activate the olefin. This could also account, at least partially, for the hydrogenation activity observed.

The hypotheses proposed in this letter, however, await further support from IR data of the active catalyst for ν_{B-H} (2300–2500 cm^{-1}), ν_{Rh-H} (1700–2200 cm^{-1}) and $\nu_{Rh-H-Rh(bridged)}$ (1150 cm^{-1}).[9]

*Author to whom correspondence should be addressed.

†Even though metallic rhodium is effective for the hydrogenation of olefins,[3] its role on polymer-anchored systems without elution is doubtful. In addition, the existence of Rh(0) was never identified by XPS.[2]

BOOK REVIEW

Structure and Bonding, Vol. 62, Clusters.
Springer, Berlin, 1985. ISBN 3-540-15731-X, 116 pp., DM 980

The latest volume of this popular series of reviews contains three surveys of aspects of polynuclear metal compounds. Each review is valuable and each shows a different way in which a review can help us master chemical information: by surveying a field for the first time, by updating our knowledge of a busy area previously well covered, or by writing an essay which is itself a contribution to science.

Günther Gliemann and Hartmut Yersin from Regensburg provide a well organized article on one-dimensional $[Pt(CN)_4]^{2-}$ species. They emphasize electronic spectra, both absorption and emission, and include effects of pressure and magnetic fields, but they do not deal with the one-dimensional electric conductance which is already well known. General inorganic chemists may find the level of theory rather tough, but they will be pleased by the many excellent diagrams of polarized single crystal spectra.

Albert Cotton and Richard Walton have updated their book on multiply bonded cluster complexes by reviewing recent work, mostly their own, on dinuclear compounds of this type. The metals covered are Cr, Mo, W, Tc, Re, Ru, Os and Pt, but not in any special order, nor at equal length. There are also short sections on spectroscopy and a note on M_2 molecules. I was sorry not to see anything about Nb=Nb bonds, so this is not quite a comprehensive study. For that matter there are plenty of interesting dinuclear complexes which are not metal–metal bonded, as in Mo and Cu chemistry, and we must take care not to forget these while we get excited about quadruple bonds. Despite these criticisms I enjoyed reading how the field is now developing from structural and bonding studies to include redox and ligand reactions. Those familiar with Dr Cotton's work will enjoy or be bored by the usual pointed refutations of the results of other workers, especially theoreticians and Russians.

The most valuable review of the three is Günter Schmid's essay about large cluster molecules. Using purely geometric arguments he explains why such a molecule as $[Au_{55}(PPh_3)_{12}Cl_6]$ is found. No molecular orbitals, no electron counting, just a simple analysis of a cubic close-packed cubo-octahedron of 55 metal atoms, the size of phosphines (at the 12 remaining vertices) and the spaces left for chlorines (over the six square faces). Dr Schmid goes on to show where these structures are found, how they are non-rigid, and how electron counting rules which apply to smaller clusters are weak here. There is a short note on magnetochemistry and this splendid essay concludes with some striking electron micrographs of Au_{55} clusters.

ANNOUNCEMENT

POLYHEDRON PUBLICATION AWARD

Pergamon Journals Ltd is pleased to announce the award annually of a cash prize of $1000 for the best paper published in *Polyhedron*.

The award will be made to the authors of the original research paper (not including *Polyhedron* Reports) judged to be the best on the basis of scientific originality, significance, clarity and style of presentation. The first award will be made for a paper published in Volume 6, 1987. Members of the Editorial Board will each be invited to nominate two papers for the award and the final selection will be made by an anonymous committee appointed by the Editors who themselves will not be eligible for the award.

The recipient of the first award will be notified early in 1988.

Istituto I.S.S.E.C.C., C.N.R., Via J. Nardi, 39, 50132 Firenze, Italia

CONTENTS

I. INTRODUCTION

Transition metals give rise to a large number of clusters which vary in nature from the simple aggregates of metal atoms to complex systems formed by transition-metal atoms and ligands of various sorts, such as carbonyls, hydrides, olefins and phosphines, as well as by interstitial atoms.[1] Metal and non-metal main-group elements, on the other hand, form a numerous class of "naked clusters". neutral or ionic, having no peripheral ligands, such as P_4, P_4S_3, Bi_5^{3+}, Bi_9^{5+}, Sn_5^{2+}, Ge_9^{2-} etc.[2] One of the most viable and stimulating fields in the chemistry of the transition metals and main-group elements is the one related to the synthesis and characterization of new cluster compounds in which main-group elements and transition-metal ligand units form linkages to each other. Among such compounds those containing naked P atoms are quickly growing in number, being at the centre of the interest of many chemists.

This report deals with compounds which contain unsubstituted P atoms or small units of such atoms bound to transition-metal–ligand moieties, and covers the literature up to the end of 1985. It focuses on three topics: (a) the survey of metal compounds containing from one to six naked P atoms, with particular emphasis on their structures and the synthetic routes leading to these

*Dedicated to Professor Luigi Sacconi on the occasion of his 75th birthday.

†Author to whom correspondence should be addressed.

compounds; (b) the examination of the reactivity of such naked P atoms or units towards additional metal–ligand moieties; and (c) the collection of ^{31}P NMR data for the compounds. Up to now no exhaustive review of this field has been published. Only cyclotriphosphorus compounds have been reviewed by Di Vaira and Sacconi,[3] while Riess, considering the coordination chemistry of polycyclic tetraphosphorus compounds,[4] has reported on the transition-metal complexes obtained by using such cage molecules as parent compounds. Finally, a recent review by Scherer on the coordinating ability of multiply bonded systems of the Group V elements has included some compounds containing the P_2 unit.[5]

II. SYNTHESES AND STRUCTURES OF COMPOUNDS WITH NAKED PHOSPHORUS ATOMS

The number of naked P atoms contained in the compounds described until now, where such P atoms are bound to metal–ligand moieties, ranges from one to six, excluding five. It was considered convenient for the discussion to group the complexes according to the number of their unsubstituted P atoms. Whenever two or more naked P atoms are present in a compound they are also bound *inter se* so that it is possible to refer to P_2, P_3, P_4 or P_6 fragments interacting with metal–ligand moieties. Moreover, numerous species having three, two or one P atom may be considered to originate from the tetrahedral P_4 molecule by progressive replacement of its atoms by appropriate metal–ligand systems. Scheme 1 summarizes the bonding modes of the mono- or polyphosphorus units of the latter type to transition-metal moieties, schematically denoted by M. On the other hand, in Scheme 1 no reference is made either to the species with P atoms in interstitial or semi-interstitial positions, which occur among the transition-metal carbonyl clusters, or to the compounds containing P units that cannot be considered as fragments of the P_4 molecule. The latter compounds have either more than four P atoms or contain chains of such atoms. All of the compounds which do not match the structural features and bonding modes summarized in Scheme 1 are included in the section devoted to miscellaneous derivatives.

II.1. *Intact* P_4 *molecule as ligand*

The first compounds which were claimed to contain the *tetrahedro*-tetraphosphorus molecule linked to a metal atom were described in 1971 by Ginsberg and Lindsell.[6,7] They were isolated by reacting Rh(I) or Ir(I) tertiary phosphine or arsine complexes with white phosphorus at low temperatures; the list of the compounds is reported in Table 1. The complexes are stable under an inert atmosphere in the solid state, whereas they slowly decompose in solution even under nitrogen. Scheme 2 shows the synthesis of $[RhCl(\eta^2\text{-}P_4)(PPh_3)_2]$ (**1**). Several pieces of evidence suggested the presence of the intact P_4 molecule in all of these compounds although it was not possible to establish how the molecule was linked to the metal atom. More recently strong evidence for the coordination mode of the P_4 species in **1** was obtained by means of $^{31}P\text{-}\{^1H\}$ NMR spectroscopy,[8] whereas the definitive proof by X-ray diffraction analysis[9] could be achieved only later due to the high reactivity of the compound at room temperature. The NMR data showed the equivalence of the two phosphines and were consistent with an A_2B_2 spin system due to the P_4 ligand, each line being doubled by ^{103}Rh (Table 4); such a pattern suggests that the P_4 molecule acts as an η^2-ligand toward the metal atom. The crystallographic analysis has shown that the metal-bonded P–P edge is essentially perpendicular to the best plane through the metal atom and the other donor atoms (Fig. 1). The most important deformation of the P_4 moiety from the tetrahedral shape with 2.21 Å edge, possessed by the free molecule,[10] is due to lengthening (by *ca* 0.25 Å) of the metal-bonded edge upon coordination. EHMO calculations suggest strong similarities between η^2-coordinated P_4 and η^2-alkene ligands.[9]

Six years after the communication by Ginsberg and Lindsell[6] Schmid and Kempny reported[11] the synthesis of an iron carbonyl derivative containing the P_4 molecule (Scheme 3), having the formula $[\{Fe(CO)_4\}_3(P_4)]$ (**2**). The complex was characterized by elemental analysis, and by Mössbauer and IR spectra.[11] Its extreme instability in solution prevented a better characterization.

The first transition-metal compounds containing the P_4 ligand and endowed with a sufficiently high stability to allow X-ray structural investigations were obtained by Sacconi and coworkers in

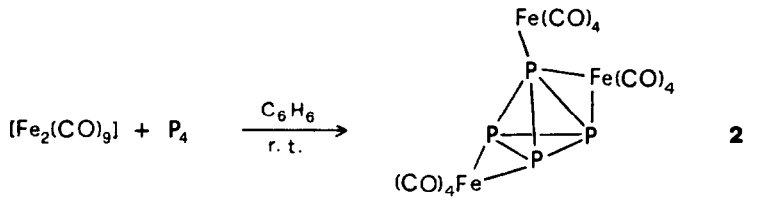

Scheme 3.

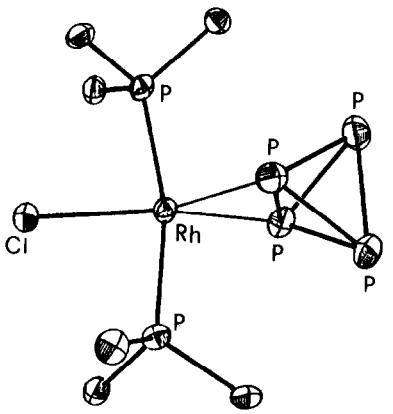

Fig. 1. Central part of $[RhCl(\eta^2\text{-}P_4)(PPh_3)_2]$.

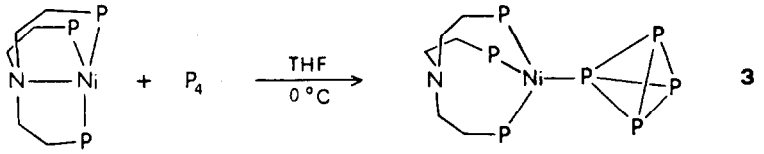
1979.[12] Reaction of the trigonal pyramidal Ni(0) complex $[(np_3)Ni]$ [np_3 = tris(2-diphenylphosphinoethyl)amine] with white phosphorus in THF at *ca* 0°C leads to the diamagnetic compound $[(np_3)Ni(\eta^1\text{-}P_4)]$ (3), which readily precipitates (Scheme 4). It is slightly air-sensitive in the solid state and is insoluble in all common organic solvents. On substitution of $[(np_3)Pd]$ for $[(np_3)Ni]$, the $[(np_3)Pd(\eta^1\text{-}P_4)]$ (4) complex is obtained by the above procedure.[13] This is isomorphous with the nickel analogue, whose structure has been determined (Fig. 2).[12] The metal atom in $[(np_3)Ni(\eta^1\text{-}P_4)]$ is bound to the three P atoms of the np_3 ligand and to one P atom of the P_4 unit in a nearly



Scheme 4.

regular tetrahedral arrangement. The N atom of the np_3 ligand is uncoordinated whereas in the educt compound it is linked to the metal atom. Upon coordination the P_4 unit undergoes a small distortion from the regular tetrahedral geometry toward that of a slightly elongated trigonal pyramid whose apex points toward the metal atom. The P_{basal}—P_{apical} distance [2.20(3) Å] is indeed significantly longer than the P_{basal}—P_{basal} one [2.09(3) Å]. Such deformation of the tetrahedral P_4 unit and the short Ni—P bond [1.99(1) Å] are indicative of appreciable interaction between the

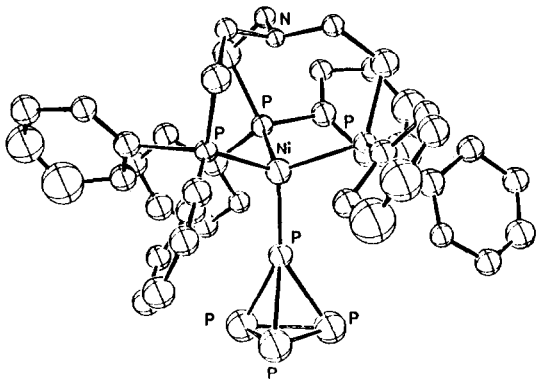


Fig. 2. Structure of the $[(np_3)(\eta^1\text{-}P_4)]$ molecule.

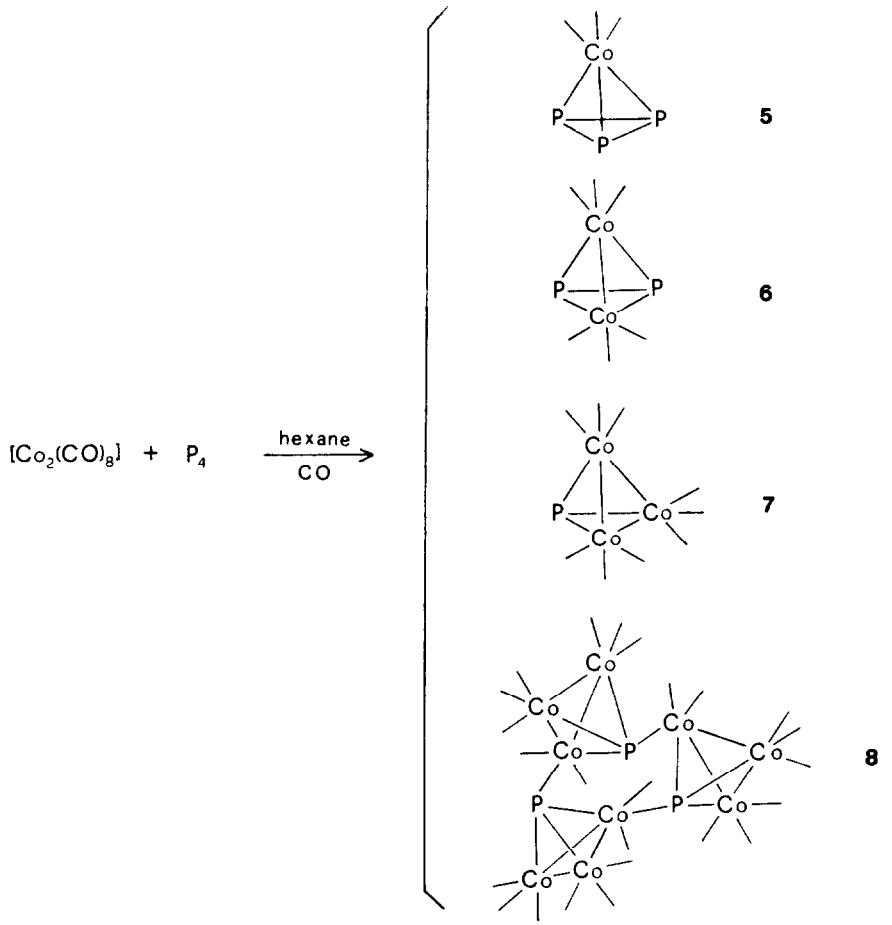
$[(np_3)Ni]$ moiety and the P_4 ligand. The formation and stability of these P_4 adducts are probably due to properties of the np_3 ligand, such as its flexibility, the nature of its donor set, its ability to impose a proper symmetry on the metal environment and the shielding effects due to its phenyl groups.[3]

The compounds reported until now show that the P_4 molecule may be bound as an η^1- or η^2-ligand to transition-metal moieties. Extended Hückel calculations have been carried out on models of η^1-, η^2- and η^3-complexes of P_4 with ML_3 fragments.[14] The η^1-square-planar and the η^2-arrangement with C_{2v}-symmetry should be preferred by a d^8-ML_3 fragment whereas the η^1-tetrahedral geometry is expected to be the most stable one for d^{10}-ML_3. The η^3-coordination should be possible with appropriate metal–ligand moieties, although no complex of this type has been described so far.

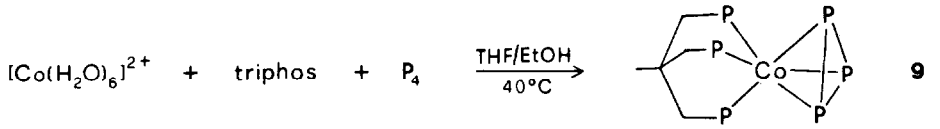
II.2. *Compounds containing the cyclotriphosphorus unit*

II.2(i) *Mononuclear metal complexes.* The first transition-metal compound containing the cyclotriphosphorus unit was reported in 1976 by Vizi-Orosz while investigating the reaction of white phosphorus with $[Co_2(CO)_8]$ under various conditions.[15] Such a reaction leads to a mixture of the carbonyl derivatives **5–8** (Scheme 5) which were separated by means of silica gel column chromatography with hexane as eluant. The relative amounts of compounds **5–8** in the mixture are controlled by the reaction conditions; in particular, the cyclotriphosphorus derivative (**5**) was obtained in the highest yield (*ca* 40%) by carrying out the reaction in an autoclave at 50°C under a 120 atm CO pressure. The yellow crystals of **5** ignite spontaneously in the air. IR data suggest that **5** has the same geometry as $[Co(CO)_3(\eta^3\text{-}As_3)]$,[16] which consists of a $Co(CO)_3$ group coordinated to a triangular As_3 fragment. Therefore **5** should contain a $Co(CO)_3$ group bound to a triangular P_3 unit. The same mixture of compounds **5–8** was also obtained by reacting $[Co_2(CO)_8]$ or $[Co(CO_4]^-$ in THF and hexane with phosphorus trihalides[15] under CO (1 atm); by this reaction **5** is obtained in a very low yield. Compound **6**, which contains the P_2 unit, will be described in some detail in Section II.3 whereas compounds **7** and **8**, having single P atoms, are postponed until Section II.4. It is worth noting at this point, however, that **5–8** form a group of related compounds, containing a tetrahedral array of Co and naked P atoms, which may be considered to originate from that of the P_4 molecule through stepwise replacement of its P atoms by the isolobal $Co(CO)_3$ units (Scheme 5).[17] Compounds **5–7**, with the general formula $[\{Co(CO)_3\}_nP_{4-n}]$ (n = 1, 2 or 3), may undergo rearrangements to each other in the presence of suitable reagents.[18]

Up to now the largest class of mononuclear metal compounds containing the cyclotriphosphorus unit corresponds to the formula $[(triphos)M(\eta^3\text{-}P_3)]^{n+}$ [M = Co,[19] Rh[20] or Ir;[20] n = 0: M = Ni,[21,22] Pd[13] or Pt;[13] n = 1: triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane]. The first derivative of this series, $[(triphos)Co(\eta^3\text{-}P_3)]$ (**9**), was obtained by reacting hydrated Co(II) salts of poorly coordinating anions with white phosphorus in the presence of triphos at *ca* 40°C (Scheme 6).[19] Orange crystals of the product separate after the addition of ethanol. An excess of white phosphorus with respect to cobalt is a crucial factor for obtaining **9**; by reacting the cobalt salts and triphos with a lower amount of phosphorus ($Co:P_4$ = 2:1) the dinuclear triple decker sandwich complex



Scheme 5.



Scheme 6.

[(triphos)Co(μ,η^3-P_3)Co(triphos)](BF_4)$_2$ is obtained [see Section II.2(ii)].[23] The structure of **9**, which is typical of the complexes of this class, is shown in Fig. 3. The metal atom is coordinated by the three P atoms of the triphos ligand and by those of the *cyclo*-P_3 group, the two sets of donor atoms being nearly staggered. A strictly similar coordination geometry exists in [(np_3)Co(η^3-P_3)] (**10**) where the nitrogen atom of the tripod ligand is uncoordinated.[24] Simple electron counting shows that removal of the nitrogen lone pair from the coordination sphere of the metal atom allows this to achieve the 18-electron configuration.

The rhodium (**11**), and iridium (**12**), analogues of [(triphos)Co(η^3-P_3)] were obtained by allowing the complexes [RhCl(C_2H_4)$_2$]$_2$ and [IrCl(CO)(PPh_3)$_2$], respectively, to react with P_4 in the presence of triphos.[20] These compounds are isomorphous with each other as well as with the cobalt complex **9**.[19] The [$MCl_2(PBu_3)$]$_2$ complexes (M = Pd or Pt) in the presence of triphos and P_4 yield the cationic complexes of *cyclo*-P_3, [(triphos)Pd(η^3-P_3)]$^+$ (**13**) and [(triphos)Pt(η^3-P_3)]$^+$ (**14**), which were isolated as the BF_4^- salts.[13] The corresponding nickel derivative [(triphos)Ni(η^3-P_3)]BF_4 (**15**) was synthesized by a different procedure,[21] i.e. cleavage of the P_4S_3 cage molecule by the Ni(II) ion in the presence of triphos (Scheme 7). The structures of both the BF_4^- and the I_3^- salts of the

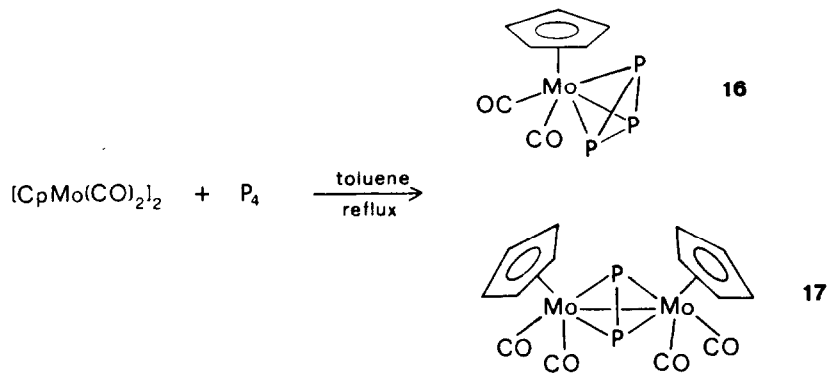
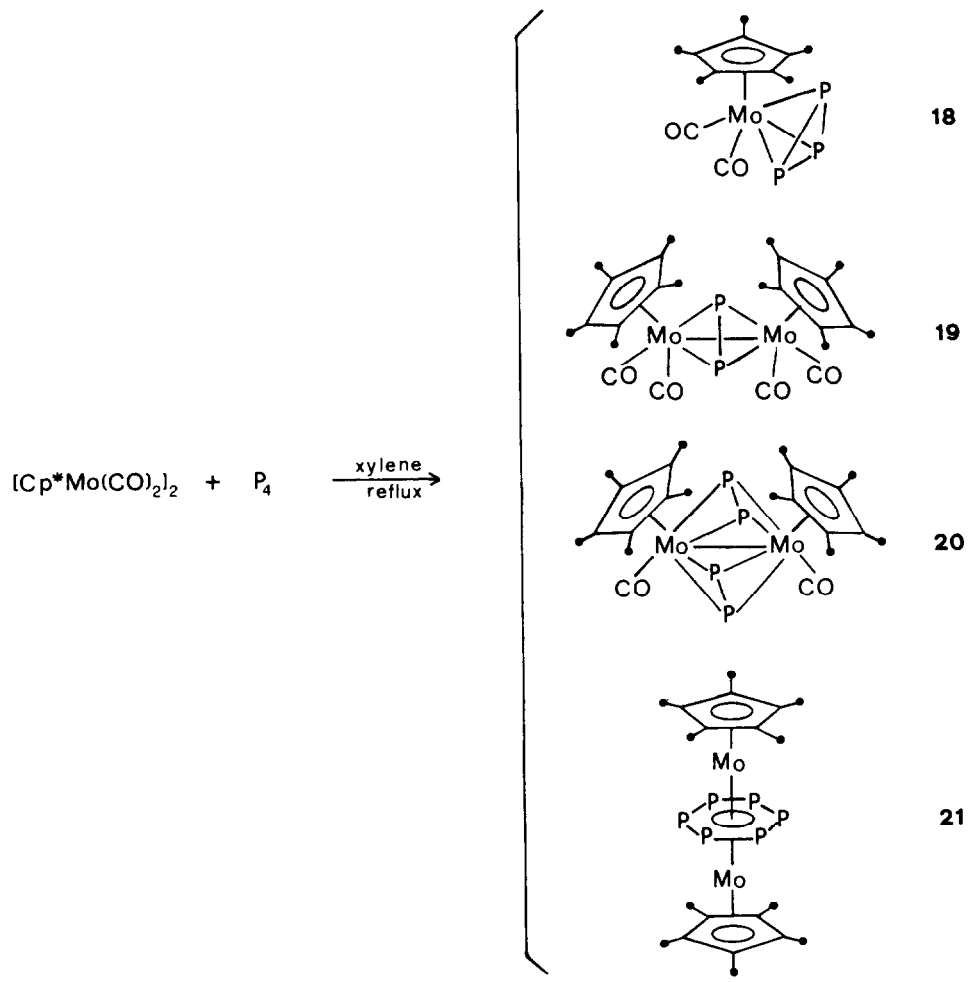
Scheme 7.

nickel complex, which are mutually isomorphous, have been determined.[21,22] Although the coordination geometry of the cationic complexes is closely similar to that of the neutral compounds of the cobalt group there are significant differences between their M—P and P—P bond distances. In particular, the M—P(triphos) distances are consistently longer in the cationic complexes than in the neutral ones.[21] It should be noted in passing that formation of the mononuclear *cyclo*-P_3 derivatives with phosphine ligands by the procedures exploited up to now has invariably involved reduction of the metal atom relative to its oxidation state in the parent compound. The mononuclear cyclotriphosphorus derivatives may be considered, on the other hand, to originate from the tetrahedral P_4 molecule by replacement of one of its P atoms by an LM (M = Co, Rh or Ir; L = triphos or np_3) or LM^+ (M = Ni, Pd or Pt; L = triphos) moiety. Such substituent groups, as well as the $Co(CO)_3$ unit of Scheme 5, are three-electron donors according to Wade's rules:[25] in this sense they are equivalent to the P atom they are considered to replace in the P_4 cage. Such considerations provide the simplest bonding approach to the mononuclear *cyclo*-P_3 derivatives. Substantial interaction occurs between the orbitals of the LM fragment and properly oriented orbitals of the η^3-P_3 ligand.[3]

Taking into account the isolobal relationship between organometallic fragments[26] it is not surprising that the $CpMo(CO)_2$ (Cp = η^5-cyclopentadienyl) and $Cp^*Mo(CO)_2$ (Cp^* = η^5-pentamethylcyclopentadienyl) fragments, that have similar frontier orbitals to those of CoL_3, stabilize compounds containing the *cyclo*-P_3 unit. Scherer *et al.*[27] have reported that the P_4 molecule undergoes cleavage in the presence of the reactive molybdenum dimer complex $[CpMo(CO)_2]_2$ in boiling toluene, yielding different compounds (Scheme 8) which have been separated by column chromatography on florisil with a toluene–pentane mixture as eluant. The presence of the cyclotriphosphorus unit η^3-bound to the $CpMo(CO)_2$ fragment, compound **16**, has been ascertained on the basis of NMR data[27] and by an X-ray diffraction study.[28] The structure has shown that the Mo atom and those of the *cyclo*-P_3 unit form a trigonal pyramid. The P_3 ligand has the shape of a nearly equilateral triangle with mean P—P bond lengths in good agreement with those existing in the compounds [(triphos)M(η^3-P_3)] (M = Co, Rh or Ir)[19,20] and [(np_3)Co(η^3-P_3)].[24] Compound **17**, containing the bridging P_2 unit, is considered in Section II.3. The pentamethylcyclopentadienyl dicarbonyl molybdenum dimer, $[Cp^*Mo(CO)_2]_2$, reacts with P_4 in high boiling solvents[29] yielding a mixture of compounds (Scheme 9) which have been separated by chromatography on florisil. **18** contains the cyclotriphosphorus unit η^3-bound to one $Cp^*Mo(CO)_2$ fragment as indicated by NMR data. As in the case of the Cp analogue[27,28] no restriction to rotation of the P_3 unit has been observed even at *ca* −80 °C. Compound **18** can also be prepared from $[Cp^*Mo(CO)_2]_2$ and



Scheme 8.



Scheme 9.

P_4S_3.[30] Compounds **19–21**, which contain P_2 or P_6 ligands, will be described in Sections II.3 and II.5, respectively. Compounds **16–19** present tetrahedral cores of molybdenum–ligand units and of naked P atoms corresponding to two members of the mixed tetrahedrane cluster family with the general formula $[(MoL)_nP_{4-n}]$ [$n = 1$, 2 or 3; MoL = $CpMo(CO)_2$ or $Cp^*Mo(CO)_2$] which parallels that already described for the cobalt derivatives (Scheme 5) of formula $[\{Co(CO)_3\}_nP_{4-n}]$ ($n = 1, 2$ or 3).

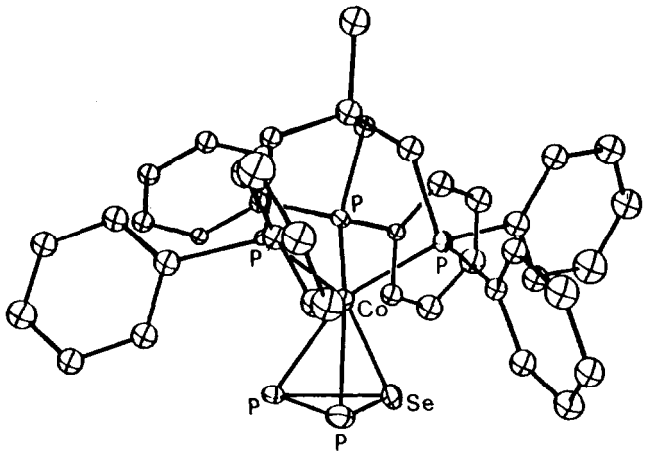


Fig. 4. View of the $[(triphos)Co(\eta^3\text{-}P_2Se)]^+$ cation.

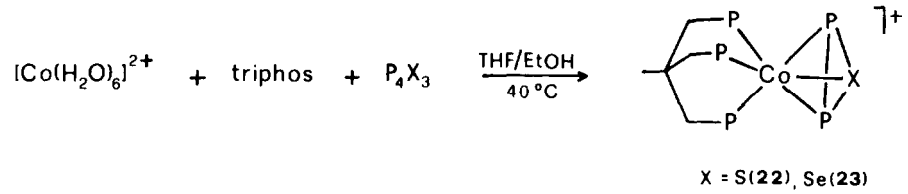


Scheme 10.

The inorganic heterocycles thiadiphosphirene, P_2S, and selenadiphosphirene, P_2Se, are closely related to the cyclotriphosphorus unit from which they may be considered to originate by replacing one P atom with a chalcogen (S or Se) atom. Such fragments are stabilized by the cobalt–triphos moiety. The reaction of Co(II) tetrafluoroborate in the presence of the tripod ligand triphos with the appropriate tetraphosphorus trichalcogenide, P_4S_3 or P_4Se_3, affords the compounds $[(triphos)Co(\eta^3\text{-}P_2S)]BF_4$ (**22**) and $[(triphos)Co(\eta^3\text{-}P_2Se)]BF_4$ (**23**), which are air-stable in the solid state (Scheme 10).[31,32] The reaction leading to compounds **22** and **23** provides an interesting example of cleavage of the tetraphosphorus trichalcogenide molecules P_4X_3 (X = S or Se) by the cobalt–triphos system. A different cleavage of the same cage molecules, yielding cyclotriphosphorus derivatives, Scheme 7, occurs with the nickel–triphos system.[21] Such reactions provide examples of selective activation of cage molecules controlled by transition-metal–ligand systems.

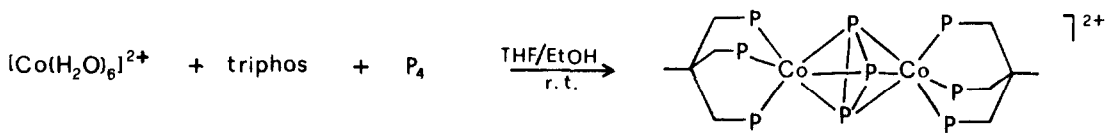
The crystal structures of the isomorphous compounds **22** and **23** consist of $[(triphos)Co(\eta^3\text{-}P_2X)]^+$ cations (X = S or Se) and BF_4^- anions, as well as of interposed benzene solvate molecules. A perspective view of the $[(triphos)Co(\eta^3\text{-}P_2Se)]^+$ cation is shown in Fig. 4.[32] The metal atom is in a six-coordinate environment formed by the triphos P atoms and by the atoms of the heterocyclic P_2X unit in a staggered arrangement similar to that found for the simple-sandwich complexes formed by the cyclotriphosphorus homocyclic ring.[3] The P_2S and P_2Se triangular units in the two compounds are disordered about the pseudo-three-fold axis of each cation so that the chalcogen atom (S or Se) is distributed over the three vertexes of the triangle.[32] The mean of the interatomic distances in the P_2S ring is slightly shorter than the value found for the *cyclo*-P_3 unit in the neutral $[(triphos)Co(\eta^3\text{-}P_3)]$[19] compound and is close to that existing in the $[(triphos)Ni(\eta^3\text{-}P_3)]^+$ cation.[21,22] Both the distances within the P_2Se group and those from this group to the metal atom are considerably affected by the presence of the large Se atom in the heterocyclic ring.

The above compounds containing the P_3 and P_2X (X = S or Se) triatomic units form a large series of isostructural and isoelectronic compounds whose ^{31}P NMR data have been considered.[21,32] This has allowed the detecting of some trends in the NMR parameters (chemical shifts and coupling constants) of the P atoms belonging both to the polyphosphine ligand and to the triatomic unit. The P(triphos) chemical shifts for the compounds $[(triphos)M(\eta^3\text{-}P_3)]$ (M = Co, Rh or Ir) and

[(triphos)M(η^3-P_3)]BF_4 (M = Ni, Pd or Pt) decrease rather smoothly and with similar trends on descending each metal atom group.[21] Such trends are consistent with that reported for phosphine complexes formed by metal atoms of different transition rows, having the same coordination number, molecular geometry, phosphine ligand and oxidation state of the metal atom. The P(triphos) chemical shift is essentially unchanged on replacing the P_3 with the heteroatomic P_2X (X = S or Se) units in the cobalt derivatives [(triphos)Co(η^3-P_2X)]BF_4.[32] The P(η^3-P_3) chemical-shift values, on the other hand, do not vary smoothly on changing the metal atom within each group of compounds although they exhibit similar trends for the neutral compounds [(triphos)M(η^3-P_3)] (M = Co, Rh or Ir) and the cationic complexes [(triphos)M(η^3-P_3)]BF_4(M = Ni, Pd or Pt). Remarkably, the ^1J[M–P(η^3-P_3)] coupling constants for M = Rh or Pt{^1J[Rh – P(η^3-P_3)] = 13 Hz and ^1J[Pt–P(η^3-P_3)] = 171 Hz} are smaller, by more than one order of magnitude, than the ^{1}J[M–P(triphos)] ones, which in turn are in the usual range for the phosphine complexes of such metals. The relative positions of the P_2X (X = S or Se) ^{31}P signals in the [(triphos)Co(η^3-P_2X)]BF_4 compounds, the P_2Se signal occurring at lower field than the P_2S one, exhibit decreasing $\delta(^{31}P)$ values with increasing size of the heteroatom.

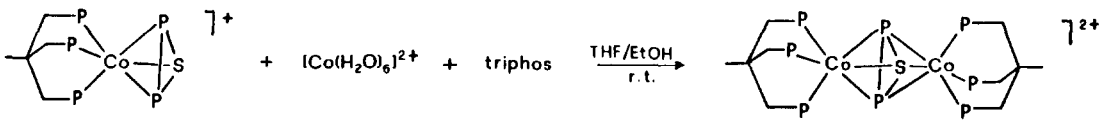
II.2(ii) *Triple decker sandwich complexes.* The cyclotriphosphorus and the isoelectronic thiadiphosphirene and selenadiphosphirene units may also act as bridging units between two metal atoms, yielding a large class of triple-decker complexes[3] that have been well characterized by Sacconi and coworkers. Dinuclear-sandwich complexes having the cyclotriphosphorus unit as the internal slice have been obtained up to now by the following procedures:[33–37]

(a) By allowing stoichiometric amounts of white phosphorus, hydrated metal salt and phosphane ligand to react in solution. THF solutions of P_4 and of the ligand have generally been used, whereas the hydrated metal salt was dissolved in ethanol. Scheme 11 summarizes the synthesis of [(triphos)Co(μ,η^3-P_3)Co(triphos)]$(BF_4)_2$.[23] By this procedure only symmetric-sandwich compounds are obtained.



Scheme 11.

(b) By allowing a mononuclear complex [(triphos)M(η^3-P_3)]$^{n+}$ (M = Co, Rh or Ir; n = 0: M = Ni, Pd or Pt; n = 1) or [(triphos)Co(η^3-P_2X)]$^+$ (X = S or Se), to react with a hydrated metal salt or a metal complex in solution, in the presence of the appropriate tripod ligand. The synthesis of [(triphos)Co(μ, η^3-P_2S)Co(triphos)]$(BF_4)_2$ by this procedure[36] is reported in Scheme 12. All reactants were generally dissolved in CH_2Cl_2 or Me_2CO, except for the hydrated metal salts, which were dissolved in ethanol. In this way both symmetric and asymmetric complexes are obtained. In the latter, the metal atoms and/or the external ligands may be different.



Scheme 12.

(c) By reducing the dinuclear *cyclo*-P_3 complexes obtained by the procedures described in (a) or (b) with $NaBH_4$ in acetone–ethanol. The [(triphos)Co(μ, η^3-P_3)Co(triphos)]$^+$ monocation has been obtained in this way (Scheme 13).[23] It has been recently reported that the *cyclo*-P_3 unit may be also generated by cleavage of the cage silylphosphane $P_7(SiMe_3)_3$ and trapped in the [(triphos)M(μ,η^3-P_3)M(triphos)]$^{2+}$ cations (M = Co or Ni).[38]

All triple-decker complexes of this type, which are listed in Table 2, are stable in the solid state. They are also rather stable in solution, except for the unsymmetrical compounds formed by two metal atoms of different transition-metal series, which decompose rather quickly. In all of these

triple-decker derivatives the external layers are formed by the triphos, etriphos [etriphos = 1, 1, 1-tris(diethylphosphinomethyl)ethane] or np_3 ligands, whereas the internal slice is formed by the *cyclo*-P_3 or *cyclo*-P_2X (X = S or Se) group. Each metal atom is bonded to the three P atoms of one external ligand and to the three atoms of the bridging η^3-P_3 or η^3-P_2X ring in a six-coordinate arrangement. A typical example is provided by the structure of the dication in the compound [(triphos)Pd(μ, η^3-P_3)Pd(triphos)]BPh_4, shown in Fig. 5.[13] A simplified approach to the bonding, magnetic properties, and redox behaviour of the complexes here described has already been reported.[3] The triple-decker dications [(triphos)M(μ, η^3-P_2S)M′(triphos)]$^{2+}$ (M = M′ = Co, or Rh; M = Co, M′ = Rh) recently reported,[36] which contain the heteroatomic P_2S ring, undergo autoreduction and exhibit transferability of the triatomic unit between metal–ligand moieties. Such features, which have never been observed for cyclotriphosphorus derivatives, suggest that cleavage of bonds between the metal and ring atoms is easier when the ring is heteroatomic.

II.3. *Compounds containing the diphosphorus unit*

The compounds containing the unsubstituted diphosphorus unit so far reported are relatively few compared with the *cyclo*-P_3 derivatives. The first compound containing the diphosphorus ligand, having the formula [{$Co(CO)_3$}$_2$(μ, η^2-P_2)] (**6**) was isolated by Markò and coworkers in 1973 as a red oil.[39] It was obtained by reacting Na[$Co(CO)_4$] with PCl_3 or PBr_3 in THF solution at room temperature (Scheme 14). The compound was assigned a structure with a tetrahedral Co_2P_2 core in which two vertexes are occupied by the P_2 unit and the other two by the $Co(CO)_3$ fragments. Such a Co_2P_2 core was proposed by comparing the IR spectrum of the compound with

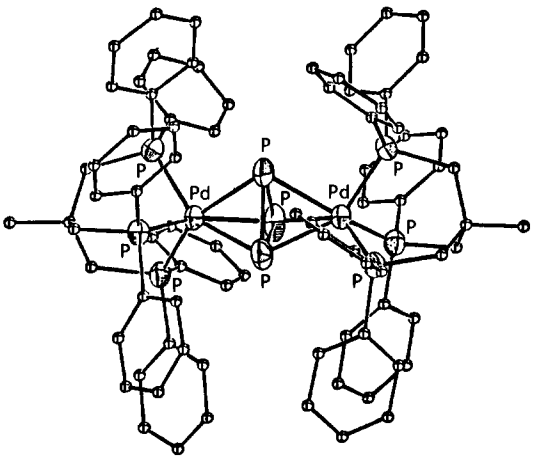

Fig. 5. View of the [(triphos)Pd(μ, η^3-P_3)Pd(triphos)]$^+$ cation.

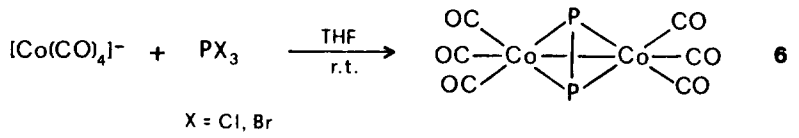


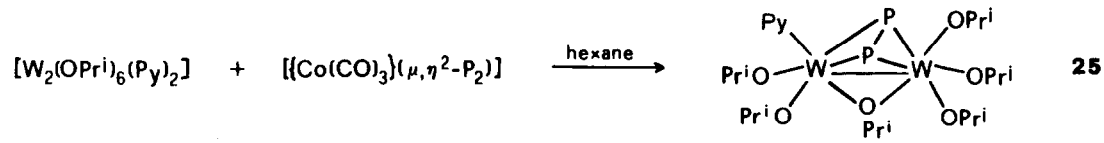
Scheme 14.

those of the related arsenic, [{$Co(CO)_3$}$_2$(μ,η^2-As_2)],[40] and alkyne, [{$Co(CO)_3$}$_2${μ,η^2-$(CR)_2$}],[41] derivatives. The geometry of the former was in turn suggested by consideration of the structure of the compound [{$Co(CO)_2(PPh_3)$}$_2$(μ,η^2-As_2)] which had been isolated from the carbonyl derivative in the presence of a large excess of triphenylphosphine.[42] The substitution of a CO by a PPh_3 group on each cobalt atom in [{$Co(CO)_3$}$_2$(μ,η^2-As_2)] actually yields a compound retaining the Co_2As_2 tetrahedral core. By carrying out a similar substitution reaction on **6** a crystalline compound of formula [{$Co_2(CO)_5(PPh_3)$}(μ,η^2-P_2)] (**24**) was obtained.[43] The X-ray analysis of **24** (Fig. 6) has shown that the skeleton of the molecule is a completely bonded Co_2P_2 fragment. The six coordination about each Co atom can be viewed as octahedral-like with a bent Co—Co bond. The Co_2P_2 tetrahedral fragment is slightly distorted due to translation of the P_2 unit toward the triphenylphosphine-substituted Co atom.

Scherer and coworkers have recently isolated from the reaction of white phosphorus with [$CpMo(CO)_2$]$_2$[27] and [$Cp^*Mo(CO)_2$]$_2$[29] three compounds, containing diphosphorus units, with

the formulae $[\{CpMo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ (**17**), $[\{Cp^*Mo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ (**19**) and $[Cp^*Mo(CO)(\mu,\eta^2\text{-}P_2)]_2$ (**20**). The reactions leading to these derivatives are reported in Schemes 8 and 9. Compound **19** has also been obtained by cleavage of the P_4S_3 cage molecule in the presence of $[Cp^*Mo(CO)_2]_2$.[30] On the other hand **17** has also been synthesized by reacting $[CpMoX(CO)_3]$ (X = Cl or Br) with the silylphosphines $P(SiMe_3)_3$, $PH(SiMe_3)_2$ and $PH_2(SiMe_3)$.[44] The crystal structure of **17** has been determined.[27] The molecule contains a pseudotetrahedral Mo_2P_2 core and each metal atom bears a cyclopentadienyl group and two CO groups as coligands; the $CpMo(CO)_2$ moieties are in a *trans* arrangement with respect to the metal–metal edge. The pentamethyl derivative (**19**) has been assigned the same structure as **17** on the basis of NMR and IR measurements.[29] As shown in Scheme 9, from the reaction of $[Cp^*Mo(CO)_2]_2$ and P_4 a second derivative containing the P_2 ligand is also obtained, i.e. $[Cp^*Mo(CO)(\mu,\eta^2\text{-}P_2)]_2$ (**20**). Mass and NMR data suggest a structure consisting of two Mo_2P_2 tetrahedra with a common Mo–Mo edge and a *cis* arrangement of the Cp* and CO ligands.[29]

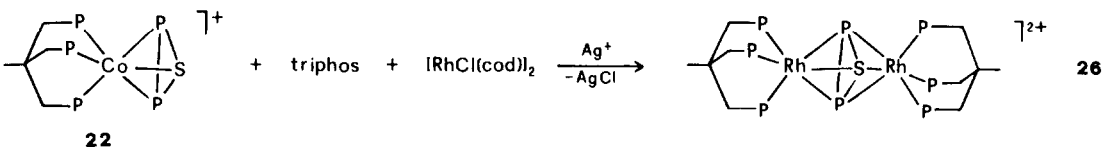
Two more reports on compounds containing the diphosphorus unit have recently appeared. The first one is from Chisholm and coworkers.[45] The reaction of Markò's compound (**6**) with $[W_2(OPr^i)_6(py)_2]$ yields the compound $[W_2(OPr^i)_6(py)(\mu,\eta^2\text{-}P_2)]$ (**25**) (Scheme 15). Its crystal structure shows a pseudo-tetrahedral W_2P_2 unit with an alkoxide group bridging the two



25

Scheme 15.

metals.[45] The substitution of the $Co(CO)_3$ fragment in the parent compound with the d^3 isolobal $W(OR)_3$ and $W(OR)_3(py)$ fragments[45] allows one to state, from a different point of view, that the diphosphorus unit may be transferred between metal moieties. It should also be mentioned at this point that the homometallic triple-decker compound $[(triphos)Rh(\mu,\eta^3\text{-}P_2S)Rh(triphos)][BPh_4]_2$ (**26**)[36] has been obtained by reacting the simple-sandwich complex (**22**) with a large excess of $[(triphos)Rh]^+$ generated *in situ* in the presence of $NaBPh_4$ (Scheme 16). Also this reaction proves that "naked" pnicogen units may be transferred between isolobal transition-metal fragments. Such interesting behaviour could open new routes to the synthesis of organometallic compounds containing small units of pnicogen atoms.



26

Scheme 16.

The second report, by Schäfer *et al.*, deals with the reaction of silylphosphines with Ni(II) complexes containing a bidentate phosphine ligand (Scheme 17).[46] Such reactions surprisingly yield diphosphorus derivatives of formula $[\{NiL\}_2(\mu,\eta^2\text{-}P_2)]$ [where L = bis(diethylphosphino)ethane (**27**), bis(dicyclohexylphosphino)ethane (**28**) or bis(diphenylphosphino)ethane (**29**)]. The crystal structure of **27** (Fig. 7) shows that each Ni atom is surrounded by four P atoms in a nearly planar arrangement, with two P atoms provided by a diphosphine ligand and the other two by the bridging diphosphorus unit. The two coordination planes are nearly perpendicular. The P_2 unit in all of the compounds described so far acts as a four-electron donor. On the other hand Huttner and coworkers have obtained compounds in which such a ligand acts as an eight-electron donor.[47] The tetracarbonyl anion $[Co(CO)_4]^-$ reacts with organometallic compounds, which have halophosphines as coligands (Scheme 18), to yield compounds where P_2 is side-on bridging two $Co(CO)_3$ units and each phosphorus of the P_2 ligand is furthermore terminally bonded to one metal–ligand ML fragment [ML = $Cr(CO)_5$ (**30**), $W(CO)_5$ (**31**) or $CpMn(CO)_2$ (**32**)]. The crystal structure of the

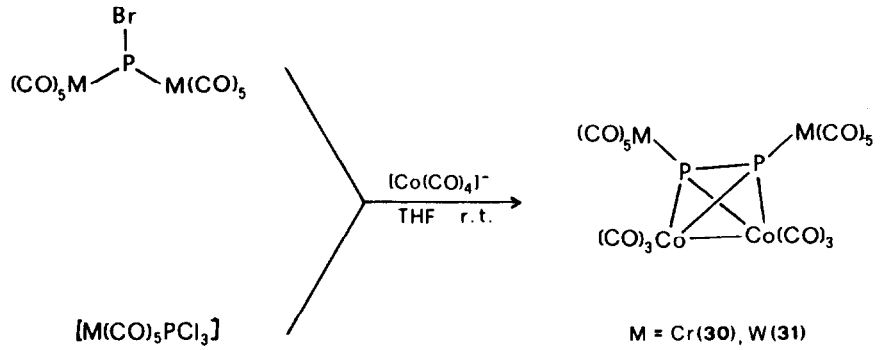
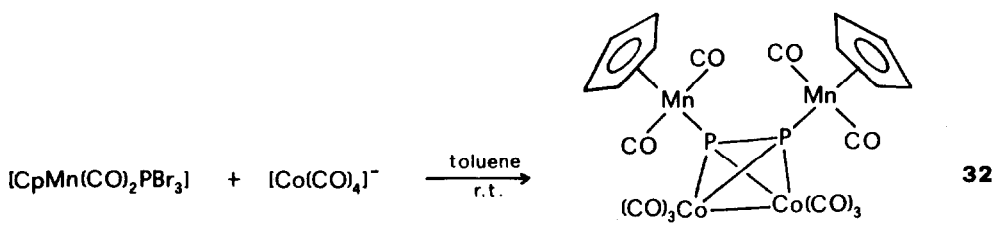
compound $[\{[Co(CO)_3]_2(\mu, \eta^2\text{-}P_2)\}\{Cr(CO)_5\}_2]$ is reported in Fig. 8.[47] Selected structural data for compounds with the P_2 ligand and a tetrahedrane M_2P_2 core are listed in Table 3.





Scheme 18.

Compound **33**, which has been isolated from the reaction mixture of $[Cp^*Mo(CO)_2]_2$ with P_4S_3,[48] contains an S_2 ligand side-on bonded to two Cp*Mo fragments and a bent PSP group whose P atoms are linked to the molybdenum centres (Scheme 19). Compound **33** is transformed in the presence of $[Co_2(CO)_8]$, yielding **34** which contains the unprecedented PS ligand. The geometry of **34**, proposed on the basis of spectral data and the crystal structure of the analogous

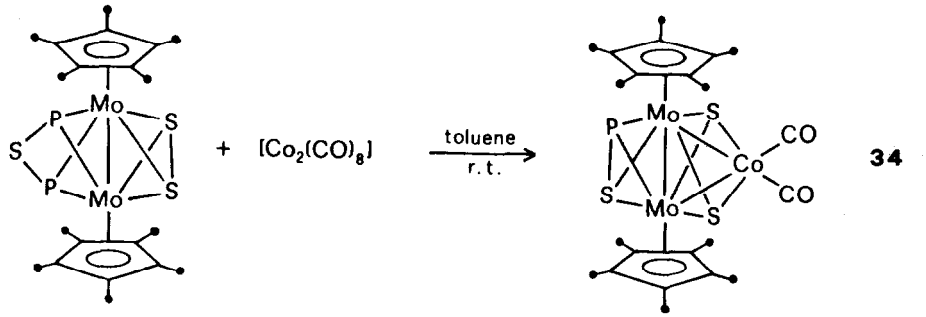
arsenic derivative, presents a Mo_2Co triangle bridged by two μ_3-S atoms, with a PS ligand acting as a bridge between two Mo atoms.[48]



33 **34**

Scheme 19.

P_2 and PS ligands act as side-on bridging units in all of the complexes reported up to now, spanning two vertexes of tetrahedrane clusters in which the other two vertexes bear metal–ligand moieties. Such a core is opened toward a butterfly geometry only in the case of the nickel derivatives

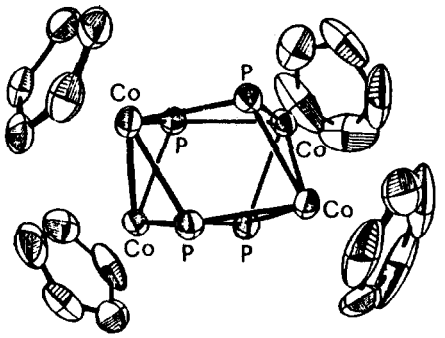


Fig. 9. View of the $[(CpCoP)_4]$ molecule.

27–29.[46] The synthesis of compounds of this type may be achieved by using an excess of the organometallic complex as the source of a metal fragment and various phosphorus derivatives as the parent compounds of the P_2 unit. Despite the apparent unpredictability in the synthesis of the present compounds two general routes may be singled out: (a) reaction of dimetallic derivatives, that easily originate mononuclear metal–ligand fragments isoelectronic to phosphorus, with labile small cluster molecules such as P_4 and P_4S_3; and (b) reaction of metal–ligand or phosphido anions, such as $[Co(CO)_4]^-$ or $[P(SiMe_3)_2]^-$, with halophosphine or phosphine halide complexes such as $[Cr(CO)_5PCl_3]$, $[NiCl_2(dppe)]$ [dppe = bis(diphenylphosphino)ethane] and so on. Procedures of type (b) yield diphosphorus derivatives from compounds containing single phosphorus atoms.

II.4. *Compounds containing single phosphorus atoms*

Transition-metal compounds which contain single P atoms are relatively few. In such derivatives the P atom acts as a bridging ligand between three or more metal–ligand fragments. It may be involved in a pseudo-tetrahedral, planar or spirane-like arrangement.

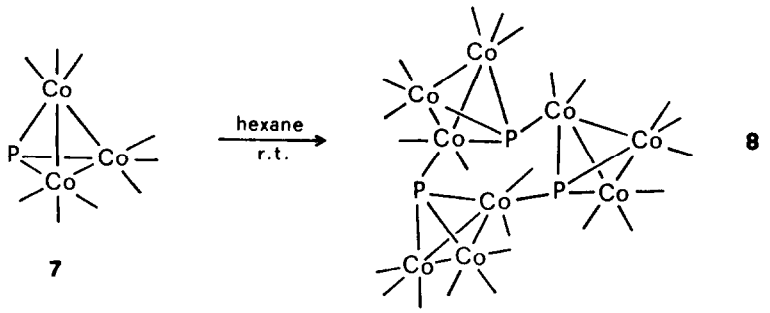
$$[CpCo(CO)_2] + P_4 \xrightarrow[\text{reflux}]{\text{toluene}} [(CpCoP)_4] \quad \mathbf{35}$$

Scheme 20.

The first compound that was reported to contain single naked P atoms belongs to the class of compounds having the pnicogen atom in a tetrahedral array as a μ_3-ligand. $[(CpCoP)_4]$ (**35**) was obtained in low yield by Simon and Dahl[49] by reacting $[CpCo(CO)_2]$ with the stoichiometric amount of white phosphorus in toluene under an inert atmosphere (Scheme 20). Compound **35** has been characterized by IR and mass spectrometry, and by X-ray diffraction analysis. The molecule has a cubane-like architecture (Fig. 9). Each cobalt atom is surrounded by one cyclopentadienyl ligand, three P atoms, and one Co atom, so that it achieves the closed-shell electronic configuration. The Co_4P_4 core is significantly deformed from the idealized cubic geometry that occurs in other cubane-like structures such as those of compounds with the M_4S_4 core.

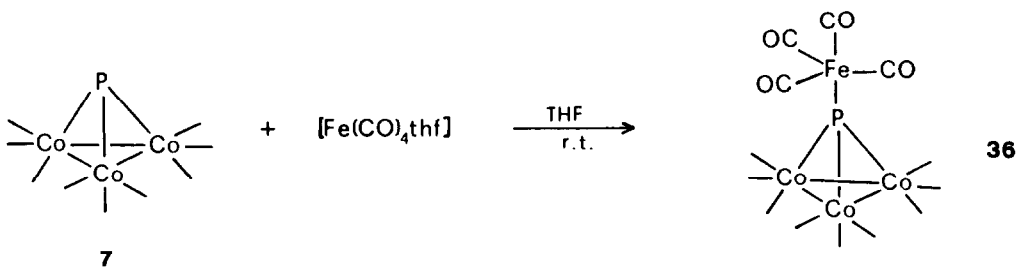
The monophosphido compound $[\{Co(CO)_3\}_3(\mu_3\text{-P})]$ (**7**) is one of the products isolated from the reaction of cobalt carbonyl and white phosphorus (Scheme 5);[15] it has also been obtained from phosphorus trihalides and $[Co(CO)_4]^-$ salts.[15] Compound **7** is the most reactive of all the members of the mixed-cluster family $[\{Co(CO)_3\}_nP_{4-n}]$ ($n = 1, 2$ or 3). It has been characterized by comparing its IR spectrum with that of the analogous arsenic derivative $[\{Co(CO)_3\}_3(\mu_3\text{-As})]$.[50] Compound **7** has a great tendency to undergo cyclotrimerization with the loss of carbon monoxide to yield **8** (Scheme 21).[15] IR studies in hexane solution have shown that the lifetime of **7** is restricted to a few minutes.[15] The monomeric compound **7** has been stabilized by adding to its solutions suitable metal–ligand units like $Fe(CO)_4$ generated *in situ* from $[Fe_2(CO)_9]$ in THF that act as scavengers for **7**, to give **36**, before it undergoes cyclotrimerization (Scheme 22).[15,50]

Compounds of formula $[\{[Co(CO)_3]_3\}(\mu_4\text{-P})\{M(CO)_5\}]$ [M = Cr (**37**), Mo (**38**) or W (**39**)] have been unexpectedly obtained[18] by reacting **6** and **5**, which contain P_2 and P_3 units, respectively, with Group VI hexacarbonyls under UV radiation. Compounds **37–39** have the same structure as



CO ligands omitted for clarity

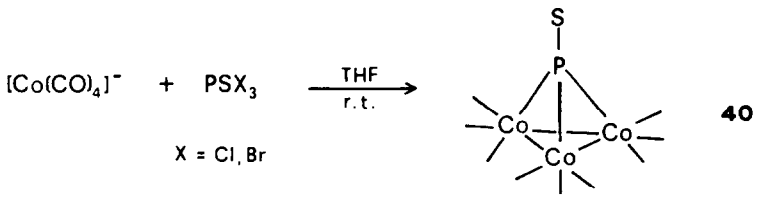
Scheme 21.



CO ligands omitted for clarity

Scheme 22.

the iron derivative **36** in Scheme 22, with the $M(CO)_5$ fragments replacing the $Fe(CO)_4$ unit. In the present synthesis the educt compounds **5** and **6**, which have pseudotetrahedral P_3M and P_2M_2 [$M = Co(CO)_3$] cores, undergo rearrangement, yielding products with a PM_3 core. A monophosphorus derivative having a PCo_3 core has been also obtained by reacting an oxidized P atom of PSX_3 (X = Cl or Br)[39] with $Na[Co(CO)_4]$ (Scheme 23). Such a reaction yields a

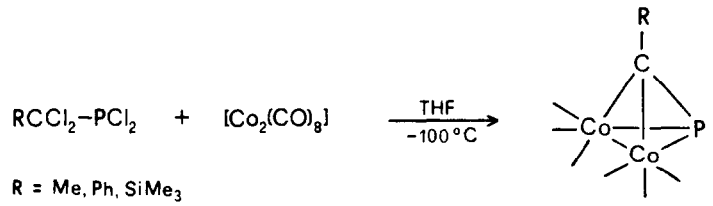


CO ligands omitted for clarity

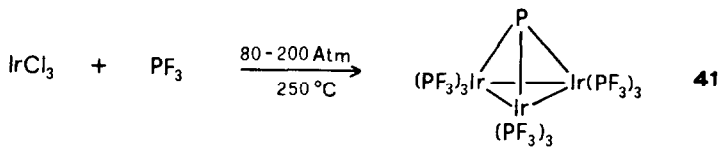
Scheme 23.

thiophosphoryl complex (**40**) having a pseudotetrahedral core where each Co atom bears three carbonyl ligands and the P atom is also bound to an S atom. In terms of structure and bonding **7** is closely related to the phosphalkyne complexes $[\{Co_2(CO)_3\}_2(\mu,\eta^2\text{-PCR})]$ in which a CR unit (R = Me, Ph or $SiMe_3$) may be assumed to replace one of the isolobal $Co(CO)_3$ fragments in **7**. Such compounds have been recently considered by several workers[51–54] and have been prepared for example by reacting cobalt carbonyl with (ω,ω'-dihaloalkyl)-dihalophosphines (Scheme 24).[51]

Iridium trichloride reacts at 80°C with PF_3 at pressures of 80–200 atm to give orange crystals of the compound with formula $[\{Ir(PF_3)_3\}_3(\mu_3\text{-P})]$ (**41**) in very poor yield (Scheme 25).[55] Mass spectra suggest for **41** a tetrahedrane geometry with a PIr_3 core where each Ir atom is linked to



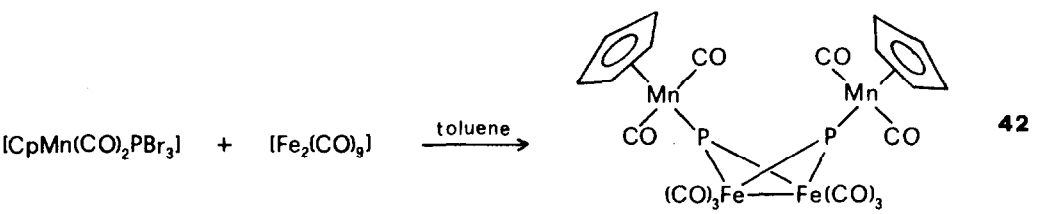
Scheme 24.



Scheme 25.

three trifluorophosphine ligands. In all complexes described above each isolated P atom always occupies a vertex of a tetrahedron and invariably acts as a μ_3- or μ_4-ligand. On the other hand, different coordination geometries are also possible for naked P atoms in transition-metal complexes and some of them have been recently achieved by Huttner and coworkers.

Compound **42** was isolated through reductive dehalogenation of $[CpMn(CO)_2PBr_3]$ with $[Fe_2(CO)_9]$ (Scheme 26).[56] The nature of **42** has been confirmed by chemical–physical measurements; the structure of the compound is shown in Fig. 10. It presents two trigonally coordinated P atoms, each linked to two iron tricarbonyl fragments and one $CpMn(CO)_2$ moiety. The short Mn—P bond distance is considered to be indicative of significant P(π)–metal $d(\pi)$ interaction.[56] The P atoms in **42** exhibit an unusual downfield shift in the ^{31}P NMR spectrum (see Section IV).



Scheme 26.

More recently a second example of a P atom bridging three metal atoms in a trigonal planar array has been reported.[57] Compound **43** was obtained by reacting the bromophosphinidene complex $[\{Cr(CO)_5\}_2PBr]$ with the strong nucleophile anion $[CpW(CO)_3]^-$ in dry THF (Scheme 27). The P atom forms a three-membered ring with the W and one Cr atom, while the second $Cr(CO)_5$ group is exocyclic. The short bond distance between the exocyclic Cr and the P atom suggests a P–Cr interaction analogous to that which is considered to exist in **42**. The P atom is in an approximately trigonal planar geometry.

The reaction of $[Fe_2(CO)_9]$ with PCl_3 leads to the crystalline compound **44** (Scheme 28).[58] Determination of its crystal structure (Fig. 11) has shown that a $Fe_2(CO)_8$ group is joined to a $Fe_2(CO)_6(\mu\text{-Cl})$ one by a P atom that is linked to all four transition-metal atoms, acting as a spiro centre. Compound **44** is the first, and up to now unique, compound in which a P atom acts as the joining centre between two cyclic fragments.

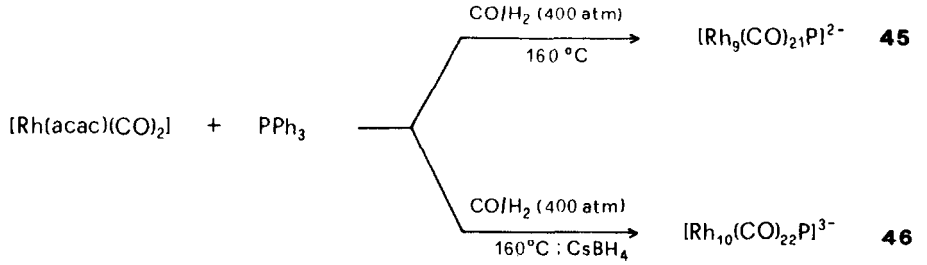
CO ligands omitted for clarity

Scheme 28.

In most of the compounds considered up to this point, containing the P_4, P_3 or P_2 units, or single naked P atoms, the pnicogen atoms occupy some of the vertexes of a polyhedron, the other vertexes being occupied by metal–ligand fragments. A few examples of different P atom environments

are provided by the compounds containing the intact P_4 molecule η^1-bound to the metal atom,[12,13] by the iron carbonyl derivative **44**[58] described above, and by complexes **42** and **43**, which contain a P atom in a trigonal planar environment.[56,57]

On the other hand, compounds have been reported in which one naked P atom is encapsulated in a interstitial or semi-interstitial position inside metal carbonyl clusters with which it shares all of its valence electrons. Vidal *et al.* have isolated compound **45**, with the formula $[NEt_3Bz]_2[Rh_9(CO)_{21}P]$,[59] by reacting $[Rh(acac)(CO)_2]$ with triphenylphosphine in a high boiling solvent under high pressures of H_2 and CO (Scheme 29). By carrying out the same reaction in the



Scheme 29.

presence of a reducing agent such as $CsBH_4$, compound **46**, containing the cluster anion $[Rh_{10}(CO)_{22}P]^{3-}$, has been isolated.[60] The two compounds have been characterized by X-ray analyses and their structures are closely related. The $[Rh_9(CO)_{21}P]^{2-}$ anion (Fig. 12) consists of eight Rh atoms arranged at the corners of a cubic antiprism, with the ninth Rh atom capping one of the two square faces. The P atom is located inside the cavity of the cluster anion while the carbonyl ligands are bonded both terminally and in a bridging position. The carbonyl ligands show fluxionality in solution; the same behaviour is suggested for the rhodium skeleton according to the 10 line multiplet [δ = 283.2 ppm, J(Rh–P) = 38.5 Hz] exhibited by the ^{31}P NMR spectrum of the compound.[59] The structure of the cluster anion in **46** consists of a square antiprism capped by two Rh atoms sitting on the square faces, with a bare P atom located at the geometrical centre of the polyhedron. This anion also presents scrambling of both the carbonyl ligands and the rhodium skeleton, the latter process being evidenced by an odd-line pattern of 11 lines at 369.3 ppm.[60] The constancy of this pattern even at −45°C is indicative of the persistence of skeletal scrambling at low temperatures. Variable-temperature multinuclear NMR studies[61,62] on the above rhodium carbonyl cluster derivatives, **45** and **46**, have been carried out, and it has been found that the skeleton is static at the lowest temperatures attained. In both compounds the time-averaged value of J(Rh–P) is close to the weighted mean of the low-temperature Rh–P couplings. It seems probable

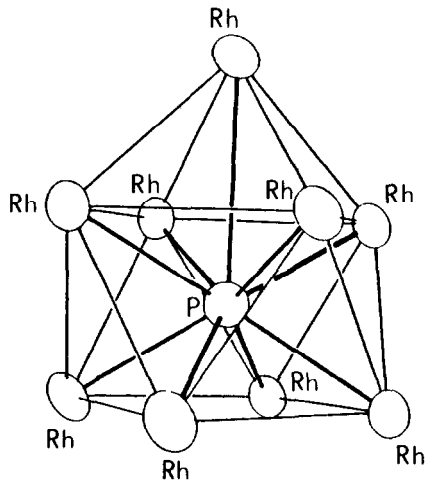


Fig. 12. Structure of the $[Rh_9(CO)_{21}P]^{2-}$ anion without the CO ligands.

that the migratory pathways of the metallic skeletons are similar to the rearrangements found for the boron polyhedra in boron hydrides.

The cobalt carbonyl salt $Na[Co(CO)_4]$ reacts with PCl_3 in THF, yielding the anion $[Co_6(CO)_{16}P]^-$ (**47**), which has been isolated as the potassium salt (Scheme 30).[63] Different salts of **47** have been obtained by metathesis in aqueous methanol; the tetraphenylphosphonium derivative has been investigated by X-ray diffraction analysis.[64] The anion **47** (Fig. 13) contains a six-metal atom array consisting of a chain of four edge-sharing triangles surrounding a semi-interstitial P atom. This phosphide ligand is probably in an intermediate condition between that of an external bridging P atom (sharing three electrons) and that of an interstitial atom (sharing five electrons). Such an array is rather uncommon and may be rationalized considering the dimensions of the Co and P atoms. The radius ratio r_P/r_{Co} is such that a P atom cannot occupy the cavity of an octahedron or of a regular trigonal prism formed by six Co atoms. The above Co_6 open array may be considered as a part of the surface of a larger polyhedron, namely an icosahedron.[64]

$$[Co(CO)_4]^- + PCl_3 \xrightarrow[KBr]{THF} K[Co_6(CO)_{16}P] \quad \mathbf{47}$$

Scheme 30.

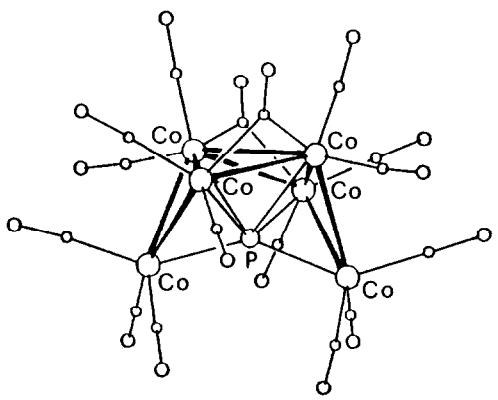

Fig. 13. View of the $[Co_6(CO)_{16}P]^-$ anion.

II.5. *Miscellaneous compounds*

In the previous sections the compounds have been grouped according to the number of bare P atoms that they contain, and considering the P_3 and P_2 units, or the isolated P atoms, as derived from the P_4 molecule by replacement of one, two or three of its atoms. In this section compounds are grouped which contain either units formed by more than four naked P atoms or chains of P atoms that cannot be considered to ideally originate from the P_4 molecule by processes in which its atoms are replaced, preserving the tetrahedral arrangement.

$[Cp^*Mo(CO)_2]_2$ reacts with white phosphorus yielding compounds **18–20** that contain P_3 or P_2 units (Scheme 9).[29] From the same reaction also compound **21** has been isolated, which is a triple-decker sandwich complex containing hexaphosphabenzene as the central bridging ligand. The crystal structure of $[\{Cp^*Mo\}_2(\mu,\eta^6\text{-}P_6)]$ (Fig. 14) shows the triple-decker arrangement with the P_6 ring forming the internal slice between two Mo atoms, each bonded in addition to a pentamethylcyclopentadienyl group which acts as an external ligand. Both Cp* rings and the P_6 ring are planar and parallel to each other. The average P—P distance (2.170 Å) lies in the range expected for such a moiety.[29] The ^1H and $^{31}P\text{-}\{^1H\}$ NMR spectra (Table 4) provide evidence for the equivalence of the methyl groups of Cp* as well as for that of the P atoms of the hexaphosphabenzene ring. The latter unit, stabilized by complexation, may be considered to derive from benzene by the isoelectronic replacement of one P atom for each CH group. This triple decker sandwich complex has 28 valence electrons.

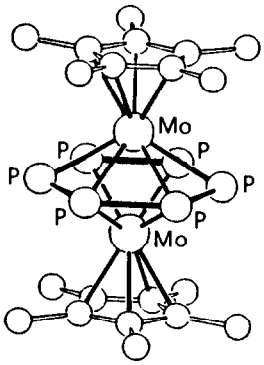

Fig. 14. Molecular structure of $[(CpMo)_2(\mu,\eta^6\text{-}P_6)]$.

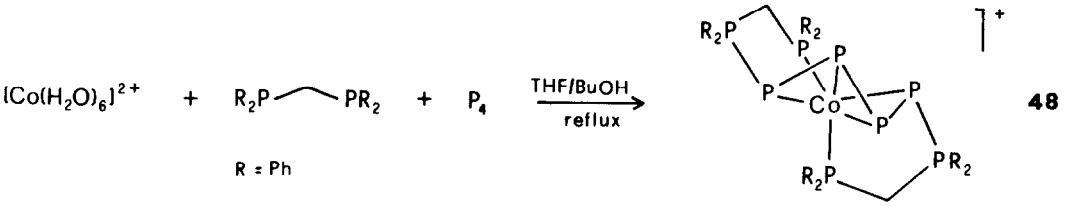
Another compound to be reported in this section is that with the formula $[Co(Ph_2PCH_2PPh_2PPPPPPh_2CH_2PPh_2)]BF_4$ (**48**).[65] It has been isolated by reacting under an inert atmosphere white phosphorus, cobalt tetrafluoroborate hydrate and the ligand bis(diphenylphosphino)methane (dppm) (Scheme 31). This complex contains an unusual zigzag type tetraphosphorus fragment  and apparently arises from a P_4 molecule which has been forced to



Scheme 31.

rearrange to a linear P_4 chain. The crystal structure reveals (Fig. 15) that a novel ligand, $Ph_2PCH_2PPh_2PPPPPPh_2CH_2PPh_2$, resulting from opening of the P_4 molecule in the presence of two dppm ligands, has been formed. The metal atom has a very distorted octahedral coordination geometry in which the new ligand coordinates through all of the P atoms of the P_4 chain and two of the four P atoms belonging to the dppm moieties; the dppm P atoms linked to the P_4 chain are uncoordinated. Among the P—P bonds within the  chain, the central one, 2.197 Å, is somewhat longer than the external bonds, 2.171 and 2.173 Å. The latter values are intermediate between those expected for double and single P–P bonds.[65] The above reaction involves oxidation of the P_4 molecule which is then nucleophilically attacked by the dppm P atoms. This compound can be used instead of white phosphorus to obtain the *cyclo*-P_3 derivative $[(triphos)Co(\eta^3\text{-}P_3)]$.[19]

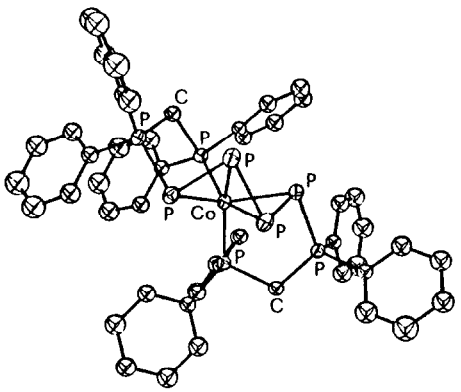


Fig. 15. View of the complex cation $[Co(Ph_2PCH_2PPh_2PPPPPPh_2CH_2PPh_2)]^+$.

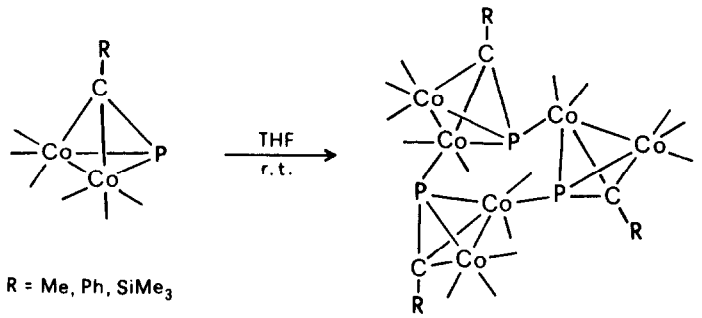
III. REACTIVITY OF COORDINATED PHOSPHORUS ATOMS AND UNITS

Most of the unsubstituted P atoms which are contained in the derivatives that have been described in Section II present non-bonding electrons which should be available for further, terminal or bridging, interactions with transition-metal–ligand units or with electrophilic organic reagents. Furthermore, the complexes present additional potentially reactive sites at the P—P and P—M bonds. The compounds containing naked P atoms or units may therefore provide the starting material for numerous derivatives. Up to now the reactivity of the above compounds toward metal–ligand fragments, but not toward organic reagents, has been investigated. The following possibilities have been detected: (a) bonding by a single P atom to one metal centre, (b) interaction between three P atoms and one metal–ligand fragment, (c) interaction of one P atom with more than one metal centre, and (d) cleavage of a P—P bond by appropriate metal–ligand moieties.

The naked P atoms of the compounds reported in Section II may act as predominantly σ- or π-donors, depending on the conditions, and the compounds themselves may function as the building blocks for cluster compounds or may provide the substrate for the insertion of new metal–ligand moieties.

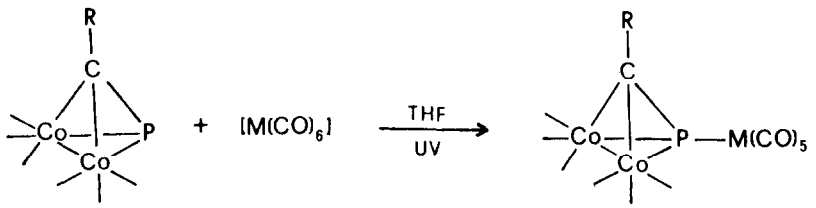
III.1. *σ- and π-donor abilities*

Naked P atoms, whether bound individually to metal centres or included in polyatomic units like P_2, P_3 and so on, have been found to be capable of acting as electron donors. If the chemical properties of the compounds containing single P atoms are compared with those of compounds containing P_2 or P_3 units it appears that the former derivatives are more basic than the latter. Thus **7**, described in Section II, is stable only for a short time in solution, where it forms the trimeric compound **8** (Scheme 21).[15] The monotetrahedrane species has been stabilized by allowing the single pnicogen atom to coordinate to an additional metal centre, as that in $Fe(CO)_4$ (**36**)[15,50] or $M(CO)_5$ [M = Cr (**37**), Mo (**38**) or W (**39**)].[18] Such a strong donor ability of single P atoms in tetrahedrane-type compounds is also confirmed by the chemical behaviour of the pnicogen atom in phosphalkyne complexes.[51–54] For example, the compounds $[\{Co(CO)_3\}_2(\mu, \eta^2\text{-PCR})]$ (R = Me, Ph or $SiMe_3$)[51] undergo cyclotrimerization in a few days (Scheme 32) but readily form adducts with chromium group carbonyls (Scheme 33). Such adducts contain the $M(CO)_5$ fragment bonded to the P atom of the phosphalkyne ligand as evidenced by NMR and IR spectra.[51]



Scheme 32.

The molybdenum derivative **17** reacts with $[M(CO)_5thf]$[5,66] (Scheme 34), yielding the compounds $[\{CpMo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)\{M(CO)_5\}_2]$ [M = Cr (**49**), Mo (**50**) or W (**51**)] which have the same Mo_2P_2 core as the parent compound and have in addition an $M(CO)_5$ fragment bound to each P atom of the P_2 unit. A similar donation of electron pairs by the P_2 bridge occurs also in the reaction with the compound $[Re_2Br_2(CO)_6(thf)_2]$, where two $Re(CO)_3thf$ units are bridged by the

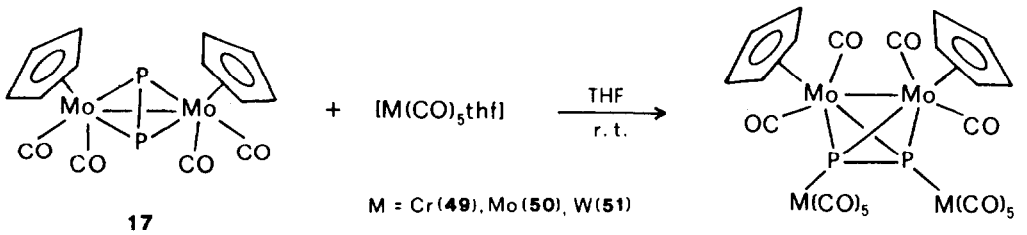


R = Me, Ph, $SiMe_3$

M = Cr, Mo, W

CO ligands omitted for clarity

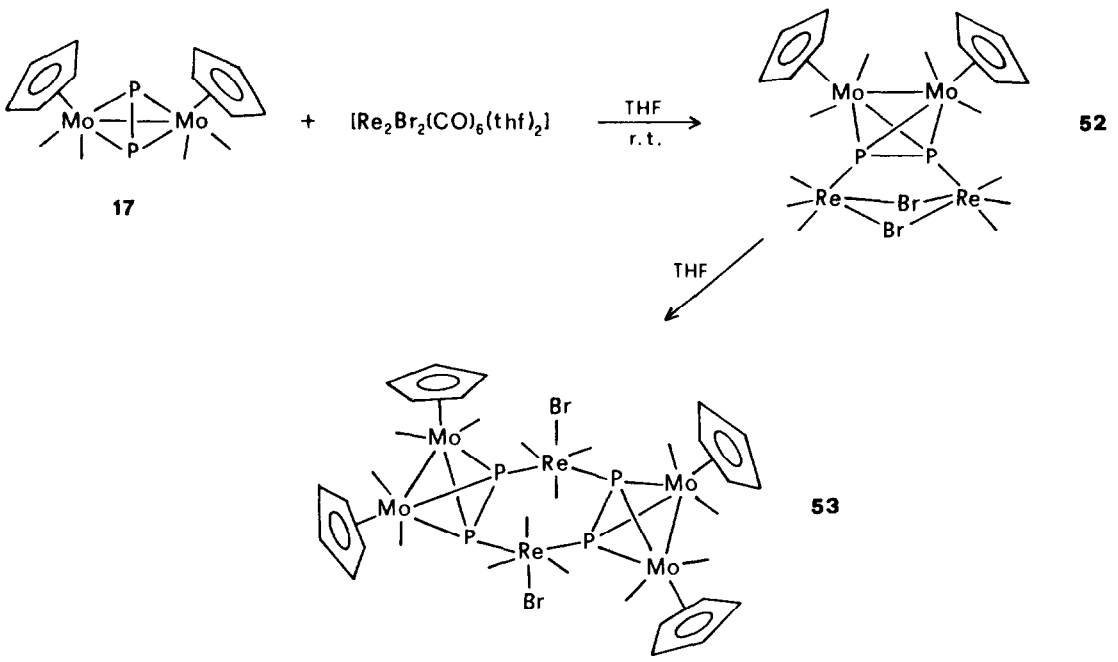
Scheme 33.



Scheme 34.

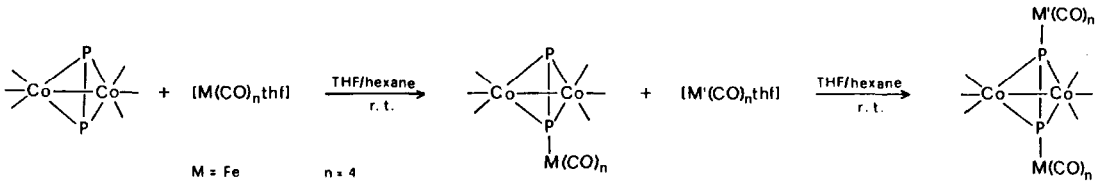
Br atoms, which yields **52** (Scheme 35).[66] In the latter the Re_2Br_2 four-membered ring is bridged by the Mo_2P_2 cluster. A THF solution of complex **52** is transformed to **53**[66] where the two Re atoms and the P_2 units of two complex ligands form a planar six-membered ring. Each Re atom is in a six-coordinate environment formed by two P atoms of different $[\{CpMo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ fragments, by three carbonyl groups and by one Br atom. The crystal structures of the two rhenium derivatives **52** and **53**[66] show that the bond lengths and angles of the coordinated Mo_2P_2 tetrahedra in both compounds differ very little from those of the uncoordinated molecule.[27] The donor ability of the P_2 unit in the $[\{Co(CO)_3\}_2(\mu,\eta^2\text{-}P_2)]$ cluster[39] as well as in its phosphine-substituted derivatives[42] has been proved recently.[67] Such compounds react with the metal carbonyl fragments $M(CO)_5$ (M = Cr, Mo or W) and $Fe(CO)_4$, yielding mono- or bimetallated derivatives depending on the ratio of the reagents (Scheme 36). The bimetallated derivatives could be also prepared starting from the monometallated compounds by addition of a further portion of the adduct (Scheme 36). This route allowed to prepare compounds in which two different transition-metal–ligand moieties are linked to the coordinated P_2 unit. The crystal structures of a homo-bimetallated compound, $[\{[Co(CO)_3]_2(\mu,\eta^2\text{-}P_2)\}\{Cr(CO)_5\}_2]$[47] (**30**), and of a hetero-bimetallated compound, $[\{[Co(CO)_3]_2(\mu,\eta^2\text{-}P_2)\}\{Cr(CO)_5\}\{W(CO)_5\}]$[67] (**54**), have been reported. Each $M(CO)_5$ (M = Cr or W) group in these compounds is bound to one P of the P_2 unit. The geometry of the Co_2P_2 core is substantially unchanged from that existing in the parent compound, the most significant difference being due to lengthening of the P—P bond (Table 3).

The double tetrahedrane complex **20**, containing two P_2 units,[39] reacts with $[Cr(CO)_5thf]$ to give (Scheme 37) the bimetallated derivative **55** in which each $Cr(CO)_5$ fragment is coordinated to one P atom of a P_2 ligand, which then functions as a six-electron donor.[5] Also the mononuclear neutral *cyclo*-P_3 complexes $[(triphos)M(\eta^3\text{-}P_3)]$ exhibit affinity for electron-acceptor groups like metal carbonyl fragments and related compounds. The cobalt derivative **9** reacts with $[Cr(CO)_6]$ under UV irradiation,[19,68] to afford (Scheme 38) complex **56** or **57**, depending on the amounts of reagents. No compound with more than two $Cr(CO)_5$ groups attached to the *cyclo*-P_3 unit of the parent complex **9** could be isolated. The adduct **58**, in which each P atom of the cyclotriphosphorus ligand of **9** is linked to an additional metal centre, has been synthesized (Scheme 38) by using the

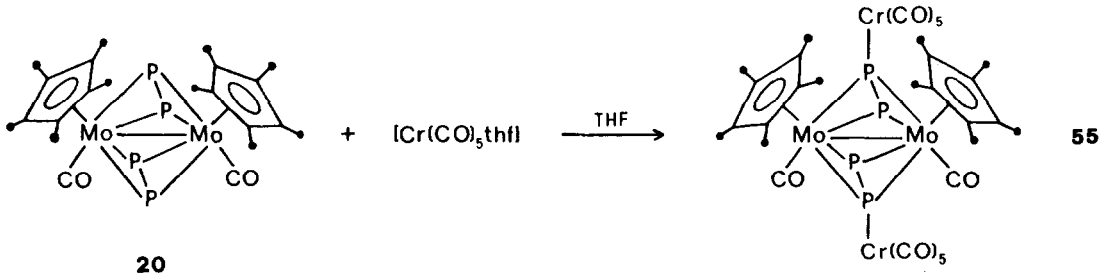


CO ligands omitted for clarity

Scheme 35.

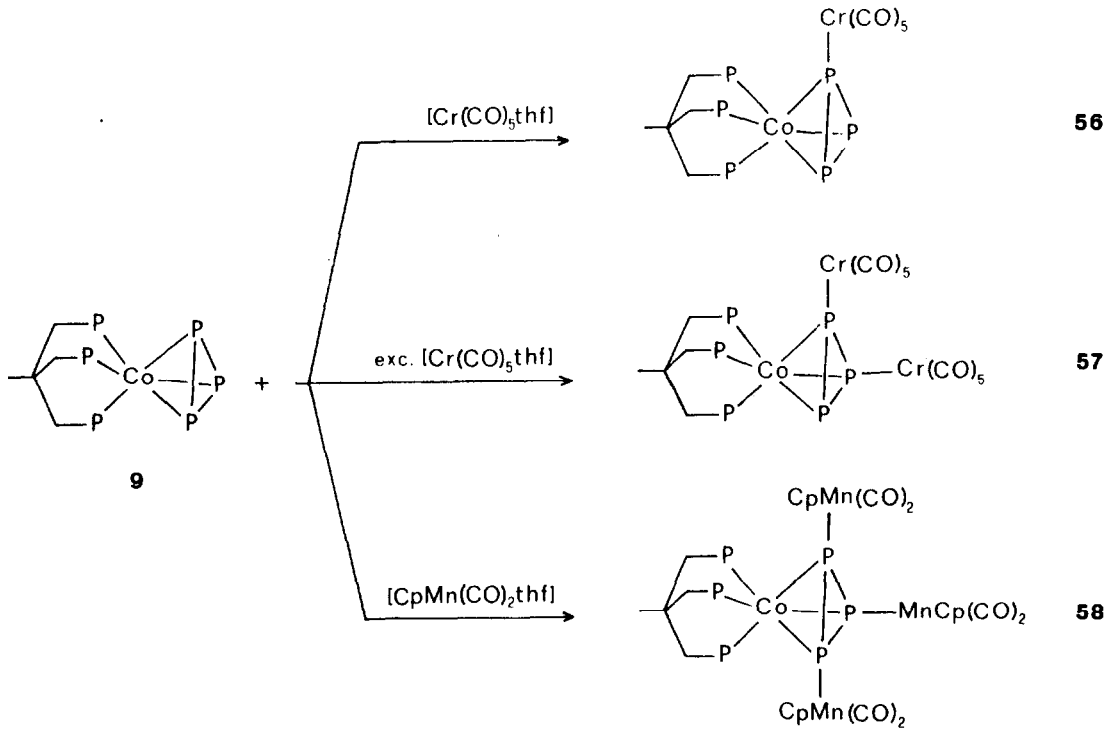


Scheme 36.

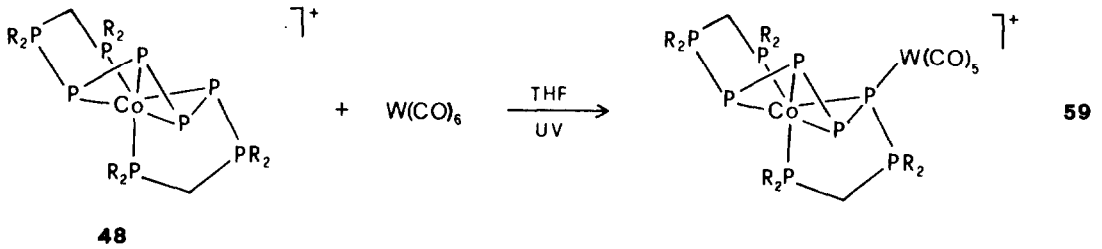


Scheme 37.

$CpMn(CO)_2$ fragment with similar electronic properties but lower steric requirements than $Cr(CO)_5$.[69] The structures of **57** and **58** show that the Cr or Mn atoms are displaced from the plane of the *cyclo*-P_3 unit on the opposite side to that of the Co atom. Bond distances within the cyclotriphosphorus group are essentially unchanged relative to those in **9**. The zigzag tetraphosphorus fragment of compound **48** reacts with $[W(CO)_6]$ in THF solution under UV radiation to form the $[Co(Ph_2PCH_2PPh_2PPPPPPh_2CH_2PPh_2)\{W(CO)_5\}]BPh_4$ derivative (**59**).[70] The



Scheme 38.



Scheme 39.

structure of the compound shows that one of the inner P atoms of the  chain is linked to the W atom of the $W(CO)_5$ fragment. The coordination geometry around the Co atom is essentially unchanged with respect to that of the mononuclear donor complex.

The mononuclear $[(triphos)M(\eta^3\text{-}P_3)]^{n+}$ (M = Co, Rh or Ir; $n = 0$: M = Ni, Pd or Pt; $n = 1$) complexes moreover react with appropriate metal–ligand fragments to yield the previously described triple-decker sandwich complexes [see Section II.2(ii)] in which the triangular P_3 unit acts as the internal layer between two metal–ligand moieties. The same reactivity is exhibited also by the mononuclear compounds **22** and **23** which contain P_2X (X = S or Se) units. Such reactions reveal the π-bonding ability of the coordinated cyclotriphosphorus ligand. None of the other P units, i.e. the P_2 one and the tetrahedral or zigzag P_4, have been found up to now to be able to bind to one metal centre through two or more P atoms acting as π-donors.

III.2. *Phosphorus complexes as building blocks in clusters*

The Lewis base character of coordinating P atoms or units that has been considered in the previous section is at the origin of the tendency of the compounds containing such units to yield polymetallic derivatives in which either single P atoms or the three P atoms of the *cyclo*-P_3 unit

are bound to a metal centre. Recently two cluster compounds have been described in which the P_3 fragment of the [(triphos)M(η^3-P_3)] (M = Co or Ir) molecule acts as a capping ligand for unusual units containing Cu and Br atoms.[71,72] The cobalt derivative **9** dissolved in CH_2Cl_2 reacts with a suspension of CuBr, affording **60** (Scheme 40).[71] The molecule of this compound consists of two [(triphos)Co(η^3-P_3)] units held together by a hexagonal Cu_6 fragment (Fig. 16) whose edges are all symmetrically bridged by bromine atoms lying approximately in the Cu_6 plane. The P atoms of the two cyclotriphosphorus units and the Cu atoms are at the vertexes of a cuboctahedron. The presence of one lone pair on each P atom of the P_3 fragments as well as the arrangement of the P_3 and Cu_6 rings suggest that bonding should be considered to be essentially delocalized.

When the iridium derivative **12** is allowed to react with CuBr in a molar ratio of 1:2 the novel ionic compound **61** is obtained (Scheme 40).[72] In the cluster cation (Fig. 17) three molecules of [(triphos)Ir(η^3-P_3)] are held together via the P_3 ligands by the central Cu_5Br_4 framework. The five Cu atoms are at the vertexes of a distorted trigonal bipyramid whose lower edges are bridged by Br atoms, while each upper triangular face is unsymmetrically capped by the P_3 group of one [(triphos)Ir(η^3-P_3)] moiety. The fourth Br atom is terminally bonded to the Cu atom in the upper apical position. The Cu atoms display three different coordination geometries. The Cu atom at the lower vertex is trigonally coordinated by three Br atoms. Each equatorial Cu atom is in an approximately tetrahedral environment formed by one bridging Br atom and three P atoms belonging to two *cyclo*-P_3 groups. Finally, the fifth Cu atom is tetrahedrally coordinated by the terminal Br atom and three P atoms, each provided by a different cyclotriphosphorus group.

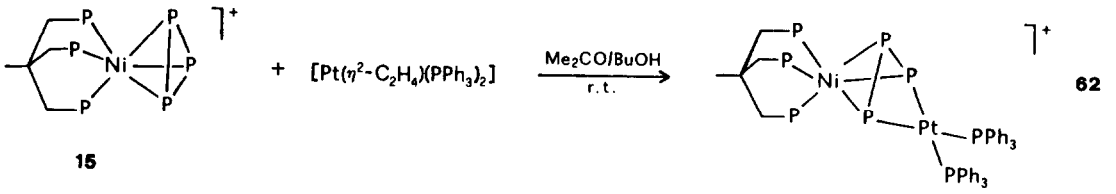
III.3. P—P *bond activation*

A further type of reaction exhibited by compounds containing bare P atoms or units is the cleavage of a P—P bond. The activation of such bonds without complete disruption of the molecule is difficult for small molecules containing few unsubstituted P atoms. The only reports on this subject deal with the opening of a P—P bond in the P_4[73–77] and P_4S_3[78,79] cages.

The activation of P—P bonds in the unsubstituted P units bound to transition-metal moieties has been considered even less: the only report presently available deals with the insertion of the $Pt(PPh_3)_2$ group into a P—P bond of the cyclotriphosphorus ligand in $[(triphos)Ni(\eta^3\text{-}P_3)]BF_4$ (**15**).[80] Insertion reactions of diphenylcarbene CPh_2[81] and the carbene-like fragments $M(PPh_3)_2$ (M = Pd or Pt)[82] occur also into a bond of the thiadiphosphirene and thiadiarsirene units in the compounds $[(triphos)Co(\eta^3\text{-}E_2S)]BF_4$ (E = P[31,32] or As[83]) which are isoelectronic to **15**. The cationic compound **15** reacts with $[(\eta^2\text{-}C_2H_4)Pt(PPh_3)_2]$ to give the cation $[(triphos)Ni\{P_3Pt(PPh_3)_2\}]^+$ (**62**) that has been isolated as the tetraphenylborate salt (Scheme 41).[80] The structure of **62** shows that the $Pt(PPh_3)_2$ fragment inserts into a P—P bond of the cyclotriphosphorus ring. The Ni atom is coordinated by the three P atoms of the triphos ligand and by the atoms of the P_3 unit. The latter is considerably distorted from the regular triangular shape that it has in the parent compound **15**, since the bond into which insertion of the $Pt(PPh_3)_2$ moiety occurs lengthens to 2.53 Å, whereas the other two bond distances average 2.17 Å. The Pt atom is in a nearly planar arrangement formed by the two PPh_3 P atoms and by the two atoms defining the long side of the distorted P_3 group. The dihedral angle between the plane of the triatomic unit and the best plane through the four atoms surrounding the Pt atom is *ca* 128°.



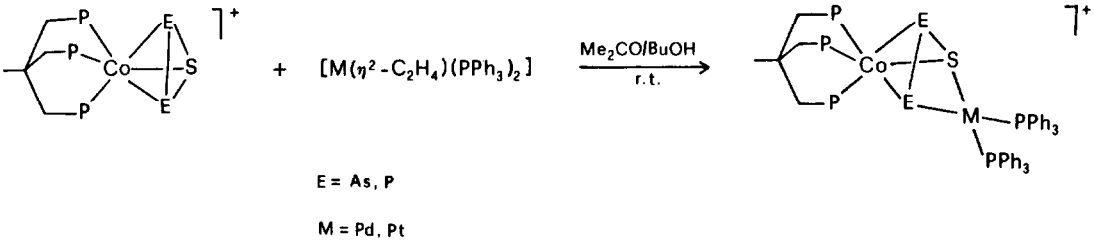
15 **62**

Scheme 41.

The ^{31}P NMR spectra of compound **62** at room temperature (Table 4) exhibit a single broad signal for the P atoms of the triphos ligand, the opened P_3 unit and the two PPh_3 groups. The resonances due to the two triphenylphosphines, which are bound to Pt, are accompanied by satellites. Such a pattern suggests a dynamic behaviour for the compound. Some broadening of the

signals occurs only at −95°C, showing a low activation energy for the process that goes on in solution.[80] Further studies are in progress in order to obtain limiting low-temperature spectra.

The [(triphos)Co(η^3-E_2S)]BF_4 (E = P or As)[31,32,83] compounds which are isoelectronic and isostructural to **15** react with [(η^2-C_2H_4)M(PPh_3)$_2$] (M = Pd or Pt),[81] yielding a series of compounds with the formula [(triphos)Co{$E_2SM(PPh_3)_2$}]BPh_4 (E = P or As, M = Pd or Pt) which have essentially the same geometry and exhibit the same behaviour in solution as **62**

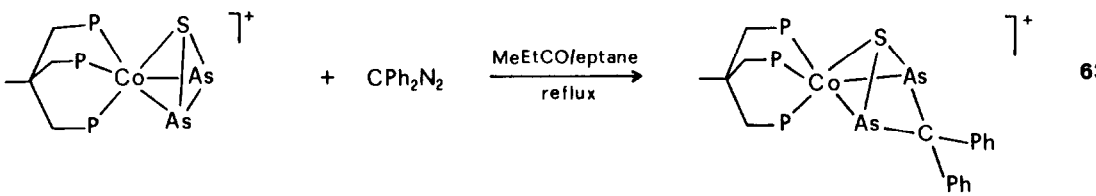


E = As, P

M = Pd, Pt

Scheme 42.

(Scheme 42). The insertion is considered to occur into one of the heteroatomic P—S or As—S bonds rather than into the P—P or As—As bond; such reactions are nevertheless reported here due to their close similarity with the process leading to **62**. Moreover the [(triphos)Co(η^3-As_2S)]BF_4 derivative[83] in the presence of CPh_2 generated *in situ* from CPh_2N_2 yields the compound [(triphos)Co{$SAsC(Ph_2)As$}]BF_4 (**63**), whose cation contains the four-membered 3,3-diphenyl-1,2,4-thiadiarsete unit 1,2,4-η^3-bound to the (triphos)Co moiety (Scheme 43).[82] Such a ring, containing three main group naked atoms and the diphenylcarbene C atom, is obtained through insertion of the CPh_2 moiety into the homoatomic bond of the As_2S unit. The generation of 3,3-diphenyl-1,2,4-thiadiarsete on the one hand, and of the platina- and pallada-triphosphete, -thiadiarsete and -thiadiphosphete units on the other hand, points to the similarities in the reactivity of all the triatomic units on the parent compounds which have been used. These results also substantiate the expected similarities in behaviour between the isolobal fragments $M(PR_3)_2$ and CR_2, even though the latter contain such atoms, as Pd or Pt on the one hand, and C on the other hand, which are considerably different from each other in most respects.



63

Scheme 43.

IV. NMR DATA FOR THE COMPLEXES

The ^{31}P NMR chemical shifts which have been reported for "naked" P atoms in transition-metal compounds are gathered in Table 4. Inspection of the data reveals a very broad range for the chemical shifts of the unsubstituted P atoms, the lowest shift occurring at +977 ppm for [{[$Fe(CO)_3$]$_2$(μ, η^2-P_2)}{$CpMn(CO)_2$}$_2$] (**42**) and the highest one at −351.5 ppm for [$CpMo(CO)_2$(η^3-P_3)] (**16**). The [(triphos)M(η^3-P_3)] (M = Co, Rh or Ir), [(triphos)M(η^3-P_3)]BF_4 (M = Ni, Pd or Pt) and [(triphos)Co(η^3-P_2X)]BF_4 (X = S or Se) compounds form an isostructural and isoelectronic series for which definite trends in the values of chemical shifts upon substitution of the metal atom or of one atom in the triangular unit have been observed, as already mentioned in Section II.2(i). The other compounds included in this survey, however, differ from each other in one or more important features, such as the nature of the metal atom and the overall electron count, the nature and number of ligands, or the molecular geometry, even though they may contain the same group of naked P atoms. For these reasons as well as for the rather small number of

compounds known, belonging to each of the classes considered here, it seems impossible to detect any definite trends in most of the ^{31}P NMR data pertaining to the unsubstituted P atoms in transition-metal compounds, except for the following general tendencies: (a) the ^{31}P chemical shifts move to higher field as the number of naked P atoms forming the units increases; (b) unsubstituted P atoms bound to magnetically active metal atoms exhibit very small coupling constants (Table 5) compared to those reported for phosphines; and (c) the P_6 and P_3 units exhibit a fluxional behavior at room temperature that persists at low temperatures consistently with the expected low energy barriers to the rotation of such units.

(*Received* 18 *April* 1986; *accepted after revision* 27 *June* 1986)

Abstract—The synthesis of diorganotincarbohydrates {R_2SnL [R = Me, Bu or Oct; L = aldotetrose (erythrose), aldopentoses (arabinose or ribose), ketohexoses (fructose or sorbose), aldohexoses (galactose or glucose) or 6-deoxyaldohexose (rhamnose)]} is reported. IR and ^{119}Sn Mössbauer spectra are consistent with the presence of tin–carbohydrate oxygen bonds in the compounds and with a trigonal bipyramidal arrangement of two alkyl and three O-containing groups about the tin atoms. The thermal decomposition of the compounds is shown to fall into one of three categories, viz: (1) aldose derivatives that decompose without melting to give SnO as the final tin-containing product, (2) ketose derivatives that decompose without melting to give SnO_2 as the final tin-containing product, and (3) aldose derivatives that melt and then decompose to give either SnO or SnO_2.

Studies on the interaction between carbohydrates and inorganic compounds have been reported for both solid and solution phases,[1–9] and an extensive review on this subject has been published.[8] There is, however, very little information on organometallic derivatives of the carbohydrates.[10–13] As part of a research program developed in our laboratories to investigate the bonding of diorganotin oxide moieties to nucleoside,[14] we now report the synthesis of some diorganotin compounds with several monosaccharides and their characterization by IR and Mössbauer spectroscopic data. Since there are no reports in the literature dealing with the modes of decomposition of the type of compounds prepared in this work, we have also studied the fate of the tin atom on thermal decomposition of the compounds.

EXPERIMENTAL

The compounds were obtained by refluxing equimolar quantities of the carbohydrate (J. T. Backer Chemicals B.V., Deventer, Holland) and the diorganotin oxide (gift from Schering AG, Bergkamen) in anhydrous methanol. Some products precipitated

*Author to whom correspondence should be addressed.

immediately from the mixture while others were obtained after removal of the solvent by rotary evaporation. The products were washed with the minimum of methanol, and dried *in vacuo*.

C and H analyses were performed at the Laboratorio di Chimica Organica, Milano. Analytical data for the compounds prepared are given in Table 1.

IR spectra were obtained as mulls of Nujol and hexaclorobutadiene in the region 4000–200 cm^{-1} using a Perkin–Elmer model 983G IR spectrometer. ^{119}Sn Mössbauer spectra were measured at liquid-nitrogen temperature with a constant acceleration and a triangular waveform, using a Laben 8001 multichannel analyzer, a Mössbauer closed refrigerator system [model 21SC Cryodyne Cryocooler (CTI-Cryogenics, U.S.A.)] and a digital temperature controller (model DRC-80C, Lake Shore Cryotronics Inc., U.S.A.).

The thermal behaviour of the complexes was studied on a Stanton Redcroft STA 780 simultaneous thermal analyser.

RESULTS AND DISCUSSION

IR vibrational data

The analytical data in Table 1 and the IR data (Table 2) are consistent with the formation of compounds of type R_2SnL (L = carbohydrato moiety) by replacement of the oxygen atom in R_2SnO (R = Me, Bu or Oct) with carbohydrate groups.

Changes occurred in the 1200–1000- and 600–400-cm^{-1} regions of the spectra for the new compounds in comparison with the carbohydrates.

These changes are typical of: (1) the replacements of C—O vibrations of the COH groups of the carbohydrate with C—O vibrations of COSn groups[16–20] in the complex, and (2) the appearance of vibrational frequencies arising from Sn—C[16,21] and Sn—O bonds.[21,22]

[a]Arabinose = β-D(−)arabinopyranose, erythrose = β-D(−)erythrofuranose, fructose = β-D(−)fructopyranose, galactose = α-D(+)galactopyranose, glucose = α-D(+)glucopyranose, rhamnose = α-L(+)-rhamnopyranose, ribose = β-D(−)ribopyranose and sorbose = β-L(−) sorbopyranose.[15]

[b]Absorber thickness (mg ^{119}Sn cm^{-2}) was ≈0.5. Mössbauer parameters were determined at 77.3 K; $\delta \pm 0.03$ mm s^{-1}, $\Delta E \pm 0.02$ mm s^{-1}.

[c]Isomer shift with respect to room-temperature $CaSnO_3$.

[d]Experimental nuclear quadrupole splitting. The calculated nuclear quadrupole splitting was 2.673 mm s^{-1}; the partial quadrupole splittings used in the point charge model formalism were according to Refs 25–27.

Mössbauer data

The ^{119}Sn Mössbauer isomer shifts (Table 1) are characteristic of dialkyltin(IV) derivatives.[23] Both the shifts and quadrupole splittings increased from the values for R_2SnO compounds (for R = Me, $\delta = 0.92$, $\Delta E = 1.82$ mm s^{-1}; for R = Bu, $\delta = 1.08$, $\Delta E = 2.06$ mm s^{-1}; for R = Oct, $\delta = 0.97$, $\Delta E = 2.00$ mm s^{-1}).

The increase in the shifts show that the bonds between tin and the carbohydrate oxygen atoms are more covalent in character than the Sn—O bonds in R_2SnO.

The increases in the splittings must result from increases in the asymmetry of the tin *p*- or *d*-electron density on formation of the carbohydrate derivatives from the oxides. The Mössbauer spectra showed for all the investigated complexes only one doublet, which strongly supported the occurrence of only one tin environment, excluding in such a way the possible coexistence of both five- and six-coordinated tin atoms in the complexes as was found by Holzapfel *et al.*[13] in methyl-4,6-*O*-benzylidene-2,3-*O*-dibutylstannilene-α-D-mannopyrano-

side by X-ray investigation.

The quadrupole-splitting data for the dialkyltin oxides have been interpreted in terms of a polymeric network with five-coordinate tin atoms[23] and the values of the splittings for the carbohydrate derivatives are also consistent with trigonal bipyramidal C_2SnO_3 coordination with equatorial Sn—C bonds.[14] The dibutylstannylene derivative of methyl-4-6-di-*O*-benzylidene-α-D-glucopyranoside, which is likely to have a tin environment similar to those in the carbohydrates prepared in this work, is known to have a trigonal bipyramidal five-coordinated structure.[24]

Assuming the tin coordination in Fig. 1, the nuclear quadrupole splittings can be rationalized in terms of the point charge model formalism using literature values for the partial quadrupole splitting of alkyl and oxygen-bonding groups (Table 1).[25–27]

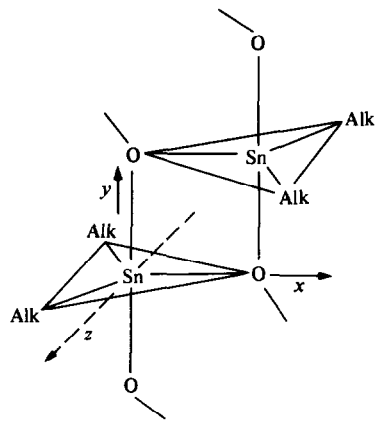

Fig. 1.

Thermal decomposition

The results show that the thermal decomposition of the complexes fall into one of three main types: viz. (1) those sugar derivatives which break down in two stages, leaving a residue of stannous oxide; (2) those which pyrolyse in a two-step process to give either SnO_2 or SnO_2 and carbon as products of decomposition, and finally (3) those compounds which melt before decomposition and give either SnO or SnO_2 as residues.

Table 3 list the dialkyltin(IV)carbohydrates under these categories.

It appears that the fate of tin during decomposition to give either a tin(II) or tin(IV) species as a product is dependent on the nature of the sugar. Monosaccharides are divided principally into two categories, those which are polyhydroxyaldehydes (aldoses) and those which are polyhydroxyketones (ketoses). Of the sugars studied here most are aldoses but fructose and sorbose are examples of ketoses. The dialkyltin(IV) derivatives of the aldoses (compounds **1–6**) are shown to decompose without melting to give SnO, whilst the derivatives of the ketoses (compounds **7** and **8**) give SnO_2, again without melting.

These results are consistent with the reducing properties of aldoses resulting in the reduction of tin(IV) to tin(II), and the oxidation of the aldehyde group of the aldoses to aldonic acids.

No such reducing reactions occur with ketoses.

The reactions in these two categories deal with the decomposition of the tin species in the solid state but different criteria apply to the third group of compounds in which melting procedes the decomposition.

Table 3. Thermal behaviour of some diorganotin(IV)carbohydrates

1	2	3
1 Bu_2Snerythrose	**7** Bu_2Snfructose	**9** Oct_2Snerythrose (m.p. 101°C)
2 Bu_2Snarabinose	**8** Bu_2Snsorbose	**10** Me_2Sngalactose (m.p. 163°C)
3 Bu_2Snribose		**11** Oct_2Sngalactose (m.p. 97°C)
4 Bu_2Sngalactose		**12** Me_2Snglucose (m.p. 155°C)
5 Bu_2Snglucose		
6 Bu_2Snrhamnose		

In a molten system, the final tin product depends not only on the nature of the sugar but also on the nature of the molten tin species. One of the aldose derivatives (compound **12**) decomposes to give the expected tin product, SnO, but this is not always the case. It is found that the aldose derivatives (compounds **9–11**) decompose from melts to give SnO_2 and not the reduced tin species, SnO, as the final tin product.

RUTHENIUM(III) PERCHLORATE COMPLEXES WITH PURINES, PYRIMIDINES AND NUCLEOSIDES

BADAR TAQUI KHAN,* AHMED GAFFURI, P. NAGESWARA RAO and S. M. ZAKEERUDDIN

Department of Chemistry, Osmania University, Hyderabad-7, India

(*Received* 14 *February* 1986; *accepted* 30 *June* 1986)

Abstract—Ru(III) perchlorate complexes of purine and pyrimidine bases and their nucleosides, viz. adenine, adenosine, guanine, guanosine, hypoxanthine, inosine, cytosine, cytidine, uracil, uridine, thymine and thymidine, were synthesized. The compounds were characterized by elemental analysis, IR, electronic and ^{1}H NMR spectroscopy, and conductivity measurements. In the complexes of purine bases and nucleosides the ligand binding site is found to be N_7, whereas in the case of complexes of pyrimidine bases and their nucleosides N_3 is the binding site.

Recently there has been an upsurge of interest in the complexes of purines, pyrimidines and nucleosides with metal ions.[1–6] This is mainly because of their role in biochemical processes involving nucleic acids.[7] The platinum group metal complexes of purines, pyrimidines and their derivatives were found to possess antitumor and antibacterial activity.[8–11] Interest has been mostly focussed on the complexes of Pt(II) and Pd(II),[1–6] and the ruthenium complexes of purines, pyrimidines and the nucleosides have been little studied.[12,13] Earlier we reported on the complexes of Ru(II) and Ru(III)[6,14,15] with purines, pyrimidines and nucleosides. Since the perchlorate anion as a ligand or as a counter ion can give rise to an interesting series of complexes, we report in the present paper the synthesis of Ru(III) perchlorate complexes of the purines adenine, guanine and hypoxanthine, and the pyrimidines uracil, cytosine and thymine, and their nucleosides. Except for hypoxanthine and inosine the purines, pyrimidines and their nucleosides studied are the natural constituents of DNA and RNA molecules. The complexes reported are binary Ru(III) purine, pyrimidine or nucleoside complexes with perchlorate present either at the outer coordination sphere or in the inner coordination sphere of the metal ion. The complexes are soluble in water which makes them useful candidates for biological studies.

EXPERIMENTAL

Ruthenium perchlorate was prepared by a metathesis reaction of ruthenium trichloride trihydrate obtained from Alfa Ventron (U.S.A.) and silver perchlorate obtained from BDH (London, U.K.). Purines, pyrimidines and nucleosides were purchased from Sigma Chemicals (U.S.A.). All solvents used were of high purity and distilled in the laboratory before use. Elemental analyses were obtained from CSIRO (Australia). Conductivity data were measured on a digital conductivity meter No. DI 909. The IR spectra were recorded in KBr pellets on a Perkin–Elmer 577 spectrophotometer. The electronic spectra were recorded on Beckman model 26 and Varian 635 M spectrophotometers. NMR was recorded on Varian A-60 and JEOL HA-100 spectrophotometers.

Preparation of Ru(III) *perchlorate*

Ruthenium trichloride trihydrate (0.5 mmol, 0.13 g) was dissolved in alcohol (15 cm^3), and to this an alcoholic solution of silver perchlorate (0.5 mmol, 0.31 g) was added. The precipitated silver chloride was separated by repeated centrifugation, and the filtrate was taken as Ru(III) perchloroate.

Preparation of complexes

Triperchloratobis(adenine)methanolruthenium-(III)methanolate $\{(Ru(ade)_2(CH_3OH)(ClO_4)_3b]\cdot CH_3OH\}$ (1),diaquo-tetra(adenosine)ruthen-

ium(III) perchlorate $\{[Ru\text{-}(adenos)_4\text{-}(H_2O)_2]\text{-}(ClO_4)_3\}$ (**2**), pentaaquo(guanine)-ruthenium-(III)perchlorate $\{[Ru(gua)(H_2O)_5](ClO_4)_3\}$(**3**), aquopenta-(guanosine)ruthenium(III) perchlorate-$\{[Ru(guanos)_5\text{-}(H_2O)](ClO_4)_3\}$ (**4**), tris(cytosine)-trimeth-anolruthenium(III) perchlorate methanolate $\{[Ru(cyt)_3\text{-}(CH_3OH\}_3](ClO_4)_3\cdot CH_3OH\}$(**5**), aquopenta(cytidine)-ruthenium(III) perchlorate dihydrate $\{[Ru(cyd)_5\text{-}(H_2O)](ClO_4)_3\cdot 2H_2O\}$ (**6**), hexa(uracil)ruthenium(III)perchlorate hydrate $\{[Ru(ura)_6](ClO_4)_3\cdot H_2O\}$ (**7**), bis-perchlorato-triaquo(uridine)ruthenium(III) perchloratehydrate $\{[Ru(urd)(H_2O)_3(ClO_4)_2](ClO_4)\cdot H_2O\}$ (**8**), perchloratodiaquotris (thymine) ruthenium (III) perchlorate$\{[Ru(thy)_3(H_2O)_2(ClO_4)](ClO_4)_2\}$ (**9**), tetraaquobis(thymidine)ruthenium(III) perchlorate $\{[Ru(thd)_2(H_2O)_4]\text{-}(ClO_4)_3\}$ (**10**), diaquotetra(hypoxanthine)ruthenium(III)perchlorate $\{[Ru(hyp)_4(H_2O)_2](ClO_4)_3\}$ (**11**), aquopenta-(inosine)ruthenium(III) perchlorate $\{[Ru(ino)_5(H_2O)]\text{-}(ClO_4)_3\}$ (**12**).

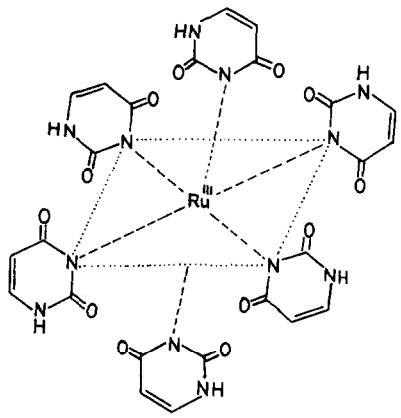

Fig. 3.

In a general method for the preparation of complexes **1–12** an appropriate quantity of ruthenium perchlorate in water is added to the required concentration of an aqueous solution of purine, pyrimidine or nucleoside. The resulting solution was refluxed on a water bath for 6–8 h and then left at room temperature overnight when complexes **1–12** separated out. The complexes were filtered, washed with acetone or ether, recrystallized from water–methanol, dried *in vacuo* and kept in a desiccator. Yield 60–70%,

The recrystallized complexes were characterized by elemental analyses, conductivity measurements, IR, electronic and NMR spectra. The analytical and conductivity data of the complexes are presented in Table 1.

RESULTS AND DISCUSSION

The ligational frequencies of importance in the complexes of purines, pyrimidines and nucleosides studied in this investigation are the ν(C=C), ν(C=N) and ν(C=O) modes. The ν(C=C) and ν(C=N) of the purines, pyrimidines and nucleosides are observed around 1450–1600 cm^{-1} and undergo a significant shift ($\sim$50 cm^{-1}) on complexation compared to the frequencies in the free ligand, indicating the involvement of ring nitrogens in coordination to the metal ion. The ligational ν(C=O) and $\delta(NH_2)$ modes observed around 1700 and 1680 cm^{-1}, respectively, are very slightly shifted on complexation, excluding the coordination of the C=O or NH_2 group of the ligands to the metal ion. The ν(OH) mode of coordinated water or methanol appears as a medium band around 3300–3400 cm^{-1}. The presence of a coordinated perchlorate in complexes **1**, **8** and **9** is observed as doubly split[16–20] ν_3- and ν_4-modes of perchlorate around 1080 and 620 cm^{-1}. The ν_1-mode of perchlorate becomes IR-active on coordination and is observed around 910 cm^{-1} as a medium peak. The presence of exclusively ionic perchlorate in complexes **2–7** and **10–12** is observed as single peaks around 1080 and 620 cm^{-1}, corresponding to the ν_3- and ν_4-modes of perchlorate which are fundamental vibrations of this group.[16–20] The presence of both ionic and coordinated perchlorate in complexes **8** and **9** is observed as triply split ν_3- and ν_4-peaks around 1080 and 620 cm^{-1}. The ν_1-mode is observed around 920 cm^{-1}. The IR spectra of the complexes exhibit a ν(M—N) around 520 cm^{-1}.[21]

The electronic spectra of the complexes and their assignments[22] are given in Table 2 and some structures are depicted in Figs 1–4.

In order to determine the binding sites of the ligands used, the NMR spectra of the complexes were of great help. The NMR spectra were recorded in D_2O. The solubility of complex **1** precludes the NMR investigation. The NMR spectrum of complex **2** exhibits peaks at δ 8.20 and 8.64 ppm corresponding to C_2H and C_8H protons, respectively, of adenosine. The peak corresponding to the C_8H protons is shifted downfield by 0.28 ppm in the complex compared to that of the ligand, whereas C_2H protons remain unaffected on complexation. This indicates that adenosine is bound to the metal ion through N_7. On the basis of the NMR spectrum of the rhodium complex of adenine[23] in which the C_8H protons alone are shifted and on the earlier

[f]In alcohol.

work on adenine complexes,[24] it can also be proposed that the adenine in complex **1** is coordinated through N_7. In the NMR spectrum of complex **3** the peak at 7.88 ppm for the C_8H protons shows a downfield shift of about 0.2 ppm, indicating that N_7 is the binding site in guanine. In complex **4** the NMR peak for C_8H protons at 8.80 ppm shows a shift of about 1.0 ppm, which is evidence for the coordination of the N_7 of guanosine to the metal ion. On the basis of the above discussion, hypoxanthine, which is also a purine base, and its nucleoside inosine can be assumed to be coordinated through N_7 in complexes **11** and **12**. Earlier literature also supports this assumption.[13] In the NMR spectrum of complex **5** the peaks at 5.26 and 7.20 ppm correspond to the C_5H and C_6H resonance, respectively, of cytosine. The peak at 5.26 ppm shows a greater upfield shift than the one at

7.20 ppm, indicating the coordination of cytosine to the metal ion through N_3. The peak at 1.8 ppm in complex **5** shows the presence of coordinated methanol. In complex **6**, the NMR spectrum shows peaks at 5.48 and 7.64 ppm. The peak at 5.48 ppm corresponding to C_5H protons shows a greater shift than the C_6H protons, indicating that the binding site in cytidine is N_3. The NMR spectrum of complex **7** exhibits two peaks for the C_5H and C_6H protons at 5.60 and 7.56 ppm, respectively. The C_5H peak shows a greater upfield shift than the C_6H peak, indicating that uracil is coordinated to the metal ion through N_3. On the basis of earlier work on uridine[1] and the NMR of the complex of uracil, uridine in complex **8** may also be proposed to be coordinated to the metal ion through N_3. The NMR spectrum of complex **10** exhibits two peaks at 1.76 and 7.5 ppm, corresponding to methyl and C_6H protons, respectively. The peak at 7.5 ppm shows a shift of about 0.20 ppm, indicating that N_3 is the binding site in thymidine. On this basis and by comparison with the complexes of other pyrimidine bases in this paper and the earlier work on Pt(II) thymine complexes,[25] the thymine in complex **9** is assumed to be bound to the metal ion through N_3.

To summarize, in the present investigation the purine bases and nucleosides studied are coordinated to the metal ion through N_7 whereas in the case of pyrimidine bases and nucleosides N_3 is the binding site.

THE INTERACTION OF 2-ACYLPYRIDINES WITH METHYLTIN, PHENYLTIN AND STANNIC CHLORIDES

H. T. BOZIMO and J. J. BONIRE*

Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 20 *December* 1985; *accepted after revision* 7 *July* 1986)

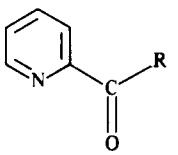
Abstract—1:1 Lewis acid: Lewis base adducts are obtained from the reaction of 2-benzoylpyridine with $MeSnCl_3$, $SnCl_4$ and $PhSnCl_3$, and of 2-pyridine carboxaldehyde with $PhSnCl_3$. The Lewis bases bind to the organotin Lewis acids through both N and O atoms of the acylpyridines. But 2-acetylpyridine reacts in a different manner with the organotin chlorides, giving what appear to be 1:2 adducts with $MeSnCl_3$, $SnCl_4$, $PhSnCl_3$ and Ph_2SnCl_2; and a product with Me_2SnCl_2 that has yet to be characterized. This suggests that, with organotin Lewis acids, 2-acylpyridines with an α-hydrogen atom on the side-chain reacts differently from 2-acylpyridines without side-chain α-hydrogen atoms.

With an acyl substituent at the 2-position on the pyridine ring (**I**) (Fig. 1) several possibilities arise in the mode of association of the Lewis base with a suitable Lewis acid: the carbonyl oxygen could coordinate along with the nitrogen on the Lewis acid, or the nitrogen could coordinate alone, being less electronegative than oxygen. Or the Lewis base might fail to bind at all because of steric repulsion if the acyl group is bulky. Also, for certain acyl groups, tautomerization in the side-chain could influence the mode of interaction between the acylpyridine and the organotin Lewis acid.

Studies of the interaction of a few 2-acylpyridines with some transition metals have been previously reported.[1–4] 2-Acetylpyridine and 2-benzoylpyridine were found to bind with both N and O on the Lewis acids studied. Jain,[5] in his study of the interaction of 2-acetylpyridine with stannic chloride, obtained what he identified as a 1:1 adduct.

According to the principle of hard and soft acids and bases, the presence of inductively positive organic groups on tetravalent tin would confer softness on the latter.[6,7] The mode of interaction of acylpyridines with transition metal Lewis acids might therefore differ from that with organotin chlorides.

No report appears to have been made so far of the interaction of organotin halides with 2-acylpyridines. We report herein a study of the mode of reaction



R = H, CH_3 or C_6H_5

Fig. 1.

of 2-acetylpyridine (2-AcPy), 2-benzoylpyridine (2-BzPy), and 2-pyridine carboxaldehyde (2-PyCHO) with methyltin chlorides, phenyltin chlorides and stannic chloride.

EXPERIMENTAL

All the reagents were ANALAR grade. The organotin chlorides and stannic chloride, and the Lewis bases were obtained from Aldrich Chemical Co.

Dichloromethane was purified by washing successively with 5% sodium carbonate solution and water, and drying over anhydrous $CaCl_2$ before distillation.

Melting points are uncorrected.

IR spectra (KBr and CsI discs) were obtained using Perkin–Elmer PE-700 and PE-710-B spectrometers.

^1H NMR spectra (in DMSO-d_6 with internal TMS reference) were obtained using a Varian T-60 spectrometer operating at a probe temperature of 38°C.

Elemental analyses (C, H, N and Cl) were carried

*Author to whom correspondence should be addressed.

out by Scandinavian Analytical Laboratories. Tin content was determined locally according to the method of Farnsworth *et al.*[8]

Preparations

Solutions (containing about 1 mmol solute in 6 cm^3 solvent) of the Lewis acid and Lewis base were mixed in a solute molar ratio of 1:2. The resulting clear mixtures were left overnight at a temperature of about 5°C to give crystalline products. The crystals were washed four times with solvent or recrystallized and dried *in vacuo*.

RESULTS AND DISCUSSION

Table 1 summarizes the methods of preparation, physical properties and elemental analytical results of the various complexes. The analytical results suggest 1:1 complex formation between benzoyl pyridine and $MeSnCl_3$, $SnCl_4$ and $PhSnCl_3$. The last two complexes decomposed on heating.

The reaction of 2-pyridine carboxaldehyde with $MeSnCl_3$, $PhSnCl_3$ and $SnCl_4$ gave a stable isolable product only with $PhSnCl_3$, Elemental analysis of this product suggested a 1:1 adduct.

Reaction of 2-acetylpyridine with $MeSnCl_3$, $PhSnCl_3$, diphenyltin dichloride (Ph_2SnCl_2) and $SnCl_4$ yielded products that were clearly different from the corresponding products with 2-benzoylpyridine. Elemental analysis of the 2-acetylpyridine products suggested 1:2 adduct formation. On the other hand, the analytical results of the reaction product with Me_2SnCl_2 conformed neither with 1:1 nor with 1:2 adduct formation. With the exception of the adduct with Ph_2SnCl_2, these adducts all decomposed at a lower temperature than the corresponding 2-BzPy complexes.

IR spectra

With 2-benzoylpyridine, complex formation resulted in a ligand carbonyl band shift from 1660 cm^{-1} to about 1610 cm^{-1}. From the work of Plytzanopoulos *et al.*[2-4] it can be inferred that this shift is an indication of binding through the carbonyl oxygen atom. For all the complexes an aromatic C=C band shift from 1580 to 1595 cm^{-1} was observed. This is an indication of binding through the nitrogen atom of the pyridine ring. Thus, taken with the inference from the elemental analyses, it can be concluded that benzoylpyridine behaves as a bidentate ligand with the tin Lewis acids. Similar evidence shows that 2-pyridine carboxaldehyde also behaves as a bidentate ligand.

The adducts with 2-acetylpyridine all lack the 1700 cm^{-1} band which is observed in the free base. All except the adduct with Me_2SnCl_2 show a band at about 3450 cm^{-1} which is assignable to —OH. The usual parent ring band shift from 1580 cm^{-1} to about 1600 cm^{-1} was observed in all the complexes. The evidence suggests, first, adduct formation through the nitrogen rather than the oxygen atom and, second, the tautomerization (enolization) of the side-chain. But because the band at 1640 cm^{-1} was broad and extended to about 1650 cm^{-1} it was not possible to confirm the presence of a band for the vinyllic C=C which would have been expected at about 1645 cm^{-1}.

The IR spectrum of the 2-acetylpyridine adduct of Me_2SnCl_2 showed no band above 3100 cm^{-1}, suggesting that no enolization occurred, and that the band at 1640 cm^{-1} was probably due to a coordinated carbonyl (Table 2).

^1H NMR spectra

The ^1H NMR spectra of the 2-benzoylpyridine adducts were simple and, except for slight downfield shifts of the ligand signals, directly derivable from those of the uncomplexed starting materials. The spectrum of the 2-pyridine carboxaldehyde complex with $PhSnCl_3$ was also simple.

The 2-acetylpyridine complexes were more complicated. The stannic chloride adduct showed singlets at 1.95, 2.40, 3.00, 5.80 and 7.00 ppm, in addition to the 2.70 ppm singlet for the $COCH_3$ side-chain. The aromatic ring of the ligand showed a complex multiplet between 9.50 and 7.00 ppm.

The spectra of the $PhSnCl_3$ complexes were relatively simple and supported the molecular formulae suggested by the elemental analyses.

The spectrum of the $MeSnCl_3$ complex showed a new singlet at 2.15 ppm in addition to those expected for $MeSnCl_3$ · bis-2-AcPy. But the most complex spectrum, which we have still not been able to interpret, is that of the reaction product of 2-acetylpyridine with Me_2SnCl_2. The spectrum lacks the singlet at 2.70 ppm for the —$COCH_3$ of the starting Lewis base but shows a signal at 2.30 ppm. The signal for the aromatic rings shows a complex pattern between 7.20 and 8.15 ppm. The mass spectrum of the product gave no indication of a simple 1:1 or 1:2 adduct. It showed a base peak at 207, an apparent molecular ion at 394, and other major peaks at 135, 155, 170, 185 and 224.

The results show a variety of reaction patterns between acylpyridines and organotin Lewis acids. 2-Benzoylpyridine acts as a bidentate ligand to give 1:1 adducts with the tin derivatives. Also, 2-pyridine carboxaldehyde reacts, at least with $PhSnCl_3$, to give a 1:1 adduct. 2-Acetlypyridine reacts with $PhSnCl_3$ and Ph_2SnCl_2 to give 1:2 adducts in which the ligand is coordinated through the nitrogen atom. Adduct

Table 1. Preparation and physical proeprties of the complexes

formation in this instance also seems to lead to extensive enolization in the ligand side-chain. With $SnCl_4$ and $MeSnCl_3$, 2-acetylpyridine gives reaction products which, from the elemental analyses, appear to be 1:2 adducts but for which spectroscopic data suggest structures that are more complex than the other simple adducts. It has not yet been possible to deduce meaningful structures from the spectroscopic data for these products.

REACTION OF PHENYLTIN CHLORIDES WITH SILVER TRIFLUOROACETATE

J. J. BONIRE

Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 5 *July* 1985; *accepted after revision* 7 *July* 1986)

Abstract—Ph_3SnCl and $PhSnCl_3$ reacted with $AgOCOCF_3$ to give $Ph_3SnOCOCF_3$ and $PhSn(OCOCF_3)_3$ respectively, but Ph_2SnCl_2 gave an oil which breaks down and rearranges by a radical mechanism to give the ditin compound $Ph_2Sn_2(OCOCF_3)_4$.

In a previous paper,[1] I reported the synthesis of some pyridine complexes of tri- and dimethyltin trifluoroacetates resulting from a study of the substitution reactions of organotin chloride pyridine adducts.

In continuation of this study, it was discovered that the pyridine adducts of diphenyltin dichloride react with silver trifluoroacetate to produce, not the expected pyridine adducts of diphenyltin bistrifluoroacetate, but salts of the pyridine Lewis bases.

Although there is a great deal of literature on the synthesis of organotin carboxylates,[2,3] there has been no report on any reaction of phenyltin chlorides with silver trifluoroacetate.

In trying to understand why diphenyltin dichloride pyridine adducts do not react with silver trifluoroacetate to give pyridine adducts of diphenyltin bistrifluoroacetate, a study of the reaction of silver trifluoroacetate with phenyltin chlorides has been undertaken, and this paper reports the results.

EXPERIMENTAL

All reagents were obtained from BDH, Aldrich, or Alfa; elemental analyses were done by the Scandinavian Microanalytical Laboratories; Sn analysis was done locally using the method of Farnsworth.[4]

IR spectra (CsI disc) were obtained using Perkin–Elmer SP 700 and 800 spectrometers; Raman and mass spectra were determined by the Butterworth Analytical Laboratories.

Dry acetone was prepared by refluxing an AnalaR grade of acetone with *p*-toluenesulphonyl chloride (1 g/l of acetone) for 45 min, and distilling.

Reaction of Ph_3SnCl *with* $AgOCOCF_3$

Triphenyltin chloride (3.85 g, 0.01 M) and silver trifluoroacetate (2.21 g, 0.01 g), each in dry acetone (50 cm^3) were mixed. The precipitated silver chloride was coagulated by boiling the mixture for 10 min in the dark, and filtered off. The clear filtrate was evaporated to dryness giving a white powder. The product (3.60 g, dry) was recrystallized 3 times from 40–60 petroleum spirit; analyses (below) show that it is triphenyltin trifluoroacetate.

Reaction of $PhSnCl_3$ *with* $AgOCOCF_3$

Phenyltin trichloride (1.51 g, 0.005 M) and silver trifluoroacetate (9.95 g, 0.015 M), each in 100 cm^3 of dry acetone, were mixed. The precipitated silver chloride was removed as above, and the clear light yellow filtrate concentrated by evaporation into a thick oil. The oil, on standing, hardened into an unpurifiable brown solid.

Extraction of the oil into 40–60 petroleum spirit, followed by boiling under reflux for 30 min, yielded a fine, white powder which was shown by analysis to be phenyltin tristrifluoroacetate.

Reaction of Ph_2SnCl_2 *with* $AgOCOCF_3$

Diphenyltin dichloride (3.44 g, 0.01 M) and silver trifluoroacetate (5.53 g, 0.025 M), each in 50 cm^3 of dry acetone, were mixed. After removal of the precipitated silver chloride the clear filtrate was concentrated into a colourless viscous oil.

The 'oil' was extracted into cold, aromatic hydrocarbon-free 40–60 petroleum spirit. Warming of the solution started the production of a white

Table 1. Elemental analysis results and IR spectra (CsI disc) of the products

Compound	Yield (%)	Melting point (°C) (uncorrected)	Elemental analysis Found C	H	Sn	Calculated C	H	Sn	IR spectra (cm^{-1}) O—C—O (assym)	O—C—O (sym)	Sn—O—C

paste, and the reaction continued in an exponential manner for several days as the solution was boiled under reflux. After four days, the fine granular precipitate was filtered off, washed four times with aromatic hydrocarbon-free petrol (40–60), and dried (2.5 g). Analyses showed the powder to be $Ph_2Sn_2(OCOCF_3)_4$.

RESULTS AND DISCUSSION

Table 1 shows the elemental analytical results for the products. Ph_3SnCl, $PhSnCl_3$ and Ph_2SnCl_2 reacted with $AgOCOCF_3$ to give products which the elemental analysis results have suggested to be $Ph_3SnOCOCF_3$, $PhSn(OCOCF_3)_3$, $PhSn(OCOCF_3)_2$, respectively.

The ^1H NMR spectra of the products obtained for Ph_3SnCl and Ph_2SnCl_2, in deuterodimethyl sulphoxide (*d*-DMSO), were simple and similar, giving multiplets assignable to the phenyl ring protons at δ 7.40 and 7.75 ppm. The product obtained from $PhSnCl_3$, however, dissolved in *d*-DMSO only with much heating, and gave just a singlet at δ 7.30 ppm (assignable to benzene protons) thereby raising the suggestion of the breakdown of the product in hot *d*-DMSO instead of a simple dissolution.

The IR (CsI discs) spectral data of the products are also shown in Table 1. The spectra of the three products were similar, showing intense bands for a bridge type of O—C—O bond among others.

A mass spectrum of the solid product obtained from Ph_2SnCl_2 gave the highest mass unit of 423, assignable to $C_6H_5Sn(OCOCF_3)_2$ but its Raman spectrum showed bands at Raman shifts of 139, 147, 183, 565, 852, 1000 and 1026 cm^{-1}. Taking into account the works of Brown *et al.*[5] and Bulliner *et al.*,[6] the Raman shift at 147 cm^{-1} has been assigned to an Sn—Sn bond in the compound. A UV spectrum of the compound in DMSO gave a band with a λ_{max} at 273 nm, assignable to an Sn—Sn bond, according to the reports of Drenth *et al.*[7] and Poller.[8] Further, the decolouration of a CCl_4 bromine solution by the compound makes it safe to conclude that the molecule of the compound contains an Sn—Sn bond, since the Sn—Sn bond is known to be broken by the halogens.

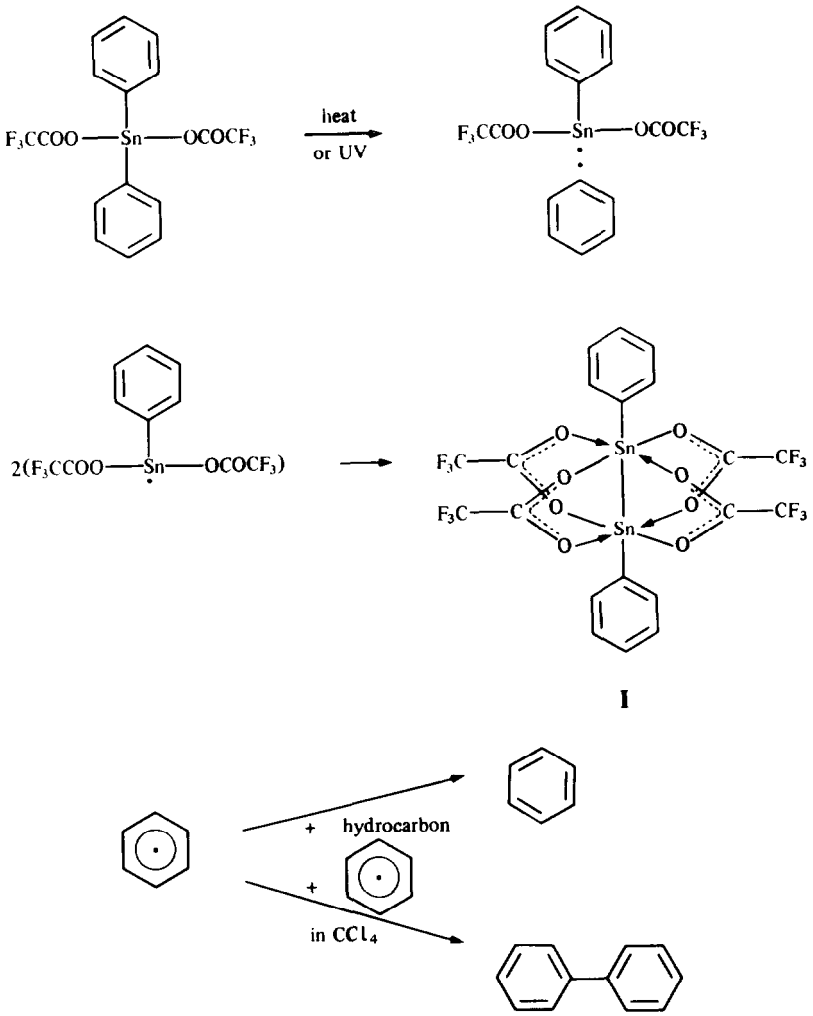
From the elemental analysis results and the above deductions the molecular formula of the solid product obtained from Ph_2SnCl_2 is $Ph_2Sn_2(OCOCF_3)_4$ or $[PhSn(OCOCF_3)_2]_2$, with an Sn—Sn linkage.

The elemental and spectral analyses have shown that Ph_3SnCl, $PhSnCl_3$ and Ph_2SnCl_2 react with $AgOCOCF_3$ to yield $Ph_3SnOCOCF_3$, $PhSn(OCOCF_3)_3$ and $Ph_2Sn_2(OCOCF_3)_4$, respectively. The synthesis of $Ph_3SnOCOCF_3$ is not new,[2] but its preparation using $AgOCOCF_3$ appears to be.

The $Ph_2Sn_2(OCOCF_3)_4$, dirty white and powdery, did not melt below 360°C. It dissolved only in highly nucleophilic solvents like dimethylsulphoxide and dimethylformamide.

Benzene was produced along with $Ph_2Sn_2(OCOCF_3)_4$ when the "oil" obtained from the reaction of Ph_2SnCl_2 with $AgOCOCF_3$ was heated in aromatic, hydrocarbon-free 40–60 petroleum spirit. The production of benzene, first indicated by ^1H NMR spectroscopy, was confirmed by subjecting a distillate of the reaction mixture to nitration with 1:1 c. H_2SO_4/c. HNO_3; crystals of *m*-dinitrobenzene were obtained. It was also found that $Ph_2Sn_2(OCOCF_3)_4$ was produced from the oil in petrol under UV and sun light. Prolonged heating of a CCl_4 extract of the oil yielded a powder that had identical spectral properties with $Ph_2Sn(OCOCF_3)_4$, and biphenyl. Heating of a benzene extract of the oil also yielded biphenyl, confirmed by spectroscopy and TLC, along with $Ph_2Sn_2(OCOCF_3)_4$. It was also found that addition of benzoquinone, a radical scavenger, to a petrol extract of the "oil" inhibited the production of $Ph_2Sn_2(OCOCF_3)_4$ when the mixture was heated.

A tin elemental analysis of the "oil" in its driest form gave an Sn content of 20.92%; further drying made the oil solidify to an amorphous light yellow powder with an Sn content of 26.75%. The IR and ^1H NMR spectra of the "oil" did not appear much different from those of $Ph_2Sn_2(OCOCF_3)_4$. There was no indication that benzene was produced along with the "oil" from Ph_2SnCl_2. Also, a Lassaigne test did not show the presence of Cl in the oil. It does appear then that the 'oil' was $Ph_2Sn(OCOCF_3)_2$.



I

Fig. 1. Behaviour of $Ph_2Sn(OCOCF_3)_2$ when heated in non-polar media and UV light.

The production of the $Ph_2Sn_2(OCOCF_3)_4$ from the 'oil' in petroleum spirit is exponential, a mode typical of radical reactions. This suggestion has further being strengthened by the ability of UV and sun light, in addition to heat, to initiate the production of the compound in non-polar media only; and by the ability of benzoquinone, a radical scavenger, to stop or inhibit its production. Benzene was produced along with $Ph_2Sn_2(OCOCF_3)_4$ in petrol, and biphenyl in CCl_4 and benzene solvents. These suggest an initial radical break of the Sn—phenyl bond, a union of two $Ph\dot{S}n(OCOCF_3)_2$ radicals, and the union of two phenyl radicals or the abstraction of a hydrogen radical from petroleum spirit by a phenyl radical, as shown in Fig. 1.

Benzene is obtained in petrol and biphenyl in CCl_4 probably because it is easier to homolytically break a C—H bond than a C—Cl bond.

The symmetrical nature of the structure (I) suggested above would explain the high melting point of the compound; its internal coordination would explain why pyridine adducts of Ph_2SnCl_2 do not react with $AgOCOCF_3$ to give pyridine adducts of $Ph_2Sn(OCOCF_3)_2$, as well as the poor solubility of $Ph_2Sn_2(OCOCF_3)_4$ in many solvents.

It cannot be said at this stage that all diphenyltin dicarboxylates would react as above in non-polar media. It is possible that the electron-withdrawing ability of the phenyl ring of $Ph_2Sn(OCOCF_3)_2$ happened to compare with that of the $Sn(OCOCF_3)_2$ moiety, thereby making possible a homolytic fission of the Sn—phenyl bond. $Ph_2Sn(OCOCH_3)_2$, reportedly first synthesized by Graddon and Rana, [10] remained stable when heated in non-polar media.

POLAROGRAPHIC STUDY OF THE COMPOSITION AND STABILITY CONSTANTS OF THALLIUM(I) CYCLOHEXYLTHIOGLYCOLATE COMPLEXES

USHA GUPTA and A. L. J. RAO*

Department of Chemistry, Punjabi University, Patiala 147002, India

(*Received* 20 *March* 1986; *accepted after revision* 7 *July* 1986)

Abstract—The complexation of thallium(I) by cyclohexylthioglycolate (CyHTG) has been studied polarographically. The reduction of Tl^+ in cyclohexylthioglycolate solution has been found to be reversible and diffusion controlled involving a one-electron transfer process. Potential vs concentration data at 0.5 M ionic strength are interpreted on the basis of the formation of two complex species, TlA and TlA_2^-. The logarithms of the stability constants of these complexes are 1.73, 3.176 at 20°C, 1.77, 3.342 at 30°C and 1.87, 3.398 at 40°C, respectively. The values of $\Delta G^\ominus$, $\Delta H^\ominus$ and $\Delta S^\ominus$ have been calculated at 30°C.

Mercapto compounds containing active SH and COOH groups have a wide variety of applications. The polarographic behaviour of Tl^+ has been studied in various media with different complexing reagents such as ethylene bis-(3-mercaptopropionate),[1] ethylthioglycolate,[2] ethane-1,2-dithiol,[1] butylthioglycolate,[3] furfuryl mercaptan,[4] 2-mercapto ethanol[5] and β-mercaptopropionic acid.[6] In the present investigations the complexation of cyclohexylthioglycolate with thallium(I) has been studied polarographically to determine the composition and stability constants of the complex ions formed. The values of $\Delta G^\ominus$, $\Delta H^\ominus$ and $\Delta S^\ominus$ have also been calculated and are reported in this paper.

EXPERIMENTAL

Cyclohexylthioglycolate (CyHTG) was used as metal binding agent. It was synthesized by the method given by Gambarov,[7] and was standardized. A stock solution of the reagent was prepared in pure ethanol. A 2 M solution of KNO_3 was used as the supporting electrolyte and 0.1% Triton X-100 as the maximum suppressor. All solutions used in the polarographic measurements had in addition to CyHTG, a Tl^+ concentration of 1.0 mM, 0.5 M KNO_3 and 0.002% Triton X-100 in 50% ethanolic media at pH 6.0. The CyHTG concentration was varied from 0.005 to 0.03 M. A manual Toshniwal polarograph (CLO_2 type) and saturated calomel electrode were used. The necessary correction for the iR drop and residual current were applied in determining the half-wave potential and diffusion current data, respectively.

The plot of i_d vs $\sqrt{h}$ and i_d vs C (C = concentration of thallium) is linear, indicating the diffusion-controlled nature of the reduction wave. The values of slopes from log plots (i.e. plot of log $i/i_d - i$ vs $E \cdot d \cdot e$) agreed with the theoretical values for one-electron transfer. The half-wave potential shifted toward more negative values with increasing CyHTG concentration indicating complex formation. The diffusion current and half-wave potential values are recorded in Table 1. A plot of $E_{1/2}$ as a function of log (CyHTG) showed the curvature indicating the formation of more than one complex. The method of Deford and Hume[8] was applied to the calculation of stability constants for the two complexes TlA and TlA_2^-. Thermodynamic parameters $\Delta G^\ominus$, $\Delta H^\ominus$ and $\Delta S^\ominus$ were also evaluated at 30°C for the two complexes and the results are summarized in Table 2. The percentage distribution of thallium present in different forms as a function of log (CyHTG) has been calculated and the results are presented in Fig. 1.

THE KINETICS AND MECHANISMS OF THE CATALYSED DECOMPOSITION OF HYDROGEN PEROXIDE BY ETHYLENEDIAMINETETRA(METHYLENEPHOSPHONATO) COMPLEX OF MANGANESE(II)

E. N. RIZKALLA,* S. S. ANIS and L. H. KHALIL

Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt

(*Received* 8 *April* 1986; *accepted after revision* 7 *July* 1986)

Abstract—The decomposition of H_2O_2 in the presence of ethylenediaminetetra(methylenephosphonato)manganate(II) complex, [Mn(II)Y] (Y represents the $(CH_2–N(CH_2PO_3H_2)_2)_2$ anion), was studied at various temperatures. The rate law:

$$\frac{-d[H_2O_2]}{dt} = \frac{K_a[H^+](k_2 + k_1K_1[H^+])}{(1 + K_a[H^+])(1 + K_1[H^+])}[MnY]_{aq}[H_2O_2]_T$$

holds over the pH range 9.0–10.30. A mechanism involving Mn(IV) and peroxy intermediates is suggested. In strongly alkaline solutions, Mn(IV) species hydrolyse to give colloidal MnO_2. At 30°C, the specific rate constants for the reactions:

$$[Mn(III)Y(OH)]^{6-} + H_2O_2 \xrightarrow{k_1} [Mn(III)Y(OOH)]^{6-} + H_2O$$

and

$$[Mn(III)Y]^{5-} + H_2O_2 \xrightarrow{k_2} [Mn(III)Y(H_2O_2)]^{5-}$$

were determined to be $k_1 = 33\,M^{-1}s^{-1}$ and $k_2 = 2.2\,M^{-1}s^{-1}$. The corresponding activation parameters are, $\Delta H_1^{\ominus} = 17 \pm 4\,kJ\,mol^{-1}$; $\Delta S_1^{\ominus} = -165 \pm 15\,J\,K^{-1}\,mol^{-1}$; $\Delta H_2^{\ominus} = 83 \pm kJ\,mol^{-1}$ and $\Delta S_2^{\ominus} = 37 \pm 55\,J\,K^{-1}\,mol^{-1}$.

The kinetics of oxidation of hydrogen peroxide by potentially oxidizing aquo metal ions in acidic media has been thoroughly investigated.[1–3] In the case of aquo manganese(III) species, two different mechanisms were postulated to cope with the observed rate data. In one set of experiments,[4] the data were analysed using a bimolecular rate equation and the apparent second-order rate constants were found to vary with varying the initial [Mn(III)], [Mn(II)], $[H_2O_2]$ and $[H^+]$ concentrations. The results indicated a first-order dependency on both [Mn(III)] and $[H_2O_2]$ and an inverse dependence on [Mn(II)]. Wells and Mays,[5] on the other hand, investigated the same system under comparable experimental conditions and found that the rate of reaction is first order in [Mn(III)] and independent of both [Mn(II)] and $[H_2O_2]$ concentrations. The enhancement in optical density at 470 nm after mixing with peroxide was attributed to the formation of a new [Mn(III)-OOH] peroxo species which decomposes slowly to the products. The discrepancy in both experiments was attributed to the inappropriate use of the bimolecular rate equation.[6] Analysis of the optical densities available for an individual run in Ref. 4 gave a reasonable first-order plot with k_{obs} approximately half of that estimated from the measurements of Wells *et al.*[5]

manganese-polyaminocarboxylates is limited to the report of Jones and Hamm.[7] The reaction of Mn(III)-CyDTA with H_2O_2 was studied in the pH range of 2–4 and found to be first-order in $[H_2O_2]$, second-order in [Mn(III)-CyDTA] and inversely dependent on both $[H^+]$ and [Mn(II)-CyDTA] concentrations. The mechanism suggested involves a fast formation of a ternary peroxo intermediate followed by the slow decomposition of these species. Such ternary complexes were also proposed for the reaction of Fe(III)-EDTA[8] and Cr(III)-EDTA[9] with hydrogen peroxide at higher pH (~6–10). In these systems, the rate was found to be first-order in both H_2O_2 and the complex species. The disagreement in the rate equation for Mn-CyDTA compared to the closely resembling Fe(III) and Cr(III) systems arises from the differences in the reactions considered in both cases. Although iron and chromium chelates were shown to act as catalyst centres for the disproportionation of H_2O_2, Mn(III)-CyDTA was shown to react with H_2O_2 to give Mn(II)-CyDTA and oxygen with an overall stoichiometry of $[Mn(III)\text{-}CyDTA]/[H_2O_2] = 2.06$. Contrary to the peroxidatic systems, the rate-determining step in the catalytic studies is that involving peroxide substitution in the inner sphere of the metal ion.

In the present investigation, we extend these studies to the Mn-ENTMP–H_2O_2 system [ENTMP = ethylenediaminetetra(methylenephosphonic) acid, $\{CH_2\text{-}N(CH_2PO_3H_2)_2\}_2$]. A slight excess of ENTMP was always present to ensure that manganese was present only in the complexed form.

EXPERIMENTAL

Materials

Ethylenediaminetetra(methylenephosphonic) acid, H_8ENTMP, was kindly donated by Monsanto Chemical Co., St. Louis, MO and was recrystallized by precipitating the ligand as the tetra lead salt, filtered, washed and allowed to react with H_2S for 2 h. The black residue of lead sulphide was removed by filtration and the mother liquor containing the ligand in the acid form was freeze dried. The purity of the ligand was checked by potentiometric titration of a suitable sample with a standard CO_2-free sodium hydroxide. Also, the ^1H NMR spectrum showed the presence of only a doublet and a singlet assigned to the α-methylene and the β-backbone protons respectively.[10] Manganese(II) chloride hexahydrate, sodium nitrate, sodium hydroxide and hydrogen peroxide were B.D.H. AnalaR grade.

The Mn(II)-ENTMP complex was prepared by adding 0.001 mol of the manganese salt solution to an equimolar amount of the ligand aqueous solution slowly with a constant stirring. The mixture was warmed and the pH was raised to 7–8 with Na_2CO_3. Twice the stoichiometric amount of magnesium nitrate was then added and the mixture was left to stand overnight. The pale pinkish crystals formed were filtered, dried and analysed for the constituent elements and found to agree well with the empirical formula $Na_2Mg_2[MnY]\cdot 18H_2O$; here and elsewhere Y represents the anion of ethylenediaminetetra(methylenephosphonate).

Spectral and cyclic voltametry measurements

Visible spectral measurements were obtained with a Tracor Northern Optical Multichannel Analyzer. The system composed of a Tracor Northern 6050 spectrometer containing a Czerny–Turner spectrograph connected to a Tracor Northern 1710 Multichannel Analyzer and a Houston Omnigraphic 2000 X-Y recorder. Wavelength calibration was achieved with a holmium oxide filter and the measurements were obtained using a 1.00-cm path length quartz cuvette.

Cyclic voltammograms were obtained using an EG&G Princeton Applied Research model 174A polarographic analyser. A conventional three-electrode system was used with a glassy carbon working electrode, a Pt wire counter electrode and a saturated sodium chloride–calomel electrode as a reference. The electrochemical solutions were isolated from the reference electrode via asbestos fritte. The voltammograms were recorded on a Houston Omnigraphic 2000 X-Y recorder and the scan rate used was $50\,mV\,s^{-1}$.

Kinetic procedure

In all kinetic measurements, fresh solutions of the manganese complex were prepared by dissolving the appropriate weight in the minimum amount of hydrochloric acid. The pH was then adjusted to the desired value by the addition of either glycine buffer[11] or ammonia buffer. Sodium nitrate was added to maintain the ionic strength at 0.10 M unless otherwise specified. The mixture was thermostated in a controlled temperature bath and the kinetic run was started by injecting the peroxide into the solution. Samples of the reaction mixture were removed at set time intervals and the reaction was quenched by KI/H_2SO_4 mixture. The liberated iodine equivalent to the residual peroxide contents was then determined iodometrically.[11]

All calculations were carried out using an IBM PC.

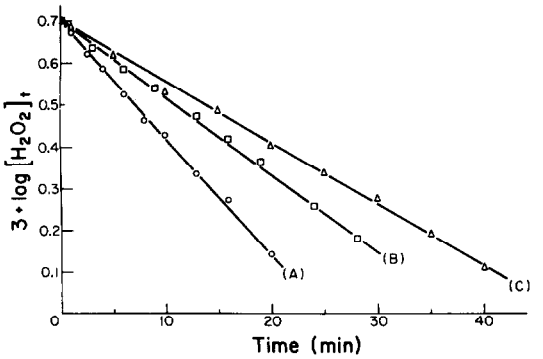

Fig. 1. Variation of residual peroxide concentration with time for the decomposition of hydrogen peroxide in the presence of $[MnY]_{aq}$: $[H_2O_2] = 5.0\,mM$, $[MnY]_{aq} = 0.0555\,mM$, $I = 0.10\,M$ (KNO_3). (A) pH = 9.88 (40°C); (B) pH = 9.80 (35°C); (C) pH = 9.79 (30°C).

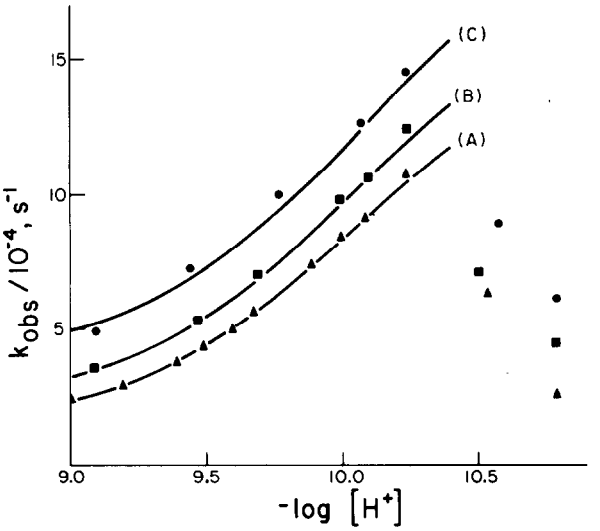

Fig. 2. Dependency of the rate constants on the pH of the medium. Solid lines represent the calculated values from eqn (5) at different pH values; the solid symbols are those obtained experimentally. (A) 30°C; (B) 35°C; (C) 40°C.

RESULTS AND DISCUSSION

The dependence of the reaction rate of the catalytic process

$$2H_2O_2 \rightarrow O_2 + 2H_2O \qquad (1)$$

on the initial conditions of the reaction mixture (namely pH, catalyst concentration, temperature and ionic strength) was investigated. Pseudo-first-order conditions were maintained in all runs by the use of a large excess of H_2O_2 over that of the manganese complex. Semi-logarithmic plots of the residual peroxide contents as a function of time were found to be linear up to a degree of completion of two half-lives or more. Representative sample plots obtained at $-\log[H^+] = 9.7$ and at various temperatures, are shown in Fig. 1. In most cases, the limiting ratio of $[H_2O_2]/[MnY]$ at 75% reaction completion is greater than 22. Only in a few cases, where the dependence of the reaction rate on the catalyst concentration is studied, did this ratio approach 6–7. The influence of the concentration of the catalyst on the disproportionation reaction was determined at several pHs and temperatures. In all cases, the rate is linearly proportional to the catalyst concentration. The slopes of these lines are a function of the medium pH and the temperature of the reaction mixture.

The rate constants determined for mixtures of fixed initial H_2O_2 and complex concentrations at variable pHs are illustrated in Fig. 2. At the three temperatures studied, the values of k_{obs} are an increasing function of pH in the range of 9.0–10.3. At higher alkalinity, the catalytic sensitivity is markedly retarded and approaches zero at pH > 11. A summary of all the results obtained at various reaction conditions is listed in Table 1.

Earlier equilibrium studies on the reaction of manganese salts with ENTMP is limited to the reports of Kabachnik *et al.*[12] and Kurochkina *et al.*[13] Manganese(II) reacts with the phosphonate ligand to form MnH_4Y^{2-} at pH ≃ 5. With increasing the pH of the medium, the complex deprotonates successively, leading to the formation of the normal complex $[MnY]^{6-}$ and the following equilibria hold

$$MnH_{n-1}Y^{-(7-n)} + H^+ \rightleftharpoons MnH_nY^{-(6-n)}$$

$$K_n = [MnH_nY^{-(6-n)}]/[MnH_{n-1}Y^{-(7-n)}][H^+] \qquad (2)$$

$$Mn^{2+} + Y^{8-} \rightleftharpoons MnY^{6-}$$

$$\beta_{101} = [MnY^{6-}]/[Mn^{2+}][Y^{8-}] \qquad (3)$$

where $pK_n = 9.06$, 7.51, 6.22 and 5.32 for $n = 1$, 2, 3 and 4, respectively, and $\log\beta_{101} = 12.70$.

The study is not as complete for manganic species and only the constant for the reaction

$$Mn^{3+} + H_2Y^{6-} \rightleftharpoons MnH_2Y^{3-} \qquad (4)$$

was evaluated to be $\log\beta_{121} = 11.20$[13] compared with $\log\beta_{121} = 7.00$ for the corresponding equilibria with Mn^{2+}. The authors showed also that the auto-reduction of manganese(III) reaches a minimum at pH ⩾ 9.[13]

According to these data in the pH range of 9.0–10.3 the ratio of [Mn(II)HY]/[Mn(II)Y] decreases from 0.72 to 0.06. Since pK_1 for trivalent ENTMP

complexes is ~7.0,[14] only [Mn(III)Y] species are dominant at pH > 9.0.

The spectral characteristics of Mn-ENTMP complexes were investigated over the pH range 5–12. In the absence of H_2O_2, Mn(II)-ENTMP has a very weak absorption over the entire pH range ($\varepsilon_{max} = 4.0\,M^{-1}\,cm^{-1}$). Addition of H_2O_2 to the mixture is accompanied by subsequent changes in colour depending on the pH of the medium. The course of the colour changes is pale pink → intense purple → yellowish pink → yellow at pH 6.3, 7.1, 7.9 and 10.0, respectively. The colour intensity reaches a maximum after 15 min of peroxide addition except at pH 10 where the yellow colour is developed instantaneously. Increasing the pH to 10.7 intensifies the yellow colour which turns to brown upon standing for 3 h followed by the deposition of MnO_2 and the pH drifts to 12.5. Figure 3 illustrates the spectral envelopes observed. The presence of a strong band at 485–495 nm in the pH range 6.3–7.9 can be assigned to the spin-allowed $^5E_g \leftarrow {}^5B_{1g}$ transition for Mn(III) in a distorted O_h symmetry.[15] These spectra resemble closely those obtained by mixing Mn(III)-pyrophosphate with ENTMP.[13] At all pHs, the colour is reversible and disappears upon the depletion of the peroxide. Hamm and Suwyn[16] attributed the change in colour from pink to yellow in the case of Mn(III)-CyDTA to the formation of the monohydroxo complex ($pK = 8.11$). At higher pHs, the formation of the unstable intense yellow-brown solutions was attributed to the formation of an oxo-Mn(IV) complex.[15] The very few reports on the spectra of Mn(IV) complexes suggests the presence of two spin-allowed transitions in the regions 355–520 and 460–628 nm assigned to $^4T_{1g} \leftarrow {}^4A_{2g}$ and $^4T_{2g} \leftarrow {}^4A_{2g}$ transitions, respectively.[17] The

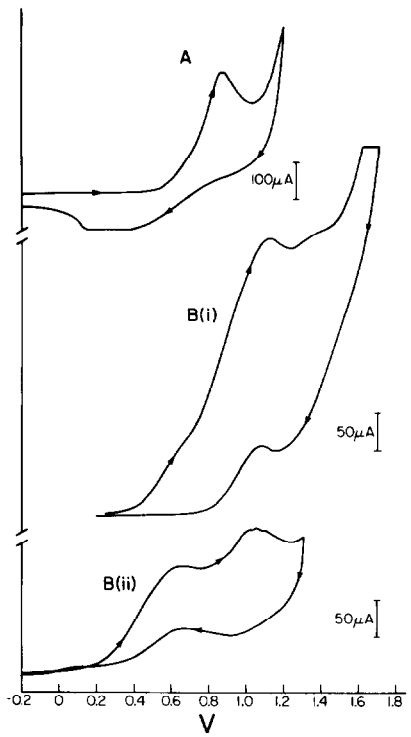

Fig. 4. Cyclic voltammograms obtained during the electro-oxidation of $[MnY]_{aq}$. (A) No peroxide (pH = 7.96); (B) in the presence of excess peroxide: (i) pH = 6.93; (ii) pH = 11.61.

spectra of Mn-ENTMP–H_2O_2 at pH 10 shows the presence of two new bands at 468 and 587 nm and the latter was masked by the intense absorption at 460 nm when the solution pH was raised to 10.7 and higher.

The cyclic voltammograms obtained for Mn(II)-ENTMP in the absence of peroxide and at pH 8.0 displayed a reversible peak with an $E^{\circ\prime}_{MnY}$ of 0.81 V vs NHE (Fig. 4A). The small cathodic current observed relative to the anodic current is presumably due to the adsorbability of the phosphonate complex on the electrode surface.[18] The voltammogram obtained for the Mn-ENTMP–H_2O_2 mixture (pH $\simeq$ 7), shows the presence of an anodic peak at E_{pa} 1.13 V and a small hump at 1.42 V and the reversed scan gave rise to a cathodic peak at E_{pc} of 1.14 V. In strongly alkaline solutions (pH = 11.6), the intensity of the anodic peak at higher potential increased at the expense of the first one. Also, the potentials of all the peaks were negatively shifted by $\sim$0.40 V. The low potential anodic peak is probably associated with the oxidation of the residual Mn(II) to Mn(III). The observed negative shift in the potential with increasing the pH of the medium is attributed to the changes in Mn(II) speciation. At pH 7, the dominant species are MnH_2Y^{4-} and MnH_3Y^{3-}; in strongly alkaline media, the electron-rich MnY^{6-} [and/or $Mn(OH)Y^{7-}$] species are dominant. The pair of peaks observed at higher potential involves a two-electron transfer reaction as indicated by the difference in ($E_{pa} - E_{pc}$). This is tentatively assigned to the oxidation of the $[Mn(III)YX]^{6-}$ complex to $[Mn(IV)YX]^{4-}$, where X is a coordinated OH^- or OOH^- group.

The kinetic data obtained in the pH region 9.0–10.3 were processed using the program KINETIC based on the SIMPLEX algorithm and written by W. Cacheris. The program allows simultaneous calculation of the rate constants associated with two reactants and their conjugate bases. Different models were considered for the reaction of H_2O_2 (and/or HOO^-) with MnY^{5-} and/or $MnY(OH)^{6-}$ complexes. Among all probabilities, only that which consider the reaction of neutral H_2O_2 with both complex species gave the best fit. The absence of ionic strength dependency of the rate constants is in support of this assumption. These results are consistent with the rate law

$$\frac{-d[H_2O_2]}{dt} = k_{obs}[MnY]_{aq}[H_2O_2]_T$$

$$= \frac{K_a[H^+](k_2 + k_1K_1[H^+])}{(1 + K_a[H^+])(1 + K_1[H^+])} [MnY]_{aq}[H_2O_2]_T \quad (5)$$

where $[MnY]_{aq}$ is the manganese concentration in all forms, K_a is the protonation constant of H_2O_2 ($pK_a = 11.75$),[19] k_1 and k_2 are the rate constants observed in the presence of $MnY(OH)^{6-}$ and MnY^{5-} species respectively, and K_1 is the protonation constant for the reaction

$$MnY(OH)^{6-} + H^+ \rightleftharpoons MnY^{5-}. \quad (6)$$

A summary of all the constants calculated together with the activation parameters are listed in Table 2. The error limits of the activation parameters were obtained at 90% confidence following standard procedures.[20] As a further check, the rate constants obtained were used to calculate the values of k_{obs} at different pHs. The solid lines shown in Fig. 2 represent these theoretical calculations; the solid symbols are the experimental values.

In the very early stages of the reaction and at the specified conditions for the kinetic runs ($[H_2O_2] \gg [MnY]_{aq}$; pH $\geqslant$ 9), most of the manganese species will resume oxidation state III. Therefore, the catalytic process is initiated by the reaction of these complexes with the peroxide. The spectral data shown in Fig. 3 are not conclusive about

Table 2. The rate constants and the activation parameters for the catalytic decomposition of hydrogen peroxide in the presence of Mn-ENTMP complex

Temperature (°C)	k_1 ($M^{-1}s^{-1}$)	k_2 ($M^{-1}s^{-1}$)	pK_1
30	33 ± 2.4	2.2 ± 0.03	10.1 ± 0.06
35	36 ± 3.3	3.7 ± 0.18	10.1 ± 0.10
40	42 ± 2.5	6.7 ± 0.31	10.1 ± 0.08
$\Delta H_1^{\ominus} = 17 \pm 4\,kJ\,mol^{-1}$,		$\Delta H_2^{\ominus} = 83 \pm 16\,kJ\,mol^{-1}$	
$\Delta S_1^{\ominus} = -165 \pm 15\,JK^{-1}\,mol^{-1}$,		$\Delta S_2^{\ominus} = 37 \pm 55\,JK^{-1}\,mol^{-1}$	

the involvement of peroxy intermediates in the mechanism. The band position is slightly blue-shifted by ~15 nm compared to that reported in Ref. 13. This shift could be due to the formation of such intermediates or perhaps an anticipated shift due to the presence of the auxiliary pyrophosphate ligand.

The negative entropy associated with the $[Mn(III)Y(OH)]^{6-}$ route suggests that substitution of H_2O_2 for the coordinated OH^- group is the rate-limiting step as in other polyaminocarboxylate systems.[8(a),9] The positive entropy observed for the [Mn(III)Y] pathway, can also be attributed to the solvent reorganization accompanying the intramolecular charge-transfer RDS.[21] However, changes in complex ion hydration can arise from H_2O_2 substitution for one of the coordinated dinegative phosphonate groups. The marked change in the energy barrier for both pathways argues for the involvement of different leaving groups. A possible mechanism consistent with these observations is

$$[Mn(III)Y(OH)]^{6-} + H_2O_2 \xrightarrow{k_1} [Mn(III)Y(OOH)]^{6-} + H_2O \quad (7)$$

$$[Mn(III)Y]^{5-} + H_2O_2 \xrightarrow{k_2} [Mn(III)Y(H_2O_2)]^{5-}. \quad (8)$$

The reaction may propagate via one-electron oxidation steps with the liberation of $OH^{\cdot}$ radicals. Accordingly

$$[Mn(III)Y(OOH)]^{6-} \rightarrow [Mn(IV)Y(O)]^{6-} + OH^{\cdot} \quad (9)$$

$$[Mn(III)Y(H_2O_2)]^{5-} \rightarrow [Mn(IV)Y(OH)]^{5-} + OH^{\cdot} \quad (10)$$

$$H_2O_2 + OH^{\cdot} \rightarrow H_2O + H^+ + O_2^{\cdot -} \quad (11)$$

$$[Mn(IV)Y(O)]^{6-} + H_2O + O_2^{\cdot -} \rightarrow [Mn(III)Y(OH)]^{6-} + O_2 + OH^- \quad (12)$$

$$[Mn(IV)Y(OH)]^{5-} + O_2^{\cdot -} \rightarrow [Mn(III)Y(OH)]^{6-} + O_2. \quad (13)$$

In strongly alkaline media, the oxo-Mn(IV) species undergo further hydrolysis leading to the formation of colloidal MnO_2 which, in turn, reduces the catalytic activity as evidenced by the kinetic observations.

Acknowledgements—The authors wish to thank Mrs S. Clark and Mr G. Peppin for their assistance with the spectral and CV measurements.

FACILE SYNTHESIS OF ANTIMONY DITHIOCARBAMATE COMPLEXES

RYOKI NOMURA,* AKIHISA TAKABE and HARUO MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Oka, Suita, Osaka 565, Japan

(*Received* 7 *May* 1986; *accepted* 7 *July* 1986)

Abstract—Antimony(III) oxide could react readily with dithiocarbamic acids ($R^1R^2NCS_2$-H, where R^1, $R^2 = C_1$–C_8 alkyls, alkylenes and $C_2H_4OC_2H_4$) and gave the corresponding antimony(III) dithiocarbamates in good yields (45–94%) at 15°C. Novel β-hydroxy or β-cyanoethyl dithiocarbamates were prepared via the condensation in 88–98% yields (R^1, $R^2 = CH_2CH_2OH$, $R^1 = Me$, and $R^2 = CH_2CH_2OH$; $R^1 = Bu^n$, and $R^2 = CH_2CH_2CN$). The larger anisobidenticity among the antimony dithiocarbamate complexes was introduced in the Sb-S_2CN moieties by hydrogen bonding from β-hydroxyl groups which was confirmed by IR, and ^1H and ^{13}C NMR spectroscopy. The quinquevalent inorganic Sb_2O_5 and Sb_2S_5, and organometallic $PhSbO_3H_2$ and Ph_3SbO, gave tervalent products. In the reactions with diethylamine and CS_2 the former three compounds afforded the corresponding dithiocarbamates and the last gave triphenylstibine, but Ph_4SbOH gave the quinquevalent $Ph_4SbS_2CNEt_2$.

Only two methods for the preparation of antimony dithiocarbamate complexes, of both Sb(III) or Sb(V), and also of inorganic or organometallic, have been available to date:[1] (i) metathesis reaction between antimony chloride and sodium or ammonium dithiocarbamate salts;[2–5] (ii) insertion of CS_2 into Sb–amide bonds[6–8]

$$Sb_2O_3 + 6R_2NCS_2H \rightarrow 2Sb(S_2CNR_2)_3 + 3H_2O. \quad (1)$$

In this paper we wish to report a facile and more operative procedure for the preparation of the antimony dithiocarbamates. We found that antimony(III) oxide could be condensed with dithiocarbamic acids, formed from dialkylamines and carbon disulphide *in situ*, to give the corresponding antimony(III) dithiocarbamates in good yields even at room temperature.[9] The reaction was not sensitive to moisture, air and temperature, and was a clean process because of the very small contamination by sodium and/or chlorine. We have extended the reaction to β-substituted amines, e.g. bis(hydroxyethyl)amine, and also succeeded in obtaining organoantimony dithiocarbamates such as tetraphenylstibonium dithiocarbamates. We have also investigated the effect of β-substituents on the dithiocarbamate bonding by means of IR, ^1H and ^{13}C NMR.

EXPERIMENTAL

General

Melting points were measured with a Yanaco micro-melting point apparatus and were uncorrected. IR spectra were recorded on a Hitachi 260-30 spectrophotometer using a KBr disk or KRS-5 windows. ^1H and ^{13}C NMR spectra were performed with a Hitachi R90H FT spectrometer (2.1138T). Cryoscopical molecular weights were measured in benzene or DMSO using a Beckmann thermometer (accuracy ±0.001°C) and indicated that the obtained dithiocarbamate complexes were monomeric in the solution. X-Ray fluorescence analysis was executed using a Rigaku 0600 type analyser (30 kV–5 mA, secondary target Ti), and showed no detectable peaks due to chlorine or sodium atoms, although the samples prepared from the metathesis

*Author to whom correspondence should be addressed.

process contained these contaminators even after some recrystallizations with respect to the peak observation.

Materials

Antimony trioxide (Sb_2O_3, Kanto Chemical Co., Inc., Tokyo) was used without purification. Tetraphenylstibonium hydroxide was prepared by basic hydrolysis of tetraphenylstibonium bromide.[10] Phenylstibonic acid ($PhSbO_3H_2$) was synthesized as reported by Doak and Steinman.[11] Triphenylstibine oxide was obtained by hydrogen peroxide oxidation of triphenylstibine.[12] These organoantimony oxides gave satisfactory analyses. Other reagents and solvents were used after purification.

Reactions

Typical procedures are described below. $Sb(S_2CNEt_2)_3$: into a suspension of Sb_2O_3 (5 mmol) in 20 cm^3 of acetonitrile and 30 mmol diethylamine, CS_2 (30 mmol) was added dropwise at 15°C. The precipitates of Sb_2O_3 disappeared with the reaction and then a yellow solution was obtained. After 1 h of stirring, the volatiles were evaporated *in vacuo*. The resulting yellow mass was then dissolved into hot $CHCl_3$ and filtered. Recrystallization was performed by addition of cold methanol to the chloroform solution. Antimony tris(diethyldithiocarbamate), was obtained as yellow needles, m.p. 133–135°C (lit. 136–137°C[7]), 88%.

$Sb(S_2CN(Me)CH_2CH_2OH)_3$: the reaction of Sb_2O_3 (5 mmol), *N*-methylethanolamine (36 mmol) and CS_2 (30 mmol) in 20 cm^3 of methanol gave a dark yellow gum after stirring for 2 h at 15°C. The gum was filtered off and washed with cold methanol in order to remove unreacted ethanolamine. The dithiocarbamate was recrystallized from MeOH–$CHCl_3$, m.p. 156–159°C, in 98% yield. Yields and analytical and spectral data of the synthesized dithiocarbamates are presented in Tables 1 and 2, respectively.

RESULTS AND DISCUSSION

The direct condensation of antimony(III) oxide (Sb_2O_3) and dithiocarbamic acids proceeded smoothly at 15°C and gave the corresponding antimony(III) dithiocarbamates ($Sbdtc_3$) in good yields. The results of the reaction are summarized in Table 1. Dialkylamines, cyclic amines and β-substituted amines could be converted into the $Sbdtc_3$ in 1–4 h. Reactions using Sb_2S_3, Sb_2O_5 and Sb_2S_5 also occurred, but the yields of the dithiocarbamate were somewhat lower compared to Sb_2O_3.

In the case of diethylamine, a solvent effect was investigated. Aprotic solvents such as acetonitrile, benzene and chloroform, irrespective of their own polarity, promoted the reaction, however, protic ones—such as methanol and water—resulted in lower yields of $Sbdtc_3$. The basicity of the starting amines (based on their pK_a values[15]) seems not to affect the reaction at all. Instead, steric hindrance largely decreases the formation of $Sbdtc_3$: for example, di(isopropyl)amine gave $Sb(S_2CNPr^i_2)$ in only 45% yield, while dipropylamine afforded $Sb(S_2CNPr^n_2)_3$ in 77% yield. Based on the above-mentioned results, we believed that the formation of $Sbdtc_3$ proceeded via stepwise condensation of Sb_2O_3 and the dithiocarbamic acids as shown below. A similar process has been reported for the case of arsenic(III) oxide and dithiocarbamic acids by Sugiyama *et al.*[14] The first step in the scheme may be rate-limiting because unreacted antimony oxide and the dithiocarbamic acids were recovered.

The most characteristic merit of this procedure is the fact that amines which have labile substituents against basic or acidic conditions could be converted to corresponding substituted $Sbdtc_3$. Thus, reactions involving the β-hydroxy or β-cyano derivatives, such as diethanolamine, *N*-methylethanolamine and butyl cyanoethylamine, gave the novel substituted dithiocarbamates in good yields with minor modification to the reaction conditions; namely, methanol was rather favourable in these reactions in place of acetonitrile.

On the other hand, some efforts on the reaction of organoantimony oxides and dithiocarbamic acids have been reported.[2,3,7] Most of the authors in the literature have used organic antimony(III) oxides in oxygen–sulphur exchange reactions. We have found that two phenylantimony(V) oxides were reduced to antimony(III) species during the condensation. Thus, phenylstibonic acid ($PhSbO_3H_2$) gave phenylantimony(III) bis(diethyldithiocarbamate) in good yield, while triphenylstibine oxide did not give any dithiocarbamate complexes, but gave the corresponding thiuram disulphide $[(Et_2NCS_2)_2]$ and triphenylstibine quantitatively. On the other hand, tetraphenylstibonium hydroxide could be converted into quinquevalent tetraphenylstibonium dithiocarbamate but in low yield.

IR spectra

It has been reported that ν(C···N) and ν(C···S) modes of the Sbdtc species appeared in the regions of 1450–1550 and 950–1050 cm^{-1}, respectively.[4,7,16–18] These bands reflect both the π character of the C—N bonds and denticity of the CS_2 moiety, respectively.

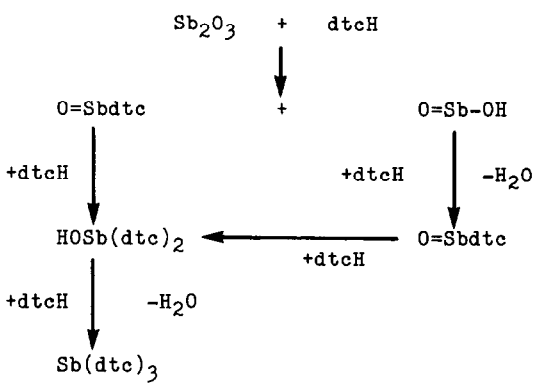

Scheme 1.

The ν(C···N) band of $Sb(S_2CNPr^i_2)_3$ appeared as a doublet at 1475 and 1440 cm^{-1}, and the ν(C···S) band shifted to 1030 cm^{-1} in comparison with those of other $Sbdtc_3$. The splitting and the higher wave number shift indicated larger π bond character in C—N bonds and monodenticity of the CS_2 moiety in $Sb(S_2CNPr^i_2)_3$, compared with other dialkyl derivatives. The larger monodenticity may be attributable to its large steric hindrance.

The existence of β-hydroxy group greatly affected the ν(C···N) and ν(C···S) bands in the two hydroxyethyl derivatives, $Sb[S_2CN(CH_2CH_2OH)_2]_3$ and $Sb[S_2CN(Me)CH_2CH_2OH]_3$. Both ν(C···N) and ν(C···S) bands in the former were split into doublets with low wave number shifts and in the latter 10 cm^{-1} splitting could be observed in the ν(C···S) band. These results indicated the possibility that the anisobidenticity of CS_2 moiety was increased or that monodentate and bidentate CS_2 moieties co-existed. These were caused by intramolecular hydrogen bonding between O—H and C—S bonds.[18]

[a]Conditions: 5–15 wt% solution, pulse interval 1.5 s, pulse width 45°, number of pulses 500–4000, resolution 0.12 Hz.

[b]Signals of ring carbons were assignable by using the reported data of several phenylantimony compounds (Refs 23 and 24).

[c]$\Delta(\nu_{2/1})$: 27.7 Hz.

[d]$\delta(^{13}C{\equiv}N)$.

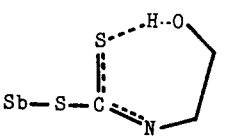
The $\nu(C{\cdots}S)$ band of $Ph_4SbS_2CNEt_2$ appeared in the higher wave-number region (1015 cm^{-1}) from which a larger ionicity of Sb—S_2C bonding was expected. Recently, Stevens and Trooster[19] have reported that the analogous $Me_4SbS_2CNEt_2$ showed an ionic structure by means of Mössbauer spectroscopy.

NMR spectra

Results of ^1H NMR measurements are also presented in Table 2. No remarkable change was observed other than some broadening in the signals of *N*-alkyl protons as reported by Sharma *et al.*[18] In particular, we could not detect the methine proton signal of $Sb(S_2CNPr^i_2)_3$. This may be derived from slow rotation around the C—N bonds. Such a significant line broadening in the isopropyl derivative was also observed in ^{13}C NMR signals. The $\Delta(\nu_{1/2})$ of methine carbon was 27.7 Hz.

^{13}C NMR investigation of the obtained Sbdtc was also carried out and the results are shown in Table 3. $\delta(N^{13}CS_2)$ of $Sb(S_2CNEt_2)_3$ in $CDCl_3$ appeared at 199.2 ppm which was between the reported chemical shifts, 198.7[17] and 199.5.[20] Dipolar solvent, Me_2SO-d_6 shifted $\delta(N^{13}CS_2)$ of $Sb(S_2CNEt_2)_3$ to higher field by about 2.3 ppm. The up-field shift of $\delta(N^{13}CS_2)$ in $PhSb(S_2CNEt_2)_2$ could be explained by its higher fraction of oxidation number (oxidation number/coordination number)[17] and supported the penta-coordinated structure reported by Meinema and Noltes.[7] Apparently, in the ionic $Ph_4SbS_2CNEt_2$ $\delta(N^{13}CS_2)$ shifted to lower field by about 1.5 ppm compared with $Sb(S_2CNEt_2)_3$.

In the β-hydroxy substituted dithiocarbamates, single and higher $\delta(N^{13}CS_2)$ shifts were detected, although the anisobidenticity was enhanced as suggested by the IR spectra. In general, an increase of the anisobidenticity has been considered to decrease the δ values. In this case, such lower field shifts were mainly attributable to an increase of total π character in whole NCS_2 moieties. As shown in **2**, the hydrogen bonding pulls the *p*-electrons in N atoms introducing an increase in total π character. Thus, it is reasonable that the increasing of double bond character in C—N bonds compensated for the decrease in C—S bonds.



2

Scheme 2.

The most awkward feature was faced on the higher $\delta(N^{13}CS_2)$ in β-cyanoethyl derivative because there was no notable change in vibrational mode. We tentatively deduced that the large lower field shift of ~3.3 ppm was brought about by the coordination of the end cyano group which cancelled the formal positive charge at a central antimony atom, and then decreased the fraction of oxidation number.

Thus, an introduction of polar substituents in

the end of *N*-alkyl group was found to cause a significant alternation on the bonding between the central antimony atoms and the ligands. It was found that the $\delta(N^{13}CS_2)$ of β-substituted antimony dithiocarbamates appeared in the most low field among these simple alkyl dithiocarbamates (193–200 ppm).[17]

(*Received* 12 *May* 1986; *accepted* 7 *July* 1986)

Abstract—Log K, ΔH and ΔS values for the 1:1 reactions at 25°C in methanol solution of Na^+, K^+ and Cs^+ with 2-methoxy-1,3-xylyl-15-crown-4 (**I**), 2-methoxy-1,3-xylyl-18-crown-5 (**II**), 2-hydroxy-1,3-xylyl-15-crown-4 (**III**), and 2-hydroxy-1,3-xylyl-18-crown-5 (**IV**) were determined by a calorimetric titration procedure. Log K values for the systems with Na^+ and K^+ were also determined by potentiometry with ion-selective electrodes. For a given cation the stability constants for the complexes with the 18-membered cycles **II** and **IV** are higher than those for the complexes with the 15-membered cycles **I** and **III**. For the ligand having the same ring size the methoxy-crown complex is always more stable than the hydroxy-crown one. The macrocyclic effect shown by the two 18-membered cycles is the result of favourable entropic factors.

A wide variety of thermodynamic parameters are now available for the complexation of cations with crown ethers.[1] The process of the ion–polyether association depends on several factors related to the characteristic properties of ligand, reacting ion and solvent.

Various modifications have been made to the basic crown ether structure in an attempt to influence the ion-binding characteristics of the ligands. Among these modifications a number of macrocyclic polyethers containing convergent methoxyaryl or phenolic groups have been reported.[2–5]

The complexing properties of macrocyclic systems bearing convergent methoxyaryl groups have been investigated by determining the free energies of their association with alkali metal and ammonium and alkylammonium picrates in chloroform.[2,4]

The host–guest complexation of a series of crown ethers bearing an intra-annular phenolic group with alkali metal cations, ammonia and primary amines has been well characterized mainly on the basis of structural studies.[5]

Recently we have examined how the ability of a crown ether to bond lanthanide ions is influenced by a convergent methoxyaryl group.[6,7]

Since no thermodynamic parameters for the reactions of these crown ether derivatives with metal ions are available in the literature, we planned to perform a calorimetric study of the interactions of two crown ether methoxyaryls (**I** and **II**) and two crown ether phenols (**III** and **IV**) with Na^+, K^+ and Cs^+ cations in anhydrous methanol solution.

From the experimental data, log K, ΔH and $T\Delta S$ values for the reactions examined were calculated. Log K values for the complexes with Na^+ and K^+ were also determined by potentiometry with ion-selective electrodes.

EXPERIMENTAL

Materials

The macrocyclic ligands I–IV were synthesized by condensation of 2,6-bis(bromomethyl)anisole with the appropriate polyethylene glycol, following the procedures described by McKervey *et al.*[3,5] The NaCl, KCl and CsCl salts (Baker) were dried at 120°C for 24 h and stored in a desiccator over P_2O_5. The absolute methanol (Baker Analyzed Reagent) was found by Karl Fischer titration to contain less than 0.01% H_2O. The concentration of NaCl, KCl and CsCl solutions were determined gravimetrically. The macrocycle solutions were prepared by dissolving known weights of each compound in methanol and by dilution. All solutions and reagents were handled and stored in a glove box filled with an inert recirculating atmosphere.

Calorimetric measurements

The calorimetric measurements were made at 25°C using a LKB 8721-2 Precision Calorimeter. The heats of reaction were determined by titrating the metal ion solution in the reaction vessel with successive additions of the ligand solution from a piston burette. Heat of dilution was measured by adding the solution of the cyclic polyether to the pure solvent.

Log K and ΔH values were calculated from calorimetric data using the least-squares program LETAGROP KALLE.[8]

Potentiometric measurements

The concentration of the uncomplexed metal cation was measured with ion-selective electrodes. A Philips G15 Na electrode was used for Na^+ and a Philips G15 K electrode for K^+. The electrodes were stepwise conditioned in aqueous solutions of increasing methanol content up to pure methanol. A calomel reference electrode was used. The electrode was connected to the measuring solution via a bridge containing 0.01 M $N(C_2H_5)_4Br$ in methanol.

A closed glass cell equipped with inlets for the electrodes and the titrant and a magnetic stirrer was used for the measurements. The temperature of the system was maintained at 25.0 ± 0.1°C with a bath of circulating water. The e.m.f. was measured with a Radiometer PHM64 pH meter. The cation selective glass electrodes were calibrated by using standard solutions of the corresponding alkali metal ion in the concentration range 10^{-5}–30×10^{-3} M.

Three runs of measurements were carried out for each cation/polyether system. Each run was started by measuring the e.m.f. of the salt solution (concentration range 10^{-3}–20×10^{-3} M). The polyether solution was added from a piston burette and the new e.m.f. value was measured after each increment.

The stability constant of the 1:1 complex, K, was computed from the relationship

$$K = \frac{C_M - [M^+]}{(C_L - C_M + [M^+]) \cdot [M^+]}$$

where $[M^+]$ is the measured equilibrium concentration of the free metal ion, and C_L and C_M are the total polyether and metal ion concentrations, respectively. Refined values of K were obtained using the least-squares program MINIQUAD.[9]

In the treatment of both potentiometric and calorimetric data we assumed that the alkali metal chlorides are completely dissociated in methanol. This assumption was proved to be justifiable by other authors[10,11] and has been applied in a number of investigations on the interaction of alkali metal cations with macrocycles in methanol.[1]

RESULTS AND DISCUSSION

Log K, ΔH and $T\Delta S$ values for the reactions of Na^+, K^+ and Cs^+ with the macrocyclic ligands studied in methanol are given in Table 1. Also included in this table, for comparison, are the corresponding values for the reactions with two simple crown ethers and their linear counterparts.

For all the systems investigated the heat generated was sufficient to allow log K, ΔH and $T\Delta S$ to be calculated, except for the Na^+/hydroxy-15-crown-4 system. In this case only a rough value of log K calculated from potentiometric data is reported. For the other systems the reliability of the log K values computed from calorimetric data is indicated by the excellent agreement with the corresponding values obtained from independent potentiometric measurements.

In all cases where the heat generated was sufficient, the log K and ΔH values computed on the assumption of 1:1 complexing were found to describe adequately the reaction occurring in the calorimeter. Reactions of stoichiometry 1:1 were also indicated by the potentiometric data treatment. Only for the reactions of methoxy-18-crown-5 with

K^+ and Cs^+ were the experimental data consistent with a small amount of 1:2 (metal:ligand) complexing.

The data in Table 1 show that all the complexes formed are enthalpy stabilized, whereas the entropy change opposes their formation. The stability sequence for the three alkali metal ions with all the four ligands is $K^+ > Cs^+ > Na^+$, except for the relative positions of K^+ and Cs^+ with the ligand hydroxy-15-crown-4.

For each of the three cations the stability constants for the complexes with the 18-membered cycles **II** and **IV** are at least one order of magnitude higher than those for the complexes with the 15-membered cycles **I** and **III**. This difference in stability is mainly due to the enthalpic contribution, which is more favourable with the larger macrocycles, as would be expected if the magnitude of ΔH is related to the number of oxygen donor atoms in the ring.[12,13]

Comparison of $\log K$ values for the complexes with methoxy and hydroxy derivatives having the same ring size shows that for each cation the methoxy-crown complex is always more stable than the hydroxy-crown one. Taking into account steric hindrance factors, a reversed trend should be expected. A similar behaviour was found by Cram *et al.*[2] in their investigations on the ion binding properties of binaphthyl-crown ethers bearing two methoxyaryl or, alternatively, two phenolic groups with alkali metal picrates in chloroform. The reason for the observed difference was attributed to the existence of strong intramolecular hydrogen bonds of the phenolic groups with the crown ether *O*-atoms in the uncomplexed macrocyclic polyethers. Complex formation requires the cleavage of these hydrogen bonds.

The well-established intramolecular O—H···O hydrogen bonding in the pure hydroxy-18-crown-5 (**IV**)[5] further supports this hypothesis for the system examined here.

It is also of interest to compare the complexing behaviour of the methoxy and hydroxy derivatives with that of the simple crown ethers which have a corresponding ring framework and the same number of oxygen donor atoms, i.e. 18-crown-6 and 15-crown-5. As can be seen in Table 1, both the simple crown ethers form more stable adducts than the corresponding methoxy- and hydroxy-crown with all the three cations. A similar behaviour was noted in the case of methoxy-18-crown-5 compared with the dicyclohexyl-18-crown-6 in chloroform.[4] The poorer complexing ability of the methoxy and hydroxy derivatives can be accounted for by structural factors. Indeed, a functional group attached to the 2-position of the 1,3-xylyl subunit can easily adopt an intra-annular orientation toward the centre of the cavity defined by the macro-ring. This conformation has to change upon complexation in order to allow a more favourable interaction between the cation and the ligand donor atoms. The energy required for this change is expected to have a destabilizing effect on the resulting metal complex.[13]

A consideration of the thermodynamic values reported in Table 1 shows that the lower stability of the methoxy- and hydroxy-crown complexes compared with that of the corresponding simple crown complexes is the result of less favourable enthalpic factors, which seems in accord with the notion that unfavourable conformational energetics are primarily responsible for the observed difference.

An additional minor contribution to this difference in stability could be ascribed to the fact that the methoxy- or hydroxy-oxygen is probably a poorer ligand for cations than purely aliphatic oxygens because of the electron-withdrawing effect of the attached aryl group.

Is this lowering of stability so great to remove the macrocyclic effect? Useful information to answer this question can be obtained by comparing $\log K$, ΔH and $T\Delta S$ values for the systems here examined with the corresponding values for the complexes of their open-chain counterparts. Among a number of available data referring to reaction of alkali metal ions with open-chain polyethers,[16] we have chosen and reported in Table 1 a complete set of stability constants and thermodynamic values for the complexes of Na^+, K^+ and Cs^+ with tetraethylene glycol dimethyl ether (TeG) and pentaethylene glycol dimethyl ether (PG), in methanol at 25°C, recently reported.[16e] To our knowledge no study has been carried out on the complexing properties of open-chain polyethers based on the 1,3-xylyl subunit, and so TeG and PG appear to be the best counterparts available for a comparison with the methoxy- and hydroxy-crowns having five and six oxygens, respectively.

The data listed in Table 1 show that all the complexes formed by a given alkali metal ion with pentaoxa-ligands **I**, **III** and TeG have stability constants of the same order of magnitude. It is difficult to admit any significant macrocyclic effect for the two 15-membered crown derivatives. Instead, a comparison of exaoxa-cycles **II** and **IV** with PG clearly indicates a greater stability for the crown derivatives complexes (maximum $\Delta \log K = 1.5$), which can be attributed to the macrocyclic effect. This is particularly true for the methoxy-18-crown-5 ligand where no interference of transannular hydrogen bonding is present. A consider-

ation of thermodynamic values shows that this macrocyclic effect is caused entirely by favourable entropic factors.

From a comparison of the data for the reaction of Na^+ and K^+ with 18-crown-6, PG and PeG (pentaaethylene glycol), Izatt *et al.* concluded that the macrocyclic effect is primarily the result of favourable enthalpic factors, not entropic factors.[16(d)] At least two effects, depending on structural peculiarities of **II** and **IV**, can be invoked to account for these different conclusions concerning the thermodynamic origin of the macrocyclic effect. (i) Owing to unfavourable conformation of methoxy- and hydroxy-crown a greater energy is required to place the donor atoms in their proper bonding locations, lowering in this way the stabilizing enthalpy change, as mentioned above. (ii) The more rigid structure imposed by the 1,3-xylyl subunit decreases the unfavourable internal entropy change upon complexation.

NEW γ,γ′-DISUBSTITUTED DERIVATIVES OF MACROCYCLIC JÄGER-TYPE Ni(II) COMPLEXES

JULITA EILMES

Institute of Chemistry, Jagiellonian University, Karasia 3, 30-060 Cracow, Poland

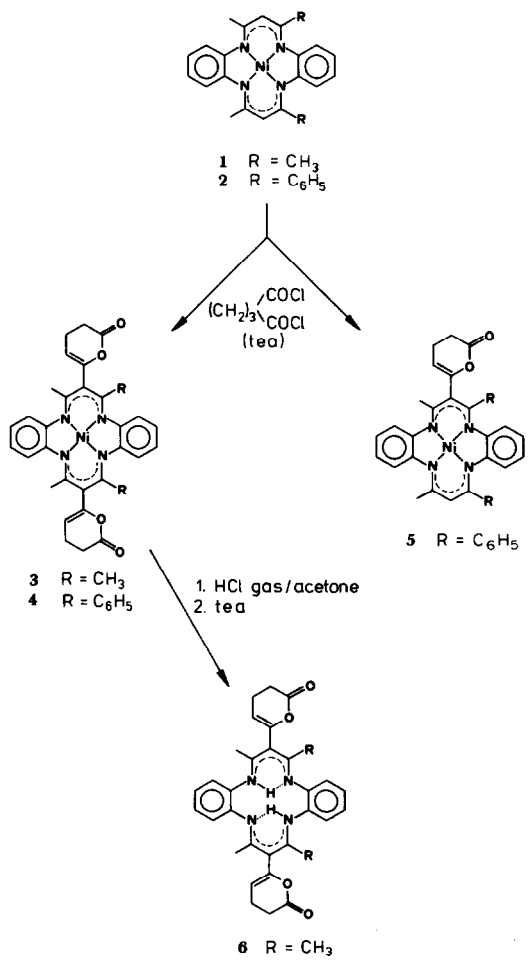
(*Received* 28 *May* 1986; *accepted* 7 *July* 1986)

Abstract—The reaction of [Bzo_2Me_4[14]hexaenato(2−)N_4]Ni(II) and [$Bzo_2Me_2Ph_2$ [14]hexaenato(2−)N_4]Ni(II) with glutaryl chloride leads to new γ,γ′-disubstituted derivatives having γ,δ-unsaturated-δ-lactonic rings as substituents. The demetalation of the new complexes by means of gaseous HCl is described. The new compounds were characterized by elemental analysis, IR, ^{1}H NMR and MS data.

The γ-position of six-membered diiminato chelate rings has been found to be a reactive nucleophilic centre. In an earlier report the reactivity of Jäger-type macrocyclic Ni(II) complexes towards benzoyl chloride was described.[1] Since there is continuing interest in the preparation of peripherally substituted macrocyclic complexes, it seemed interesting to use the dichlorides of dicarboxylic aliphatic acids as acylating agents.

It is believed that the reaction with such difunctional electrophilic reagents will give rise to a variety of derivatives. First of all, γ,γ′-disubstituted complexes are expected to be formed. It is also possible that, depending on the length of the aliphatic chains, more complicated compounds can be produced. Bi- and polynuclear systems linked by the difunctional acyl groups, and lacunar-type complexes seem to be also accessible in this way.

This paper summarizes the results of the reaction of Jäger-type Ni(II) complexes with glutaryl chloride.



RESULTS

The reaction of the complex **1** and glutaryl chloride in the 1:2 molar ratio in the presence of triethylamine was performed in refluxing benzene. In this manner γ,γ′-disubstituted compound **3**, with two γ,δ-unsaturated-δ-lactonic rings as substituents, was obtained in good yield.

The sterically more crowded complex **2** had to be acylated with an excess of the acylating agent, otherwise about equal quantities of unreacted complex **2**, monosubstituted product **5** and disubstituted complex **4** were isolated from the reaction mixture.

Demetalation of these disubstituted complexes

was conducted in the manner similar to that earlier described.[1] This procedure, however, appeared to be inefficient for complex **4** which underwent a partial decomposition with the loss of substituents.

DISCUSSION

The formation of γ,δ-unsaturated-δ-lactonic rings connected with the macro cyclic ring at δ-carbon atoms, can be explained in terms of intramolecular *O*-acylation within the glutaryl groups. Examples of this type of lactonization and discussions of the mechanism are described in the literature.[2-4] The reaction is considered to involve enolization of the ketomethylene group or alternatively formation of a saturated chlorolactonic intermediate. Further elimination of hydrogen chloride gives rise to the final unsaturated product.

Evidence for the proposed structure of the products **3–6** is given by spectral ^{1}H FT NMR and IR data. ^{1}H NMR spectra show a signal corresponding to the protons of vinyl groups in the region typical for unsaturated δ-lactones.[5] This signal appears as a triplet at δ 5.35, 5.0, 5.0, 5.5 ppm ($J \sim 4$ Hz), for the compounds **3–6**, respectively. Protons of the —CH_2—CH_2— groups which are an A_2B_2 part of the A_2B_2X pattern give rise to a complicated multiplet in the region of aliphatic protons. When the vinyl signals are decoupled, this multiplet collapses to an A_2B_2 multiplet. Conversely, irradiation with the frequency of the adjacent methylene protons causes the vinyl signal to appear as a sharp singlet. The other lines in the ^{1}H NMR spectra are fully consistent with the structure of the macrocyclic framework.

The IR spectra show an intense absorption of a carbonyl group in the region which is characteristic for γ,δ-unsaturated-δ-lactons[5,6] at 1750 cm^{-1}. A band of middle intensity at 1680 cm^{-1} corresponds to the C=C stretching vibration and is typical for an endocyclic double bond of γ,δ-unsaturated-δ-lactons.[4,6]

The presence of signals of parent molecular ions in the mass spectra is supporting evidence for the proposed structure of the products.

EXPERIMENTAL

Melting points are uncorrected. IR spectra were recorded in Nujol and hexachlorobutadiene on a Zeiss UR-10 spectrometer. ^{1}H NMR spectra were taken on a Tesla BS 567A, 100 MHz instrument in $CDCl_3$ using TMS as internal standard. Mass spectra were taken on an LKB 900 instrument.

Parent complexes **1** and **2** were prepared by a procedure described earlier.[7,8]

Reaction of [Bzo_2Me_4[14]hexaenato(2−)N_4] Ni(II) (**1**) *with glutaryl chloride*

3.75 g (0.02 mol) of glutaryl chloride, diluted with 5 cm^3 of benzene was added dropwise to a slurry of complex **1** (4 g, 0.01 mol) and triethylamine (5 cm^3) in dry benzene (80 cm^3). The reaction mixture, protected from moisture, was heated under gentle reflux for 2 h with stirring and then left overnight at room temperature. A grey-green precipitate was filtered off, dried and washed carefully with hot water to separate the product from triethylamine hydrochloride. The crude, green product was dried and recrystallized from dimethylformamide–water. Yield 5.5 g (93%). M.p. 320°C.

Found (**3**): C, 64.7; H, 5.0; N, 9.3; Ni, 10.0%. Calc. for $C_{32}H_{30}N_4O_4Ni$: C, 64.8; H, 5.1; N, 9.4; Ni, 9.9%. MS: 592 (P^{+58}Ni). IR (cm^{-1}): 1680(s) (νC=C), 1750(s) (νC=O). ^{1}H NMR (δ (ppm)]: 2.2 (s, 12H) —CH_3, 2.5 (m, 8H)—CH_2—CH_2—, 5.35 (b.t, 2H) =CH—, 6.7 (b.s, 8H)—*o*-C_6H_4.

Reaction of [$Bzo_2Me_2Ph_2$[14]hexaenato(2−)N_4] Ni(II) (**2**) *with glutaryl chloride*

The reaction of the complex **2** (5.24 g, 0.01 mol) with glutaryl chloride (6.8 g, 0.04 mol) and triethylamine (13 cm^3) in dry benzene (150 cm^3) was carried out for 3.5 h in the same way as described above. After standing for 24 h a colourless precipitate of triethylamine hydrochloride was filtered off and benzene was removed from the filtrate on a rotatory evaporator. Green, resinous product was dissolved in acetone and diluted with cold water. A green solid product which appeared in the solution was filtered off. The crude complex **4** was purified by dissolving in a small amount of dimethylformamide and re-precipitating with cold water. Yield 6.6 g (92%). M.p. 280°C.

A 1:2 molar ratio of reagents produces a mixture of approximately equal quantities of the parent complex **2**, monosubstituted product **5** and disubstituted complex **4** (TLC). The separation of these complexes was performed chromatographically on silica gel (0.05–0.2 mm, Merck) using benzene, chloroform–benzene (1:1), and chloroform as eluents.

Found (**4**): C, 69.9; H, 4.7; N, 7.7; Ni, 8.3%. Calc. for $C_{42}H_{34}N_4O_4Ni$: C, 70.3; H, 4.8; N, 7.8; Ni, 8.2%. MS: 716 (P^{+58}Ni). IR (cm^{-1}): 1680 (m) (νC=C), 1760 (s) (νC=O). ^{1}H NMR [δ (ppm)]: 2.0 (m, 8H)—H_2—CH_2—, 2.3 (s, 6H)—CH_3, 5.0 (b.t, 2H)=CH—, 5.7 (m, 4H) AA′BB′—*o*-C_6H_4, 6.8 (m, 4H)—*o*-C_6H_4, 7.3 (m, 10H)—C_6H_5.

Found (**5**): C, 71.8; H, 4.5; N, 9.1; Ni, 9.8%. Calc. for $C_{37}H_{30}N_4O_2Ni$: C, 71.5; H, 4.9; N, 9.0; Ni, 9.4%.

MS: 620 (P^{+58}Ni). IR (cm^{-1}): 1680(m) (νC=C), 1750(s) (νC=O). ^1H NMR [δ(ppm)]: 2.0 (m, 4H)[—CH_2—CH_2—, 2.2 (s, 3H)—CH_3, 2.3 (s, 3H)—H_3, 4.9 (s, 1H)=CH—, 5.0 (b.t, 1H)=CH—(lact.), 5.7 (m, 4H) AA'BB'—o-C_6H_4, 6.7 (m, 4H)—o-C_6H_4, 7.4 (m, 10H)—C_6H_5.

Demetalation of the complex **3**

A stream of anhydrous hydrogen chloride was passed through a magnetically stirred suspension of complex **3** (3 g) in 150 cm^3 of acetone. The colour of the reaction mixture changed slowly from dark green to orange-yellow and a yellow precipitate began to appear. After about 15 min, the passage of hydrogen chloride was stopped and the tightly closed reaction flask was left overnight under magnetic stirring. Crystalline solid material which accumulated was filtered off, washed with acetone and dried. It was then treated with dilute (1:10) hydrochloric acid to dissolve the nickel chloride. Orange, undissolved solid was filtered off, washed carefully with dilute hydrochloric acid and then immediately with acetone, while still wet. The deprotonation of this hydrochloride of the disubstituted ligand was achieved with the use of triethylamine by the previously described procedure.[1] Recrystallization of the crude product from dimethylformamide–water afforded the ligand **6** as yellow crystals. Yield 1.6 g (59%). M.p. 280°C.

Found (**6**): C, 71.2; H, 5.9; N, 10.2%. Calc. for $C_{32}H_{32}N_4O_4$: C, 71.6; H, 6.0; N, 10.4%. MS: 536 (P^+), IR (cm^{-1}): 1680 (m) (νC=C), 1750 (s) (νC=O), 2700–2900 (v.w) (νN—H), ^1H NMR: 2.2 (s, 12H)—CH_3, 2.6 (m, 8H)—CH_2—CH_2—, 5.5 (t, 2H, J = 4 Hz)=CH—, 7.1 (s, 8H)—o-C_6H_4, 14.5 (broad, 2H) N—H (in py-D_5).

SYNTHESIS AND CHARACTERIZATION OF COPPER(II) BIS(DIZIRCONIUM-*ENNEA*-ALKOXIDES)

R. K. DUBEY, A. SINGH and R. C. MEHROTRA*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 18 *February* 1986; *accepted* 17 *July* 1986)

Abstract—Copper(II) bis(dizirconium-*ennea*-isopropoxide), $[Cu\{Zr_2(OPr^i)_9\}_2]$, has been synthesized by the interaction of $CuCl_2$ with $K\{Zr_2(OPr^i)_9\}$ in a 1:2 molar ratio. The compound undergoes exchange reactions with alcohols of varying steric bulk to yield products of the composition, $[Cu\{Zr_2(OR)_9\}_2]$ (where R = Me, Et, Pr^n, Bu^n, Bu^i and Bu^s); $[Cu\{Zr_2(OPr^i)_6(OEt)_3\}_2]$; $[Cu\{Zr_2(OPr^i)_6(OBu^s)_3\}_2]$; $[Cu\{Zr_2OPr^i)_3(OBu^s)_6\}_2]$; $[Cu\{Zr_2(OPr^i)_7(OBu^t)_2\}_2]$; $[Cu\{Zr_2(OPr^i)_3(OBu^t)_6\}_2]$; and $[Cu\{Zr_2(OPr^i)_4(OAm^t)_5\}_2]$. These derivatives have been characterized by IR, electronic and ESR studies as well as by magnetic susceptibility and molecular weight determinations.

For many years, the alkoxide chemistry of transition metals has centred mainly on the earlier members of the series.[1] During the past few years we have made a detailed study of simple as well as some bimetallic alkoxides of later transition metals.[2–6] The synthesis and alcoholysis reactions of simple copper alkoxides,[1–3] $\{Cu(OR)_2\}_n$ as well as of bis-tetraisopropoxyaluminates $[Cu\{Al(OPr^i)_4\}_2]$ have been described over the past few years by our laboratory.[4]

In view of an unprecedented interest in the bimetallic alkoxides as a source of ceramic and other materials,[7] we report in this paper the synthesis, reactivity and structural characteristics (with the help of IR, electronic, ESR and magnetic studies) of some novel copper bis(dizirconium-*ennea*-alkoxides), $[Cu\{Zr_2(OR)_9\}_2]$.

EXPERIMENTAL

Glass apparatus with standard joints were used throughout the experimental work and stringent precautions were taken to exclude moisture.

Anhydrous $CuCl_2$ was prepared by heating the hydrated $CuCl_2 \cdot 2H_2O$ (B.D.H.) in a current of dry HCl gas. (Found: Cu, 47.3; Cl, 52.7%. Calc. for $CuCl_2$: Cu, 47.2; Cl, 52.8%.) $K\{Zr_2(OPr^i)_9\}$ was synthesized[8] by the (1:2 molar) reaction of $KOPr^i$ with $Zr(OPr^i)_4 \cdot Pr^iOH$ in Pr^iOH. Found: Zr, 24.6; OPr^i, 70.4%. Calc. for $K\{Zr_2(OPr^i)_9\}$: Zr, 24.2; OPr^i, 70.6%.)

Copper in bimetallic alkoxides was estimated iodometrically[9] and zirconium was estimated as oxide after precipitation as mandelate. Alcohols were determined by an oxidimetric method[10] after using a correction for copper(II) content of the sample.

The magnetic susceptibility measurements were made on a Gouy balance using $Hg[Co(CNS)_4]$ as standard. The magnetic moments, μ_{eff}, were calculated by the expression: $\mu_{eff} = 2.84\sqrt{\chi_M^{corr} \cdot T}$ (where χ_M^{corr} is the observed molar susceptibility after correction for the diamagnetism of the constituent atoms).

Preparation of $[Cu\{Zr_2(OPr^i)_9\}_2]$

To a suspension of $CuCl_2$ (0.34 g, 2.52 mmol) in Pr^iOH (*ca* 5 cm^3) was added a benzene solution (*ca* 35 cm^3) of $K\{Zr_2(OPr^i)_9\}$ (3.7 g, 5.03 mmol) and the reaction mixture was refluxed for *ca* 5 h, during which the colour of the reaction mixture changed from light green to bluish green. The precipitated KCl was filtered, and the filtrate concentrated (*ca* 15 cm^3) and left at room temperature for a few hours to afford a bluish green crystalline product (3.10 g, 83.8%). The product was further recrystallized unchanged from *n*-hexane. Analysis and physical characteristics of $[Cu\{Zr_2(OPr^i)_9\}_2]$ are given in Table 1.

Alcoholysis reactions of $[Cu\{Zr_2(OPr^i)_9\}_2]$

(*a*) *With* MeOH *in different molar ratios*

(i) *With excess of* MeOH. A slight heat was evolved on addition of an excess of methanol (*ca* 40 cm^3) to a benzene solution (*ca* 30 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (2.00 g). The reaction mixture was stirred for *ca* 6 h, during which its colour changed from bluish green to turquoise and an insoluble product separated out. The solid with the composition $[Cu\{Zr_2(OMe)_9\}_2]$ was isolated (1.24 g, 94%) by decantation and dried under reduced pressure.

(ii) *With* MeOH *in* 1:6 *molar ratio.* The above reaction was repeated in 1:6 molar ratio $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.43 g, 0.95 mmol) with MeOH (0.19 g, 5.93 mmol) in benzene (*ca* 15 cm^3). Although the colour of the solution became lighter, it remained clear even after 6 h of stirring, after which the volatile components were removed under reduced pressure yielding a green solid (1.24 g, 98%), which was purified by volatilization at 180°C/0.2 mm to afford a green coloured solid of composition $[Cu\{Zr_2(OPr^i)_6(OMe)_3\}_2]$.

(iii) *With* MeOH *in* 1:12 *molar ratio.* From the reaction of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.25 g, 0.83 mmol) with MeOH (0.33 g, 10.30 mmol) in benzene, under conditions similar to those in the previous experiment, a green coloured solid product (0.94 g, 98%) of formula $[Cu\{Zr_2(OPr^i)_3(OMe)_6\}_2]$ could be isolated.

(iv) *With* MeOH *in* 1:14 *molar ratio.* Interaction of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.82 g, 1.21 mmol) with methanol (0.55 g, 17.18 mmol) in benzene resulted in the appearance of turbidity after *ca* 4 h. The reaction mixture was allowed to stand at room temperature overnight. After filtration of the insoluble material and drying it under reduced pressure a turquoise

coloured solid compound (1.32 g, 100%) of composition $[Cu\{Zr_2(OPr^i)_2(OMe)_7\}_2]$ was isolated.

(*b*) *With excess of* EtOH (*at room temperature*). To a benzene solution (*ca* 10 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.00 g) was added an excess of ethanol (*ca* 25 cm^3) and the mixture was stirred for *ca* 6 h at room temperature. The solvent was removed from the clear solution under reduced pressure, affording a green solid (0.93, 98%) product which corresponded in analysis to $[Cu\{Zr_2(OPr^i)_6(OEt)_3\}_2]$.

(*c*) *With excess of* EtOH (*under refluxing conditions*). $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.27 g) was dissolved in benzene (*ca* 20 cm^3) and treated with an excess of EtOH (*ca* 35 cm^3) and the mixture was refluxed for *ca* 6 h during which the colour changed from bluish green to turquoise. After stripping off the solvent, a turquoise coloured solid (0.89 g, 85%) product of composition $[Cu\{Zr_2(OEt)_9\}_2]$ was isolated. In a similar manner derivatives of *n*-propanol, *n*-butanol and *i*-butanol were prepared.

(*d*) *With excess of* Bu^sOH *at room temperature.* To a benzene solution (*ca* 20 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.32 g) was added an excess of *s*-butanol (*ca* 20 cm^3). The reaction mixture was stirred for *ca* 6 h, after which the solvent was stripped off under reduced pressure to afford a green solid, (1.37 g, 98%) which corresponded in analysis to $[Cu\{Zr_2(OPr^i)_6(OBu^s)_3\}_2]$.

(*e*) *With excess of* Bu^sOH *in refluxing benzene* (*without azeotropic fractionation of* Pr^iOH). To a benzene (*ca* 15 cm^3) solution of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.20 g) was added *s*-butanol (*ca* 20 cm^3). The reaction mixture was refluxed for *ca* 5 h, after which the solvent was removed under reduced pressure, yielding a green solid product (1.24 g, 93%) with composition $[Cu\{Zr_2(OPr^i)_3(OBu^s)_6\}_2]$.

(*f*) *With excess of* Bu^tOH *in refluxing benzene* (*without azeotropic fractionation of* Pr^iOH). Bu^tOH (*ca* 25 cm^3) was added to the benzene solution (*ca* 10 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.24 g). After refluxing the mixture for *ca* 4 h, the solvent was removed under reduced pressure and finally a green coloured solid (1.26 g, 98%) product of composition $[Cu\{Zr_2(OPr^i)_7(OBu^t)_2\}_2]$ was obtained.

(*g*) *Alcoholysis reaction with excess of* Bu^sOH (*with continuous azeotropic removal of* Pr^iOH). To a benzene solution (*ca* 15 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (2.10 g) was added *s*-butanol (*ca* 35 cm^3). The reaction mixture was refluxed for *ca* 7 h, during which the liberated isopropanol was continuously fractionated out azeotropically. After complete removal of the isopropanol, the solvent was removed under reduced pressure to yield a green coloured solid compound (2.28 g, 93%) of the composition corresponding to $[Cu\{Zr_2(OBu^s)_9\}_2]$.

(*h*) *With excess of* Bu^tOH *and* Am^tOH (*with continuous azeotropic fractionation of* Pr^iOH). To a benzene solution (*ca* 15 cm^3) of $[Cu\{Zr_2(OPr^i)_9\}_2]$ (1.94 g) was added *t*-butanol (*ca* 40 cm^3). The reaction mixture was refluxed for *ca* 25 h with continuous azeotropic removal of the liberated isopropanol, which was collected and estimated. The reaction was stopped when isopropanol could no longer be detected in the azeotrope; the solvent was removed from the final reaction mixture under reduced pressure to yield a green solid product (2.10 g, 97%) of composition $[Cu\{Zr_2(OPr^i)_3(OBu^t)_6\}_2]$.

The reaction with excess of *t*-amyl alcohol was carried out in a similar manner.

Analyses as well as physical characteristics for all the products isolated from the above reactions are compiled in Table 1.

RESULTS AND DISCUSSION

The reaction of copper(II) chloride (anhydrous) with $K\{Zr_2(PPr^i)_9\}$ in 1:2 molar ratio in benzene containing a few drops of isopropanol (which probably facilitates the dissolution of $CuCl_2$ in the solvent) affords quantitatively the bimetallic isopropoxide of copper(II), $[Cu\{Zr_2(OPr^i)_9\}_2]$:

$$CuCl_2 + 2K\{Zr_2(OPr^i)_9\} \xrightarrow[\text{reflux}]{\text{PhH}} [Cu\{Zr_2(OPr^i)_9\}_2] + 2KCl\downarrow.$$

The bluish green solid product can be purified unchanged by volatilisation (230°C/0.2 mm) or recrystallization (from Pr^iOH/C_6H_6 or *n*-hexane); it shows monomeric behaviour in freezing benzene.

The alcoholysis reactions of the isopropoxide derivative $[Cu\{Zr_2(OPr^i)_9\}_2]$ with different alcohols have shown interesting results in the following order of reactivity:

$$\underbrace{\text{MeOH} \gg \text{EtOH, } n\text{-PrOH, } n\text{-BuOH, } i\text{-BuOH}}_{\text{(a)}} \gg \text{s-BuOH} \gg \underbrace{t\text{-BuOH, } t\text{-AmOH}}_{\text{(c)}}$$
(b)

For example, with methanol the replacement of the isopropoxy group is quantitative even at room temperature:

$$[Cu\{Zr_2(OPr^i)_9\}_2] + 18\underset{\text{(excess)}}{MeOH} \rightarrow [Cu\{Zr_2(OMe)_9\}_2] + 18Pr^iOH\uparrow.$$

On the other hand, with EtOH, *n*-PrOH, *n*-

BuOH, *i*-BuOH and *s*-BuOH at room temperature only six isopropoxy groups out of 18 could be replaced:

$$[Cu\{Zr_2(OPr^i)_9\}_2] + \underset{(excess)}{6ROH} \rightarrow [Cu\{Zr_2(OPr^i)_6(OR)_3\}_2] + 6Pr^iOH\uparrow$$

The primary alcohols out of the above could effect complete replacement of isopropanol in $[Cu\{Zr_2(OPr^i)_9\}_2]$ when the reaction was carried out under refluxing conditions:

$$[Cu\{Zr_2(OPr^i)_9\}_2] + \underset{(excess)}{18ROH} \xrightarrow[reflux]{PhH} [Cu\{Zr_2(OR)_9\}_2] + 18Pr^iOH\uparrow$$

(where R = Et, Pr^n, Bu^n and Bu^i).

However, even in refluxing benzene, the reaction with an excess of *s*-butanol yielded a product corresponding in analysis to $[Cu\{Zr_2(OPr^i)_3(OBu^s)_6\}_2]$:

$$[Cu\{Zr_2OPr^i)_9\}_2] + \underset{(excess)}{12Bu^sOH} \xrightarrow[reflux]{PhH} [Cu\{Zr_2(OPr^i)_3(OBu^s)_6\}_2] + 12Pr^iOH\uparrow.$$

The complete replacement of isopropoxy groups with *s*-butanol was possible when the liberated isopropanol was continuously fractionated out from the refluxing reaction mixture.

$$[Cu\{Zr_2(OPr^i)_9\}_2] + \underset{(excess)}{18Bu^sOH} \rightarrow [Cu\{Zr_2(OBu^s)_9\}_2] + 18Pr^iOH\uparrow.$$

At room temperature, no reaction appeared to take place between $[Cu\{Zr_2(OPr^i)_9\}_2]$ and *t*-butanol. In refluxing benzene, however, four isopropoxy groups could be replaced:

$$[Cu\{Zr_2(OPr^i)_9\}_2] + \underset{(excess)}{4Bu^tOH} \rightarrow [Cu\{Zr_2(OPr^i)_7(OBu^t)_2\}_2] + 4Pr^iOH\uparrow.$$

The above reaction under the condition of azeotropic removal (for *ca* 25 h) of Pr^iOH finally gave a solid product which corresponded in analysis to $[Cu\{Zr_2(OPr^i)_3(OBu^t)_6\}_2]$:

$$[Cu\{Zr_2(OPr^i)_9\}_2] + \underset{(excess)}{12Bu^tOH} \rightarrow [Cu\{Zr_2(OPr^i)_3(OBu^t)_6\}_2] + 12Pr^iOH\uparrow.$$

The product obtained as a result of the reaction with Am^tOH (with azeotropic fractionation) corresponded in analysis to $[Cu\{Zr_2(OPr^i)_4(OAm^t)_5\}_2]$.

In a number of publications from these laboratories it has been shown that in alcoholysis reactions of alkoxides of earlier transition metals (e.g. Zr),[11] the terminal isopropoxy groups are replaced with greater facility than the alkoxy groups bridging the metal atoms. In the case of mixed methoxide isopropoxide, although the interchange occurs initially at the terminal positions, the methoxy groups tend to change the bridging positions, so that the molecule finally tends to show properties ascribable to the greater steric bulk of the terminal isopropoxy groups.[11] Further, the alcoholysis reactions of such (zirconium) isopropoxides with more ramified tertiary alcohols do not tend to go to completion. More recently, it has been shown that, as far as bimetallic alkoxides of later transition metals (like copper)[4] are concerned, the alkoxy groups bridging copper with main group metals like aluminium tend to show no difference in the facility with which these are replaced in alcoholysis reactions.

In order to understand the results of the alcoholysis reactions of $[Cu\{Zr_2(OPr^i)_9\}_2]$ with different alcohols, it becomes necessary to postulate a plausible structure for the same. In an earlier publication[11] from these laboratories, a plausible structure was suggested for $K\{Zr_2(OPr^i)_9\}$, which appears to have received some corroboration in the structure determined recently[12] for $K\{U_2(OCMe_3)_9\}$. As it would be rather speculative to suggest a structure for the derivatives $[Cu\{Zr_2(OR)_9\}_2]$ described in these investigations, the structure may be considered similar to that of $K\{U_2(OCHe_3)_9\}$ which is reproduced in Fig. 1, with the copper atom in place of potassium; the 6-coordinated copper ion is held by two bridging and one terminal oxygen atom from each $\{Zr_2(OPr^i)_9\}^-$ moiety:

In the structure suggested above, ignoring the alkoxy bridge between Zr and Cu, there are three bridging alkoxy groups between each pair of zirconium atoms and every zirconium atom has three terminal groups. The results of alcoholysis reactions can, therefore, be explained easily on the following lines: (i) only 12 groups are replaced by alcohols of group (a) and *s*-butanol at room temperature; (ii) both types of alkoxy groups are replaced by alcohols (a) under refluxing and by methanol at room temperature; (iii) only partial replacement of terminal groups with *t*-butanol occurs under refluxing conditions, and all the terminal groups 12 are replaced by *t*-butanol under refluxing and continuous removal of the liberated isopropanol azeotropically; it may be further concluded that the

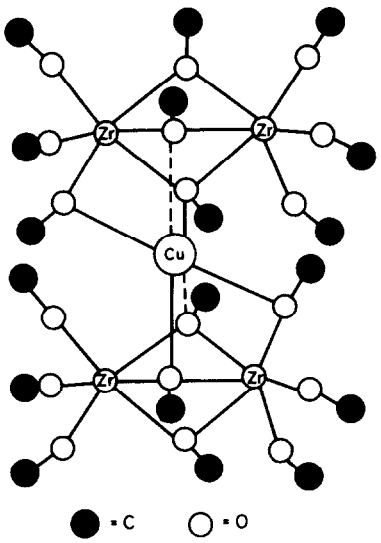

Fig. 1.

last stages of this final reaction become too slow with *t*-amyl alcohol. The alcoholysis of $[Cu\{Zr_2(OPr^i)_9\}_2]$ with methanol is quite facile at room temperature; by carrying out the methanolysis reactions in different molar ratios it has been shown that the derivatives $[Cu\{Zr_2(OPr^i)_6(OMe)_3\}_2]$ and $[Cu\{Zr_2(OPr^i)_3(OMe)_6\}_2]$ are soluble but further replacement tends to make the product insoluble. As mentioned above, it may be that the replacement of isopropoxy by methoxy groups occurs initially at the terminal positions, but in view of their (OMe) tendency to form stronger bridging bonds, these tend to shift to the latter positions. The volatility of the derivative $[Cu\{Zr_2(OPr^i)_6(OMe)_3\}_2]$ can be explained on the basis of all the methoxy groups occupying the bridging positions. Further, the presence of three isopropoxy and three methoxy groups on the terminal positions on zirconium atoms tends to hinder further association and hence the product remains soluble and becomes insoluble only when more than three OPr^i groups per zirconium atom are replaced by OMe groups.

All these bimetallic alkoxides of copper(II) are highly soluble (except the homoleptic methoxide derivative, which is insoluble) in common organic solvents (such as benzene, carbon tetrachloride and *n*-hexane), but these depict lower solubility in parent alcohols.

The analytical data and physical characteristics of these derivatives are compiled in Table 1.

IR studies

The IR spectra (in the range 4000–400 cm^{-1}) of these compounds exhibited structurally significant bands[13,14] (Table 2) at 950–1160 cm^{-1} for ν(C—O)M, and 510–580 cm^{-1} for the ν(Zr—O) and at 440–470 cm^{-1} ν(Cu—O).

Electronic spectral studies

The electronic spectra of a large number of copper(II) complexes are reported in the literature and it is believed that the absorption connected with the $^2E_g \rightarrow {}^2T_{2g}$ transition is characteristic of octahedral geometry.[15] However, in a tetragonal ligand field it may split into two bands, $^2A_{1g} \rightarrow {}^2B_{1g}(\nu_1)$ and $^2E_g \rightarrow {}^2B_{1g}(\nu_2)$, in the visible

region, possibly due to distortion.[15,16] The electronic spectra of the bimetallic alkoxides of copper(II) studied here showed broad asymmetric bands at 15.3 and 17.5 kK (Table 3), are characteristic of distorted octahedral geometry[17] in tetragonal ligand field. The visible spectral studies of $[Cu\{Zr_2(OPr^i)_9\}_2]$ in different solvents (non-coordinating and coordinating) reveal: (i) disappearance of the higher frequency bands (ν_1); and (ii) shifting of ν_2 bands towards lower frequency side with increasing coordinating tendency of the solvent.

In view of the above findings a sandwich-type structure (Fig. 1) can be suggested for the derivatives $[Cu\{Zr_2(OR)_9\}_2]$ in which $\{Zr_2(OR)_9\}^-$ units behave as tridentate ligands conferring a distorted octahedral geometry on copper(II). It is of interest that for the compound $K(U_2(OCMe_3)_9\}$ the crystal structure[12] is similar to that suggested above.

Magnetic studies

For the Cu^{2+} ion (d^9) having only one unpaired electron, the spin-only magnetic moment should be 1.73 BM. However, the observed values are generally higher due to some orbital contribution.

The observed magnetic moments (at room temperature) for these new bimetallic copper(II) alkoxides are in the 1.69–1.81 BM range and are in agreement with reported values (1.8–2.4 BM) for Cu(II)d^9 systems. The slightly lower value (1.59 BM) observed only in the case of the methoxide derivative, possibly due to its polymeric nature, is given in Table 2.

The low temperature (77.8–295 K) magnetic susceptibilities have been made on $[Cu\{Zr_2(OBu^n)_9\}_2]$ and indicated a decrease in magnetic moment with lowering of temperature. The plot of T vs $1/\chi_M^{corr}$ is a straight line showing Curie–Weiss behaviour with $\theta = -17$ K suggestive of antiferromagnetic exchange. The variable temperature magnetic susceptibility data are given in Table 4.

ESR studies

The ESR spectra of polycrystalline Cu^{2+} derivatives exhibits two types of g values, $g_\parallel$ and $g_\perp$, and these have been used to distinguish[18] unambiguously between $d_{x^2-y^2}$ (or d_{xy}) ground state on one hand and $d_{x^2-y^2}$ ground state on the other hand. For example, in $d_{x^2-y^2}$ (or d_{xy}) ground state ESR spectrum indicate $g_\parallel > g_\perp > 2.02$ in most cases whilst a d_{z^2} ground term usually gives a spectrum with $g_\perp > g_\parallel \sim 2.00$. The bimetallic alkoxides of copper(II), studied here, show a pronounced peak (for which $g_\perp \sim 2.10$) and a broad shallow quadruplet peak (for which $g_\parallel \sim 2.40$). These observations are characteristic[19,20] of axially distorted octahedral copper(II) complexes in which the unpaired electron is present in the $d_{x^2-y^2}$.

In an axial symmetry the g values are related by the expression $G = (g_\parallel - 2)/(g_\perp - 2)$, which measures the exchange interaction between copper centres in the polycrystalline solid,[21] if $G > 4$ exchange interaction is negligible, values of $G < 4$ indicate considerable exchange interaction in the

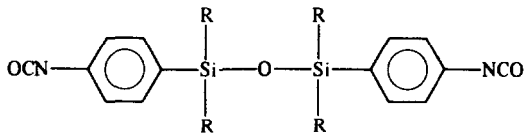
DISILOXANE-CONTAINING DIFUNCTIONAL COMPOUNDS: SYNTHESIS AND REACTIVITY OF 1,3-BIS-(*p*-ISOCYANATOPHENYL) DISILOXANES*

N. D. GHATGE† and S. S. MOHITE

Division of Polymer Chemistry, National Chemical Laboratory, Pune 411008, India

(*Received* 11 *November* 1985; *accepted after revision* 17 *July* 1986)

Abstract—Disiloxane-containing diisocyanates having the following general structure:



where R = CH_3 and C_6H_5, have been synthesized by the Curtius rearrangement of acid diazides. Both the diazides and one diisocyanate (R = C_6H_5) are new. The other diisocyanate (R = CH_3) was prepared by following a new synthetic route. All the compounds were characterized by IR and ^1H NMR spectroscopy. The reactivity of the diisocyanates with 2-ethyl-1-hexanol was studied using the IR spectroscopic technique.

The uniqueness of the isocyanates lies in their high reactivity towards compounds containing active hydrogen atoms, leading to wide-ranging applications in organic as well as polymer chemistry. Isocyanates can serve as the backbone for a wide variety of polymers other than the conventional polyurethanes and polyureas.[1]

During our research on the syntheses of silicon-containing diisocyanates[2,3] we have synthesized and characterized the following disiloxane-containing diisocyanates which were obtained from the corresponding diacids via the Curtius rearrangement of acid diazides:

(i) 1,3-bis-(*p*-isocyanatophenyl)-1,1,3,3-tetramethyldisiloxane (DMIS);
(ii) 1,3-bis-(*p*-isocyanatophenyl)-1,1,3,3-tetraphenyldisiloxane (DPIS).

DPIS is a new compound. DMIS was previously prepared by Bonnet and Marechal by the phosgenation of the corresponding diamine,[4,5] however, in the present study DMIS was prepared by following a different synthetic route. Both the diazides were synthesized for the first time.

EXPERIMENTAL

Synthesis

p-Tolyldimethylchlorosilane (DMSCL). To a solution of dimethyldichlorosilane (105 g, 0.81 mol) in dry ether (100 cm^3), an ethereal solution of *p*-tolylmagnesium bromide [prepared from magnesium (12.15 g, 0.5 g atoms) and *p*-bromotoluene (85.5 g, 0.5 mol) in dry ether (200 cm^3)] was added dropwise with stirring. The reaction mixture was stirred for an additional 12 h after the addition had been completed. The supernatant liquid was then poured from the salts which had formed, and the latter were washed with 150 cm^3 of dry ether. After distillation of solvent and unreacted dimethyldichlorosilane, vacuum was applied and 59.96 g (65%) of the product boiling at 95°C (11 mmHg) were obtained.

p-Tolyldiphenylchlorosilane (DPSCL). An ethereal solution of *p*-tolylmagnesium bromide [prepared from magnesium (12.15 g, 0.5 g atoms) and *p*-bromotoluene (85.5 g, 0.5 mol) in dry ether (200 cm^3)] was added dropwise with stirring to a solution of diphenyldichlorosilane (253 g, 1 mol) in dry ether (100 cm^3). The reaction mixture was refluxed for 2 h. The ether was distilled out, at the same time dry toluene (300 cm^3) was added dropwise and the reaction mixture was refluxed for 4 h. After the magnesium salts were filtered off,

toluene was removed under reduced pressure. The fractional distillation gave 114.14 g (74%) of DPSCL.

p-*Tolyldiphenylsilanol* (*DPOH*). A drop of phenolphthalein indicator was added to a solution of DPSCL (61.7 g, 0.2 mol) in ether (300 cm^3). Sodium hydroxide solution (1 N) was added with vigorous stirring till a light pink colour was obtained. The ether layer was separated, washed with water and dried over sodium sulphate. After removal of ether, the solid obtained was recrystallized from hexane to afford 52.20 g (90%) of DPOH.

1,3-*Bis*-(p-*tolyl*)-1,1,3,3-*tetramethyldisiloxane* (*DMDM*). A solution of DMSCL (40 g, 0.217 mol) in ether (250 cm^3) was shaken with successive portions of cold water until the water was no longer acidic. The ether layer was then dried and after removal of the ether, the liquid residue was distilled under reduced pressure to obtain 26.9 g (79%) of DMDM.

1,3-*Bis*-(p-*tolyl*)-1,1,3,3-*tetraphenyldisiloxane* (*DPDM*). A mixture of DPOH (72 g, 0.248 mol) and sodium hydroxide solution (4 cm^3, 0.1 N) was heated at 218°C for 1.5 h, during which time water was eliminated. The temperature was then raised to 260°C for 1 h and the melt was allowed to cool. The product was purified by recrystallization from heptane. Yield: 65 g (95%).

1,3-*Bis*-(p-*carboxyphenyl*)-1,1,3,3-*tetramethyldisiloxane* (*DMAC*). The temperature of the solution of DMDM (30 g, 0.095 mol) in water (100 cm^3) and pyridine (200 cm^3) was raised to 95°C, and potassium permanganate was added portionwise to maintain a slow reflux. The mixture was then refluxed for 3 h. The excess permanganate was destroyed by adding methanol. The MnO_2 was removed by filtration and washed with a large volume of boiling water, and the washings were combined with the filtrate. The filtrate, after removal of excess pyridine was treated with activated charcoal and acidified with dilute HCl. The precipitated acid was collected by filtration, washed with water, then dissolved in sodium carbonate solution, again treated with activated charcoal and finally acidified with HCl to get 25 g (70%) of DMAC after recrystallization from alcohol.

1,3-*Bis*-(p-*carboxyphenyl*)-1,1,3,3-*tetraphenyldisiloxane* (*DPAC*). A mixture of glacial acetic acid (620 cm^3) and acetic anhydride (200 cm^3) was cooled to −5°C and concentrated sulphuric acid (50 cm^3) was added dropwise with stirring. The mixture was allowed to warm to 10°C and DPDM (43 g, 0.0765 mol; in 11 g portion) and chromium trioxide (76.8 g, in 19 g portions) were added with rapid stirring. The portions of the chromium trioxide were added at 0.5 h intervals, followed 10 min later by a portion of DPDM with the temperature maintained at 10–14°C during the additions. After the additions were complete, stirring was continued for 3 h at 12–17°C and the mixture was poured over crushed ice. The precipitated acid was filtered, washed thoroughly with water and dried. It was further washed with methylene chloride (150 cm^3) by stirring for 30 min. Treatment with charcoal and recrystallization from ethanol afforded 32.4 g (68%) of DPAC.

1,3-*Bis*-(p-*chlorocarbonylphenyl*)-1,1,3,3-*tetraphenyldisiloxane* (*DPACL*). DPAC (20 g, 0.032 mol) and thionyl chloride (150 cm^3) were refluxed for 8 h. Excess of thionyl chloride was removed under reduced pressure and the residue was recrystallized from dry toluene. Yield: 14 g (66%).

1,3-*Bis*-(p-*chlorocarbonylphenyl*)-1,1,3,3-*tetramethyldisiloxane* (*DMACL*). This compound was synthesized by following a similar procedure as that described for DPACL.

1,3-*Bis*-(p-*azidocarbonylphenyl*)-1,1,3,3-*tetraphenyldisiloxane* (*DPAZ*). (a) To a cooled (5°C) solution of sodium azide (2.60 g, 0.04 mol) in water (15 cm^3) was added a solution of DPACL (6.59 g, 0.01 mol) in methylene chloride (15 cm^3) with efficient stirring. After stirring for 20 min, the water layer was separated and the methylene chloride layer was washed with water and dried over sodium sulphate. The methylene chloride was removed under reduced pressure to obtain 4.64 g (69%) of DPAZ.

(b) The suspension of DPAC (6.22 g, 0.01 mol) in acetone (40 cm^3) was cooled to 0°C and triethylamine (2.02 g, 0.02 mol) in acetone (15 cm^3) was added over a period of 10 min. The reaction mixture was stirred for further 10 min and then a solution of ethyl chloroformate (2.17 g, 0.02 mol) in acetone (15 cm^3) was added at 0°C over a period of 10 min. The resulting reaction mixture was stirred for 1 h at the same temperature and then a solution of sodium azide (2.60 g, 0.04 mol) in water (60 cm^3) was added dropwise. Finally, the reaction mixture was stirred for 4 h at 0°C and then poured into 200 cm^3 of ice-cold water. The solid was collected by filtration. It was dissolved in methylene chloride and dried over sodium sulphate. After filtration, methylene chloride was removed under reduced pressure to get 5.71 g (85% of DPAZ).

1,3-*Bis*-(p-*azidocarbonylphenyl*)-1,1,3,3-*tetramethyldisiloxane* (*DMAZ*). The reaction conditions described for the synthesis of DPAZ were followed to obtain DMAZ—by both routes (a) and (b).

1,3-*Bis*-(p-*isocyanatophenyl*)-1,1,3,3-*tetraphenyldisiloxane* (*DPIS*). A solution of DPAZ (3.36 g, 0.005 mol) in dry benzene (35 cm^3) was refluxed for 12 h. The benzene was removed by distillation under

reduced pressure and the residue was recrystallized from dry hexane. Yield: 2.84 g (92%).

1,3-*Bis*-(p-*isocyanatophenyl*)-1,1,3,3-*tetramethyldisiloxane* (*DMIS*). The procedure described for the preparation of DPIS was used to obtain DMIS.

Reactivity measurements

The intense absorption of IR caused by the isocynate group was used for plotting the course of the reaction. The IR spectra were recorded on a PYE UNICAM SP-3 300 IR spectrophotometer equipped with sodium chloride cells. The instrument was previously calibrated with standard polystyrene film. All measurements were done at 24 ± 1°C with the same pair of cells (path length 0.5 mm).

Reaction of DMIS with 2-ethyl-1-hexanol. In a 10 cm^3 volumetric flask, a 0.02 M solution of DMIS was prepared by dissolving 73.6 mg of it in dry benzene up to the mark. It was used as standard solution. In another 10 cm^3 volumetric flask, 73.6 mg of DMIS and 520 mg of 2-ethyl-1-hexanol were dissolved in dry benzene and the solution was standardized to 10 cm^3. This was the reaction mixture, 0.02 M with respect to diisocyanate and 0.4 M with respect to 2-ethyl-1-hexanol. Absorption (A_s) was recorded by scanning the IR spectrum of the standard solution which filled the cell. The reaction mixture was also run for IR spectrum in the cell, and absorbance (A_t) at different time, t, was recorded. The percentage of unreacted isocyanate was calculated with the help of A_s and A_t values.

Reaction of DPIS with 2-ethyl-1-hexanol. The procedure described for DMIS–2-ethyl-1-hexanol reaction was used for this reaction also.

RESULTS AND DISCUSSION

The scheme for the synthesis of diisocyanates is outlined in Fig. 1.

The physical characteristics and spectral data (IR and ^1H NMR) of the compounds prepared are given in Table 1.

The compounds DMSCL[6] and DPSCL[7] were prepared from the Grignard reagent of *p*-bromotoluene and excess of the appropriate dichlorosilane. All the reactions were carried out under a dry and inert atmosphere.

The hydrolysis and concurrent dehydration of DMSCL gave DMDM.[8]

An ethereal solution of DPSCL with a drop of phenolphthalein indicator was hydrolysed by sodium hydroxide solution at room temperature. A light pink colour ensured the completion of hydrolysis. In this case the free silanol, DPOH, rather than disiloxane, results. It was identified as silanol by the fact that the benzene (dry) solution reacted with sodium. Also a band at 3300 cm^{-1} in the IR spectrum and D_2O exchange in the NMR spectrum confirmed the presence of an OH group.

The dehydration of DPOH in the presence of sodium hydroxide at elevated temperature[8] afforded DPDM.

The oxidation of DMDM was carried out with potassium permanganate in pyridine/water mixture as described by Speck.[8] The complete oxidation of the aryl CH_3 groups was confirmed by the ^1H NMR spectrum of the resulting compound in pyridine which showed the absence of singlet peak of aryl CH_3 at δ 2.20 ppm.

DPAC was prepared following chromic acid oxidation of DPDM as reported by Breed and Wiley[9] but with a different purification procedure. Before washing the DPAC by methylene chloride, the ^1H NMR spectrum showed a peak at δ 2.27 ppm due to aryl CH_3. After washing with methylene chloride the spectrum showed the absence of the peak at 2.27 clearly indicating the removal of DPDM.

The diacid chlorides, DMACL[10] and DPACL,[9] were prepared by reacting the corresponding diacids with excess of thionyl chloride at reflux temperature.

The synthesis of the two new acyl azides was accomplished by two reaction pathways. Method (a) consists of treating DMACL/DPACL in methylene chloride with sodium azide in water. The other method (b) involved the conversion of carboxylic groups of diacids (DMAC and DPAC) into the azido carbonyl groups by an adaptation of the elegant Weinstock modification of the Curtius reaction.[11] The diacids were treated successively with 2 moles each of triethylamine, ethyl chloroformate and sodium azide. This is a "one-flask" reaction which does not involve the isolation of intermediate compounds and gives the product in pure form with good yields. A strong absorption band at 2130 cm^{-1} is observed which is due to the asymmetric stretching vibration of the N_3 group. A slight splitting of this absorption band is observed which may be explained as due to Fermi interaction with a combination tone involving the N_3 symmetric or C—N stretching vibration and other low-lying frequencies.[12]

The desired disiloxane-containing diisocyanates were obtained by the thermal decomposition of the corresponding acid diazides. The Curtius rearrangement was carried out in dry benzene at reflux temperature. The rearrangement took place

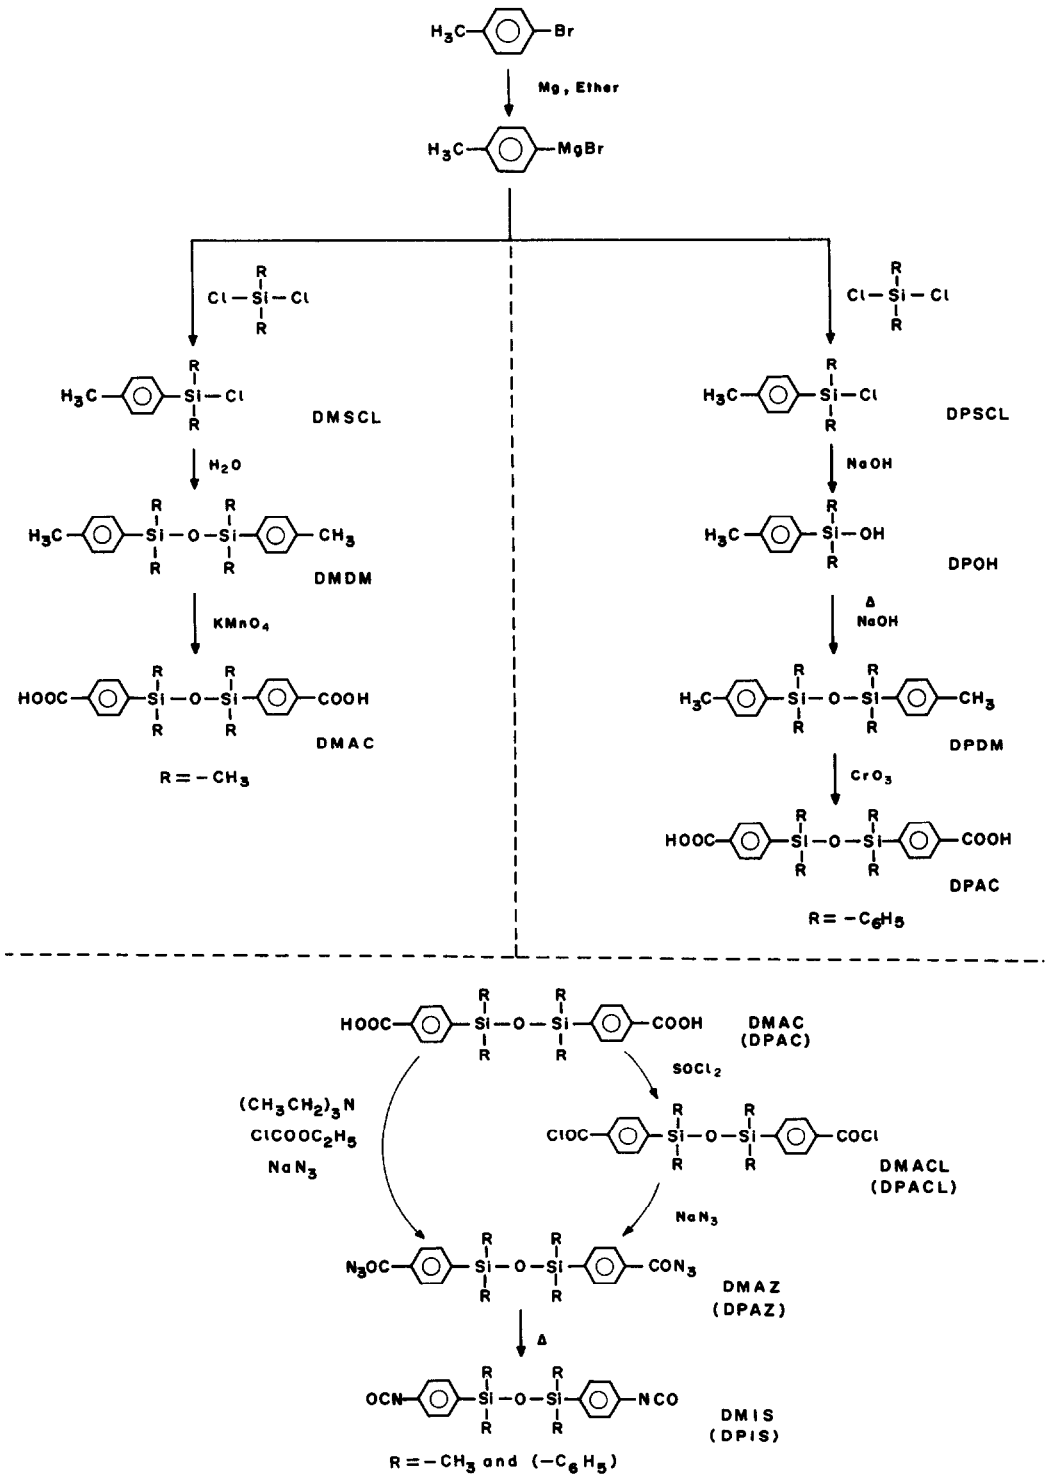

Fig. 1. Synthesis of disiloxane-containing diisocyanates.

Table 1. Physical characteristics and spectral data of the compounds

Compound	Yield (%)	m.p./b.p. [°C/(mm)]	^{1}H NMR[a] [δ (ppm)]	IR (cm^{-1})
DMSCL	65	95/(11)	0.33 (s, Si—CH_3, 6H), 2.0 (s, Ar—CH_3, 3H) 6.73 (d, Ar—H *ortho* to Si, 2H), 7.13 (d, Ar—H *ortho* to CH_3, 2H)[b]	550 (Si—Cl), 800, 840, 1260 (Si—CH_3)[g]

smoothly and required 12 h for completion (confirmed by IR spectra taken after every 2 h). During the rearrangement, CON_3 rearranges to NCO with evolution of nitrogen. Hence, the aryl protons which were *ortho* to CON_3 in azidocarbonyl compounds became *ortho* to NCO in isocyanate, thereby producing an upfield chemical shift.

The method of Ghatge and Dandge[13] was followed for plotting the course of the reaction between the diisocyanates and 2-ethyl-1-hexanol. Although the alcohol isocyanate reactions have been shown to follow second-order kinetics, approximately first-order kinetics can be assumed to be due to the large excess of the alcohol used. The pseudo-first-order reaction rate constants for diisocyanates at various degrees of reaction along with the time required for completion of reaction at these degrees are given in Table 2. Bailey *et al.*[14] have shown that the electron-withdrawing substituent groups increase the reactivity of the isocyanate group by increasing the partial positive charge on the isocyanate carbon. In contrast, the electron-donating substituent groups decrease the reactivity of the isocyanate group by increasing the electronegativity of the carbon atom of the isocyanate group. However, in the present investigation CH_3 and C_6H_5 groups may not be expected to influence the reactivities of the isocyanate groups in the neighbouring aromatic rings because of the presence of saturated silicon atoms in between the aromatic nuclei.

Abstract—H_2, Ge_2H_6 and a solid material $(GeH_x)_n$ ($x = 0.55$–1.81) are produced by γ-radiolysis of GeH_4. The relative amount of all the products and the composition of the solid are reported vs the pressure of GeH_4 in the sample and the radiation dose. The composition of the solid approaches the formula Ge_nH_{2n} as the pressure increases while the production of H_2 and Ge_2H_6 decreases.

Until some years ago research on the IVth group semi-conductors was directed to the preparation of crystalline materials of very high purity.[1] Only recently has attention been focused, at least for silicon, on the amorphous form in an effort to obtain cheaper and more efficient material for solar photovoltaic cells. It has been demonstrated that amorphous silicon cells (containing a small percentage of bonded hydrogen) can collect the energy of the solar spectrum with higher efficiency than monocrystal cells.[1]

Germanium has not yet been considered for solar cell technology, but because its energy gap is lower than that of silicon, it might be added to silicon to build solar cells of higher efficiency utilizing the sun's spectrum in the lower energy region.[1]

The decomposition of monogermane has been studied by thermal methods and by mercury photosensitization. Thermal decomposition in a static system has been interpreted as caused by both a zero-order reaction occurring on the surface of the reaction vessel and a first-order reaction occurring in the gas phase, the former being predominant at low pressures and the latter at higher pressures.[2]

To our knowledge no radiolysis studies have been reported for GeH_4. Radiolytical decomposition is a suitable method to get useful information on mechanisms which can be easily transferable to other decomposition methods, such as glow-discharge—which is one of the most popular techniques used for the commercial production of amorphous semiconductors.

In this study we report the first results of the $\gamma + GeH_4$ experiments. T-labelled GeH_4 was used the better to trace the hydrogen content of the products.

EXPERIMENTAL

GeH_4 was prepared by reduction of GeO_2 with KBH_4.[3] After purification from CO_2, it was mixed with ^3He, sealed in quartz ampoules, and neutron bombarded for T-labelling with the nuclear recoil method.[4] The irradiated mixture was purified by gas chromatography using a 1 m × 1 cm i.d. column filled with Chromosorb 102, 60/80 mesh (J. Manville) at 310 K, He carrier 300 cm^3 min^{-1}. The T-labelled GeH_4 was then diluted with pure unlabelled GeH_4 to a specific activity of 5.62×10^3 Bq cm^{-3} at STP as measured by a static ion chamber (Nuclear Chicago).

*Author to whom correspondence should be addressed.

Germane, or mixtures of germane with oxygen or neon, sealed in Pyrex cylindrical ampoules (10 cm^3 vol.) were radiolysed with ^{60}Co γ-rays in a Gamma cell 200 (Atomic Energy of Canada Ltd.) at a dose rate of 150 Gy min^{-1} for total doses of 1.0×10^5, 8.0×10^5 and 1.2×10^6 Gy.

Several samples were prepared for each radiation dose, filling pressure and composition of the mixture, in order to carry out, for all experimental conditions, the gas-phase analysis and that of the solid product, both for Ge and H content.

The gas phase was analysed on a Cary-Loenco radio gas chromatograph[4] using 2 m × 0.6 cm i.d. columns in the 280–353 K temperature range; Chromosorb 102 (60/80 mesh) was used to get a good separation of HT and GeH_3T; G.C. Durapack *n*-octane porasil C, 80/100 mesh (Waters Associates) was used to separate HT + GeH_3T, Ge_2H_5T and higher germanes.

After the analysis of the gas phase one half of the samples were washed with concentrated nitric acid to dissolve the solid product. The acidic solution was analysed for Ge content by plasma emission spectroscopy. A DC Spectraspan IV (SMI Andover) spectrometer was employed. A two-point calibration method was used. The remaining samples were analysed for the H (T) content by combustion at 980 K in a wet oxygen stream.[5] The stream at the exit of the combustion tube was collected in a 10 cm^3 of cooled distilled water. The collected water was mixed with 10 cm^3 of Instagel (United Technologies Packard) scintillation cocktail and counted in a Tri-Carb (Packard) liquid scintillator counter (9.1% efficiency).

RESULTS

Gas-phase products

At the temperature of the irradiation (300–315 K depending on the irradiation time) the gaseous products of the radiolysis of GeH_4 are H_2, Ge_2H_6 and traces of Ge_3H_8 (the last easily detectable only in the higher dose and pressure runs). Figure 1 shows the trends of the labelled products yields as a function of the dose at 6.7 and 1.6×10^2 kPa. The products' yields increase with the dose, reaching, at 1.2×10^6 Gy, the total values of 9 and 5% in samples at 6.7 and 1.6×10^2 kPa, respectively—indicating that H_2 and Ge_2H_6 are primary products. Figure 2 shows the trend of the GeH_4 decomposition as a function of the pressure at the dose of 8×10^5 Gy. No strong dependence of the radiolytic products upon the reactant pressure can be observed, especially in the case of the Ge_2H_5T production, indicating that the experiments have been performed in the 'high-pressure region'.[6] Due to experimental difficulties the 'low-pressure region' has not been studied.

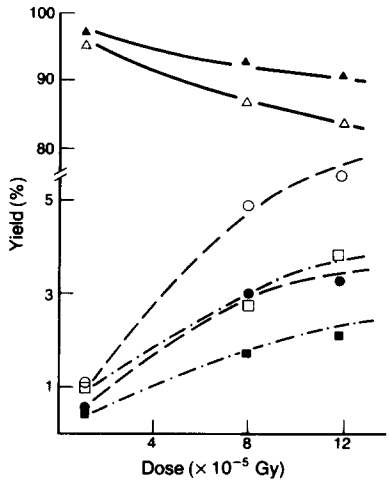

Fig. 1. Yields of GeH_3T, HT and Ge_2H_5T at 6.7 kPa (light points) and at 1.6×10^2 kPa (black points) as function of the absorbed dose: (——) GeH_3T, (-----) HT, and (-·-·-) Ge_2H_5T.

Figure 2 also shows the effect of added inert gas (Ne). When Ne is added the decomposition increases and the yields of the products are higher than those obtained not only at the same total pressure but even at the same reactant pressure.

Table 1 shows that the addition of O_2 as a radical scavenger has no effects on the Ge_2H_5T yield and only minor effects on the HT yield.

It should be pointed out that the results reported in Figs 1 and 2 refer only to the observed labelled products. Actually GeH_3T^* decomposes via a route leading to HT or H_2, and hence to GeH_2 or GeHT, respectively, with the same probability (see Discussion). By radio GC only the products containing the label will be detected, consequently the observed yields of both HT and Ge_2H_5T are only half of the actual hydrogen and digermane yields from GeH_3T^*.

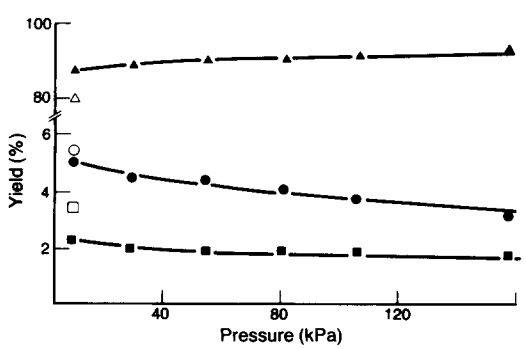

Fig. 2. Yield (%) in the system γ + GeH_4 as a function of the reactant pressure: (▲) GeH_4, (●) HT, and (■) Ge_2H_5T. △, ○ and □ = the same products in the presence of Ne (2:1). Dose = 8×10^5 Gy.

Table 1. Effect of oxygen on yield of products

Oxygen (kPa)	Products: Ge in solid total Ge (wt%)	T (solid)	HT (% of total activity)	Ge_2H_5T
2.7	3.79	1.8	2.40	1.8
6.6	3.98	1.35	2.61	1.8
13.3	4.18	1.65	2.82	1.5
20.0	3.87	2.01	2.77	1.3

The solid product

The solid product appears as a dark brown waxy material which covers the lower wall of the ampoule. In the oxygen-containing samples, the solid product is pale yellow, indicating the possible presence of hydrated oxides.

The compound is quite stable, in fact combustion of identical samples performed after prolonged exposures to the atmosphere gave the same results. The compound is remarkably different from the so-called "polymeric GeH_x"[3] which indeed contains oxygen.

Table 2 shows the composition of the solid as a function of the sample composition, pressure and the total dose. As expected the solid contains a lower fraction of the total Ge as the pressure increases and also its composition is pressure dependent: the H/Ge ratio is higher when obtained at higher pressures. The samples containing Ne show fairly enhanced yields.

Experiments carried out with ampoules filled with glass wool showed no surface effect, the observed deposition of the solid over the bottom of the ampoule also confirms the absence of any appreciable wall effect.

Table 2. Composition of the solid vs pressure and dose

Pressure GeH_4 (kPa)	Ne (kPa)	Dose (Gy)	Total T in solid (%)	Wt of Ge in solid (mg)	H/Ge ratio in solid
6.7		1×10^5	0.52	0.080	0.55
53.3		1×10^5	0.25	0.196	0.86
80.0		1×10^5	0.29	0.228	1.29
160.0		1×10^5	0.28	0.392	1.47
6.7		8×10^5	1.93	0.224	0.73
26.7		8×10^5	1.86	0.735	0.86
53.3		8×10^5	1.79	1.093	1.11
80.0		8×10^5	1.81	1.680	1.10
106.6		8×10^5	1.84	2.056	1.81
6.7		12×10^5	3.01	0.323	0.78

6.7	13.4	8×10^5	3.47	0.372	0.77

Table 3. *G* values of reactant and products at various pressures at the dose of 8×10^5 Gy

Pressure (kPa)	*G*: $-GeH_4$	H_2	Ge_2H_6	Ge (solid)
6.7	19.5 ± 2.1	17.1 ± 1.3	6.9 ± 1.5	16.5 ± 0.7
53.3	15.7 ± 1.8	15.1 ± 2.5	5.4 ± 0.6	10.1 ± 1.2
106.6	12.6 ± 0.4	11.9 ± 1.9	5.1 ± 1.0	8.2 ± 0.9
160	9.4 ± 1.1	9.2 ± 0.7	4.8 ± 0.8	6.3 ± 1.1

The *G* values for all the components of the system at 8×10^5 Gy and various pressures are reported in Table 3. The values at 1.0×10^5 Gy are about 1.5 times higher and those at 12×10^5 Gy do not differ substantially from those reported in the table, showing a stabilization at the per 100 eV yields over 8×10^5 Gy; a similar trend has been observed for SiH_4.[7]

DISCUSSION

In gas-phase radiolysis both radicals and ions are responsible for the final products. Apart from the mechanistic point of view, it is interesting to consider evidence for ionic reaction paths, to determine whether their contribution is significant, and whether their final products are expected to be different from those of the radical path.

The average energy absorbed for the formation of an ion pair (W) in the gas phase is about 5.3×10^{-18} J (34 eV) which is appreciably greater than the first ionization potential (I) of any gas.[8] The excess energy ($W - I$) is then available to form excited molecules. The ionization potential of GeH_4 has been found to be about 1.7×10^{-18} J (10.7 eV),[9] therefore in the upper limiting conditions, three molecules could be excited at about 1.2×10^{-18} J (7.7 eV) per each ion pair formed.

Moreover from the relation $G = 3M/N$, where M = number of molecules transformed, N = number of ions formed, it can be calculated that in our high-pressure conditions (where G has the lower value) $N = M/3$, i.e. the ions could account for ~25% of the reactive species. On the other hand, at least for H_2 production, the per 100 eV yield obtained in absence of ions, as in mercury-photosensitized decomposition of GeH_4 with 7.7×10^{-19} J (4.8 eV) photons, is the same as in our experiments at 6.3 kPa.[10] Besides, if an ionic mechanism similar to that of silane is supposed, the first step will give $GeH_3^+ + H$ and/or $GeH_2^+ + H_2$.[14] In the first instance scavengable hydrogen is produced, which has been observed to be a minor product. In the second instance molecu-

lar hydrogen is produced and the reactions of GeH_2^+ will produce detectable amounts of higher germanes (see below). It can then be inferred that for GeH_4 radiolysis the behaviour of the ions will not sensibly differ from that of radicals.

The following discussion will then deal with radicals, though some considerations could also apply to GeH_2^* species. Previous decomposition studies of GeH_4 suggest that excited GeH_4^* molecules could react as follows[10]

$$GeH_4^* + M \rightarrow GeH_4 + M \quad (1)$$

$$GeH_4^* \rightarrow GeH_3 + H \quad (2)$$

$$GeH_4^* \rightarrow GeH_2 + H_2 \quad (3)$$

$$GeH_4^* \rightarrow GeH + H_2 + H. \quad (4)$$

Reaction (2) involves the rupture of H_3G—H bond and hence requires at least 346 kJ mol^{-1}, while reaction (3) requires an activation energy of about 200 kJ mol^{-1} [12] and is then much more probable even in radiation and nuclear chemistry where the available excitation energies may be very high.[4]

As hypothesized above, if only three molecules could be excited for each ion formed, their excitation energy should be 1.2×10^{-18} J. In such conditions the unimolecular rate constants for reactions (2) and (3), calculated from equation (5):[13]

$$K_a = \alpha\nu\left(\frac{E + E_z - E_0}{E + E_z}\right)^{s-1} \quad (5)$$

are $1.4 \times 10^{10}\,s^{-1}$ and $1.9 \times 10^{12}\,s^{-1}$, respectively.

However in our mean experimental conditions (80.0 kPa and 8.0×10^5 Gy) the calculated mean energy absorbed per molecule is only about 9.8×10^{-20} J, so that the effective excitation energy of the GeH_4 molecule should be in the 1.2×10^{-18}–9.8×10^{-20} J range, with a higher probability for intermediate values. In such an energy range reaction (2) could then be easily suppressed by collision deactivation.

Furthermore experiments performed at 160 kPa and 1.2×10^6 Gy with variable amounts of O_2 (Table 1) show that the HT yield is scarcely affected by the scavenger; this finding makes it possible to exclude significant contributions of reactions (2) and (4) to the decomposition.

To sum up, it appears that the primary decomposition of excited GeH_4 species occurs mainly according to reaction (3), leading to H_2 and germylene (GeH_2).

The decomposition reaction (3) is, however, in competition with the stabilization reaction (1), which is of increasing importance as the collision frequency increases.

The poor pressure dependence of $-(GeH_3T)$ indicates that K_{dec} is greater than the collision frequency ω (ranging from 1.3×10^8 to 1.6×10^9) at least by one order of magnitude, i.e. $\sim 10^{10}$.

The calculation based on eqn (5) indicates that such a reaction rate requires an excitation energy of at least about 4.5×10^{-19} J, which is a reasonable value between the mean energy absorbed per molecule (9.8×10^{-20} J) at 8×10^5 Gy and the maximum energy of 1.2×10^{-18} J assuming only three excited molecules per ion pair.

The finding that GeH_2 is the main reactive species produced by decomposition of GeH_4^* suggests that germylene is the precursor of Ge_2H_6 through the insertion reaction (6), as it has been observed also in recoil Ge chemistry,[9] and of the solid product.

$$GeH_2 + GeH_4 \rightarrow Ge_2H_6. \quad (6)$$

The small pressure dependence of digermane yield could suggest that GeH_2 is very reactive by reaction (6), also at low energy content.

Actually the amount of germylene in the system decreases by about 6% (i.e. as $-GeH_4$) as the pressure increases from 6.3 to 160 kPa. If Ge_2H_6 is assumed to be produced by reaction of GeH_2, its yield reported in Fig. 2, is apparently only scarcely affected by the pressure; in fact the yield of reaction (6) is sharply dependent upon the collisional survival of GeH_2, and competes with the decomposition reactions (7) and (8)

$$GeH_2 + M \rightarrow Ge + H_2 + M \quad (7)$$

$$GeH_2 + M \rightarrow GeH + H + M \quad (8)$$

both of which are thermochemically feasible. It is suggested that they compete in the ratio 9:1.[12]

The solid product formation could be attributed to two different reaction sequences: (a) excited germylene insertion into the Ge—H bond of GeH_4, followed by hydrogen elimination and chain propagation as it has been suggested for the ionic mechanism in SiH_4[14,15] and for the radical mechanism in methylgermane.[16] Such a sequence will lead to a solid with a composition very close to Ge_nH_{2n} at any pressure condition and to the formation of detectable amounts of higher germanes. (b) Aggregation of Ge, GeH species [from reactions (7) and (8)] and perhaps GeH_2, leading to a hydrogen-poor solid. The composition of the solid reported in Table 2 and the absence of any substan-

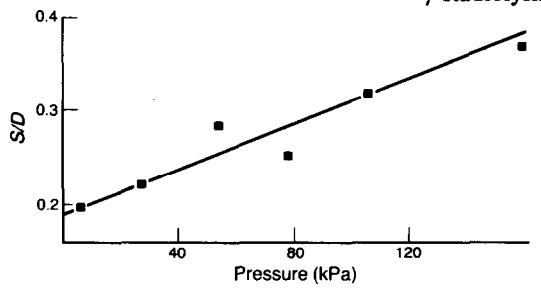

Fig. 3. Stabilization/decomposition for germilene radicals, vs total pressure. Intercept = 0.194; slope = 0.00118.

tial amount of higher germanes strongly supports this second reaction sequence.

The energetics of the reactivity of GeH_2 can be studied considering the competition between reactions (6), and (7) + (8). Using the symbology of decomposition–stabilization studies, we can call S (stabilized in gas phase) the fraction of GeH_2 species which reacts to Ge_2H_6 and D the fraction which through decompositions (7) + (8) is found in the solid.

Then the apparent rate constant for the unimolecular decomposition of germylene can be obtained by eqn (9) at the pressure where $D/S = 1$.

$$K_a = P\left(\frac{S}{D}\right)^{-1} Z \qquad (9)$$

Z is the collision number and P the pressure in torr. Z has been obtained using $\sigma_{GeH_4} = 5.1 \times 10^{-8}$ cm; D is the ratio (Ge in solid GeH_4) and S is (Ge_2H_6/−GeH_4). The plot of S/D vs pressure (Fig. 3) is linear enough to support the hypothesis that both Ge_2H_6 and the solid are formed in direct competition from the same precursor.[17] Linear least-square interpolation in Fig. 3 indicates that $D/S = 1$ at 7.2×10^5 kPa pressure, where the apparent unimolecular decomposition rate constant K_a for reaction (7) is: $ZP = K_a = 7.2 \times 10^9\,s^{-1}$.

The excitation energy for reaction (7), calculated by eqn (5) using the above rate constant, overcomes the activation energy used (1.18×10^{-19} J molecule^{-1})[12] by less than 1.6×10^{-22} J (0.001 eV). Because the energy used as activation energy is the lowest possible value for E_a, other values (2–3 times larger) have been tested. Nevertheless the decomposition rate does not change substantially, because the high decomposition rate is due to the very small number of degree of freedom of the GeH_2. Using the simplified RRK formula (i.e. neglecting te zero point energy E_z), K_a becomes one order of magnitude higher than ZP at an excitation energy 6.4×10^{-21} J higher than E_a. However, it should be noted that by neglecting the zero point energy, at low excitation energy, uncorrected values for K_a are obtained.[18]

It therefore appears quite strange that so much GeH_2 can be found in so narrow energy a range ($E - E_a$) to give the observed 'stabilization' yield (i.e. digermane).

The above findings can be explained taking into account that GeH_4^* molecules can undergo decomposition before or after any collision with the surroundings. GeH_2 species obtained by decomposition before collisions may carry higher excitation energy and be easily decomposed [reactions (7) + (8)], whereas the species obtained after collisions may be in a very low excitation state and be quite stable also. As the pressure increases the fraction of GeH_2 in low energy states increases and the ratio (Ge_2H_6/Ge in solid), i.e. S/D, is enhanced. As a consequence, the amount of undecomposed GeH_2 increases; this then takes part in the formation of the solid, which thus becomes richer in hydrogen.

Although the results at lower radiation doses and pressure (Table 2) are probably affected by larger errors, the composition of the solid does not appear to change in the 1.0×10^5–1.2×10^6 Gy range. This indicates that the solid is not sensibly affected by radiation damage up to 1.2×10^6 Gy, at least as far as the loss of hydrogen is concerned.

We also tested the influence of inert gas bath (Ne) at the lowest pressure. The sharp increase of volatile products, mainly HT, at the same partial pressures of GeH_4 indicates that the added Ne not only is unable to quench the excited GeH_4^* molecules but also favours some collisional decomposition [reaction (3b)] and consequently the insertion reaction (6)

$$GeH_4^* + Ne \rightarrow GeH_2 + H_2 + Ne. \qquad (3b)$$

The added Ne also affects the amount of the solid, the composition of which is apparently the same as that obtained from pure GeH_4.

Oxygen added as scavenger leads to a solid which appears different from that obtained from pure GeH_4. The analytical procedure used in this work, for the study of the solid has been devoted to the sole determination of the H/Ge ratio. Oxygen is known to react with radicals GeH_x, though its reactivity with such species is not known.[9] Nevertheless it can be inferred that the solid contains germanoxane chains, in fact the presence of oxygen does not affect the H/Ge ratio, indicating that oxygen does not substitute hydrogen atoms but

rather is inserted between two Ge atoms. The nature of the oxygen-containing solid will be the subject of a further report.

CONCLUSION

Though the bond dissociation energy for Si—H is higher than for Ge—H (378 vs 346 kJ mol^{-1}),[11] GeH_4 appears to be somewhat more stable than SiH_4 towards radiolysis, e.g. at 6.7 kPa: $G(-SiH_4) = 22$,[14] $G(-GeH_4) = 19$. Also for the formation of the solid the G values for silane[19] are higher than for germane, moreover the hydrogen content of the former is lower than for the latter. On the other hand some other contradictory properties of silicon and germanium compounds have been already pointed out. Possibly the nature of germanium d orbitals is relevant to this behaviour.[20]

The ionic contribution to the radiolysis of GeH_4 has been considered as similar to the radical contribution. However, the specific contribution of the ionic mechanism to the overall process should be tested, even if at very low pressures, by means of instrumental techniques such as MS and ICR spectrometry.

The deposition rate of the solid film, which is a determining parameter for practical application, has been estimated (for the 150 Gy min^{-1} dose rate), to range from 0.05–0.10 μm h^{-1} at the lowest pressure to 2–4 μm h^{-1} at the highest pressure. The above values are comparable with those usually observed for glow discharge deposition of amorphous silicon.

STABILITY CONSTANTS OF THE TERNARY COMPLEXES OF PALLADIUM(II) WITH THIODIPROPANOIC ACID AND CHLORIDE ION

S. HERNÁNDEZ CASSOU* and H. ITURRIAGA MARTÍNEZ†

Departamento de Química Analítica, Facultad de Ciencias, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain

(*Received* 6 *June* 1986; *accepted* 24 *July* 1986)

Abstract—The formation of the ternary complexes between palladium(II) ions and 3,3′-thiodipropanoic acid (TDPA) and chloride ion as ligands has been studied using spectrophotometric methods in acidic aqueous media with a constant ionic strength 0.5 M ($Na^+, H^+)(Cl_4^-, Cl^-$). The stoichiometries of the detected ternary complexes are: $[Pd(TDPA)Cl_3]^-$, $[Pd(TDPA)_2Cl_2]$ and $[Pd(TDPA)_2Cl]^+$. The spectrophotometric characteristics and the equilibrium constants for the different ternary species have been calculated with the LETAGROP-SPEFO computer program.

The ability of $Pd^{2+}(aq)$ to form different complexes with chloride ions is well known and the equilibrium constants corresponding to this binary system have been already summarized in the literature.[1] In a previous communication[2] the direct complexation between $Pd^{2+}(aq)$ and thiodipropanoic acid (TDPA) without chloride ions being present in the medium was studied and the values of the equilibrium constants of the resulting complexes $[Pd(TDPA)]^{2+}$ and $[Pd(TDPA)_2]^{2+}$ were reported.[2] Likewise, ternary systems containing palladium(II), chloride ions and thioethers[3–5] or sulphur-related compounds[6,7] have also been described and some of these results indicate that TDPA would be able to form this kind of mixed complex in a similar way. On this basis, and following our previous research with thio- and dithiodiacids,[2] a fundamental spectrophotometric study was carried out to elucidate the displacement reactions which could be produced when these two ligands (TDPA and chloride) compete for the same central atom (palladium) in acidic media.

EXPERIMENTAL

Apparatus and reagents

The apparatus has been previously described.[2]

Sodium chloride (Merck analytical reagent grade) was dried at 110°C and used without further treatment.

Hydrochloric acid (Probus analytical reagent grade) was standardized with HgO, KI.

All other reagents and solutions have been already indicated.[2]

Preliminary studies

Spectral characteristics. In the range of palladium concentration studied (10^{-5}–10^{-4} M), the species tetrachloropalladate(II), in aqueous media, shows two absorption bands: a broad one around 280 nm and a sharper one at 222 nm.

In the experimental conditions of this work, the predominant binary species from the system Pd–TDPA that has to be considered is the complex $Pd(TDPA)_2$, which denotes an absorption maxima at 272 nm.[2]

Initial assays evidenced the formation of ternary complexes $[Pd–TDPA–Cl]^-$ which presented a shoulder at 234 nm, and new absorption bands at the 280–300 nm zone shifted to higher wavelengths with respect to that of the binary systems.

Variation of absorbance with pH. No changes in the absorbance value of solutions with $C_{Pd} = 10^{-5}$ M, $C_{TDPA} = 10^{-2}$ M and $C_{Cl} = 1.0$ M were observed when the pH was varied in the range 0.7–2.1. Therefore a $pC_H = 1.3$ was chosen to avoid problems with hydroxocomplexes of palladium in a way similar to that of a previous work.[2]

Variation of absorbance with time. The absorbance values of 10 solutions containing $C_{Pd} = 2.7 \times 10^{-5}$ M, $C_{TDPA} = 4 \times 10^{-4}$ M and chloride concentration in the range 1.7×10^{-4}–6.1×10^{-2} M were followed during two days, and indicated that during this period of time the solutions were stable.

Ionic strength. Some preliminary attempts were made with solutions containing different concentrations of chloride (3, 1 or 0.5 M depending on the series), a palladium concentration of 10^{-5} M and TDPA:Pd ratios of 1, 5, 50, 100 and 1000. These studies showed that, as could be predicted, TDPA molecules more easily replaced the chloride ions from the ternary complexes at lower concentrations of chloride. In consequence, and to work in experimental conditions analogous to those of a previous paper,[2] a total ionic strength of 0.5 M was chosen for the following studies.

RESULTS AND DISCUSSION

Because the species in solution, corresponding to the different binary and ternary systems, could be numerous it was necessary to establish the experimental conditions in such a way that only $[Pd(TDPA)_2]^{2+}$, $[PdCl_4]^{2-}$ and mixed complexes predominate. Two series of solutions were outlined: (i) a series with constant concentrations of metal and TDPA, 5.3×10^{-5} and 8.0×10^{-4} M, respectively, varying the concentration of chloride in the range 1.0×10^{-4}–10^{-1} M; and (ii) a series with constant concentrations of metal and chloride, 5.3×10^{-5} and 0.4 M, respectively, varying the concentration in the range of TDPA 2×10^{-5}–1.8×10^{-3} M.

The analytical concentration of hydrogen in all solutions was $pC_H = 1.3$ and the total ionic strength was always kept constant at 0.5 M (Na^+, H^+) (ClO_4^-, Cl^-). Some spectra corresponding to each series can be seen in Figs 1 and 2, respectively. Thirty minutes after each solution had been prepared, its absorbance values were read at different wavelengths in the range 320–235 nm in order to get enough experimental data to study quantitatively all species absorbing in the wavelength zone. The TRIANG[8] numerical program was simultaneously applied to both series of solutions. It was possible to conclude that at least two ternary species were present in solution if an error matrix from 0.004–0.009 was tolerated, and a third one, probably present in low proportion appeared for an error matrix <0.004.

Treatment of the experimental data

The spectra of Figs 1 and 2 show that mixed species are gradually formed. It can be observed that the band of $[Pd(TDPA)_2]^{2+}$ (Fig. 1) decreases and shifts to higher wavelengths, and finally a well-defined band around 300 nm appears. In Figure 2, the 280 nm band corresponding to $[PdCl_4]^{2-}$ also shifts, and it is possible to appreciate two new zones, one at 290 nm and other at 300 nm. It seems that the final species at 300 nm is the same in both series. On this basis, and taking into account that at $pC_H = 1.3$ TDPA acts as a monodentate ligand,[2] the ternary complexes could be: (i) $[Pd(TDPA)Cl_3]^-$ and $[Pd(TDPA)_2Cl_2]$ resulting from the displacement of chloride ions in $[PdCl_4]^{2-}$ by TDPA molecules; and (ii) $[Pd(TDPA)_2Cl]^+$ and $[Pd(TDPA)_2Cl_2]$ formed when chloride ions are added to the $[Pd(TDPA)_2]$ complex, trying to satisfy the four coordination positions of palladium(II).

The system can be represented by the following equations:

$$[PdCl_4]^{2-} + TDPA \rightleftharpoons [Pd(TDPA)Cl_3]^- + Cl^-;$$

$$K_1 = \frac{[[Pd(TDPA)Cl_3]^-][Cl^-]}{[[PdCl_4]^{2-}][TDPA]} \quad (1)$$

$$[Pd(TDPA)Cl_3]^- + TDPA \rightleftharpoons [Pd(TDPA)_2Cl_2] + Cl^-;$$

$$K_2 = \frac{[Pd(TDPA)_2Cl_2][Cl^-]}{[[Pd(TDPA)Cl_3]^-][TDPA]} \quad (2)$$

$$[Pd(TDPA)_2]^{2+} + Cl^- \rightleftharpoons [Pd(TDPA)_2Cl]^+;$$

$$K_3 = \frac{[[Pd(TDPA)_2Cl]^+]}{[[Pd(TDPA)_2]^{2+}[Cl^-]} \quad (3)$$

where TDPA represents the totally protonated form of the ligand. In the following, the charges of the species will be omitted.

Graphical methods. Newman and Hume's method[9] was used to corroborate this initial hypothesis. This graphical method has already been applied to displacement reactions between palladium chloride and some thioethers similar to thiodipropanoic acid.[3] The method must be followed in conditions where the coordination of the central atom is completely fulfilled and, in this

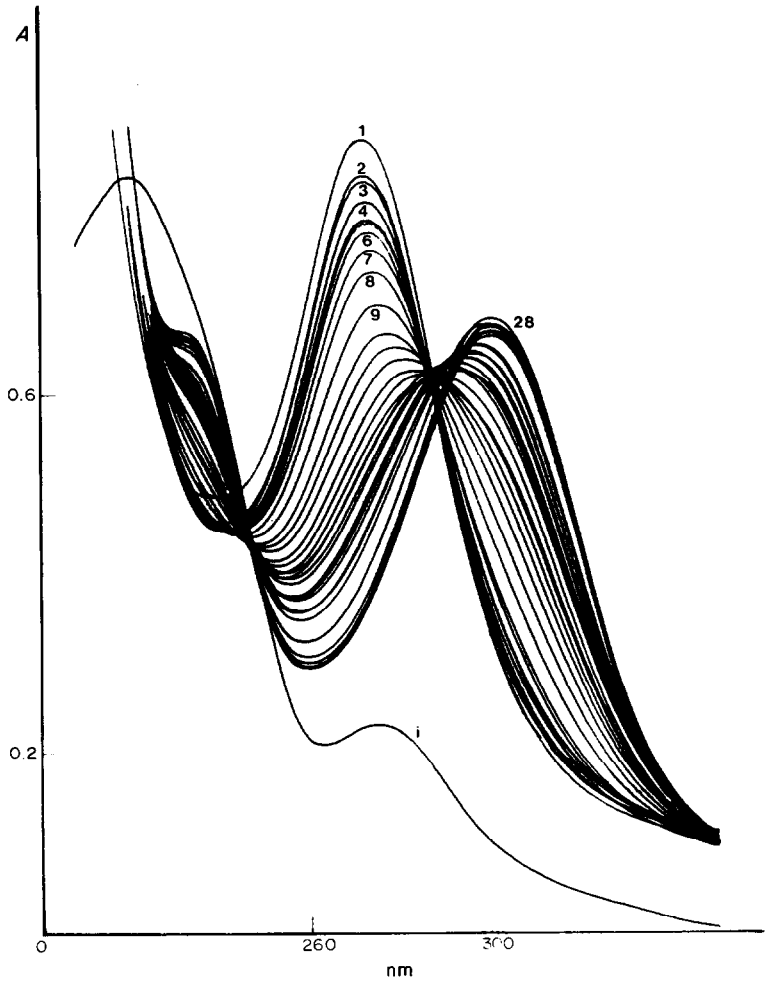

Fig. 1. Absorption spectra of Pd–TDPA–Cl system. Displacement of Pd–TDPA complexes. All solutions contained a concentration of palladium and TDPA equal to 5.3×10^{-5} and 8×10^{-4} M, respectively, and the chloride concentration was: (1) none, (2) 1.01×10^{-4} M, (3) 2.02×10^{-4} M, (4) 3.03×10^{-4} M, (5) 4.04×10^{-4} M, (6) 5.05×10^{-4} M, (7) 6.06×10^{-4} M, (8) 8.08×10^{-4} M, (9) 1.01×10^{-3} M, (10) 1.51×10^{-3} M,...,(28) 4.00×10^{-2} M. Solution (i) contained 5.3×10^{-5} Pd^{2+}, 3×10^{-2} M Cl^- and no TDPA was present.

work, only eqns (1) and (2) satisfy them. Two equations analogous to those of Newman and Hume were derived:

—two species, $PdCl_4$ and $Pd(TDPA)Cl_3$, exist and both absorb

$$|(\varepsilon_{PdCl_4} \cdot C_{Pd}) - A| \frac{C_{Cl}}{C_{TDPA}} = A \cdot K_1 - C_{Pd} \cdot \varepsilon_{Pd(TDPA)Cl_3} \cdot K_1 \quad (4)$$

—two species, $Pd(TDPA)Cl_3$ and $Pd(TDPA)_2Cl_2$, exist and only one, $Pd(TDPA)_2Cl_2$, absorbs.

$$A = \frac{1}{K_2}(-A)\frac{C_{Cl}}{C_{TDPA}} + \varepsilon_{Pd(TDPA)_2Cl_2} \cdot C_{Pd} \quad (5)$$

where C_{Pd}, C_{Cl} and C_{TDPA} are the analytical concentrations of palladium, chloride and thiodipropanoic acid, respectively and A is the experimental absorbance. The molar absorptivities of $[PdCl_4]^{2-}$ at different wavelengths, ε_{PdCl_4}, were obtained from a separate experiment, which is indicated in the next section on numerical methods. When ε_{PdCl_4} is known then K_1 and $\varepsilon_{Pd(TDPA)Cl_3}$ at 280 and 290 nm, from eqn (4), and K_2 and $\varepsilon_{Pd(TDPA)_2Cl_2}$ at 310 and 320 nm, from eqn (5), can be calculated and these results are given in the table 1.

Numerical methods. Newman and Hume's method needs the molar absorptivities of the tetrachloropalladate complex. So a series of solutions with high chloride concentration (3 M) and palladium varying between 3.2×10^{-5} and 6.4×10^{-5} M was prepared. The molar absorptivities obtained are shown in Table 2 at some wavelengths and agree with those of Pitombo *et al.*[3] At a chloride

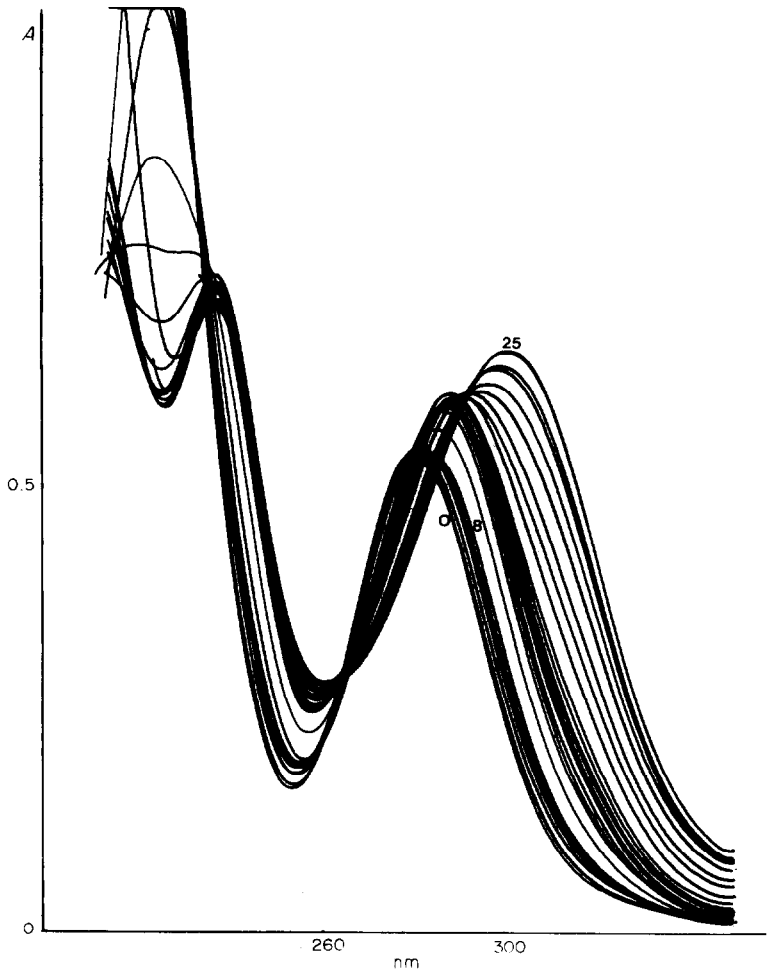

Fig. 2. Absorption spectra of Pd–TDPA–Cl system. Displacement of palladium chlorocomplexes. All solutions contained a concentration of palladium and chloride equal to 5.3×10^{-5} M and 0.4 M, respectively, and the TDPA concentration was: (1) 1×10^{-5} M, (2) 1.2×10^{-5} M, (3) 1.4×10^{-5} M, (4) 1.6×10^{-5} M, (5) 1.8×10^{-5} M, (6) 2.2×10^{-5} M, (7) 2.6×10^{-5} M, (8) 4.0×10^{-5} M, (9) 5.0×10^{-5} M, (10) 6.0×10^{-5} M,..., (25) 1.8×10^{-3} M.

Table 1. Results obtained by means of Newman and Hume's method[9]

Wavelength (nm)	$\varepsilon_{Pd(TDPA)Cl_3}$ ($l\,mol^{-1}\,cm^{-1}$)	Log K_1	$\varepsilon_{Pd(TDPA)_2Cl_2}$ ($l\,mol^{-1}\,cm^{-1}$)	Log K_2

310			12,290	3.30
320			8571	3.26

concentration of 0.4 M, the species $[PdCl_3]^-$ must also be considered (it can be present up to 5%); then a series in these conditions and with palladium concentrations in the range 3.2×10^{-5}–6.4×10^{-5} M was prepared. Table 2 also gives the molar absorptivities of $[PdCl_3]^-$, and the overall stability constants of the palladium binary species with chloride ion, β_4 and β_3, calculated by means of the LETAGROP-SPEFO program[10] were $\log\beta_4 = 11.39$ and $\log\beta_3 = 10.27$ which are in concordance with the results of Ref. 1. The LETAGROP-SPEFO computer program was used to treat simultaneously the experimental data from eight wavelengths. Because of the difficulty of the whole system, the binary systems (molar absorptivities and equilibrium constants) were fixed and only those of the ternary species were left to refine. The initial refinement cycle was done with the values found by graphical methods. The final computer results are listed in Table 3 where overall formation constants for the system

$$pPd^{2+} + q\text{TDPA} + rCl^- \rightleftharpoons [Pd_p(\text{TDPA})_qCl_r]^{(2p-r)+}$$

are expressed as $\log\beta_{pqr} \pm 3\sigma_{(\beta)}$, where σ is the

(X) $[PdCl_3(H_2O)]^- + Cl^- \rightleftharpoons [PdCl_4]^{2-}(aq) + H_2O$	$\log K_4'' = 1.30$	1

standard deviation. As can be seen, the molar absorptivities calculated by numerical and graphical methods are in agreement (the differences oscillate between 3 and 6%), more so if the complexity of the solution system is taken into account.

The particular stoichiometries and types of the ternary complexes found in this study reinforce our previous work[2] about the monodentate character of 3,3′-thiodipropanoic acid when it reacts with palladium(II) in highly acidic solutions (where the TDPA will be totally protonated) supposing that the coordination number of this cation is four. Table 4 shows all the equilibria of the binary and ternary systems of Pd–TDPA–Cl which can be compared in this way. If the Pd^{2+} ion, in the absence of chloride, is considered surrounded by water, $[Pd(H_2O)_4]^{2+}$, then the displacement by TDPA of one molecule of water is approximately 100 units easier than the analogous case with chloride in $[PdCl_4]^{2-}$ species. The ratios K_1/K_2 and K_1'/K_2' (2.55 and 1.82 in logarithmic units, respectively) would indicate that there is an extra effect in the steric hindrance of chloride, with respect to the water, when a second bulky molecule of TDPA approximates in both cases. Obviously, the lower values of second stepwise constants compared to the first ones are due to this hindrance.

The $-I$ effect of the COOH group, which is mentioned in some works,[3] would be very much diminished in the mixed complexes with TDPA because in this system the carboxylic group is in the γ-position with regard to the sulphur atom, and in consequence the values of these equilibrium constants would be greater, although for TDPA only one chloride is displaced and two chlorides were substituted in the COOH case.

The comparison between equilibria III and VII of Table 4 shows that the constants in these two

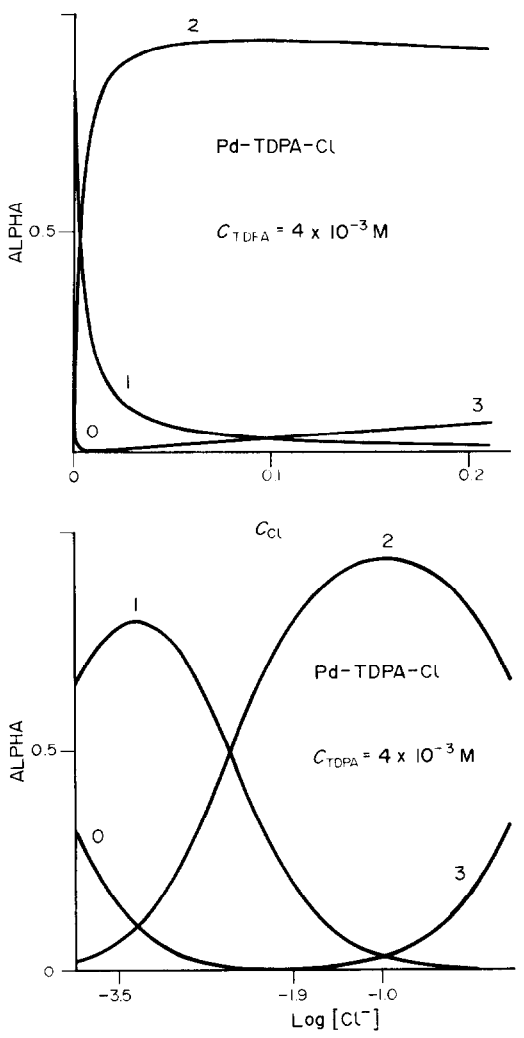

Fig. 3. Species distribution diagrams of Pd–TDPA–Cl system calculated by the Haltafall program: (0) $[Pd(TDPA)_2]$, (1) $Pd(TDPA)_2Cl]$, (2) $[Pd(TDPA)_2Cl_2]$, (3) $[Pd(TDPA)Cl_3]$.

systems are nearly equal, $\log K_3 = 4.30$ and $\log K_1'' = 4.47$, and it is possible to conclude, in consequence, that the behavior of TDPA in $[Pd(TDPA)_2]^{2+}$ is like a monodentate ligand because the tendency of chloride ion to coordinate with $[Pd(TDPA)_2(H_2O)_2]^{2+}$ or $[Pd(H_2O)_4]^{2+}$ is exactly the same. Moreover, in both cases, there is a mononegative anion (Cl^-) that approximates to a dispositive cation, $[Pd(H_2O)_4]^{2+}$ or $[Pd(TDPA)_2(H_2O)]^{2+}$, indicating that the electrostatic effect of the attraction predominates over the hindrance of TDPA with respect to chloride and, of course, this would only be possible if the TDPA is totally protonated and is coordinated only by the sulphur atom.

Recently Kragten *et al.*[11] have studied the palladium(II)–EDTA–chloride system and they have found a value of $\log K = 5.3 \pm 0.1$ for the equilibrium

$$PdH_2Y + Cl^- \rightleftharpoons PdH_2YCl^-$$

in agreement with the result calculated in this paper for the formation constant of equilibrium III, which is similar.

Figure 3 shows the species distribution diagrams, calculated from the final equilibrium constants by means of the computer program Haltfall,[12] and indicates that the species $[Pd(TDPA)_2Cl_2]$ is predominant (>90%) over a wide range of the chloride concentration. Then, on the basis of this complex, it would be possible to develop a method for the determination of palladium(II) by TDPA in the presence of chloride ion.

OXOVANADIUM(IV) COMPLEXES WITH 2-(2′-PYRIDYL)BENZIMIDAZOLE

P. K. NATH, N. C. MISRA,* V. CHAKRAVORTTY and K. C. DASH†

Departments of Chemistry and *Physics, Utkal University, Bhubaneswar 751004, India

(*Received* 11 *June* 1986; *accepted* 24 *July* 1986)

Abstract—The bidentate ligand, 2-(2′-pyridyl)benzimidazole (PBH), forms both five- and six-coordinated complexes with oxovanadium(IV), (VO^{2+}). The complexes $[VO(PBH)_2](NCS)_2$, $[VO(PBH)SO_4]$ and $[VO(PBH)_2]SO_4$ are five-coordinated while $[VO(PBH)_2X]X$ (X = Cl, Br or NO_3) are six-coordinated. Elemental analyses, electrical conductivity in non-aqueous media, electronic and IR spectra, mass and EPR spectra, magnetic susceptibility measurements and thermal analysis (TGA, DTG or DTA) studies adequately characterize the complexes.

The chemistry of oxovanadium(IV) has received considerable attention[1] as the VO^{2+} unit can readily coordinate four and five donor atoms to form VOL_4 and VOL_5 complexes, respectively. Additional interest has been generated due to the increasing discoveries of the biological importance of vanadium.[2] Several types of invertebrates accumulate vanadium in their blood. Thus, the ascidian seaworm *Phallusia mammilata* has a blood concentration of vanadium up to 1900 p.p.m., which represents more than a 10^6-fold concentration with respect to the sea-water in which it lives.[3] In this instance, vanadium was believed to play a role in the oxygen transport cycle.[4] Vanadium is also known to be an essential nutrient in higher life forms,[2,5] where it is involved in phospholipid oxidation, sulphur metabolism and cholesterol biosynthesis[6] and also plays a role in other biochemical processes. Oxovanadium(IV) complexes find use in chemical-reactivity studies either as models for V—O bond reactivity[7] or as potential free-radical like activators of organic and inorganic molecules. Oxovanadium(IV) porphyrins are commonly found in petroleum,[8] although their origin is not clear. Furthermore, the chemistry of vanadium is also of interest due to its close similarity to molybdenum, which is an essential co-factor in a number of oxidation–reduction enzymes.[9,10]

The ligand, 2-(2′-pyridyl)benzimidazole (PBH, see Scheme 1) is of interest in view of its similarity with 2,2′-bipyridyl and 1,10-phenanthroline in containing the —N=C—C=N— grouping and as it contains the imidazole group, which is present in many important biological systems. It also has potential use as a biochemical, anticancer and analytical reagent. The complexes formed due to the interaction of this ligand with dioxouranium(VI) and thorium(IV) have already been reported by us.[11] In continuation of our earlier work on imidazoles[12–14] and on the complexes of vanadium,[15,16] we report here the complexes formed by the interaction of several oxovanadium(IV) compounds with the ligand 2-(2′-pyridyl)benzimidazole. All of these complexes were adequately characterized on the basis of a number of spectral techniques in addition to the data based on analyses, electrical conductivity, magnetic susceptibility and thermogravimetric analyses.

EXPERIMENTAL

Materials

The ligand 2(2′-pyridyl)benzimidazole was synthesized as reported earlier.[11] V_2O_5 and $VOSO_4 \cdot 5H_2O$ were BDH reagent grade chemicals and were used as such. Syrupy $VOCl_2$ and $VOBr_2$ were prepared by a literature method.[17] $VO(NO_3)_2$ was obtained in solution by treating $VOSO_4$ with NaOH and treating the precipitated $VO(OH)_2$ with 50% HNO_3 followed by concentration of this solution.

Analyses

Vanadium was estimated either as V_2O_5 or as $AgVO_3$[18]; Cl and Br were estimated as silver halides and S as $BaSO_4$ after fusion of the sample with NaOH and Na_2O_2 and extraction of the melt with H_2O followed by acidification and addition of either $AgNO_3$ or $BaCl_2$, respectively. C, H and N microanalyses were made using a Carlo Erba instrument in CDRI, Lucknow. All melting points were determined in sealed capillaries and are uncorrected.

Physical measurements

The room temperature magnetic moments were determined in a Gouy balance using $HgCo(CNS)_4$ as calibrant. The electrical conductivity was measured in DMF solution ($\sim 10^{-3}$ M) using a Systronics 304 digital conductivity bridge and a dip type Pt cell with a cell constant of 1.0. The electronic spectra were recorded in a Varian 634 spectrophotometer and IR spectra were recorded as KBr pellets or polyethylene discs in the range 4000–200 cm^{-1} in a Perkin–Elmer 983 spectrophotometer. The EPR spectra were recorded as polycrystalline solids in a Varian E-4 spectrometer operating at X-band frequency. The mass spectra were recorded in a Varian CH-7 MAT spectrometer operating at an electron energy of 70 eV. The ion source was maintained at 473 K and the emission current was 300 μA. The thermogravimetric measurements were made using a Shimadzu DT-30 thermalanalyser which records T, TG, DTG and DTA simultaneously.*

Synthesis of complexes

Chloro bis-2-(2′-pyridyl)benzimidazole oxovanadium(IV) chloride, $[VO(PBH)_2Cl]Cl$ (**1**). Syrupy $VOCl_2$ (1 mmol) in acetone (5 cm^3) was added dropwise to the ligand PBH (2 mmol, 0.49 g) in the same solvent (5 cm^3) with stirring when a light green-yellow precipitate formed. The mixture was stirred further for 30 min under reflux, cooled and the solid filtered, washed with small aliquots of acetone, followed by ether and dried *in vacuo*.

Bromo bis-2-(2′-pyridyl)benzimidazole oxovanadium(IV) bromide, $[VO(PBH)_2Br]Br$ (**2**). Addition of aq. $VOBr_2$ (1 mmol) in acetone (5 cm^3) to PBH (2 mmol, 0.4 g) with stirring yields a viscous green liquid which was dissolved in 1:1 acetone–ethanol mixture and stored in a refrigerator for 12 h when green solid deposited. This was collected on a frit, washed with acetone–ethanol mixture and dried *in vacuo*.

Nitrato bis-2-(2′-pyridyl)benzimidazole oxovanadium(IV) nitrate, $[VO(PBH)_2(NO_3)]NO_3$ (**3**). Syrupy $VO(NO_3)_2$ (1 mmol) in acetone (5 cm^3) and PBH (2 mmol, 0.4 g) in acetone (5 cm^3) on stirring for 30 min yields a green compound, which was collected and dried as above.

Bis-2-(2′pyridyl)benzimidazole oxovanadium(IV) thiocyanate, $[VO(PBH)_2](CNS)_2$ (**4**). $VO(CNS)_2$, prepared by metathesis of aq. $VOCl_2$ and NH_4CNS in EtOH, was added dropwise to a stoichiometric amount of PBH in EtOH, and stirred for 1 h. The volume was reduced and the resultant concentrate was stored in a refrigerator for 12 h. A brown-yellow solid deposited, which was collected, washed with Et_2O and dried *in vacuo*.

Bis-2-(2′-pyridyl)benzimidazole oxovanadium(IV) sulphate, $[VO(PBH)_2]SO_4$ (**5**). $VOSO_4$ (1 mmol, 0.26 g) dissolved in 1:1 ethanol–water mixture was added to PBH (2 mmol, 0.4 g) in EtOH with stirring. A bulky yellow precipitate formed immediately and the mixture stirred for 30 min for completion of reaction. The compound was collected on a frit washed with small volumes of acetone, followed by ether and dried *in vacuo*.

Sulphato 2-(2′-pyridyl)benzimidazole oxovanadium(IV), $[VO(PBH)SO_4]$ (**6**). $VOSO_4$ (1 mmol, 0.26 g) dissolved in DMF was added to a solution of PBH (1 mmol, 0.2 g) in DMF and stirred. Initially the solution turned green from which on further stirring a grey powder separated out. This was collected, washed with EtOH and then ether and dried *in vacuo*.

RESULTS AND DISCUSSION

The compounds reported in this work are presented in Table 1 along with their analytical data, conductance, magnetic moments and the EPR $\langle g \rangle$ parameters. The conductance measurements were made in dilute solutions ($\sim 10^{-3}$ M) of DMF, $MeNO_2$ and MeOH. On the basis of observed

*The TGA and DTA data have been deposited with the Editor as supplementary data available on request.

Table 1. Colour, analyses, conductivity data, magnetic moment and EPR parameters $\langle g \rangle$ of oxovanadium complexes with PBH ligand

Compound	Colour	Analytical data; found (calc.) % V	C	H	N	Λ_M (in DMF)	μ_{eff} (BM)	$\langle g \rangle$
$[VO(PBH)_2Cl]Cl$	Green yellow	10.2 (9.7)	54.4 (54.5)	3.5 (3.4)	15.8 (15.9)	63.1	1.86	1.993
$[VO(PBH)_2Br]Br$	Green	9.0 (8.3)	46.5 (46.7)	2.8 (2.9)	3.4 (3.6)	89.8	1.70	2.002

$[VO(PBH)_2](CNS)_2$	Green yellow	10.9 (10.7)	54.4 (54.4)	3.1 (3.1)	19.6 (19.5)	170.0	1.87	1.99
$[VO(PBH)_2]SO_4$	Yellow	9.5 (9.2)	52.0 (52.0)	3.2 (3.2)	15.0 (15.2)	57.4	1.78	1.989
$[VO(PBH)SO_4]$	Grey	13.8 (14.2)	40.0 (40.2)	2.2 (2.5)	11.5 (11.7)	25.0	1.79	1.9835

Table 2. Prominent IR absorption bands of VO^{2+} complexes with PBH ligand (in cm^{-1})[a]

Complex	ν(V=O)	Anion vibrational modes				Remarks
$[VO(PBH)_2Cl]Cl$	980					
$[VO(PBH)_2Br]Br$	980					
$[VO(PBH)_2(NO_3)]NO_3$	985	1400				Ionic NO_3^-
		1255	1060	750		Unidentate NO_3^-
$[VO(PBH)_2](CNS)_2$	980	2074				Ionic CNS^-
$[VO(PBH)_2](SO_4)$	982	1100	1000	620	450	Ionic SO_4^{2-}
$[VO(PBH)SO_4]$	985	1060	985	605		Bidentate SO_4^{2-}

[a]In all cases the following important ligand vibrations were observed: ν(N—H), 3400–3500; ν(C=N), 1590–1610; pyridine ring vibration, 1560–1580; N—H out of plane deformation 790–800 cm^{-1}.

conductivity values in these solvents,[19–21] the $[VO(PBH)_2X]X$ (X = Cl, Br or NO_3) and $[VO(PBH)_2]SO_4$ are formulated as 1:1 electrolytes, the $[VO(PBH)_2](NCS)_2$ as a 1:2 electrolyte and $[VO(PBH)SO_4]$ as a non-electrolyte. The electronic spectra of the complexes in solution exhibit ligand-field bands in the 17–19 and 12–13 kK regions corresponding to the $b_2 \rightarrow b_1$ and $b_2 \rightarrow c$ transitions.[22–24]

The IR spectra were recorded in the 4000–200 cm^{-1} region and in all cases the spectra due to the ligand, the polyatomic anions and the ν(V=O) were observed. The prominent ligand bands are either split or shifted due to coordination.[25] The IR spectra show that the ligand is coordinated in a bidentate manner through the unsaturated N atom and the N atom of the pyridine ring.[26] The $[VO(PBH)_2(NO_3)](NO_3)$ complex has a strong band at 1400 cm^{-1} due to the ionic nitrate group and bands at 1255, 1060 and 750 cm^{-1} corresponding to the ν_1, ν_2 and ν_3 vibrations for the nitrate group coordinated in a unidentate manner.[27,28] The thiocyanate complex has a strong absorption band at 2074 cm^{-1} due to the ionic thiocyanate group[29,30] in $[VO(PBH)_2](CNS)_2$ which is in agreement with the conductivity data. The sulphato complex $[VO(PBH)SO_4]$ has IR bands at 1060, 605 and 985 cm^{-1} corresponding to the bidentate coordination[31] of SO_4^{2-} group and the sulphate complex $[VO(PBH)_2]SO_4$ exhibits bands at 1000, 450, 1100 and 620 due to the ν_1, ν_2, ν_3, ν_4 vibrations, respectively of the uncoordinated ionic sulphate group.[32] The ν(V=O) stretching frequency is observed in all complexes at 980–985 cm^{-1} region except for the $[VO(PBH)_2NO_3]NO_3$ complex where it occurs at 998 cm^{-1}. These values indicate that V=O bond in VO^{2+} consists of a combination of σ-bond and p_π–d_π donation of electrons from the vanadyl oxygen to the vanadium atom.[24]

The observed magnetic moments of these complexes are approximately in agreement with the spin-only value of a d^1 system,[33,34] where the orbital contribution to the magnetic moment is quenched[35] due to the strong axial ligand field in oxovanadium(IV) complexes. Antiferromagnetic couplings of spin are also not observed at room

temperature[36] and the complexes do not exhibit any dependence on the magnetic field strength indicating the absence of ferromagnetic interactions. The results of magnetic moment studies are supported by the measurement of EPR spectra of polycrystalline compounds at X-band frequencies at room temperature. In all cases the g_{av} values lie in the range 1.983–2.002 close to the free-electron spin-only value of 2.0023. Both this result and the fact that the anisotropy of the g values is small in comparison with that for the magnetically similar d^9 complexes indicate that the axial component to the ligand field is high and the unpaired electron lies in an orbital of b_2 symmetry. In all cases the EPR signal appears as unresolved broad line except for the $[VO(PBH)_2(NO_3)](NO_3)$ complex, which shows[37] fairly well resolved hyperfine lines due to ^{51}V ($I = 7/2$). The anisotropic g values for this complex are $g_{\|}$ 1.957 and $g_{\perp}$ 2.017 with a g_{av} of 1.997; $A_{\|}$ is 175 G and $A_{\perp}$ is 60 G. The g_{av} values for $[VO(PBH)_2](CNS)_2$ and $[VO(PBH)_2]SO_4$ are 1.99 and 1.89, respectively, which are very close, indicating that the extent of delocalization in both cases are almost similar due to identical structural and electronic environment around vanadium. In both cases the five-coordinate $[VO(PBH)_2]^{2+}$ species is present as is clear from both conductance and IR results. The other five-coordinate species containing the bidentate PBH ligand and the bidentate sulphate group, $[VO(PBH)SO_4]$, also has a similar g_{av} value of 1.984. Incorporating a weak donor, e.g. Cl, Br or NO_3, in the vacant sixth position results in an increase of the g_{av} value towards the free-electron value for $[VO(PBH)_2X]X$ (X = Cl, Br or NO_3) complexes.

The mass spectra of the ligand and the complexes were investigated and in no case was the complex molecular ion nor any fragment of the ligand involving the metal ion obtained. In all cases peaks corresponding to the ligand molecule and its fragmentation products were obtained. The ligand molecular peak is obtained at m/z 195, from which two successive losses of HCN give peaks at m/z 168 and 141. Two prominent fragmentation peaks are obtained at m/z 90 and 91 corresponding to loss of $C_6H_5N_2$ or $C_6H_4N_2$. Thermal studies of simple ligand and the complexes were carried out. The PBH ligand gives a sharp endothermic peak at 221°C where it melts and around 450°C the entire ligand is volatilized leaving no residue. For the oxovanadium(IV) complexes with this ligand, the decomposition takes place in several stages corresponding to the loss of ligand in varying proportions, ultimately giving V_2O_5 as the end product. However, in some cases around 800–900°C there is considerable volatilization of the residue leaving only 3–4% residue, a fact which was substantiated by heating the compounds at the same temperature in a furnace and estimating the loss on heating. Such thermal behaviour was observed earlier for copper(II) complexes with imidazoles.[38]

THE INTERACTION OF NITROGEN AND SULPHUR DONOR MACROCYCLIC LIGANDS WITH DIRHODIUM(II) TETRACARBOXYLATES

ALAN J. HOLDER, MARTIN SCHRÖDER* and T. ANTHONY STEPHENSON*

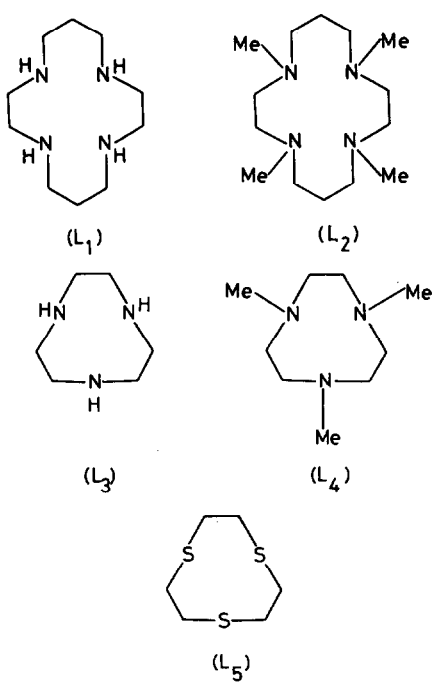
Department of Chemistry, West Mains Road, University of Edinburgh, Edinburgh EH9 3JJ, U.K.

(*Received* 11 *March* 1986; *accepted* 24 *July* 1986)

Abstract—Reaction of dirhodium(II) tetracarboxylates $[Rh_2(O_2CR)_4]$ with 1,4,8,11-tetraazacyclotetradecane (cyclam, L_1) under ambient conditions leads to the formation of the stable adducts $[Rh_2(O_2CR)_4(cyclam)]_n$. Under similar conditions reaction of dirhodium(II) tetracarboxylates with the tridentate macrocycles 1,4,7-triazacyclononane (L_3), *N,N',N''*-trimethyl-1,4,7-triazacyclononane (L_4) and 1,4,7-trithiacyclononane (L_5) gives adducts of 3:2 stoichiometry $[\{Rh_2(O_2CR)_4\}_3(L)_2]_n$. The stoichiometries of these polymeric adducts illustrate the *exo* manner in which the macrocyclic ligands bind to the binuclear metal substrates.

Extensive work on dirhodium(II) tetracarboxylates $[Rh_2(O_2CR)_4X_n]$ ($n = 1, 2$) has been carried out chiefly to study the variations in Rh—Rh and Rh—X bond lengths as a function of substituent X (X = C, N, O, P or S donor ligands) and carboxylate moiety.[1] The dirhodium(II) tetracarboxylates can react therefore either via carboxylate exchange with another carboxylate or bridging ligand (e.g. CO_3^{2-}, SO_4^{2-}), or via adduct formation by replacement of X. The exchange reaction with the unsaturated tetradentate macrocycle L (L = 5,7,12,14-tetramethyldibenzo[b, i] [1,4,8,11]-tetraazacyclotetra-2,4,6,9,11,13-hexaene) yields the binuclear complex $[Rh_2L_2]$ containing an unsupported metal–metal bond;[2] the related binuclear species $[Rh_2(OEP)_2]$[3] and $[Rh_2(dmg)_2(PPh_3)_2]$[4] have also been synthesized but via monomeric precursors, while bi- and polydentate ligands have been shown to form adducts linking dirhodium(II) tetracarboxylate units in a polymeric chain, e.g. $[Rh_2(O_2CEt)_4(DDA)]$ (DDA = durenediamine).[5]

We report here a study on the interactions of dirhodium(II) tetracarboxylates with saturated tetra- and tridentate macrocycles L_1–L_5. These ligands incorporate suitable donor arrays for adduct formation with the $[Rh_2(O_2CR)_4]$ moiety, and also for potential carboxylate exchange to generate new cationic macrocyclic complexes.



RESULTS AND DISCUSSION

Dirhodium(II) tetraacetate, -propionate, -butyrate, -pivalate and 4-^{t}butylbenzoate react as solutions or slurries in methanol with one equivalent

of cyclam (L_1) at room temperature to give pink products. These compounds were obtained in virtually quantitative yield and analysed for $[Rh_2(O_2CR)_4(L_1)]_n$ (Table 1). The nature of the products isolated was independent of the molar ratio of $[Rh_2(O_2CR)_4]$:cyclam used (1:1 to 1:10). IR spectra showed absorptions due to N—H stretching vibrations near 3300–3200 cm^{-1}, these bands being sharper than for the free ligand L_1. As well as bands due to L_1, bands characteristic of the parent carboxylate were retained with $\nu_{asym}(CO_2)$ near 1600 cm^{-1} and $\nu_{sym}(CO_2)$ near 1420 cm^{-1}. ^1H NMR spectra of the more soluble adducts confirm the ratio of L_1 to carboxylate as 1:4. Confirmatory evidence for the retention of the $[Rh_2(O_2CR)_4]$ unit was obtained from the ready conversion of these 1:1 adducts to the known 1:2 pyridine adducts $[Rh_2(O_2CR)_4py_2]$ on reaction with an excess of pyridine.

The 1:1 stoichiometry is indicative of a chain polymeric structure in which L_1 is bound via two of its four nitrogen donors to separate $[Rh_2(O_2CR)_4]$ units, with the other two nitrogen donor atoms remaining unbound. A polymeric structure would account for the general insolubility of these compounds.

Reaction of dirhodium(II) tetracarboxylates with L_2(1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) and 1,4,8,11-tetrathiacyclotetradecane gave pink polymeric products of stoichiometry $[\{Rh_2(O_2CR)_4\}_2(L)]_n$.

The tridentate macrocyclic ligands L_3–L_5 react with the dirhodium(II) tetracarboxylates to yield pink polymeric adducts; in these cases however a stoichiometry of $[\{Rh_2(O_2CR)_4\}_3(L)_2]_n$ gave best agreement with the analytical data (Table 1). This stoichiometry is consistent with that expected for a network structure in which each nitrogen or sulphur donor atom of the macrocycle is coordinated to separate rhodium centres. Again, IR spectral evidence confirmed the presence of the macrocyclic ligand and retention of the $[Rh_2(O_2CR)_4]$ moiety.

The pink colour (λ_{max} = 535 nm for $[Rh_2(O_2CPr)_4(L_1)]_n$ in benzene) of all the products is consistent with adduct formation via nitrogen or sulphur coordination to $[Rh_2(O_2CR)_4]$.[6] Heating $[Rh_2(O_2CR)_4L]_n$ or $[\{Rh_2(O_2CR)_4\}_3(L)_2]_n$ in $CHCl_3$ in the presence of excess of L yields red solutions presumably containing the species $[Rh_2(O_2CR)_4(L)_2]$; these compounds however could not be obtained in the solid state, the less soluble polymeric adducts being isolated in each case.

In contrast to the above reactions in which the carboxylate bridged framework is retained, preliminary studies indicate that treatment of $[Os_2(O_2CR)_4Cl_2]$ (R = Me, "Pr) with L_1 in CH_2Cl_2 at room temperature gives air-sensitive, diamagnetic purple cations of probable formula $[Os(O_2CR)(L_1)]_n^{n+}$ (n = 1 or 2). With $[Ru_2(O_2CR)_4Cl]$ and L_1 in THF under reflux, air-sensitive yellow solids of similar stoichiometry can be isolated. Oxidative dehydrogenation reactions of the cyclam ligand in these systems likely;[7] further studies on these and related osmium and ruthenium compounds are now in progress.

EXPERIMENTAL

Except where otherwise stated all reactions were performed under a nitrogen atmosphere using Schlenk tube techniques and distilled solvents. Methanol and ethanol were distilled from magnesium; benzene and THF were dried over sodium, and for the latter benzophenone was added. Dichloromethane was dried over calcium hydride and distilled. IR spectra were recorded on a Perkin–Elmer 548 spectrometer as Nujol and hexachlorobutadiene mulls. ^1H NMR spectra were recorded on

a Bruker WP80 (80 MHz) spectrometer. Electronic spectra were obtained on a SP8 400 spectrophotometer while elemental analyses were carried out at the Chemistry Departments of the University of Edinburgh and University of St Andrews. L_1 and L_2 were purchased from Aldrich Chemical Co.; L_3 L_5 were prepared by the literature procedures.[8-10]

Preparation of $[Rh_2(O_2CR)_4]$

$[Rh_2(O_2CMe)_4(MeOH)_2]$ was prepared via the literature method.[11] The corresponding propionate, butyrate and pivalate complexes were prepared by exchange reaction of the acetate in neat carboxylic acid. The solution was refluxed for 1 h and the excess acid evaporated *in vacuo*. The 4-^{t}butylbenzoate derivative was obtained by heating the acetate in a melt of 4-^{t}butylbenzoic acid for 4 h. The exchanged complex was recovered by dissolving the cooled residue in ethanol and collecting the product by filtration. The purity of the acetate and 4-^{t}butylbenzoate was checked by preparation of their pyridine adducts.

Preparation of cyclam (L_1) *adducts of* $[Rh_2(O_2CR)_4]$

The dirhodium(II) tetracarboxylates were reacted with a slight molar excess of cyclam (L_1) at room temperature as slurries (acetate, 4-^{t}butylbenzoate) or solutions (propionate, butyrate and pivalate) in methanol. For the solutions, reaction was fast to give pink precipitates of $[Rh_2(O_2CR)_4(L_1)]_n$. Similar products were obtained for the acetate and 4-^{t}butylbenzoate but a reaction time of 24 h was required for completion. The adducts of L_2 were obtained in a similar manner.

Preparation of adducts of L_3–L_5 *with* $[Rh_2(O_2CR)_4]$

Dirhodium(II) tetraacetate was reacted with L_3 or L_4 in aqueous solution, and in acetone–methanol for L_5. The dirhodium(II) tetrapropionate and tetrabutyrate analogues were reacted with L_3 or L_4 in acetone–water, and in acetone alone for L_5. In each case, the adduct precipitates out in almost quantitative yield.

Acknowledgements—We thank the SERC for financial support (to A.J.H.), Johnson Matthey PLC for very generous loans of platinum metals, and Mr M. N. Bell for preparation of L_5.

(*Received* 12 *February* 1986; *accepted after revision* 24 *July* 1986)

Abstract—The synthesis and structure elucidation of the dimeric form of molybdenum(IV) oxo-complexes with *N*-alkylphenothiazines as ligands have been studied. These complexes were identified by IR and electronic spectra, magnetic susceptibility, DTA, TGA, conductometric and analytical data. These results permit us to assign the formula $Mo_2O_4(L)_2(H_2O)_2$ (where L = *N*-alkylphenothiazine). Some interactions of these complexes with biologically important compounds like L-cysteine and histidine and potential ligands such as 1,10-phenanthroline and 2,2′-bipyridyl have been reported.

It is well known that molybdenum as a trace element plays an important role in metabolic processes.[1] Complexes of molybdenum(V) and (VI) with cysteine[2,3] histidine,[4] other amino acids[5] and organic sulphur compounds[6] are of interest as models for molybdenum-containing enzymes. These enzymes are known to catalyse a number of important biological oxo-transfer reactions where valence of molybdenum cycles between molybdenum(VI) and molybdenum(IV) states in their reaction with substrates and subsequent reactivation.[7]

N-Alkylphenothiazines (NAP) are versatile anticholinergic and antihistamine compounds.[8] Formation of complex or cation radical between platinum metals and phenothiazines in aqueous media has provided a basis for the spectrophotometric determination of platinum metals[9–12] and complexometric determination of palladium.[13] Recently the possible use of metal–phenothiazine complexes as fungicides and a considerable increase in the fungicidal activity by complexation of phenothiazines with copper(II) and dioxygenyl uranium(II) have been reported.[14] In view of the importance of phenothiazines as analytical reagents, metal–phenothiazine complexes as fungicides and molybdenum(V)–cysteine or histidine complexes as possible models for molybdoenzymes, it was considered worthwhile to study the molybdenum(IV)–NAP complexes and their interactions.

In this paper, we report the synthesis and characterization of molybdenum(IV)–NAP complexes and their interactions with biologically important compounds such as L-cysteine and histidine and potential ligands like 1,10-phenanthroline and 2,2′-bipyridyl (Fig. 1).

EXPERIMENTAL

Materials

$(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, L-cysteine, L-histidine hydrochloride monohydrate, 1,10-phenanthroline and 2,2′-bipyridyl were BDH Analar grade.

NAP: CPH, PMH, BPD, PPP, PPC and MTM from Bayer A.G., Leverkusen, F.R.G.: MH and PDM from Byk Gulden Pharmazeutika, Konstanz, F.R.G. were used as received. Dimethyl formamide (DMF) and dimethyl sulphoxide (DMSO) were BDH Analar products.

Analytical procedures

Elemental analysis were performed at Bioorganic chemistry division, Bhaba Atomic Research Centre, Bombay, India. Molybdenum was deter-

Fig. 1. Structure of *N*-alkylphenothiazines.

mined by atomic absorption (AA/AE spectrophotometer model 751) after decomposing the complexes with a 1:1 mixture of concentrated sulphuric and nitric acids. The analytical data are given in Table 1.

Methods

The magnetic susceptibilities were determined by the Gouy method at *room temperature* using $Hg[Co(SCN)_4]$ as calibrant ($\chi_g = 16.4$ c.g.s.u.). Molar susceptibilities were corrected for the diamagnetism for the constituent molecules and magnetic moments calculated according to the formula $\mu = 2.84\ (\chi'_M \cdot T)^{0.5}$ BM where χ'_M is the corrected molar susceptibility.[15]

The IR spectra were recorded on a Perkin–Elmer spectrophotometer model 781. The samples were pressed in KBr pellets. Far IR spectra were obtained using a Polytech far-IR spectrophotometer model 30. The samples were examined as polythene pellets. The important IR absorption bands for these complexes are listed in Table 2.

The UV–VIS spectra of the complexes in DMF were measured in the range 200–800 nm on a Beckman spectrophotometer model DB. The results obtained are given in Table 3. The electrical conductances of the complexes were measured in DMF using Philips PR 9500 conductivity bridge. Thermal analysis was carried out on a Stanton Redcraft TG 750/770 electrobalance with a heating rate of 6°C min^{-1} in air. The X-ray diffraction data was obtained using JEOL X-ray diffractometer model JDX-8P with a monochromatic Fe K_α ($\lambda = 1.934$ Å) as the source.

Preparation of the complexes

$(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (2.1 g) dissolved in 2 M hydrochloric acid (30 cm^3) was added to a solution of CPH (3.0 g) in water (50 cm^3) with vigorous stirring. There was an immediate formation of the solid complex. The suspension was set aside for 2 h, filtered, washed several times with water, then with ethanol and dried *in vacuo* over fused $CaCl_2$. Yield 76%.

The above procedure was repeated for the preparation of the complexes with other phenothiazines. The yield varied from 67–79%.

Interaction of molybdenum(IV)*–NAP complexes with* L-*cysteine*, L-*histidine*, 1,10-*phenanthroline and* 2,2′-*bipyridyl*

Molybdenum(IV)–NAP complex (1.8 g) dissolved in DMF (60 cm^3) was treated with L-cysteine (2.6 g) in 2 M hydrochloric acid (80 cm^3) or with an aqueous solution of histidine (2.75 g). The solid complexes separated immediately, were filtered, washed with ethanol and dried *in vacuo* over fused $CaCl_2$.

Molybdenum(IV)–NAP complex (1.4 g) dissolved in DMF (50 cm^3) was added to the DMF solution of 1,10-phenanthroline (2.45 g in 90 cm^3) or with 2,2′-bipyridyl (23.2 g in 80 cm^3). The suspension was set aside for 1 h, filtered, washed with ethanol and dried *in vacuo* over $CaCl_2$.

DISCUSSION

The interaction of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ with NAP results in the formation of molybdenum(IV) complex. The reduction of molybdenum(VI) to molybdenum(IV) may be attributed to the behaviour of phenothiazines which are excellent electron donors.[16] The analytical data presented in Table 1

Table 1. Colour, analytical data and molar conductance of molybdenum(IV)–NAP complexes

$Mo_2O_4(P)_2(H_2O)_2$	Yellowish-brown	50.2 (49.5)	6.0 (5.6)	8.3 (8.7)	19.6 (19.8)	22.7

correspond with the formula $Mo_2O_4(L)_2(H_2O)_2$, where L = CP, PM, BP, PP, PPC, MTM, M or P (hydrochloride, maleinate, phosphate and malonate remain in solution and do not take part in coordination).

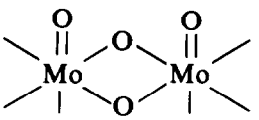
The complexes are coloured, non-hygroscopic and are stable at room temperature for long periods. They do not possess sharp melting points. The complexes are insoluble in common organic solvents but soluble in DMF and DMSO. The molar conductance of the complexes in DMF given in Table 1 indicate the non-electrolytic nature of the complexes and the ion-exchange studies show that the complexes are neutral. These are in consistent with the stoichiometry assumed for the complexes on the basis of analytical data.

Magnetic properties

The magnetic susceptibility measurements for the dioxo-bridge molybdenum(IV) complexes suggest the spin–spin interactions through the oxygen bridges in the dimeric complexes or by direct metal–metal bond comparable to that found in other complexes of molybdenum(IV) which have been reported.[17]

IR spectra

The selected IR frequencies of the dimeric molybdenum(IV)–NAP complexes are given in Table 2. The IR spectra of $Mo_2O_4(L)_2(H_2O)_2$ complexes contain five bands assignable to the



moiety. The strong bands observed at 965–945 cm^{-1} are due to terminal Mo=O vibrations. The antisymmetric stretching mode is not found. However the presence of the symmetric stretching mode is quite sufficient to designate a *cis* disposition of the two terminal Mo=O in the dimeric complexes.[18] The antisymmetric and symmetric vibrations due to the Mo—O bridge are found at 680–658 and 452–425 cm^{-1}, respectively. These values are in good agreement with those found in complexes suggested to have an MoO_2Mo bridge.[17,19,20] All these complexes exhibit strong and broad bands at 3500–3110 cm^{-1} which are assigned to coordinated water. The Mo—N bond is confirmed by the presence of the medium intensive band at 356–334 cm^{-1}.

Bands observed in the 2860–2825 cm^{-1} region

Table 2. IR absorption maxima (cm^{-1}) of molybdenum(IV)–NAP complexes

Complex	ν_s(Mo=O)	ν_a(Mo—O_b)	ν_s(Mo—O_b)	ν(Mo—N)	$\nu(H_2O)$

					3442

of the NAP IR spectra may be assigned to the heterocyclic nitrogen atom attached to an alkyl group.[21] In the IR spectra of the corresponding complexes, this band is either disappeared or has been shifted to higher frequency ($\Delta\nu = 30$–$40\,cm^{-1}$) suggesting the coordination of heterocyclic nitrogen atom.

In NAP, R_3NH^+ interaction with Cl^- gives rise to a broad band in the 2500–2300 cm^{-1} region.[22] A broad band observed at 2600–2350 cm^{-1} region in the IR spectra of the ligands corresponds to the $CH_2NR_2H^+$ (R = Me, Et or Bu) together with X^- (X = Cl, PO_4, malonate and maleinate). In the IR spectra of the corresponding complexes of molybdenum(IV), this band has totally disappeared indicating that the tertiary nitrogen atom of the side chain is the another site of coordination.

Visible and UV spectra

All the complexes studied here show a peak or shoulder at 652–742 and 530–598 nm, which are assigned to $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions,[17,19] respectively. The three bands observed at 306–320, 272–300 and 250–262 nm are attributed to intraligand transitions. The electronic spectra of the NAP also consist of three bands at the same wavelength and differences are not significant.

TGA and DTA

TG studies indicate that the decomposition pattern consists of two steps (Table 4). The first step consists of the loss of water molecules at 118–184°C. The second step involves the decomposition of the organic moiety and oxidation until the formation of MoO_3. In the above two cases, the intermediate was revealed by elemental analysis and IR data and the end product was identified by X-ray diffraction method (Table 5). The DTA studies show that the loss of water molecules is accompanied by an endothermic process at ~140°C and the formation of MoO_3 at 590–698°C by an exothermic process.

Interactions of molybdenum(IV)–NAP complexes with some biologically important and potential ligands

The interactions of molybdenum(IV)–NAP complexes with biologically important ligands such as L-cysteine, L-histidine and potential ligands like 1,10-phenanthroline and 2,2′-bipyridyl were carried out to find the ease of substitution of the coordinated ligands. These interactions result in the immediate formation of solid complexes by displacement of the phenothiazine ligands. The molybdenum(IV) complexes thus obtained are quite stable for long periods. They exhibit low magnetic moments in accordance with the dimeric molybdenum(IV)–NAP complexes due either to spin–spin interaction or to direct metal–metal bond.

The analytical and magnetic data are given in Table 6, show that there is no significant change in the composition or structure of the substituted products.

The IR spectra of all these complexes possess a strong band at 970–930 cm^{-1} assigned to the stretching vibration of the Mo=O group. The bridged vibrations of the Mo=O group are

Table 3. Electronic spectra of molybdenum(IV)–NAP complexes

observed at 752–740 and 462–434 cm^{-1}. The medium intensive bands at 3224 and 3218 cm^{-1} in the molybdenum(IV)–cysteine complex and at 3240 and 3232 cm^{-1} bands in the molybdenum(IV)–histidine complex are assigned to NH_2 stretching modes. In these complexes, the COO group exhibits bands at 1654–1588 cm^{-1}. For complexes with 1,10-phenanthroline and 2,2′-bipyridyl, the assignments of bands to metal–oxygen bridge vibrations[23–25] are become uncertain because of the ligand vibrations in the same region (800–700 cm^{-1}). The presence of 1,10-phenanthroline is shown by the characteristic bands at 1632, 1420, 1308, 846 and 732 cm^{-1}. The weak band at 788 cm^{-1} and the strong band at 772 cm^{-1} indicate the coordination of 2,2′-bipyridyl in the complex. The medium band at 345 cm^{-1} in all complexes is attributed to the Mo—N bond. The strong and broad bands at 3465–3218 cm^{-1} are assigned to coordinated water. These assignments are consist-

(*Received* 7 *March* 1986; *accepted after revision* 24 *July* 1986)

Abstract—The preparation and characterization of Ru(II)–arene compounds $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-L-L})]$ where *p*-cym = *p*-$MeC_6H_4CHMe_2$; and L-L = diphenylphosphinomethane (**I**), 1,1′-bisdiphenylphosphinoferrocene (**II**), pyrazine (**III**) and 4,4′-bipyridine (**IV**), are described. Electrochemical data for these compounds obtained by cyclic voltammetry and coulometry are reported. The electrochemical reduction of compounds **I** or **II** yields ruthenium(0) species. However, compounds **III** or **IV** containing ligands with delocalized π orbitals undergo one-electron reduction. The ESR signal detected during the electrolysis of compounds **III** or **IV** is consistent with one delocalized electron through the whole dinuclear unit.

The electrochemical oxidation of dinuclear Ru(II)–Ru(II) compounds has been extensively studied.[1–3] In some cases two single-electron transfer processes are observed and the mixed valence compound Ru(II)–Ru(III) can be isolated.[1] The electrochemical reduction which would generate *a priori* Ru(II)–Ru(I) or Ru(I)–Ru(I) species has been studied much less.

We have recently described how the electrochemical reduction of compounds of the type $\{RuCl_2(arene)\}_2$ generates Ru(I) compounds of only limited stability in solution at room temperature.[4] The number of Ru(I) compounds described in the literature is very limited and in all the cases where a metal–metal bond is present.[5]

The electrochemical generation of Ru(I) species seems to be possible only if a metal–metal bond can be formed. We assumed that by using adequate bridging ligands we could stabilize binuclear Ru(I)–Ru(I) compounds. So we have prepared and studied the electrochemical properties of several new dinuclear ruthenium compounds containing phosphorus bridging ligands. Other compounds containing nitrogen ligands with delocalized π orbitals are also studied.

EXPERIMENTAL

All solvents were reagent grade and were degassed and dried prior to use by standard procedures. All the reactions were carried out under argon using the Schlenk technique, although the isolated compounds were air-stable.

Preparation of the compounds

$\{RuCl_2(p\text{-cym})\}_2$, $\{RuCl_2(p\text{-cym})\}_2$dppe and $[\{Ru_2Cl_3(p\text{-cym})_2\}BPh_4]$ were prepared by literature methods.[6–8]

(*a*) $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-dppm})]$ (**I**). A solution of dppm (77 mg, 0.2 mmol) in CH_2Cl_2 (5 cm^3) was added to a solution of $\{RuCl_2(p\text{-cym})\}_2$ (122 mg,

*Author to whom correspondence should be addressed.

0.2 mmol) in CH_2Cl_2 (10 cm^3). The solvent was evaporated under reduced pressure and upon addition of hexane a red precipitate was formed. The precipitate was filtered, washed with hexane and dried *in vacuo*. Yield 72%. Found: C, 50.3; H, 4.9%. Calc. for $C_{45}H_{50}Cl_4P_2Ru_2 \cdot CH_2Cl_2$: C, 51.0; H, 4.7%.

(*b*) $[\{RuCl_2(p\text{-cym})\}_2\{\mu\text{-}Fe(C_5H_4PPh_2)_2\}]$ **(II)**. A solution of $Fe(C_5H_4PPh_2)_2$ (73 mg, 0.13 mmol) in CH_2Cl_2 (3 cm^3) was added to a solution of $\{RuCl_2(p\text{-cym})\}_2$ (80 mg, 0.13 mmol) in CH_2Cl_2 (6 cm^3). Hexane was added and the solvent evaporated under reduced pressure. The red precipitate was filtered, washed with hexane and dried *in vacuo*. Yield 87%. Found: C, 56.1; H, 5.1%. Calc. for $C_{54}H_{56}Cl_4FeP_2Ru_2$: C, 55.6; H, 4.8%.

(*c*) $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-pyz})]$ **(III)**. A solution of pyrazine (16 mg, 0.2 mmol) in CH_2Cl_2 (3 cm^3) was added to a solution of $\{RuCl_2(p\text{-cym})\}_2$ (122 mg, 0.2 mmol) in CH_2Cl_2 (10 cm^3). At 10 min the solution was cloudy and in 1 h the precipitation of an orange-yellow compound was completed. The precipitate was filtered, washed with CH_2Cl_2 and dried *in vacuo*. Yield 70%. Found: C, 39.8; H, 4.6; N, 3.7%. Calc. for $C_{24}H_{32}Cl_4N_2Ru_2$: C, 41.0; H, 4.5; N, 4.0%.

(*d*) $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-4,4'-bipy})]$. **(IV)**. A solution of 4,4'-bipyridine (39 mg, 0.25 mmol) in CH_2Cl_2 (5 cm^3) was added to a solution of $\{RuCl_2(p\text{-cym})\}_2$ (153 mg, 0.25 mmol) in CH_2Cl_2 (15 cm^3). The solution was stirred for 2 h at room temperature, during which a yellow precipitate was formed. The precipitate was filtered, washed with CH_2Cl_2 and dried *in vacuo*. Yield 76%. Found: C, 46.3; H, 4.6; N, 3.3%. Calc. for $C_{30}H_{36}Cl_4N_2Ru_2$: C, 46.8; H, 4.6; N, 3.6%.

Instrumental

IR spectra were recorded on a Pye–Unicam SP-2000 spectrometer. NMR spectra were recorded on a Brucker AC-200 spectrometer. ESR spectra were recorded on a Varian E-12 spectrometer provided with a 100 kHz field modulation. The g factor was obtained by means of relation $g = 0.714484\nu$ (MHz)/H(G) where the magnetic field H (in Gauss) at the sample was measured using a Gaussmeter and the microwave frequency (ν) (in MHz) was measured with a high precision frequency meter.

For complicated spectra the hyperfine coupling constants were obtained by comparing experimental and computer-simulated spectra, assuming a Lorentzian line-shape.

The electrochemical experiments were carried out in a three-electrode cell. The working and auxiliary electrodes were platinum, the reference was a saturated calomel electrode, electrically connected to the non-aqueous solution by a "salt-bridge" containing the non-aqueous solvent and the supporting electrolyte.

Cyclic voltammograms were obtained with a programming function generator 305 H.Q. Instruments which was connected to a 552 Amel potentiostat and recorded with a Riken-Denshi F 35 x–y recorder.

The solvents were THF, freshly distilled over Na–benzophenone and DMSO dried by elution through a column of activated alumina and distilled under reduced pressure. The supporting electrolyte was Bu_4NPF_6 recrystallized from ethanol and dried at 80°C *in vacuo* for 48 h.

In order to prove the presence of paramagnetic binuclear Ru(II)–Ru(I) species, we carried out simultaneous ESR and electrochemical experiments. The electrolysis is performed by placing a special flat cell inside the microwave cavity of the X-band spectrometer. We used the Willmad and Glass Co. Electrolytic Cell Assembly for ESR studies.

To obtain ESR spectra with high resolution, we prepared dilute solution of the studied compounds (1 mM) and used very low microwave power (2–5 mW). The solutions were degassed for 30 min to avoid the scavenging effect of dissolved oxygen. All the electrochemical experiments were carried out under an inert atmosphere.

RESULTS AND DISCUSSION

Compounds I–IV are prepared by reacting $\{RuCl_2(p\text{-cym})\}_2$ with a stoichiometric amount of the ligand L-L in CH_2Cl_2 at room temperature. Compounds **III** and **IV** are of limited solubility in CH_2Cl_2 or THF and all the spectroscopic and electrochemical measurements have been performed in DMSO. The compounds are non-electrolytes in solution. (The measurements of conductivity were carried out in CH_2Cl_2 for compounds **I** or **II** and in DMSO for compounds **III** or **IV**.)

^1H and ^{31}P NMR spectra support the dinuclear stoichiometry $[(p\text{-cym})RuCl_2(\mu\text{-L-L})RuCl_2(p\text{-cym})]$ proposed for these compounds (Table 1). Compounds **I** and **II** show singlet signals in the ^{31}P NMR spectra at 21.1 and 18.3 ppm, respectively, indicating that both phosphorus nuclei are coordinated.

The four protons of the pyrazine ligand in compound **III** are equivalent and they appear as a sharp resonance at $\delta = 9.03$ ppm. Both C_5H_4N moieties of the bipy ligand in compound **IV** give two doublets in the ^1H NMR spectrum at 9.1 and 7.4 ppm ($J = 7$ Hz). All the proton resonances corresponding to the *p*-cymene ligand are also observed for compounds **I–IV**.

[d]Reversible anodic peak.

A compound of stoichiometry $[RuCl_2(p\text{-cym})(dppm)]$ has been previously described,[9] suggesting that the phosphine coordinates to the ruthenium atom only through one phosphorus atom. We have repeated the reported preparative method, obtaining the same spectroscopic and analytical results as for compound **I**. The bidentate coordination of dppm ligand is evident from the analytical data and from the integration of the ^1H NMR signals which fit better a bimetallic stoichiometry.

Electrochemical data

Table 2 summarizes the electrochemical data for compounds **I–IV** as well as for $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-dppe})]$ (**V**) and $[\{Ru_2(Cl_3(p\text{-cym})_2\}BPh_4]$ (**VI**). Compounds containing phosphorus ligands reduce at higher potential values. $Fe(C_5H_4PPh_2)_2$ behaves as a stronger electron donor ligand than dppm or dppe and consequently compound **II** reduces with more difficulty than compounds **I** or **V**. Only one reduction peak is observed for compounds **I–IV**, while compound **V** shows some splitting in the first process.

Potential-controlled electrolysis on the plateau of peak A_1 gives a consumption of 4 F mol^{-1} for compounds **I**, **II** and **V**. This indicates that in A_1 a complicated process yielding Ru(0) species takes place.

According to this, these three compounds do not show any clear tendency to stabilize the oxidation state (I) as observed for $\{RuCl_2(p\text{-cym})\}_2$. They behave like other mononuclear compounds such as $RuCl_2(p\text{-cym})PPh_3$. This compound shows two close reduction peaks, A_1 (−1.54 V) and A_2 (−1.64 V) each corresponding to one-electron transfer processes.

Compounds **I**, **II** and **V** oxidize reversibly with **II** showing the lowest oxidation potential.

Another aspect related to the electrochemical behaviour of $\{RuCl_2(p\text{-cym})\}_2$ is the fact that the first reduction peak A_1 at −0.98 V corresponds to the simultaneous reduction of both Ru atoms. No evidence of an intermediate Ru(II)–Ru(I) species has been observed.

We considered the cationic species $\{Ru_2Cl_3(p\text{-cym})_2\}^+$ an interesting compound to generate Ru(II)–Ru(I) species. As cationic compounds usually reduce at lower potentials than neutral ones with the same oxidation state, we should expect $\{Ru_2Cl_3(p\text{-cym})_2\}^+$ to show a separate reduction peak corresponding to Ru(II)–Ru(II) → Ru(II)–Ru(I) process. This compound reduces at −0.74 V. The exhaustive electrolysis at this potential value gives a consumption of 1 F mol^{-1}. From the resulting solution, $\{RuCl_2(p\text{-cym})\}_2$ can be isolated in a low yield. This indicates that the product of the reduction is not stable and shows a chemical evolution, probably such as Ru(II)–Ru(I) → Ru(II)–Ru(II) + Ru(I)–Ru(I). EPR measurements on the reduced solution of $\{Ru_2Cl_3(p\text{-cym})\}^+$ fail to show any evidence of a paramagnetic species in solution.

Another possible way to stabilize mixed valence species might be the use of bridging ligands capable of delocalizing electron density as pyrazine or 4,4'-bipyridine.

The complexes $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-pyz})]$ and $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-4,4'-bipy})]$ show a monoelectronic reduction peak at −1.28 V assignable to the Ru(II)–Ru(II) → Ru(II)–Ru(I) process. This reduction peak is in both cases irreversible. A second reduction peak is also observed for each compound. The potential values for the second peak are very similar to the reduction potential values of the corresponding ligands pyz and 4,4'-bipy.

The reduced species are fairly stable in solution and have been detected by ESR spectroscopy. The

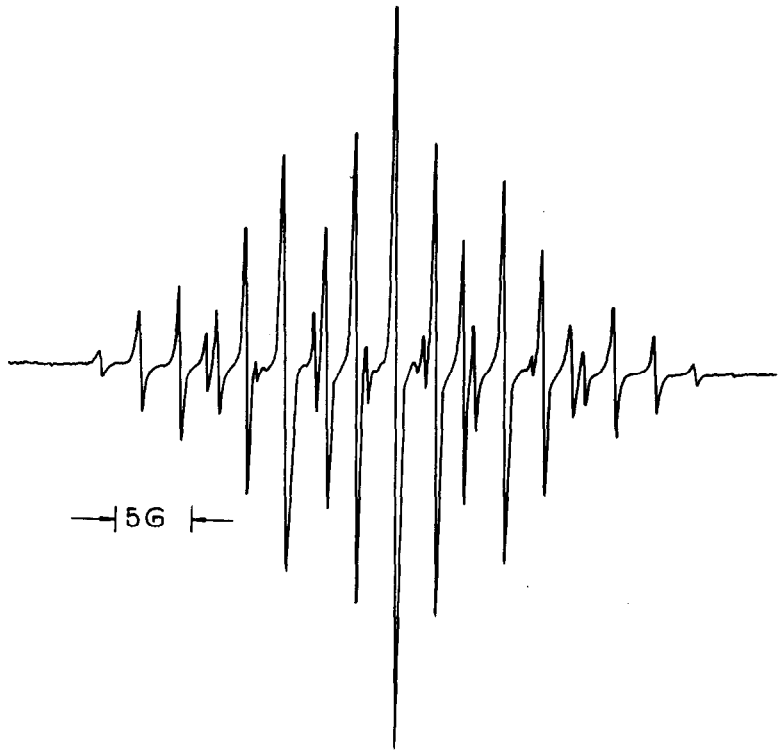

Fig. 1. EPR spectrum of reduced [{$RuCl_2$(*p*-cym)}$_2$(μ-pyz)].

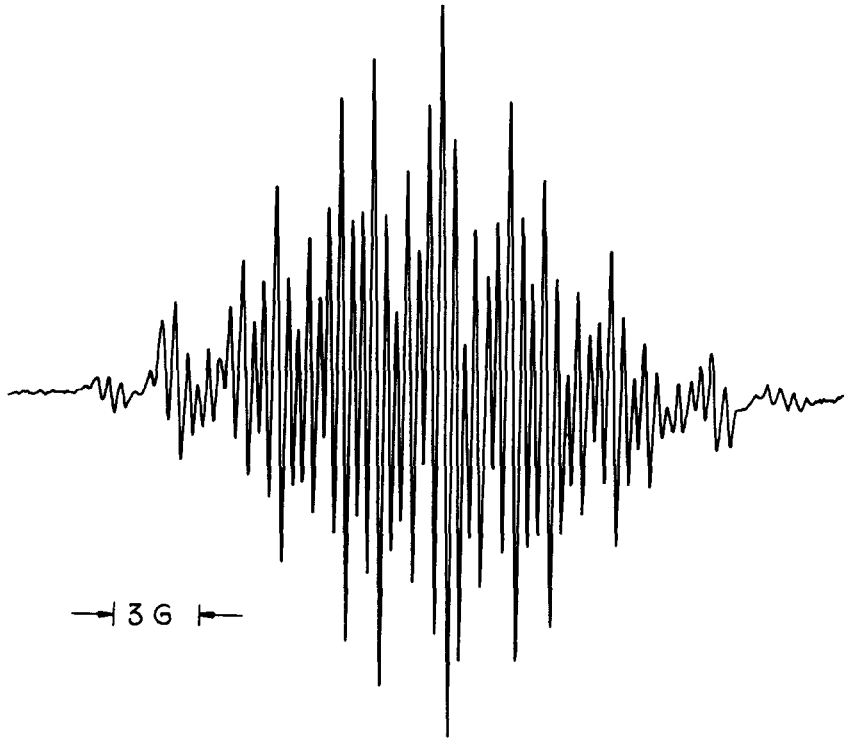

Fig. 2. EPR spectrum of reduced [{$RuCl_2$(*p*-cym)}$_2$(μ-4,4′-bipy)].

ESR spectra obtained are shown in Figs 1 and 2. These spectra are very well resolved and show a metal–ligand isotropic superhyperfine interaction. The spectrum of the reduced complex $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-pyz})]$ is composed of two quintets with the following hyperfine splittings: $a_N = 7.20$ G and $a_H = 2.65$ G (pyrazine ring protons). Its g factor is 2.0036.

The spectrum of the reduced complex $[\{RuCl_2(p\text{-cym})\}_2(\mu\text{-4,4'-bipy})]$ is complicated and from its analysis by simulation assuming Lorentzian line-shape, three hyperfine coupling constants were obtained, whose values (in G) are: 3.50 (Q, 1:2:3:2:1), 2.35 (Q, 1:4:6:4:1) and 0.45 (Q, 1:4:6:4:1). The first quintet corresponds to the nitrogen splittings and we assign the quintets with 2.35 and 0.45 G to the *ortho* and *meta* protons of the bipyridine rings, respectively. This assignment is based on the analysis of the canonical structure of this compound. Its g factor is 2.0030. Further studies of these and other related ruthenium arene complexes containing ligands with delocalized π orbitals are in progress.

COMMENTS ON THE CLAIMED NOVEL COMPOUND CYCLOHEPTATRIENYL THALLIUM(III) DICHLORIDE

M. B. MILLIKAN and B. D. JAMES*

Department of Chemistry, La Trobe University, Bundoora, Victoria 3083, Australia

(*Received* 1 *July* 1986; *accepted* 24 *July* 1986)

Abstract—Reaction of pyridinium pentachlorothallate(III) with cycloheptatriene and triethylamine in dichloromethane yielded the pyridine adduct $(C_5H_6N)TlCl_4 \cdot C_5H_5N$ and not the novel complex originally claimed. Cycloheptatriene does not interact at all with the metal under the experimental conditions.

Cycloheptriene forms well-known complexes of the $C_7H_7^+$ ligand when a hydride has been abstracted from the parent hydrocarbon. The ligand formally is a six-electron donor akin to $C_5H_5^-$ and C_6H_6. Similarly, a formal seven-electron donor function is obtained if a hydrogen atom is abstracted (e.g. by using Pt).[1,2] A third ligating function has been claimed for cycloheptatriene: namely that of acting as $C_7H_7^-$ after proton abstraction from the parent. This was proposed on the basis of a number of reactions reported with various transition metal chlorides such as $TaCl_5$ and $WOCl_4$ in refluxing benzene, when hydrogen chloride was evolved.[3,4]

An extension of this function to Main Group compounds of Sn(IV), Pb(IV) and Tl(III) was also claimed, although only the thallium reaction has apparently been published.[5] The reaction involved the interaction of pyridinium pentachlorothallate(III) with the hydrocarbon in dichloromethane, using triethylamine as a proton abstractor:

$$(C_5H_6N)TlCl_5 + C_7H_8 + (C_2H_5)_3N \rightarrow C_7H_7TlCl_2 + 2C_5H_6NCl + (C_2H_5)_3NHCl.$$

On the basis of the reported IR spectral frequencies, a π-bonding function for the C_7 ligand was suggested. This seemed unusual because cyclic hydrocarbon derivatives of Group III metals do not generally form well-defined π-bonded complexes in the same manner as transition metals. For example, the species $C_5H_5MR_2$ (M = Al, Ga or In; R = CH_3, C_2H_5) appear to form a series in which the C_5 ring is not bonded in a η^5 manner.[6] Likewise none of the rings in tris(cyclopentadienyl) indium can be classified as π-bonded in the 'sandwich' manner.[7] While the large Tl(III) cation probably could accommodate a π-bonded planar ring, it seemed more likely that the marked stability of di-organothallium(III) compounds would tend to force a product to that stoichiometry or, alternatively, sufficient electron density would be donated to the metal to cause its facile reduction to the +I state.[8]

Of further interest to us was the reactivity of the chlorothallate reagent. Leaving aside for the moment the confusion over whether the authors' description of the use of the pentachlorothallate really meant that reagent,[9] it appeared to be a possibility that one mole equivalent of the amine added to $(C_5H_6N)_2TlCl_5$ could form a donor–acceptor complex as was found with dimethylsulfoxide.[10] In addition, unless the product was exceptionally stable, it seemed unlikely that cycloheptatriene ($pK_a \sim 30$[11]) would be deprotonated by the amine under the mild reaction conditions reported. In view of the novel nature of the reported compound, we have reinvestigated the stated synthetic procedure, using both $(C_5H_6N)_2TlCl_5$ and $(C_5H_6N)TlCl_4$ as starting materials.

EXPERIMENTAL

Pyridinium salts of $TlCl_5^{2-}$ and $TlCl_4^-$ were prepared from Tl_2O_3 as described previously[9,12] and triethylamine and cycloheptatriene of good commercial quality were purified according to the directions given by Perrin *et al.*[13] Reactions were

[a]Microanalyses were performed by AMDEL, Melbourne or by Malissa and Reuter, Engelskirchen, F.R.G. Values in parentheses are those calculated for the product suggested.

performed in a N_2-filled glovebox and manipulations were performed using appropriate vacuum line procedures when necessary.

The reaction described by Kumar and Sharma[5] was performed with both possible chlorothallate starting materials as described below.

(i) *Using* $(C_5H_6N)_2TlCl_5$. Equimolar quantities (10 mmol) of pyridinium pentachlorothallate (5.4 g), cycloheptatriene (0.92 g) and triethylamine (1.0 g) were mixed in CH_2Cl_2 (350 cm^3) and left to stand for ½ h at 18°C in a glovebox. A slight turbidity was observed and was removed by filtration through a G4 frit. This operation caused some white crystals, m.p. 151°C, to precipitate in the filtrate. Once these had been removed, the remainder of the filtrate was concentrated on a vacuum line and yielded two more crops of the same material, m.p. 151°C. Microanalysis: sample A (Table 1).

(ii) *Using* $(C_5H_6N)TlCl_4$. The above procedure was repeated with equimolar quantities (2 mmol) of $(C_5H_6N)TlCl_4$ (1.0 g), triethylamine and cycloheptatriene. After 1 h, a slightly cloudy orange solution was obtained which was filtered to remove the very fine suspension. Part of the resulting solution was concentrated on a rotary evaporator (under a N_2 bleed), while the remainder was concentrated on a hot-water bath in the air. Both methods yielded a brown-orange oil, but operations in air result in the oil decomposing faster as evidenced by its progressive darkening.

The oil obtained from the rotary evaporator was examined by ^{13}C NMR spectroscopy (JEOL JNM-PS-100 PFT instrument operating at 25 MHz; ~600 pulses, 2.5 s repetition time; $CDCl_3$ solution) (Table 2).

The potential for triethylamine and cycloheptatriene to react separately with each of the chlorothallate reagents was examined as described below.

Reactions with triethylamine

(i) *Pyridinium pentachlorothallate*(III). To a solution of $(C_5H_6N)_2TlCl_5$ (2 g, 4 mmol) in 200 cm^3 CH_2Cl_2 was added an equimolar amount of triethylamine (0.51 cm^3). The mixture was allowed to stand for 1 h after which the cloudiness was removed using filter aid and the resulting clear solution was concentrated on a vacuum line. The white solid which separated on concentrating the solution had a m.p. 144–145°C. Microanalysis: sample B (Table 1).

(ii) *Pyridinium tetrachlorothallate*(III). A similar reaction was performed using $(C_5H_6N)TlCl_4$ (1.0 g, 2.3 mmol) and triethylamine (0.35 cm^3). The slightly cloudy orange solution obtained after ~1½ h was filtered and separated into two portions. One of these was evaporated quickly on a vacuum line and the oil so obtained was redissolved in $CDCl_3$ for a ^{13}C NMR spectrum. The remainder was concentrated on a hot water bath and also yielded an oil from which thallium(I) chloride precipitated over some hours.

Reactions with cycloheptatriene

(i) *Pyridinium pentachlorothallate*(III). To a solution of $(C_5H_6N)_2TlCl_5$ (1.92 g, 3.5 mmol) in 300 cm^3, was added cycloheptatriene (0.37 cm^3) and the mixture allowed to stand for ~1 h after which it was concentrated on a vacuum line to yield a white solid, m.p. 130°C. Microanalysis: sample C (Table 1).

(ii) *Pyridinium tetrachlorothallate*(III). In a similar reaction, $(C_5H_6N)TlCl_4$ (1.0 g, 2.3 mmol) was mixed with cycloheptatriene (0.25 cm^3) in CH_2Cl_2 (300 cm^3). The very fine white solid which developed over ~4 h was removed by filtration and the filtrate was concentrated on a vacuum line to yield a crystalline material. Microanalysis: sample D (Table 1).

RESULTS

Microanalytical data obtained on the precipitated products are given in Table 1, while the ^{13}C NMR spectra obtained on the oily products are presented in Table 2. Samples A and B appear to be chlorothallate–pyridine adducts and their IR spectral data are given in Table 3.

DISCUSSION

It is quite clear from the results obtained here that an 85% yield of a red-brown compound with formula $C_7H_7TlCl_2$ was not obtained under the conditions described by Kumar and Sharma.[5] From the pentachlorothallate(III) starting material, the colorless product obtained analyzed well for the adduct $(C_5H_6N)TlCl_4 \cdot C_5H_5N$ and this formulation was supported by the IR spectrum which displayed vibrations characteristic of coordinated pyridine[14] in addition to those of the pyridinium ion (Table 3). Evidence for interaction of the metal with cycloheptatriene was not forthcoming. Using the tetrachlorothallate(III) instead, an orange oil could be isolated, but this was unstable at room temperature and decomposed within 5 h. The ^{13}C NMR spectrum obtained while the sample was still fresh showed that those peaks which were due to cycloheptatriene were virtually unchanged from those of the pure hydrocarbon (Table 2). Certainly, they bore no resemblance to those spectra which have been reported for authentic η^7-C_7H_7 or even for η^6-C_7H_8 complexes, in which considerable shifts are observed for the various C resonances.

In the absence of the amine, cycloheptatriene also did not interact with the thallium center. Its addition to a solution of $(C_5H_6N)_2TlCl_5$ caused $(C_5H_6N)_3Tl_2Cl_9$ to separate. It appears that the hydrocarbon merely changes the properties of the solvent, so as to shift the chlorothallate equilibrium in favor of the rather stable enneachloride. With $(C_5H_6N)TlCl_4$, somewhat impure starting material was the only solid product obtained.

Any orange colors which were observed appeared to arise from oxidation of the amine by $(C_5H_6N)TlCl_4$. Highly colored materials have been

[a]From Ref. 4.

recognized from such reactions for many years, but these have not been investigated further.[8] There was a small (~2.5 ppm) downfield shift for the C_1 atom of the amine when the reaction occurred. This change in the NMR spectrum was, however, very much larger than was observed for any of the carbon atoms of the cycloheptatriene.

It is evident, then, that the major role of the amine in the reaction mixture is to remove a proton from the pyridinium cation rather than from the cycloheptatriene, which thus remains unreacted. Free pyridine is thereby released and is able to form an adduct with one of the chlorothallate species in solution. Such proton transfer behavior is quite consistent with the relative acidities of the species involved: cycloheptatriene, being an exceptionally weak acid, while triethylamine ($K_b = 5.6 \times 10^{-4}$) is a stronger base than pyridine ($K_b = 2.3 \times 10^{-9}$).[15]

Consequently, we remain unconvinced of the π-cycloheptatrienyl thallium(III) dichloride reported by Kumar and Sharma and are left querying whether some essential experimental details were omitted from their paper. We have had cause to complain before about what appeared to be unreliable analytical procedures employed by this group[9,16] but in this instance in which there appears to be no resemblance at all to the product claimed, the standard of the work appears to be very disappointing.

THE SOLUBILIZATION OF METALLIC GOLD AND SILVER: EXPLANATION OF TWO SIXTH-CENTURY CHINESE PROTOCHEMICAL RECIPES

ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL,*
SHEILA M. GLIDEWELL and SHAREE E. PRITCHARD

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

and

JOSEPH NEEDHAM

The Needham Research Institute, East Asian History of Science Library, Cambridge CB2 2BB, U.K.

(*Received* 28 *April* 1986; *accepted* 24 *July* 1986)

Abstract—According to two early Chinese protochemical procedures, metallic gold and silver can be brought into solution by a mixture of nitre and vinegar, together with iron(II) sulphate and various organic additives, respectively. We conclude that for the solubilization of gold, iodide formed by reduction of iodate, a common impurity in crude nitrate deposits, is required, but that the nitrate has no role other than to introduce the iodate: for the solubilization of silver, nitrite formed by reduction of nitrate by organic matter is essential. The role of iron(II) sulphate in the solubilization of gold appears to be the reduction of iodate.

The properties of gold have exerted a unique fascination from the earliest times[1,2] to the present day.[2,3]

Because of its ability to resist corrosion, medieval Chinese protochemists considered gold as one of the keys to immortality. By its consumption it was hoped a man would be able so to refine his body so that he would never grow old or die. Moreover, Ko Hung, in the *Bao-pu zi*, a text of *ca.* AD 300 indicates that artificial 'Alchemical Gold' was regarded as superior to natural gold as an ingredient of the elixirs of immortality. The challenge was to render gold in a form suitable for use as a drug.

Consequently the two techniques of aurifaction (the conversion of other materials into gold; cf. aurifiction, involving wilful deceit[2]) and of solubilization to form potable gold were of the utmost importance, and upon them much effort was expended. To understand the practical, as well as the philosophical, background of the protochemists of early medieval China it is important that these techniques be subjected to experimental scrutiny.

One published method for the production of potable gold is that described in the protochemical manual, the *San-shi-liu Shui Fa*[4] (*Thirty-six Methods for the Bringing of Solids into Aqueous Solutions*). Needham *et al.*[5] have published a full translation of this text, and have dated it as of about the sixth century AD. However, some of the procedures described in the *San-shi-liu Shui Fa* probably date from as early as the second century BC:[5] some are described in the *Bao-pu zi* of Ko-Hung, and others come from the *San-shi-liu Shui Ching* (*Manual of the Thirty-six Aqueous Solutions*) which predates Ko Hung. As printing was in use in China during the eighth century AD, it is probable that the copy of the *San-shi-liu Shui Fa* which survives is an accurate reproduction of the sixth-century original. While the *San-shi-liu Shui Fa* is tersely written with precise and unambiguous instructions for bringing various minerals into solution, many of the procedures appear at first sight to be rather startling, for example the solubilization

*Author to whom correspondence should be addressed.

of mercury sulphide or of elemental lead using only very dilute acetic acid (vinegar), and potassium nitrate (nitre), together with copper sulphate in the case of mercury sulphide.

However, experimental study of the solubilization of mercury sulphide showed[6] that in the presence of chloride, a common impurity in naturally occurring nitre, dissolution of HgS proceeds readily with formation of $HgCl_2$ and sulphate: similarly, the solubilization of elemental lead was shown[7] to be dependent upon the presence of traces of nitrite, again a common impurity in nitre exposed to organic materials such as the hollow bamboo tubes prescribed[5] as the reaction vessels. Given the presence of only chloride or nitrite, respectively, the otherwise wholly insoluble mercury(II) sulphide and metallic lead readily dissolve in dilute acetic acid/nitre mixtures, confirming the accuracy at least for these two procedures of the observations recorded in the *San-shi-liu Shui Fa.*

The procedure for the production of tin(IV) sulphide (mosaic gold) described in the *Bao-pu zi* of Ko Hung, provides a further example of the accuracy of observation and description displayed by the early Chinese protochemists: according to the essentials of this recipe, mosaic gold (SnS_2) is produced by heating elemental tin with potassium alum, $KAl(SO_4)_2$. This would require the sulphate ion to act as a powerful oxidant, itself being reduced to sulphide. Experimental study of Ko Hung's procedure confirms the formation of SnS_2 from alum or, more simply, from aluminium sulphate:[8]

$$\rightarrow \tfrac{2}{3}\,Al_2(SO_4)_3 + 4Sn \rightarrow \tfrac{2}{3}\,Al_2O_3 + 3SnO_2 + SnS_2.$$

Thermochemical calculations on this, and similar processes, indicate[8] that the principal driving force for the reaction is the formation of tin(IV) oxide, but that most metal sulphates should be capable of oxidising elemental tin to ($3SnO_2 + SnS_2$). Similarly aluminium sulphate should be capable, thermodynamically, of oxidising elemental hydrogen to ($3H_2O + H_2S$):[9] experimental verification of this point predates its thermochemical prediction by *ca.* 150 years.[10]

The experimental verification[6–8] of the essential correctness of three apparently remarkable recipes from the *San-shi-liu Shui Fa* and the *Bao-pu zi* indicates most strongly that chemical procedures given in early Chinese sources, no matter how unlikely they may at first appear in the content of modern chemical knowledge, ought not to be dismissed without experimental investigation.[11]

The solubilization of gold

The *San-shi-lui Shui Fa* procedure is as follows:[4,5]

(29) *Huang-jin shui*—an aqueous solution of gold. 1 lb of gold and 2 lb of green vitriol (*lü fan*), sealed in a bamboo tube with lacquer and placed in vinegar for 50 days will form an aqueous solution.

Green vitriol is the mineral copperas or melanterite, iron(II) sulphate heptahydrate, $FeSO_4 \cdot 7H_2O$ (but see below). Unlike most of the *San-shi-lui Shui Fa* recipes, this procedure does not explicitly mention the addition of nitre, just as one of the recipes for dissolution of mercury sulphide does not include the addition of any liquid phase, although vinegar is clearly required.[5,6] However the commentary in the *Huang-Di Jiu Ding Shen Dan Jing Jue* (*Explanation of the Yellow Emperor's Manual of the Nine-vessel Magical Elixir*)[12] states that 'all the methods depend upon the use of nitre'.[5] Needham *et al.* regard the occasional omission of similar vinegar or nitre from the directions given in the *San-Shi-liu Shui Fa* as no more than inadvertence, or considered unnecessary by the author.

The recipe as it stands immediately poses problems: Needham comments[5] that 'one cannot feel that the gold recipe gave the alchemists much satisfaction'. Uniquely amongst the metallic elements, gold forms no aqua ions which are stable in aqueous media, and hence in the absence of coordinating ligands gold cannot be oxidized from the elemental state at any pH in aqueous solution.[13] To dissolve metallic gold in aqueous media, both an oxidizing agent and a good coordinating ligand for a class b (soft) metal ion are required: neither alone is sufficient. Both acetate and nitrate are extremely poor ligands towards soft cations, and hence it seemed probable that any dissolution of metallic gold in acetic acid/potassium nitrate mixtures would be dependent upon the presence of specific impurities, as found for the dissolution in such media of mercury(II) sulphide[6] and of metallic lead.[7]

We first confirmed that acetic acid/potassium nitrate mixtures do not dissolve metallic gold. Under our normal experimental conditions (see Experimental section) we estimate that dissolution of as little as 0.5% of the original charge of metallic gold would be accurately and reproducibly measurable. In fact in these experiments, no gold was detected in solution even after a reaction time of 70 days, thus confirming the requirement of an impurity if any gold is to be brought into solution by such a solution.

We then surveyed the effects not only of iron(II)

salts and potassium alum, a common ingredient in the recipes of the *San-shi-liu Shui Fa*, but also of likely impurities in the potassium nitrate. The production of potassium nitrate, by extraction from soil, remained as a primitive technique from ancient times until well into the present century,[14] and the composition of the end-product varied widely depending upon the area of production. While samples containing up to 97% KNO_3 were found[14] in some areas, other samples contained as little as 50% ($NaNO_3 + KNO_3$): with nitrate contents averaging ~70–75%, the scope for various active impurities to be present is wide.

Potassium alum, a common ingredient in *San-shi-liu Shui Fa* procedures, was without effect, as were the iron(II) salts, iron(II) chloride, sulphate, and gluconate. The impurities found earlier to be important in the solubilization of mercury (II) sulphide[6] and metallic lead,[7] namely chloride and nitrite, respectively, were also wholly ineffective, as was iodate(V), $[IO_3]^-$. Of the plausible impurities, only iodide is really effective in promoting the solubilization of gold, although bromide has a very modest effect. Further investigation showed that not only was nitrite wholly ineffective alone, and in combinations with iron(II) salts, with chloride, or with potassium alum, but that it completely suppressed the solubilizing action of iodide, by oxidizing it all to elemental iodine. Iodine was shown independently to be entirely ineffective as an additive, although a mixture of iodide and iodine, i.e. tri-iodide $[I_3]^-$, was extremely active. These observations all support the view that the primary role of the iodide is to act as a complexation agent towards gold and that any further additive in combination with iodide which destroys this capability will suppress the solubilizing action of iodide.

For standard 10-mg charges of gold wire in acetic acid/potassium nitrate mixture in the presence of added potassium iodide, the extent of dissolution increases with time for any non-zero level of iodide added, and the rate of dissolution increases with KI level, attaining a constant rate around 5% added KI. When the potassium nitrate was omitted entirely, dissolution still occurred for all non-zero levels of added KI, and the general pattern of the dependence of the reaction upon KI level was unchanged: however, there was a modest, but wholly reproducible *increase* in the rate of dissolution at any level of added KI. Hence potassium nitrate is not an essential requirement for the production of the aqueous gold solutions described in the *San-shi-liu Shui Fa*, save only as a possible means for the introduction of the crucial impurity, iodide.

Examination of the standard reduction e.m.f.s[15] for the half reactions:

$$Au + 2I^- \rightarrow [AuI_2]^- + e^-$$

$$e^- + H^+ + \tfrac{1}{4}O_2 \rightarrow \tfrac{1}{2}H_2O$$

shows that the oxidation of gold, by atmospheric oxygen in the presence of iodide as ligand, is thermodynamically feasible at any pH below 8: hence in dilute acetic acid media, the sole requirements for the solubilization of gold as the iodocomplex $[AuI_2]^-$ are air and iodide ions, and the possible sources of iodide in the *San-shi-liu Shui Fa* recipe must now be considered.

Although iodide is absent from nitrate deposits, iodate $[IO_3]^-$ is a common impurity.[16–18] Iodate is very readily reduced by iron(II), in dilute acetic acid, to yield iodine, although iodide is absent. The standard reduction e.m.f.s[15] show that, in isolation, iron(II) cannot reduce iodine to iodide, but that such reduction is possible in strongly acid media ($pH < 1$) when coupled to the oxidative complexation of gold to yield $[AuI_2]^-$. Such strongly acidic solutions are probably not relevant to the *San-shi-liu Shui Fa* procedure, but organic matter (cf. the use of bamboo tubes sealed with lacquer which are prescribed[5] as reaction vessels in the *San-shi-liu Shui Fa* recipe for the preparation of an aqueous solution of gold) will readily reduce iodine to iodide, as required for the complexation of gold in soluble $[AuI_2]^-$.

Hence the primary role of the potassium nitrate in this recipe is to introduce the common impurity, iodate, as the primary source of the crucial iodide; the role of the iron(II) sulphate is to effect the reduction of iodate to iodine; and the role of the lacquer-sealed bamboo tubes is to act not only as a reaction vessel (for which purpose alone any container would suffice) but, most importantly, as the final reductant of iodine to iodide.

In the published procedure the ingredient *lü fan* was translated[5] as green vitriol, $FeSO_4 \cdot 7H_2O$. However, there is the possibility[19] of confusion of the terms for iron sulphate and copper sulphate, with the possibility therefore that the recipe in the *San-shi-liu Shui Fa* actually calls for blue vitriol instead of green vitriol, i.e. for copper(II) sulphate. The possible involvement of copper is interesting in view of reports[20,21] that metallic gold is somewhat soluble in hot HCl solutions of copper(II) chloride, although much less soluble at normal temperature. However, under similar reaction conditions,[20,21] none of copper(II) sulphate, iron(II) sulphate or iron(III) sulphate in sulphuric acid effected solution unless chloride was added.

Substitution of copper sulphate for iron(II) sulphate has no effect alone on the solubilization of gold, but diminishes the effectiveness of iodide: although, unlike iron(II), copper(II) cannot (cf. Ref. 15) reduce iodate to iodine, it will however readily oxidize iodide to iodine:

$$Cu^{2+} + 2I^- \rightarrow CuI(s) + \tfrac{1}{2}I_2.$$

If *lü fan* were interpreted[5,19] to mean copper(II) sulphate instead of iron(II) sulphate, the quantity prescribed by the recipe[5] would be sufficient to prevent any reduction of iodine-containing precursors to iodide: all would be converted to elemental iodine and the wholly insoluble copper(I) iodide, and solubilization of gold would be prevented. Hence, experiment discounts the possibility that *lü fan* here means copper(II) sulphate and confirms the rendering[5] of this term as iron(II) sulphate.

The solubilisation of silver

We have also investigated briefly the solubilization of metallic silver, for which the *San-shi-liu Shui Fa* procedure[4,5] is as follows:

(30) *Bai-yin shui*—an aqueous solution of silver. 1 lb of silver, 2 pints of clear wheat sauce, 2 pints of vinegar, and 1 pint of wine made from glutinous millet and the fruits of the *mu jing* shrub; sealed in a bamboo tube with lacquer put in vinegar for 30 days will form an aqueous solution.

Glutinous millet (*Qi Shu*) is *Panicum miliaceum*, and *mu jing* is *Vitex negundo*, both medicinal plants.[5,22] As in the gold recipe, no explicit mention is made of nitre: as before its omission is inadvertent. For the sake of simplicity, we have investigated the solubilization of silver only in the context of those components of the *San-shi-liu Shui Fa* procedure which are reproducibly accessible: thus we have omitted all of the organic components, apart from the acetic acid, just as in our previous investigation of the solubilization of cinnabar.[6]

Although silver metal readily dissolves in nitric acid, Mellor records[23] a number of reports in the older literature that it does so only in the presence of nitrite. Preliminary experiments with mixtures of 60% acetic acid with various concentrations of potassium nitrate showed that no dissolution occurred in the absence of added nitrite. For standard 100-mg charges of silver wire in acetic acid–nitre mixtures (see Experimental section) the initial rate of silver dissolution, as measured by the extent of reaction, after 24 h varied linearly with concentration of added nitrite, for nitrite levels between zero and 0.4%.

In weakly acidic aqueous media, as here, the nitrite anion is protonated to yield either the nitrosonium cation, NO^+, or its mono-solvate, the nitrous acidium ion $H_2NO_2^+$:[24,25] the nitrosonium cation has an electron affinity 9.27 eV[26] rather greater than that first ionization energy of silver, 7.57 eV,[27] and hence, even when solvation energies and the sublimation energy of silver are taken into account, the nitrosonium ion is expected to oxidize silver metal, with an overall $\Delta H^{\ominus}$ in aqueous solution of $\sim 80\,kJ\,mol^{-1}$. Consistent with this, we observed that solutions of nitrosonium tetrafluoroborate in either acetonitrile or sulpholane (tetramethylene sulphone) readily oxidized and solubilized metallic silver: the nitronium ion also readily oxidized metallic silver under these conditions although at a higher rate. Thus a 100-mg charge of solver was 49% dissolved after 30 min exposure to $10\,cm^3$ of $0.5\,mol\,cm^{-3}$ $NOBF_4$, but 81% dissolved after 30 min exposure to $10\,cm^3$ of $0.5\,mol\,dm^{-3}$ NO_2BF_4: when the solution was $0.5\,mol\,dm^{-3}$ in each salt, the silver charge was wholly dissolved in 30 min.

These observations confirm that, as in the solubilization of metallic lead,[7] the crucial impurity is nitrite, without which the standard nitre/acetic acid mixture will not effect dissolution. Nitrite is of course readily formed from nitrate in the presence of organic matter acting as a reducing agent, such as the organic components prescribed in the *San-shi-liu Shui Fa* procedure.[5]

The mechanistic role of nitrite has not been investigated in this work, but it is possible that its efficacy depends upon the possibility of a simple one-electron redox reaction with silver, to producing silver(I) and the volatile by-product nitrogen(II) oxide:

$$Ag + NO_2^- + 2H^+ \rightarrow Ag^+ + H_2O + NO.$$

DISCUSSION

Each of the four procedures from the *San-shi-liu Shui Fa* which has been investigated by contemporary chemical techniques, namely the solubilization of mercury(II) sulphide (cinnabar),[6] and metallic lead,[7] gold and silver depends for its effectiveness upon the presence of a highly specific impurity: nitrite for metallic lead or silver, chloride for mercury(II) sulphide, and iodide for gold. We have shown above a plausible source of the iodide in the

original[5] reaction mixture, while chloride is also[28] a common impurity in crude nitre: nitrite is readily formed from nitrate by the reducing agents, such as the organic matter frequently found in *San-shi-liu Shui Fa* procedures.

While in a number of procedures the additives other than nitre and vinegar may appear somewhat capricious, for those examples which we have investigated, these additives appear to have a chemical purpose. Thus in the solubilization of cinnabar,[6] copper sulphate is prescribed[5] as an additive, whose purpose is to catalyse the oxidation by nitrate of the chloride impurity to give elemental chlorine, which in turn acts as the primary oxidant of mercury(II) sulphide, yielding mercury(II) chloride, and sulphite. For the solubilization of metallic silver, which depends upon the formation of nitrite by reduction of nitrate, the original recipe[5] prescribes (see above) the addition of several organic components other than bamboo and lacquer, while the recipe for gold, whose solubilisation has no such requirement for nitrite, prescribes none of these. It is therefore interesting that the recipe[5] for the solubilization of elemental sulphur, which has not yet been reinvestigated in modern times, requires mulberry dew, presumably as a crucial additive.

Potassium alum was found above to exhibit no effect on the solubilization of gold by nitre–vinegar mixtures. Use was made of this lack of action of alum solutions upon gold in early medieval Colombian metallurgy[29,30] in the process of gilding of copper objects, and of enriching in gold the surface of copper–gold alloys (*tumbaga*). Upon heating the alloy or mixture in air, the gold is unaffected but the copper is oxidized to copper(I) oxide, Cu_2O. Experiment shows that aqueous potassium alum solutions are sufficiently acidic to dissolve the copper(I) oxide, while leaving the metallic gold unchanged: repeated application of heat, followed by treatment with the acidic alum solution therefore leads to a surface layer composed almost entirely of metallic gold, even when the original alloy is copper-rich. The process relies first on the ability of air to oxidize copper but r t gold to the metal oxide, and secondly on the solubility of copper(I) oxide, but not gold, in aqueous potassium alum solution.

EXPERIMENTAL

Gold and silver wire, of 0.5 mm diameter, and 99.9% minimum purity were obtained from Alfa, and were used as received. Iodine, of Analar quality, was exhaustively washed with distilled water, dried, and then sublimed. All other chemicals were of the best quality commercially available, and were used as received.

Gold and silver concentrations were measured in solution using a Perkin–Elmer model 360 atomic absorption spectrophotometer, interfaced to a BBC microcomputer for curve analysis and interpolation: multiple sampling (between 5 and 10 aliquots per solution) was routinely employed. All measurements were made on experiments conducted in triplicate.

In a typical experiment, 10 mg of gold wire was placed in 10 cm^3 of aqueous acetic acid (either 30 or 60% w/v) together with appropriate additives. Potassium nitrate, potassium iodide and iron(II) sulphate were at one of the concentrations 0, 0.2, 0.5, 1, 2, 5%; potassium chloride or bromide were at one of 0, 1, 2 or 5%; sodium or potassium nitrite was at 0, 0.5 or 2%; other additives were generally at 0 or 2%. Reaction mixtures were shaken, in air, continuously at 21°C, and the metal concentrations monitored over periods ranging up to 70 days. Under these conditions $[AuI_2]^-$ only is formed: $[AuI_4]^-$ requires[31] large concentrations of free iodine for stability.

^{13}C and ^{14}N ISOTROPIC NMR SHIFTS IN ANIONIC NITRATOLANTHANATE(III) COMPLEXES WITH QUATERNARY CATIONS

NAILIN CHEN, PHIL J. WITTON, CLIVE E. HOLLOWAY and IAN M. WALKER*

Department of Chemistry, York University, Downsview, Ontario, Canada M3J 1P3

(*Received* 21 *April* 1986; *accepted after revision* 28 *July* 1986)

Abstract—The ^{14}N NMR of nitrate ion coordinated to paramagnetic lanthanide cations in a series of penta- and hexanitratolanthanate(III) anions has been recorded in nitrobenzene–dichloromethane mixtures for all naturally occuring members of the lanthanide series except gadolinium. The nitrate ^{14}N signals show large shifts from their normal values in diamagnetic environments. These isotropic shifts are analysed in terms of a mixture of Fermi contact and through-space dipolar effects. The nitrogen and carbon isotropic shifts from the ammonium cation were shown to be exclusively dipolar in nature. Estimation of the approximate relative amounts of contact and dipolar shift in the nitrate isotropic shifts was attempted. Mixtures of diamagnetic and paramagnetic complexes show separate nitrate ^{14}N resonance signals under our operating conditions. A brief discussion of the kinetics of exchange of nitrate ion between different lanthanide environments is presented.

NMR spectra of salts of the type $[R_4N]_a(MX_n)$ containing paramagnetic metal ions M in moderate dielectric solvents are unusual in that the signals of probe nuclei on the R_4N^+ cation are shifted from their normal frequencies.[1] This is a consequence of the formation of ion-pairs or higher aggregates in solution. These cation isotropic NMR shifts have often been shown, at least for protons, to be due to a predominantly axial dipolar shift mechanism. It is therefore possible to obtain some measure of the structure of the cation in the ion-pair complex. In so doing, use is made of the well-known dependence of the dipolar shift on distances and angles (see below).

Paramagnetic anions of formula $Ln(NO_3)_5^{2-}$ have been shown to be effective shift reagents for R_4N^+ cations, and we have already presented proton NMR isotropic shifts and structural information on several ion-paired systems containing these anions.[2] This choice of anion has several advantages over those derived from the common beta-diketonate shift reagents, including low cost and insensitivity to moderate amounts of hydroxylic solvents.

X-ray studies on salts containing this type of anion show that nitrate acts as a bidentate chelating ligand.[3] It is often convenient for many purposes, in view of the short bite distance of nitrate, to view the 10-coordinate $Ln(NO_3)_5^{2-}$ ion as a trigonal bipyramid. Twelve-coordinate $Ln(NO_3)_6^{3-}$ ions also exist, but are less common.[4,5]

There are several small details concerning the proton isotropic shift patterns in $Ln(NO_3)_5^{2-}$ salts which have puzzled us for some time. It is well known that in a normally behaved, isostructural series of lanthanide complexes of axial symmetry, the Tb, Dy and Ho homologues give shifts in the same direction, while the Er, Tm and Yb homologues give NMR shifts in the opposite direction.[6] In our system, $Er(NO_3)_5^{2-}$ is distinctly anomalous, causing cation isotropic shifts in the same direction as does $Ho(NO_3)_5^{2-}$.

In view of this interesting anomaly, we decided to learn more about the magnetic properties of the $Ln(NO_3)_5^{2-}$ anions in solution, by means of NMR spectroscopy. The most convenient probe nucleus is the almost 100% abundant ^{14}N of the nitrate ion. A great deal of useful information would also be available from studies of the rarer and considerably less sensitive ^{17}O nucleus.[7]

In general, the isotropic shift, $\Delta_T^M(i)$, at the ith

*Author to whom correspondence should be addressed.

nucleus in a metal complex M consists of three terms, the through-space axial and rhombic dipolar shifts $\Delta^M_{ax}(i)$ and $\Delta^M_{rh}(i)$, and the through-bond Fermi contact shift $\Delta^M_c(i)$.

$$\Delta^M_T(i) = \Delta^M_{ax}(i) + \Delta^M_{rh}(i) + \Delta^M_c(i). \quad (1)$$

Since the nitrate nitrogen is separated from the paramagnetic centre by only two bonds, large Fermi contact contributions to the isotropic shift are expected. Fortunately, recent theoretical developments due to Golding and Halton,[8] Bleaney *et al.*[9,10] and Reilley *et al.*[11] now make it possible to partition the observed isotropic shift of a nucleus into its contact and dipolar parts. In this article, we apply these approaches in order to elucidate the origins of the isotropic shift in both the cationic and anionic parts of the homologous series $(R_4N)_{x-3}Ln(NO_3)_x$, where R is *n*-butyl or *n*-propyl, and $x = 5$ or 6. A complete set of ^{13}C isotropic shifts for the cations has also been recorded, and is used to effect a separation of the nitrate isotropic shift into contact and dipolar parts.

In addition, we report preliminary results on the kinetics of nitrate exchange between paramagnetic environments.

EXPERIMENTAL

The preparation of all complexes has been previously described.[5] All solvents used were reagent grade, and were dried over molecular sieves before use. NMR spectra for solutions of 0.15–0.20 mol l^{-1} concentration were obtained at 5.74 MHz (^{14}N) and 20.0 MHz (^{13}C) on a Varian FT-80 NMR spectrometer, using 10-mm sample tubes and the external D_2O lock. ^{13}C spectra were obtained in the proton-decoupled mode, using pulse parameters appropriate for best sensitivity. ^{14}N spectra were obtained using a near 90° pulse with minimum acquisition time (~0.2 s) such that line-shape distortions were avoided, while the advantages of a short T_1 were retained.

The internal reference for the carbon spectra was TMS, while the chosen internal reference for the nitrogen spectra was nitrobenzene. In order to provide a solvent suitable for both ^{14}N and ^{13}C measurements, so that all reported shifts would be measured under identical conditions, a mixture of 10% (v/v) TMS, and 10% (v/v) nitrobenzene in dichloromethane was adopted as the standard solvent for isotropic shift work. Kinetic measurements were made in acetone, which had been dried for at least 48 h over molecular sieves.

RESULTS

^{13}C *Chemical shifts*

Spin-decoupled ^{13}C spectra of quaternary cations are markedly superior to proton spectra in paramagnetic salts, since broadening and signal overlap are nearly always absent. The data reported in Table 1 therefore represent a major improvement in quality over the proton data which we reported earlier.[5] The carbon isotropic shifts are reported in ppm with respect to the corresponding signal of the $Lu(NO_3)_5^{2-}$ salt. A positive shift represents a shift to high field (low frequency).

As with proton spectra, only one signal for a given carbon is observed, even in mixtures of paramagnetic and diamagnetic lanthanide salts. This is a consequence of fast exchange of cations between different ion-pairs.

^{14}N *Chemical shifts*

The spectra of the diamagnetic standards $(Bu_4N)_2Lu(NO_3)_5$ and $(Bu_4N)_3La(NO_3)_6$ in acetone consist of a sharp resonance at high field due to the cation, and a broader resonance due to nitrate at low field. The data are reported in Table 1. Careful measurements have shown that under our experimental conditions, the chemical shift of nitrobenzene is coincident with that of nitrate in diamagnetic environments. Isotropic shifts of the nitrate resonance are therefore referred to the internal standard, nitrobenzene, a positive shift being to high field, as in the carbon spectra. The width of the nitrobenzene signal introduces a small error into our isotropic shifts; we estimate this to be at most 2 ppm.

Studies of the pentanitrato complexes in low dielectric solvents such as acetone, dichloromethane and nitrobenzene show that the nitrate isotropic shift is not sensitive to either solvent or concentration.

^{14}N *Linewidth studies*

The width of the nitrate resonance in free tetrapropylammonium nitrate is broader in organic solvents such as acetone than it is in water (width at half height = 6 Hz in water). Changes in viscosity cannot account for this effect. Increased ion association in the organic solvents is a more likely explanation. The nitrate resonance also broadens considerably on formation of the diamagnetic $Lu(NO_3)_5^{2-}$ complex (width at half height = 40 Hz in acetone). This effect can be due to both an increase in the correlation time associated with a

[a]Isotropic shifts in ppm with respect to the corresponding resonances in the diamagnetic Lu complex. Upfield shifts are indicated by a positive sign. The solvent is 10% (v/v) TMS and 10% nitrobenzene in dichloromethane. Unless otherwise indicated, the cation is tetra-*n*-butylammonium.

[b]The ^{14}N isotropic NMR shift of coordinated nitrate ion. The uncertainty is ±2 ppm.

[c]The ^{14}N isotropic shift of the central tetrabutylammonium nitrogen. The cation signal occurs 306.8 ppm to high field of nitrobenzene in the Lu complex. The uncertainty is ±2 ppm.

[d]The $^{\beta}C$ isotropic shift of the α-carbon of the tetrabutylammonium ion. The α-signal occurs at 58.9 ppm with respect to TMS in the Lu derivative.

[e]SR_i is defined as the ratio of the isotropic shift on the *i*th carbon with respect to the α-carbon, i.e. $\Delta_T^M(i\text{-}C)/\Delta_T^M(\alpha\text{-}C)$. The β- and γ-carbon signals are at 24.1 and 19.9 ppm with respect to TMS in the Lu derivative, respectively.

[f]Data recorded on tetra-*n*-propylammonium salts in acetone.

larger anion, as well as the induction of a field-gradient at the quadrupolar nitrogen nucleus.

The quadrupolar broadening increases markedly on cooling for all salts, a factor which may be primarily due to an increase in viscosity. The paramagnetic lanthanide ions exert about the same broadening effect on the nitrate signal (width at half height = 100 ± 20 Hz) in this solvent mixture. The sole exception is the Gd complex, in which the resonance signals of all nuclei are unobservably broad.

DISCUSSION

Isotropic shifts

We now provide a short synopsis of the modern theory used in the analysis of isotropic NMR shifts.[11,12] It is customary to write the dipolar shift expression as the product of metal dependent factors D_{1M} and D_{2M}, appropriate to axial and rhombic symmetry, respectively, and axial and rhombic geometric factors $G_1(i)$ and $G_2(i)$, which depend only on the metal–nucleus distance, R_i, and on angles θ_i, ϕ_i:

$$\Delta_{ax}^M(i) + \Delta_{rh}^M(i) = G_1(i)D_{1M} + G_2(i)D_{2M} \qquad (2)$$

where

$$G_1(i) = R_i^{-3}(3\cos^2\theta_i - 1)$$

and

$$G_2(i) = R_i^{-3}(\sin^2\theta_i \cos 2\phi_i).$$

The angles are as defined in Ref. 12. The Fermi contact shift is written as the product of the metal-dependent effective spin magnetization, $\langle S_z\rangle_M$, and

the hyperfine coupling constant, A_i:

$$\Delta_c^M(i) = A_i\langle S_z\rangle_M. \quad (3)$$

It can be shown[12] that on combining and rearranging these equations:

$$\Delta_T^M(i)/\langle S_z\rangle_M = A_i + K[D_{1M}/\langle S_z\rangle_M] \quad (4a)$$

Thus, a plot of $\Delta_T^M(i)/\langle S_z\rangle_M$ vs $D_{1M}/\langle S_z\rangle_M$ should result in a straight line of intercept A_i, and slope K, where

$$K = G_1(i) + D_{2M}G_2(i)/D_{1M}. \quad (4b)$$

Straight line behaviour will result in our case only if the following conditions are met:

(a) The ion pair complexes must all have the same structure on a time average. In addition, the coordination polyhedron about the lanthanide ion must not vary significantly across the lanthanide series;
(b) rhombic terms are unimportant, or:
(c) there is a proportionality between D_{1M} and D_{2M} which extends across the lanthanide series:
(d) the hyperfine coupling constant, A_i, is constant across the lanthanide series.

Values of D_{1M} have been given by Bleaney *et al.*,[9,10] while values of $\langle S_z\rangle_M$ are available from Golding and Halton.[8]

Cation isotropic shifts

Since the cation nuclei are many bonds removed from the paramagnetic centre, Fermi contact terms would be expected to be very small. This can be seen by comparing the α-carbon isotropic shifts in Table 1 with the proton data previously reported for these systems.[5] The isotropic shifts for proton and carbon are nearly the same in sign and magnitude, as would be expected for nuclei which occupy nearly the same average positions in space. The cation nitrogen data show considerable scatter due in part to the larger uncertainty; nonetheless, they are essentially in agreement with the carbon shifts. Thus the predominant mechanism is dipolar for $Ln(NO_3)_5^{2-}$ complexes. This is in strong contrast to the behaviour of tetrahalocobaltate(II) ion pairs, in which cation proton and carbon isotropic shifts are in opposite directions[13] due to the presence of sizeable contact contributions in the ^{13}C spectra.

For systems in which the contact term is absent, a plot of $\Delta_T^M(i)$ vs D_{1M} should give a straight line, provided the rhombic terms are well-behaved [see (c) above], and that the ion-pair complexes are isostructural.

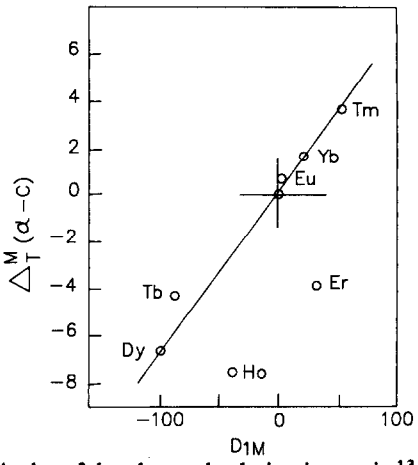

Fig. 1. A plot of the observed solution isotropic ^{13}C NMR shifts at the α-carbon of the cation, $\Delta_T^M(\alpha\text{-C})$, vs Bleaney factors D_{1M} for $[(C_4H_9)_4N]_2Ln(NO_3)_5$ complexes. The data are taken from Table 1.

In Fig. 1, we show such a plot for the α-carbon isotropic shift data for the $[(n\text{-}C_4H_9)_4N]_2Ln(NO_3)_5$ series, for which a straight line may be drawn through nearly all of the lathanide data. We note that Tb gives a small positive deviation, while Ho and Er give significant negative deviations.

Recently, single crystal ESR data have been obtained on $[(C_6H_5)_4As]_2Yb(NO_3)_5$ in a diluent host lattice. Three unequal g factors were observed,[14] showing that in a magnetic sense, the trigonal bipyramid model, with its implicit axial symmetry, is not an accurate description for this type of ion in the solid state. It now appears from consideration of Fig. 1 that rhombic terms must also be considered to make a significant contribution to the cation isotropic shifts in solution. The reason why most lanthanides lie on the line is probably that D_{1M} and D_{2M} are in the same ratio for these complexes; this proportionality breaks down significantly for Ho and Er, however.

We have been aware for some time that the ratios of shifts of cation nuclei, SR_i, are independent of the metal ion. This is apparent in all of the proton studies,[2,5] and can also be seen from Table 1. This behaviour is due to the fact that the cationic part of this system shows effective axial symmetry. The reader may consult Refs 15 and 16 for a further discussion of this problem. In short, the ratios of the shifts of the ith and jth NMR signal will be independent of the metal ion, and will appear to be axial-dipolar, even though the magnetic properties of the anion are rhombic.

Nitrate isotropic shifts

In separating the contact and dipolar parts of the isotropic shift, we make use of eqn (4). The relevant quantities have been collected in Table 2,

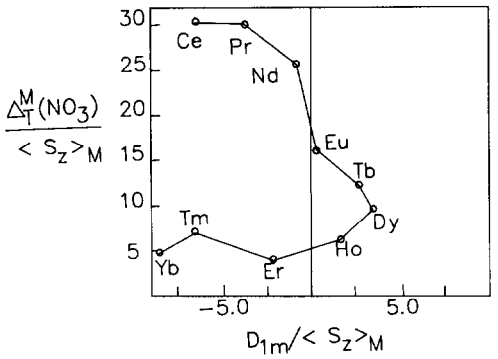

Fig. 2. A plot of $\Delta_T^M(NO_3)/\langle S_z\rangle_M$ vs $D_{1M}/\langle S_z\rangle_M$ for the $Ln(NO_3)_5^{2-}$ complexes. Here, $\Delta_T^M(NO_3)$ is the observed solution ^{14}N isotropic shift at the nitrate ion coordinated to lanthanide ion M, D_{1M} is the corresponding Bleaney factor, and $\langle S_z\rangle_M$ is the effective spin magnetization. The data are taken from Table 2.

Yb	4.7	−8.50	−0.66

[a]Nitrate isotropic shifts taken from Table 1 for penta-nitrato-complexes. Values of $\langle S_z\rangle_M$ were taken from Ref. 8, while values of D_{1M} were taken from Refs 9, 10.

[b]Data for Ce, Pr and Nd are from $[(C_3H_7)_4N]_2Ln(NO_3)_5$ salts in acetone. All other data are from $[(C_4H_9)_4N]_2Ln(NO_3)_5$ salts in dichloro-methane–nitrobenzene–TMS mixture.

and a plot of $\Delta_T^M(NO_3)/\langle S_z\rangle_M$ vs $D_{1M}/\langle S_z\rangle_M$ is shown in Fig. 2.

We note the total lack of linearity; the plot suggests that all three mechanisms are significant contributors to the overall isotropic shift. The $Sm(NO_3)_5^{2-}$ ion has a considerably larger nitrate shift than expected from the $\langle S_z\rangle_M$ value quoted for this ion by Golding and Halton.[8] Although the sign of the shift is consistent with theory, the ratio $\Delta_T^{Sm}(NO_3)/\langle S_z\rangle_{Sm} = 243$ is grossly out of line (Table 2). Interestingly, $Eu(NO_3)_5^{2-}$ seems well-behaved, although it should exhibit similar problems.[8] The derivation of accurate values for $\langle S_z\rangle_M$ for Eu and Sm complexes has been the subject of a recent article.[17]

Recently, a modification of eqn (4) has been

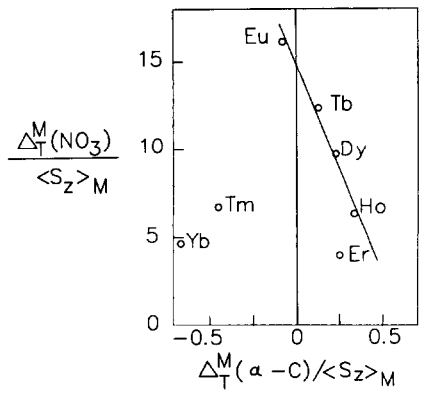

Fig. 3. A plot of $\Delta_T^M(NO_3)/\langle S_z\rangle_M$ vs $\Delta_T^M(\alpha\text{-C})/\langle S_z\rangle_M$ for the $Ln(NO_3)_5^{2-}$ complexes. $\Delta_T^M(NO_3)$ is the observed solution isotropic ^{14}N NMR shift at coordinated nitrate, $\Delta_T^M(\alpha\text{-C})$ is the solution ^{13}C isotropic shift at the cation α-carbon, and $\langle S_z\rangle_M$ is the effective spin magnetisation. The data are taken from Table 2.

suggested by Pinkerton and co-workers.[18–20] The shift of a nucleus which has both contact and dipolar terms may be written:*

$$\Delta_T^M(i)/\langle S_z\rangle_M = A_i + C[\Delta_T^M(j)/\langle S_z\rangle_M] \quad (5)$$

where $\Delta_T^M(j)$ is the shift at a nucleus which is predominantly dipolar in nature. Thus a plot of $\Delta_T^M(i)/\langle S_z\rangle_M$ vs $\Delta_T^M(j)/\langle S_z\rangle_M$ will give a straight line of intercept A_i, assuming the system obeys the conditions for good behaviour (see above). The slope of this plot, C, is a complicated function of D_{1M}, D_{2M} and the geometric factors, and contains no readily useful information.

The value of this method has been amply demonstrated for the series of complexes $[(C_6H_5)_4As]Ln(S_2PR_2)_4$, where R represents a series of alkyl and alkoxy substituents.[18–20] This treatment has the advantage that it compensates for deficiencies in the theoretical values of D_{1M}. In addition, the method appears to be very well adapted to showing up subtle changes in solution geometry.

Choosing the α-carbon shifts as our contact-free shifts, we show such a plot in Fig. 3. Data for the early lanthanides have been omitted, due to variations in stoichiometry; also, the small size of the carbon shifts for these systems renders any conclusions not very meaningful. Several points emerge from this plot: much better linearity is obvious for the four ions Eu–Ho than was found in Fig. 2. The erbium value now lies closer to the Eu–Ho line than before, although the deviation is still significant. The Pinkerton method thus at least

*Our notation is a modification of that used by Pinkerton and co-workers, in order to make it compatible with that of Shelling *et al.*[12]

Table 3. Separation of the ^{14}N isotropic shift in nitrate ion[a]

Ln	$\Delta^M_T(NO_3)$	$\Delta^M_c(NO_3)$	$\Delta^M_{dip}(NO_3)$
Eu	−172	−160	−12

Ho	−140	−339	199

[a]Data in ppm.

partially compensates for the presence of rhombic shift effects in the $Ln(NO_3)_5^{2-}$ system.

We may use these four points in an attempt to estimate the size of the contact shift. Taking the intercept $A_i = 16$ from the plot, and multiplying by the appropriate $\langle S_z \rangle_M$ value, we obtain the contact terms shown in Table 3; application of eqn (1) then yields the dipolar term. The reader is cautioned that these numbers are order-of-magnitude estimates only. It appears safe to conclude, however, that the contact and dipolar contributions are opposite in sign for the ions Tb, Dy and Ho.

Figures 2 and 3 reveal distinctly anomalous behaviour for Tm and Yb data. It has likewise been found[18–20] that data for the $Ln(S_2PR_2)_4^-$ cannot be fitted to one straight line; rather the early lanthanides Ce–Dy fall on one line, while the heavy lanthanides Ho–Yb fall on a line of opposite slope. There appears to be a different A_i value associated with each group of lanthanides. It has been postulated that a structural change in the coordination polyhedron can account for this behaviour, but with the retention of axial symmetry.

It is entirely possible that some of the anomalies which we have noted in the $Ln(NO_3)_5^{2-}$ ion-pairs are due to structural changes. We suspect that breakdown of any of the conditions (a)–(d) could also lead to anomalies in our system, but there does not appear to be any definitive way to pinpoint the precise cause of the breakdown at present.

Kinetics of nitrate exchange

There are relatively few kinetic studies which use ^{14}N as the probe nucleus, probably because the range is somewhat limited by the quadrupolar broadening referred to earlier. In the present case, we have carried out two kinds of experiments:

(1) Exchange of nitrate ion between diamagnetic $Ln(NO_3)_5^{2-}$ or $LuLn(NO_3)_5^{2-}$ and a paramagnetic $Ln(NO_3)_5^{2-}$ complex in acetone.
(2) Exchange of non-coordinated nitrate, as the tetrapropylammonium salt, with paramagnetic $Ln(NO_3)_5^{2-}$ complexes in acetone.

The total concentrations of salts were varied, but in order to simplify the analysis, and to maximize the sensitivity for both peaks, the systems were always studied under conditions of equal site populations. Thus, in the experiments of type 2, the ratio of NO_3^- to paramagnetic $LnNO_3)_5^{2-}$ was always kept as 5:1. The approximate standard equations for two-site line-shape kinetics were used.[21] Despite the broadness of the resonances, the very large shifts permit the same approximations to be used as for non-quadrupolar nuclei. Spectral data were observed from both the fast and slow exchange sides of the coalescence condition, but only the fast exchange data were used for kinetic analysis, in order to minimize quadrupolar broadening problems.

Our results are as follows:

(a) Rates of exchange between small diamagnetic and paramagnetic centres such as Y and Ho, or Lu and Ho do not depend significantly on the metal ion. Thus, small differences in ionic radii do not show up in the kinetics. The $\Delta G\dagger$ values range from +14 to +15 kcal mol^{-1}, while the coalescence temperature varies from 35 to 60°C.

(b) Changing the total concentration of such a mixture has no effect on the rate of reaction. The reaction is thus pseudo-first order in both complex species.

(c) Comparison of data for $Y(NO_3)_5^{2-}$–$Ho(NO_3)_5^{2-}$ exchange with data for $Ho(NO_3)_5^{2-}$–NO_3^- exchange at the same conditions shows that the coalescence temperatures are essentially the same within experimental error (+2°C). We conclude from this that the reactions involving heavy lanthanides are not catalysed by nitrate; this implies a dissociative mechanism. The following scheme is therefore suggested:

$$Ho(NO_3)_5^{2-} \xrightarrow{slow} Ho(NO_3)_4^- + NO_3^-$$

$$Y(NO_3)_5^{2-} \xrightarrow{slow} Y(NO_3)_4^- + NO_3^-*$$

$$NO_3^-* + Ho(NO_3)_4^- \xrightarrow{fast} [Ho(NO_3)_4(NO_3)^*]^{2-}.$$

The large metal ions Ce, Pr, Nd behave differently. Examination of $[(C_3H_7)_4N]_2Ln(NO_3)_5$ and $[(C_3H_7)_4N]_2Ln(NO_3)_5$ were carried out in acetone, as before. Addition of $(C_3H_7)_4NNO_3$ to solutions of either series gives only one line at temperatures where the heavy lanthanides gave two lines; this indicates fast exchange between free and coordinated nitrate. Further, it can be seen from Table 1 that the solution isotropic shifts in the $Ln(NO_3)_5^{2-}$ are very nearly 5/6 as large as those in the $Ln(NO_3)_5^{2-}$ series (Ln = Ce, Pr, Nd). This

observation can be explained by the dissociation reaction:

$$Ln(NO_3)_6^{3-} \underset{slow}{\overset{fast}{\rightleftharpoons}} Ln(NO_3)_5^{2-} + NO_3^-$$

permitting fast exchange of free and coordinated nitrate.

Conclusions

The axial symmetry observed in the organic ligands in the $Ln(S_2PR_2)_4$ complexes[18-20] is not observed in the $Ln(NO_3)_5^{2-}$ complexes. This may seem surprising, since the ligands are both bidentate chelating, and the approximate structural analogy between a tetrahedron in the former case and a trigonal bipyramid in the latter is not without some foundation. The reasons for this difference in behaviour are unclear; however, we have shown that it is inaccurate to describe these pentanitrato-anions as trigonal bipyramids in solution.
solution.

Lanthanide coordination polyhedra are fluctional. It is safe to say therefore that each nitrate ion in these anionic complexes can experience several different magnetic environments over the life of the NMR experiment. This averaging takes place in such a way that both rhombic and axial dipolar terms are generally present in the dipolar shift for both the organic cation and the nitrate anion. In addition, we have detected a large Fermi contact term in the nitrate spectrum.

We have undertaken a preliminary investigation of the kinetics of nitrate exchange in these systems. The exchange reaction appears to take place by a dissociative mechanism for the heavier lanthanides. The exchange rates in the earlier lanthanides are generally faster, and there is evidence that $Ln(NO_3)_6^{3-}$ species undergo dissociation in acetone solution.

SOLVENT EFFECT ON THE LIQUID–LIQUID PARTITION COEFFICIENTS OF BIS(DIMETHYLDITHIOCARBAMATO)NICKEL(II) AND BIS(THENOYLTRIFLUOROACETONATO)NICKEL(II)

NOBUO SUZUKI,* SATORU MATSUMORA and HISANORI IMURA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980, Japan

(*Received* 18 *February* 1986; *accepted* 8 *May* 1986)

Abstract—Partition coefficients of nickel(II) chelates with thenoyltrifluoroacetone (Htta) and dimethyldithiocarbamic acid (Hdmdtc) into various organic solvents were measured at 25°C. The effect of solvent on the partitition coefficients was evaluated with the aid of a modified equation of the regular solution theory. A great difference in the partition coefficients between $Ni(tta)_2$ and $Ni(dmdtc)_2$ can be interpreted by a preferential solute–solvent interaction for the former chelate. The ability of the divalent metal chelates to accept additional solvation is an important factor governing the partition coefficient.

Recently the liquid–liquid partition coefficient (P) of organic chemicals has been used as a simple measure for the prediction of permeation of these compounds into the environment.[1] Fundamentally the partition coefficient is the key process governing the separation efficiency of the compounds of interest including metal species in chemical separation methods such as solvent extraction and liquid chromatography. It is a surprising fact that only a few systematic studies on the partition coefficient of different kinds of nonelectrolytes, including metal complex compounds, have been made.[2]

In some pioneering work done in 1964, the partition coefficients of β-diketones and their scandium tris-chelates were measured in different organic solvent systems and discussed with the aid of the regular solution theory,[3–5] and one of the important conclusions was expressed as $\log P_{MA_n} = (V_{MA_n}/V_{HA}) \log P_{HA} + C$ where V denotes molar volume, and subscripts MA_n and HA are metal chelate and acidic chelating ligand, respectively. This relation was confirmed experimentally for several types of metal chelates.[6–10] In this original equation, the second term of the right-hand side expressed as C is a correction factor depending on experimental conditions, and ideally this constant term can be neglected. If so this equation simply shows that the partition coefficient of the metal chelate combined with n moles of chelating ligands into an organic solvent is always simply the nth power of the partition coefficient of the chelating ligand into the same organic solvent under the assumption that $V_{MA_n}/V_{HA} \simeq n$.[2,4] In other words, the partition coefficients of the same type of metal chelates MA_n into an organic solvent are equal to each other and not influenced by the central metal ion itself. More detailed studies on the partition coefficient of metal chelates with different central metal ions have been done previously,[7] where the partition coefficients of seven acetylacetonate chelates with Pt(II), Pd(II), Be(II), VO(IV), Cr(III), Al(III) and Co(III) were studied, and an apparent discrepancy from the original equation was discussed in relation to the hydration to chelates. The solute–solvent interaction including hydration may differ in different combinations of central metal ions and acidic chelating ligands.

In this study, the partition coefficients of nickel(II) chelates with thenoyltrifluoroacetone (which is one of β-diketones having oxygen donor atoms) and with dimethyldithiocarbamic acid (which is one of dithiocarbamate family having sulfur donor atoms) are determined in the liquid–liquid system of different organic solvents and an aqueous perchlorate solution. These β-diketones and dithiocarbamates are quite popular chelating agents and extensively exploited in the solvent extraction of

metal ions. The partition coefficients are also compared with those for the copper(II) chelates.[9,10]

EXPERIMENTAL

Reagents and apparatus

Thenoyltrifluoroacetone (Htta) was obtained from Dojindo Laboratories and purified by vacuum sublimation. Sodium dimethyldithiocarbamate (Nadmdtc·$2H_2O$) was obtained from Tokyo Kasei Co., Ltd. and purified by recrystallization from acetone–absolute ether. Nickel(II) thenoyltrifluoroacetonate chelate was synthesized in the usual way and recrystallized from 75–99% ethanol. Nickel(II) dimethyldithiocarbamate chelate was obtained from Tokyo Kasei Co., Ltd. and purified by vacuum sublimation. The results of the elemental analysis of each chelate were as follows: $Ni(tta)_2 \cdot 2H_2O$ (Found: C, 35.9; H, 2.2; S, 11.7%; Calc.: C, 35.8; H, 2.2; S, 11.9%); $Ni(dmdtc)_2$ (Found: C, 24.2; H, 3.9; N, 9.4; Calc.: C, 24.1; H, 4.0; N, 9.4%). Based on the experimental results obtained by thermogravimetry, in which the dehydration of $Ni(tta)_2 \cdot 2H_2O$ and its thermal decomposition were observed at 123–156°C and 230°C, respectively, anhydrous $Ni(tta)_2$ was prepared by heating the hydrated chelate at 135–140°C for 2 h.

Carrier-free ^{57}Ni was produced by 24 MeV α-bombardment of iron foil (99.99% purity) with a cyclotron of Tohoku University and isolated by means of anion exchange chromatography (column): Dowex 1X8, 8 mm × 150 mm) with 10 M hydrochloric acid. The effluent was evaporated to dryness and dissolved in 0.01 M perchloric acid. Then carrier-free ^{57}Ni solution was added to an aliquot of a standard solution of nickel(II) perchlorate prepared from the high purity metal (99.99% purity), evaporated to dryness and dissolved in 0.01 M perchloric acid. Other reagents and apparatus were the same as those used previously.[8]

Procedures

An aqueous sodium perchlorate solution (ionic strength 0.10) prepared from 0.01 M perchloric acid and 0.01 M sodium hydroxide was shaken with 0.01–0.10 M Htta in an organic solvent to attain a preliminary equilibrium. A 10-μl portion of 5×10^{-5}–5×10^{-2} M nickel(II) solution labeled with ^{57}Ni was added to the contents and shaken for 2–12 h at 25±0.5°C. In the case of dimethyldithiocarbamate, the aqueous perchlorate solution (ionic strength 0.10) of pH 7–8 containing 1×10^{-4}–1×10^{-2} M Nadmdtc and 2×10^{-7}–1×10^{-4} M radioactive nickel(II) was shaken with an organic solvent for 15–60 min at 25±0.5°C. After centrifuging, an aliquot (0.1–3 ml) was very carefully taken from each phase. The γ-activities of both phases were measured with a well-type NaI(Tl) scintillation counter and the distribution ratio (D) of nickel(II) was calculated. The equilibrium pH value was measured with a glass electrode. Attainment of the partition equilibrium was always checked by forward extraction and backward extraction. Additionally, the partition coefficients of copper(II) thenoyltrifluoroacetonate chelate into isobutylmethyl ketone and diisobutyl ketone were measured in the same way as described previously.[9]

RESULTS AND DISCUSSION

Figure 1 shows typical extraction curves of nickel(II) thenoyltrifluoroacetonate into benzene, isobutylmethyl ketone, and diisobutyl ketone as well as nickel(II) dimethyldithiocarbamate into heptane. The concentration of each chelating anion in the aqueous phase [A^-] was calculated by using the acid dissociation constant and the partition coefficient of Htta[9] and Hdmdtc.[10] In principle the partition coefficient of metal chelate can be directly determined as the limiting value of the distribution ratio in the plateau region. However, since the partition coefficient of $Ni(tta)_2$ in ketone solvents was too high to be accurately measured by this technique, it was determined from the linear section with the slope of two of the distribution curves as shown in

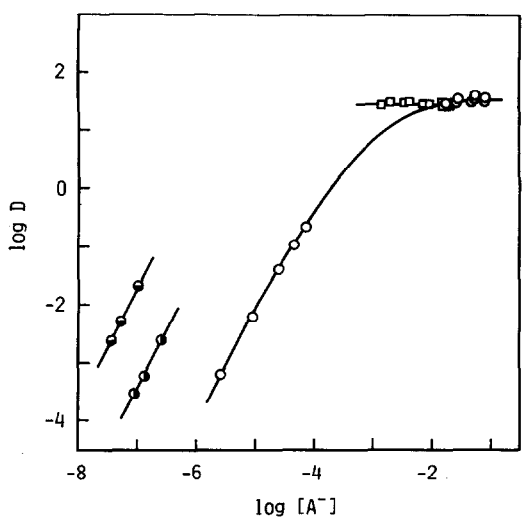

Fig. 1. Distribution ratio of nickel(II) *vs* concentration of chelating anion in the aqueous phase. Initial concentration of Htta: 0.08–0.11 M; pH 2.0–8.2. Initial concentration of Nadmdtc: 0.002–0.020 M; pH 6.0–8.5. ○ Htta–benzene; ◒ Htta–isobutylmethyl ketone; ◑ Htta–diisobutyl ketone; □ Nadmdtc–heptane.

Table 1. Partition coefficients of $Ni(tta)_2$ into benzene

8.3×10^{-8}	0.10	8.12	1.591
3.5×10^{-7}	0.11	7.92	1.594
3.5×10^{-7}	0.11	8.21	1.550
8.7×10^{-7}	0.11	7.44	1.439
8.7×10^{-7}	0.11	7.77	1.522
8.7×10^{-7}	0.11	7.92	1.530
8.7×10^{-7}	0.11	8.21	1.512
1.6×10^{-6}	0.11	7.94	1.436

Fig. 1. The linear section is expressed by $D = P_M\beta_2[A^-]^2$[9] and the overall chelate formation constant β_2 does not depend on the organic solvent itself, hence we can use β_2 determined by analyzing the extraction curve in an appropriate solvent system where P_M is obtained directly from the plateau region. Here from the distribution curve in benzene, β_2 for $Ni(tta)_2$ is obtained as $10^{6.54}$. The β_2 for $Ni(tta)_2$ has not been reported yet, but this value may be comparable with those for Ni(II) chelates with other β-diketones; β_2 for trifluoroacetylacetonate and benzoyltrifluoroacetonate are $10^{6.68}$ and $10^{6.68}$, respectively.[11]

It has been said that nickel(II) chelates, especially with β-diketone, show a strong tendency to form a polymerized species such as $[Ni(\beta\text{-diketonate})_2]_3$ in organic solvent.[12] The partition coefficients of nickel(II) chelates into nonpolar solvents were measured at different initial concentrations of chelates. The results for nickel(II) chelate with thenoyltrifluoroacetonate are listed in Table 1. A constant P_M value for each chelate is obtained within experimental uncertainty. The same was true for nickel(II) chelates with dimethyldithiocarbamate in carbon tetrachloride solvent. These results show that both nickel(II) chelates in the concentration range as low as 10^{-8}–10^{-6} M are present as a monomeric species in both organic and aqueous phases.

The P_M values of $Ni(tta)_2$ and $Ni(dmdtc)_2$ between various organic solvents and 0.10 M perchlorate solution are summarized in Table 2 together with those of the corresponding copper (II) chelates.[9,10] A large solvent effect on the partition coefficients of these chelates is clearly observed. In the thenoyltrifluoroacetonate system, a greater difference in the partition coefficients between nickel(II) and copper(II) chelates is observed, that is, the partition coefficients of copper(II) chelate are larger than those of nickel(II) chelate by a factor of 10^4 in most of the solvents. In the dimethyldithiocarbamate system, the partition coefficient of copper(II) chelate is roughly the same or a little larger than that of nickel(II) chelate.

Following the regular solution concept the partition coefficient of a nonelectrolyte, expressed in a molar fraction scale, can be formulated as[8]

$$\ln P_s^\circ = \frac{V_s}{RT}[C_{ww} - C_{oo} + 2(C_{so} - C'_{sw})] \qquad (1)$$

where V and C are the molar volume and the cohesive energy density, respectively, and the subscripts s, w and o denote solute, water and organic solvent, respectively. In this formulation, the parameter C'_{sw} involves overall interaction between solute and water. If the geometric mean approximation is valid for C_{so}, eqn (1) can be rewritten by the solubility parameters δ as

$$\frac{RT}{V_s}\ln P_s^\circ + C_{oo} = 2\delta_s\delta_o + C_{ww} - 2C'_{sw}. \qquad (2)$$

A linear relationship between the left-hand side of eqn (2) and δ_o can be expected, and the apparent solubility parameter of the solute δ_s, can be obtained from the slope. Figure 2 shows the plots for $Ni(dmdtc)_2$ together with those for Hdmdtc and $Cu(dmdtc)_2$ reported previously.[10] The molar volume of $Ni(dmdtc)_2$ was assumed to be the same as that of $Cu(dmdtc)_2$, i.e. 190 cm^3 mol^{-1}.[10] The plots for each solute give a good linear relationship apart from the plots in dibutyl ether solvent. The apparent solubility parameter of $Ni(dmdtc)_2$ obtained was 13.3 $cal^{1/2}$ $cm^{-3/2}$, slightly larger than that for Hdmdtc (δ: 12.2) and $Cu(dmdtc)_2$ (δ: 12.7).

Figure 3 shows the same type of plots for $Ni(tta)_2$, $Cu(tta)_2$ and Htta, but Htta is a tautomeric mixture of keto and enol isomers hence the partition coefficient of the enol type of Htta is plotted in Fig. 3.[3,13] Here the molar volume of the nickel(II) chelate was assumed to be the same as that of the copper(II) chelate, 304 cm^3 mol^{-1}.[9] For each solute, a good linear relationship holds for nonpolar solvents, but a positive deviation is clearly observed in polar solvents such as ether and ketone. The apparent solubility parameter of $Ni(tta)_2$ is obtained to be 11.0 $cal^{1/2}$ $cm^{-3/2}$ from the slope of the straight line drawn for nonpolar solvents. This value is the same as that of $Cu(tta)_2$.[9] A similarity between the solubility parameter of $Ni(tta)_2$ and that of $Cu(tta)_2$ suggests a similarity in the chemical state of these extractable chelates in nonpolar solvents. If $Ni(tta)_2$ is extracted as a dihydrate (or monohydrate) species into nonpolar solvents, its apparent solubility parameter can

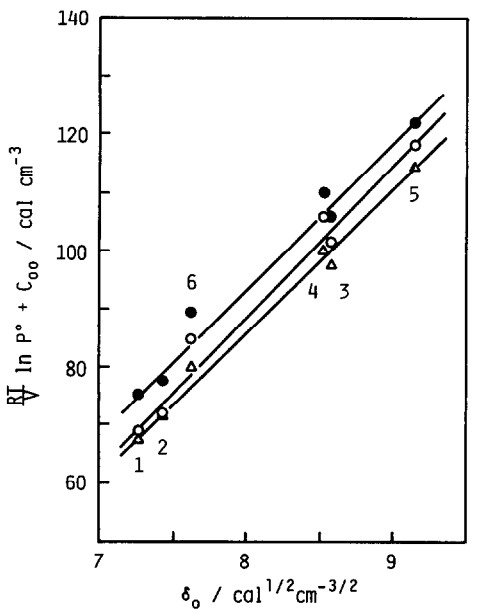

Fig. 2. Evaluation of partition coefficients with eqn (2). The numbers correspond to those in Table 2. ○ $Ni(dmdtc)_2$; ● $Cu(dmdtc)_2$;[10] △ Hdmdtc.[10]

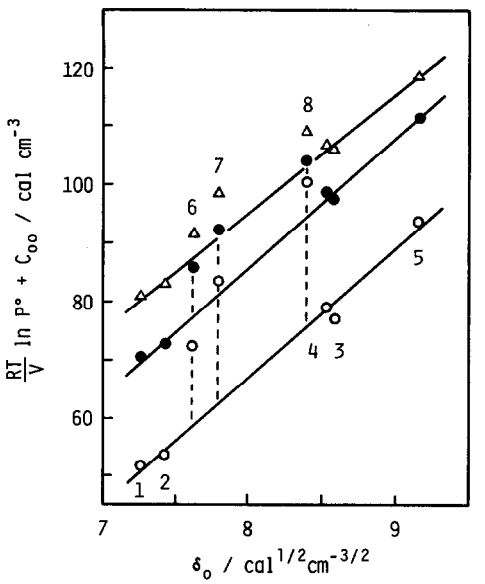

Fig. 3. Evaluation of partition coefficients with eqn (2). The numbers correspond to those in Table 2. ○ $Ni(tta)_2$; ● $Cu(tta)_2$;[9] △ Htta(enol).[9]

be expected to be larger than that of $Cu(tta)_2$, which is extracted without appreciable hydration in nonpolar solvents, due to a contribution of the coordinated water having a high solubility parameter (δ: 23.4). Accordingly, it may be speculated that $Ni(tta)_2$ is not extracted as a rigid hydrated state in the nonpolar solvents. The plots for polar solvents always deviate from the straight line and the extent of deviation is greatly different in different solutes. The observed deviation may be ascribed to additional interaction between the solute and these polar solvents.

Under the assumption that eqn (2) holds for the partition coefficients of acidic chelating ligand P_A°, and also for that of its metal chelate, P_M°, the following relation is readily derived

$$\log P_M^\circ = \frac{V_M}{V_A}\log P_A^\circ + \frac{2V_M}{2.303RT}(\delta_M - \delta_A)\delta_o + \frac{2V_M}{2.303RT}(C'_{wA} - C'_{wM}). \quad (3)$$

The plots of $\log P_M^\circ$ *vs* $\log P_A^\circ$ in thenoyltrifluoroacetonate and dimethyldithiocarbamate systems are shown in Fig. 4. The plots for both $Ni(dmdtc)_2$ and $Cu(dmdtc)_2$ are close to the *ideal* straight line with the slope of two passing through the origin. This *ideal* straight line can be expected when the second and third terms on the right-hand side of eqn (3) are negligible, and this is fulfilled at $\delta_M \simeq \delta_A$ and $C'_{wA} \simeq C'_{wM}$. On the other hand, the plots for $Ni(tta)_2$ and $Cu(tta)_2$, particularly for the

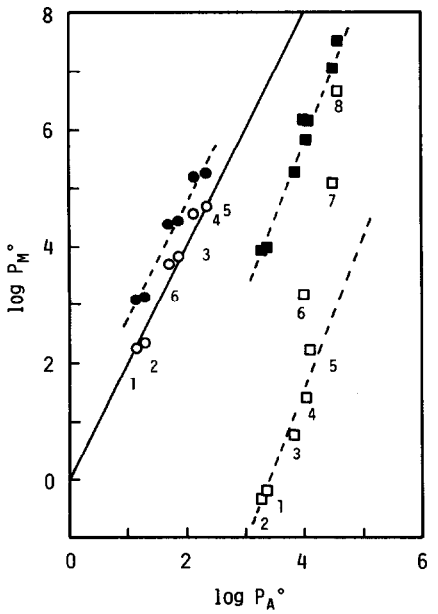

Fig. 4. Linear free energy relationship between the partition coefficients of acidic chelating ligand and its divalent metal chelate. The numbers correspond to those in Table 2. ○ $Ni(dmdtc)_2$; ● $Cu(dmdtc)_2$;[10] □ $Ni(tta)_2$; ■ $Cu(tta)_2$.[9]

former chelate, are in a region remarkably lower than those of the dimethyldithiocarbamate system. By knowing a similarity between the solubility parameters of the solutes $Ni(tta)_2$, $Cu(tta)_2$ (δ: 11.0)[9] and Htta(enol) (δ: 10.2),[9] it is considered that such a lower straight line observed for $Ni(tta)_2$ is caused by a large negative contribution of the third term in eqn (3), i.e. $C'_{wM} > C'_{wA}$. Additionally, the plots for $Ni(tta)_2$ in ether and ketone solvents deviate remarkably from the straight line drawn for the nonpolar solvents. These results suggest that an interaction with water in the aqueous phase is the dominant factor governing the partition coefficient of $Ni(tta)_2$ and also that an interaction of this chelate with polar organic solvents also plays an important role. A preferential solvation of water to $Ni(tta)_2$ over $Ni(dmdtc)_2$, $Cu(dmdtc)_2$ and $Cu(tta)_2$ is demonstrated by the next experiment. A known amount of the anhydrous chelates was left under a constant vapor pressure of water, 9.76 mmHg, which is maintained by an equilibrium atmosphere over 10 mol kg^{-1} lithium chloride solution at 25°C. The result is shown in Fig. 5 where the amount of water absorbed into the chelates was determined by weight variation. Only the $Ni(tta)_2$ chelate gradually takes up water until an equilibrium weight corresponding to $Ni(tta)_2 \cdot 2H_2O$.

A characteristic trend of $Ni(tta)_2$ in the liquid–liquid partition is demonstrated also by a linear free energy relationship between the partition coefficient

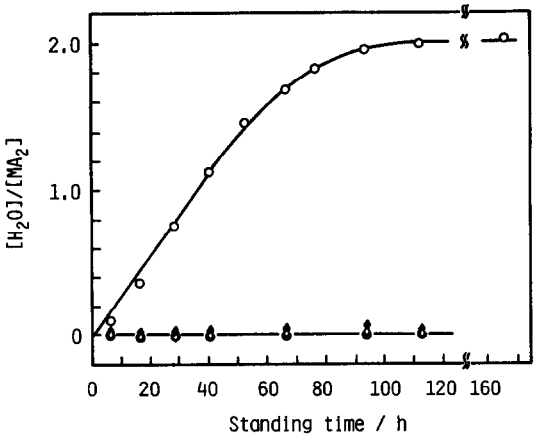

Fig. 5. Hydration of the divalent metal chelates under a constant vapor pressure of water (9.76 mmHg) at 25°C. ○ $Ni(tta)_2$; ● $Cu(tta)_2$; ◇ $Ni(dmdtc)_2$; ◆ $Cu(dmdtc)_2$.

of nickel(II) chelate, P_{Ni}, and that of copper(II) chelate, P_{Cu}, with a given chelating ligand. The relationship is simply derived from eqn (2) as

$$\log P°_{Ni} = \frac{V_{Ni}}{V_{Cu}} \log P°_{Cu} + \frac{2V_{Ni}}{2.303RT}(\delta_{Ni} - \delta_{Cu})\delta_o + \frac{2V_{Ni}}{2.303RT}(C'_{wCu} - C'_{wNi}). \quad (4)$$

The plots of $\log P_{Ni}°$ *vs* $\log P_{Cu}°$ are shown in Fig. 6.

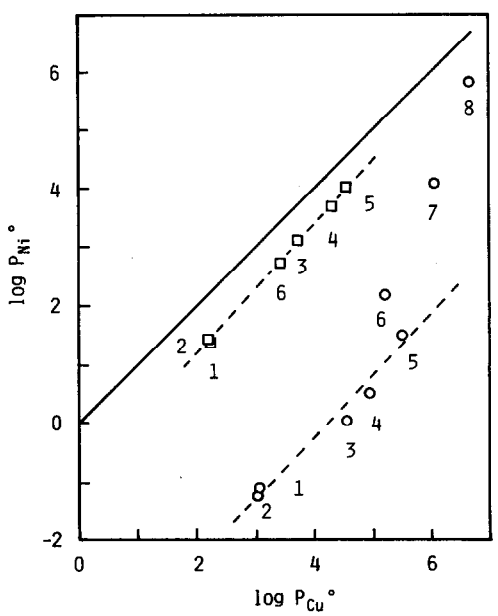

Fig. 6. Linear free energy relationship between the partition coefficients of nickel(II) chelate and copper(II) chelate. The numbers correspond to those in Table 2. □ dimethyldithiocarbamate; ○ thenoyltrifluoroacetonate.

The plots of two metal chelates with dimethyldithiocarbamate are close to the straight line with the unit slope passing through the origin, and this is reasonably understood by considering that the second and third terms in eqn (4) are almost negligible as discussed above. On the other hand, the plots of two metal chelates with thenoyltrifluoroacetonate show a linear correlation with the unit slope of nonpolar solvents, but have a large negative intercept due to much larger solvation of water to $Ni(tta)_2$ compared to $Cu(tta)_2$, and it is again clear that the plots for polar organic solvents deviate remarkably from the straight line due to an appreciable interaction of these polar organic solvents with $Ni(tta)_2$. A noticeable difference in the solute–water and the solute–polar organic solvent interaction observed in two nickel(II) chelates with thenoyltrifluoroacetonate and dimethyldithiocarbamate may be ascribed to the chemical nature of these chelates. Nickel(II) chelate with thenoyltrifluoroacetonate has a strong tendency to form a high-spin complex, by readily forming an adduct compound with donor molecules, such as polar solvents including water, and takes an octahedral structure. On the other hand, dimethyldithiocarbamate chelate involving sulfur donor atoms is a diamagnetic complex with a square planar structure, and shows very little tendency towards coordination of additional donor molecules.[14] In this connection, the partition coefficient of $Ni(dmdtc)_2$ into heptane was measured in the presence of tributylphosphate (tbp), this having a higher coordination ability. The addition of tbp in as high a concentration as 0.10 M has little influence on the P_M ($\log P_M$: 1.66 ± 0.12). This result shows the great difficulty of further coordination of such a strong Lewis base as tbp to $Ni(dmdtc)_2$.

In conclusion, the partition coefficient of nickel(II) chelate with dimethyldithiocarbamate can be quantitatively evaluated by the simple equation based on the regular solution concept, but the partition coefficient of nickel(II) chelate with thenoyltrifluoroacetonate is highly susceptible to water and polar organic solvents. A large difference in the partition coefficients of two nickel(II) chelates with different chelating ligands but of a similar stoichiometry MA_2 is clearly demonstrated.

THE $^1A_1 \rightarrow {}^1E$ TRANSITION AS A MEASURE OF THE π-ACCEPTOR ABILITY IN $M(CO)_5L$ COMPLEXES

C. DÍAZ* and N. YUTRONIC

Universidad de Chile, Facultad de Ciencias, Casilla 653, Santiago, Chile

(*Received* 28 *August* 1985; *accepted after revision* 13 *May* 1986)

Abstract—It has been found that the position of the λ_{max} for d–d $^1A_1 \rightarrow {}^1E$ transition for $M(CO)_5L$ (M = Cr, Mo and W) complexes is determined by the π-acceptor ability of the L ligand estimated by the Graham π-parameter. The utility of electronic spectra data in the determination of the π-acceptor property of ligands is discussed.

In general, the transfer of electrons from the metal to the ligand (π-back-bonding) in metal carbonyl compounds depends on the properties of the metal and the ligand. For a constant metal this π-back-bonding depends solely of the nature of the ligand and several techniques have been used for the investigation of this matter: IR,[1–4] photoelectron[5] and ^{13}C NMR spectroscopy.[6] Theoretical studies[7] also have been made for a major understanding of this problem.

Although carbonyl frequencies ν(C—O) and force constants k_1 and k_2 have been largely employed in the estimation of the π-acceptor capacity of the ligand L in the $M(CO)_5L$ system,[1,4,8] the M—C bond distances obtained from X-ray crystallographic studies are actually most used.[9,10] Nevertheless, this technique can be employed only for those compounds for which suitable crystals can be obtained. As a more simple method of determining this property the estimation of the π-acceptor ability of L ligand in complexes $M(CO)_5L$ (M = Cr, Mo and W) from their UV–vis spectra is proposed in this paper and its validity and reliability discussed.

RESULTS AND DISCUSSION

As a measure of the π-acceptor ability of ligand we have used the Graham π-parameter[11] because it appears as the best method to estimate this property; in fact this parameter correlates well with the M—C *trans* bond distance in $Cr(CO)_5L$ complexes.[12] Thus the decrease of Cr—CO (*trans*) length bond has been usually discussed on the basis of the π-acceptor capacity of the L ligand.[10]

The π-acceptor ability expressed by the Graham π-parameter was calculated for the $M(CO)_5L$ complexes through the k_1 (axial) and k_2 (equatorial) Cotton–Kraihanzel force constants obtained from the carbonyl ν(C—O) stretching frequencies, previously reported in the literature.[2,3,13,14] For the complexes $[M(CO)_5(THF)]$ (M = Cr, W) no carbonyl stretching and UV–vis data have been reported. Hence they were obtained through irradiation of a solution of $M(CO)_6$ and the ligand in THF as solvent.[14] Because they are highly unstable they cannot be isolated and the IR and visible spectra were recorded from freshly prepared solutions of the complexes. The complex $[Cr(CO)_5(C_6H_5SH)]$ was synthesized from the reaction of $[Cr(CO)_5(THF)]$ photochemically generated with C_6H_5SH and subsequent purification.[14] The yellow solid obtained is highly unstable and the IR and UV–vis spectra were rapidly recorded.

The lowest energy absorption in the complexes $M(CO)_5L$ have been assigned to the ligand field $^1A(e^4b_2^2) \rightarrow {}^{1,3}E(e^3b_2^2a_1^1)$ transition[15,17] (see Fig. 1). Variations of λ for this transition as a function of the acceptor ability of L expressed by the Graham π-parameter are illustrated in Fig. 2 in which λ_{max} is plotted *vs* π for 16 complexes $Cr(CO)_5L$. For $Mo(CO)_5L$ and $W(CO)_5L$ complexes (Figs 3, 4) similar relationships are obtained. The points lie within straight lines:

1. $\lambda_{max}Cr(CO)_5L = -137.7\pi + 407.2$ (1)

2. $\lambda_{max}Mo(CO)_5L = -136.0\pi + 387.84$ (2)

3. $\lambda_{max}W(CO)_5L = -141.74\pi + 391.75.$ (3)

From Figs 3–4 it is immediately evident that, from an increase of π-acceptor capacity of L, a decrease of λ_{max} for the transitions is observed and vice versa.

This trend can be qualitatively understood if we consider the one-electron energy ordering for $C_{4v}d^6$ $M(CO)_5L$ complexes[18] which is shown in the scheme of Fig. 1.

A better π-acceptor ligand causes a decrease in interelectron repulsion by π-back-bonding M → L interaction and therefore a stabilization of the π levels. Consequently a Δ increase and a diminution of λ_{max} is obtained. On the contrary, poor π-acceptor (or π-donor, π with negative values) produces an increase of the energy of π level, and hence a decrease of Δ.

Accordingly a relationship of the type $1/\lambda = a\pi$ could be expected rather than equations (1)–(3) but better correlations were obtained in these latter expressions. When λ^{-1} is plotted against parameter π a smooth curve is obtained, due to the deviation of extremes points. This effect is less notorious when the data are fitted by linear correlation of λ with π. Further straightforward expressions are practically most useful.

From Figs 2–4, however, it is observed that somewhat different values of π give similar values of λ_{max}: hence for these cases λ_{max} could be used only roughly as a measure of the π-acceptor capacity of ligands. From this can be concluded that λ_{max} is not able to distinguish ligands with only slightly different acceptor ability.

Table 1. π values calculated from IR and UV–vis data for $M(CO)_5L$, L = 4-vinyl pyridine, and for $W(CO)_5(Te{=}CPh_2)$

	π(IR)	π(UV–vis)
$Cr(CO)_5$(4-VP)	−0.07	−0.05
$Mo(CO)_5$(4-VP)	−0.01	−0.06
$W(CO)_5$(4-VP)	−0.09	−0.086
$W(CO)_5(Te{=}CPh_2)$	0.11	0.22

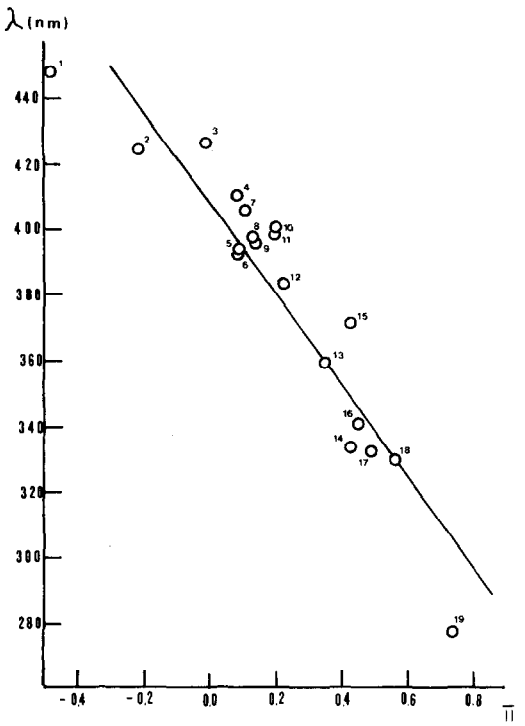

Fig. 2. Dependence from the π-acceptor capacity of λ_{max} for $Cr(CO)_5L$.

Data for $M(CO)_5L$, L = carbenes[19] and thioureas,[20,21] fall out of the relationships (1)–(3).

It is noteworthy that the slopes of the straight lines shown in Figs 2–4 are equal. From this it can be concluded that the π-acceptor ability measured by the relationships 1, 2 and 3 is a property that

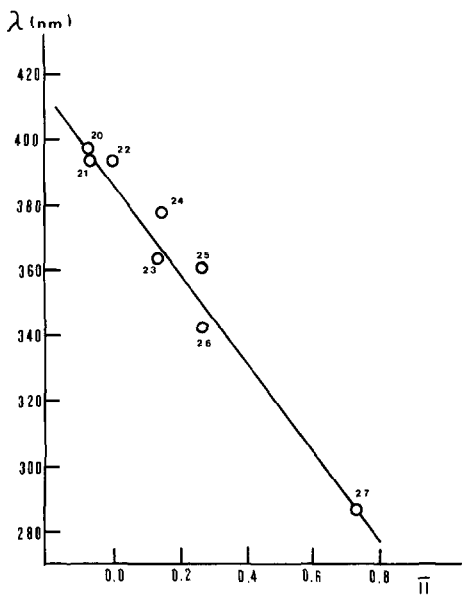

Fig. 3. Dependence from the π acceptor capacity on λ_{max} for $Mo(CO)_5L$.

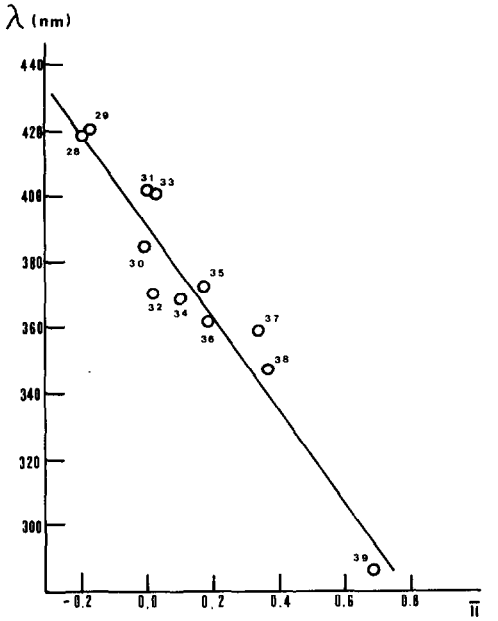

Fig. 4. Dependence from the π-acceptor capacity on λ_{max} for $W(CO)_5L$.

does not depend on the metal (Cr, Mo or W) and hence λ_{max} can be viewed as a sort of 'spectrochemical series' for π-bonding neutral ligands.

As an example of the validity of equations (1)–(3) we have estimated the π parameter from UV–vis data for $M(CO)_5$(4-VP) (4-VP = 4-vinyl pyridine; M = Cr, Mo and W) reported recently.[22] This is shown in Table 1 where the values are close that those calculated from IR data. For the complex $[W(CO)_5(Te{=}CPh_2)]$[23] a satisfactory agreement was also found.

These results suggest that in spite of the fact that UV–vis spectral data are rarely included in the characterization of $M(CO)_5L$ derivatives,[24] electronic spectra can afford valuable information about the π-acceptor ability of the ligand similar to that obtained by IR spectroscopy and other methods. The estimation of this property using UV–vis data is particularly useful when the $M(CO)_5L$ is not soluble in apolar and inert solvents, in such a case it is not possible to record the IR spectra in the C—O stretching region which precludes the estimation of the π-parameter. Then, a diffuse reflectance spectra should be utilized for estimation of the π-acceptor capacity.

(*Received* 11 *February* 1986; *accepted* 29 *July* 1986)

Abstract—Organoindium compounds of general formula Bu_2InX [where X is OBu^t, OPh, O_2CEt, O_2CPh, $O_2CCH(Et)(CH_2)_3CH_3$ or $C_5H_7O_2$ (acetylacetonate)] were synthesized, and their thermal decomposition was investigated by means of thermogravimetry. The main pyrolysis of the dibutylindium compounds was exothermic and their thermal weight loss occurred below *ca* 400°C. In contrast, metallo-organics such as $In(acac)_3$ and $In[O_2CCH(Et)(CH_2)_3CH_3]_3$ decomposed endothermically in the temperature range between 190 and 480°C. Chemical liquid pyrolysis of dibutylindium octanoate and propionate in *p*-xylene below 450°C, along with dibutyltin oxide as a dopant, gave highly conductive (*ca* 10^{-3} Ω cm) and transparent indium–tin-oxide films.

The chemistry of organoindium compounds has been one of the less studied areas of organometallic chemistry, and synthetically and industrially they have been almost ignored.[1] Recently, studies on the organoindiums have increased since MOCVD (metal organic chemical vapour deposition, alternatively termed OMCVD) techniques for the production of III/V semiconductor thin films have been remarkably developed.[2] However, MOCVD has usually been carried out with indium trialkyls, and the use of organoindium compounds other than the trialkyls has been limited.

On the other hand, some recent reports have shown that indium–tin-oxide (ITO) films as one example of III/VI semiconductors, which are most useful as conducting and transparent oxide films for displays or solar cell windows,[3] could be prepared by chemical pyrolysis of metallo-organics of indium such as chelates,[4,5] acylates[6] and alkoxides.[7–9] However, the chemical pyrolytic preparation of ITO films by using such metallo-organics must usually be carried out with substrate temperatures greater than about 500°C to obtain highly conductive films.

We expected that the chemical liquid pyrolysis of organoindium compounds, because of the lability of their In—C bonds[10] compared with metallo-organics, could give highly conductive ITO films even at moderate temperatures. However, the thermal behaviour of the organoindium derivatives is not known in detail. Hence, we investigated the thermal decomposition of organoindium compounds (Bu_2InX) [where X is OBu^t, OPh, O_2CEt, O_2CPh, $O_2CCH(Et)(CH_2)_3CH_3$ or $C_5H_7O_2$ [acetylacetonate (acac)], aiming at establishment of suitable organometallics for the preparation of ITO films by means of chemical liquid pyrolysis.

EXPERIMENTAL

General

IR and ^{1}H NMR spectra were recorded on a Hitachi 260-30 spectrophotometer and a JEOL JMX-100 spectrometer, respectively. Thermogravimetric analyses were performed with a Rigaku DG-C1H type thermogravimeter. Film thickness was measured by a multiple reflection interferometer, using nitric acid etched samples as reported by Ogihara and Kinugawa.[4] Surface resistivity of the films was measured with a Tycoon 841 type four-probe apparatus, a Takasago CCP10-1MR Dc constant-current power supply and Sanwa 9000EA digital multimeter. Indium chloride ($InCl_3 \cdot 3.5H_2O$), indium tris(2-ethylhexanoate) and dibutyltin oxide as a dopant were from commercial sources.

Preparation of organoindium compounds

Tributylindium was synthesized by the Grignard method reported by Runge *et al.*[11] by using $InCl_3$ which was prepared by dehydration of commercial $InCl_3 \cdot 3.5H_2O$ *in vacuo* (10^{-4} torr) at 160°C for 1 h. The crude tributylindium was purified by distillation twice *in vacuo* [yield 60%, b.p. 117°C/3 torr (lit.[12] 86–7°C/0.4 torr)]. Dibutylindium derivatives were then prepared by the direct reaction of the corresponding oxygen acids with tributylindium in ether as reported by Clark and Pickard,[13] and were recrystallized from ether or distilled *in vacuo*. The results of the analyses and the properties of the dibutylindium derivatives are summarized in Table 1. In addition, it is very interesting that tributylindium was converted into pure indium tris(acetylacetonate) quantitatively in acetylacetone solution: m.p. 188–190°C (lit.[15] 186°C); IR (KBr): 440 cm^{-1} (ν_{In-O}); ^{1}H NMR ($CDCl_3$): δ 2.00s (6H, CH_3), 5.41s (1H, CH). Found: C, 44.2; H, 5.3. Calc. for $C_{15}H_{21}InO_6$; C, 43.7; H, 5.1%.

Film preparation

ITO films were prepared as follows. To 10 cm^3 of absolute *p*-xylene, prescribed amounts of organoindium compounds and dibutyltin oxide were dissolved (boiled if necessary). About 100 μl of the resulting solution was dropped upon a glass sub-

strate (Matsunami slide glass No. S-111, 76 × 26 mm) and spread over the surface by tipping. The substrate was then heated in air at 100°C for 40 min, resulting in the formation of a transparent film. However, films thus obtained were not conductive. The films on the substrate were then baked in a quartz tube at 350–500°C for 1 h in air.

RESULTS AND DISCUSSION

The results of the thermogravimetric analyses of the dibutylindium derivatives along with two metallo-organics of indium are summarized in Table 2 and typical thermograms are presented in Fig. 1. The thermal weight loss of indium tris(acetylacetonate) and indium tris(2-ethylhexanoate), which are the most popular metallo-organics for the preparation of ITO films,[4–6] occurred sharply at *ca* 300 and 380°C, respectively, along with large endothermic DTA peaks. The weight loss, however, continued beyond 400°C. The sharp and endothermic decomposition indicates that bond dissociation between the indium atom and ligands is the initial process, and degradation of ligands follows later.

The behaviour of dibutylindium derivatives in thermal decomposition seems apparently opposite to that of the metallo-organics. The dibutylindiums were found to decompose *via* complex multi-steps as can be seen from TG and DTA curves. The main thermal decomposition process is exothermic, and occurred below 300°C. Thus, it can be said that these dibutylindium compounds are superior to the metallo-organics for the preparation of ITO films at lower temperatures. Travkin *et al.*[15] and Aleksandrov *et al.*[16] have reported that trialkylindiums, including tributylindium, decomposed exothermically at temperatures between 200 and 300°C.

$Bu_2In(acac)$

Three peaks appeared in the DTA curve. A sharp endothermic peak at 83°C means that $Bu_2In(acac)$ melts at this temperature. The exothermic and broad DTA peak centered at 260°C seems to characterize the thermal decomposition of $Bu_2In(acac)$, in contrast to the other metallo-organics. The main thermal weight loss occurred exothermically and the presence of one inflection point was observed at 260°C, based on DTG. At the point of inflexion, the weight loss reached 35.5%, which corresponds to the loss of two Bu groups.

The main decomposition process ceased at 310°C, after a weight loss of 56.4%. Thus, $Bu_2In(acac)$ was pyrolysed into In_2O_3 up to 310°C. The

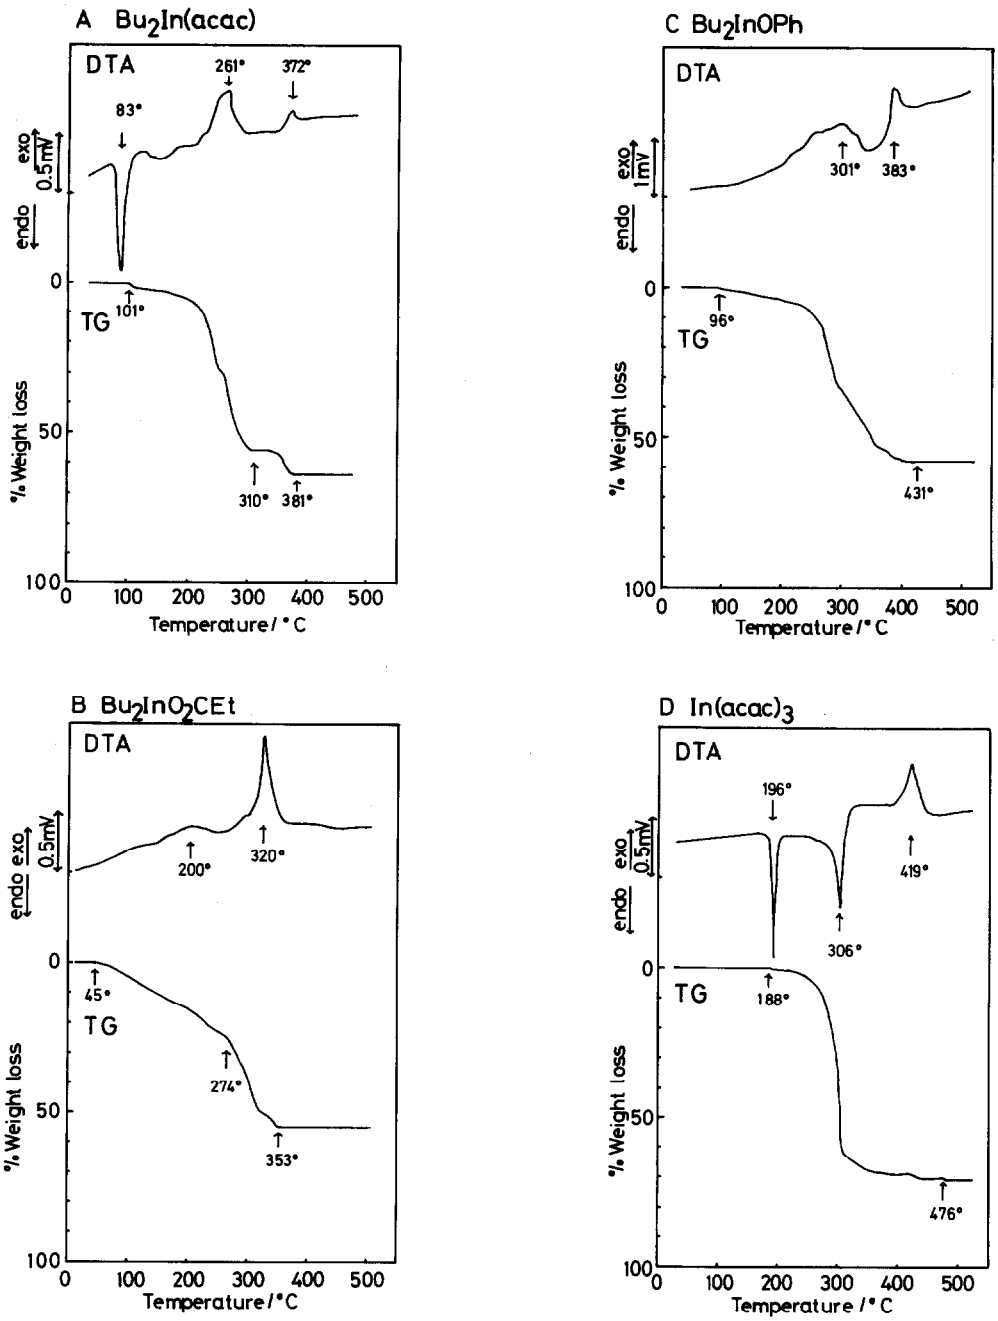

Fig. 1. Thermograms of organoindium compounds: (A) $Bu_2In(acac)$, (B) $Bu_2In(O_2CEt)$, (C) $Bu_2In(OPh)$, and (D) $In(acac)_3$.

weight loss again started exothermically at 350°C and finally ended at 381°C, followed by indium metal deposition. In general, because of the insufficiency of oxygen, organoindium derivatives employed here often gave an oxygen-deficient indium oxide or indium metal via pyrolysis under an inert atmosphere. In the decomposition of $Bu_2In(acac)$, a trace of carbon contamination derived from butyl substituents might catalyse the reduction of the resulting indium oxide. However, it is important that the temperature for decomposition into In_2O_3 was about 100°C lower than that of $In(acac)_3$.

$Bu_2In(O_2CEt)$ *and* $Bu_2In[O_2CCH(Et)(CH_2)_3CH_3]$

These acylates did not give indium metal on thermal decomposition. The main decomposition processes are also exothermic, but the exothermic DTA peaks shifted to a higher temperature compared to

$Bu_2In(acac)$. Especially for $Bu_2In(O_2CEt)$, a significant weight loss was observed over a wide range of temperature, 45–353°C. Although a clear inflection point was present at 274°C in the TG curve, where the total weight loss could be read as 23.3%, the weight loss could not be correlated with the simple liberation of any individual substituent. In addition, the controlled degradation experiment of $Bu_2In(O_2CEt)$ at 250°C for 1 h under N_2 gave *ca* 30% of butyl propionate.

Hence, the thermal decomposition of $Bu_2In(O_2CEt)$ evidently proceeded via a complex process, such as the combination of free-radical elimination of the butyl group bonded to central indium atoms to give alkanes, hydride transfer to afford alkenes as in the thermal decomposition of indium trialkyls,[15,16] and reductive-elimination to form butyl propionate. As shown in TG and DTA, dibutylindium 2-ethylhexanoate, possessing a long carbon chain, behaved rather similarly to $Bu_2In(acac)$ and no weight loss far below the m.p. was detected.

$Bu_2In(OR)$ (R = Bu^t *and* Ph)

The thermal behaviour of $Bu_2In(OBu^t)$ could not be investigated in detail because it vaporized above 330°C. An exothermic peak at 280°C was observed, which indicated that the dibutylindium *tert*-butoxide was partially decomposed. In the case of the phenoxide, two exothermic peaks at 301 and 383°C were observed. Thus, the decomposition process could be divided into two steps. In the former step, $Bu_2In(OPh)$ lost two butyl groups and, in the latter, the Ph group was formally liberated, based on % weight loss observation. Thus, $Bu_2In(OPh)$ can be said to be thermally the most stable of the organoindium compounds employed here.

Preparation of ITO films and their resistivities

In this study, we selected Bu_2SnO as a source of tin dopant, because of its high reactivities to active hydrogen compounds[17] and towards other organometallics to give Sn—O—metal bonds on heating.[18] Thus, we expected that if indium alkoxide or indium hydroxide were formed in the primary pyrolysis of organoindium compounds,[19] an In—O—Sn linkage or even network could be easily afforded by disproportionation with dibutyltin oxide. The formation of an In—O—Sn linkage disperses Sn moieties uniformly over the indium oxide layers. Results of the preparation of ITO films when the ITO solution in *p*-xylene was heated at 120°C for 40 min and baked at 450°C for 1 h are summarized in Table 3.

Clear and transparent ITO films were obtained by using dibutylindium acylates or acetylacetonate. Volatile $Bu_2In(OBu^t)$ gave no film and relatively stable $Bu_2In(OPh)$ afford opaque and highly resistive films. in contrast, dibutylindium acylates yielded highly conductive films: in the lower end of the order of 10^{-3} Ω cm. The temperature dependency of the ITO film resistivities was further investigated using the octanoate, which afforded the most conductive ITO films. The resistivity reached

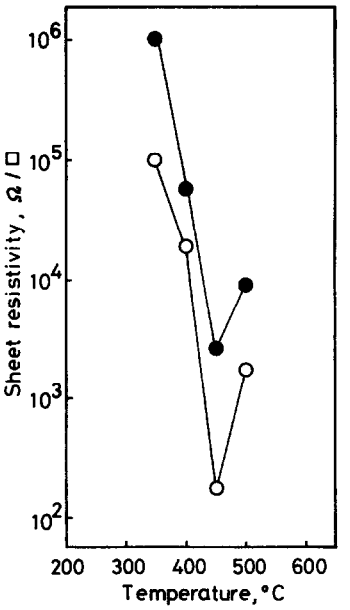

Fig. 2. Relation between sheet resistivities of ITO films prepared from $Bu_2In(O_2CCH(Et)(CH_2)_3CH_3)$ with or without Bu_2SnO and baking temperature; solvent was *p*-xylene and the dibutylindium octanoate concentration was kept at 5 wt %. The Bu_2SnO content varied between 0 (●) and 2 wt % (○), with respect to the indium compounds.

Table 3. Resistivity of ITO films prepared from dibutylindium compounds and dibutyltin oxide[ab]

Bu_2InX X	Film thickness (Å)	Resistivity (Ω cm)	Appearance
OBu^t	—	$> 10^2$	—
OPh	2000	$> 10^2$	Opaque
acac	3100	7.1×10^{-1}	Clear
O_2CEt	860	3.5×10^{-3}	Clear
O_2CC_7[c]	1400	1.9×10^{-3}	Clear

[a] ITO solution composition: solvent, *p*-xylene; organoindium compounds, 5 wt %; Bu_2SnO as dopant, 0.25 wt %.

[b] Conditions of ITO film preparation: 100°C, 40 min; 450°C, 1 h.

[c] 2-Ethylhexanoate.

a minimum at 450°C and then increased with rise in temperature. In chemical pyrolysis, the resistivity has been reported generally to decrease with temperature till 600°C.[6] An increase in resistivity with rising temperature above 450°C resulted from the partial reduction of deposited In_2O_3 derived from the organoindium compounds into indium metal or oxygen-deficient indium oxides.

In conclusion, the organoindium compounds containing at least one In—O bond are thermally unstable relative to the corresponding metallo-organics. Thus, the chemical pyrolysis of the organoindium compounds could give highly conductive ITO films even at 400–450°C.

SYNTHESES AND PROPERTIES OF *STRATI-BIS* COPPER(II) COMPLEXES WITH $[N_2O_2]_2$ TYPE SCHIFF BASES

MASAAKI NAKAMURA,* TAKESHI MASUMOTO and FUMIAKI KAI

Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860, Japan

(*Received* 1 *May* 1986; *accepted* 29 *July* 1986)

Abstract—The new *"strati-bis"* Schiff base ligands, H_4(R,R′-sabzta), and their binuclear copper(II) complexes, Cu_2(R,R′-sabzta), were prepared and characterized, where H_4(R,R′-sabzta) denotes 1,2,3,4-tetrakis(R′-salicylideneamino)-2,3-bis(R-phenyl)butane (R = H or *p*-Cl; R′ = H, 5-Me or 5-Bu^t). No substantial differences in the electronic and ESR spectra were observed between these binuclear and the corresponding mononuclear copper(II) complexes. In each of those binuclear complexes, only one redox wave was observed at nearly the same potential as their corresponding mononuclear complexes. The redox wave was tentatively assigned to a total two-electron transfer process, Cu(II)–Cu(II) → Cu(I)–Cu(I), involving two one-electron reduction waves. These spectral and electrochemical properties of the binuclear complexes could be attributed to the two copper(II) ions not interacting through the intramolecular π–π stacking of the two metal coordination planes.

"*Strati-bis*" binuclear complexes in which the two metal coordination planes are held in a face-to-face manner by flexible or non-flexible linkages have been investigated as model systems for the active sites of some biological bimetal systems.[1–3] It has been mainly focused on bis(porphyrin) metal complexes, whereas studies on the metal complexes with Schiff bases are few in number.

Previously, Ōkawa *et al.*[4–8] reported the syntheses and characterization of *strati-bis* Schiff base ligands, 1,2,3,4-tetrakis(R′-salicylideneamino)-2,3-dimethylbutane [H_4(R′-sata)] and 1,2-bis(R′-salicylideneamino)-1,2-bis(R′-salicylideneaminomethyl)-cyclohexane [H_4(R′-sacta)] (R′ are the substituents on salicylaldehyde), and their binuclear metal complexes. The metal ions in these complexes are held in the "salen-like" donation site [H_2(salen) = 1,2-bis(salicylideneamino)ethane] and their two [MN_2O_2] coordination planes can be stacked in a face-to-face manner in solution. The stacked species of these complexes showed the unique properties in contrast with the corresponding mononuclear complexes. The most striking characteristics of the species are the facile reduction to the mixed valence [M(II)–M(I) or M(III)–M(II)] complexes and considerable stabilization of these reduced species. This can be rationalized in terms of the electron delocalization over the whole molecule by the π–π stacking of the two metal coordination planes.

In this study, the new *strati-bis* Schiff base ligands which contain the aromatic rings as the substituents on the tetraamine moiety, 1,2,3,4-tetrakis(R′-salicylideneamino)-2,3-diphenylbutane [H_4(R′-sabzta)] and 1,2,3,4-tetrakis(R′-salicylideneamino-2,3-bis-(4-chlorophenyl)butane [H_4(*p*-Cl,R′-sabzta)] (R′ are the substituents on the salicylaldehyde), and their binuclear copper(II) complexes were prepared and characterized. The structures of these ligands are given in Fig. 1. Each ligand has also two "salen-like" donating sites which are linked to each other making a bond between carbon atoms of the ethylenediamine moieties. It is expected in the present complexes that the two metal coordination planes would be stacked in a face-to-face manner and the two aromatic rings at the tetraamine moiety stacked to each other by molecular model considerations. The spectroscopic and redox properties of those complexes were investigated in connection with the effects of the introduced aromatic rings on the π–π stacking between the two metal coordination planes.

EXPERIMENTAL

Synthesis

1,2-Bis(4-chlorophenyl)ethanedione was prepared by the method described in the literature.[9] 1,2,3,4-Tetraamino-2,3-diphenylbutane and 1,2,3,4-tetraamino-2,3-bis(4-chlorophenyl)butane were synthesized in nearly the same way as 1,2,3,4-tetraamino-2,3-dimethylbutane[4] from 1,2-diphenylethanedione and 1,2-bis(4-chlorophenyl)ethanedione, respectively. 5-Methyl- and 5-*t*-butylsalicylaldehyde were prepared by the formylation (Duff's reaction)[10] of 4-methyl- and 4-*t*-butylphenol, respectively. The binucleating ligands, H_4(R,R'-sabzta) (R = H or *p*-Cl; R' = H, 5-Me or 5-Bu^t), were prepared by the condensation of the tetraamine and salicylaldehyde or its derivatives in ethanol in a 1 : 4 mole ratio.

Cu_2(sabzta). Copper(II) acetate monohydrate (1.44 mmol) and H_4(sabzta) (0.72 mmol) were suspended in absolute ethanol (20 cm^3) and the mixture was refluxed for 4 h. A purple crystalline powder formed was collected. The product was recrystallized from a chloroform–ethanol mixture. Found: C, 63.1; H, 4.3; N, 6.6%. Calc. for $C_{44}H_{34}N_4O_4Cu_2 \cdot \frac{3}{2}H_2O$: C, 63.2; H, 4.5; N, 6.7%.

Cu_2(5-Me-sabzta). Copper(II) acetate monohydrate (1.92 mmol) and H_4(5-Me-sabzta) (0.96 mmol) were suspended in absolute ethanol (20 cm^3) and the mixture was refluxed for 4 h. The green crystalline powder precipitated was collected and washed with a small amount of ethanol, the product was dissolved in chloroform and the solution was passed through a silica gel column (3 × 15 cm). The eluant was concentrated to *ca* 5 cm^3 and allowed to stand overnight at room temperature to give Cu_2(5-Me-sabzta) as a purple crystalline powder. Found: C, 65.0; H, 5.0; N, 6.1%. Calc. for $C_{48}H_{42}N_4O_4Cu_2 \cdot H_2O$: C, 65.2; H, 5.0; N, 6.3%.

Cu_2(5-Bu^t-sabzta). A mixture of copper(II) acetate monohydrate (1.92 mmol), H_4(5-Bu^t-sabzta) (0.96 mmol), and triethylamine (3.84 mmol) in absolute ethanol (20 cm^3) was refluxed for 3 h. The purple powder precipitated was collected. The purple crystal was obtained by recrystallization of the crude product from ethanol–chloroform. Found: C, 68.4; H, 7.0; N, 5.0%. Calc. for $C_{60}H_{60}N_4O_4Cu_2 \cdot 2C_2H_5OH$: C, 68.2; H, 7.0; N, 5.0%.

Cu_2(*p*-Cl-sabzta). This complex was obtained as a purple crystalline powder by reacting copper(II) acetate monohydrate (2.06 mmol) and H_4(*p*-Cl-sabzta) (1.03 mmol) in absolute ethanol (20 cm^3) in a way similar to that for Cu_2(5-Me-sabzta). Found: C, 53.6; H, 3.6; N, 5.4%. Calc. for $C_{44}H_{32}N_4O_4Cl_2Cu_2 \cdot CHCl_3 \cdot \frac{1}{2}H_2O$: C, 53.7; H, 3.4; N, 5.6%.

Cu_2(*p*-Cl,5-Me-sabzta). This complex was also obtained as a purple crystalline powder by reacting copper(II) acetate monohydrate (2.06 mmol) and H_4(*p*-Cl,5-Me-sabzta) (1.03 mmol) in absolute ethanol (20 cm^3) in a way similar to that for Cu_2(5-Me-sabzta). Found: C, 61.5; H, 4.5; N, 5.8%. Calc. for $C_{48}H_{40}N_4O_4Cl_2Cu_2$: C, 61.7; H, 4.3; N, 6.0%.

The mononuclear copper(II) complexes, Cu(R,R'-sabzen) (R = H or *p*-Cl, R' = H or 5-Me), were synthesized by the method described in the literature.[11]

Measurements

IR spectra were recorded on a JASCO IRA-1 grating spectrometer on a KBr disk. ^{1}H NMR spectra were recorded on a Hitachi–Perkin–Elmer R-24 spectrometer with tetramethylsilane as the internal reference. Electronic spectra were recorded on a Hitachi 220 A recording spectrophotometer in dichloromethane. Polarograms were recorded on a Yanagimoto voltammetric analyzer Model P-1000 in dichloromethane containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. A three-electrode cell was used for measurements, in which the working electrode is a dropping mercury electrode or a glassy carbon, and the auxiliary electrode a platinum coil. A saturated calomel electrode (SCE) was used as the reference electrode. In practice, instead of the reference

electrode an internal standard, the ferrocene–ferricinium(1+) couple, was utilized.[12] ESR spectra were measured with a JES-FE3X ESR instrument in frozen chloroform solutions near liquid-nitrogen temperature and at room temperature.

RESULTS AND DISCUSSION

The synthesis of new tetraamines, 1,2,3,4-tetraamino-2,3-diphenylbutane and 1,2,3,4-tetraamino-2,3-bis(4-chlorophenyl)butane, were carried out in the way similar to that for 1,2,3,4-tetraamino-2,3-dimethylbutane.[4,5] In these processes, each diaminodinitrile, 1,2-dicyano-1,2-diphenyl-1,2-ethanediamine and 1,2-dicyano-1,2-bis(4-chlorophenyl)-1,2-ethanediamine, gave two isomers which can be attributed to two geometrical isomers (*meso*- and *dl*-); one is liquid and the other is solid. The presence of two products of diaminodinitrile is similar to the case of 2,3-dicyano-2,3-butanediamine.[4,5] In this study, the solid product can be attributed to the *dl*-isomer by comparing with the case of the previous reports[4,5] which used $LiAlH_4$ reduction. In Fig. 1, the structures of the binucleating ligands H_4(R′-sata) and H_4(R,R′-sabzta) of the *dl*-tetraamines are shown.

The IR spectra of these complexes showed strong absorption bands at 1625–1628 and 1530–1535 cm^{-1} which could be assigned to a stretching vibration of the azomethine moiety and a skeletal vibration of the aromatic ring of the ligands, respectively. The frequencies of these characteristic bands are similar to those of the corresponding mononuclear copper(II) complexes, Cu(R,R′-sabzen) [R = H or *p*-Cl, R′ = H or 5-Me, H_2(R,R′-sabzen) = 1-(R-phenyl)-1,2-bis(R′-salicylidene amino)ethane], and other copper(II) complexes with "salen" type ligands.

Electronic spectra of the complexes obtained were measured in dichloromethane. The results are given in Table 1 and the spectrum of Cu_2(sabzta) is shown as an example in Fig. 2, together with the spectrum of Cu(sabzen). The absorption bands which can be assigned to a *d–d* transition of the central copper(II) ion are observed near 17,000 cm^{-1} with no substantial change in the frequency and the intensity between the binuclear and mononuclear complexes. This implies that the copper(II) ions of the binuclear complexes, as well as the mononuclear complexes, have a square planar configuration involving a $[CuN_2O_2]$ chromophore as already demonstrated for Cu(salen).[13] The bands near 27,000 cm^{-1} can be assigned to the π–π^* trans-

Cu(*p*-Cl,5-Me-sabzen)	−1.77	46	−1.75

[a] E_{Fc-Fc^+} is the oxidation potential of the ferrocene–ferricinium couple.

ition involving the azomethine π-character.[14] It is observed that there is no appreciable difference in the frequency between the bands of Cu(salpn) [H_2(salpn) = 1,2-bis(salicylideneamino)propane] (27,250 cm^{-1})[4] and Cu(R-sabzen) (27,000–27,100 cm^{-1}). This suggests that the substitution of a methyl group for aromatic rings at the ethylenediamine moiety of the ligands does not affect the electronic states of the azomethine moiety. Furthermore, the binuclear copper(II) complexes also showed the π–π^* transition band at essentially the same frequency as the mononuclear complexes, which implies the absence of appreciable π–π interaction between the two [CuN_2O_2] coordination planes of these complexes.

ESR spectra of the complexes obtained were measured at room and liquid-nitrogen temperature in chloroform solution, and the results are given in Table 2. All the spectra have the four-line hyperfine structure at both temperatures and a typical axial pattern ($g_\parallel > g_\perp$) at liquid-nitrogen temperature. These results suggest that the geometry around the copper(II) ions of the present binuclear complexes is almost the same as that of the mononuclear complexes and the intra- and intermolecular magnetic interaction between the copper(II) ions of the binuclear complexes are negligible.

Redox properties of the complexes obtained were examined by DC and differential-pulse polarography in dichloromethane containing 0.1 mol dm^{-3} TBAP as a supporting electrolyte. The differential-pulse polarograms were recorded by a dropping mercury electrode (DME) and a glassy carbon electrode (GCE). In Table 3, the half-wave potential and the slope of the potential vs log $(i/i_d - i)$ plot are given. The wave observed around −1.7 vs E_{Fc-Fc^+} in the mononuclear complexes is assigned to a quasi-reversible one-electron transfer process, Cu(II) → Cu(I), on the basis of their potentials and slopes (44–48 mV). On the other hand, only one redox wave was observed in the binuclear complexes at essentially the same potential as their corresponding mononuclear complexes. These redox waves can be also attributed to an apparent quasi-reversible one-electron transfer process, judging from the results of the standard polarographic plot of potential vs log $(i/i_d - i)$. The electrochemical properties of the present binuclear complexes resembled closely those of Cu_2(5-Me-sata) and Cu_2(5-Bu^t-sata),[4,5] in which the Cu(II)–Cu(II) species are reduced to Cu(I)–Cu(I) species by two simultaneous monoelectronic steps at nearly the same potential as those of the corresponding mononuclear complexes. From the resemblance of the electrochemical properties between Cu_2(R,R′-sabzta) and Cu_2(R′-sata), it is concluded that the apparent one-electron reduction wave for the former complexes can be assigned to a total two-electron transfer involving two one-electron reduction waves at the same potential. The results indicated that the two [CuN_2O_2] chromophores of the present binuclear complexes do not interact each other. This can be attributed to the steric hindrance of aromatic rings as substituents on the tetraamine moiety.

Acknowledgements—We wish to express our thanks to Professor Sigeo Kida and Associate Professor Hisashi Ōkawa of Kyushu University for help in obtaining the ESR and electrochemical data.

CHARGE-TRANSFER ABSORPTION SPECTRA OF SOME TUNGSTEN(VI) AND MOLYBDENUM(VI) POLYOXOANIONS

KENJI NOMIYA, YOSHINOBU SUGIE, KOICHI AMIMOTO and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 7 *April* 1986; *accepted* 29 *July* 1986)

Abstract—The charge-transfer (CT) absorption spectra in the UV region (30,000–50,000 cm^{-1}) of most W(VI) and Mo(VI) polyoxoanions, attributed to the oxygen-to-metal transitions, are interpreted on the basis of structural considerations through edge- and/or corner-sharings of some octahedral units. Polyoxoanions studied here are classified into two groups according to a common fragment constituting their structures; one group contains an 'M_5O_{18}' fragment [M = W(VI) and Mo(VI)] such as Weakley-type $[Ce(IV)(W_5O_{18})_2]^{8-}$ anion, $[W_{10}O_{32}]^{4-}$ and $[M'W_5O_{19}]^{n-}$ [M′ = V(V), Nb(V), W(VI)] polyanions and the other contains an A-α-'XM_9O_{34}' fragment (X = heteroatom) such as Keggin-type $[\alpha\text{-}XM_{12}O_{40}]^{n-}$ and Dawson-type $[\alpha\text{-}P_2M_{18}O_{62}]^{6-}$ heteropolyanions. The first- and second-lowest energy CT (LECT) bands of the respective group are qualitatively discussed from the CT interactions among some fragments.

UV absorption spectra of most polyoxometalates (hetero- and isopolyanions of W and Mo) have been attributed to the charge-transfer (CT) transitions of oxygens to W(VI) and Mo(VI). In the polyoxometalates, there exists two or three chromophores due to the bonding with metal ion of unshared (terminal) oxygens, edge- and/or corner-shared oxygens. The bonding between terminal oxygen and metal ion possesses greater double-bond character and its CT transition appears usually in the highest energy region (> 40,000 cm^{-1}). The absorptions due to the other chromophores are seen in the lower energy region. This is assumed from the facts that new absorption bands due to the formation of M—O—M bridges are observed in the 30,000–40,000 cm^{-1} region as well as the absorption maximum in the higher energy region by acidifying the aqueous solution of molybdate and tungstate.[1] Although such spectra should be significantly related to the structural feature through edge- and/or corner-sharings of octahedral units, a rational interpretation involving origins of the first- and second-lowest energy charge-transfer (LECT) bands has not yet been given.[2] The purpose of this work is to provide an interpretation of the CT absorption spectral data of some polyoxometalates on the basis of structural considerations. We here assume that the formation of polyanion from some fragments and some octahedral units results from a stabilization by edge- and/or corner-sharing interaction between building blocks 'A' (HOMO) and 'B' (LUMO), where the HOMO level of 'A' has an oxygen character and the LUMO one of 'B' has a metal character. In this approach, the LECT bands are qualitatively understood from a CT interaction between the HOMO and the LUMO levels. Using a similar model, Madic *et al.*[3] have recently explained the origin of the red colour of the vanadium(V) dimer. Applying the model to our absorption spectral data of some W(VI) and Mo(VI) polyoxometalates, it is convenient to abstract a building block 'A' as a common fragment constituting their structures. From the structural considerations as shown in Figs 1 and 2,[4] two fragments are selected as such for 'A'; one is 'M_5O_{18}' (M = W, Mo) for Weakley-type $[Ce(IV)(W_5O_{18})_2]^{8-}$, $[W_{10}O_{32}]^{4-}$ and $[M'W_5O_{19}]^{n-}$ (M′ = V, Nb, W) polyoxoanions and the other A-α-'XM_9O_{34}' (X = heteroatom) for Keggin and Dawson α-heteropolyanions.

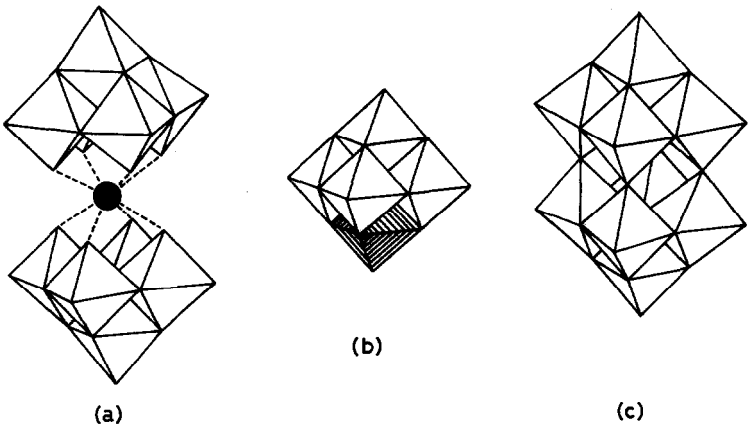

Fig. 1. Polyhedral models of polyanion-group containing 'M_5O_{18}' fragment; Weakley-type $[X(W_5O_{18})_2]^{n-}$ polyanion (a), $[M'M_5O_{19}]^{n-}$ polyanion (b) and $[W_{10}O_{32}]^{4-}$ isopolyanion (c). In (a), central filled circle shows the X (rare-earth) atom and the geometry around it is square antiprismatic. Each of two 'W_5O_{18}' fragments coordinates to X atom as a quadridentate ligand. In (b), a shaded octahedron represents a substituting M′ atom (V, Mo, W, Nb and so on) and the residual part corresponds to the 'W_5O_{18}' fragment (M = W and Mo). In (c), two 'W_5O_{18}' fragments are linked by corner-sharings to D_{4h} symmetry.

EXPERIMENTAL

Measurements

UV absorption spectra were measured by a Hitachi 340-spectrophotometer with a computer keyboard attached. Solvents were acetonitrile distilled before use for tetrabutylammonium (TBA) salt and redistilled water for some lacunary species. IR spectra were recorded with a JASCO IR-G spectrophotometer. All measurements were made at room temperature.

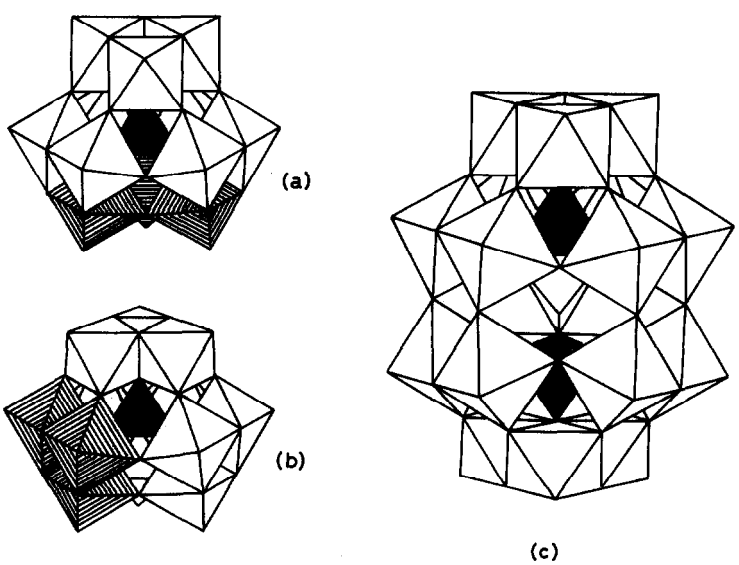

Fig. 2. Polyhedral models of polyanion-group containing 'XM_9O_{34}' fragment; Keggin $[\alpha\text{-}XM_{12}O_{40}]^{n-}$ (a), Keggin $[\beta\text{-}XM_{12}O_{40}]^{n-}$ (b) and Dawson $[\alpha\text{-}X_2M_{18}O_{62}]^{6-}$ (c) heteropolyanions. Central filled tetrahedra show the heteroatom X. In (a), the residual part other than three shaded octahedra corresponds to A-α-'XM_9O_{34}' fragment. In (b), upper M_3O_{13} unit rotates 60° with respect to the Keggin α-structure. The residual part other than shaded M_3O_{13} unit corresponds to B-β-'XM_9O_{34}' fragment. The notation of α and β of the 'XM_9O_{34}' is based on the parent Keggin structure and that of A and B is based on the positions of three octahedra removed. In (c), two A-α-'XM_9O_{34}' fragments are linked by corner-sharings to D_{3h} symmetry.

Preparations

The TBA salts of polyanions were prepared according to procedures previously described; $(TBA)_4[W_{10}O_{32}]$,[5] $(TBA)_2[M_6O_{19}]$ (M = W, Mo),[6] $(TBA)_6[\alpha\text{-}P_2W_{18}O_{62}]$,[6] $(TBA)_5H[\alpha\text{-}P_2Mo_{18}O_{62}]$,[6] $(TBA)_3[\alpha\text{-}PW_{12}O_{40}]$ (M = W, Mo),[7] $(TBA)_4[\alpha\text{-}SiM_{12}O_{40}]$ (M = W, Mo),[7] $(TBA)_4[\beta\text{-}SiW_{12}O_{40}]$,[7] $(TBA)_3Na[\beta\text{-}SiMo_{12}O_{40}]$,[7] $(TBA)_4[\alpha\text{-}GeM_{12}O_{40}]$ (M = W, Mo),[7] $(TBA)_4[\beta\text{-}GeM_{12}O_{40}]$ (M = W, Mo)[7] and $(TBA)_4K[\alpha\text{-}BW_{12}O_{40}]$.[7] They were isolated without any solvation. These compounds were identified by elemental analysis of the counterion part, shown in Table 1, and by comparison of the spectra (Table 2) with the already established IR spectra of the polyanion moiety.[5,8–11] Some lacunary species were also prepared according to the literature: $K_7[\alpha\text{-}PW_{11}O_{39}]\cdot 28H_2O$,[12] Na_3H_6

Table 2. Absorption spectral data in acetonitrile solution

RESULTS AND DISCUSSION

1. *Group containing* 'M_5O_{18}' *fragment*

The position and intensity of absorption maxima of this polyanion group are depicted as a bar graph in Fig. 3. The fragment 'M_5O_{18}' itself has not been found because of its instability. However, derivatives are seen as in the ligand of the Weakley-type polyanion $[X(W_5O_{18})_2]^{n-}$ (X = rare-earth metal ion), the $[W_{10}O_{32}]^{4-}$ isopolyanion resulting from corner-sharing between two 'W_5O_{18}' fragments and also the $[M'W_5O_{19}]$-type isopolyanion (M' = V, Mo, W, Nb and so on) from edge-sharing between 'W_5O_{18}' and '$M'O_6$' units.

For the UV spectrum in the aqueous media of the $[Ce(IV)(W_5O_{18})_2]^{8-}$ polyanion, we have previously assigned two CT bands of the ligand-to-Ce(IV) and the intra-ligand by MCD measurement.[14] The absorption maxima and intensities are 30,000 cm^{-1} (ε 5600) and 38,000 cm^{-1} (ε 19,000), respectively. In this polyanion, the geometry around the central Ce(IV) ion is square antiprismatic and two 'W_5O_{18}' ligands contribute independently to the intensity of the intra-ligand CT. On the other hand, the UV spectrum of $[W_{10}O_{32}]^{4-}$ polyanion, formed by the corner-sharings between two 'W_5O_{18}' units, shows three CT bands; 30,800 cm^{-1} (ε 14,000), 38,000 cm^{-1} (ε 16,500) and 45,700 cm^{-1} (ε 50,000). It should be noted that the position and intensity of the second LECT are very close to those of the intra-ligand CT of the Weakley polyanion. This indicates that the two half-units of the $[W_{10}O_{32}]^{4-}$ polyanion contribute independently to the second LECT. The first LECT band is a new absorption, which could not be seen in the 'W_5O_{18}' unit alone, and probably stems from an interaction between two identical fragments. When two 'W_5O_{18}' units approach in the manner that four oxygen-legs of each unit face each other and finally two sets of four legs coalesce into one, a large delocalization of charge through the corner-shared oxygens linking two units can be expected. This leads to the formation of stable $[W_{10}O_{32}]^{4-}$ polyanion and a new lower-energy CT becomes possible. Thus, the first LECT is considered to be a transition through such oxygens.

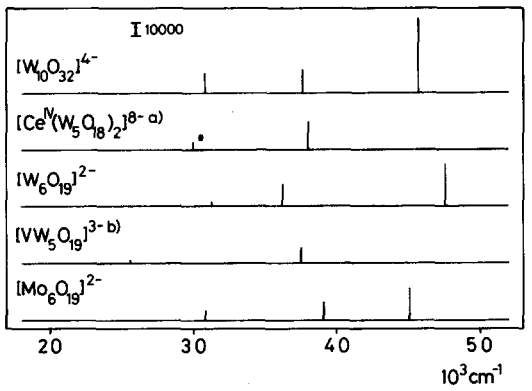

Fig. 3. Bar graphs of absorption maxima of a polyanion-group containing 'M_5O_{18}' (M = W and Mo) fragment. Height shows relative intensity and abscissa shows wavenumber. The data of (a) and (b) are reported in Refs 14 and 15, respectively. Asterisked peak indicates a CT band of ligand-to-Ce(IV).

Another way of stabilizing a 'W_5O_{18}' fragment is found in the formation of a $[M'W_5O_{19}]^{n-}$-type polyanion by edge-sharings between '$M'O_6$' and 'W_5O_{18}' units. In this polyanion-series, an intra-'W_5O_{18}' CT and new inter-CT transitions are expected. The absorption band of the former CT should appear near 38,000 cm^{-1} as observed in the intra-CT of Weakley polyanion and in the second LECT of $[W_{10}O_{32}]^{4-}$ isopolyanion. On the other hand, the band of the latter CT presumably depends strongly upon the electronegativity of M' atom, if it is assumed that the group overlap of edge-sharing interaction is unchanged by M' atom. The optical electronegativity χ of some M' atoms has been previously estimated by So and Pope;[2] χ = 2.7 for V(V), 2.5 for Mo(VI), 2.3 for W(VI) and 2.0 for Nb(V). In the Figs 4a–c, the HOMO–LUMO interaction models leading to the formation of $[M'W_5O_{19}]^{n-}$ polyanion are depicted. In Fig. 4a at least two inter-CT bands are possible in the lower energy region than the intra-CT band, while in Figs 4b and c at least one inter-CT band is expected. In the model of Fig. 4b, the inter-CT will shift to the higher energy region against the more electronegative M' atom, because the HOMO level of '$M'O_6$' becomes energetically lower.

The $[W_6O_{19}]^{2-}$ polyanion shows the first LECT as a weak and broad shoulder band at ~ 31,300 cm^{-1} (ε 3400) and the second LECT as a prominent band at 36,200 cm^{-1} (ε 14,900). Moreover, the first and second LECT measured in methanol solution of $[VW_5O_{19}]^{3-}$ polyanion, which contains the most electronegative V(V) atom substituted, are reported at 25,600 cm^{-1} (ε 2580) and 37,500 cm^{-1} (ε 11,000), respectively.[15] If the second LECT bands can be attributed to the intra-'W_5O_{18}' CT transitions, the first LECT bands are assigned to the inter-CT ones. This feature rules out the transitions based on the model of Fig. 4a and is consistent with the transitions by the model of Fig. 4c, where the LUMO level of '$M'O_6$' is lying between HOMO and LUMO levels of 'W_5O_{18}'. Dabbabi and Boyer[16] have pre-

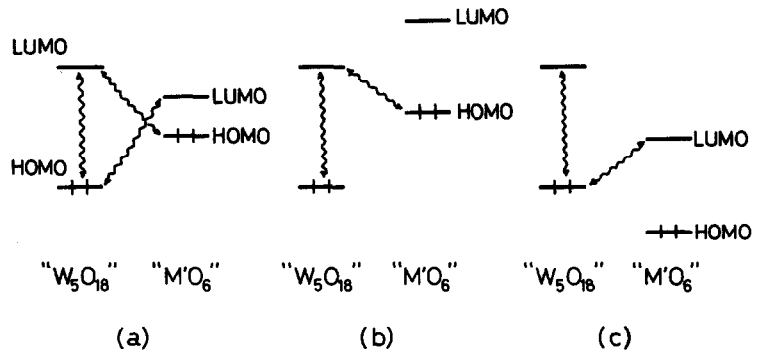

Fig. 4. Formation of $[M'W_5O_{19}]^{n-}$-type polyanion and the models of HOMO–LUMO interaction between 'W_5O_{18}' and '$M'O_6$' fragments. HOMO and LUMO levels of '$M'O_6$' fragment in (a), only the HOMO level in (b) and only the LUMO level in (c) are situated between HOMO and LUMO levels of 'W_5O_{18}' fragment. Wave-like lines represents the HOMO–LUMO interaction leading to the formation of polyanion. Degeneracy of HOMO and LUMO levels is out of consideration.

viously reported an absorption maximum of the $[NbW_5O_{19}]^{3-}$ polyanion, substituted with the less electronegative Nb(V) atom, at 36,600 cm^{-1} (ε 11,300). However, they have not referred to other low energy bands.

On the other hand, the UV spectrum of the $[Mo_6O_{19}]^{2-}$ polyanion shows the first LECT at 30,800 cm^{-1} (ε 6600) and the second one at 39,100 cm^{-1} (ε 13,100). They are clearly separated in contrast to those of an isostructural tungsto-analogue. Using the model of Fig. 4c, these bands are also assigned to the inter- and intra-CT transitions, respectively. The clear separation implies that (i) the LUMO–LUMO gap between 'Mo_5O_{18}' and 'MoO_6' fragments is larger than that between 'W_5O_{18}' and 'WO_6' and (ii) the HOMO–LUMO gap of 'Mo_5O_{18}' itself is larger than that of 'W_5O_{18}'.

2. *Group containing* A-α-'XM_9O_{34}' *fragment*

Analogous approaches are also applied to the interpretation of the CT spectra of Keggin $[\alpha\text{-}XM_{12}O_{40}]^{n-}$ and Dawson $[\alpha\text{-}P_2M_{18}O_{62}]^{6-}$ (M = Mo or W) polyanions (abbreviated to α-XM_{12} and α-P_2M_{18}, respectively, hereafter) in solution. Their absorption maxima and intensities are shown as bar graphs in Figs 5 and 6. When the A-α-'PM_9' fragment is considered as a common unit in these polyanions, the Keggin anion comprises edge- and corner-sharings of A-α-'PM_9' with three 'MO_6' units and the Dawson anion corner-shares two A-α-'PM_9' fragments. In the Keggin anion it should be noted that three 'MO_6' units inserted into the A-α-'XM_9' fragment by edge(corner)-sharings result in mutual corner(edge)-sharings.

The A-α-'PM_9' fragment actually exists as some protonated forms of $[PM_9O_{34}]^{9-}$ polyanion. As shown in Fig. 5, the second LECT position (41,700 cm^{-1}) of Dawson α-P_2Mo_{18} polyanion is situated near the first LECT (43,100 cm^{-1}) of A-α-PMo_9 polyanion which corresponds to the half-unit structure of the Dawson anion, and further the intensity (ε 109,000) of the former LECT is about twice that of the latter (ε 52,600). Thus, just like the $[W_{10}O_{32}]^{4-}$ polyanion, the LECT of α-P_2Mo_{18} (31,400 cm^{-1}; ε 21,700) can be assigned to the CT transition containing corner-sharing oxygens which link two A-

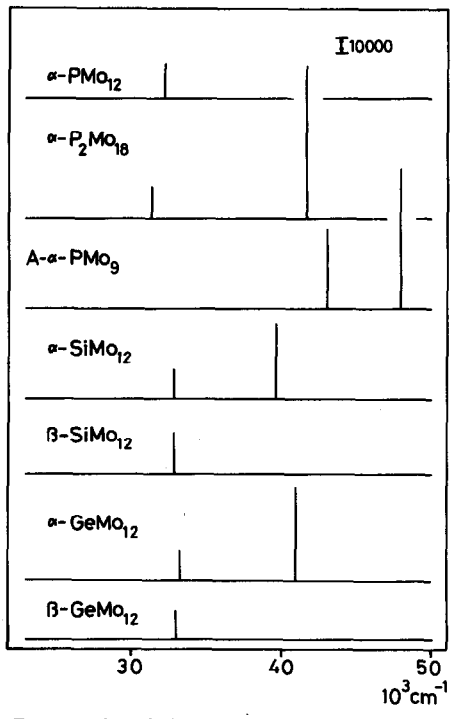

Fig. 5. Bar graphs of absorption maxima of a polyanion-group containing 'XMo_9O_{34}' (X = P, Si, Ge) fragment. Height shows relative intensity and abscissa shows wavenumber.

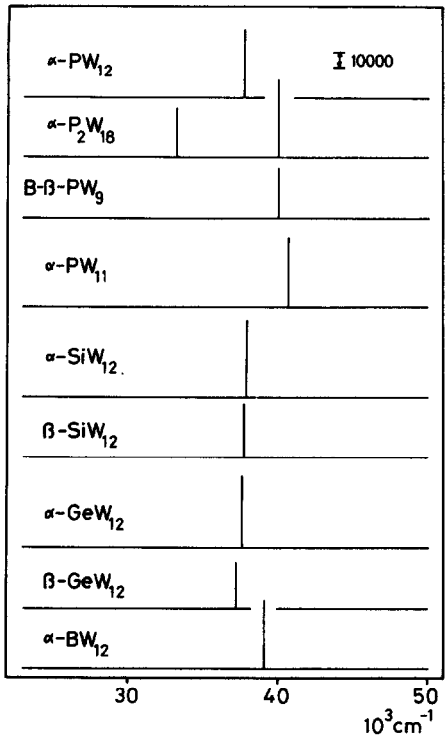

Fig. 6. Bar graphs of absorption maxima of a polyanion-group containing 'XW_9O_{34}' (X = P, Si, Ge, B) fragment. Height shows relative intensity and abscissa shows wavenumber.

α-'PMo_9' fragments and the second LECT to the intra-CT of the fragment.

The Keggin α- and β-molybdopolyanions show the first LECT bands, independent of heteroatoms, at energetically close positions ($\sim$ 33,000 cm^{-1}) to that of Dawson α-molybdopolyanion. Furthermore, some Keggin polyanions such as α-$SiMo_{12}$ and α-$GeMo_{12}$ show explicitly the second LECT bands as broad shoulders near the second LECT position in the Dawson polyanion. These facts suggest that the A-α-'XMo_9' unit becomes a discrete chromophore-group and all the first LECT bands of four geometrical isomers (A-α, B-α, A-β and B-β) of the 'XMo_9' fragment are also energetically comparable. An equivalent energy appearance of the first LECT bands of Keggin and Dawson molybdopolyanions indicates that the stabilization of the Dawson anion by corner-sharing interaction becomes nearly equal to that of the Keggin ones by the interactions between 'XMo_9' and three 'MoO_6' fragments. Moreover, a large LUMO–LUMO gap between A-α-'XMo_9' and 'MoO_6' units can be proposed.

On the other hand, the first LECT at 33,200 cm^{-1} (ε 32,500) and the second LECT at 40,000 cm^{-1} (ε 52,000) of the Dawson α-P_2W_{18} polyanion are assigned to the CT transition due to the corner-sharing oxygens which link two identical fragments and the intra-CT transition of the fragment, respectively. Although a reference band, i.e. the first LECT of the A-α-type tungsto-fragment is not provided, it is assumed not to deviate significantly from the second LECT of the Dawson tungstopolyanion and further to be close to the LECT position of the B-β isomer of the PW_9 polyanion as shown in Fig. 6. In contrast to the molybdopolyanions, all Keggin tungstopolyanions except the α-BW_{12} anion show the first LECT located at $\sim$ 38,000 cm^{-1}, which is lower by $\sim$ 2000 cm^{-1} than the assumed position of the A-α-'XW_9' fragment, and no second LECT. This probably accounts for the averaging of the inter- and intra-CT due to small LUMO–LUMO gap between 'XW_9' and 'WO_6' fragments.

THE SYNTHESIS AND STRUCTURE OF BIS(ACETYLACETONATO)(2-HYDROXYPHENOLATO)-ALUMINIUM: A STABLE DIMER

E. W. MEIJER

Philips Research Laboratories, P.O. Box 80.000, 5600 JA Eindhoven, The Netherlands

(*Received* 12 *November* 1985; *accepted after revision* 29 *July* 1986)

Abstract—The dimeric structure of bis(acetylacetonato)(2-hydroxyphenolato)aluminium (I) has been elucidated using NMR spectroscopy and vapour phase osmometry. It has been shown that in solution the three geometrical isomers of the dimer are in equilibrium with monomeric species. At high concentrations even trimeric and/or polymeric species have to be considered in the equilibrium.

The homopolymerization of epoxides is catalysed by the combination of tris(acetylacetonato)aluminium (II) and phenols.[1,2] Catechol (III) has proved to be the most effective phenol. We have observed by NMR and HPLC the formation of a reactive intermediate in the homopolymerization of cyclohexene oxide.[3] This intermediate proves to be the actual catalytic species and is the reaction product of II and III.[3]

Although a long history exists on the structure, properties, and chemistry of aluminium alkoxides[4] and β-diketonates,[5] knowledge of the reactions of II with phenols is limited to monodentate ligands.[6] Bidentate ligands are only studied in reactions with aluminium alkoxides[4] and aluminium salts.[7] Most studies are dealing with the complexation of aluminium alkoxides or mixed alkoxide-β-diketonates. In a recent paper Wengrovius *et al.* described the synthesis of several dimeric complexes of Al(OR)(β-diketonate)$_2$.[8] These dimers are thermally unstable in solution and decompose via ligand disproportionation. No monomer–dimer equilibrium is observed, probably due to the unfavourable five-coordinated aluminium in the monomer. We have synthesized bis(acetylacetonato)(2-hydroxyphenolato)aluminium (I) from II and III as an example of Al(OR)(β-diketonate)$_2$, in which the OR group is provided with a hydroxy functionality. We have studied in detail the dimeric structure of this effective catalyst for ring-opening polymerization by NMR spectroscopy.

EXPERIMENTAL

Preparation of bis(acetylacetonato)(2-hydroxyphenolato)aluminium (I)

Catechol (5.0 g, 45 mmol) was added to a solution of 9.6 g (29 mmol) tris(acetylacetonato)aluminium in 500 cm^3 of diethylether and the mixture was refluxed for 48 h. The product precipitated during the reaction and was collected by filtration, thoroughly washed with diethylether and dried at reduced pressure, affording 2.4 g (10.2 mmol, 35%) spectroscopically pure bis(acetylacetonato)(2-hydroxyphenolato)aluminium, m.p. 192–194°C (dec.). An analytically pure sample was obtained upon crystallization from benzene, m.p. 195°C. Found: C, 56.9; H, 5.5; Al, 8.0. Calc. for ($C_{32}H_{38}O_{12}Al_2$): C, 57.5; H, 5.7; Al, 8.1%. HPLC analysis of the raw reaction mixture showed the presence of II, III, acetylacetone, and a product with the same retention time as I.

Measurements

The ^{1}H- and ^{13}C-NMR spectra were recorded at 80 and 20 MHz respectively with a Bruker WP-80-SY spectrometer. ^{27}Al-NMR spectra were recorded at 52 MHz with a Nicolet NT200. Solid state ^{13}C-NMR spectra were recorded at 100 MHz with a Bruker MSL 400 using CP/MASS and TOSS for side band reduction. The two-dimensional NOE

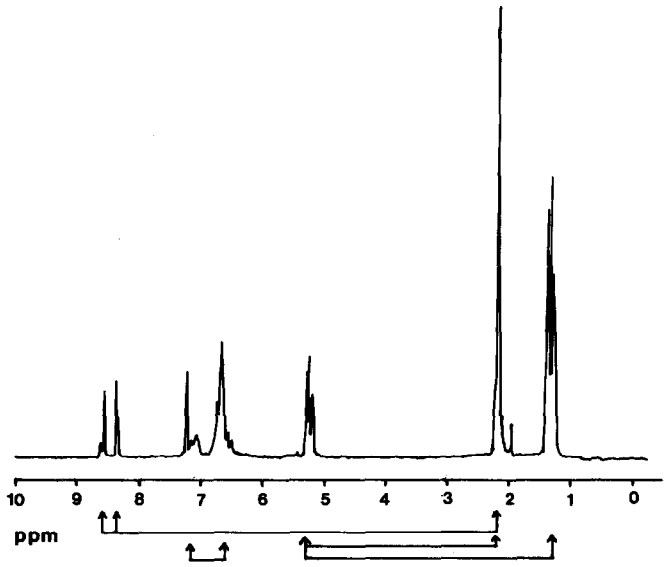

Fig. 1. ^{1}H-NMR spectrum of a freshly prepared sample of **I** in $CDCl_3$; the connectivities indicated at the bottom are NOE interactions as measured with a mixing time of 1.4 s.

(NOESY) and COSY spectra were recorded at 250 MHz with a Bruker AM 250, using mixing times of 0.9, 1.4, and 1.9 s, respectively. The chemical shifts are reported in δ units (parts per million) relative to $CHCl_3$ and converted to δ TMS values using δ $CHCl_3$ = 7.25 ppm. The vapour phase osmometric measurements were performed at the analytical department of the university of Groningen using 0.5% solutions in $CHCl_3$ at a temperature of 37°C.

RESULTS AND DISCUSSION

The reaction of **II** and **III** in ether at reflux temperature for 48 h yields **I** as a white precipitate in 35% yield. The substitution of a second acetylacetonate ligand is not observed despite a high ratio **III** over **II**. The ^{1}H-NMR spectrum of a freshly prepared sample of **I** in $CDCl_3$ is depicted in Fig. 1. The difference in chemical shift for the methyl groups of the acetylacetonate moiety (δ = 2.2–2.0 vs δ = 1.3–1.1 ppm) is remarkable. The three resonances at δ = 8.3, 8.5 and 8.55 ppm indicate the presence of three isomers. This is supported by the observation that the relative intensities of the three isomers are dependent on the history of the sample (twice vs not recrystallized). The proximity of protons within **I** is assessed in a two-dimensional nuclear Overhauser enhancement (NOE) exper-

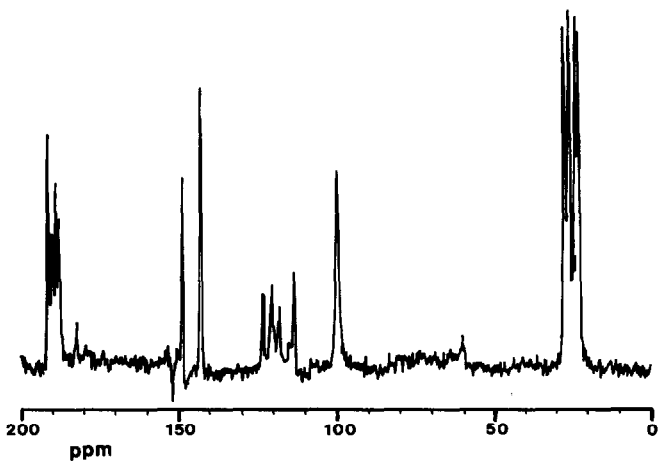

Fig. 2. ^{13}C-NMR spectrum of **I** in the solid state using CP/MASS.

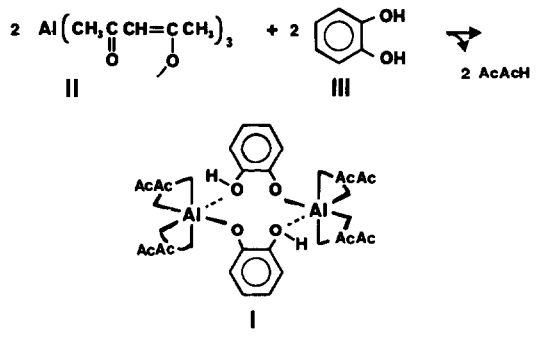
iment. The NOE connectivities are indicated in Fig. 1. Besides the expected connectivities on the basis of adjacent hydrogens in the molecule, the experiment indicates a remarkable short distance between the acidic phenol hydrogens and the downfield CH_3 group of the acetylacetonate ligand. A solid state ^{13}C-NMR spectrum of **I** shows four resonances for both the carbonyl carbons and the methyl carbons of the acetylacetonate moiety (Fig. 2).

The NMR data cannot be explained by a simple monomeric structure of bis(acetylacetonato)(2-hydroxyphenolato)aluminium. However, the data are in complete accordance with a dimeric structure of **I**, in which the catechol ligands are responsible for the bridging (see Scheme 1). A CPK model of the dimer shows that the two benzene rings are located perpendicular to each other and that three geometrical isomers are possible, in which the four acetylacetonate ligands are all orientated longitudinally, all transversally, or in a combination of two longitudinal and two transverse dentations with respect to the Al–Al axis, respectively. Furthermore and most striking, the two phenolic hydroxyl groups are forced to close proximity at the same site of the dimer molecule offering a very acid proton by hydrogen bonding of these two hydroxyl groups. The model also clearly demonstrates that one CH_3 group of each acetylacetonate moiety is located in the shielding zone of the benzene ring, while the other is situated in the deshielding zone. Models of monomer and trimer do not show these (de)shielding effects.

We propose that the first step in the reaction of



Scheme 1.

II and **III** consists of a ligand exchange equilibrium between catechol and acetylacetone. This equilibrium has been confirmed by HPLC analysis.[3] The primary monomeric product bis(acetylacetonato)(2-hydroxyphenolato)aluminium is in equilibrium with its dimer **I**, which separates from the reaction mixture. The ratio **II** over **III** and their concentrations determine the yield of **I**. Dimer **I** is an amorphous mixture of three isomers and is stable in air.

Dynamic NMR spectroscopy

When a sample of **I** in $CDCl_3$ was stored for several hours at room temperature the ^1H-NMR spectrum (see Fig. 3) deviated from that of a freshly prepared sample (Fig. 1). Apparently the dimer partially dissociates into monomeric species, to which the resonances at $\delta = 1.94$ and $\delta = 5.42$ ppm can

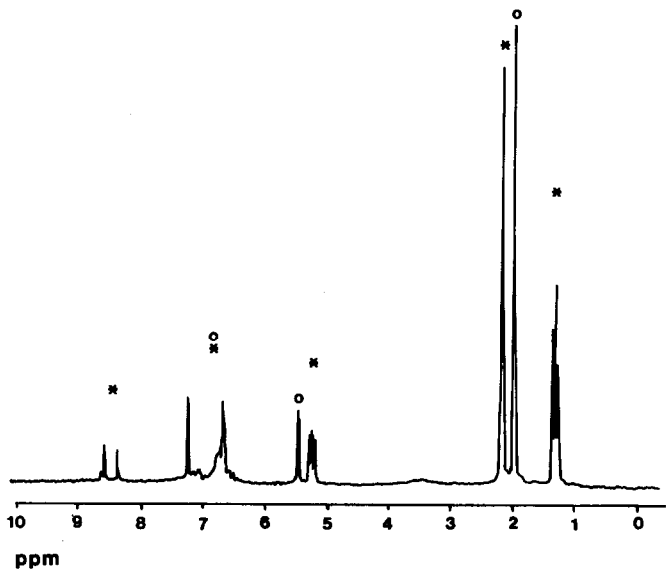


Fig. 3. ^1H-NMR spectrum of a sample of **I** in $CDCl_3$ after 2 h storing at room temperature; the resonances indicated with * correspond to dimer and with ○ to monomer.

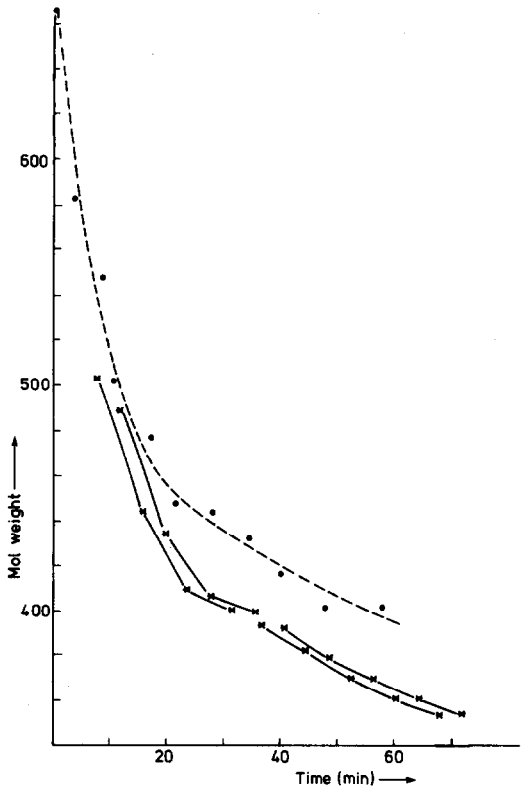

Fig. 4. The change in molecular weight in time of a solution of I in $CHCl_3$ using VPO (*) and in $CDCl_3$ using ^{1}H-NMR (●).

be assigned. The spin-lattice relaxation times for all hydrogens of the dimer are shorter than the T_1 values of the corresponding atoms in the monomer. The information obtained from ^{27}Al-NMR spectroscopy is scarce. The singlet for dimer and monomer of I are indistinguishable, while the resonance is shifted 2 ppm upfield and broadened by a factor of 1.5 with respect to the tris(acetylacetonato)-aluminium resonance.

The dissociation of I is confirmed by vapour phase osmometry. The changes in molecular weight during the dissociation of the dimer I were measured using a dilute solution of $CHCl_3$ at 37°C (Fig. 4). At these low concentrations a simple dimer–monomer equilibrium was observed in which the equilibrium constant is high. The observed decrease in molecular weight in time is in full agreement with the NMR kinetic measurements in $CDCl_3$ under the same conditions (Fig. 4).

The equilibrium constant of the dimer–monomer interchange proved to be dependent on concentration, solvent and temperature. Lowering the concentration of I furnishes a higher degree of dissociation. Variable temperature ^{1}H-NMR spectroscopy of I in ODCB-d_4 were performed to study the dynamics of the geometrical isomerization in the dimer and of the dimer–monomer equilibrium. The results are presented in Fig. 5. As the temperature was raised the resonances due to the acidic phenol hydrogens of the three isomers of the dimer were shifted upfield and coalesced at 138°C. This coalescence corresponds to an isomerization of the acetylacetonate ligands. The $\Delta G^{\neq}$ of isomerization of the three isomers is established at 21.7 ± 0.7 kcal/mol. This free energy of activation is similar to those found for the isomerization of the octahedral tris(β-diketonato) complexes,[9] but significantly higher than found for the Al(OR)(β-diketonate)$_2$ dimers.[8] This observation is consistent with a normal β-diketonate octahedral isomerization, without going through a transition state in which one of the catecholate–aluminium bonds is broken. Furthermore, no coalescence was observed for the intermolecular dimer–monomer interchange.

At the high concentrations of I, used in this experiment, no linear correlation was found for the logarithm of the equilibrium constant (K) and the reciprocal temperature when K was calculated on the basis of a dissociation of the dimer alone (Fig. 5). Satisfactory fits could only be obtained when it was assumed that at high dimer concentrations trimeric or even polymeric species were involved.

The results presented above force us to propose that the reaction of II and III furnishes the dimer of bis(acetylacetonato)(2-hydroxyphenolato)aluminium (I). The dimer is present in three geometrical isomers and in solution these isomers are

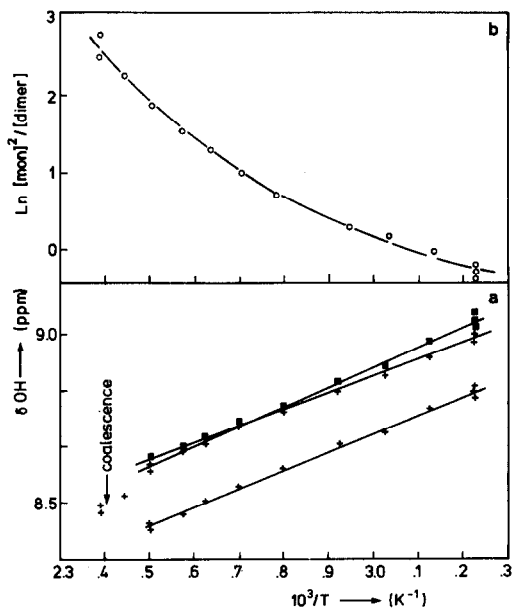

Fig. 5. (a) The chemical shift of the acid phenolic hydrogens of the dimer as a function of temperature. (b) The calculated equilibrium constant as a function of temperature.

in equilibrium with monomeric and polymeric species. The unique structure of the dimer, with the close proximity of the acidic phenol hydrogens and both catechol ligands attached to two aluminium atoms, makes **I** an active catalytic species. Investigations concerning the catalytic role of **I** in the ring-opening of epoxides is in progress.[3]

HYDROLYSIS REACTION OF INORGANIC CYCLOPHOSPHATES AT VARIOUS ACID STRENGTHS

GENICHIRO KURA

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41, Japan

(*Received* 14 *July* 1986; *accepted* 29 *July* 1986)

Abstract—Hydrolysis rate constants of six-, eight-, twelve- and sixteen-membered inorganic cyclophosphates at various acid strengths at 40°C were determined. Six-membered cyclotriphosphate was the most rapidly hydrolyzed at almost all acid concentrations, as a result of its interaction with hydrogen ion, and strain in the six-membered ring structure. The hydrolysis rate of the cyclophosphate which has a stronger affinity with hydrogen ions was faster than that of others. Binding of hydrogen ions renders the phosphorus atoms more susceptible to nucleophilic attack by water molecules.

Of the cyclophosphates ($M(I)_nP_nO_{3n}$) classified as a condensed phosphate which are produced by the condensation reaction of oxoacids of phosphorus of oxidation number five, cyclo-tri- and cyclo-tetraphosphate have been well known and studied by a number of investigators.[1]

The existence of cyclophosphates with degrees of polymerization greater than four in the aqueous solution of Graham's salt was first reported by Van Wazer and Karl-Kroupa in 1956.[2] In 1965, cyclopenta- and cyclo-hexaphosphate were prepared by Thilo and Schülke from the fractional precipitation of Graham's salt.[3] The synthesis of cyclo-hexa- and cyclo-octaphosphate from the source material other than Graham's salt were reported by Griffith and Buxton,[4] and by Schülke,[5] respectively. Cyclo-heptaphosphate was first isolated by the use of an anion-exchange dextran gel column by the author and Ohashi.[6]

Various properties of these higher-membered cyclophosphates have been investigated from various viewpoints.[7] These cyclophosphates are very interesting electrolytes because of their high negative charge on relatively compact molecular structures. When using these anions in the aqueous state for various purposes, their hydrolysis properties must be known clearly.

The hydrolysis reaction of cyclo-tri-, cyclo-tetra-, cyclo-hexa- and cyclo-octaphosphate have been investigated using automatic anion-exchange chromatography.[8–10] The half-life period of the hydrolysis reaction of cyclo-triphosphate in 0.1. M HCl solution at 40°C is 1.87 h and this phosphate is the most unstable. Those of cyclo-tetra- and cyclo-hexaphosphate are 16.1 and 11.4 h, respectively, and these are relatively stable compared with the cyclo-octaphosphate, with the highest degree of polymerization in the cyclophosphate series, for which the half-life is 4.53 h. The stability of the P—O—P bonds in the ring structure decreases from tetramer to octamer. This decrease is ascribed to the increase of the affinity between cyclophosphate and hydrogen ion due to the increase of the flexibility of ring structure. In acidic solutions, the degree of interactions with hydrogen ions has been considered[10] as the major factor affecting the hydrolysis rate of cyclophosphates.

This paper reports the hydrolysis rate of cyclophosphates at various hydrogen ion concentrations.

Cyclophosphate is abbreviated to P_{nm} where n is the degree of polymerization.

EXPERIMENTAL

Materials

As an anion-exchanger, Hitachi Custom Ion No. 2630 and TSK Gel SAX were used. Inorganic cyclophosphates were prepared by the methods described in our earlier paper.[7]

Chromatographic system

The separation and detection system was as described earlier.[10]

Hydrolysis procedure

The initial concentration of cyclo-octaphosphate to be hydrolyzed was varied from 9×10^{-3} to 5×10^{-5} M to study the effect of the initial concentration on the hydrolysis rate at 40°C in 0.1 M HCl. Then the initial concentration of the cyclophosphate to be hydrolyzed was adjusted to 1.25×10^{-3} M. Hydrochloric acid was added to each solution to control acid strength. The hydrolysis reaction was then performed in a water bath, the temperature of which was maintained within ±0.1°C. At measured time intervals, the hydrolysis reaction of sample solutions withdrawn was stopped by a rapid neutralization and cooling. The sample solutions were stored in a refrigerator until taken out for analysis.

RESULTS AND DISCUSSION

When cyclophosphate is hydrolyzed, the corresponding linear phosphate with the same degree of polymerization is first observed. Subsequently the linear phosphate degrades to the lower linear phosphates. To determine the hydrolysis rate of the parent phosphate, it is necessary to separate the phosphate from the hydrolysis products. We have successfully applied the automatic anion-exchange chromatographic system to the analysis of the hydrolysis samples. As mentioned previously,[8] the initial concentration of cyclophosphates affects the hydrolysis rate constant. We measured the half-life period of the hydrolysis rate of cyclo-octaphosphate of various initial concentrations in 0.1 M HCl at 40°C. As shown in Fig. 1, a constant value of half-life period was obtained when the initial concentration of cyclo-octaphosphate was lower than 1.25×10^{-3} M. Then, the initial concentration was fixed at 1.25×10^{-3} M and the hydrolysis rate in HCl solution of various concentrations was measured at 40°C.

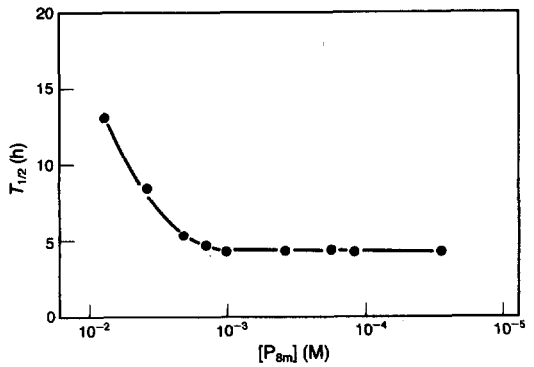

Fig. 1. Concentration dependence of half-life period of cyclo-octaphosphate hydrolysis in 0.1 M HCl at 40°C.

The rate of the hydrolysis reaction of cyclophosphates in 0.1 M HCl solution was first order. The basicity of cyclophosphate anion for hydrogen ion is relatively weak compared with linear phosphates, however, the interaction with hydrogen ion was observed and some dissociation constants of cyclophosphoric acids were determined.[7] The first-order rate equation can be presented as follows,

$$-\frac{dc}{dt} = k_0[P_nO_{3n}^{n-}] + k_1[HP_nO_{3n}^{1-n}] + \cdots + k_n[H_nP_nO_{3n}] \quad (1)$$

where k_i and c are the rate constant of the individual protonated species and the total concentration of the phosphate, respectively. When the molar fraction of the protonated species, $H_iP_nO_{3n}^{i-n}$ is defined as X_i for the total concentration, the rate equation is represented as

$$-\frac{dc}{dt} = (k_0X_0 + k_1X_1 + \cdots + k_nX_n)c. \quad (2)$$

Equation (2) is rearranged to

$$-\frac{dc}{dt} = k_{obsd}c \quad (3)$$

where k_{obsd} is a function of X_i, and varies with hydrogen ion concentration. A relation of k_{obsd} and $-\log[H^+]$ is shown in Fig. 2. The apparent rate constant k_{obsd} increases with the increase of hydrogen ion concentration. If the value of X_i is known accurately, k_i can be calculated from the combination of k_{obsd} and X_i at various hydrogen ion concentrations. Because of lack of enough data on the acid dissociation constants of $H_nP_nO_{3n}$ accurate values of X_i and k_i could not be obtained.

However, the author has tried to predict an

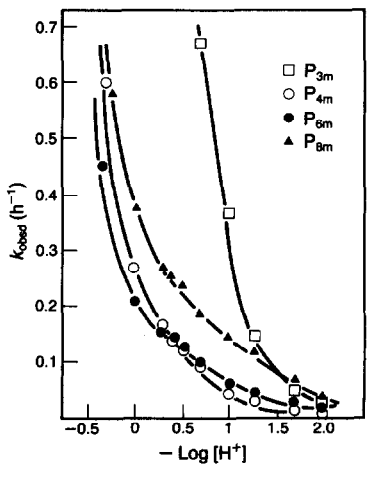

Fig. 2. Hydrolysis rate constants for cyclophosphates at various acid strengths at 40°C.

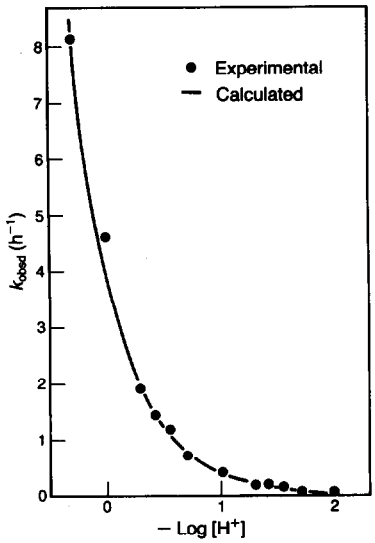

Fig. 3. Hydrolysis rate constants of cyclo-triphosphate at various acid strengths at 40°C.

approximate value of k_i for cyclo-triphosphate system from the very rough estimation of the acid dissociation constants of $H_3P_3O_9$. We have already obtained the linear relation between pK_{an} of $HP_nO_{3n}^{1-n}$ acid and the anion charge, n.[7] Using this linear relation and taking into account the statistical factor, K_{a1}, K_{a2} and K_{a3} of $H_3P_3O_9$ acid were estimated as 18.9, 1.6 and 0.1, respectively, at ionic strength 0.1. By neglecting the difference in the ionic strength, the molar fraction of the individual protonated species, X_i at each hydrogen ion concentration was calculated by using these K_{ai} values. From the set of k_{obsd} and X_i values and by the use of successive approximations, a rough value of the rate constant of the individual protonated species was determined as $k_0 = 4 \times 10^{-4}$, $k_1 = 0.5$, $k_2 = 5$ and $k_3 = 100\ h^{-1}$. The solid line in Fig. 3 presents the k_{obsd} value calculated from these constants. Coincidence of the calculated and experimental value is satisfactory.

The large difference between k_0 and k_1 values suggest that the hydrolysis rate of cyclophosphates are greatly accelerated by the bonding with hydrogen ion. The cyclo-triphosphate of the smallest six-membered ring in the cyclophosphate series is very readily hydrolyzed. This instability is ascribed not only to the interaction with hydrogen ion but to the strain in the six-membered ring structure. The strain has been supposed to be the reason of the non-existence of cyclo-diphosphate anion containing two PO_4 tetrahedra.[1] The next-most unstable species is the sixteen-membered cyclo-octaphosphate, which has the largest ring structure. The phosphate has so much flexibility in its ring structure that the affinity with the hydrogen ion increases. This is suggested as the reason of the increase in k_{obsd}. Cyclo-tetra- and cyclo-hexaphosphate have similar stability, however, at lower hydrogen ion concentration cyclo-hexaphosphate is much more rapidly hydrolyzed as a result of the increase of proton affinity. In neutral aqueous solution, hydrolysis rates of these four cyclophosphates are very slow even in boiling water.

SPECTROPHOTOMETRIC STUDY OF SOME ALKALINE-EARTH AND OF SILVER COMPLEXES WITH DIBENZO-30-CROWN-10 IN METHANOL, DIMETHYLFORMAMIDE AND DIMETHYLSULFOXIDE SOLUTIONS

MOHAMMAD BAGHER GHOLIVAND, SOHEILA KASHANIAN and MOJTABA SHAMSIPUR*

Department of Chemistry, Razi University, Bakhtaran, Iran

(*Received* 21 *May* 1986; *accepted after revision* 31 *July* 1986)

Abstract—The interaction between Ag^+, Ca^{2+}, Sr^{2+} and Ba^{2+} ions and the cyclic polyether dibenzo-30-crown-10 (DB30C10) in methanol, dimethylformamide and dimethylsulfoxide solutions has been studied by a visible spectroscopic technique, using murexide as a metal ion indicator. The stabilities of the resulting complexes were determined. Strontium ion was found to form the most stable complex with the ligand in all three solvents used. There is an inverse relationship between the stabilities of the complexes and the Gutmann donicity of the solvents. The effect of the solvent on the stability of the alkaline-earth complexes is most notable with DB30C10–Ca^{2+} and the least with DB30C10–Ba^{2+}. The data obtained in this study support the existence of a 'wrap around' structure for the above complexes in solutions.

Among the macrocyclic crown ethers first synthesized by Pedersen,[1] large ligands, such as dibenzo-13-crown-10 (DB30C10), have some interesting properties. These are very flexible molecules, with enough oxygen atoms in the ring to enable them to twist around a metal ion of suitable size to envelope it completely and form a three-dimensional 'wrap around' complex.[2–5]

Some alkali complexes of large crown ethers (i.e. larger than 18-crown-6) have been studied in different solvents.[3–6,14] Negative enthalpies and entropies of complexation of cesium ion complexes of large crowns in different non-aqueous solvents, which are definitely solvent dependent, have been reported.[4,5] It is assumed that the decrease in the conformational entropy of the large crown ethers, from a rather flexible free molecule to a rigid 'wrap around' complex, would be the main reason for the large negative values of entropy changes.

Despite the interesting properties of large crowns, not much attention has been focused on the study of metal ion complexes of these ligands, so that the information for understanding their behavior in solution is quite sparse.

It was of interest to us to study the interactions of alkaline earth and of silver ions with a large crown ether, capable of forming three-dimensional complexes with these cations. In this paper, we report the study of Ag^+, Ca^{2+}, Sr^{2+} and Ba^{2+} complexes with DB30C10 in methanol, dimethylformamide and dimethylsulfoxide solutions, by a previously described visible spectroscopic technique, using murexide as a metal ion indicator.[7,8]

EXPERIMENTAL

DB10C10 was synthesized by a slight modification of Pedersen's method.[1] The product was recrystallized from reagent grade acetone and vacuum dried. Methanol (Baker, MeOH), dimethylformamide (Fisher, DMF) and dimethylsulfoxide (Fisher, DMSO) were purified and dried by the previously described method.[9] Reagent grade murexide (Merck), calcium chloride (Merck), strontium nitrate (Merck), barium chloride (Fluka), and silver nitrate (Merck), were dried over P_2O_5 under vacuum for 72 h. All spectra were obtained with a model 34 Beckman UV-Vis spectrometer at $25 \pm 1°C$.

The formation constants for the metal ion–

*Author to whom correspondence should be addressed.

murexide complexes were determined from the spectra of a series of solutions in which varying amounts of the metal ions were added to a fixed concentration of murexide in different solvents. The formation constants of various DB30C10 complexes were determined by recording the spectra of a series of solutions containing varying amounts of the crown ether and fixed concentrations of metal ion and murexide. Attainment of equilibrium was checked by the observation of no further change in the spectra after several hours. Errors associated with the various formation constants were reported as ± standard deviations.

RESULTS AND DISCUSSION

In order to determine the stabilities of metal ion–murexide and metal ion–DB30C10 complexes, the spectra of a series of solutions of fixed murexide concentration and varying concentrations of the metal ions and ligand were recorded. In all cases, maximum absorption of free and complexed murexide molecules were separated by 20–55 nm. All spectra presented satisfactory isobestic points. The deviations of the spectra from the isobestic points were at most ± 5%. The spectra of mixtures of murexide, strontium ion and DB30C10 in DMSO are shown in Fig. 1. All the calculated formation constants for metal ion–murexide and metal ion–DB30C10 complexes are presented in Table 1. The relationships between the stabilities of the DB30Cl0 complexes of alkaline-earth ions and their crystal radii[10] in different solvents are shown in Fig. 2.

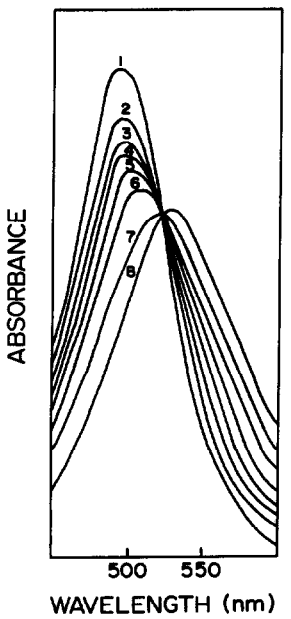

Fig. 1. Visible spectra of mixtures of murexide (m, 2.0×10^{-5} M), Sr^{2+} ion, and DB30C10 in DMSO at 25°C. 1, m+Sr^{2+} (8.0×10^{-5} M); 2, m+Sr^{2+} (6.0×10^{-5} M); 3, m+Sr^{2+} (4.0×10^{-5} M); 4, m+Sr^{2+} (4.0×10^{-5} M)+DB30C10 (8.0×10^{-5} M); 5, m+Sr^{2+} (4.0×10^{-5} M)+DB30C10 (1.2×10^{-4} M); 6, m+Sr^{2+} (2.0×10^{-5} M); 7, m+Sr^{2+} (1.0×10^{-5} M); 8, m alone.

Table 1. Log K_f of different Ag^+ and alkaline-earth cation complexes with murexide and DB30C10 in various solvents at 25°C

Solvent	Cation	Murexide	DB30C10
MeOH (DN = 25.7)[a]	Ag^+	3.87±0.07	4.31±0.19
	Ca^{2+}	6.09±0.09	4.25±0.14
	Sr^+	5.68±0.10	4.74±0.12
	Ba^{2+}	5.40±0.11	4.37±0.13
DMF (DN = 26.6)	Ag^+	4.33±0.11	3.42±0.14
	Ca^{2+}	3.98±0.08	3.28±0.13
	Sr^{2+}	4.52±0.09	3.86±0.11
	Ba^{2+}	4.43±0.07	3.51±0.09
DMSO (DN = 29.8)	Ca^{2+}	4.64±0.06	2.92±0.09
	Sr^{2+}	4.35±0.09	3.61±0.15
	Ba^{2+}	4.05±0.07	3.40±0.2

[a] DN = donor number, Ref. 11.

All of our solvents have relatively high dielectric constants and at the very low salt concentration we used, (10^{-4}–10^{-5} M), the amount of ion pairing with the free cation, and especially with the large complex ion, is negligible. Therefore, the nature of the anion should not influence the complexation reaction.

As it can be seen, the solvent plays a very fundamental role in the complexation reactions. There is an inverse relationship between log K_f of the metal ion–DB30C10 complexes and the donor (or sol-

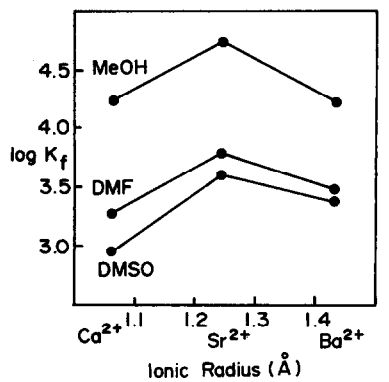

Fig. 2. Stability constants of the alkaline-earth–DB30C10 complexes vs ionic radii of the cations in various solvents at 25°C.

vating) ability of the solvents, as expressed by the Gutmann donor number.[11] In fact, the complexation takes place by replacement of the inner solvation shell of the cation by crown ether oxygen atoms. Thus, there is a competition between macrocycle and solvent molecules for cations in solution. As a result, in solvents with higher solvating power there is a drastic decrease in the stabilities of the crown complexes. The same solvent effect has already been reported for different alkali ion–crown ether complexes in various solvents.[5,12,13]

It is interesting to note that the solvent effect on the stability constants of the alkaline-earth complexes is most notable with DB30C10–Ca^{2+} and the least with DB30C10–Ba^{2+} complex. Since the Ba^{2+} ion is rather weakly solvated because of the low charge density of the cation, it is not surprising that the stability of its complex is less affected by the nature of the solvent molecules. On the other hand, the charge density of the calcium ion is much greater than that of the larger sized strontium and barium ions, which results in a much stronger solvent–cation interaction for this ion. Thus, the solvent effect on the stability of the DB30C10–Ca^{2+} complex is more evident.

Figure 2 shows that the variation of the stability of the three alkaline-earth–DB30C10 complexes with the size of the cations in all solvents used follows the same trend. Strontium ion forms the most stable complex with the ligand in all three solvents used. The stabilities of the other alkaline-earth complexes are about the same within experimental error. In the study of the complexes of large flexible crown ethers that are capable of forming of a three-dimensional 'wrap around' complex, we would expect to see the maximum binding energy when fit conditions are optimized. Metal ions with smaller or larger radii would fail to achieve the maximum stability because of the repulsive forces resulting from the effects of oxygen atoms of the ring on each ether, and/or steric hindrance inhibiting the ligand from achieving the 'best fit' configuration. Among the alkali ions, potassium has been shown to have the best size to fit inside the cavity of the twisted DB30C10 ligand, resulting in a complete 'wrap around' structure both in solid state[2] and in solution.[3,4]

Results obtained in this study for Ca^{2+}, Sr^{2+} and Ba^{2+} complexes with DB30C10 make it clear that the barium ion is too large to form a complete 'wrap around' complex. Thus just some, but not all, of the oxygen atoms of the ring can bond the cation; consequently a weaker complex results. On the other hand, the calcium ion is too small for the cavity of the twisted ligand. In this case, the ligand can still form the 'wrap around' structure, but here the oxygen atoms of the ligand have to be in close proximity, and the resulting repulsive forces weaken the complex. The strontium ion, with ionic size very close to that of the potassium ion,[10] seems to have the most suitable size for this ligand and, therefore, its resulting 'wrap around' complexes are the most stable ones in all three solvents.

The stability of the DB30C10–K^+ complex in methanol solution has been reported by Chock,[14] and is $\log K_f = 4.57 \pm 0.11$ which is somewhat less stable than DB30C10–Sr^{2+} ($\log K_f = 4.74 \pm 0.12$) probably because of the higher charge of Sr^{2+} ion. In contrast, monovalent silver ion, with about the same ionic radius as bivalent calcium ion,[10] despite its lower charge, forms a more stable complex with DB30C10 in MeOH and DMF solutions (Table 1). This is because in the case of small cations, such as Ag^+ and Ca^{2+} ions, the hydration energy of the cations becomes predominant in the complexation reactions. Thus, considering the competition between the solvent and the ligand for the cations, the much larger solvation effect of the bivalent cation over the monovalent cation results in a more univalent complex. Similar results have been reported for dicyclohexyl-18-crown-6 complexes with sodium and calcium ions.[15,16]

Abstract—Reaction of Lawesson's reagent (**1**) with $Pt(C_2H_4)(PPh_3)_2$ in benzene gives *cis*-$Pt\{S_2P(S)(C_6H_4OMe)\}(PPh_3)_2$ (**2**), in 63% yield. (**2**) was characterised by IR, ^{31}P NMR and X-ray crystallography: monoclinic, space group $P2_1/c$ with $a = 10.489(3)$, $b = 18.373(7)$ and $c = 22.591(9)$ Å, $\beta = 91.34(3)°$. The molecule has square planar platinum co-ordination with non-equivalent Pt—S bond lengths [2.369(2), 2.351(2) Å] and a folded (19.4° dihedral angle) PtS_2P ring. The P—S bond lengths are equal.

The preparation of transition metal complexes containing alkoxythiophosphate ligands is an important area of research since the zinc compounds in particular are useful lubricant additives.[1,2] Surprisingly, although a great deal of work has been reported[3,4] on RPS_2^- complexes there has been only one report on the preparation of thiophosphoryl compounds.[5] Organoperthiophosphinic acid anhydride dimers $P_2R_2S_4$ are readily prepared, synthetically useful sulphurating agents both in organic synthesis[6] and, more recently, in the preparation of a molybdenum sulphur compound.[7] However, their potential as source reagents in the preparation of new metal complexes has not been established. We wish to report the results of our investigations into the cleavage reaction of Lawesson's reagent (**1**) (R = *p*-$MeOC_6H_4$) with $Pt(C_2H_4)(PPh_3)_2$. The product of this reaction, *cis*-$Pt\{S_2P(S)(C_6H_4OMe)\}(PPh_3)_2$ (**2**) was characterized by IR/Raman, ^{31}P NMR and X-ray crystallography.

EXPERIMENTAL

All chemicals were of reagent grade. K_2PtCl_4 and Lawesson's reagent were purchased from Johnson Matthey and Aldrich Chem. Co. respectively and were used without further purification. $Pt(C_2H_4)(PPh_3)_2$ was prepared as described in the literature.[8] All manipulations were carried out under argon. Solvents were dried before use: thf, diethyl-ether and benzene were distilled from Na/benzophenone; dichloromethane was distilled from calcium hydride. ^{31}P–[^1H] NMR spectra were recorded on a JEOL FX90Q spectrometer and are referred to external 85% H_3PO_4. IR spectra were obtained as KBr discs using a Perkin–Elmer 683 spectrometer. Raman spectra were obtained using a SPEX Ramalog system (647.1 nm excitation Innova 90 laser). Elemental analyses were performed by the microanalytical department of Imperial College and by Pascher, FRG.

Preparation of $Pt\{S_2P(S)(C_6H_4OMe)\}(PPh_3)_2$ (2)

Degassed thf (10 cm^3) was added to $Pt(C_2H_4)(PPh_3)_2$ (50 mg, 0.07 mmol) and Lawesson's reagent (30 mg, 0.07 mmol) and the resulting yellow solution was stirred for 1 h during which time it darkened to orange. The solution was evaporated to dryness *in vacuo*. The resulting solid was extracted with dichloromethane (5 cm^3) and to this solution was added benzene (2 cm^3) and diethyl ether (30 cm^3). Cooling to −20°C gave the product as pale yellow crystals (40 mg, 63%). ^{31}P–[^1H] NMR (thf/$CDCl_3$) $\delta = 18.62$ $^1J[^{31}P–^{195}Pt]$ 3254 Hz, $\delta = 87.75$ $^2J[^{31}P–^{195}Pt]$ 225 Hz. ^{13}C $\delta = 55.9$ (singlet, 1) OMe group, $\delta = 112–136$ (multiplet, 42) phenyl rings. Analysis: Found, C, 51.2; H, 3.9. Required for the dichloromethane solvate. $C_{44}H_{39}Cl_2OP_3PtS_3$: C, 50.9; H, 3.8%.

Crystals suitable for X-ray analysis were obtained by addition of chloroform to a thf solution of (2).

Crystal data

$C_{43}H_{37}OP_3S_3Pt \cdot 0.2(X_3)$,* $M = 961.14$,† monoclinic, $a = 10.489(3)$, $b = 18.373(7)$, $c = 22.591(9)$ Å, $\beta = 91.34(3)°$, $U = 4352(3)$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.47$ g cm^{-3}.† Yellow, air stable prisms, dimensions $0.10 \times 0.15 \times 0.40$ mm, μ(Cu-K_α) = 87 cm^{-1},† $\bar{\lambda} = 1.54178$ Å, $F(000) = 1910$.†

Data collection and processing

Nicolet R3m diffractometer, ω-scan method, ($\theta \leqslant 50°$), graphite monochromated Cu-K_α radiation; 4342 independent measured reflections, 3945 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarisation factors; numerical absorption correction (face indexed crystal).

Structure analysis and refinement

The structure was solved by the heavy atom method and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealised (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U\text{eq}(C)$ and allowed to ride on their parent carbons. An unidentified solvent fragment was located from a ΔF map and refined isotropically as three 20% occupancy carbon atoms. Refinement was by block-cascade full-matrix least squares to $R = 0.031$ ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.034$ ($w^{-1} = \sigma^2(F) + 0.00042F^2$).‡ The maximum residual electron density in the final ΔF map was 0.6 e Å^{-3} and the mean and maximum shifts/error in the final refinement cycle were 0.004 and 0.029 respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system[9] and published scattering factors.[10]

* X represents unidentified solvent fragment assigned atomic mass of carbon.

† Includes contribution from unidentified solvent fragment.

‡ Final values of atomic positional and thermal coefficients and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Reaction of Lawesson's reagent (1) with (η^2-ethene)bis(triphenylphosphine) platinum(0) in thf proceeds smoothly at room temperature to give (2) in good yield [equation (1)]. It is somewhat surprising that heterolytic cleavage of the P_2S_2 ring has taken place. The absence of any metal complex containing P(III) is good evidence that (1) is not readily dissociated in solution. A speculative mechanism for the formation of (2) would involve initial coordination of (1) via sulphur followed by elimination of an RPS fragment. We do not consider it likely that a four-membered P_2S_2Pt ring is an intermediate (although some workers have proposed this type of species for a titanium complex[5]) since this type of system would not readily rearrange to (2). The ^{31}P NMR of the crude reaction mixture contains several bands between 70 and 100 ppm and these are tentatively assigned to cyclic $(RPS)_n$ species

$$Pt(C_2H_4)(PPh_3)_2 + P_2S_4(C_6H_4OMe)_2 \rightarrow Pt\{S_2P(S)(C_6H_4OMe)\}(PPh_3)_2 + \frac{1}{n}(MeOC_6H_4PS)_n. \quad (1)$$

Characterisation of (2) was accomplished by IR, NMR, microanalysis and X-ray crystallography. The vibrational spectra of (2) contain the expected bands due to triphenylphosphine and the C_6H_4OMe group. (1) has a band at 694 cm^{-1}, due to ν(P═S), in its Raman spectrum and this band is observed at 692 cm^{-1} in (2), consistent with the P(V) oxidation state. In the low frequency region the ν(M—S) vibration in (2) is seen at 369 and 357 cm^{-1} in the IR and Raman respectively. The ^{31}P NMR of (2) (Fig. 1) consists of two singlets with platinum satellites. The band due to the PPh_3 groups is seen at $\delta = 18.62$ with $^1J[^{195}Pt-^{31}P] = 3254$ Hz appropriate to a Pt(II) complex with phosphorus *trans* to sulphur. The thiophosphoryl group gives rise to a resonance at $\delta = 87.75$ with $^2J[^{195}Pt-^{31}P] = 225$ Hz. For comparison, in (1) $\delta = 77.9$ ppm (thf/$CDCl_3$). The ^{2}J in (2) is intermediate in magnitude between those observed for $Pt(S_2P(OEt)_2)_2$ (3) (445 Hz) and $Pt(S_2P(OEt)_2)_2(PPh_3)$ (4) (120, monodentate ligand and 336 Hz, bidentate ligands).[11] These values suggest that there is less π-delocalisation in the PtS_2P ring of (2) than in (3) or (4) which is reasonable since (2) is dianionic whilst the chelate ligands in (3) and (4) are monoanionic and, formally, contain P═S groups.

The crystal structure of (2) reveals (Fig. 2, Table

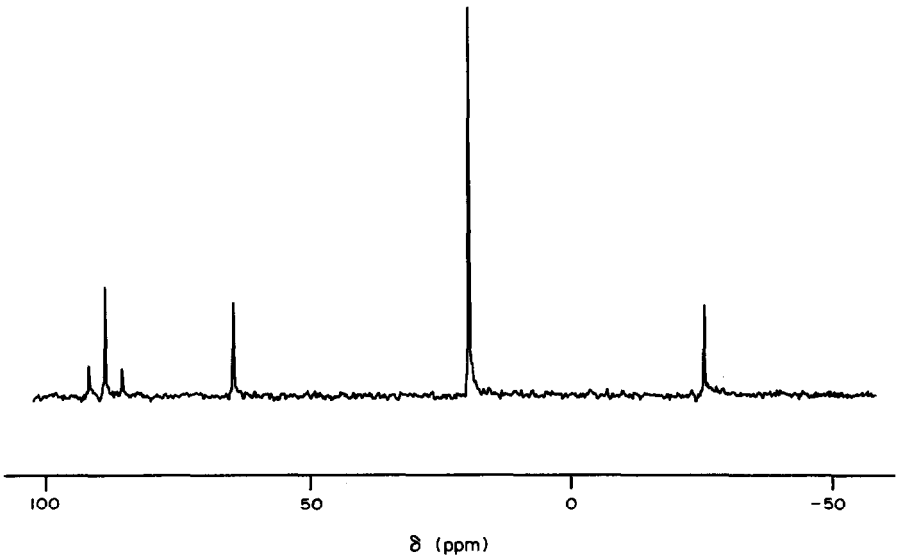

Fig. 1. ^{31}P–[^1H] NMR of **2**.

1) square planar co-ordination of the platinum by two *cis*-triphenylphosphine groups and a bidentate $(MeOC_6H_4)(S)PS_2^{2-}$ ligand. The ligand shell of the platinum, Pt, S(1), S(2), P(1), P(2), has a maximum deviation from planarity of 0.056 Å for S(2). As is commonly observed, steric effects force apart the phosphine ligands with a P(1)—Pt—P(2) angle of 101.2(1)° whilst S(1)—Pt—S(2) is contracted to 81.7(1)°. The Pt—P distances [2.291(2) and 2.293(2) Å] are normal for a Pt(II) complex. The X-ray structure of Lawesson's reagent has not been reported, though the structures of $PhSPS_2PSPh$ (**5**), $MeSPS_2PSMe$ (**6**) and the related titanium complex (**7**) have been established.[5,12,13] Comparison of the geometry in the four-membered rings in (**2**), (**4**)–(**7**) reveals some interesting features. In both (**5**) and (**6**) the structures contain a crystallographic centre of symmetry at the centre of the rings and are therefore planar. However, in the metal complexes (**2**) (**4**) and (**7**) there are varying degrees of distortion of the four-membered rings, the rings being folded with dihedral angles between the MS_2 and PS_2 planes of 19.4°, 10.2° and 12.9° respectively. In (**2**) a consequence of this significant dihedral angle is a displacement of P(3) of 0.48 Å from the ML_4 plane; this results in pseudo-axial/equatorial dispositions of the exocyclic sulphur atom and the $MeOC_6H_4$ group relative to the ML_4 plane. In all cases except (**5**) the two ring P—S distances are equivalent. In (**5**) there is a small, but statistically significant, difference in the bond lengths [2.108(2) and 2.133(2) Å]. The P—S bond lengths do vary between the different compounds. The shortest values are in (**4**), 1.97(2) and 2.00(1) Å, whilst (**2**) and (**7**) are intermediate, 2.063(2), 2.065(2) and 2.062(1), 2.060(1) Å respectively, and the longest distances are in (**5**) and (**6**), 2.108(2), 2.133(2) and 2.141(6) Å respectively. The M—S bonds differ in length within (**2**), (**4**) and (**7**) though the differences in (**4**) are probably not statistically significant. In (**2**) the Pt—S distances are 2.369(2) and 2.351(2) Å and in (**7**) Ti—S are 2.490(1) and 2.464(1) Å respectively. In (**2**) there is an accompanying non-equivalence of the P(1)—Pt—S(1) and P(2)—Pt—S(2) angles, 87.4(1) and 89.8(1)° respectively. There is no ready explanation for this effect and we note that the ^{31}P NMR spectrum of (**2**) shows only one type of PPh_3 environment in solution. The exocyclic P(3)=S(3), 1.945(3) Å, is intermediate in length between the values for the equivalent bonds in (**5**) and (**7**), 1.920(2) and 1.970(1) Å respectively. There appears to be an inverse correlation between the *exo* and *endo* P—S bond lengths. The differences in the ring

CRYSTAL STRUCTURES OF $[Co\{P(OPh)_3\}_4(HgX)]$, X = Cl, Br; NON-LINEARITY OF Co—Hg—X ARISING FROM INTRAMOLECULAR PHOSPHORUS–MERCURY INTERACTIONS

DAVID M. L. GOODGAME,* ALEXANDRA M. Z. SLAWIN and DAVID J. WILLIAMS*

Chemistry Department, Imperial College of Science and Technology, London SW7 2AY, U.K.

(*Received* 10 *June* 1986; *accepted* 4 *August* 1986)

Abstract—Single crystal X-ray diffraction studies have been carried out on the compounds $[Co\{P(OPh)_3\}_4(HgX)]$, X = Cl, Br. Crystals of the bromide, (**1**), are monoclinic, $C2$, $a = 22.391(4)$, $b = 13.643(3)$, $c = 22.851(6)$ Å, $\beta = 101.37(2)°$, $Z = 4$. The structure was refined on 4388 reflections to $R = 0.059$. Crystals of the chloride (**2**), are monoclinic, $C2$, $a = 22.300(5)$, $b = 13.632(3)$, $c = 22.743(4)$ Å, $\beta = 100.98(2)°$, $Z = 4$. The structure was refined on 4124 reflections to $R = 0.061$. In each case the molecule adopts a distorted trigonal bipyramidal geometry with a non-linear P(1)—Co—Hg axis, with corresponding short intramolecular Hg—P contacts. The Co—Hg—X (X = Cl, Br) chain is also significantly bent. Raman spectral data for the compounds, and for the iodide analogue, are also reported.

Many compounds are known which contain a mercury atom bonded to a transition metal atom. X-Ray structural studies on complexes of the type L_nMHgX, where X is a halogen atom, have shown that when the mercury is bonded to only one transition metal, M, the M—Hg—X unit is essentially linear, though deviations of up to ~ 20° from this linearity have been reported.[1–6]

These distortions of the M—Hg—X group have arisen because of intermolecular interactions between the Hg atom in one molecule and one or more halogen atoms from neighbouring molecules. In $(\eta^5\text{-}C_5H_5)Mo(CO)_3HgCl$, for example, each Hg atom interacts with the chlorine atoms of two neighbouring molecules at distances Hg···Cl of 3.079(3) and 3.078(4) Å resulting in a 160° bond angle for Mo—Hg—Cl.[6] We report here the structures of the compounds $[Co\{P(OPh)_3\}_4(HgX)]$, X = Cl, Br, described by Anderson and co-workers,[7] and some Raman spectral data for the complexes and for their iodo-analogue.

* Authors to whom correspondence should be addressed.

EXPERIMENTAL

Samples of $[Co\{P(OPh)_3\}_4(HgX)]$, X = Cl, Br, I, were prepared by the method of Anderson *et al.*[7] and crystallized from acetone/water.

The Raman spectra were obtained on the solid samples using a Spex Ramalog V instrument with a Coherent model 52 Krypton ion laser. The exciting lines used were 568.2 nm for the chloride complex and 647.1 nm for the bromide and iodide. Data were collected using a Spex Datamate computer controller.

X-Ray studies

Crystal data. (**1**) $C_{72}H_{60}O_{12}P_4BrCoHg$, monoclinic, $a = 22.391(4)$, $b = 13.643(3)$, $c = 22.851(6)$ Å, $\beta = 101.37(2)°$, $U = 6844$ Å^3, space group $C2$, $Z = 4$, $M = 1580.6$, $D_c = 1.53$ g cm^{-3}, μCu-$K_a = 84$ cm^{-1}.

(**2**) $C_{72}H_{60}O_{12}P_4ClCoHg \cdot C_{1.5}$, monoclinic, $a = 22.300(5)$, $b = 13.632(3)$, $c = 22.743(4)$ Å, $\beta = 100.98(2)°$, $U = 6787$ Å^3, space group $C2$, $Z = 4$, $M = 1554.2$, $D_c = 1.52$ g cm^{-3}, μCu-$K_\alpha = 81$ cm^{-1}.

Measurements. Refined unit cell parameters were obtained by centring in (**1**) 11, and in (**2**) 18 reflections on a Nicolet R3m diffractometer. Using the omega scan measuring routine, in (**1**) 4817, and in (**2**) 4813 independent reflections ($\theta \leqslant 58°$) were measured with Cu-K_α radiation (graphite monochromator). Of these in (**1**) 4388 and in (**2**) 4124 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. Lorentz and polarisation corrections were applied. In (**1**) a numerical absorption correction (face indexed crystal) was applied. In (**2**) an empirical absorption correction based on 324 azimuthal measurements was applied.

Structure analysis. The structure of (**1**) was solved by the heavy atom method, which gave the position of the mercury atom. All other non-hydrogen atoms were located from subsequent ΔF maps. Because of the large number of atoms in the structure, the geometries of the phenyl rings were idealised, C—C = 1.395, C—H = 0.96 Å, and the groups refined as rigid bodies. The ring carbon atoms were assigned individual isotropic thermal parameters which were allowed to refine. The hydrogen atoms were given constrained isotropic thermal parameters $U(\mathrm{H}) = 1.2U(\mathrm{C})$. The remaining atoms were refined anisotropically.*

Structure (**2**), being isostructural with (**1**), was solved by refining the coordinates of (**1**), omitting the bromine atom, using the data for (**2**) and allowing the halogen to come up in a ΔF map. This also revealed the presence of three partial atoms of an unidentified solvent fragment. These were refined isotropically, as carbons each with a site occupancy of 0.5. The remaining refinement procedure was as for (**1**).

The polarities of the structures were in both cases determined by *R*-factor tests. Refinement in both cases was by block-cascade full-matrix least-squares to for (**1**) $R = 0.059$, $R_w = 0.064$ $[w^{-1} = \sigma^2(F) + 0.00266F^2]$, and (**2**) $R = 0.061$, $R_w = 0.062$ $[w^{-1} = \sigma^2(F) + 0.00154F^2]$. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[8] Scattering factors were taken from the *International Tables for X-Ray Crystallography*.[9]

Final atomic coordinates, thermal parameters and structure factors have been deposited with the Editor as supplementary data. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

* Allowing anisotropic thermal values for the ring carbon atoms increased significantly the number of variable parameters but did not produce any improvement in the *R* values. Final refinement was therefore carried out using isotropic values.

RESULTS AND DISCUSSION

Tables 1 and 2 give selected bond lengths and angles for (**1**) and (**2**). Figure 1 shows a perspective view of (**1**).

In view of the very close correspondence between the geometries of the two structures we shall quote average numerical values in the following discussion. The cobalt has distorted trigonal bipyramidal geometry (Fig. 2) with all four Co—P bonds the same length, within statistical significance. The cobalt atom is displaced 0.21 Å (in both structures) towards P(1) relative to the P(4)—P(7)—P(10) plane. The P(1)—Co—Hg axis is bent with a P(1)—Co—Hg angle of 172.8(1)°. This bending of the Co—Hg bond relative to the axis of the bipyramid takes place in the direction of the Co—P(4)—P(10) plane, with resulting short contacts between the mercury atom and P(4) [3.035(5) Å] and P(10) [2.949(7) Å]. The Hg—Co bond is inclined by 68° to the Co—P(4)—P(10) plane. The Hg—P(7) distance is significantly longer (3.36 Å). There are notable departures from trigonal geometry for the three equatorial phosphorus atoms, the angles at cobalt being: P(4)P(7) 109.4(3)°, P(7)P(10) 118.4(3)°, and P(4)P(10) 129.2(3)°.

The Co—Hg bond [2.484(3) Å] is towards the lower end of the range (2.43–2.71 Å) found for the nine reported structures containing Co—Hg bonds, and consistent for essentially two-coordinate mercury.[10–18] The Co—Hg—X (X = Cl, Br) unit is significantly bent [172.8(2)°].

There are no major differences in the P—O bond distances in these structures and they are all in accord with expected values.

The coordination geometry about the cobalt atom can be thought of either in terms of a distortion from an idealised trigonal bipyramidal geometry, as observed[16] in $Hg\{Co[P(OCH_3)_3]_4\}_2$,

or a distortion from tetrahedral geometry resulting from the insertion of the Hg—Br unit. In the latter case this insertion could take place either along the three-fold direction of the CoP_4 tetrahedron or along one of the two-fold axes. On balance, we favour the distorted tetrahedral geometry because of the observed equivalence in the lengths of the four Co—P bonds. Also the preferred geometry for a CoL_4 complex of Co(−I) is tetrahedral.[19] In trigonal pyramidal geometry one would expect the Co—P(1) bond to be longer than the other three, though this could be influenced by the *trans*-disposition of the mercury atom.

Neither of these arguments, however, resolves the

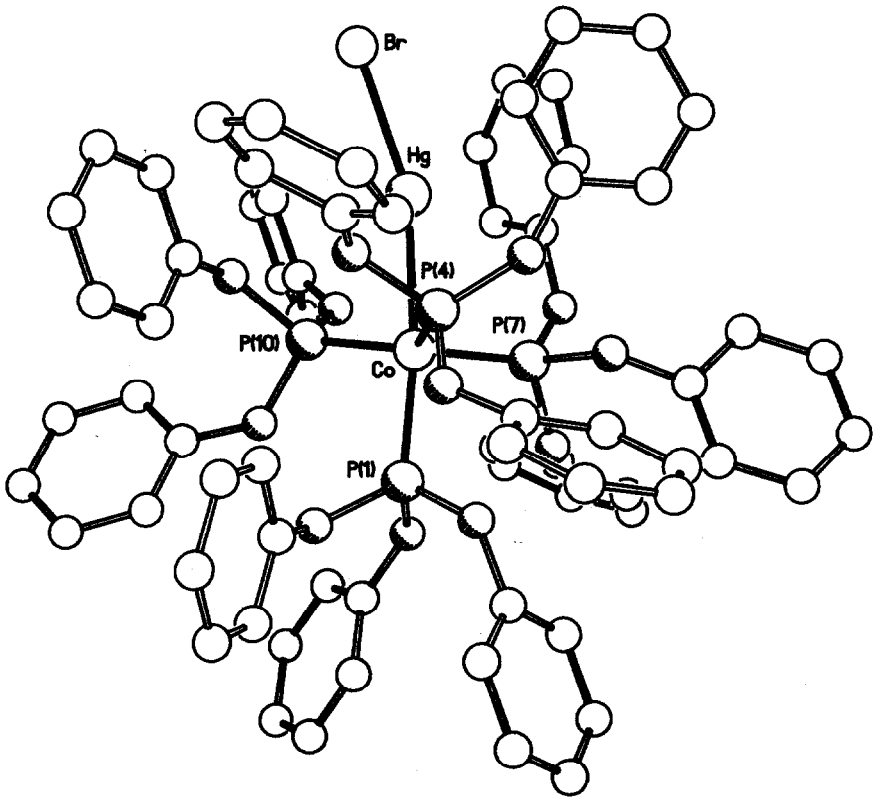

Fig. 1. Molecular structure of $[Co\{P(OPh)_3\}_4HgBr]$.

question as to whether the interactions between the mercury atom and P(4) and P(10) are repulsive or attractive. Both of these Hg—P distances are significantly shorter than the sum of the van der Waals' radii of the component atoms, and both P(4) and P(10) have larger angles at the cobalt atom, with respect to P(1), than does P(7). On the other hand, the angle formed by P(4) and P(10) at cobalt [129.2(3)°] is significantly larger than the other two equatorial angles. Further evidence for interactions between P(4), P(10) and the mercury is provided by the significant bending of the Co—Hg—X chain. Steric factors due to the phenyl rings appear to play no significant part in causing this bending, as the effect is the same regardless of the size of the halogen atom (Fig. 3).

Raman spectra

The bands observed in the Raman spectra of $[Co\{P(OPh)_3\}_4(HgX)]$ below 400 cm^{-1} are listed in Table 3. In each case, the dominant feature is a strong, halogen dependent band at 278 cm^{-1} (X = Cl), 198 cm^{-1} (X = Br) and 160 cm^{-1} (X = I) which is readily assigned as ν(Hg—X). [In using this designation we recognize that the actual mode concerned is not pure ν(Hg—X) but will have at least some ν(Co—Hg) character, particularly in the case of the iodide.] The values for ν(Hg—Br) and ν(Hg—I) are close to those reported[20] for Ph—Hg—Br (199 cm^{-1} IR; 193 cm^{-1} Raman) and Ph—Hg—I (160 cm^{-1} IR; 156 cm^{-1} Raman), but ν(Hg—Cl) is higher in Ph—Hg—Cl (330 cm^{-1} IR; 316 cm^{-1} Raman). Values of ν(Hg—Cl) in the range 252–219 cm^{-1} are, however, commonly found for other M—Hg—Cl species.[21]

Table 3. Low frequency (< 400 cm^{-1}) Raman bands (cm^{-1}) for the complexes $Co[P(OPh)_3]_4(HgX)$, X = Cl, Br, I

X = Cl	Br	I	Assignment[a]
278s	—	—	ν(Hg—Cl)
210br m	215br m	201br m	ν(Co—P)
—	198s	160s	ν(Hg—X)
129m	128m	109m	ν(Co—Hg)

[a] Designations represent likely major contribution as there will be significant mixing, particularly when X = Br and I.

Bearing in mind the masses of the phosphite ligands bonded to cobalt, the ν(Co—Hg) bands in $[Co\{P(OPh)_3\}_4(HgX)]$ would be expected to be at quite low frequencies. Even when Hg is bonded to first row transition metal ions linked to relatively light ligands, such as CO, the modes approximating to ν(Hg—M) are below 200 cm^{-1}.[21] The large mass of the $Co[P(OPh)_3]_4$ unit would be expected to lower ν(Co—Hg) even further. It seems probable that the medium intensity bands at 129 cm^{-1} (X = Cl), 128 cm^{-1} (X = Br) and 109 cm^{-1} (X = I) in the Raman spectra of $[Co\{P(OPh)_3\}_4(HgX)]$ are due to modes with significant ν(Co—Hg) character. On the basis of literature assignments of ν(M—P) for other phosphite complexes of low-valent M atoms,[22] the broad, medium intensity bands in the 200–215 cm^{-1} region are assigned to ν(Co—P).

CATIONIC COMPLEXES OF TRIMETHYLPLATINUM(IV) WITH TRIDENTATE LIGANDS—II. FLUXIONAL BEHAVIOUR

EDWARD W. ABEL, KENNETH KITE* and PHILLIP S. PERKINS

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 22 *July* 1986; *accepted* 8 *August* 1986)

Abstract—Variable temperature ^{1}H NMR studies on the ionic compounds $[PtMe_3\{MeE(CH_2)_nE'(CH_2)_nEMe\}]^+X^-$ ($n = 3$, E = E′ = S: $n = 2$, E = Se or S; E′ = O, S, Se: $n = 2$, E = S, E′ = SS: X = I, BPh_4 or BF_4) have shown that pyramidal inversion takes place only at the terminal chalcogen atoms. High-temperature studies on these complexes and $[PtMe_3\{(H_2NCH_2CH_2)_2E'\}]^+BF_4^-$ (E′ = O or SS) show that only those with E′ = O undergo ligand scrambling processes. Computer simulation of the static and dynamic spectra gives accurate energy barriers for both fluxional processes.

Earlier studies[1] on the fluxional behaviour of uncharged complexes of trimethylplatinum(IV) halides with bidentate thioethers and selenoethers $[(PtMe_3X)MeE(CH_2)_nE'Me]$ ($n = 2$ and 3, E = E′ = S and Se: $n = 2$, E = S, E′ = Se; X = Cl^-, Br^-, I^-) have shown that pyramidal inversion at E and E′ takes place in an uncorrelated manner, and that the inversion energy barriers are higher at Se than at S, and higher in the five- compared to the six-membered rings. We now consider the effect of introducing a third potential inverting centre into the system using tridentate ligands of the general type $MeE(CH_2)_nE'(CH_2)_nEMe$, which should form charged complexes. The effect of ring size has been examined with the ligands having $n = 2$ and 3, and E = E′ = S. Ligands having E = S or Se allow us to test the relative rates of inversion of these atoms, and whether the expected inversion at the terminal chalcogens is uncorrelated here also. Molecular models indicate that inversion at the central atom E′ is likely to be disfavoured on steric grounds, but this possibility has been explored using ligands with E′ = O, S and Se. Additionally, ligands with E′ = O and SS may be used to test respectively the effect of a significantly weaker donor to Pt(IV) than N, S or Se,[2] and the possibility of a 1,2-metallotropic shift between the SS atoms. Two ligands with no possibility of inversion at the terminal donor atoms $[(H_2NCH_2CH_2)_2E']$ (E′ = O or SS) are included for comparison. The tridentate ligands allow us to explore the effect of a third donor atom on any high temperature ligand scrambling processes comparable to those reported for complexes of the bidentate ligands. Characterisation of these complexes is reported in an earlier paper.[3]

EXPERIMENTAL

The compounds were prepared and characterised as described.[3] The ^{1}H NMR spectra were recorded at 100 MHz on a JEOL PS/PFT-100 equipped with standard accessories for variable temperature work. Temperature measurements were made using a copper–constantan thermocouple. The 400 MHz spectra were run on a Bruker WH-400 spectrometer.

Band shape analyses were carried out using a modified version of the DNMR programme of Kleier and Binsch.[4] Computer simulated spectra were fitted visually, and energy parameters derived from standard Arrhenius and Eyring plots are based on least-square fitting. The errors quoted for the free energies of activation $\Delta G^{\ddagger}$ are based on the numerical difference between the standard deviations of $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$ (where $T = 298.15$ K) following the practice of Binsch and Kessler.[5]

RESULTS AND DISCUSSION

In considering the ^{1}H DNMR behaviour of the compounds shown in Fig. 1, it is convenient to distinguish the low temperature pyramidal inversion processes from the ligand scrambling which is a feature of the spectra at higher temperatures.

Low-temperature studies

In the majority of the compounds the tridentate ligand is symmetrical with three potential inverting centres (compounds **I–VII**). For compound **VIII** (E′ = SS) which lacks a plane of symmetry more complicated behaviour is found, while compounds **IX** and **X** with chalcogen atoms present only in the middle of the ligand show no spectral changes in this temperature range. ^1H NMR data at the fast and slow inversion limits are recorded in Table 1, with assignments as indicated in Fig. 2. The coupling constants are in the expected ranges found for complexes with the analogous bidentate ligands,[1] and will not be discussed further.

The temperature variations observed in the spectrum of $[PtMe_3\{(MeSCH_2CH_2)_2S\}]^+$ (**III**) are typical of complexes (**I–VII**). The S atoms are centres of chirality, so that in the absence of sulphur inversion four diastereoisomers are possible, a degenerate pair of *dl*-isomers and two distinct *meso*-isomers (Fig. 3). Inversion at the central S atom would give another set of four diastereoisomers. There is, however, no experimental evidence for the presence of more than one set of diastereoisomers, and molecular models show that such a central S atom

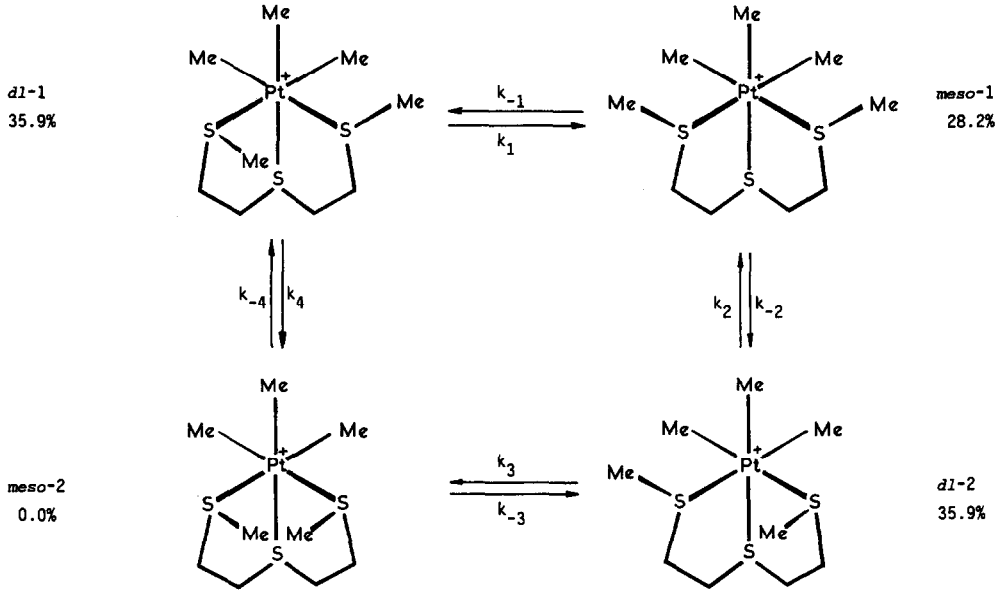

Fig. 3. Diastereoisomers of $[PtMe_3(MeSCH_2CH_2)_2S]^+$ showing isomer abundance.

inversion would lead to a highly strained conformation. With the supporting evidence that there are also no changes attributable to central chalcogen atom inversion in the spectra of compounds **IX** and **X**, it is reasonable to conclude that this process is energetically inaccessible, and the problem is simplified to one involving four interconvertible diastereoisomers.

At low temperatures (−54.6°C), the S—Me region of the spectrum of **III** contains only three signals (plus ^{195}Pt satellites) (Fig. 4), assignable to the two *dl*-isomers and one of the *meso* isomers. This assignment is confirmed by the presence of five signals in the Pt—Me region, a set of three in the rate 1 : 1 : 1 from the asymmetric *dl*-isomers, and two signals ratio 2 : 1 from the one *meso*-isomer (Fig. 5). No signals from the second *meso*-isomer could be detected, possibly due to coincidental over-

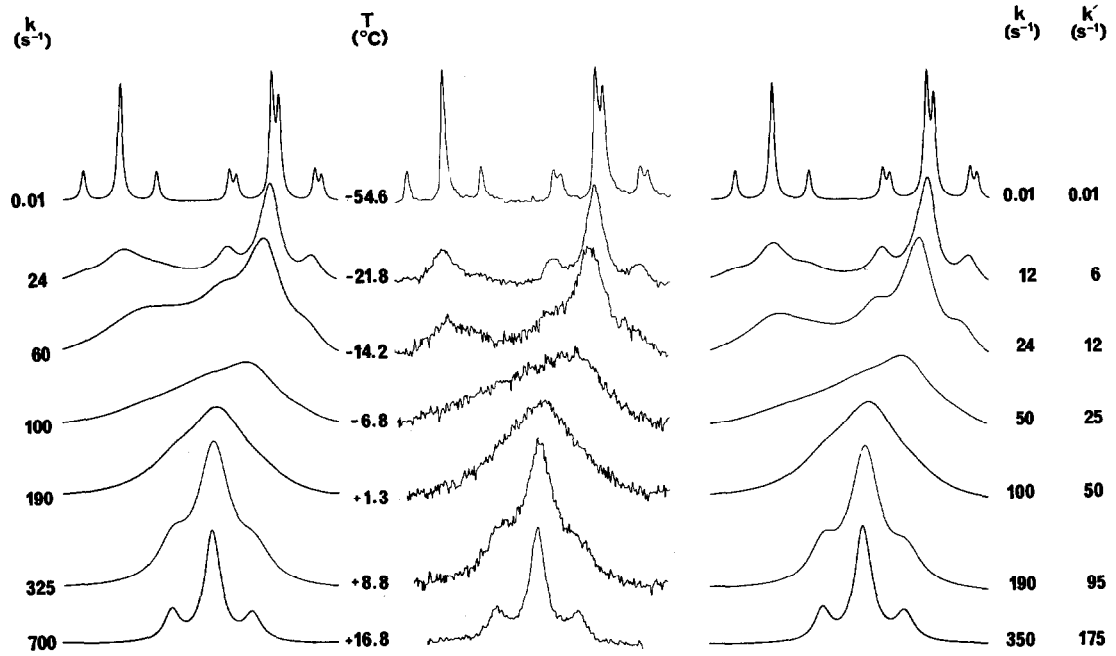

Fig. 4. Experimental and computer synthesised variable temperature ^1H NMR spectra of $[PtMe_3(MeSCH_2CH_2)_2S]^+I^-$ in the S—Me region.

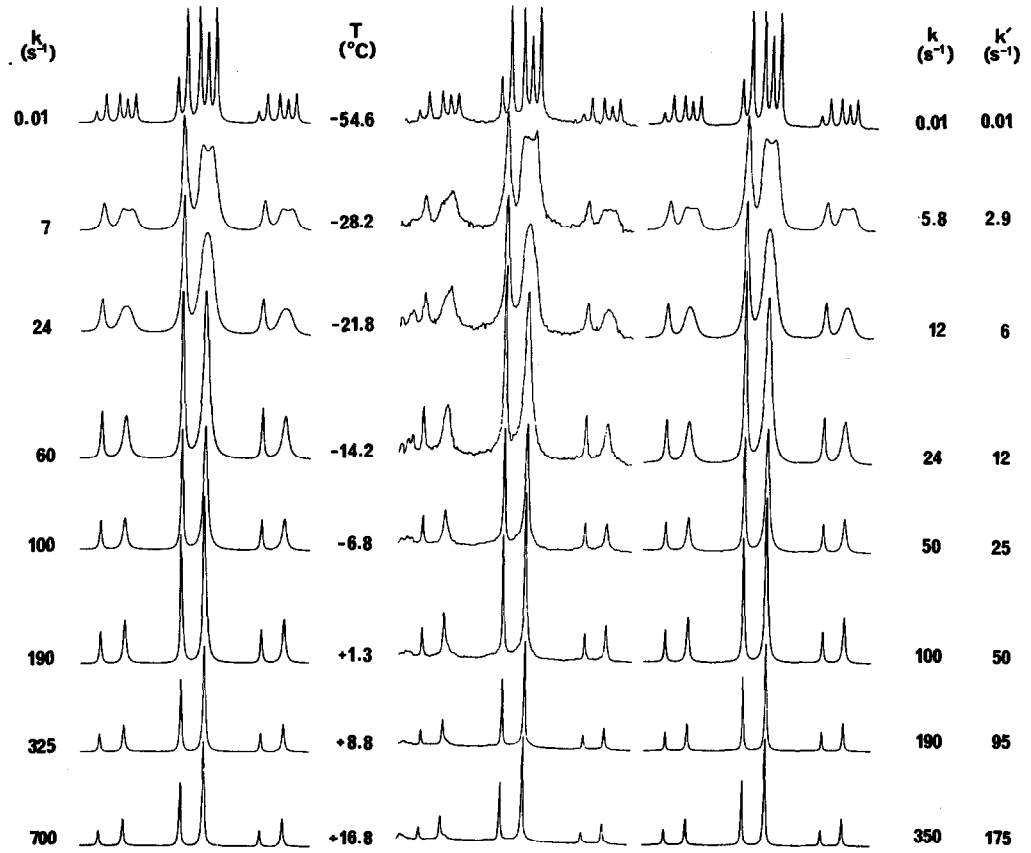

Fig. 5. Experimental and computer synthesised variable temperature ^1H NMR spectra of $[PtMe_3(MeSCH_2CH_2)_2S]^+I^-$ in the Pt—Me region.

lap of the signals, but much more probably to a very low abundance for this isomer. Molecular models of *meso*-2 show severe steric interaction between the two S—Me groups, and our analysis below assumes an assignment of the signals to the *meso*-1 form and the *dl*-pair (see below). Signal area determinations gave the relative isomer populations shown in Fig. 3.

On warming the sample, the three SMe signals coalesced as a result of S-inversion, until at 16.8°C a single averaged peak (with ^{195}Pt satellites) was observed (Fig. 4). At the same time the PtMe signals coalesced to two, with intensity ratio 2:1 (Fig. 5). Both regions showed complete retention of coupling to ^{195}Pt at all temperatures, proving that a non-dissociative fluxional process was responsible for the changes. Computer simulation of the spectra was performed assuming that the isomers were interconverted by pyramidal inversion at the sulphur atoms (Fig. 3). Since the two *dl*-isomers are identical, it necessarily follows that $k_1 = k_2$ $(= k)$, and $k_3 = k_4$ $(= k'')$. As no *meso*-2 isomer was evident, the initial assumption was made that $k_3 = k_4 = 0$, thus reducing the spin problem to one involving three isomers (Fig. 6, spin system 1). However, while it was possible to obtain good agreement between simulated and experimental spectra in both the S—Me and Pt—Me regions, the k values necessary for the former were 5–10% higher than for the latter. Compromise values could be found which gave reasonable agreement in both regions, but the need to consider an alternative spin system was clear. Since the signal to noise ratio and peak width at the low temperature limit would allow for up to 4% of the *meso*-2 isomer, the initial assumption was revised, and allowance made for the presence of very small amounts of *meso*-2, so that rate constant k_3 and k_4 now have equal but non-zero values, and spin-system 2 (Fig. 6) applies. A simplification of this system is possible by combining the effects of k_3 and k_4 in the form of one rate constant k' which represents the overall rate of interconversion of the two *dl*-isomers via a short-lived *meso*-2 intermediate (spin system 3). This implies a practically simultaneous inversion at both sulphur atoms. Simulations based on spin system 3 gave excellent agreement with the observed spectra in both S—Me and Pt—Me regions throughout the temperature range studied. The simulated spectra using spin system 1 (left of figures) and spin system

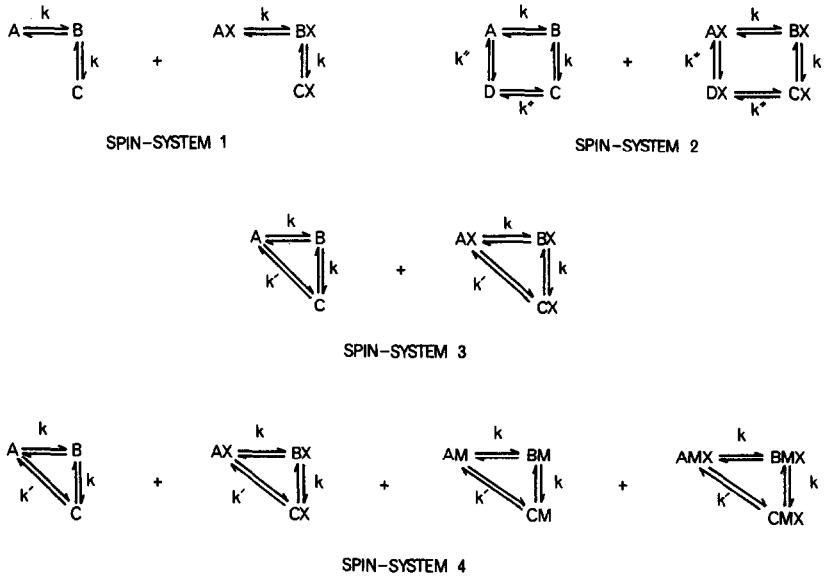

Fig. 6. Spin systems on which the computer synthesised spectra are based. A, B, C and D refer to the proton environments in the *dl*-1, *meso*-1, *dl*-2 and *meso*-2 isomers in Fig. 2 respectively. X denotes the ^{195}Pt nucleus and M the ^{77}Se nucleus.

3 are compared with the experimental spectra in Figs 4 and 5 (note the incompatibility of the spectra at −14.2°C using the former system). Spin-system 3 was also used for compounds **I**, **II** and **IV–VII**, since inclusion of the spin-active selenium nuclei in the computations (spin system 4) had negligible effect on the overall line shape.

For the symmetrical compound **I** $[PtMe_3\{(MeSCH_2CH_2CH_2)_2S\}]^+$ good agreement was obtained only when k' was put equal to zero. In this complex the two six-membered rings undergo rapid ring reversal even at −56.5°C, and molecular models show that this process increases the steric interaction in the *meso*-2 isomer such that it is inaccessible as an intermediate for the *dl–dl* interconversion. This is supported by the observation that the *dl*-isomers are only 12.3% abundant compared to *c.* 35% for the corresponding five-membered ring systems (Table 2). The low-temperature spectrum of **I** in the S—Me region could not be assigned owing to signal overlap and the relatively low abundance of the *dl*-invertomers, and energy barriers were obtained from the Pt—Me region only. The spectra of **V** proved impossible to simulate, as selenium inversion takes place in the same temperature range as Pt—Me scrambling (*vide infra*).

The spectral changes shown by the unsymmetrical ion **VIII** are more complex, as four pairs of *dl*-isomers are possible (Fig. 7), each of which has a non-superimposable mirror image (though as the respective mirror images give identical NMR spectra, only one set of conformers needs to be considered). At −67.1°C (the slow inversion limit), the S—Me region of the 400 MHz spectrum shows six signals assignable to *dl*-1, *dl*-2 and *dl*-3. The remaining undetected isomer is analogous to the *meso*-2 isomer in **I–VII**, and its absence may be explained by the same reasoning. The assignment is confirmed by the presence of either signals in the Pt—Me region (the ninth methyl signal overlaps). The spectra at 100 MHz were not so clearly resolved, but it was possible to use the data from 400 MHz spectra to simulate them. Figure 7 illustrates how the conformers are related by the rate constants k_1–k_5, but similar reasoning to that used for **I–VII** shows that only k_1, k_2 and k_3 are needed

Table 2. Relative isomer abundance for the thio- and selenoether complexes at the slow inversion limits

Complex	Relative percentage abundance[a] *dl*-1	*meso*-1	*dl*-2
I	12.3	75.4	12.3
II	39.0	22.0	39.0

for successful simulation. Comparison of data obtained with compounds **I** and **III** (containing six- and five-membered rings respectively) shows it is reasonable to assume that $k_3 > k_1 > k_2$ at all temperatures.

On warming compound **VIII**, spectral changes occur in two distinct stages (Figs 8 and 9). From −67 to −27°C signals (spectra a–g) from *dl*-1 stay sharp, so simulations were done assuming $k_1 = k_2 = 0.01\ s^{-1}$. By the onset of the second stage collapse (−27 to +33°C) (spectra g–m), a linear correlation between $\log_{10} k_3$ and $1/T$ had already been established, thus enabling values of k_3 to be estimated by extrapolation. Manipulation of the three rate constants gave excellent agreement between experimental and simulated spectra throughout the two ranges. The k values determined are given in Table 3, and the energy barriers to inversion in Table 4.

As found for the bidentate analogues,[1] the inversion rates for this series of compounds are extremely fast compared to those found for sulphoxides,[6] selenoxides,[7] thiosulphinates[8] and sulphonium ions.[9] As expected, the free energies of activation at the selenium atoms are *c.* 15 kJ mol^{-1} higher than those for sulphur inversion, presumably due to increased *s*-character of the lone pair on the chalcogen atom. The energy barriers to inversion at E (Fig. 1) were found to depend on the central chalcogen E′ in the order Se ~ S > 0, which is related to the length of the Pt—E bond reflected in the ^2J(Pt—Me) coupling constants. The markedly weaker Pt—O bond clearly makes the transition state more accessible,[10] and predominates over the competing effect of decreasing the chalcogen—carbon bond length and decreasing electron density at platinum.

Comparison of complexes **I**, **III** and **VIII** reveals a decrease of *c.* 9 kJ mol^{-1} in inversion energy barriers as the heterocyclic ring changes from five to six members, consistent with results obtained elsewhere.[1,10–12] In complex **VIII** the inversion energy barriers for the five- and the six-membered

Table 3. Rate constants and temperatures for the variable temperature ^1H NMR spectra of complex **VIII** in Figs 8 and 9

rings are both higher than those found for the five-membered rings in **II–IV** and the six-membered rings in **I**. These observations are not unexpected on steric grounds, and reflect trends that have been observed for the incorporation of different numbers of sulphur atoms into six-membered rings.[13]

High-temperature studies

The behaviour of the compounds at high temperatures falls into one of three categories depending on the Pt–ligand bonding modes. For complexes **I, III, IV, VI** and **VII** the spectral changes associated with **III** are typical. With iodide as counter ion (**IIIa**), at *c.* 75°C (Fig. 10A), an additional set of lines (plus ^{195}Pt satellites) appears in the Pt—Me region and a new singlet at *c.* δ 2.2 (Table 5). A Pt—Me signal with ^2J = 69.3 Hz shows that a neutral iodide-coordinated complex[1] has been formed by displacement of a terminally coordinated sulphur atom. The ligand clearly prefers to form a five-membered ring rather than the eight-membered

ring that would result if the central sulphur atom were displaced. Furthermore ^2J values for Pt—Me groups *trans* to sulphur increase by *c.* 4 Hz when the uncharged complex is formed, showing a decreased Pt—S bond strength. The analogous complex with BPh_4^- as counter ion (**III**) was non-fluxional when heated in DMSO-d_6 up to 135°C (Fig. 10C). The other members of this group were also non-fluxional at high temperatures, though there was slight evidence of peak broadening and changes in the coupling constants that showed the onset of ligand dissociation.

Complexes **VIII** and **X** have the metal coordinated to the central disulphide group. Similar systems are known to undergo 1,2 shifts at high temperatures,[14] and the same process here would give a highly fluxional pseudo-seven-coordinated system. The spectrum of a solution of **VIII** in DMSO-d_6 showed three Pt—Me signals (plus ^{195}Pt satellites) at room temperature. On warming, spectral collapse

occurred until at 155°C only one broad Pt—Me signal (plus satellites) was apparent. This effect is illustrated with a mixture of **III** and **VIII** at 125°C (Fig. 10B) which clearly shows that while the disulphide complex undergoes methyl scrambling (one broad peak), the sulphide complex remains rigid and exhibits two sharp signals. A second high temperature run on **VIII** using a different solvent ($C_6D_5NO_2/C_6D_6$; 2:1 by volume) showed that the fluxional behaviour of **VIII** was solvent dependent. In this solvent three broadened lines are present at 120°C (Fig. 10D) whereas in DMSO the signals had coalesced at this temperature (Fig. 10B). Further heating showed spectral changes comparable to those observed in DMSO, but at 150°C decomposition of the complex occurred. By comparison the ^{1}H NMR spectrum of **X** in DMSO shows three signals (plus ^{195}Pt satellites) at room temperature which stay sharp on warming to 130°C with very little change in chemical shifts or coupling constants (Fig. 10E). Evidently **X** is non-fluxional in the temperature range studied.

Finally, complexes **II**, **V** and **IX** undergo fluxional changes resulting from the centrally coordinated oxygen atom. The inherent weakness of the Pt—O bond[15–18] favours dissociation leading to a stereochemically non-rigid five-coordinate intermediate. Coalescence of the Pt—Me signals was observed for each of these complexes with complete retention of coupling to ^{195}Pt. The spectral changes observed for **II** are reproduced in Fig. 11. Similar changes were recorded for **IX**, but for **V** inversion at Se occurs over the same temperature range as methyl scrambling. For **II** and **IX**, computer simulation gave excellent agreement between experimental and simulated spectra when a single rate constant was used ($A \rightleftarrows B + AX \rightleftarrows BX$; A = PtMe *trans* to N, S or Se, B = PtMe *trans* to O, X = ^{195}Pt). Simulated spectra for **II** are reproduced alongside the experimental spectra in Fig. 11 and the rate constants measured for **II** and **IX** are given in Table 6.

This study shows that ligand scrambling via a 120° pseudo-rotation of the tridentate ligand does not occur for this type of complex, in contrast to the bidentate analogues, for which a 'pancake flip' movement of the bidentate ligands has been well established elsewhere.[19] One explanation may be that the tridentate ligands are more strongly bound, the increase in Pt—ligand bond strength shown by the decrease in Pt—Me coupling of *c.* 4 Hz being enough to inhibit ligand scrambling processes. Spectral changes associated with the disulphide complexes show that here the fluxional process is solvent dependent, which points to a dissociative mechanism. However, this work does show that the rate of dissociation is also dependent on the

Table 6. Energy parameters for the high-temperature scrambling processes in complexes **II** and **IX**

	Complex	E_a (kJ mol^{-1})	$\log_{10} A$	ΔH^+ (kJ mol^{-1})	ΔG^+ (kJ mol^{-1})	ΔS^+ (kJ mol^{-1})
(II)	$[PtMe_3(MeSCH_2CH_2)_2O]^+BF_4^-$	75±0.6	13.5±0.1	71.1±0.1	72±0.6	4±1.9
(IX)	$[PtMe_3(H_2NCH_2CH_2)_2O]^+BF_4^-$	79±0.8	13.2±0.1	76±0.8	76.6±0.1	−1±2.3

presence of both terminal chalcogen and disulphide coordination. Complexes with a coordinated oxygen atom undergo high-temperature ligand scrambling that is fully reversible and purely intramolecular. The energy parameters are slightly affected by the nature of the terminal bonding and therefore a value for $\Delta G^{\ddagger}$ of around 75 kJ mol^{-1} can be expected for ligand scrambling and selenium inversion in complex **V**.

ON THE EXTRACTION WITH LONG-CHAIN AMINES—XXXVII. THE EXTRACTION OF LEAD(II) BY TRILAURYLAMINE AND TRILAURYLAMMONIUM, TRI-*n*-OCTYLAMMONIUM AND TRI-*n*-HEXYLAMMONIUM CHLORIDES DISSOLVED IN BENZENE

M. P. ELIZALDE,* J. M. CASTRESANA, L. A. FERNANDEZ and M. E. ASTIGARRAGA

Departamento de Quimica, Universidad del Pais Vasco, Apartado 644, 48080 Bilbao, Spain

(*Received* 27 *May* 1986; *accepted* 12 *August* 1986)

Abstract—The extraction of Pb(II) from 1.0 mol dm^{-3} NaCl with trilaurylamine (TLA) and trilaurylammonium, tri-*n*-octylammonium and tri-*n*-hexylammonium chlorides (TLAHCl, TOAHCl and THAHCl) dissolved in benzene has been studied at 298 K. The extraction of Pb(II) by TLA and TLAHCl can be explained by the formation of the species (TLAHCl)($PbCl_2$) and $(TLAHCl)_3(PbCl_2)$ in the organic phase. The use of TOAHCl and THAHCl as extractants leads to the formation of the same kind of species in the organic phase indicating that the length of the alkylic chain of the amine does not influence the metal extraction. Conditional equilibrium constants for the extracted species are given.

The extraction of lead from chloride solutions by long-chain tertiary amines has been scarcely studied.[1–4] Furthermore, information about lead extraction by other amine and quaternary ammonium salts is also rather scarce[5–10] if compared with the larger number of studies performed with inner and outer transition metal ions.

The lack of information about the extraction behaviour of Pb(II) in these systems together with its great environmental importance made us initiate a study on the extraction of this metal from aqueous 1.0 mol dm^{-3} NaCl solutions by trilaurylamine (TLA) dissolved in benzene.

This work is part of a systematic study on the extraction of metal chlorides by long-chain tertiary alkylamines and presents a detailed description of the factors affecting the extraction such as the aqueous pH (in the extraction by TLA alone), the ammonium salt concentration [extraction by trilaurylammonium chloride (TLAHCl)] and the length of the amine chain [extraction by tri-*n*-octylammonium and tri-*n*-hexylammonium chlorides (TOAHCl and THAHCl)]. The effect of the ionic strength in the extraction of Pb(II) by TLAHCl will be discussed in a subsequent publication. The data in the present study have been treated by graphical and numerical methods in order to ascertain the composition of the species extracted as well as the extraction constants.

EXPERIMENTAL

Reagents

Lead chloride, $PbCl_2 \cdot H_2O$ (Merck, p.a.), was purified by recrystallization before use and analysed trimetrically according to standard methods.[11] Sodium chloride (Merck, p.a.) was recrystallized as described elsewhere.[12] TLA, benzene and mercaptosuccinic acid (Merck, p.a.) were used as supplied. TLAHCl, TOAHCl and THAHCl were prepared from TLA (Merck, p.a.), TOA (Eastman Kodak, p.a.), and THA (Eastman Kodak, p.a.), as described in Ref. 13. Distilled deionised water was used throughout the work. All other chemicals were of analytical-grade quality.

Experimental procedure

Equal volumes (10 cm^3) of organic solutions containing TLA or the ammonium salts in benzene

* Author to whom correspondence should be addressed.

ranging from 0.005 to 0.100 mol dm^{-3} were shaken with aqueous solutions of Pb(II) in 1.0 mol dm^{-3} NaCl using special stoppered tubes on a continuous rotating rack. The total concentration of Pb(II) was varied from 0.2 to 0.8 mmol dm^{-3}. The free hydrogen ion concentration was varied from 10^{-5} to 10^{-1} mol dm^{-3} when using TLA, and kept around 10^{-2} mol dm^{-3} when the ammonium salts were used as extractants. Preliminary experiments showed that extraction equilibrium was attained within 2 min although a shaking time of 15 min was always used.

After centrifugation, aliquots of the aqueous phases were taken for analysis. The metal concentration was measured spectrophotometrically using mercaptosuccinic acid in $Na_2B_4O_7$–NaOH buffer at pH = 10.5.[14] By measuring the concentration of Pb(II) in the organic phase after its stripping with NaOH, the mass balance for lead could be checked.

RESULTS AND GRAPHICAL DATA TREATMENT

Extraction by the amine

The extraction of Pb(II) by TLA dissolved in benzene can be described by:

$$j\mathrm{Pb}^{2+} + n\mathrm{Cl}^- + q\mathrm{H}^+ + p\mathrm{TLA}_{\mathrm{org}} \rightleftharpoons \mathrm{TLA}_p\mathrm{H}_q\mathrm{Pb}_j\mathrm{Cl}_{n\,\mathrm{org}}, \quad (1)$$

for which the stroichiometric equilibrium constant is given by:

$$\beta_{pqjn} = \frac{[\mathrm{TLA}_p\mathrm{H}_q\mathrm{Pb}_j\mathrm{Cl}_n]_{\mathrm{org}}}{[\mathrm{Pb}^{2+}]^j[\mathrm{Cl}^-]^n[\mathrm{H}^+]^q[\mathrm{TLA}]^p}. \quad (2)$$

The stoichiometric distribution coefficient of Pb(II) is given by:

$$D = C_{\mathrm{Pb,org}}/C_{\mathrm{Pb,aq}} = \sum_p\sum_q\sum_j\sum_n j\beta'_{pqjn}[\mathrm{Cl}^-]^n[\mathrm{Pb}^{2+}]^{j-1}[\mathrm{H}^+]^q[\mathrm{TLA}]^p \quad (3)$$

β'_{pqjn} being a conditional formation constant defined by:

$$\beta'_{pqjn} = \beta_{pqjn}\alpha_{\mathrm{Pb}}^{-1}. \quad (4)$$

The side-reaction coefficient α_{Pb} remained constant since the chloride concentration was kept constant and the contribution of metal hydroxo-complexes can be considered negligible in the pH range studied.

The experimental results, $\log D = f(\mathrm{pH})$ at several total concentrations of TLA are given in Fig. 1. Additional experiments carried out at several total Pb(II) concentrations indicated absence of polynuclear lead species in the organic phase.

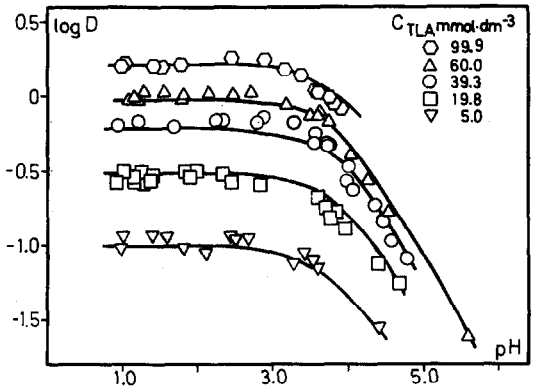

Fig. 1. Plot of $\log D$ vs pH data for the different total concentration of TLA. The solid lines have been drawn using the proposed extraction constants.

On the other hand, a preliminary analysis of the data in Fig. 1 made by plotting $\log D = F(\log [\mathrm{TLA}]_{\mathrm{org}})$ at selected fixed pH values gave rise to curves of increasing slope indicating the extraction of more than one lead species. Hence, assuming as simplest hypothesis the formation of two species with stoichiometries $\mathrm{TLA}_p\mathrm{H}_q\mathrm{PbCl}_n$ and $\mathrm{TLA}_r\mathrm{H}_s\mathrm{PbCl}_m$, the distribution coefficient can be expressed, according to eqn (3), by:

$$D = \beta'_{pqn}[\mathrm{Cl}^-]^n[\mathrm{TLA}]^p[\mathrm{H}^+]^q + \beta'_{rsm}[\mathrm{Cl}^-]^m[\mathrm{TLA}]^r[\mathrm{H}^+]^s \quad (5)$$

where β'_{pqn} and β'_{rsm} are the respective conditional extraction constants.

Equation (5) can be rearranged to:

$$\frac{D}{\beta'_{rsm}[\mathrm{Cl}^-]^m[\mathrm{TLA}]^r[\mathrm{H}^+]^s} = 1 + \frac{\beta'_{pqn}}{\beta'_{rsm}}[\mathrm{Cl}^-]^{n-m}[\mathrm{TLA}]^{p-r}[\mathrm{H}^+]^{q-s}. \quad (6)$$

The experimental functions $(\log D - \log [\mathrm{TLA}]_{\mathrm{org}}) = f(\log [\mathrm{TLA}]_{\mathrm{org}})$ obtained for different integer values of r, at constant selected pH values, were compared with:

$$\log Y = \log(1 + X^i) = f(\log X), \quad (7)$$

where Y and X are normalized variables defined by:

$$Y = \frac{D}{\beta'_{rsm}[\mathrm{Cl}^-]^m[\mathrm{TLA}]^r[\mathrm{H}^+]^s}, \quad (8)$$

$$X = \left(\frac{\beta'_{pqn}}{\beta'_{rsm}}[\mathrm{Cl}^-]^{n-m}[\mathrm{H}^+]^{q-s}\right)^{1/(p-r)}[\mathrm{TLA}]_{\mathrm{org}}, \quad (9)$$

and $i = p - r$.

Free TLA concentrations were calculated from the mass balance for the reagent by neglecting the contribution from the lead species due to the high

C_{TLA}/C_{Pb} ratio used in the experiments:

$$C_{TLA} = [TLA]_{org} + \beta_{11}[TLA]_{org}[Cl^-][H^+] + 2\beta_{22}[TLA]^2_{org}[Cl^-]^2[H^+]^2, \quad (10)$$

where β_{11} and β_{22} were taken from Ref. 13.

The best agreement between experimental and theoretical functions, for which the position of best fit is shown in Fig. 2, was found for $i = 2$ and $r = 1$. Therefore, the value of the stoichiometric coefficient p equals 3.

In order to determine the stoichiometric coefficients s and q, as well as the extraction constants, the differences between experimental and theoretical functions defined by:

$$\Delta Y = (\log D - \log[TLA]_{org}) - \log Y = \log \beta'_{rsm}[Cl^-]^m - s\,pH, \quad (11)$$

$$\Delta X = \log[TLA]_{org} - \log X = -\frac{1}{p-r}\log\frac{\beta'_{pqn}}{\beta'_{rsm}}[Cl^-]^{n-m} + \frac{q-s}{p-r}pH \quad (12)$$

were plotted as a function of pH as shown in Fig. 3. Straight lines of slope values -1 and 1, respectively, were observed from which the values $s = 1$ and $q = 3$ can be deduced from eqns (11) and (12).

From the intercepts on both axes in Fig. 3, values of the extraction constants for the species $(TLAHCl)(PbCl_2)$ and $(TLAHCl)_3(PbCl_2)$ were obtained. The number of chloride ions in the extracted species has been deduced from the electroneutrality condition in the organic phase. Values of the constants are collected in Table 1.

The extraction of Pb(II) from chloride medium with TLAHCl, TOAHCl and THAHCl, generically

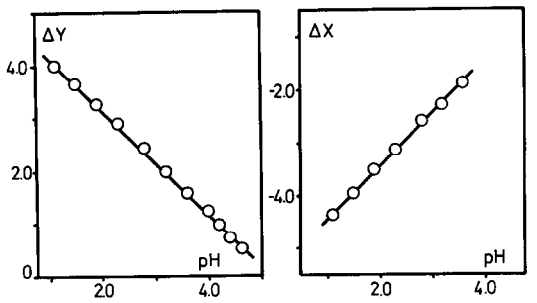

Fig. 3. Differences on both axes in Fig. 2 as a function of pH.

represented by R_3NHCl, can be described by:

$$jPb^{2+} + 2jCl^- + zR_3NHCl_{org} \rightleftharpoons (R_3NHCl)_zPb_jCl_{2j\,org}. \quad (13)$$

Since Pb(II) is only present in tracer amounts, polynuclear complexes of lead in the organic phase need not to be considered. This assumption is supported by the fact that the curves $\log D$ vs $\log C_{R_3NHCl}$ coincide for different Pb(II) concentrations (cf. Fig. 4).

Taking into account the mass balance equation for the metal, with k'_{z2} being the conditional extraction constant for reaction (13), the distribution coefficient of Pb(II) can be expressed by:

$$D = \sum_z k'_{z2}[Cl^-]^2[R_3NHCl]^z_{org}. \quad (14)$$

In order to deduce values of the stoichiometric coefficient z, the functions $\log D = f(\log [R_3NHCl]_{org})$ have been obtained using the aggregation constants for TLAHCl, TOAHCl and THAHCl given in Refs 13, 15 and 16, respectively. The contribution of the lead species to the mass balance equations for the ammonium salts has been

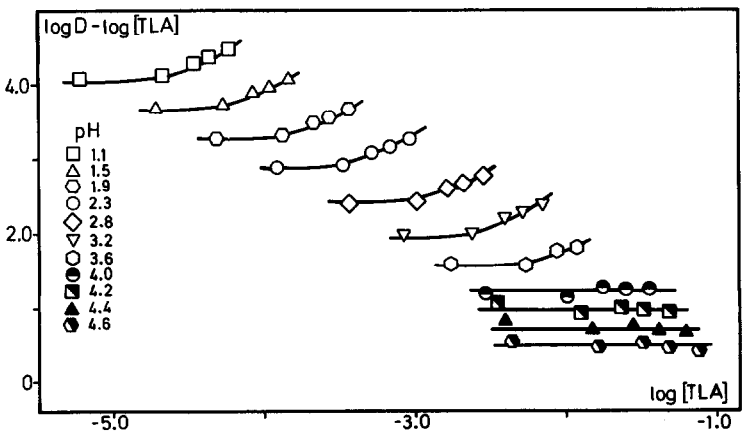

Fig. 2. Comparison between the experimental functions $\log D - \log[TLA] = f(\log [TLA])$ and the theoretical $\log Y = \log(1 + X^2) = f(\log X)$ in the best-fit position.

Table 1. Values of the conditional extraction constants obtained by the graphical and numerical data treatments

	TLA		TLAHCl	
	Log β'_{113}	Log β'_{335}	Log k'_{12}	Log k'_{32}
Graphical	5.15	16.15	1.49	4.91
LETAGROP	5.19±0.03	16.11±0.07	1.54±0.03	4.82±0.10
	TOAHCl		THAHCl	
	Log k'_{12}	Log k'_{32}	Log k'_{12}	Log k'_{32}
Graphical	1.55	5.23	1.50	5.36

considered as negligible since lead is present in tracer amounts. The plots are presented in Fig. 5. It can be appreciated that similar curves, with a lower limiting slope value close to 1.0 and higher ones when increasing the concentration of the extractants, are obtained for the three systems studied. Therefore, assuming the formation in the organic phase of two metallic species with $z = 1$ and $z = z$, eqn (14) can be transformed into:

$$Dk'_{12}[Cl^-]^2[R_3NHCl]_{org}^{-1} = 1 + k'_{z2}(k'_{12})^{-1}[R_3NHCl]_{org}^{z-1}. \quad (15)$$

In a similar way to the treatment carried out with the results of the Pb(II)–TLA system, the experimental functions $(\log D - \log [R_3NHCl]_{org}) =$

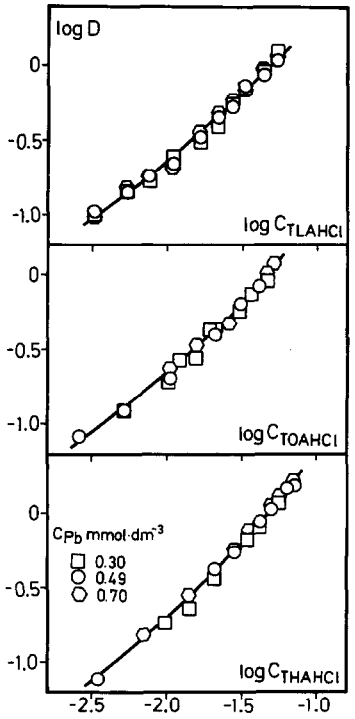

Fig. 4. Plot of log D vs log C_{R_3NHCl} data at different total Pb(II) concentrations. Continuous lines have been drawn using the proposed extraction constants.

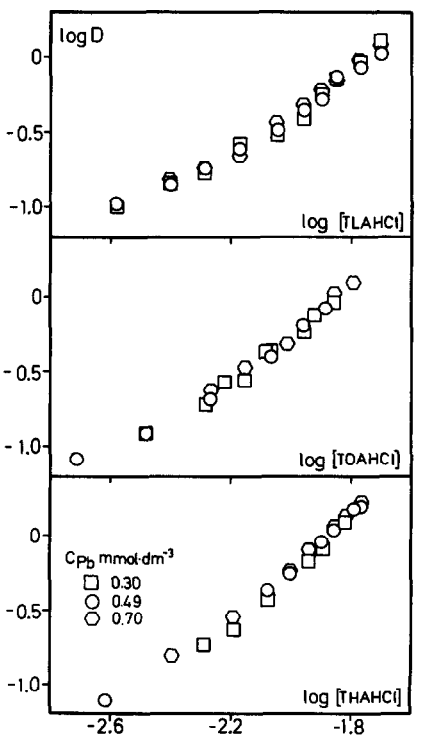

Fig. 5. Log D as a function of the free ammonium salts concentrations at the different Pb(II) concentrations.

$f(\log[R_3NHCl]_{org})$ were compared with the theoretical curves defined by eqn (7), with:

$$Y = Dk'_{12}[Cl^-]^2[R_3NHCl]_{org}^{-1}, \quad (16)$$

$$X = (k'_{z2}/k'_{12})^{1/(z-1)}[R_3NHCl]_{org}, \quad (17)$$

$$i = z^{-1}. \quad (18)$$

The best fit in the three systems was obtained from $i = 2$, as shown in Fig. 6 where the theoretical curves have been drawn with $i = 2$, indicating $z = 3$. From the differences on both axes, values of the conditional constants for the extraction of the species $(R_3NHCl)(PbCl_2)$ and $(R_3NHCl)_3(PbCl_2)$ collected in Table 1 were deduced.

Numerical treatment

The version DISTR[17] of the general minimizing program LETAGROP for the treatment of distribution data was used for the refinement of the graphically obtained equilibrium constants. The function to be minimized is the error squares sum, U, defined by:

$$U = \sum_{N_p} (\log D_{calc} - \log D_{exp})^2, \quad (19)$$

with D_{exp} being the experimentally measured distribution coefficient, D_{calc} the corresponding quantity calculated by the program and N_p the number

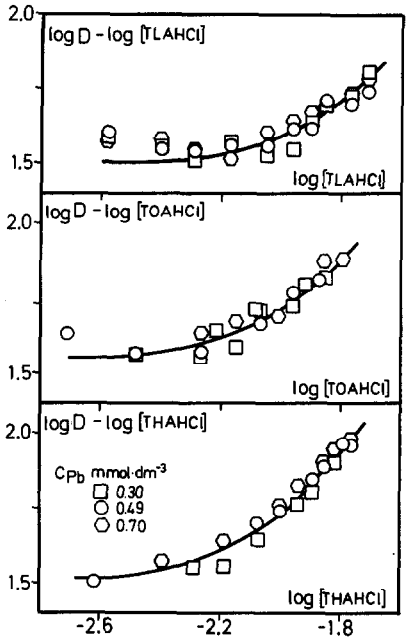

Fig. 6. Comparison between the experimental functions $\log D - \log[R_3NHCl] = f(\log[R_3NHCl])$ and the theoretical $\log Y = \log(1+X^2) = f(\log X)$ in the best-fit positions.

of experimental points. Together with the U_{min} values, the standard deviation $\sigma(\log D)$ is also given for each set of complexes.

From Table 2 it can seen that the graphically obtained model gives the lowest values for U_{min} and $\sigma(\log D)$ for the three systems studied. Models containing more than two metallic extracted species did not improve the fit to the experimental data. The conditional equilibrium constants obtained by numerical treatment are given in Table 1. With the proposed extraction constant values the theoretical $\log D = f(\mathrm{pH})_{C_{TLA}}$ and $\log D = f(\log C_{R_3NHCl})_{C_{pB}}$ functions have been plotted together with the experimental points in Figs 1 and 4, respectively.

Conclusions

The extraction of Pb(II) from chloride medium by TLA and TLAHCl dissolved in benzene can be explained by the formation of $(TLAHCl)(PbCl_2)$ and $(TLAHCl)_3(PbCl_2)$. Taking into account the values of the conditional extraction constants collected in Table 1 for the extraction of Pb(II) by TLA and TLAHCl, the value of the equilibrium extraction constant β_{11} for the reaction:

$$TLA_{org} + H^+ + Cl^- \overset{\beta_{11}}{\rightleftharpoons} TLAHCl_{org} \quad (20)$$

can be obtained combining the reactions:

$$Pb^{2+} + 3Cl^- + TLA_{org} + H^+ \rightleftharpoons (TLAHCl)(PbCl_2)_{org}, \quad (21)$$

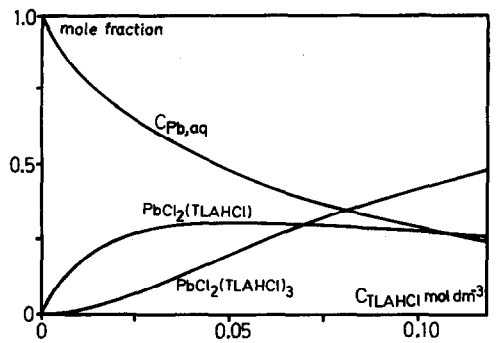

Fig. 7. Distribution diagram of Pb(II) species in the system Pb(II)–Cl^-/TLAHCl–benzene at pH = 2.00.

$$Pb^{2+} + 2Cl^- + TLAHCl_{org} \rightleftharpoons (TLAHCl)(PbCl_2)_{org}, \quad (22)$$

and

$$Pb^{2+} + 5Cl^- + 3TLA_{org} + H^+ \rightleftharpoons (TLAHCl)_3(PbCl_2)_{org}, \quad (23)$$

$$Pb^{2+} + 2Cl^- + 3TLAHCl_{org} \rightleftharpoons (TLAHCl)_3(PbCl_2)_{org}. \quad (24)$$

The values of $\log\beta_{11} = 3.65$ and $\log\beta_{11} = 3.76$ obtained in this way agree acceptably with that obtained by two phase titrations, $\log\beta_{11} = 3.78 \pm 0.06$.[13] This supports the validity of the model proposed.

The same model applies to TOAHCl and THAHCl. This supports the hypothesis that the length of the alkyl chain does not influence the composition of the metal species formed. Similar conclusions were drawn by Aguilar[18] in the extraction of Zn(II) by the three amines.

As an example of the predominance of the metallic species in the systems studied, Fig. 7 shows the distribution diagram of Pb(II) as a function of C_{TLAHCl}. It can be appreciated that $(TLAHCl)(PbCl_2)$ is predominant at low values of the reagent concentration whereas when increasing this concentration the metallic ion is mainly extracted as $(TLAHCl)_3(PbCl_2)$.

^1H AND ^{13}C NMR SPECTRA OF Pd(II) AND Pt(II) AMINOPOLYCARBOXYLATES

M. G. BASALLOTE, R. VILAPLANA and F. GONZÁLEZ-VÍLCHEZ*

Departamento de Química Inorgánica, Facultad de Ciencias de Cádiz, Apartado 40, Puerto Real (Cádiz), Spain

(*Received* 5 *February* 1986; *accepted after revision* 12 *August* 1986)

Abstract—^1H and ^{13}C NMR spectra of palladium and platinum aminopolycarboxylate complexes have been studied. The spectra of $[M(Y\text{-}H_4)Cl_2]$, $[M(Y\text{-}H_2)]$ and $(Y\text{-}H_6)[MCl_4]$ compounds (M = Pd or Pt; Y = EDTA, PDTA or CDTA) dissolved in DMSO-d_6 are discussed. Proton spectra are less complicated than those recorded in D_2O solution because of faster nitrogen inversion. Carbon spectra clearly demonstrate bidentate and tetradentate behaviour of these ligands.

Palladium and platinum complexes of aminopolycarboxylates have been extensively studied in recent years.[1–6] Most of these complexes can be classified into two types: dichlorocomplexes with bidentate aminopolycarboxylate and complexes where the ligand acts as tetradentate (Fig. 1). IR spectroscopy is very useful for distinguishing both types of compounds. Thus, dichlorocomplexes show a single band at *ca* 1700 cm^{-1}, which corresponds to $\nu_{C=O}$(COOH), whereas complexes with tetradentate aminopolycarboxylates show two bands at *ca* 1700 and 1600 cm^{-1}, the first one corresponding to the stretching of carbonyls in COOH groups and the second one to those in carboxylate groups.[7]

Although IR spectra of D_2O solutions of these compounds can be obtained,[8–10] they are very complicated and a complete assignment is not possible because of many overlapping bands. For this reason, it is impossible in many cases to determine if the spectrum corresponds to a single compound or to a mixture. In this sense, NMR spectroscopy provides an easily available technique that can be advantageously used for studying the nature of complexes in solution. Proton spectra have been used so far for this purpose.[11–14] D_2O has been commonly used as solvent, with AB patterns being frequently observed for CH_2(ac) protons (Fig. 1). The actual pattern of these signals for an octahedral complex depends on the rates of inversion of the nitrogen atoms and on the labilities of metal–nitrogen and metal–oxygen bonds. Intramolecular scrambling processes also affect the pattern of CH_2(ac) signals.[11,12,15,16] This results in extremely complicated spectra, specially for complexes of asymmetric aminopolycarboxylates.[12,17,18] Moreover, new complications appear due to acid- and base-catalyzed deuteration processes, that occur with different rates for the several types of CH_2(ac) protons.[17–20] In square-planar complexes, intramolecular scrambling processes are less complicated, but inversion of nitrogen atoms may be slow on the NMR time scale, giving rise to AB patterns. Other authors[21,22] have observed complicated spectra with overlapping quartets for Pd–EDTA and Pt–EDTA complexes in D_2O because of the existence of more than one complex in solution.

^{13}C NMR spectra have been less used for studying the nature of aminopolycarboxylate complexes.[23–25] However, when they are recorded with proton decoupling, they are less complicated than proton spectra and may be used for obtaining complementary information.

In this paper, we report ^1H and ^{13}C NMR spectra of DMSO-d_6 solutions of Pd(II) and Pt(I) complexes with EDTA, PDTA and CDTA. These compounds illustrate both bidentate and tetradentate behaviour of aminopolycarboxylates. $(Y\text{-}H_6)[MCl_4]$ salts have been also obtained and included in the study.

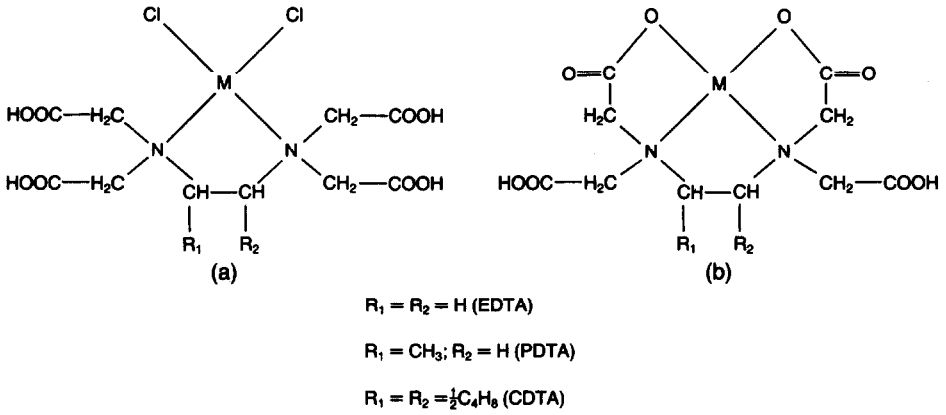

Fig. 1. Aminopolycarboxylate complexes of Pd(II) and Pt(II): (a) dichloro complexes, and (b) complexes with tetradentate aminopolycarboxylate.

EXPERIMENTAL

All compounds were synthesized as described in another paper.[26] Samples for obtaining NMR spectra were prepared by dissolving 50–100 mg of compound in 0.5 cm^3 of DMSO-d_6. Solutions were placed in 5-mm tubes and TMS was added as internal reference.

NMR spectra were recorded at the probe temperature (40°C) with a Varian FT-80A spectrometer.

RESULTS AND DISCUSSION

EDTA complexes

The shifts of the signals in the ^1H and ^{13}C spectra of EDTA complexes are shown in Table 1. Proton spectra of (EDTA-H_6)[$PtCl_4$] and [Pd(EDTA-H_4)Cl_2]·$5H_2O$ are similar to that of free EDTA except for the displacement to lower field of both signals. However, in the spectrum of [Pt(EDTA-H_4)Cl_2]·$5H_2O$ a quartet appears for CH_2(ac) pro-

Table 1. NMR spectra of EDTA complexes (all chemical shifts are reported in ppm and referenced to TMS)[ab]

[b] AB quartet with $\delta_A - \delta_B = 0.49$ ppm and $J_{AB} = 17.7$ Hz.

tons, in a similar way to that observed for palladium complexes in D_2O solution.[21] Thus, interchange of metal–nitrogen bonds is slower for the platinum complex than for its palladium analogue. The absence of AB splitting in the spectrum of (EDTA-H_6)[$PtCl_4$] shows that protonation of nitrogen atoms does not cause inversion of these atoms to be slow on the NMR time scale.

Carbon spectra of these compounds also show two signals for CH_2(ac) groups, with one more for the carbons of free carboxylic groups. All of these signals are little displaced from their positions in free EDTA. There is a single exception, which corresponds to both types of CH_2 in the spectrum of [Pt(EDTA-H_4)Cl_2]·$5H_2O$. These signals are displaced more than 3 ppm to lower field with respect to the other compounds. This behaviour also resembles that of analogous complexes in D_2O solution.[23–25]

Tetradentate coordination of EDTA results in more complicated spectra. From symmetry considerations, two AB quartets and one A_2B_2 multiplet must appear for CH_2(ac) and CH_2(en) protons, respectively. However, the proton spectrum of [Pd(EDTA-H_2)]·$5H_2O$ shows two singlets for every type of CH_2 groups. In the case of CH_2(en), both signals appear near their positions in the spectra of dichlorocomplexes, and they must correspond to a degenerate A_2B_2 pattern. In the case of CH_2(ac), both singlets result from collapse of AB quartets, and one of them is displaced to lower field because of palladium–carboxylate coordination. This collapse of AB patterns has been previously observed by many workers for several aminopolycarboxylate complexes.[19–21,27,28] The carbon spectrum shows two signals for both carbonyl and methylene carbons of acetate groups, and one more for CH_2(en). This spectrum is also consistent with tetradentate coordination of EDTA and it suggests that there is not interconversion between coordinated and free acetate arms.

PDTA complexes

Proton spectrum of PDTA in D_2O shows two AB quartets for CH_2(ac) [Fig. 2(a)]. This pattern is due to the asymmetry caused by the methyl group and to the slow inversion of nitrogen atoms.[11–14] However, when the spectrum is recorded in DMSO-d_6 solution, two singlets at 3.50 and 3.43 ppm are observed for these protons [Fig. 2(b)]. So, it is concluded that inversion is faster in DMSO-d_6 than in D_2O, what results in simpler spectra. In palladium and platinum complexes (Table 2), these signals are displaced to lower field, as in the case of the EDTA analogue complexes. A displacement is also observed for the doublets of CH_2(en) and CH_3, although no significant changes of the coupling constants are detected. The spectra of [Pt(PDTA-H_4)Cl_2]·$2H_2O$ is similar to that of the analogous EDTA complex with AB quartets appearing for CH_2(ac) protons.

The methyl group appears at 12.93 ppm in the carbon spectrum of free PDTA and it causes the splitting of the CH_2(ac) and COOH signals (Table 2). It is interesting to note that [Pt(PDTA-H_4)Cl_2]·$2H_2O$ does not show a behaviour similar to the EDTA dichlorocomplex, i.e. the signals of

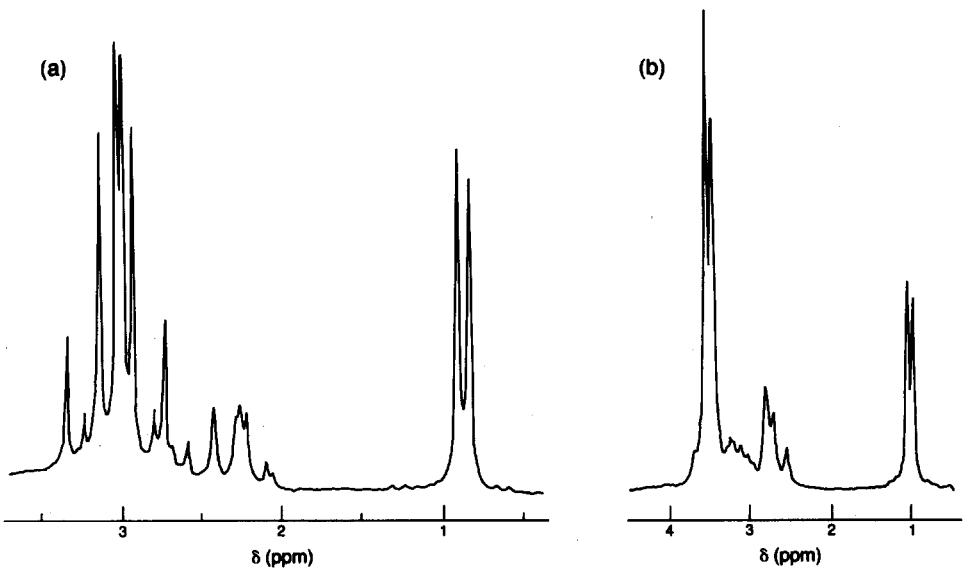

Fig. 2. ^1H NMR spectrum of PDTA: (a) D_2O solution, and (b) DMSO-d_6 solution.

[a] CH proton gives a multiplet superimposed to other signals.
[b] Coupling constants values (Hz) included in parentheses.
[c] Corresponds to the most intense of signals appearing between 3.50 and 4.76 ppm.

CH_2(ac) are only slightly displaced. The spectra of complexes with tetradentate PDTA are even more complicated and difficult to interpret. In the case of [Pd(PDTA-H_2)]·$4H_2O$, a mixture of complexes seems to be formed in DMSO-d_6 solution. Moreover, the spectra of [Pt(PDTA-H_2)]·$3H_2O$ change with time and they are practically coincident with those of free PDTA when the equilibrium state is attached (2 days after preparation of the sample). These results can be interpreted in terms of partial or total substitution of PDTA by DMSO, and it indicates that caution must be taken when interpreting spectra of similar compounds. It is, however, surprising that this reaction only occurs for complexes with tetradentate PDTA and not for dichlorocomplexes.

CDTA complexes

Dichlorocomplexes of Pd(II) and Pt(II) with CDTA could not be isolated in the solid state, although they are formed in aqueous solution.[26]

Table 3. NMR spectra of CDTA complexes (all chemical shifts are reported in ppm and referenced to TMS)

Compound	(a) ^{1}H spectra CH_2(ac)	CH(en)	$CH_2(\beta)_{ec}$	$CH_2(\gamma)_{ec}$	$CH_2(\beta, \gamma)_{ax}$

[Pd(CDTA-H_2)]·H_2O	64.81, 59.19	78.47	26.59	24.01	178.83, 176.35
	58.83, 55.92	70.38	25.74	23.65	168.31, 167.84

$(CDTA\text{-}H_6)[MCl_4]$ salts (M = Pd or Pt) give NMR spectra similar to free CDTA (Table 3). It is important to note that AB patterns are not observed in the proton spectra because of fast inversion of nitrogen atoms. The singlet of CH_2(ac) protons is displaced from 3.53 ppm in CDTA to 3.75 and 3.80 ppm in the salts.

The signals of protons in the cyclohexane ring are very broad because of multiple couplings between many types of symmetrically different atoms. The assignment included in Table 3 has been performed by integration of the signals and comparing their positions with literature data.[29,30] This part of the spectrum is similar to that of CDTA in D_2O except for the appearance of a single signal for $CH_2(\beta)_{ax}$ and $CH_2(\gamma)_{ax}$.

Carbon spectra of CDTA and $(CDTA\text{-}H_6)[MCl_4]$ salts are also very similar, with a single signal for COOH, CH_2(ac) and CH(en). The CH(en) signal appears at lower field than in EDTA and PDTA, showing that substitution in the ethylenediamine backbone leads to a displacement of the signal to higher δ values. The signals of carbon atoms in β- and γ-positions of cyclohexane ring are easily recognized in the spectra.

The spectra of $[Pd(CDTA\text{-}H_2)]\cdot H_2O$ are much more complicated. Coordination of carboxylate groups results again in the nonequivalence of atoms. The assignment of signals in the proton spectrum is difficult because it consists of a mountain of broad resonances. Despite its complexity, the carbon spectrum reveals clearly the tetradentate character of the ligand, with a signal appearing for every carbon atom. Coordinated carboxylate carbons appear at 178.83 and 176.35 ppm, and free carboxylic carbons at 168.31 and 167.84 ppm. The assignment of CH_2(ac) and CH(en) resonances has been performed with the aid of the APT spectrum.

The use of DMSO-d_6 as solvent for obtaining NMR spectra of aminopolycarboxylates results in higher rates of nitrogen inversion, what causes CH_2(ac) protons to appear as singlets in proton spectra. This is clearly seen in the spectra of free PDTA and CDTA, where singlets appear for those protons, in contrast to the spectra recorded in D_2O solutions, where AB patterns are observed. Protonation of nitrogen atoms does not cause important differences in the rate of nitrogen inversion, as shown by the maintenance of the singlets in the spectra of $(PDTA\text{-}H_6)[PtCl_4]$ and $(CDTA\text{-}H_6)[MCl_4]$ salts. When aminopolycarboxylates coordinate to Pd(II) ion, fast exchange of Pd—N bonds also results in the appearance of singlets for acetate protons. However, the spectra of platinum dichlorocomplexes show AB quartets for these protons because of slow interchange of Pt—N bonds. In any case, proton spectra recorded in DMSO-d_6 solutions are easier to interpret than those obtained in D_2O.

An interesting observation is that either protonation of nitrogen atoms or coordination to a metal ion in a bidentate way results in similar displacements to lower field of the signals of CH_2(ac) and CH_2(en), as shown in Table 4. This result may be important for characterization of analogous complexes.

When carboxylate groups are also coordinated, a further displacement of the signal of coordinated acetate CH_2 is observed, although those of CH_2(en) and uncoordinated acetate CH_2 are still equally displaced. However, carboxylate coordination causes complicated proton spectra due to the nonequivalence of different types of CH_2(ac) and CH_2(en) groups. In this sense, ^{13}C NMR spectroscopy can be more useful for studying coordination of aminopolycarboxylates to d^8 ions. The spectra of free ligands are very simple, with one signal for every type of different carbon atoms. Substitution results in a displacement to higher δ values of the resonances of carbon atoms in the ethylenediamine backbone of the molecule.

When these ligands are protonated or coordinated to a metal ion in a bidentate way, the appearance of the spectra is maintained, with small displacements of the signals. However, for those complexes where exchange of metal–nitrogen bonds is slow, an important displacement of CH_2(ac) signal to higher δ values is observed. The same effect is observed when the ligand is linked in a tetradentate way. In this latter case, more resonances appear in the spectra because of the nonequivalence of coordinated and uncoordinated acetate arms.

Another interesting observation is the absence of ^{195}Pt–^1H or ^{195}Pt–^{13}C coupling (^{195}Pt: $I = 1/2$, 34% abundance) in the spectra of the platinum chlorocomplexes. In these cases, the rate of Pt–N

[a] Considering the center of the quartet.
[b] Considering the media of both signals.

interchange is slow and so, the absence of ^{195}Pt side bands can not be explained in terms of a rapid interchange causing the ^{195}Pt nucleus to loose its magnetic character. There are some previous reports of platinum complexes where the absence of ^{195}Pt side bands can not be related to ligand exchange, and the results have been interpreted as a consequence of a dominant chemical shift anisotropy relaxation mechanism.[31,32] The absence of ^{195}Pt side bands can not be used as an evidence of lack of metal coordination because of the AB patterns and of the magnitude of the displacements observed for those complexes where Pt–N interchange is slow.

Although the species studied in this paper have been previously characterized in solid state,[1–6,26,33] some doubt can appear about their nature in solution because of the simplicity of the spectra. This result differs greatly from those previously reported for Pd–EDTA and Pt–EDTA systems in D_2O solution.[21,22] In both cases complicated spectra reveal the existence of several species in solution and so spectra obtained in D_2O can not be used for characterization purposes. In the case of DMSO-d_6 solutions, spectra are more simple with a number of signals equivalent to the expected for the proposed structures from symmetry considerations. Reaction of platinum complexes with DMSO must be ruled out except in the case of $[Pt(PDTA\text{-}H_2)]\cdot 3H_2O$, where the equilibrium spectra are identical to those of free PDTA. In the other cases there is a displacement of the signals from their positions in the spectra of free ligand. These displacements are consequence of protonation or metal coordination, as revealed by the spectra of complexes with tetradentate aminopolycarboxylates, where the displacements of the signals of uncoordinated acetate arms are similar to those observed for bidentate complexes.

POTASSIUM-39 NUCLEAR MAGNETIC RESONANCE STUDY OF THE COMPLEXATION OF POTASSIUM THIOCYANATE BY DIBENZO-30-CROWN-10 IN NITROMETHANE

HARALD D. H. STÖVER, MARC ROBILLARD and CHRISTIAN DETELLIER*

Ottawa-Carleton Chemistry Institute, University of Ottawa Campus, Ottawa(Ont.) K1N 9B4, Canada

(*Received* 25 *April* 1986; *accepted* 15 *August* 1986)

Abstract—A 2:1 potassium:dibenzo-30-crown-10 complex is formed in nitromethane solution. Taking into account the ion-pairing equilibrium of KSCN in that solvent, an equilibrium constant for the 2:1 complex formation ($K_{2c} = 52 \pm 5$) has been calculated. The characteristic K-39 relaxation rate and chemical shift of the 2:1 complex are compatible with an open structure of the crown, in which the two potassium cations are exposed to the solvent molecules and the thiocyanate counteranion.

Large crown ethers are known to wrap around alkali metal cations in both solid state and solution. The wrapping of dibenzo-30-crown-10 (DB30C10) around the potassium cation has been shown by the X-ray crystal structures of the potassium iodide DB30C10[1] and of the potassium thiocyanate DB30C10 complexes.[2] The main difference between the X-ray structures of the uncomplexed and the potassium complexed DB30C10 consists in the conversion of four anti C–O conformations of the uncomplexed crown into four gauche C–O conformations in the complex.[1]

In solution, evidence has been given by H-1 and C-13 NMR that the K^+–DB30C10 complex has the same configuration as in the crystal, with complete desolvation of the cation upon complexation.[3,4] The Na^+–DB30Cl0 complex displays a different configuration[3] and complexes with other stoichiometries (2:1 and 3:2) are formed as well.[4,5] Dibenzo-24-crown-8 (DB24C8) wraps around the sodium cation, expelling the solvent molecules from the first solvation shell.[6] With tetraphenylborate as the counteranion, $(n+1)$: n Na^+: DB24C8 aggregates are formed to a small extent.[7,8] Wrapping of ligands around the alkali metal cations is also observed in the case of acyclic polyethers.[9,10]

K-39 is a quadrupolar nucleus ($I = 3/2$) whose receptivity is only 2.69 compared to C-13. This explains why potassium has been much less used than sodium for direct metal cation NMR studies.[11] Shih and Popov have published a K-39 NMR study of potassium salts in non-aqueous solvents.[12] Kinetics studies of the complexation of the potassium cation with dibenzo-18-crown-6[13] and 18-crown-6[14] have been carried out in various solvents. Neurohr *et al.*[15] studied the complexation of K^+ with several ionophores using K-39 NMR and the K^- anion has been observed both in solution and in crystalline potassides.[16,17]

We report here a K-39 NMR study of the complexation of K^+ by DB30C10 in nitromethane. We show that a 2:1 K^+:DB30C10 complex coexists with the 1:1 complex in nitromethane solutions. Taking into account the ion-pairing equilibrium of KSCN in that solvent, we calculate an equilibrium constant for the 2:1 complex formation and the characteristic values of the relaxation rate and chemical shift of the 2:1 complex.

EXPERIMENTAL

After recrystallization from ethylacetate, dibenzo-30-crown-10 (Parish Chem.) was vacuum-dried at 60°C for several hours. Potassium thiocyanate (Aldrich, 98%+) was dried under vacuum at 60°C for at least three hours prior to use. Nitromethane

* Author to whom correspondence should be addressed.

(Baker) was dried under reflux over calcium hydride, fractionally distilled, and stored over 4 Å molecular sieves, under argon.

Measurements of K-39 chemical shifts and bandwidths at half-height were made at 21°C on a Varian XL-300 NMR spectrometer operating at 13.997 MHz. The K-39 chemical shifts are expressed relative to 0.1 M KCl in H_2O (10% D_2O v/v). Bandwidths at half-height were measured graphically. We checked that all the bands obtained had a Lorentzian shape. A line broadening of up to 5 Hz was used. The 90° pulse length was 90 μs. The transverse relaxation rates were derived from the linewidths. The longitudinal relaxation times were measured using a 180°–τ–90° pulse sequence, and T_1 was calculated using a three-parameters non-linear regression.

Procedures for the non-linear regression analysis of the chemical shifts and of the linewidths data were described previously.[5,7]

RESULTS

Figure 1 shows the K-39 NMR chemical shifts of KSCN solution in nitromethane as a function of ρ, the ratio [DB30C10]/[KSCN]. Contrary to what we have observed in other non-aqueous solvents (pyridine, acetone, acetonitrile),[18] the chemical shift variation in the range $0 < \rho < 1$ is not linear, which indicates either the step-wise formation of two or more complexes[5,7] or ionic association, or a combination of both. The observed curvature depends upon the total concentration of potassium thiocyanate, being more pronounced at higher concentrations. For $\rho \geqslant 1.0$, the chemical shift values are constant ($\delta = 13.0$ ppm), regardless of the total KSCN concentration. This is indicative of the formation of a stable 1:1 K^+:DB30C10 complex ($\log K_c > 5$).[4] The "wrapped around" structure is confirmed by the similarity of the observed K-39 chemical shifts of the 1:1 complex in various non-aqueous solvents.[18]

In order to test for the influence of ion pairing phenomena upon the observed chemical shift variation, we have carried out a concentration study. Figure 2 shows the K-39 chemical shift dependence upon the KSCN concentration (10^{-3} M to 7×10^{-2} M) in nitromethane. The observed curvature can be accounted for by a simple ion-pairing model [eqn (1)],

$$(K^+)_s + (SCN^-)_s \overset{K_p}{\rightleftharpoons} (K, SCN)_s \qquad (1)$$

where $(K^+)_s$ and $(SCN^-)_s$ stand for the solvated potassium cation and the solvated thiocyanate anion respectively. $(K, SCN)_s$ refers to an ion pair. Equation (1) leads to eqns 2 and 3 describing the observed

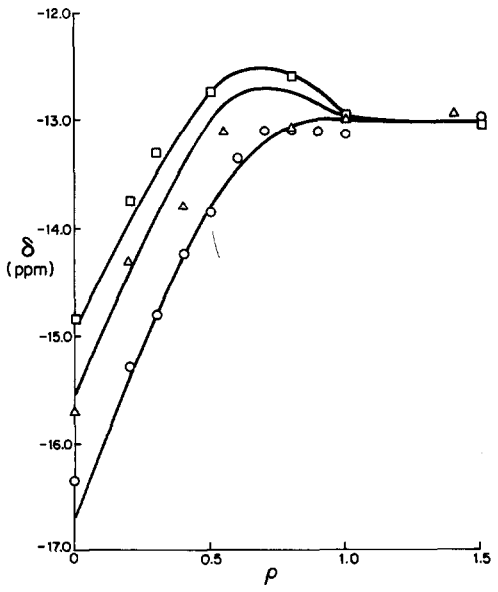

Fig. 1. K-39 chemical shifts as a function of the ratio [DB30C10]/[KSCN] for different total KSCN concentrations. ○: [KSCN] = 0.025 M; △: [KSCN] = 0.050 M; □: [KSCN] = 0.070 M. The data points are experimental and the curves were calculated following the results of the regression analysis displayed in Table 1.

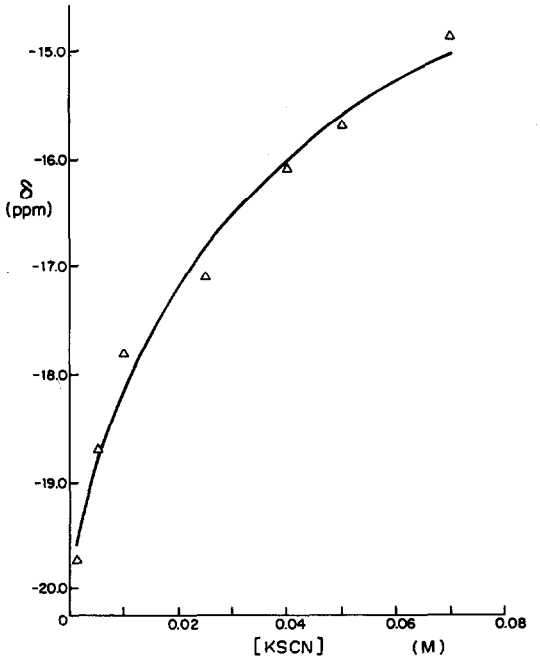

Fig. 2. K-39 chemical shifts as a function of the total KSCN concentration in nitromethane. The data points are experimental and the curve was calculated from the results of the non-linear regression analysis on eqns (2) and (3). $K_p = 24$; $\delta_P = -9.7$ ppm and $\delta_F = -19.8$ ppm; RMS of the fit is equal to 0.3 ppm.

chemical shift as a function of the KSCN concentration,

$$\frac{\delta_{obs}-\delta_P}{\delta_F-\delta_P}=\frac{[(K^+)_s]}{[KSCN]_T} \qquad (2)$$

where δ_{obs}, δ_F and δ_P are, respectively, the observed K-39 chemical shift and the characteristic chemical shifts for the solvated and ion-paired potassium cation. $[(K^+)_s]$ is a function of the ion-pairing equilibrium constant K_p and of the total KSCN concentration, $[KSCN]_T$. This is shown in eqn (3).

$$K_P=\frac{[KSCN]_T-[(K^+)_s]}{[(K^+)_s]^2}. \qquad (3)$$

In Fig. 2, the data points are experimental and the curve is calculated following the results obtained from a non-linear regression analysis on the three parameters, δ_P, δ_F and K_P from eqns (2) and (3).

Figure 3 shows the K-39 linewidths dependence upon the KSCN concentration. The data points are experimental and the curve is calculated following a two-parameters $[(\nu_{1/2})_F$ and $(\nu_{1/2})_P]$ non-linear regression analysis. The agreement between the two sets of independent measurements is good, and this militates in favour of the simple model of ion-pairing [eqn (1)]. In Fig. 1, the data points are experimental and the curves have been calculated following the eqns (1), (4) and (5) and the results given in Table 1.

$$(K^+)_s+(C)_s \overset{K_c}{\rightleftharpoons} (K^+,C)_s \qquad (4)$$

$$(K^+)_s+(K^+,C)_s \overset{K_{2c}}{\rightleftharpoons} (K^+,C,K^+)_s. \qquad (5)$$

$(C)_s$, $(K^+,C)_s$ and $(K^+,C,K^+)_s$ stand for the solvated crown, the solvated 1 : 1 K^+ : DB30C10 complex and the solvated 2 : 1 K^+ : DB30C10 complex, respectively. A two-parameters non-linear regression has been carried out simultaneously on the three curves of Fig. 1, corresponding to different

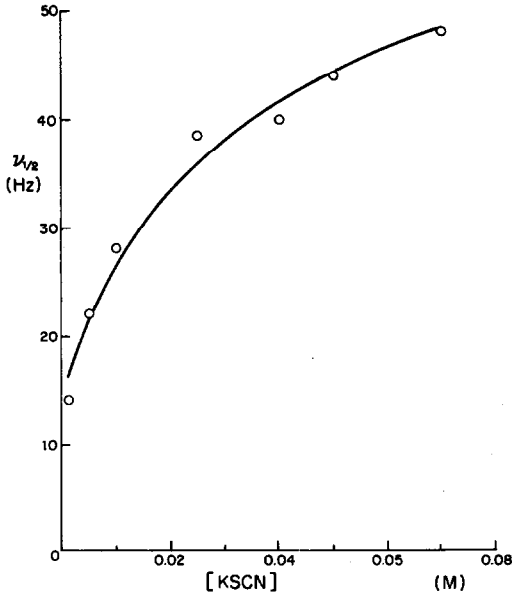

Fig. 3. K-39 linewidths of half-height as a function of the total KSCN concentration in nitromethane. The data points are experimental and the curve was calculated from the results of the non-linear regression analysis on eqns (2) and (3) applied to the linewidths. $(\nu_{1/2})_F = 14$ Hz; $(\nu_{1/2})_P = 87$ Hz. The RMS on the regression was 2.5 Hz.

total potassium concentrations. The two parameters were K_{2c} [eqn (5)] and δ_{2c}, the chemical shift of the 2 : 1 complex. The value of K_c [eqn (4)] in the regression analysis was taken as 10^6, since the equilibrium constant formation of the 1 : 1 complex has been shown to be greater than 10^5 in nitromethane.[4] Moreover, we have checked that values of K_c taken greater than 10^4 do not modify the results of the regression analysis.[5] The observed curvature could not be accounted for by consideration of eqns (1) and (4) only, that is to say that if the complexation of the potassium cation by

the crown leads to an increase in the ion pairing of the uncomplexed potassium cation [eqn (1)] this effect does not account for the observed curvature. Typically, it accounts for half of it. We had to envisage another hypothesis: namely the 2:1 K^+:DB30C10 complex formation [eqn (5)]. There are precedents in the literature for such stoechiometries in the cases of large crown ethers complexing sodium or potassium cations in non-aqueous solutions.[4,5,7] The non-linear regression analysis gave the results of Table 1. K_P, δ_F and δ_P [eqn (1)] were carried over from the concentration study (Figs 2 and 3).

Figure 4 shows a similar trend in the K-39 linewidth variation as a function of ρ. The characteristic linewidth for the 1:1 complex is 71 Hz when the curve displays a maximum at 77 Hz for a ratio $\rho = 0.7$. The curve of Fig. 4 is calculated from the results of the regression which are given in Table 1. The agreement between the chemical shifts data and the relaxation rates data is again very good, specially if one considers that the regressions of Figs 1 and 4 did not involve more than two fitting parameters: δ_{2c} and K_{2c} in the case of the chemical shifts data, $T_{2,2c}^{-1}$ and K_{2c} in the case of the linewidths data. The agreement between the two independent determinations of K_{2c} is indeed excellent: 54 ± 3 from the linewidths data and 50 ± 5 from the chemical shifts data.

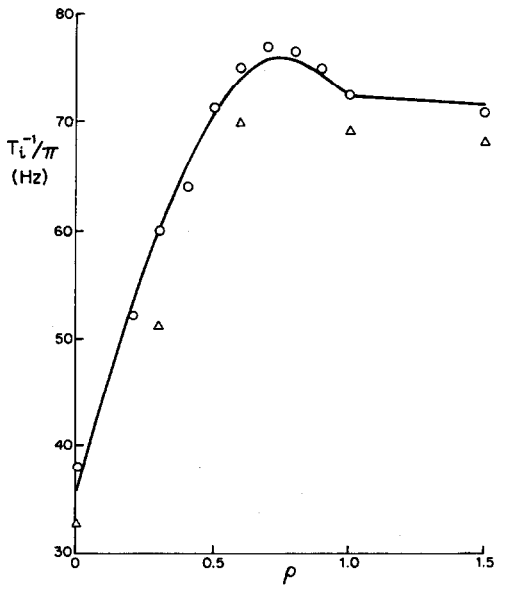

Fig. 4. K-39 transverse and longitudinal relaxation rates as a function of the ratio [DB30C10]/[KSCN] for [KSCN] = 0.025 M. ○: transverse relaxation data ($i = 2$); △: longitudinal relaxation data ($i = 1$). The data points are experimental and the curve was calculated following the values from Table 1.

We have checked that there was no exchange broadening contribution to the linewidth. The variation of the longitudinal relaxation rate as a function of ρ parallels the transverse relaxation rate (Fig. 4). The difference between the two relaxation rates was in the order of magnitude of the expected inhomogeneity contribution to the linewidth.

DISCUSSION

We can account for the KSCN concentration dependence of the chemical shifts and linewidths on the basis of a simple model involving only two thermodynamically stable species: the solvated cation and a solvated ion pair. The observation that the chemical shifts and the linewidths are linearly related is a strong support for this model (combining data of Figs 2 and 3 affords the equation: $\delta = 0.14\nu_{1/2} - 21.7$, with a correlation coefficient of 0.981 on seven data points). The same type of linear relationship was found for ^{23}NaSCN and ^{23}NaI in nitromethane.[19] Maynard *et al.*[20] have mentioned the formation of (K, SCN) ion pairs in dimethylformamide in the course of their kinetic study of the complexation of potassium with 18-crown-6, and KSCN has been shown to associate and dimerize in dioxolane.[21] A similar downfield shift of the K-39 resonance of KSCN in an other poorly coordinating solvent, acetonitrile, has been reported.[12]

The chemical shift of the 1:1 complex, −13.0 ppm, is independent of the nature of the solvent,[18] and is characteristic of an oxygen environment of the potassium cation. The chemical shift of K^+ is −10.5 ppm in acetone and −10 ppm in methanol.[12] The chemical shift of the sandwiched K^+(15-crown-5)$_2$ in dimethylether with K^- as the associated counteranion falls in the same range (−9.9 ppm).[16] Similarly to what we have found previously for the Na-23 chemical shift of the 2:1 Na^+:DB24C8 complex,[5] the K-39 chemical shift of the potassium cation in the 2:1 K^+:DB30C10 complex is not comprised between the two values of the solvated K^+ (−19.8 ppm) and of the 1:1 complexed K^+ (−13.0 ppm). Neurohr *et al.* have reported K-39 chemical shift data for K^+-39 complexed by ionophores.[15] Referencing their values to the commonly accepted standard, K^+ in water, one obtains −24 ppm for the K^+–valinomycin complex where K^+ is embedded into a symmetrical cavity made of six carbonyl oxygens, a situation comparable to the symmetrical environment of the potassium cation in the K^+–DB30C10 complex.[18] The K^+–18C6 complex resonates at −3 ppm in methanol[14,15] or acetone.[14] This value, for a complexed K^+ exposed to the solvent, is in agreement with the one that we determine in the

case of the 2:1 K^+:DB30C10 (−10.5 ppm), since the value at higher field for the latter case is expected on the basis of the lower donicity number of nitromethane, compared to methanol or acetone. However, this chemical shift value does not rule out the possibility of a structure consisting of two ion pairs linked by the large crown ether, since the chemical shift of $(K, SCN)_s$ is −9.7 ppm in nitromethane (Table 1). We should probably envisage the characteristic data of the 2:1 complex given in Table 1 as the weighted average of the two limiting values resulting from the equilibria of eqn (6).

$$(K^+, C, K^+)_s \rightleftharpoons (SCN, K, C, K^+)_s \rightleftharpoons (SCN, K, C, K, SCN)_s. \quad (6)$$

The transverse relaxation rate of the 1:1 complex was found to be twice as large as the one of the 1:1 complex, reflecting the higher dissymetry of the potassium environment in the 2:1 complex. The quadrupolar coupling constant of K^+-39 in the 1:1 complex will be reported and discussed elsewhere.[18]

All our data are consistent with the presence of potassium thiocyanate ion pairs in nitromethane solutions, as well as with the formation of a 2:1 K^+:DB30C10 complex, in addition to the strongly favoured "wrapped around" 1:1 complex.

NONCOVALENT INTERACTIONS IN METAL COMPLEXES—XI.* SYNTHESIS AND STEREOSELECTIVITY OF 1:3 COBALT(III) COMPLEXES OF 1-*l*-MENTHYLOXY-3-ACYLACETONES

S. MAEDA, M. NAKAMURA, H. ŌKAWA† and S. KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812, Japan

(*Received* 17 *December* 1985; *accepted after revision* 15 *August* 1986)

Abstract—1 : 3 Cobalt(III) complexes of 1-*l*-menthyloxy-3-acylacetones [*l*-menthyl–O–CH_2–CO–CH_2–CO–R: R = C_2H_5(Et), *n*-C_3H_7 (*n*Pr), *i*-C_3H_7 (*i*Pr), *n*-C_4H_9 (*n*Bu), *i*-C_4H_9 (*i*Bu), *n*-C_5H_{11} (*n*Am), *i*-C_5H_{11} (*i*Am)] have been synthesized, and their stereochemistries were examined. CD and NMR spectra revealed that the complexes of R = Et and *i*Bu preferred the *fac*-Δ configuration while the complexes of R = *i*Pr and *i*Am the *fac*-Λ configuration. The complexes of R = *n*Pr, *n*Bu and *n*Am showed no significant CD at the first *d–d* band. The stereoselectivities of the complexes were discussed in comparison with those of tris(1-*l*-menthyloxy-3-benzoylacetonato)cobalt(III) and its homologs previously reported.

Stereoselectivities of tris(1,3-diketonato)M(III) complexes have been investigated using (+)-hydroxymethylenecamphor (+hmc)[2–4] and (+)-3-acetylcamphor (+atc).[4–6] Resolution of the diastereomers (*fac*-Δ, *fac*-Λ, *mer*-Δ, *mer*-Λ) was achieved for [Cr(+atc)$_3$][5] and [Co(+atc)$_3$],[5,6] and the isomer predominantly formed was shown to be *mer*-Λ. The ratio of the *mer*-Λ, however, is only 45–48% for [Co(+atc)$_3$] and 38% for [Cr(+atc)$_3$], indicating that the stereoselectivities of the complexes are relatively low. Single-crystal X-ray analysis for *mer*-Λ-[Cr(+atc)$_3$][7] suggests no appreciable interligand interaction within a molecule, and the factors governing stereoselectivity in [M(+atc)$_3$] and [M(+hmc)$_3$] are still obscure.

Recently, we have shown that tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III), [M(*l*-moba)$_3$] (M = Co, Cr, Mn, lanthanoid),[8,9] show a high stereoselectivity giving rise to the *fac*-Δ isomer. The stereoselectivity of these complexes can be attributed to intramolecular CH/π interaction[10] (bonding interaction) operating between the phenyl and *l*-menthyl groups (see Fig. 1), because the stereoselectivity is enhanced when (1) the size of the π system becomes larger[1] or (2) the π electron density of the ring is increased.[11] Based on 400 MHz ^{1}H-NMR spectra, tris{1-*l*-menthyloxy-3-(4-methylbenzoyl)acetonato}cobalt(III) [Co(*l*-moba-Me)$_3$] is revealed to be pure *fac*-Δ isomer.[12]

These facts prompted us to examine if intramolecular, interligand "hydrophobic" interaction between alkyl or alicyclic groups can also give rise to a stereoselectivity of tris(1,3-diketonato)M(III) complexes. For this purpose a series of 1-*l*-menthyloxy-3-acylacetones (*l*-menthyl–O–CH_2–CO–CH_2–CO–R) were prepared, whose abbreviations are given in Table 1. The 1 : 3 cobalt(III) complexes of these ligands were obtained, and their configurations were examined by means of CD and ^{1}H-NMR spectra and discussed in terms of intramolecular, interligand *l*-menthyl/alkyl interaction.

[b] Calculated value for mono-benzene adduct.

Our preliminary investigation on the complexes of 1-*l*-menthyloxy-3-acetylacetone[13] has suggested that the interligand *l*-menthyl/methyl interaction leads to a stereoselectivity distinctly differing from that in [M(*l*-moba)$_3$] and its homologs.

EXPERIMENTAL

Syntheses

H(*l*-mo-R). To a mixture of ethyl *l*-menthyloxyacetate (2×10^{-2} mole) and NaH (2×10^{-2} mole) in dry ether (50 cm^3) was added dropwise a solution of ketone (1×10^{-2} mole) in dry ether (20 cm^3) at 45°C in 30 min. The mixture was stirred for additional 2 h at this temperature. Unreacted NaH was decomposed by adding ethanol (30 cm^3), and the mixture was poured onto ice-water (100 cm^3) containing hydrochloric acid (5 cm^3). The upper ethereal layer was separated, and the aqueous layer was extracted with two 50 cm^3 portions of ether. The combined ethereal solution was shaken with saturated sodium bicarbonate solution and then with water. To this solution was added a solution of copper(II) acetate monohydrate (3 g) in aqueous ammonia (15%, 50 cm^3), and the mixture was vigorously stirred to give blue mass of the copper(II) complex. It was collected and recrystallized from a chloroform–methanol mixture. The yield was 40–50%.

The copper complex was dissolved in ether (100 cm^3), and the solution was vigorously shaken with 20% sulfuric acid (100 cm^3). The ether layer was separated, washed with a saturated sodium bicarbonate solution and then with water, and dried over anhydrous sodium sulfate. Evaporation of the solvent left H(*l*-mo-R) as a pale yellow, oily substance. The yield based on the copper complex was *ca* 90%.

[Co(*l*-mo-R)$_3$]. To a mixture of cobalt(II) hydroxycarbonate (1.5×10^{-4} mole) and a ligand (1.5×10^{-3} mole) was added dropwise hydrogen peroxide (30%, 10 cm^3) at 90°C. The reaction mixture assumed an intense green color. After being cooled to room temperature, the complex was extracted with ether and the extract was shaken with 3% KOH solution and then with water. The crude product obtained on evaporating the solvent was dissolved in a benzene–methanol (1 : 1) mixture and passed through an alumina column (ϕ 15 mm × 100 mm). Evaporation of the solvent left [Co(*l*-mo-R)$_3$] as a green oily substance. It was dried over P_2O_5 in a vacuum desiccator.

Elemental analyses of the copper(II) and cobalt(III) complexes are given in Table 1.

Physical measurements

The ^{1}H-NMR spectra were recorded on a JEOL Fourier Transform NMR Spectrometer Model FX90Q in $CDCl_3$. Tetramethylsilane was used as an internal standard. The electronic and CD spectra were obtained in CCl_4 on a Shimadzu UV–Visible Recording Spectrometer UV-240 and a JASCO J-500C Spectropolarimeter, respectively. The elemental analyses were obtained at the Elemental Analysis Service Center, Kyushu University.

RESULTS AND DISCUSSION

The ligands H(*l*-mo-R) were identified by elemental analyses of their copper(II) complexes (Table 1) and ^{1}H-NMR spectra (Table 2). Each NMR spectrum of H(*l*-mo-R) shows a broad signal at 14–15 ppm attributable to the enolic proton.[14] The signal for the methine proton on the chelate ring appears at 5.8–5.9 ppm. The signal for the meth-

Abbreviations: AB = AB quartet, b = broad, m = multiplet.

ylene protons adjacent to the *l*-menthyloxy group appears at 4.0–4.1 ppm. The AB quartet pattern of this signal is presumably due to the chirality of the neighbouring *l*-menthyl group.[12]

The methine proton signal of [Co(*l*-mo-R)$_3$] is broad and in the case of [Co(*l*-mo-*i*Pr)$_3$] the splitting of the signal is clearly seen. This fact suggests that the stereoselectivity of [Co(*l*-mo-R)$_3$] is not so high as found for [Co(*l*-moba)$_3$] and its homologs, and the *mer* isomer is more or less formed together with the *fac* isomer as the main species. The signal for the methylene protons adjacent to the *l*-menthyloxy group (near 4.2 ppm) is no more AB quartet pattern but essentially multiplet. This suggests that the free rotation about the methylene group is restricted because of the interligand *l*-menthyl/alkyl interaction. A similar NMR pattern is seen for the methylene protons of [Co(*l*-moba-Me)$_3$],[13] which is proved to be of pure *fac*-Δ.

All the complexes show the first *d–d* transition band near 17×10^3, characteristic of tris(1,3-diketonato)cobalt(III) complexes.[15,16] The CD spectra in the first *d–d* band region were measured. A typical CD spectrum is shown in Fig. 2 together with its absorption spectrum, and the numerical data are included in Table 3. As seen in Table 3, [Co(*l*-mo-Et)$_3$], [Co(*l*-mo-*i*Pr)$_3$], [Co(*l*-mo-*i*Bu)$_3$] and [Co(*l*-mo-*i*Am)$_3$] show distinct CD in the first *d–d* band region whereas [Co(*l*-mo-*n*Pr)$_3$], [Co(*l*-mo-*n*Bu)$_3$], and [Co(*l*-mo-*n*Am)$_3$] show practically no CD in this region. The CD for the former complexes probably arises from the dissymmetry about the metal center (configurational effect) but not vicinal effect from the *l*-menthyl group, because no CD is induced for the latter complexes. However, judging from the CD intensities, the stereoselectivity of these complexes is much lower compared with that of [Co(*l*-moba)$_3$] and its homologs. It is also seen from Table 3 that the preferred configuration depends upon the R group; Δ configuration for [Co(*l*-mo-Et)$_3$] and [Co(*l*-mo-*i*Bu)$_3$] whereas Λ configuration for [Co(*l*-mo-*i*Pr)$_3$] and [Co(*l*-mo-*i*Am)$_3$]. For tris(1-*l*-menthyloxy-3-acetylacetonato)cobalt(III) the preferred configuration was Λ.[13]

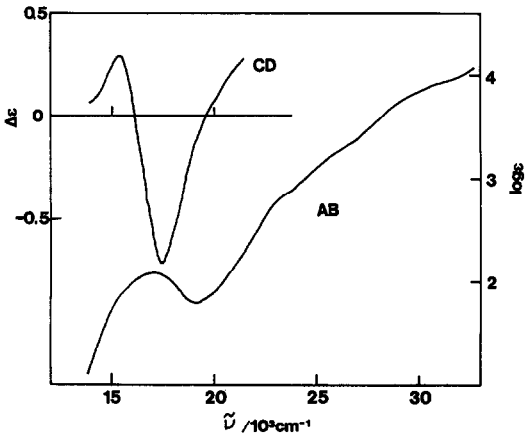

Fig. 2. Absorption (AB) and circular dichroism (CD) spectra of [Co(*l*-mo-Et)$_3$].

Recently we have suggested for [Co(*l*-moba-Me)$_3$][12] that one of the methyl groups of the *l*-menthyl moiety, probably one of the isopropyl group, plays the major role in the CH/π interaction with the aromatic ring. Such a methyl-ring coupling has a directionality, as pointed out by Nishio[10] based on the X-ray analysis for *t*-butyl 1-phenylethyl sulfoxide.[17,18] Because of this directionality, the *l*-menthyl and aryl groups should take a specific orientation to each other when the CH/π interaction operates, and this may lead to a controlled disposition of the diketonate ions about the central metal. The interaction ("association") between alkyl and alicyclic groups seems to have less directionality than CH/π interaction. The CD spectral results for [Co(*l*-mo-R)$_3$] (Table 3) suggest that the *l*-menthyl group can associate with alkyl groups in two different ways: one leads to the predominant formation of the *fac*-Δ isomer (R = Et and *i*Bu) whereas the other to the *fac*-Λ isomer (R = *i*Pr and *i*Am). It is likely that in the complexes

[Co(*l*-mo-*n*Am)$_3$]	16.8 (2.06)			
[Co(*l*-mo-*i*Am)$_3$]	16.8 (2.01)	15.4 (−0.03)	17.4 (+0.34)	Λ

ε: extinction coefficient in the unit dm^3 mole^{-1} cm^{-1}.

of R = *n*Pr, *n*Bu or *n*Am there is no significant difference in free energy between the two ways of associations and thence no appreciable stereoselectivity is caused in these complexes.

From the present study on [Co(*l*-mo-R)$_3$], together with our previous results for [Co(*l*-moba-R)$_3$] and its homologs, we may conclude that the interligand CH/π interactions are much more effective than the hydrophobic interactions to give rise to stereoselectivities of metal complexes.

TRIORGANOTIN(IV) DERIVATIVES OF FIVE MEMBERED HETEROCYCLIC 2-CARBOXYLIC ACIDS

G. K. SANDHU* and S. P. VERMA

Department of Chemistry, Guru Nanak Dev University, Amritsar 143005, India

(*Received* 6 *March* 1986; *accepted after revision* 15 *August* 1986)

Abstract—A series of 20 complexes of general formula R_3SnL (R = CH_3, n-C_3H_7, n-C_4H_9, C_6H_5, c-C_6H_{11}; L = anion of thiophene 2-, thiophene 2-acetic, furoic 2- and pyrrole 2-carboxylic acids) has been prepared. All of these complexes are monomers except those of triphenyltin(IV) which are polymers and have been characterised by molecular weight determination, IR, ^{1}H-NMR and ^{119m}Sn Mössbauer studies. Tetrahedral and trigonal bipyramidal structures have been assigned and it has been found that none of the ring hetero atoms bond to tin(IV).

Fungicidal and bacteriocidal carboxylates of tributyltin(IV) with furoic and thiophene acids are known through patents.[1,2] Structural information about very few diorganotin(IV)[3] and tributyltin(IV)[4] compounds with furoic and pyrrole acids is available. A possible biological activity is expected from the triorganotin carboxylates reported in this paper since all the hetero atoms of the five membered carboxylic acids are free and are not bonded to tin(IV).

EXPERIMENTAL

Chemicals

Thiophene 2-carboxylic acid (ThioH), thiophene 2-acetic acid (ThioAH), furoic 2-carboxylic acid (FuH) and pyrrole 2-carboxylic acid (PyrH) were obtained from Aldrich Chemicals (England) and are used as such. Trimethyltin(IV) chloride and tributyltin(IV) chloride were procured from Alpha Products (USA) and Fluka Chemicals (Germany), respectively and are used as such while tripropyltin(IV) chloride,[5] triphenyltin(IV) chloride[6] and tricyclohexyltin(IV) chloride[7] were prepared by the reported methods.

Preparation of the sodium salt

Sodium hydroxide (BDH) (4.0 g, 0.1 mole) was added to a solution of ThioH (12.8 g, 0.1 mole) in ethanol (95%, 50 cm^3) and refluxed till a clear solution resulted (pH 7–7.2). After removing the excess alcohol by distillation, dry benzene (20 cm^3) was added to remove water azeotropically using a Dean and Stark trap. Thiophene 2-sodium carboxylate separated out and was filtered, washed several times with acetone and then with dry ether and dried *in vacuo*. Sodium salts of the remaining acids were prepared in a similar way.

Preparation of complexes

To a solution of triorganotin(IV) chloride (0.001 mole) in absolute alcohol (30 cm^3) was added the sodium salt of the acid (0.00104 mole). The reaction mixture was refluxed on a water bath for 3–4 h when a clear solution was produced. From the reaction mixture half of the alcohol was removed by distillation. On cooling some sodium chloride separated which was filtered through a sintered glass funnel (G-4) under reduced pressure. To the clear solution was added thiophene-free dry benzene (20 cm^3) followed by refluxing on a water bath using a Dean and Stark trap for 2 h. Sodium chloride that separates on cooling was filtered. Refluxing followed by cooling and subsequent filtration of the solution was repeated till the removal of sodium chloride was complete. After removing the solvents completely, the residue was dried *in vacuo*. All the compounds are solids except Nos 8, 12 and 18 (Table 1) which are liquids. Compound 12 solidifies on long standing whereas 18 becomes a semi-solid on keeping. Compounds 1–4 and 17–20 have been

recrystallized from ethanol while 5–7 and 9–12 from pet-ether (60–80°C). The triphenyltin(IV) derivatives (13–16) could not be recrystallized because of their insolubility in common organic solvents but were washed with pet-ether (40-60°) to remove Ph_3SnCl.

Physical measurements

Melting points were determined in open capillaries and are uncorrected. Elemental analysis was carried out by microanalytical service, Calcutta University, Calcutta. Tin was estimated as SnO_2.[8] Molecular weights were determined both cryoscopically in benzene and by Rast's method (in molten camphor, 175°C). Infrared spectra were recorded on Pye-Unicam $Sp_{3\text{-}300}$ spectrophotometer in KBr and in neat polythene strips in 4000–200 cm^{-1} range. ^{1}H-NMR spectra were recorded on Tesla BS487C (80 MHz) using TMS as internal standard. The ^{119m}Sn Mössbauer spectra were recorded at 77 K on a Ranger Engineering constant acceleration spectrometer equipped with an NaI scintillation counter using $Ca^{119m}SnO_3$ as the source and Ca $^{119m}SnO_3$ was the reference material for zero velocity at room temperature. The velocity calibration was based on β-tin and natural iron foils. The resultant spectra were fitted using standard least squares techniques assuming a Lorentzian shape.

RESULTS AND DISCUSSION

All the complexes except triphenyltin(IV) derivatives are soluble in common organic solvents. The analytical data are given in Table 1. Molecular weight determination of all the complexes except those of triphenyltin(IV) complexes by Rast and cryoscopic methods indicates a monomeric nature of the compounds. Insoluble nature of the triphenyltin(IV) complexes indicates polymeric structures.

The assignments of important infrared bands are shown in Table 2 both for ligands and complexes. A band around 2900–2500 cm^{-1} in the spectra of acids disappears in the spectra of their respective sodium salts and complexes which indicates deprotonation of the carboxylic group. A lower ν(N–H) in the PyrNa as compared to PyrH supports the presence of hydrogen bonding in the PyrH. A higher ν(N–H) value in complexes 4, 8 and 12 or its unchanged value in 16 and 20 show non-participation of nitrogen atom in bonding to tin.

The $\Delta\nu$ value [$\Delta\nu = \nu(COO)_{asym} - \nu(COO)_{sym}$] which is useful in drawing structural inferences in the case of metal carboxylate[9] is used to determine the nature of bonding of the carboxylate to tin(IV). In the seven complexes 8, 12, 13 and 17–20, Table 2, the $\Delta\nu$ value is higher by 90–65 cm^{-1} than in the sodium salts and indicates either asymmetric or a unidentate bonding of the carboxylate group to tin(IV)[10] while in the remaining complexes the carboxylate group behaves in a bidentate manner since $\Delta\nu$ value is comparable to the sodium salt of the acids.[11] However, polymeric triphenyltin(IV) complexes have asymmetrically bonded bridging bidentate carboxylate group since $\nu(COO)_{asym}$ and $\nu(COO)_{sym}$ fall in the range of bridging carboxylates.[12] Observation of both $\nu(Sn–C)_{asym}$ and $\nu(Sn–C)_{sym}$ modes in the infrared spectrum of all the compounds studied rules out the planar arrangement for the SnC skeleton. The assignment of ν(Sn–C) and ν(Sn–O) are consistent with the values reported in literature.[11]

The ^{1}H-NMR spectra of the ligands and soluble complexes are given in Table 3. The carboxylic acid proton signal in the acids disappears in the spectra of all the complexes. However in pyrrole 2-carboxylic acid the two protons of the COOH and the NH groups appear as a broad multiplet which may be due to strong hydrogen bonding. The N–H resonance appears as a broad highfield signal in the spectra of all the pyrrole derivatives which is indicative of the non-participation of the nitrogen atom of the ligand to tin(IV). Integrations tally with the expected ratio. In the derivatives of triphenyltin(IV), the signals for protons of the rings (acid) overlap with those of the aromatic protons and are thus difficult to distinguish. Since a multiplet is observed for CH_3 protons in all the trimethyltin(IV) complexes so a *cis* or a *mer* trigonal bipyramidal structure may be present. However, the possibility of a distorted planar Me_3Sn skeleton cannot be ruled out.

The quadrupole splitting parameter (QS) is very useful for interpreting Mössbauer data.[13] A higher QS value in the range 3.69–3.82 mm s^{-1} for complexes 1, 5 and 9, Table 4, is consistent with five coordination. The ratio ρ = QS/IS also favours a five coordinated structure.[15] $Ph_3SnThio$ which is a monomer has much lower QS value and involves monodentate carboxylate. Both properties are consistent with four coordination for tin as reported for other tri-organotin carboxylates.[16]

CONCLUSIONS

All the four Cy_3Sn, *n*-Pr_3SnPyr, *n*-Bu_3SnPyr and $Ph_3SnThio$ complexes are monomers with a unidentate carboxylate which bonds to tin(IV) tetrahedrally. Mössbauer parameters of $Ph_3SnThio$ further support a four coordinate structure. Me_3Sn-, 1–4, *n*-Pr_3Sn-, 5–7, and *n*-Bu_3Sn-, 9–11,

derivatives are monomers with a bidentate carboxylate in a five coordinate structure. Mössbauer data of three complexes $Me_3SnThio$, $n\text{-}Pr_3SnThio$ and $n\text{-}Bu_3SnThio$ further support a trigonal bipyramidal structure for these complexes. Three remaining Ph_3Sn-, 14–16, derivatives, which are polymers, have a five coordinate carboxylate bridged structure.

EMISSION AND ELECTROCHEMICAL STUDIES OF 2-PYRIDYLCARBONYLMETHYLIDE–RHENIUM(I) COMPLEXES

GEN-ETSU MATSUBAYASHI* and KOSUKE UEYAMA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565, Japan

(*Received* 9 *April* 1986; *accepted* 15 *August* 1986)

Abstract—Re(I)Br(CO)$_3$(2-pyridylcarbonylmethylide) and Re(I)Br(CO)$_3$(2-acetylepyridine) were prepared by reactions of Re(I)Br(CO)$_5$ with 2-pyridylcarbonylmethylides, $C_5H_4NC(O)\bar{C}H\overset{+}{Z}$ [$\overset{+}{Z}$ = $\overset{+}{P}Ph_3$ (Y_P), $\overset{+}{As}Ph_3$ (Y_{As}), $\overset{+}{S}Me_2$ (Y_S) and $\overset{+}{N}C_5H_4R$-4 (Y_{N-R}; R = CN, Ph, H and Me)], and 2-acetylpyridine. These complexes are concluded to assume an octahedral geometry containing the chelation by the carbonyl oxygen and pyridyl nitrogen atoms and the *facial*-coordination of metal carbonyl groups on the basis of IR and ^{1}H-NMR spectra. Although the 2-acetylpyridine complex gave no emission, the Y_P, Y_{As} and Y_S complexes showed an emission due to the metal-to-ligand charge transfer (MLCT) transition at 77 K in MeOH/EtOH (1:4 v/v). On the other hand, the Y_{N-R} complexes showed emissions due to both the MLCT and the intraligand CT transitions. All the present ylide complexes were oxidized at +0.71 to +0.82 V vs Ag/Ag$^+$ in acetonitrile. The Y_P, Y_{As} and Y_S complexes were reduced at −1.91 to −2.00 V, while reduction of the Y_{N-R} complexes occurred on the pyridinium ring of the ylides at less negative potentials (−1.68 to −1.04 V).

Photo-physical properties of charge transfer (CT) transitions between metal ions and ligands have been investigated in order to clarify mechanisms of photo-reactions of organometallic complexes.[1–3] Many rhenium(I) complexes with nitrogen donor ligands were reported to show intensive emissions due to metal-to-ligand CT transitions even at room temperature.[3] Moreover, it is of interest that some of them display multiple emissions due to intraligand and metal-to-ligand CT transitions.[4]

Ylide molecules in which carbanions are directly attached to hetero-atoms, such as phosphorus, arsenic, sulfur and nitrogen, exhibit various unique reactivities that are characteristic of the ylide bonding.[5] Moreover, ylide–metal interactions have attracted much interest.[6,7] However, photo-physical properties of ylides and their metal complexes are little known.[8] Ylide molecules generally exhibit intensive absorption bands due to an intramolecular CT transition[9] and some of them are known to give noticeable emissions caused by this transition.[10] In order to investigate the effect of the ylide structure in the ligand on photo-physical properties of metal complexes, we have chosen rhenium(I)–ylide complexes which have been expected to exhibit intensive emissions.

This paper reports configurations of Re(I)Br(CO)$_3$L (L = several 2-pyridylcarbonylmethylides (**1**) and 2-acetylpyridine) and their emission properties, together with electrochemical behaviors of the complexes.

EXPERIMENTAL

Preparation of 4-substituted pyridinium 2-pyridylcarbonylmethylides

A benzene (25 cm^3) solution of 4-phenylpyridine (1.9 g, 12 mmol) was added to a benzene (25 cm^3)

* Author to whom correspondence should be addressed.

solution of 2-(bromoacetyl)pyridine[11] (2.5 g, 12 mmol) and the mixture was refluxed for 4 h to give white precipitates of 4-phenyl-*N*-(2-pyridylcarbonylmethyl)pyridinium bromide (4.3 g, 98% yield). To its aqueous (150 cm^3) solution was added an aqueous (70 cm^3) solution of K_2CO_3 (3.9 g, 29 mmol) and the precipitates obtained were extracted with dichloromethane (400 cm^3). After the solution was concentrated to one third volume under reduced pressure, it was kept at $-10°C$ overnight to give red crystals of 4-phenylpyridinium 2-pyridylcarbonylmethylide (Y_{N-Ph}) (2.0 g, 61% yield), m.p. 163°C (decomp.). Found: C, 78.5; H, 4.9; N, 10.2. Calc. for $C_{18}H_{14}N_2O$: C, 78.8; H, 5.1; N, 10.2%.

Pyridinium 2-pyridylcarbonylmethylide (Y_{N-H}) was prepared as yellow needles according to the same method described above (43% yield), m.p. 138°C (decomp.). Found: C, 67.9; H, 4.9; N, 12.8. Calc. for $C_{12}H_{10}N_2O \cdot 0.2CH_2Cl_2$: C, 68.1; H, 4.9; N, 13.2%. The presence of solvent molecules was confirmed by the ^{1}H-NMR spectrum.

4-Cyanopyridinium (Y_{N-CN}) and 4-methylpyridinium 2-pyridylcarbonylmethylide (Y_{N-Me}) were prepared according to the literature methods.[12,13]

Preparation of triphenylarsonium (Y_{As}), *triphenylphosphonium* (Y_P) *and dimethylsulfonium* 2-*pyridylcarbonylmethylide* (Y_S)

A methanol (50 cm^3) solution containing triphenylarsine (1.9 g, 6.2 mmol) and 2-(bromoacetyl)pyridine (2.0 g, 9.9 mmol) was stirred overnight at room temperature. After the solvent was evaporated to dryness, the residue was washed with benzene and dried *in vacuo* (1.9 g, 60% yield). To its aqueous (200 cm^3) solution was added an aqueous (60 cm^3) solution of NaOH (5.0 g). White precipitates were filtered off and recrystallized from a mixture of dichloromethane and diethyl ether at $-10°C$ to give white crystals of Y_{As} (1.2 g, 84% yield), m.p. 96°C (decomp.). Found: C, 68.6; H, 5.0; N, 3.2. Calc. for $C_{25}H_{20}NOAs \cdot 0.5H_2O$: C, 69.1; H, 4.9; N, 3.2%. The presence of solvent molecules was confirmed by the IR spectrum.

Y_P and Y_S were prepared according to the literature method.[10]

Preparation of bromotricarbonyl(2-pyridylcarbonylmethylide and 2-acetylpyridine)rhenium(I), ReBr$(CO)_3$L [L = Y_P, Y_{As}, Y_S, Y_{N-R} (R = CN, Ph, H *and* Me) *and* 2-AcPy]

A benzene (60 cm^3) solution of Y_{N-Ph} (56 mg, 0.20 mmol) was added to a benzene (70 cm^3) solution of bromopentacarbonylrhenium(I)[14] (82 mg, 0.20 mmol) and the solution was refluxed for 2 h. Yellow precipitates of $ReBr(CO)_3Y_{N-Ph}$ were filtered off and dried *in vacuo* (86 mg, 83% yield). The other ylide– and 2-acetylpyridine–rhenium(I) complexes were prepared by the similar method.

Melting points, analyses and reaction yields for the rhenium(I) complexes are summarized in Table 1.

n-Butyltrichloro(4-cyanopyridinium 2-pyridylcarbonylmethylide)tin(IV)[15] and 4-substituted (CN, Ph, H and Me)-N-(2-pyridylcarbonylmethyl)pyridinium perchlorates[16] were prepared as described elsewhere.

Physical measurements

IR, ^{1}H-NMR and emission spectra[8] as well as ESR spectra[17] were measured as described previously. For the measurement of emission lifetimes, deaerated methanol/ethanol (1:4 v/v) solutions containing metal complexes were irradiated at 337.1 nm with a pulsed nitrogen-laser (pulse width of ~ 2 ns).[18] Lifetimes were calculated from oscilloscope tracings of the decay of emission intensities.

All cyclic voltammograms were recorded in an acetonitrile solution containing $[NBu^n_4]ClO_4$ (0.05–0.1 mol dm^{-3}) as a supporting electrolyte, as described elsewhere.[16]

RESULTS AND DISCUSSION

Configuration of the rhenium(I) complexes

The ν(C≡O) bands of $ReBr(CO)_3Y_{N-R}$ and $ReBr(CO)_3$(2-AcPy) are observed at lower frequencies than those of the free ligands, indicating that the ligands coordinate to the rhenium(I) ion through the carbonyl oxygen atom (Table 2).[10] In ^{1}H–NMR spectra of these complexes, the signals of the proton (H_6) bound with the carbon atom adjacent to the pyridyl nitrogen atom are observed at lower fields than those of free ligands, which suggests that Y_{N-R} and 2-AcPy chelate to the rhenium(I) ion through the carbonyl oxygen and pyridyl nitrogen atoms.

In $ReBr(CO)_3Y_S$, the ν(C≡O) bands occurs at a slightly higher frequency than that of the free ylide. This behavior is also the same as $W(CO)_4Y_S$,[10] and the IR spectra due to the coordinating Y_S ligand are almost the same for these two complexes. Since the X-ray crystallographic analysis revealed that $W(CO)_4Y_S$ has the chelate coordination through the carbonyl oxygen and pyridyl nitrogen atoms, the rhenium(I)–Y_S complex seems to assume the same configuration around the metal atom to $W(CO)_4Y_S$. Although the Y_P and Y_{As} complexes also have exhibited the ν(C≡O) bands of the coordinating ylides at slightly higher frequencies than the free ylides, they are reasonably likely to have the chelation by oxygen and nitrogen atoms as well as the Y_S complex. These small higher frequency shifts of the ν(C≡O) bands are in contrast to the large higher frequency shifts (167 and 160 cm^{-1}) of the ν(C≡O) ones which were seen on the chelation by the ylide carbon and pyridyl nitrogen atoms in $PtCl_2Y_S$[19] and $PtCl_2Y_P$.[20]

In the ^{1}H-NMR spectrum of $ReBr(CO)_3Y_P$ in dimethyl sulfoxide-d_6, the spin-spin coupling constant between the ylide proton and ^{31}P nucleus has been measured 18 Hz which is close to 20 Hz of $W(CO)_4Y_P$ having the chelation by the oxygen and nitrogen atoms.[10] Although the magnitude is smaller than 27 Hz of the free Y_P, it is significantly large compared with those (6 and 10 Hz) of $PdCl_2Y_P$ and $PtCl_2Y_P$ having the chelation by the ylide carbon and pyridyl nitrogen atoms.[20] These findings also suggest an sp^2 geometry around the ylide carbon atom of Y_P in the present complex which is caused by the coordination through the carbonyl oxygen atom. In Y_P–, Y_{As}– and Y_S–Re(I) complexes, the H_6 proton signals appear at lower fields than those of free ligands (Table 2). These results support the chelation to the metal through the carbonyl oxygen and pyridyl nitrogen atoms.

All the complexes exhibit the three IR bands in the region of the C≡O stretching frequencies (Table 2), suggesting that the three carbonyl ligands coordinate to the rhenium(I) ion in a *cis*-arrangement (**2**).[21,22] The ^{1}H-NMR spectrum of $ReBr(CO)_3Y_S$ has shown two S–CH_3 signals (2.90 and 2.93 δ in dimethyl sulfoxide-d_6), confirming this configuration.

Electronic absorption spectra

$ReBr(CO)_3$(2-AcPy) exhibits an intensive absorption band at 430 nm in MeOH/EtOH (1 : 4 v/v), while both 2-acetylpyridine and $ReBr(CO)_5$[23] have no band in this region (Fig. 1). This band is reasonably assigned to a metal-to-ligand charge transfer (MLCT) transition, since $ReX(CO)_3L_2$ complexes (L = pyridine and its derivatives,[24] L_2 = di-imines;[22] X = Br and Cl) were reported to exhibit MLCT bands at 290–520 nm. Moreover, this band displays an appreciable blue shift in polar solvents (Table 3), as was seen in MLCT bands of other rhenium(I) complexes,[24,25] which supports this assignment.

Table 3. Solvent dependence on absorption band maxima of $ReBr(CO)_3L$ at 298 K

Solvent	Band (nm) L = 2-AcPy	L = Y_P	L = Y_{N-H}
DMSO	394	378	446
MeCN	423	379	440
MeOH/EtOH (1 : 4 v/v)	430	380	430
CH_2Cl_2	452	388	455
THF	444	391	459
$CHCl_3$	466	391	463

Figure 2 shows the spectrum of $ReBr(CO)_3Y_P$ in MeOH/EtOH (1 : 4 v/v), together with that of free ylide in 2-MeTHF. The band at 380 nm also is attributed to the MLCT transition on the basis of the spectrum of the 2-AcPy–Re(I) complex. Free Y_P exhibits a strong band at 348 nm which can be assigned to an intramolecular CT transition from the negatively charged ylide-carbon to the phosphonium moiety.[5] Assuming the coordination of the carbonyl oxygen-to-rhenium(I) for $ReBr(CO)_3Y_P$, this intraligand CT (ILCT) band of

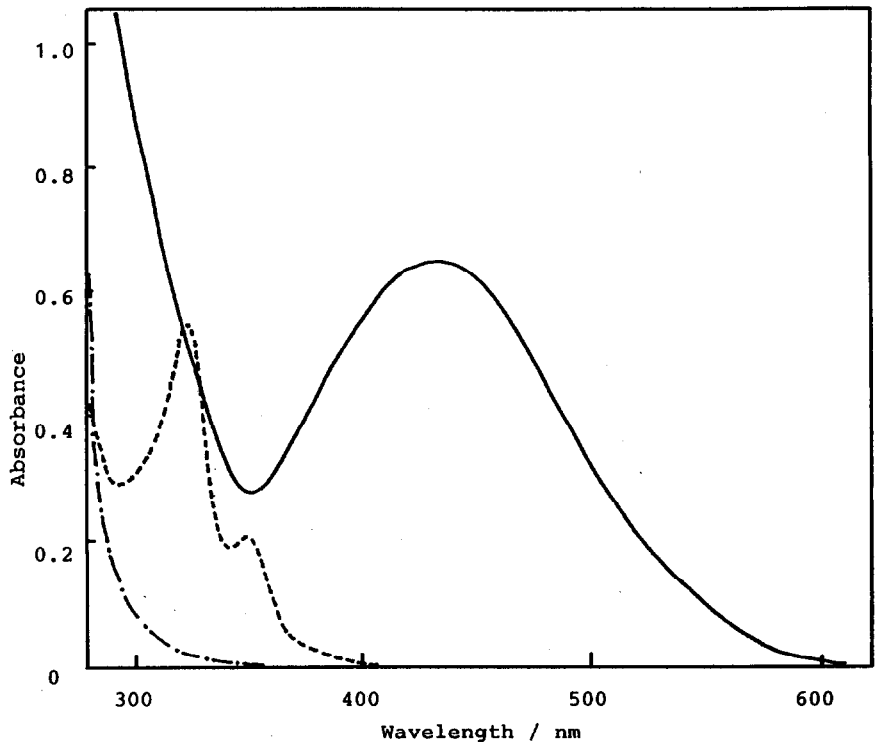

Fig. 1. Electronic absorption spectra of $ReBr(CO)_3$(2-AcPy) (——) in MeOH/EtOH (1 : 4 v/v), $ReBr(CO)_5$ (– – –) and 2-AcPy (– · – · –) in MeCN at 298 K : 3.0×10^{-4} mol dm^{-3}.

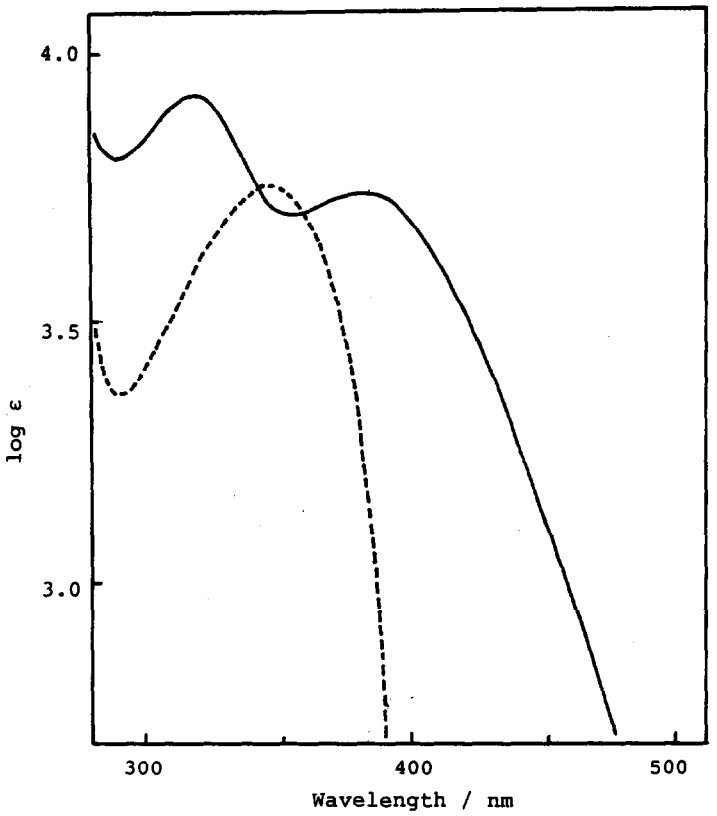

Fig. 2. Electronic absorption spectra of $ReBr(CO)_3Y_P$ (——) in MeOH/EtOH (1 : 4 v/v) and of Y_P (– – –) in 2-MeTHF.

the complex is likely to occur at a higher energy than free Y_P, as was seen in several 4-substituted pyridinium 2-pyridylcarbonylmethylide-$SnBu^nCl_3$ complexes.[15] Hence, the strong band of the Y_P–Re(I) complex observed at 327 nm is possibly due to the ILCT transition. Y_{As}– and Y_S–Re(I) complexes also have exhibited both ILCT and MLCT bands at quite similar wavelengths to the Y_P complex.

The spectra of $ReBr(CO)_3Y_{N-H}$ and free Y_{N-H} in MeOH/EtOH (1 : 4 v/v) are illustrated in Fig. 3. The band at 426 nm observed for free Y_{N-H} is referred to a CT transition from the ylide carbon to the pyridinium ring.[9] On the other hand, the Y_{N-H}–Re(I) complex shows an extremely broad band near 430 nm, where the ILCT band due to the $\bar{C}$–$\overset{+}{N}$ ylide structure and the MLCT one seem to be overlapped. The other Y_{N-R}–Re(I) complexes also exhibit the similar broad absorptions to the Y_{N-H} complex. The absorption maxima of the Y_{N-R} complexes occur at lower energies than the Y_P, Y_{As} and Y_S complexes which are summarized in Table 4. This finding is plausibly indicative of much stabilization of excited states of the Y_{N-R} complexes compared with the Y_P, Y_{As} and Y_S ones, which is

consistent with the electrochemical properties of the complexes as described later.

Emission spectra

Complexes of the type of $ReX(CO)_3L_2$ (L_2 = pyridine and 1,10-phenanthroline derivatives; X = Br and Cl) are known to exhibit intensive emissions due to the MLCT transition even at room temperature.[3,4,23] $ReBr(CO)_3$(2-AcPy), however, has shown no emission even at 77 K, although it contains the coordination of pyridyl nitrogen and shows an intensive absorption band due to the MLCT transition. This is possibly due to any appreciable quenching through the coordinating carbonyl group, considering the fact that $ReBr(CO)_3$(4-acetylpyridine)$_2$ gave a strong emission.[26]

The Y_P, Y_{As} and Y_S complexes have shown appreciable emissions at 77 K. Figure 4 shows the emission spectrum of $ReBr(CO)_3Y_P$ in MeOH/EtOH (1 : 4 v/v) at 77 K, together with its excitation spectrum. The excitation spectrum is almost identical with the absorption spectrum measured at room temperature. Therefore, the emission is attributed to the MLCT transition. The emission lifetime of 10.0 μs also supports the above assignment, since several $ReBr(CO)_3L_2$ (L_2 = pyridine derivatives) had MLCT emission lifetimes of ≈ 40 μs.[3,27]

Although the Y_P complex has the same configuration around the metal as the 2-AcPy complex, the presence of the ylide structure which is adjacent to the coordinating carbonyl group in the former complex seems to play a role in the appearance of the emission. Free Y_P itself has exhibited a noticeable emission due to the intramolecular CT transition based on the ylide structure. Therefore, in the rhenium complex, an effective energy transfer from the ylide CT level to the metal-to-ligand CT one seems to cause the appearance of the emission. The emissive behavior is the same also in the Y_{As}–rhenium(I) complex (Table 4). The Y_S–rhenium(I) complex also has exhibited an MLCT emission,

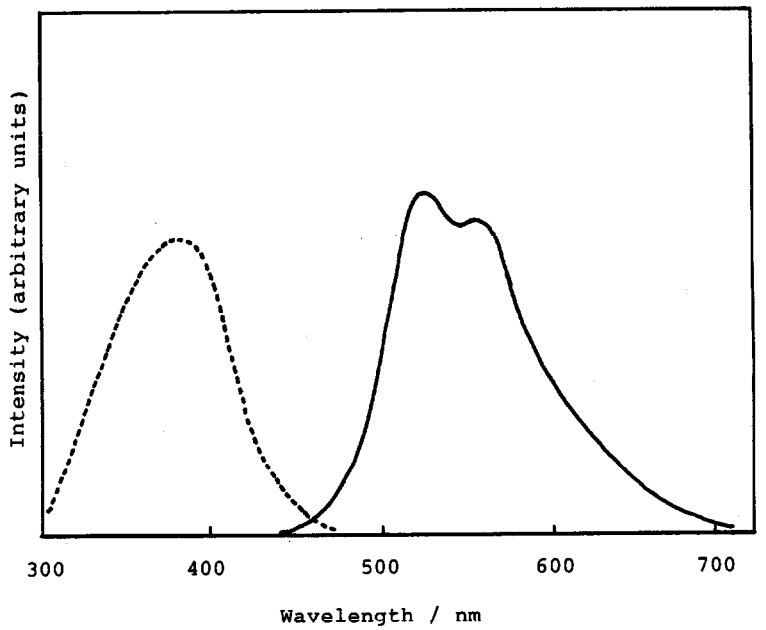

Fig. 4. Emission (——) and excitation (– – –) spectra of $ReBr(CO)_3Y_P$ in MeOH/EtOH (1 : 4 v/v) at 77 K.

although free Y_S has given no emission even at 77 K.

Figure 5 shows the emission and excitation spectra of $ReBr(CO)_3Y_{N-H}$ in MeOH/EtOH (1 : 4 v/v) at 77 K. Since free Y_{N-H} also has exhibited a ylide CT emission at 463 nm, the emission band at 467 nm of the rhenium(I) complex is favorably ascribed to the fluorescence coming from the ILCT transition of the coordinating ylide. The fact that the excitation band essentially agrees with the ILCT absorption band, together with the emission lifetime of < 8 ns, supports this assignment. The complex has another emission band near 632 nm. Although the measurement of the lifetime has been unsuccessful owing to the weak intensity, this emission can be reasonably assigned to the MLCT transition in analogy with the emission bands of the Y_P–, Y_{As}– and Y_S–rhenium(I) complexes. The complex has shown no phosphorescence, while free Y_{N-H} affords a phosphorescence at 460 nm (~ 800 ms) from the carbonyl $^3(n-\pi^*)$ state. This phosphorescence seems to be quenched in the complex owing to the MLCT triplet state which lies at lower energy than the $^3(n-\pi^*)$ state.

As shown in Table 5, in a series of the Y_{N-R} complexes a more electron-withdrawing substituent of the pyridinium ring results in the occurrence of both the ILCT and MLCT emission bands at lower energies.

The observation of the dual emissions in the Y_{N-R} complexes is likely to be related to the energetically closely lying ILCT and MLCT states. As apparent from the absorption spectra of the Y_{N-R} complexes as well as the excitation ones for their emissions, these two excited states have quite similar energies. Hence, both the states can emit simultaneously, although the energy of the MLCT state is relaxed to its lowest level by a radiationless internal conversion, followed by the emission at much lower energy. On the other hand, the Y_P–, Y_{As}– and Y_S–

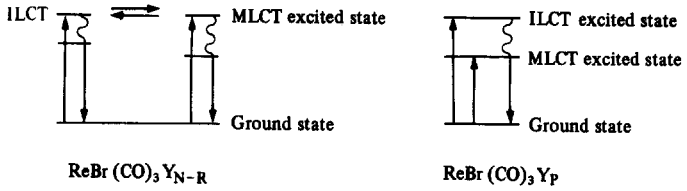

Scheme 1.

rhenium(I) complexes have given only the MLCT emission. In these complexes the ILCT level lies at a considerably higher energy than the MLCT level. Excitation to the ILCT level is followed by an effective radiationless quenching to the MLCT level, resulting in the appearance of only the MLCT emission (Scheme 1).

Electrochemical properties of the rhenium(I) complexes

Electrochemical properties of the $ReBr(CO)_3L$ complexes (L = 2-AcPy and 2-pyridylcarbonylmethylides) have been investigated by cyclic voltammetry. The data are summarized in Table 6. The 2-AcPy complex has revealed an irreversible wave at +1.20 V (vs Ag/Ag^+). This peak seems to correspond to the oxidation from Re(I) to Re(II), since free 2-AcPy has exhibited no anodic peak up to +1.7 V and $ReCl(CO)_3$(2,2′-bipyridine) and $ReCl(CO)_3$(1,10-phenanthroline) were reported to have oxidation peaks at 1.35 and 1.33 V vs SCE, respectively.[27]

The oxidation peaks of the Y_P–, Y_{As}– and Y_S–rhenium(I) complexes have appeared at significantly less positive potentials than that of the 2-AcPy complex. This suggests that these ylide complexes have greater electron densities on the metal compared with the 2-AcPy complex. Increased electron densities on the metal are expected to lead to less favorable reduction. In fact, Y_P–, Y_{As}– and Y_S–rhenium(I) complexes exhibit the cathodic peaks at extremely negative potentials, although the 2-AcPy complex reveals a peak at −1.04 V.

Figure 6 shows the cyclic voltammogram of the Y_{N-CN} complex in acetonitrile. While the irreversible oxidation wave is observed at a similar potential to those of the Y_P, Y_{As} and Y_S complexes, two cathodic peaks appear. The reduction from Re(I) to Re(0) seems to occur at −1.71 V which is close to the reduction potentials of Y_P, Y_{As} and Y_S complexes. The Y_{N-CN} complex has another less negative cathodic peak which accompanies a reversible anodic peak. This peak is reasonably assigned to the reduction process of the pyridinium ring of the ylide ligand on the basis of the following results. (1) At quite a similar potential (−0.94 V) has been observed the reversible cathodic peak also in $Sn(IV)Bu^nCl_3Y_{N-CN}$ in which Y_{N-CN} coordinates to the tin atom through the carbonyl oxygen and pyridyl nitrogen atoms[15] as well as the Y_{N-CN}–rhenium(I) complex. (2) The ESR spectrum measured under the electrochemical reduction of $Sn(IV)Bu^nCl_3Y_{N-CN}$ at −1.2 V has shown the signal at $g = 2.004$ with hyperfine structures, although the signal ($g = 2.003$) of the electrochemically reduced $ReBr(CO)_3Y_{N-CN}$ has not been sufficiently resolved. (3) The cathode peak potentials of the Y_{N-CN}–rhenium(I) complexes are similar to those of the corresponding 4-substituted-(2-pyridylcarbonylmethyl)pyridinium perchlorates ($[Y_{N-R}H]ClO_4$) (see Table 7). Moreover, these peak potentials are very sensitive to the electron-withdrawing property

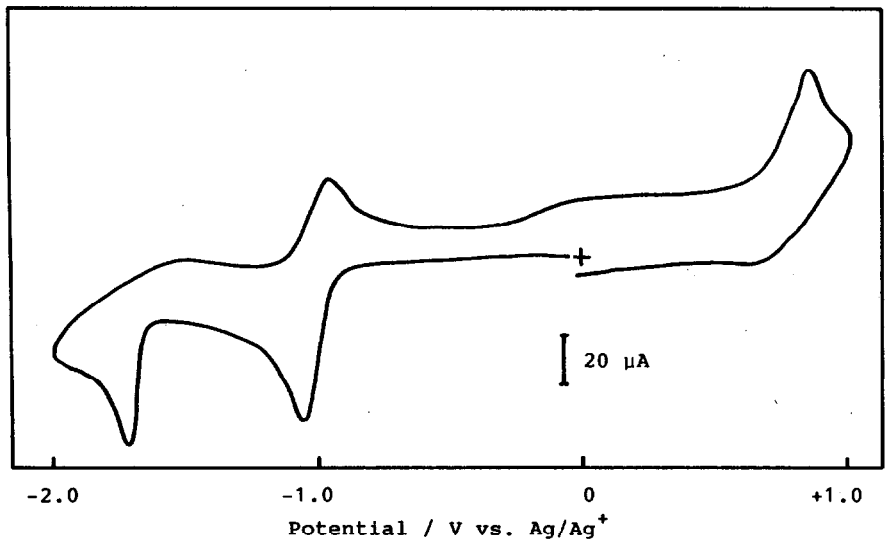

Fig. 6. Cyclic voltammogram of $ReBr(CO)_3Y_{N-CN}$ in MeCN containing $[NBu^n_4]ClO_4$ (0.05 mol dm^{-3}), measured with a scan rate of 0.1 V s^{-1}.

of a substituent on the pyridinium ring; a more electron-withdrawing substituent gives a less negative cathodic peak potential.

Since cathodic peaks of these free pyridinium-ylides have been observed at much more negative potentials (−1.50 V for Y_{N-CN} and −2.02 V for Y_{N-Me}) (Table 7), less negative potentials of the rhenium(I) complexes indicate a significant decrease of the electron density on the pyridinium ring of the ylide caused by coordination through the carbonyl oxygen atom. The fact that the lowest excited states of the Y_{N-R} complexes lie at appreciably low energies compared with those of the Y_P, Y_{As} and Y_S complexes is consistent with the fact that absorption and emission bands of the former complexes occur at much lower energies than those of the latter ones.

Acknowledgements—We wish to express hearty thanks to Professor Toshio Tanaka of Osaka University for his continuous encouragement throughout this study. We thank Dr Masaoki Furue of Osaka University for the measurement of the emission lifetimes.

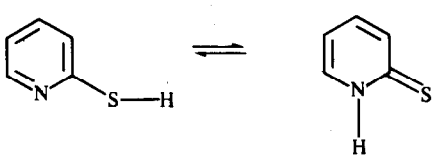
Abstract—The chemistry of the pentadentate edta complexes of ruthenium(III) and (II) with 2-mercaptopyridine (HSpy) has been investigated based on spectroscopic, kinetic and electrochemical techniques. The reaction of $[Ru(III)(edta)H_2O]^-$ with HSpy proceeds with a specific rate of 1.05×10^4 M^{-1} s^{-1} (25°C, I = 0.10 M, acetate buffer), forming a red complex (λ_{max} = 550 nm) which undergoes a relaxation process as a function of pH, with an apparent $pK_a = 4.35$ and $k_{obs} = 0.31$ s^{-1}. The second reaction depends on the concentration of HSpy and leads to a stable green product (λ_{max} = 630 nm). A pronounced enhancement has been observed in the Raman spectra of the complexes, particularly in the region of the metal–ligand vibrations. The electronic and resonance Raman spectra are consistent with the coordination of HSpy via the sulfur atom in the red complex, and with a chelate binding in the green species.

The 2-mercaptopyridine ligand exists (> 99%) in aqueous solution in the tautomeric form (**1B**) with a protonated N-atom,[1] but having available a thione group to bind transition metal ions.[2]



(1)

A **B**

In the course of our studies on linkage isomerism in transition metal complexes[3–5] we observed that the reaction of $[Ru(III)(Hedta)H_2O]$ with 2-mercaptopyridine led to a mixture of red and green species in equilibrium. The complexes have been investigated in detail in the present work, based on resonance Raman spectroscopy, spectroelectrochemistry, cyclic voltammetry and stopped-flow techniques. We concentrated our interest on the dynamics of the equilibrium reactions, stimulated by the extraordinary substitution reactivity of the pentadentate edta complexes of ruthenium(III).[6–8]

EXPERIMENTAL

The $[Ru(III)(Hedta)H_2O]\cdot 4H_2O$ complex was prepared according to the procedures previously described in the literature.[8,10] Found: C, 26.0; N, 5.7; H, 3.7. Calc. for $RuC_{10}N_2H_{23}O_{13}$: C, 25.0; N, 5.83; H, 4.82%. The red [Ru(III)(Hedta) HSpy]·$4H_2O$ complex was prepared by reacting stoichiometric amounts of $[Ru(III)(Hedta)H_2O]$ and 2-mercaptopyridine (Aldrich), and evaporating the solution to dryness, under vacuum, in the presence of concentrated sulfuric acid. Found: C, 31.0; N, 7.1; H, 3.8. Calc. for $RuC_{15}N_3H_{26}O_{12}S$: C, 31.3; N, 7.32; H, 4.40%. The red complex was converted to the green compound by reacting with an excess of ammonium hydroxide and evaporating the sol-

* Author to whom correspondence should be addressed.

ution to dryness, under vacuum. The product was very hygroscopic. The C/N and C/H ratios were consistent with the composition $(NH_4)_2$[Ru(III)(edta)Spy]·nH_2O. The complex anion [Ru(II)(edta)H_2O]$^{2-}$ was prepared *in situ* by the reduction of [Ru(III)(edta)H_2O]$^-$ with zinc amalgam under argon atmosphere. All other reagents were of high purity, and were used as supplied.

The electronic spectra of the complexes were recorded on a Cary 17, or a Hewlett–Packard 8451-A diode array spectrophotometer. Resonance Raman spectra were recorded on a Jarrell-Ash instrument using Spectra Physics argon and krypton ion lasers. Measurements were carried out in aqueous solution, using a spinning cell to avoid local heating and decomposition of the complexes. The relative intensities were measured as peak heights relative to the sulfate Raman band at 994 cm^{-1}. The IR spectra were recorded on a Zeiss Specord 75 instrument, with the samples dispersed in KBr pellets.

Cyclic voltammetry was carried out with a Princeton Applied Research instrument, consisting of a 173 potentiostat and a 175 universal programmer. A gold disc electrode was employed for the measurements, using the conventional Luggin capillary arrangement with the Ag/AgCl (I = 1 M KCl) reference electrode. A platinum wire was used as the auxiliary electrode. The measured potentials were converted to the normal hydrogen scale by adding 0.222 V. For the spectroelectrochemical measurements, the PARC 173 potentiostat was used in parallel with the diode-array spectrophotometer. A three-electrode system was designed for a rectangular quartz cell of 0.03 cm internal path-length. A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl reference electrode and of a platinum auxiliary electrode. The experiments were carried out at 25°C under semi-infinite diffusion conditions, as described by Kuwana and Winograd.[11]

The determination of the apparent pK_a was carried out spectrophotometrically and by cyclic voltammetry as a function of pH. Cells specially designed for the experiments were used, combining simultaneous pH measurements with absorption spectra and cyclic voltammetry. The substitution kinetics were investigated using a Durrum D-110 stopped-flow instrument equipped with a Kel-F flow system.

RESULTS AND DISCUSSION

The reaction of [Ru(III)(Hedta)H_2O] with 2-mercaptopyridine in neutral or slightly acidic solutions leads to a red complex absorbing at λ_{max} = 550 nm (ε = 2600 M^{-1} cm^{-1}). Above pH 6, the reaction is followed by the conversion of the red species to a green product absorbing at λ_{max} = 630 nm (ε = 1700 M^{-1} cm^{-1}). Within the pH interval from 3 to 6, these species co-exist in equilibrium, with an isosbestic point at 595 nm, as shown in Fig. 1A.

The pK_a measured in this work for the free ligand was 9.72, in agreement with that reported in the literature.[1] In the thione form (**1B**) the N-atom is protonated and the ligand can only bind via the sulfur atom. As a matter of fact, the red color seems to be characteristic of Ru(III)(edta) complexes with sulfur-containing ligands, being consistent with a ligand-to-metal charge-transfer transition.[10] Similar complexes with pyridine ligands display no charge-transfer bands in the visible.

The distribution of the red and green species can be expressed as in a typical acid–base equilibrium (2), with an apparent pK_a of 4.35 ($K_a = k_3/k_{-3}$ = 4.4×10^{-5} M^{-1}) at 25°C and I = 0.10 M lithium *p*-toluenesulfonate (Lipts)

$$\text{red complex} + H_2O \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \text{green complex} + H_3O^+. \quad (2)$$

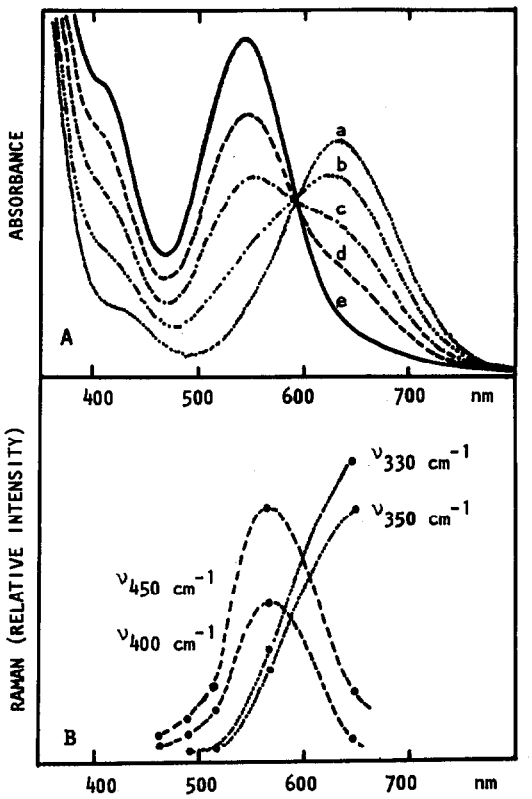


Fig. 1. (A) Electronic spectra of the Ru(III)(edta) complex with 2-mercaptopyridine at pH (a) 6.2; (b) 5.1; (c) 4.4; (d) 4.1; (e) 3.2. (B) Resonance Raman profiles for the most enhanced vibrational bands of the red complex (400, 450 cm^{-1}) and of the green complex (330, 350 cm^{-1}).

Comparative experiments using the 4-mercaptopyridine and 2-mercaptopyridine-N-oxide ligands led exclusively to red products, with no evidence of green species even under strongly alkaline conditions. Presumably, a new chromophore group is present in the green complex, arising from the bidentate properties of the deprotonated 2-mercaptopyridine ligand.

Vibrational spectra

The infrared (IR) and Raman (R) spectra of the 2-mercaptopyridine ligand can be seen in Figs 2A and 3A, respectively. X-ray studies have shown that the ligand molecule exists in the solid state as the thione species (**B**), with a C—S distance of 0.168 nm consistent with 65% double bond character.[12] Based on the examples from the literature, the 'thioamide' I, II, III and IV vibrations[13,14] were tentatively assigned to the observed frequencies at 1360 (w), 1250 (s), 1137 (s) and 740 cm^{-1} (s) in the IR spectra, and at 1375 (w), 1265 (w), 1135 (m) and 737 cm^{-1} (s) in the R spectra, respectively. The ring stretching modes were assigned to the IR peaks at 1610 (w), 1570 (s) 1495 (m), 1440 (m) and to the R peaks at 1613 (w), 1580 (w), 1505 (m), 1450 cm^{-1} (w). The breathing vibrational modes were observed at 980 (m) or 995 cm^{-1} (m) in the IR or R spectra, respectively. The remaining IR bands at 600 (w), 475 (w) and 430 cm^{-1} (w), and R bands at 625 (w), 450 (w) and 395 cm^{-1} (w) are related with the

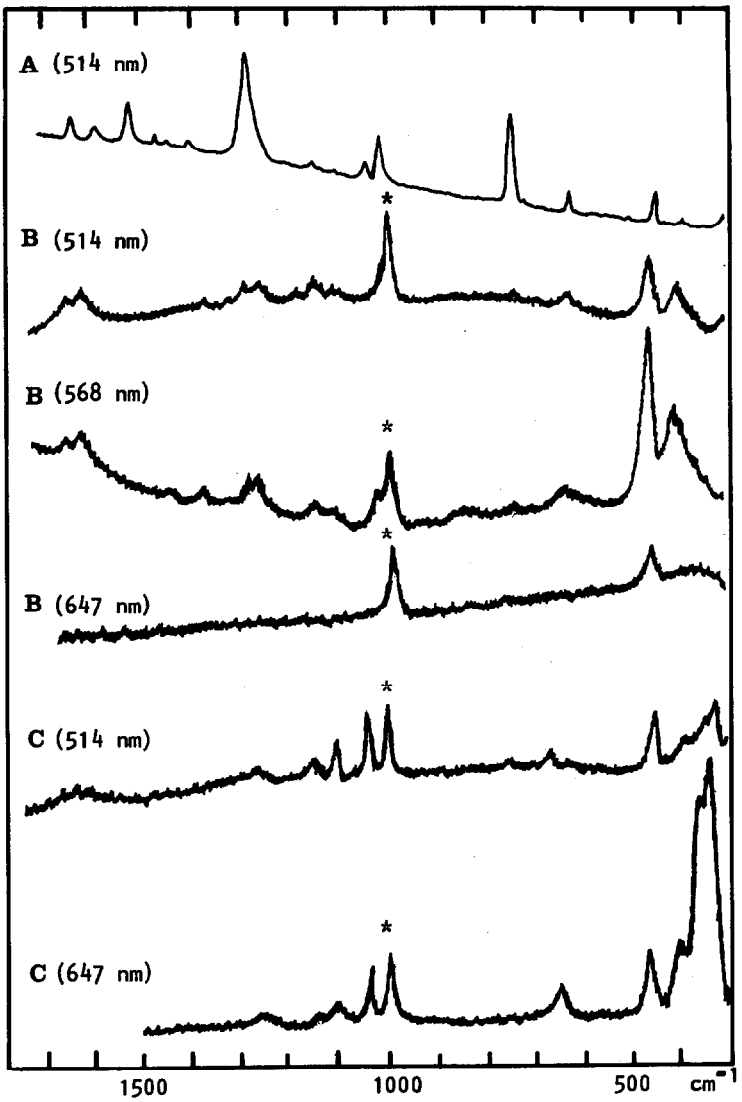

Fig. 3. (A) Raman spectra of the 2-mercaptopyridine ligand in the solid state, and (B) of aqueous solutions of the red (0.5 mM), and green Ru(III) complex (1 mM), at several excitation wavelengths, in the presence of 0.10 M sodium sulfate (* = sulfate band).

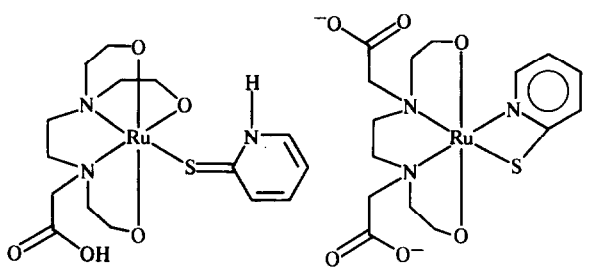
several deformation modes involving the C—H and C—C bonds (w = weak, m = medium, s = strong).

The IR spectra of the red [Ru(III)(Hedta) HSpy]·$4H_2O$ and green $(NH_4)_2$[Ru(III)(edta) Spy]·nH_2O complexes (Fig. 2) are complicated by the strong overlap of the vibrational bands of the Ru(Hedta) or Ru(edta)$^-$ moieties with those of the 2-mercaptopyridine ligand. The non-coordinated carboxylic group in the red complex is responsible for the absorption band at 1725 cm^{-1}, in the IR spectra. The ring vibrational bands are masked by the strong absorptions at 1625 cm^{-1} associated with the asymmetric vibrational modes of the carboxylate groups. The thioamide bands are less intense in the red complex, being practically negligible in the green species. This kind of behavior is consistent with the expected decrease of the C=S double bond character due to the coordination to the ruthenium(III) ion. As a matter of fact, for a number of thione ligands coordinated through the sulfur, it has been observed that the C=S stretching band around 1150 cm^{-1} decreases dramatically in intensity and in most cases completely disappears.[15,16]

The R spectra exhibit a resonance effect, leading to an enhancement of the vibrational bands associated with the Ru(III)-HSpy chromophore. In this way, several vibrational bands which are masked in the IR spectra can be detected in the resonance Raman (RR) spectra of the complexes, as shown in Fig. 3. Typical RR excitation profiles for the red and green species are shown in Fig 1B. The maximum

enhancement is observed for the low frequency vibrations at 450 and 400 cm^{-1} for the red species, and at 458, 400, 350 and 330 cm^{-1} for the green one. Because of the specific electronic states involved in the RR effect, the enhanced bands in the region of the metal–ligand vibrations can be particularly useful in the assignment of the chromophore groups. Recent work[17,18] has shown that the metal–sulfur stretching vibrations usually appear in the region of 400–500 cm^{-1}. Therefore, the enhancement observed in this region is consistent with the presence of a Ru(III)—S bond in the complexes. On the other hand, the strongly enhanced vibrational bands at 330 and 350 cm^{-1} are only observed in the spectra of the green species, suggesting the existence of an additional Ru(III)—N bond in a chelate configuration. Although five geometrical isomers are theoretically possible in this case, recent studies[19,20] on tetradentate ruthenium–edta complexes have indicated a *trans* configuration for the carboxylate groups, with the bidentate ligand lying in the plane of the nitrogen atoms. According to these arguments, the following structures can be proposed for the red and green species:



Red complex A **Green complex B** (3)

Kinetic studies

The kinetics of the substitution reactions of $[Ru(III)(Hedta)H_2O]$ with various entering monodentate ligands have been previously investigated by Matsubara and Creutz.[7] The observed rate constants were dependent on the pH, exhibiting a maximum value within the pH range from 2.4 to 7.6, which correspond to the pK_as of the Hedta and H_2O ligands in the complex, respectively.[7,9] In the acetate buffer pH region, the kinetics are associated with the $[Ru(III)(edta)H_2O]^-$ complex. Our preliminary results obtained for the substitution reactions with HSpy were similar to those reported by Matsubara and Creutz.[7] The reactions proceeded according to a pseudo-first-order kinetics for at least two half-lives. The observed rate constants exhibited a maximum, practically constant value in the $4 < pH < 6$ region. However, in contrast with the preceding cases, two successive reactions were detected in this work. The first reaction leading to the red complex was ascribed to the substitution of H_2O by the thione ligand. The second reaction was associated with the partial or total conversion of the red complex to the green one.

Table 1 summarizes the kinetic data for the successive reactions. The observed rate constants for the first reaction are proportional to the concentration of the 2-mercaptopyridine ligand, leading to the specific rates and activation parameters shown in Table 2, along with some related data from the literature, for comparison purposes. The substitution rates for the $[Ru(III)(edta)H_2O]^-$ complex and the corresponding activation parameters depend on the nature of the entering ligands, and are consistent with an associative mechanism, as previously proposed in the literature.

In the presence of acetate buffer, the second reac-

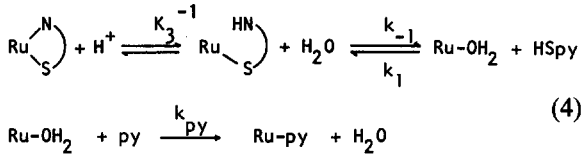
tion proceeds to an equilibrium position [equation (2)], with an apparent $pK_a = 4.35$. The observed rate constants shown in Table 1 do not depend on the concentration of 2-mercopyridine, and are coherent with a relaxation process involving the deprotonation of the coordinated ligand. In this case, the formal equilibrium constant can be expressed by $K = k_3/k_{-3} \cdot [H^+]$, and the observed rate constants are given by $k_{obs} = k_3 + k_{-3} \cdot [H^+]$. The calculated values of k_3 and k_{-3} were 1.9 s^{-1} and 1.2×10^4 M^{-1} s^{-1}, respectively.

It should be noted that the relaxation process observed in this work is relatively slow. Since the proton transfer reactions are diffusion controlled,[21] the measured rate can not be ascribed to a simple acid–base reaction. The changes in the absorption spectra are consistent with an appreciable reorganization of the coordination sphere. Considering that the deprotonated 2-mercaptopyridine ligand is potentially bidentate, the displacement of a coordinated carboxylate group would lead to a chelate chromophore group, as deduced from the RR spectra. This explanation is in harmony with the several examples of chelate complexes of 2-mercaptopyridine, previously reported in the literature.[2,22]

The substitution of the HSpy ligand from the complex was not detected in the presence of a ligand such as thiocyanate, isonicotinamide or pyrazine, because of their unfavorable stability constants (Table 2). However, by using a high excess of pyridine the substitution reaction proceeded to completion, leading to the decay of the characteristic charge-transfer bands in the visible. A pseudo-first-order behavior was observed for at least two half-lives, with a saturation of k_{obs} versus the concentration of the pyridine ligand, as shown in Table 1. A similar behavior has been reported by Matsubara and Creutz[7] for the substitution reactions of [Ru(III)(edta)L] (L = $NCCH_3$ or SCN^-) in the presence of pyrazine, to form [Ru(III)(edta)pz]$^-$. In both cases the observed rate constant was independent of the pyrazine concentration, and practically identical to the dissociation rate constant k_{-L}. No evidence of direct replacement of L by pyrazine has been found, leading to the conclusion that the reaction proceeds through [Ru(III)(edta)H_2O]$^-$ formed by dissociation of [Ru(III)(edta)L].

Based on the considerations from the literature, and on the microscopic reversibility principle, we propose the following mechanism for the substitution reactions in the [Ru(III)(edta)Spy]$^{2-}$ complex:



(4)

Assuming a steady-state approximation for the concentration of the [Ru(III)(edta)H_2O]$^-$ complex,

$$-\frac{d[Ru(III)(edta)Spy^{2-}]}{dt} = k_{obs}[Ru(III)(edta)Spy^{2-}] \quad (5)$$

$$k_{obs} = \frac{k_{py}k_{-1}K_3^{-1}[H^+][py]}{k_1[HSpy] + k_{py}[py]}.$$

Under the conditions of this work [py] ≪ [HSpy], and the pyridine term predominates in the denominator of equation (5). Therefore,

$$k_{obs} = k_{-1}K_3^{-1}[H^+] = 2.5 \times 10^{-4}\,s^{-1}.$$

Since $K_3^{-1} = 2.2 \times 10^4$ M^{-1} and $[H^+] = 3.3 \times 10^{-6}$ M, k_{-1} can be calculated as 3.4×10^{-3} s^{-1}. The equilibrium constant for the formation of the red complex is given by $K_1 = k_1/k_{-1} = 3.1 \times 10^6$ M^{-1}.

The substitution reaction of $[Ru(II)(edta)H_2O]^{2-}$ with HSpy was also studied in this work, in order to compare with the Ru(III) reaction. The kinetics was typically of first order for at least two half-lives. The observed rate constants were proportional to the concentration of the HSpy ligand, as shown in Table 1, with $k_2 = 2.45 \pm 0.8 \times 10^3$ M^{-1} s^{-1} at 25°C, $I = 0.10$ M Lipts, pH 4.5 (acetate buffer). This value is two orders of magnitude higher than those reported by Matsubara and Creutz,[7] suggesting an associative mechanism for the substitution reaction in the $[Ru(II)(edta)H_2O]^{2-}$ complex.

Electrochemistry

Cyclic voltammograms of the [Ru(III)(edta) HSpy]$^-$ complex, obtained at several pHs, are shown in Fig. 4. Below pH 3 and above pH 6 only a pair of anodic and cathodic waves can be observed, corresponding to the reversible monoelectronic reduction of the red [Ru(III)(Hedta) HSpy] and green [Ru(III)(edta)Spy]$^{2-}$ species, with $E_{1/2} = 0.134$ V ($D = 4 \times 10^{-6}$ cm^2 s^{-1}) and -0.103 V versus NHE ($D = 4 \times 10^{-6}$ cm^2 s^{-1}), respectively. The spectroelectrochemical behavior of the complexes (Fig. 5) was typically reversible, with a Nernst slope of 0.058 V and $E^\ominus$ values consistent with those obtained from the cyclic voltammograms. The electronic spectra of the ruthenium(II) complexes can also be seen in Fig. 5.

In the pH range from 3 to 6, the equilibrium between the red and green species can be readily detected in the cyclic voltammograms, as shown in Fig. 4A. The apparent pK_a value based on the cathodic peak heights was 4.34 ± 0.05, in agreement with the spectrophotometric results. Three additional points can be explored in the cyclic voltammograms of Fig. 4. The first point is the systematic shift of the anodic and cathodic peaks of the red species as a function of pH. This particular kind of dependence is illustrated in the internal plot of Fig. 4. The Nernst slope of 0.060 V/pH is consistent with a reversible deprotonation of the oxidized complex. The estimated pK_a for the [Ru(III)(Hedta)HSpy] complex was 2.9 ± 0.2. This value is comparable with that previously reported for the $[Ru(III)(Hedta)H_2O]$ complex[9] (p$K_a = 2.36$), involving the deprotonation of the non-coordinated carboxylic group. The corresponding pK_a for the $[Ru(II)(Hedta)H_2O]^-$ complex is 3.20,[9] in comparison with p$K_a \cong 4$ for the [Ru(II)(Hedta)HSpy]$^-$ species, estimated from the second intercept in the internal plot of Fig. 4. The half-wave potential for the reduction of [Ru(III)(edta)HSpy]$^-$, measured at pH 4.5, was 0.082 V versus NHE.

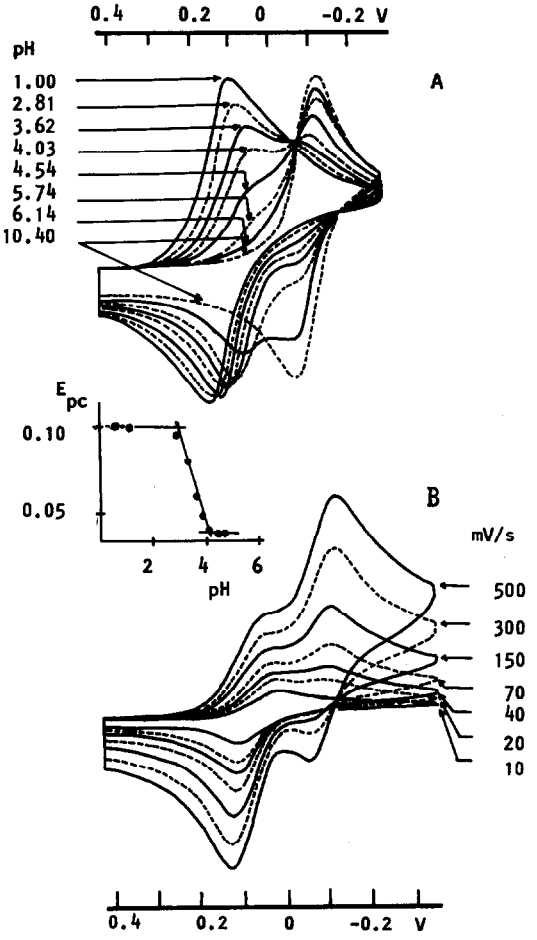


Fig. 4. Cyclic voltammograms of the ruthenium(III)/(II)–(edta) complexes of 2-mercaptopyridine (5 mM, $I = 0.10$ M Lipts, 25°C) at several pHs (scan rate = 0.10 V s^{-1}) and at several potential scan rates (pH = 4.43). The internal plot illustrates a typical dependence of $E_{1/2}$ versus pH for the red species.

Using the redox potentials and equilibrium constants for the Ru(III)(edta) complexes, a complete thermodynamic cycle can be proposed, as shown in Fig. 6, allowing the evaluation of the corresponding parameters for the reduced species.

A second point which has been analyzed in Fig. 4B is the pronounced dependence of the relative heights of the cathodic waves of the red and green species with respect to the potential scan rates. This kind of behavior is consistent with scheme (6) involving an electrochemical process proceeded by

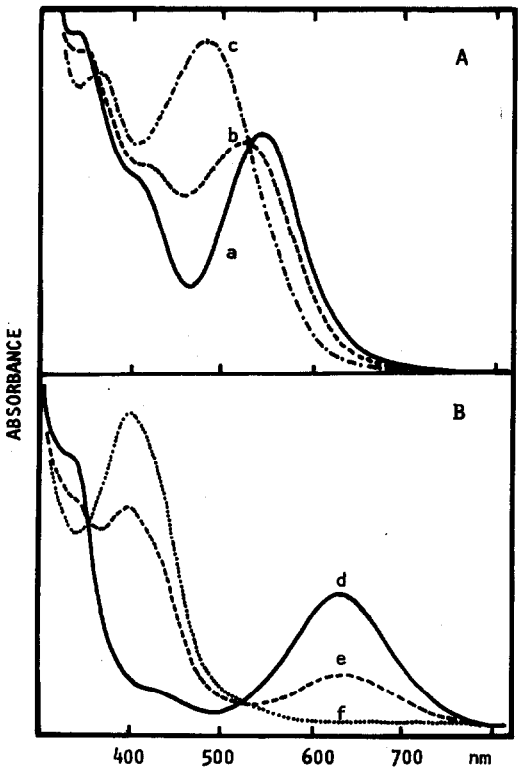

Fig. 5. Spectroelectrochemistry of the ruthenium(III)/(II)–(edta) complexes of 2-mercaptopyridine at (A) pH 2.8, and (B) pH 9.2, $I = 0.10$ M Lipts. Applied potentials. (a) 0.22, (b) 0.32, (c) 0.42, (d) 0.12, (e) −0.13 and (f) −0.28 V versus NHE.

a chemical reaction:

$$[(\text{edta})\text{Ru(III)Spy}]^{2-} + \text{H}^+ \underset{k_3}{\overset{k_{-3}}{\rightleftharpoons}} [(\text{edta})\text{Ru(III)HSpy}]^- \xrightarrow{+e} [(\text{edta})\text{Ru(II)HSpy}]^{2-} \quad (6)$$

At low potential scan rates, the chemical reaction competes with the electrochemical process and the current function becomes dependent on the kinetic constants k_{-3} and k_3, as well as, on the potential scan rates a. In this case, the kinetic constants can be estimated using Nicholson and Shain's[23] equation (7), where i is the observed cathodic current for the red species and i_d is the diffusion-controlled current calculated from the data in the absence of chemical reactions.

$$\frac{i_d}{i} = 1.02 + \frac{0.471}{K}\left(\frac{a}{k_3 + k_{-3}[\text{H}^+]}\right)^{1/2}. \quad (7)$$

Theoretical analysis has shown that the contribution of the green species to the currents measured at the peak potentials of the red species is

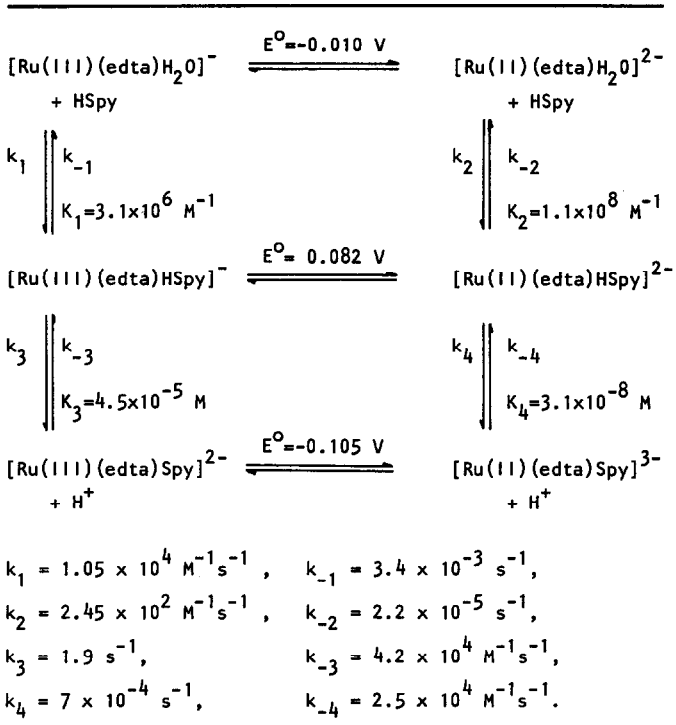

Fig. 6. Thermodynamic cycle for the ruthenium(III)/(II)–(edta) complexes of 2-mercaptopyridine (25°C, $I = 0.10$ M Lipts, pH 4.54 acetate buffer).

practically zero. Typical results for $k_{obs} = k_3 + k_{-3}\cdot[H^+]$ obtained at pH 4.55 and at potential scan rates of 0.200, 0.100, 0.075, 0.050 V s^{-1} were 3.0, 3.3, 3.2 and 3.0 s^{-1}, respectively, with an average of 3.1 ± 0.2 s^{-1}. From the values of K and k_{obs}, the kinetic constants k_3 and k_{-3} were calculated as 1.9 s^{-1} and 4.2×10^4 M^{-1} s^{-1}, respectively, in excellent agreement with the stopped-flow results.

The third interesting aspect is the dependence of the relative heights of the anodic peaks on the potential scan rates, as shown in Fig. 4B. At high rates, the reduced forms of the red and green species are reoxidized rapidly enough during the reverse scan, allowing the evaluation of the interconversion rates from the measurements of the anodic peak heights as a function of time. The observed rate constant, $k_{obs} = k_4 + k_{-4}\cdot[H^+]$, obtained in this way at pH 4.55, was 0.68 ± 0.07 s^{-1}. Based on the equilibrium constant of the ruthenium(II) complex estimated from the thermodynamic cycle in Fig. 6 ($K_4 = k_4/k_{-4}\cdot[H^+]$), we obtained $k_4 = 7 \times 10^{-4}$ s^{-1} and $k_{-4} = 2.5 \times 10^4$ M^{-1} s^{-1}.

A comparison of the thermodynamic and kinetic parameters of the ruthenium(III) and (II) complexes can be seen in Fig. 6. The Ru(II) complexes are relatively more stable and inert than the Ru(III) ones, with $k_{-2} = k_2/K_2 = 5 \times 10^{-5}$ s^{-1}. According to the thermodynamic data, the bidentate ruthenium(II) species is more susceptible to protonation than the corresponding ruthenium(III) analog. The difference, however, is associated with the k_3 and k_4 constants, rather than with the k_{-3} and k_{-4} protonation constants. The higher basicity of the ruthenium(II) mercaptopyridine complex is consistent with the expected backbonding interactions in the system.

A POTENTIOMETRIC STUDY ON COMPLEX FORMATION OF NICKEL(II) AND ZINC(II) IONS WITH 3-(2-NAPHTHYL)-2-MERCAPTOPROPENOIC ACID

ALVARO IZQUIERDO* and JOSE LUIS BELTRAN

Department of Analytical Chemistry, Faculty of Chemistry, University of Barcelona, 08028 Barcelona, Spain

(*Received* 29 *April* 1986; *accepted* 15 *August* 1986)

Abstract—Protonation and complex formation equilibria between zinc and nickel ions with 3-(2-naphthyl)-2-mercaptopropenoic acid (NMPA) have been studied in 50% (v/v) water–ethanol solutions containing 1 M $NaClO_4$ as constant ionic medium at 25°C using glass electrode potentiometry. Initial estimates of complex formation constants were refined with the MINIGLASS program. Protonation constants for the ligand and formation constants for the complexes Ni(NMPA), $Ni(NMPA)_2$, Zn(NMPA)H, Zn(NMPA) and $Zn(NMPA)_2$ are reported.

Studies of several 3-aryl-2-mercaptopropenoic acids as analytical reagents for the spectrophotometric determination of metal ions have been reported because of their selectivity and high sensitivity for certain metal ions as nickel(II),[1] titanium(IV)[2] or molybdenum(VI).[3] Although there are few references about the complexation of metals with these compounds,[4,5] it has been shown that the metal complexes formed with the 3-aryl-2-mercaptopropenoic acids are more stable that the formed with 3-aryl-2-mercaptopropanoic acids;[6] this effect is due to the conjugated double bond between carbonyl and aryl groups.

In biological studies, Foye and Lo[4] reported antibacterial activity for the 3-phenyl-2-mercaptopropenoic acid, and Wagner *et al.*[5] found that the aryl-mercaptopropenoic acids were potent inhibitors of metalloenzymes; it seems that the strong complexation of this type of compounds with metal ions has effect in trace metal metabolism.

In the present work we have studied the complexation of 3-(naphthyl)-2-mercaptopropenoic acid against the nickel(II) and zinc(II) metal ions by glass electrode potentiometry[7] to find the effect of enlarging the 3-aryl group in the stability of complexes with divalent ions. This study has been carried out in water–ethanol medium (50% v/v) because of the low solubility of this ligand in aqueous medium. The ionic strength of medium was 1.00 M in $NaClO_4$, and the temperature was kept constant to 25 ± 0.1°C.

EXPERIMENTAL

Materials

3-(2-Naphthyl)-2-mercaptopropenoic acid (NMPA) was synthesized following the procedure of Campaigne and Cline[8] by condensation of 2-naphthaldehyde with rhodanine, subsequent hydrolysis in alkaline medium, and acidification with mineral acid. By twice recrystallization from benzene under nitrogen the NMPA was obtained as yellow crystals with m.p. 170°C. The purity was determined by potentiometric titration with sodium hydroxide and by iodometric titration with potassium iodate solution.[9] Both sets of titrations were performed in water–ethanol medium because of the low solubility of NMPA in water. Found: C, 64.9; H, 4.32; S, 13.70. Required for $C_{13}H_{10}O_2S$: C, 64.60; H, 4.38; S, 13.90%.

Solutions of NMPA were prepared immediately before use to avoid the oxidation of the mercapto group.

Nickel(II) and zinc(II) perchlorates were pre-

* Author to whom correspondence should be addressed.

pared by dissolving $NiCO_3$ and ZnO, respectively, in a 1 : 1 perchloric acid solution and recrystallized from water. Nickel(II) stock solution was standardized gravimetrically as dimethylglioximate and the zinc(II) solution was determined by complexometric titration with EDTA.[10]

Carbonate-free sodium hydroxide solution in water–ethanol medium (50% v/v) was prepared from sodium hydroxide pellets, and standardized by titration against potassium hydrogen phthalate.

Stock solutions of aqueous perchloric acid were standardized against recrystallized sodium tetraborate.[11]

Solutions were prepared with double distilled water and absolute ethanol, so that all solutions were 50% (v/v) water–ethanol. To maintain ionic strength, the solutions were made up to a perchlorate concentration of 1.00 M by addition of sodium perchlorate stock solution. The ionic medium ($NaClO_4$) was prepared from sodium carbonate and perchloric acid by a literature method.[12]

All solutions were deaerated with nitrogen before use, and all reagents were of analytical grade.

Apparatus

Radiometer PHM 84 pH-meter was used with a Radiometer G 202 B glass electrode and an Ag/AgCl reference electrode[13] in a Wilhelm-type salt bridge.[14] The titrations corresponding to a complex formation with NMPA with Ni(II) and Zn(II) were performed with an automatic titration and data acquisition assembly described in a previous work.[15]

The sodium hydroxide solution was added with a Metrohm E 415 automatic burette. The temperature was controlled by a Selecta mod. Tectron thermostat.

Method

Protonation constants for NMPA and formation constants for their metal complexes were determined by potentiometric titration in a jacketed vessel, thermostatted at 25 ± 0.1°C by circulating water. Acidic solutions (T.S.) containing the reagents (ligand or ligand–metal) were titrated with sodium hydroxide solution, and during the titration pure nitrogen[16] was passed through the solution to remove dissolved oxygen. The variation of free hydrogen ion concentration was measured using the cell:

$$\text{Ag/AgCl(s)} \;\Big|\; \begin{matrix}0.01\text{ M NaCl*}\\ 0.99\text{ M NaClO}_4\end{matrix} \;\Big|\; \begin{matrix}1\text{ M NaClO}_4\text{*}\end{matrix} \;\Big|\; \text{T.S.*} \;\Big|\; \begin{matrix}\text{Glass}\\ \text{electrode}\end{matrix}$$

* 50% (v/v) ethanol–water.

The electrode system was calibrated in terms of hydrogen ion concentration by the Gran method.[17]

Protonation curves of NMPA were obtained at several ligand concentrations, and the complex formation curves were obtained at different metal concentrations and different ligand : metal ratios. The experimental conditions of titrations performed are listed in Table 1. The concentration of ligand is limited by its low solubility, even in the water–ethanol medium.

RESULTS AND DISCUSSION

The protonation curve of NMPA shows two protonation constants, corresponding to carboxylate and thiol groups. By comparing this curve with a set of normalized curves,[18] approximate values

Table 1. Experimental conditions of potentiometric titrations

11	2.369	—	2.050	1.2	2.0–3.6

found for the constants were $\log(\beta_{101}) = 8.9$ and $\log(\beta_{102}) = 13.05$.

The formation curves for the Ni(II)–NMPA system corresponding to several metal concentrations were all superimposable (Fig. 1); thus indicating that for this system only the mononuclear NiL and NiL_2^{2-} species were present in the concentration range studied. Initial values for stability constants obtained by comparison with normalized curves were $\log(\beta_{110}) = 9.85$ and $\log(\beta_{210}) = 20$.

For the Zn(II)–NMPA system, the formation curves from different titrations were not all superimposables (Fig. 2), as those corresponding to a low ligand : metal ratio show a deviation. Furthermore, the other curves showed no correspondence with the set of normalized curves, showing the presence of another species other than the mononuclear ones.

Numerical calculations of these systems were performed on a HP 9816 S desk computer, by using the MINIGLASS program.[15] The protonation constants were refined using the PKAS procedure; in this case the function minimized (U) is defined by:

$$U = \sum_{i=1}^{n} (-\log[H^+]_{i,\text{exp}} + \log[H^+]_{i,\text{calc}})^2.$$

The complex equilibria between NMPA and Ni(II) and Zn(II) were studied using the COMPLEX procedure of MINIGLASS. For comparison of results, we have used the two possible options, refining by the $-\log[H^+]$ of the solution and by the titrant volume added (V_t). For the Ni(II)–NMPA system, the obtained values of formation constants were consistent with those calculated graphically. In the Zn(II)–NMPA system the best set of species compatible with the experimental data were 1 : 1 : 1, 1 : 1 : 0 and 2 : 1 : 0 (referred to ligand : metal : hydrogen), and the values obtained refining by $-\log[H^+]$ and V_t were virtually the same. With the set of constants obtained for this system, were have constructed the theoretical formation curves for titrations 8–11 (Fig. 3), showing good agreement with the experimental formation curves.

The results of calculations for protonation and complex formation constants, together with the final values, are summarized in Table 2.

By comparing the pK_a values for NMPA calculated from the protonation constants ($pK_{a_1} = 4.16$, $pK_{a_2} = 8.89$) with those of the analogous compound, 3-(1-naphthyl)-2-mercaptopropenoic acid[19] with $pK_{a_1} = 4.07$ and $pK_{a_2} = 9.32$ in the same medium, we have seen that the dissociation constants for the carboxyl groups are very similar, but the acidity of thiol group is higher in 3-(2-naphthyl)-2-mercaptopropenoic acid than in the 1-naphthyl derivative, as might be expected from the different resonant effect in the position 2 of the naphthyl group.

[a] The estimated standard deviation on the final digit is given in parentheses.
[b] Calculated by PKAS procedure.
[c,d] Calculated by COMPLEX procedure (by V_t and $-\log[H]$, respectively).

In reference to complex formation with Ni(II) and Zn(II) ions, the lack of formation of polynuclear species founded in saturated mercaptoacids without arylic substituent with these metal ions, as in mercaptoacetic[20] or 2-mercaptopropanoic[21] acids, can be explained by steric hindrance and the resonance effect between the sulphur atom and the naphthyl group through the conjugated double bond in the 3-aryl-2-mercaptopropenoic acids. Similar evidence was found by Wagner *et al.*[5] in studying the complexation of several 3-aryl-2-mercaptopropenoic acids with these metal ions.

With the final values of constants in Table 2, we have studied the species distribution for the systems Ni(II)–NMPA and Zn(II)–NMPA–H (see Figs 4 and 5) for a metal and ligand concentrations of 1 mM and 3 mM, respectively. The obtained distributions show the high affinity of NMPA for these divalent ions as, at $-\log[H^+] = 4$, less than 1% of metal ion remains uncomplexed. Analytical interest has the reaction of NMPA with the Ni(II) ion, because at this acidity level the complex $Ni(NMPA)^{2-}$ is practically the only Ni(II) species present.

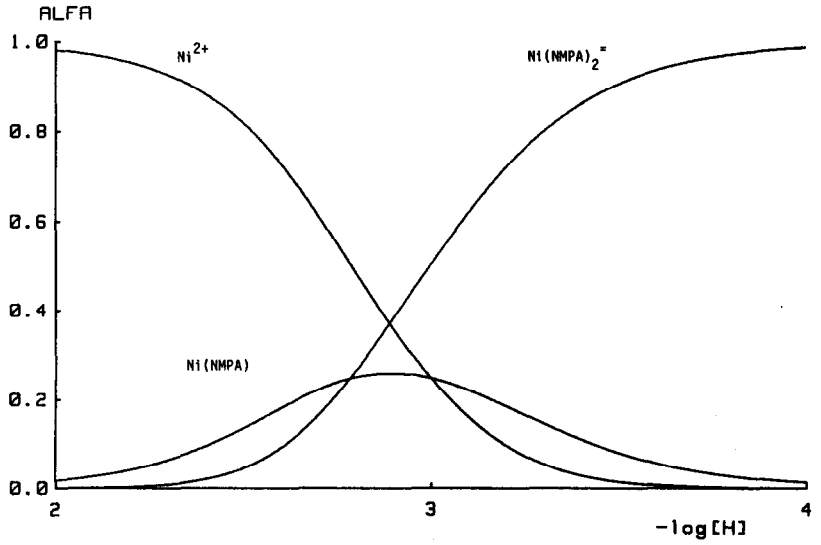

Fig. 4. Species distribution for Ni(II)–NMPA complexes. $[Ni^{2+}] = 1$ mM, [NMPA] = 3 mM.

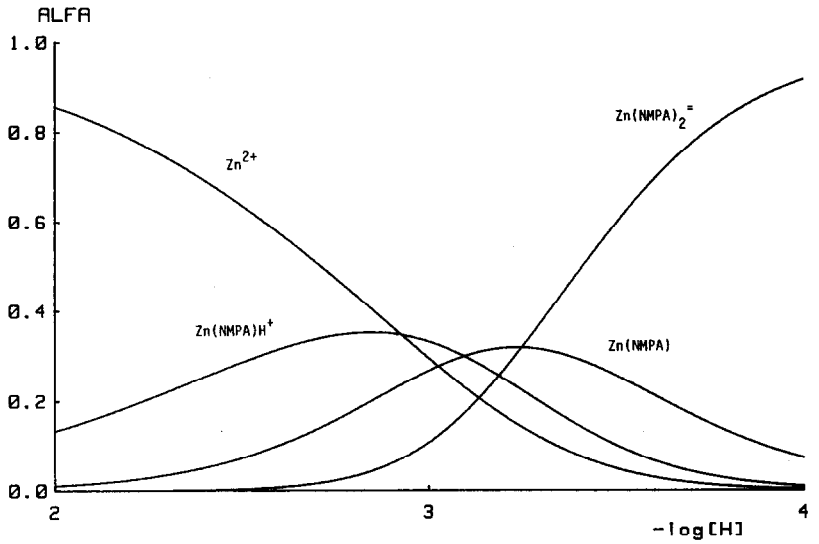

Fig. 5. Species distribution for Zn(II)–NMPA–H complexes. $[Zn^{2+}] = 1$ mM, [NMPA] = 3 mM.

ELECTRON-RICH BORANES AND RELATED MOLECULES

BRIAN W. CLARE and DAVID L. KEPERT*

School of Chemistry, University of Western Australia, Nedlands, Western Australia, Australia

(*Received* 1 *May* 1986; *accepted* 15 *August* 1986)

Abstract—The mathematical modelling procedure developed previously for predicting the structure of *closo*-$B_nH_n^{2-}$, *nido*-$B_nH_n^{4-}$ and *arachno*-$B_nH_n^{6-}$ has been extended to the next two homologous series, for which the names *eka*-$B_nH_n^{8-}$ and *dva*-$B_nH_n^{10-}$ are proposed. Specific structural predictions are made for each of these molecules, most of which have yet to be synthesised. An atom–electron map is proposed that conveniently shows the relation between the boron hydrides and the hydrocarbons (and related species such as the polyphosphide and polysulfide ions).

The *closo*-boron hydrides, $B_nH_n^{2-}$, consist of polyhedral clusters of boron atoms, the structures of which can be mathematically modelled if it is assumed that each boron atom interacts with every other boron atom in the cluster, the extent of the interaction depending only upon the interatomic distance.[1–3] A useful potential that relates the energy between any pair of boron atoms, u_{B-B}, to the internuclear distance, d_{B-B}, is given by the bi-reciprocal expression (1):

$$u_{B-B} = \frac{1}{d_{B-B}^2} - \frac{1}{d_{B-B}}. \quad (1)$$

In comparison with molecular orbital methods, this technique replaces a small number of very strongly bonding interactions across the interior of the polyhedron by a larger number of weaker cross-polyhedral interactions that have bonding energies comparable to the interactions around the surface of the cluster.

The structures of the *nido*-boron hydrides that are based on the formula $B_nH_n^{4-}$ can be obtained in the same manner if an interaction, u_{B-ep}, between the additional electron pair and each boron atom is incorporated into the model,[4] a suitable expression being:

$$u_{B-ep} = \frac{2.2}{d_{B-ep}^4} - \frac{1.2}{d_{B-ep}}. \quad (2)$$

Increasing the number of electron pairs in the molecule, as in *arachno*-$B_nH_n^{6-}$, requires the addition of an interaction between the electron pairs, u_{ep-ep}, an appropriate expression being:

$$u_{ep-ep} = \frac{0.1}{d_{ep-ep}^4}. \quad (3)$$

In the expressions (1)–(3), energy and distance are both in arbitrary units but nevertheless the stereochemical arrangement of atoms can be accurately predicted.

In this work, these three potentials are used to extrapolate these structural predictions to molecules based on the series $B_nH_n^{8-}$ and $B_nH_n^{10-}$. Some comments are first made on the extent of this area of interest.

THE RELATION BETWEEN THE HOMOLOGOUS SERIES OF BORON HYDRIDES AND THE HOMOLOGOUS SERIES OF HYDROCARBONS

The addition of successive pairs of electrons to the *closo*-boron hydrides, $B_nH_n^{2-}$, forms homologous series based on the formulae *nido*-$B_nH_n^{4-}$ and *arachno*-$B_nH_n^{6-}$, the structural prefixes denoting closed convex polyhedral structures, partially opened out nest-like structures, and more completely opened out and more complex spider web-like structures, respectively. The addition of n electron pairs to the *closo*-compounds would form $B_nH_n^{(2n+2)-}$, isoelectronic with the homologous series of saturated hydrocarbons C_nH_{2n+2}. Progressing in the reverse direction, that is by the removal of an

* Author to whom correspondence should be addressed.

electron pair from the saturated hydrocarbons and the addition of one "bond", forms the cyclic hydrocarbons and the alkenes, C_nH_{2n}. (In this electron counting exercise, a double bond can simply be imagined as a two-membered ring.) Removal of a second electron pair and addition of another bond forms C_nH_{2n-2}, the bicyclic alkanes, monocyclic alkenes, dienes and alkynes. A dominant feature of this area of chemistry is the very large number of structural isomers possible for any chemical composition.

We propose that the relation between the homologous series based on the boron hydrides and the homologous series based on the hydrocarbons is conveniently depicted by the atom–electron map shown in Fig. 1. Each hexagonal cell represents a fixed number of skeletal atoms and a fixed number of electron pairs. The number of skeletal atoms, n, increases on descending the map and the number of electron pairs increase from left to right. The three sloping columns on the left hand side corresponding to the three homologous series of boron hydrides are indicated, as are the three sloping columns on the right hand side corresponding to the first three series of hydrocarbons. It is clear that these two sets of homologous series meet and cross near the top of the map. The top hexagonal cell at $n = 0$ corresponds to H_2, the two cells at $n = 1$ correspond to BH_3 and CH_4, respectively (and isoelectronic species such as BH^{2-} and BH_4^-), the three cells at $n = 2$ correspond to $B_2H_2^{2-}$, B_2H_6 (or C_2H_4) and C_2H_6, respectively, and so on.

The observation that these two sets of homologous series, one based on the boron hydrides and one based on the hydrocarbons, are not parallel with one another leads to a dilemma in chemical

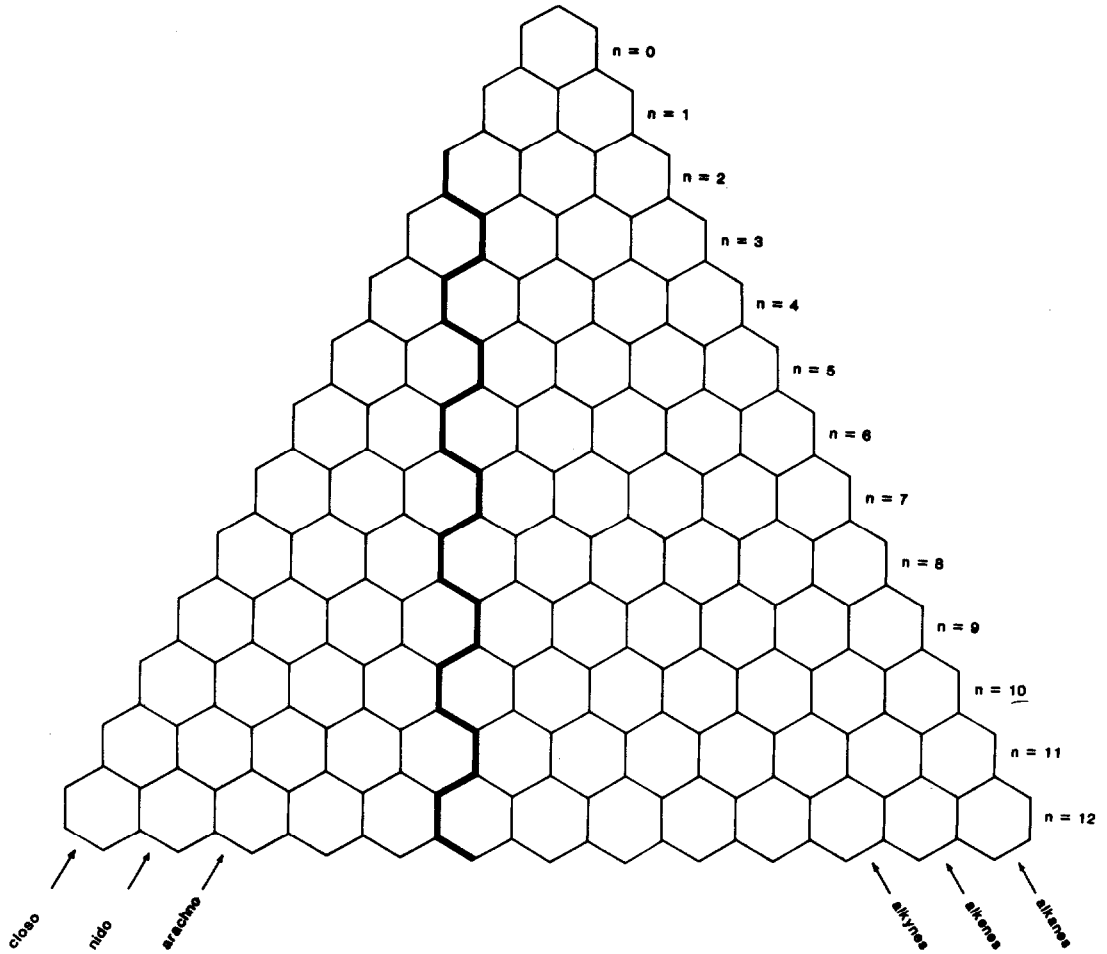

Fig. 1. Atom–electron map. Each hexagonal cell represents a fixed number of atoms and a fixed number of electron pairs, the number of atoms n increasing from top to bottom and the number of electron pairs increasing from left to right. The locations of the first three homologous series of boron hydrides are shown, as are the first three homologous series of hydrocarbons. The heavy zig-zag vertical line represents the left hand limit for which two electron/two atom bonding schemes can be drawn.

nomenclature. Continuation of the structural prefixes, *closo-*, *nido-*, *arachno-* to subsequent series $B_nH_n^{x-}$, where $x = 8$, 10, 12, is not appropriate as the type of structure is expected to depend upon the size of the cluster. Smaller members, for example $B_4H_4^{10-}$ which is isoelectronic with the alkene C_4H_{10}, would be expected to have opened out structures whereas the larger members of the same series, for example $B_{12}H_{12}^{10-}$, would be expected to retain much of the cluster characteristics of the *closo-*, *nido-* and *arachno*-compounds. Prefixes that have been used include *hypho-* and *conjuncto-*. There are very few compounds known of the types $B_nH_n^{8-}$ and $B_nH_n^{10-}$ and until more information is available we propose the use of the following temporary prefixes. The first is *eka-* (Sanskrit: one), which has an illustrious chemical tradition as it was chosen by Mendeleev for unknown elements whose existence was required to fill the spaces in his Periodic Table; it could also be used for the first series beyond the *arachno*-series. The subsequent series would then become *dva-* (Sanskrit: two).

The heavy vertical zig-zag line in Fig. 1 is the left hand limit for which classical two electron/two atom bonding schemes can be drawn for molecules containing skeletal atoms restricted to a valency of four and in which each skeletal atom is bonded to one non-skeletal atom or group, or contains one non-bonding pair of electrons. Examples to the immediate right hand side of this zig-zag line include C_nH_n or P_n (n = even) and $C_n H_{n+1}$ or P_n^- (n = odd). For example, P_7^{3-} [5] and Sb_7^{3-} [6] are adequately represented as analogues of tricycloheptane C_7H_{10}, with P atoms replacing CH groups and P^- ions replacing CH_2 groups.

It is not clear where the right hand limit for compounds based on clusters exists in Fig. 1, although it does appear to overlap the left hand limit of the classical structures.

It is also clear from Fig. 1 that for larger molecules there is an area between the *arachno*-series and the classical structure limit. This area of chemistry is relatively unknown.

These questions are further explored in this paper using the mathematical modelling procedures that have been developed for cluster compounds and summarized above.

RESULTS

As might have been expected, the structural chemistry of the compounds in the area investigated is complicated by the large number of isomers that occur and it did not appear to be feasible to locate all possible minima on the potential energy surfaces. The more stable isomers that have been located so far for each member of the *eka*-$B_nH_n^{8-}$ series are shown in Fig. 2; only those isomers that are within 0.1000 energy units of the most stable structure are shown (Table 1). Similarly Fig. 3 and Table 2 list the more favourable structures found for the *dva*-$B_nH_n^{10-}$ series.

Table 1. Energies (arbitrary units) for those *eka*-$B_nH_n^{8-}$ depicted in Fig. 2 (in the same order)

$B_nH_n^{8-}$	Energies
$B_3H_3^{8-}$	−4.7897
$B_4H_4^{8-}$	−6.8350, −6.7772
$B_5H_5^{8-}$	−9.0768
$B_6H_6^{8-}$	−11.4974, −11.4498, −11.4163
$B_7H_7^{8-}$	−14.1054, −14.1074, −14.1113, −14.1314
$B_8H_8^{8-}$	−16.9436, −17.0434
$B_9H_9^{8-}$	−20.0775, −20.1581, −20.0816
$B_{10}H_{10}^{8-}$	−23.4723, −23.4285, −23.4676, −23.4380
$B_{11}H_{11}^{8-}$	−26.9791, −26.9981, −26.9646
$B_{12}H_{12}^{8-}$	−30.7655, −30.7254

The eka-$B_nH_n^{8-}$ *series*

The calculations show that *eka*-$B_3H_3^{8-}$ is expected to have a bent structure with the three electron pairs in a plane at right angles to the plane of the three skeletal atoms. This structure is in contrast to the equilaterial triangular arrangement predicted[7] for *closo*-$B_3H_3^{2-}$, *nido*-$B_3H_3^{4-}$ and *arachno*-$B_3H_3^{6-}$, an example of the latter structure being Pr_3P_3.[8] Examples of the bent *eka*-$B_3H_3^{8-}$ structure include the isoelectronic propane C_3H_8, and groups of heavier atoms such as P_3^{5-}, S_3^{2-}, Te_3^{2-} and I_3^+.[9-11]

Figure 2 shows the two possible structures for *eka*-$B_4H_4^{8-}$. The first is a four-membered ring as is observed in cyclobutane, C_4H_8, P_4^{4-} and As_4^{4-}.[12,13] The second possible structure is the less stable planar open-chain trapezoidal arrangement. A

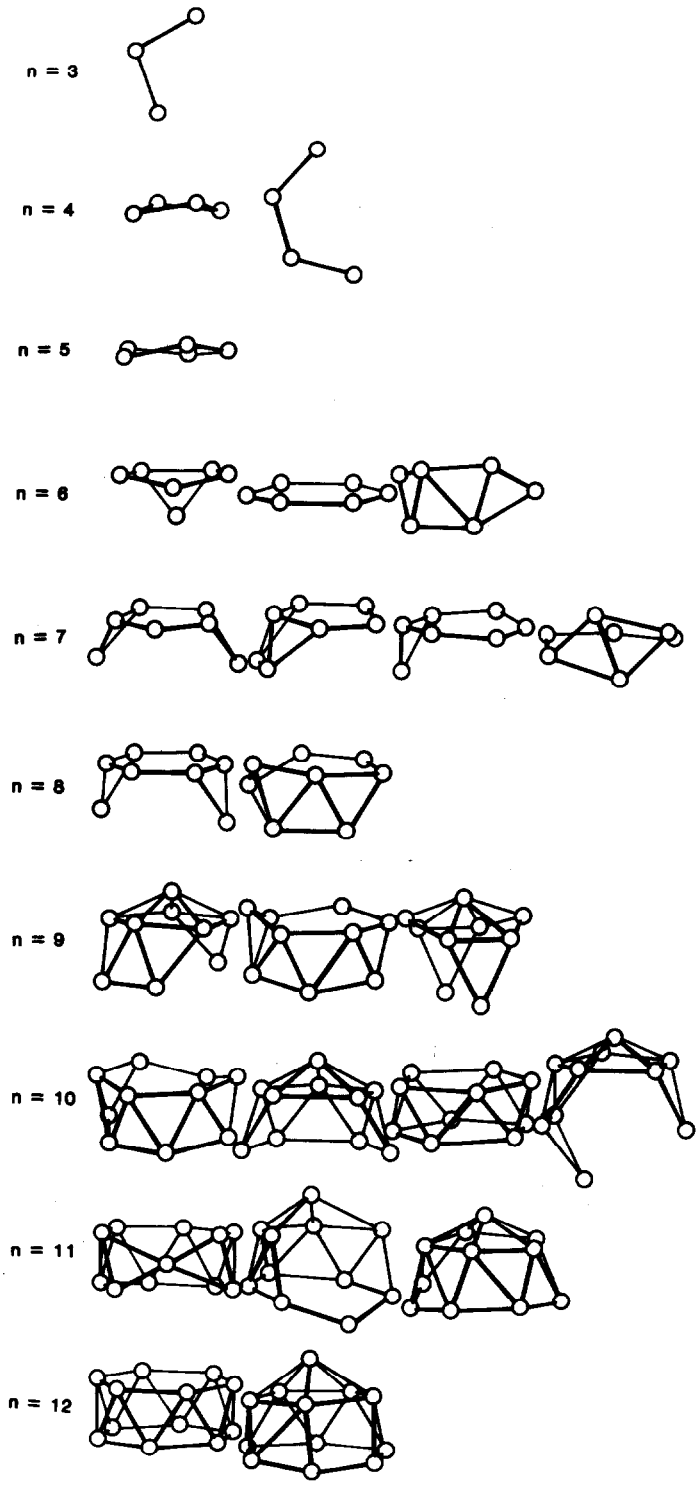

Fig. 2. Structures of *eka*-$B_nH_n^{8-}$.

cyclic structure is also predicted as the most stable arrangement for *eka*-$B_5H_5^{8-}$, or cyclopentene, C_5H_8.

A number of isomers are possible for $B_6H_6^{8-}$. The most stable structure consists of a five-membered ring linked to a three-membered ring while a closely related monocyclic structure is formed by breaking the 1–3 "bond"; both structures can be considered as isomers of C_6H_8. If the three electron pairs are arranged on the same side of the molecule, a structure of four linked triangles is formed, as is observed in $B_6H_{10}(PMe_3)_2$.[14] A fourth isomer, existing as a

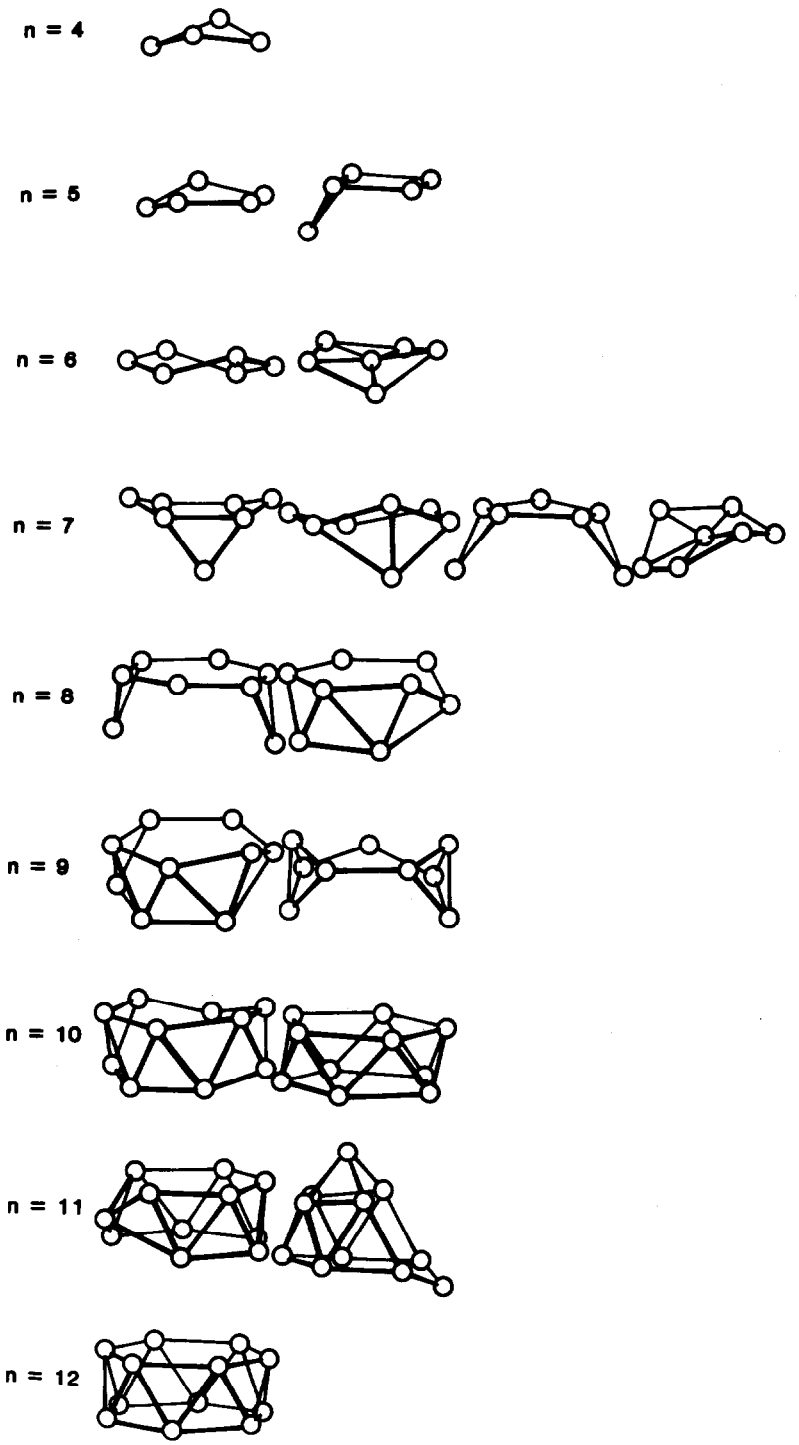

Fig. 3. Structures of *dva*-$B_nH_n^{10-}$.

minimum on the potential energy surface but not shown in Fig. 2 because it is 0.1088 energy units less stable than the bicyclic structure, consists of a trigonal prismatic arrangement of atoms with a pair of electrons outside each of the rectangular faces. This trigonal prismatic structure is experimentally known for Te_6^{4+},[15] although it may be noted that molecular orbital calculations have been used to predict a significant distortion of the prism.[16]

Figure 2 shows that for *eka*-$B_nH_n^{8-}$, where $n = 7$–12, the predicted structures are complex clusters but there appears to be little experimental confirmation for compounds in this area. Some structural relationships are discussed later.

The dva-$B_nH_n^{10-}$ *series*

Ring structures are predicted for $B_4H_4^{10-}$ and $B_5H_5^{10-}$ (Fig. 3) with two pairs of electrons on each side of the ring. In addition, a second isomer is possible for $B_5H_5^{10-}$, with one electron pair on one side of the molecule and three electron pairs on the other side of the molecule. Similarly,the most stable structure for $B_6H_6^{10-}$ is a planar six-membered ring with two electron pairs on each side. This structure is known for the P_6^{4-} anion.[17] It may be noted, however, that the structure of the P_7^{3-} anion[5] (and a number of closely related species[18]), does not have any of the structures shown in Fig. 3 for $B_7H_7^{10-}$, but has a conventional structure based on simple electron pair bonds with octets about each atom.

The larger *dva*-boranes consist of complex clusters of atoms only some of which have high symmetry, for example the pentagonal antiprismatic structure of $B_{10}H_{10}^{10-}$ and the hexagonal antiprismatic structure of $B_{12}H_{12}^{10-}$. Another interesting structure is the second isomer found for $B_{11}'H_{11}^{10-}$ which can be considered as a 156 stack with one atom in the pentagonal plane missing (Fig. 3). This structure has C_{2v} symmetry, the two-fold axis passing through the atom in the bottom right hand corner of the view shown in Fig. 3. Alternatively, this structure can be considered to be based on two linked six-membered rings forming a wedge enclosing the other two atoms, with two pairs of electrons outside each hexagonal ring. Replacement of the two enclosed atoms with electron pairs would form a highly symmetrical D_{3h} structure composed of two three-membered rings and three six-membered rings, with two electron pairs outside each six-membered ring. This structure also occurs as a minimum on the potential energy surface and is predicted for *catur*-$B_9H_9^{14-}$ (*catur*: Sanskrit for *four*) and related molecules including P_9^{5-} and S_9^{4+}.

DISCUSSION

It has been noted previously[4] that one of the isomers for each of the *arachno*-$B_nH_n^{6-}$ compounds has a structure closely related to the single structure for each of the *nido*-$B_nH_n^{4-}$ compounds, in which the single electron pair in the *nido*-compound is replaced by two adjacent electron pairs in the *arachno*-compound. Similarly in this work it is found that many of the *eka*-$B_nH_n^{8-}$ compounds are related to an *arachno*-isomer, and that many of the *dva*-$B_nH_n^{10-}$ isomers are related to an *eka*-isomer. In some instances the same structure is observed across the three series, *arachno*-$B_nH_n^{6-}$, *eka*-$B_nH_n^{8-}$ and *dva*-$B_nH_n^{10-}$. For example, the most stable structure found for $B_5H_5^{6-}$, $B_5H_5^{8-}$ and $B_5H_5^{10-}$ is a pentagonal ring with electron pairs distributed on both sides of the ring. Similarly a hexagonal ring is found for $B_6H_6^{6-}$, $B_6H_6^{8-}$ and $B_6H_6^{10-}$. In $B_7H_7^{x-}$ there are two isomers common across the three series, the first consisting of a hexagon and a triangle sharing an edge, and the second consisting of two edge-shared triangles with three additional atoms completing the ring (Figs 2 and 3). An even more extensive structural series is found for the nonaboranes, where the structure derived from an icosahedron by removal of the three atoms from the same face and replacing them with a region of increasing electron density is found for *nido*-$B_9H_9^{4-}$, *arachno*-$B_9H_9^{6-}$, *eka*-$B_9H_9^{8-}$ (0.1110 energy units less stable than the most stable structure and therefore not shown in Fig. 2) and *dva*-$B_9H_9^{10-}$ (0.2153 energy units higher than the most stable structure and therefore not shown in Fig. 3).

In order to examine the overall structural pattern in these molecules it is instructive to consider the series of twelve atom clusters, $B_{12}H_{12}^{x-}$, where $x = 2$, 4, 6, 8 and 10 (Fig. 4). The *closo*-compound, $B_{12}H_{12}^{2-}$, is a regular icosahedron. The icosahedron is also obtained for *nido*-$B_{12}H_{12}^{4-}$, which contains the additional pair of electrons at the centre of the cluster. The second additional pair of electrons in *arachno*-$B_{12}H_{12}^{6-}$ opens out the polyhedron to form a distorted 156 stack in which one pair of electrons is at the centre of the cluster and the other is outside the hexagonal face. A distorted variant of this structure is found in $C_4Me_4B_8H_8(C_5H_4)Co(C_5H_5)$[19] (the cobalt atom is not part of the cage formed by the four carbon atoms and eight boron atoms). Extension to *eka*-$B_{12}H_{12}^{8-}$ yields two possible isomers as separate potential energy minima. The first is the hexagonal antiprism in which one electron pair is situated in the centre of the cluster with the other two electron pairs situated outside the two hexagonal faces. The second isomer is the 156 stack in which one electron pair is in the interior of the molecule, one near the centre of the hexagonal face and one outside the hexagonal face. Addition of a fourth electron pair to form *dva*-$B_{12}H_{12}^{10-}$ leads only to a distorted hexagonal antiprism with one electron pair near the centre, one outside one hexagonal face and two outside the other.

It is often convenient to consider *nido*-compounds containing less than twelve skeletal atoms to be fragments of icosahedra, the only exception being the small $B_5H_5^{4-}$, which is square pyramidal. Similarly, the *arachno*-compounds can be considered as fragments of an icosahedron or fragments of a 156 stack, or both, the only exception being the square isomer of the small $B_4H_4^{6-}$ anion. These descriptions in terms of fragments of these twelve-vertex polyhedra appear to be more useful

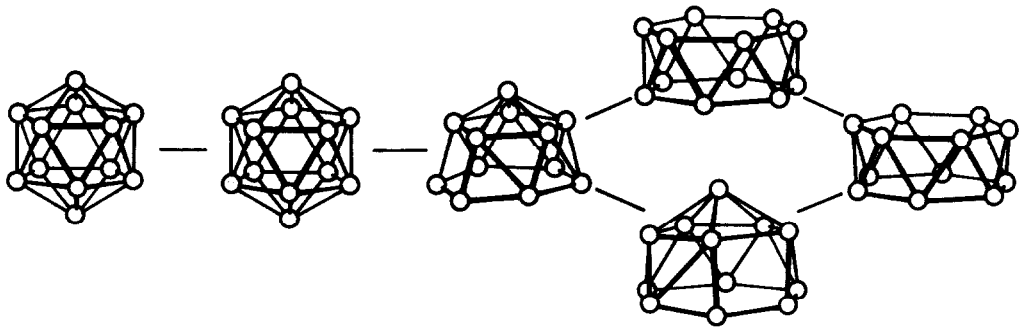

Fig. 4. Structures, from left to right, of *closo*-$B_{12}H_{12}^{2-}$, *nido*-$B_{12}H_{12}^{4-}$, *arachno*-$B_{12}H_{12}^{6-}$, *eka*-$B_{12}H_{12}^{8-}$ (two isomers) and *dva*-$B_{12}H_{12}^{10-}$.

than the description as fragments of the *closo*-compounds.

The structural predictions made in this work in general cannot as yet be verified because boranes corresponding to many of the hexagonal cells in Fig. 1 have not yet been synthesized. A great many carboranes are now known but the vast majority contain only two skeletal carbon atoms as they are usually synthesized by incorporating alkynes into boranes. Care needs to be taken in extrapolating the structural correlations found here to molecules containing other elements. There are two main reasons for this caution:

(1) The atom–atom potential (1) used in this work was derived from the structures of *closo*-$B_8H_8^{2-}$ and *closo*-$B_9H_9^{2-}$.[1] However, mathematical modelling of clusters of the heavier *p*-block elements, for example, Sn_5^{2-}, $TlSn_8^{3-}$ and $TlSn_9^{3-}$, yield significantly "harder" potentials such as:[3]

$$u_{Sn-Sn} = \frac{1}{d_{Sn-Sn}^4} - \frac{1}{d_{Sn-Sn}}.$$

Further extension to transition metal organometallic clusters yields very hard potentials as in, for example, $[Os_5(CO)_{16}]$ and $[Rh_9(CO)_{19}]^{3-}$:[3]

$$u_{Os-Os} = \frac{1}{d_{Os-Os}^{10}} - \frac{1}{d_{Os-Os}^4}.$$

At the present time nearly all the electron-rich compounds beyond the *arachno*-series contain organometallic fragments incorporated into the borane fragment and the resulting distortions make the perception of structural correlations difficult.[20]

Even replacement of a boron atom in the formula of a borane by an isoelectronic carbon cation, C^+, is possible to only a limited extent before substantial structural changes are observed. For example,in *nido*-$C_4Me_4B_8H_8$[21] and *nido*-$C_4Et_4B_8H_8$[20] the C_4B_8 icosahedra are distorted due to the lengthening of the C–C edges so that the coordination number of the carbon atoms is reduced from six to five. In many carbon-rich carboranes the carbon atom is bonded to two terminal groups and the group is displaced out of the cluster of remaining atoms until it approximates to a methylene group bridging two of the remaining cluster atoms.[20] Conversely, it is possible to visualize many carbon-rich carboranes as basic hydrocarbon skeletons in which a CH_2 group is replaced by a BH group, regardless of electron count. Thus $C_4H_4B_6Me_6$ adopts the adamantane structure rather than that expected for *nido*-$B_{10}H_{10}^{4-}$.[22]

(2) The atom–electron pair potential used in this work was derived from *nido*-$B_{10}H_{14}$ and the minimum potential occurs at about the same boron–electron pair distance as the boron–boron distance corresponding to the minimum boron–boron potential.[4] That is, in a borane the electron pair occupies approximately the same space as a boron atom. Thus addition of one electron pair to the tetrahedral *closo*-$B_4H_4^{2-}$ forms *nido*-$B_4H_4^{4-}$ in which the structure is partially opened out and consists of only two triangles sharing an edge.[4] However P_4, As_4 and Sb_4, which have the *nido*-electron count, appear to be regular tetrahedral.[23] This structure can be attributed to the additional electron pair occupying less space than the phosphorus atoms and can be accommodated at the centre of the cluster. The situation can be likened to the contraction of non-bonding pairs of electrons in simple compounds such as $[MX_3(\text{lone pair})]$ as the Periodic Table is descended.[24] Similarly many Zintl phases AX and BX_2 (A = Na, K, Rb, Cs; B = Sr, Ba; X = Si, Ge, Sn, Pb) contain tetrahedral X_4^{4-} ions,[25,26] as do $Na_8(Tl_4)$[27] and $[K(2,2,2\text{-crypt})]_2(Pb_2Sb_2)$.[28] On the other hand, molecules such as P_4 can be simply represented as each phosphorus atom forming simple localized electron pair bonds to the other three phosphorus atoms, with a non-bonding pair of electrons completing a tetrahedral arrangement of electron pairs.

For these heavier elements a second electron pair

is required to form the opened out structure, as in P_4H_2[29] and Si_4^{6-},[30] similar to B_4H_{10} or dicyclobutane, C_4H_6. In these compounds the two electron pairs occupy the *cis*-sites of an octahedron with the four skeletal atoms at the other four vertices. An octahedral structure with electron pairs in *trans*-sites and a square planar arrangement of atoms is compounds such as $[K(crypt)]_2(Sb_4)$,[31] $[K(crypt)]_2(Bi_4)$,[32] $(Se_4)(HS_2O_7)_2$[33] and $(Te_4)(AlCl_4)_2$.[34]

Larger clusters of the *p*-block elements with the *nido*-electron count also have polyhedral structures closely related to the *closo*-compounds and the additional electron pair can again be imagined as being located in the centre of the cavity. Examples include Ge_9^{4-},[35] Sn_9^{4-}[36-38] and Bi_9^{5+}.[39]

In an analogous manner the electron count of the larger transition metal carbonyl clusters can also be interpreted in terms of the 18-electron rule with an additional electron pair being located at the centre of the cluster leading to, for example, the 86 electron octahedral clusters such as $[Rh_6(CO)_{16}]$.

REACTION OF $[Ni(CN)_4]^{2-}$ WITH POLYSULFIDE: SYNTHESIS OF $[Ni(S_4)_2]^{2-}$ AND ITS REACTIONS WITH CARBON DISULFIDE AND ACTIVATED ACETYLENES

K. NAGENDRA UDPA and SABYASACHI SARKAR*

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 20 *June* 1986; *accepted* 15 *August* 1986)

Abstract—Bis(tetrasulfido)nickelate(II) is synthesized by the reaction of tetracyanonickelate(II) with polysulfide. The reaction of $[Ni(S_4)_2]^{2-}$ with CS_2 and substituted acetylenes forming the perthiocarbonato and dithiolene complexes is described. The dithiolene complexes are found to be oxidized by one unit. The compounds are characterized by various physicochemical methods. The biorelevance of this work is very briefly outlined.

The dissolution of certain transition metal salts in aqueous ammonium polysulfide solution has long been known and was generally attributed to the formation of soluble metal polysulfides. Although the first example of such a compound came in 1903 when Hofmann and Höchten reported[1] the synthesis of $(NH_4)_2PtS_{15}\cdot 2H_2O$, a systematic approach to a study of these systems started only a few years back. This is mainly due to the advent of the spectroscopic and structural techniques which made it possible to characterize and study these compounds. Since then a host of polysulfido complexes with a variety of metal ions have been synthesized and characterized and a recent review[2] summarizes the results of investigations carried out on these systems so far. The polysulfide ions are capable of coordinating to metal centers in a variety of ways thereby giving complexes with novel structural features. They are purely inorganic chelating ligands and the size of the sulfur chain can be varied by changing the reaction conditions. They can undergo unusual reactions leading to the formation of new novel complexes. They may find applications in catalysis[3] and help in understanding certain biochemical reactions.[4] In this paper we describe the synthesis of $[Ni(S_4)_2]^{2-}$ by the interaction of $[Ni(CN)_4]^{2-}$ with polysulfide and its reactions with carbon disulfide and activated acetylenes forming the perthiocarbonato and dithiolene complexes, respectively.

EXPERIMENTAL

Materials and methods

Reagent grade chemicals and solvents were employed. Solvents were distilled before use. $K_2[Ni(CN)_4]\cdot H_2O$,[5] dibenzoylacetylene (DBA),[6] dimethylacetylene dicarboxylate (DMAD)[7] and ammonium polysulfide[8] solution were prepared by literature methods. Potassium polysulfide solution in methanol was prepared by passing a moderately fast stream of hydrogen sulfide gas into a suspension of sulfur (20 g) and potassium hydroxide (4 g) in methanol (100 cm^3) for about 2 h with occasional stirring. The orange–red solution of the polysulfide was filtered to remove the excess sulfur. Only freshly prepared polysulfide solutions were used in the reactions.

C, H and N were analyzed at the Microanalytical Laboratories, I.I.T., Kanpur. Nickel was estimated gravimetrically as the dimethylglyoximate after decomposing the compounds with *aqua regia*. Sulfur in the compounds was oxidized to sulfate by alkaline bromine and estimated as barium sulfate. Electronic spectra were recorded on Cary-17D and Shimadzu UV-190 spectrophotometers. The infrared spectra as CsI pellets were obtained on a Perkin–Elmer Model-580 spectrophotometer. Magnetic susceptibility measurements were carried out on an EG and G Model-150A parallel field vibrating sample magnetometer. Electron spin resonance spectra were obtained on a Varian E-109 EPR system working at X-band frequencies using DPPH as standard.

$(PPh_4)_2[Ni(S_4)_2]$, *Method A*

$K_2[Ni(CN)_4]\cdot H_2O$ (0.5 g, 1.93 mmol) was added with stirring to 25 cm^3 of aqueous ammonium polysulfide solution. After the mixture was stirred for 5 min in a stoppered flask, the dark brown solution was filtered into a solution of PPh_4Cl (1.5 g, 4 mmol) in 25 cm^3 of methanol. Allowing the solution to stand for 30 min gave reddish brown microcrystals, which were filtered, washed with little deoxygenated water, methanol, toluene and finally with diethylether. The product was dried under vacuum; yield 0.77 g (40%).

Method B

PPh_4Cl (1.5 g, 4 mmol) was dissolved in 50 cm^3 of methanolic potassium polysulfide solution. $K_2[Ni(CN)_4]\cdot H_2O$ (0.5 g, 1.93 mmol) dissolved in minimum amount of water (*ca* 1 cm^3) was added with stirring. The resulting solution was boiled on a water bath for 5 min when the color of the solution became very dark brown. It was quickly filtered and the filtrate was allowed to stand in a stoppered flask at room temperature. In about an hour, dark brown crystals precipitated, which were filtered, washed with methanol, toluene and diethylether; yield 0.67 g (35%).

$(Et_4N)_2[Ni(S_4)_2]$

Tetraethylammonium bromide (1.0 g, 4.76 mmol) was dissolved in 50 cm^3 of methanolic potassium polysulfide solution. $K_2[Ni(CN)_4]\cdot H_2O$ (0.5 g, 1.93 mmol) was added in small portions with stirring and the reaction mixture was boiled on a water bath for 10 min. The dark brown solution was filtered and the filtrate was allowed to stand at 5°C for several hours. The precipitated shining black crystals were filtered, washed and dried as described above; yield 0.33 g (30%).

$(PPh_4)_2[Ni(CS_4)_2]$

Carbon disulfide (5 cm^3) was added to a solution of freshly prepared $(PPh_4)_2[Ni(S_4)_2]$ (0.5 g, 0.5 mmol) in dichloromethane (40 cm^3). The solution was stirred for 10 min and filtered. Addition of diethylether to the filtrate gave yellow–brown microcrystals, which were filtered, washed with diethylether and dried; yield 0.36 g (70%).

$(PPh_4)[Ni(S_2C_2(COC_6H_5)_2)_2]$

0.5 g (0.5 mmol) of freshly prepared $(PPh_4)_2[Ni(S_4)_2]$ and DBA (0.25 g, 1.07 mmol) were dissolved in dichloromethane (50 cm^3) and stirred at room temperature for 20 min. The solution was filtered and to the filtrate an excess of petroleum ether (40–60°C) was added. An oily mass separated. The supernatant liquid was decanted off and the oil was repeatedly washed with petroleum ether whereby it solidified. Recrystallization by CH_2Cl_2–petroleum ether gave the product as brown microcrystals; yield 0.2 g (40%).

$(PPh_4)[Ni(S_2C_2(COOCH_3)_2)_2]$

Freshly prepared $(PPh_4)_2[Ni(S_4)_2]$ (0.3 g, 0.3 mmol) and DMAD (0.1 cm^3, 0.81 mmol) were stirred in CH_2Cl_2 at room temperature for 20 min. A work-up similar to the one given above, gave the product as brown microcrystals; yield 0.05 g (20%).

RESULTS AND DISCUSSION

Tetracyanonickelate(II) is one of the most stable complexes of nickel and only very few substitution reactions of this anion are reported in the literature.[9] The ready enhancement of the coordination number of this anion and the synthesis of $[Ni(CN)_3S]^{3-}$ by a curious cyanide elimination reaction by sulfide[10] prompted us to study the elimination of coordinated cyano groups with polysulfide.

The reaction of $[Ni(CN)_4]^{2-}$ and polysulfide is quite facile both in aqueous and methanolic media, $[Ni(S_4)_2]^{2-}$, thus formed was briefly reported by us.[11] Almost simultaneously Müller and coworkers[12] published the X-ray crystal structure of this anion prepared by the reaction of nickel(II) acetate with methanolic ammonium polysulfide. The elemental analysis of this and the other compounds are presented in Table 1. The synthesis of $[Ni(S_4)_2]^{2-}$ probably proceeds by the stepwise replacement of coordinated cyanide ligands. The cyanide is converted into thiocyanate as soon as it gets replaced by reaction with sulfide of the polysulfide. The tentative scheme (Scheme 1) given below for this reaction with the proposal of the formation of the dicyano(tetrasulfido)nickelate(II) as intermediate seems reasonable in the light of the isolation of $[Ni(CN)_2(S_5)]^{2-}$ by the reaction of *in*

$$[Ni(CN)_4]^{2-} \xrightarrow{S_4^{2-}} \{[Ni(CN)_2(S_4)]\}^{2-} + 2CN^-$$

$$\{[Ni(CN)_2(S_4)]\}^{2-} \xrightarrow{S_4^{2-}} [Ni(S_4)_2]^{2-} + 2CN^-$$

$$CN^- + S_x^{2-} \longrightarrow SCN^- + S_{x-1}^{2-}$$

situ generated polysulfide using sulfur and KOH in DMF in $[Ni(CN)_4]^{2-}$.[3]

The reaction of $[Ni(S_4)_2]^{2-}$ with CS_2 in dichloromethane readily yields the bis(perthiocarbonato)nickelate(II) anion.[14] Recently, the X-ray crystal structure of this anion has been reported by Coucouvanis and coworkers.[15] The reactivity of $[Ni(S_4)_2]^{2-}$ is further demonstrated by its reactions with substituted acetylenes giving the corresponding dithiolene complexes. The reaction of coordinated polysulfide with activated acetylenes is known for other metal systems also.[2] The interesting feature of our reactions is that the dithiolene complexes formed are found to be oxidized by one unit. The oxidizing agent here could be the sulfur formed as a byproduct in the reaction. The reaction of $[Ni(S_4)_2]^{2-}$ with substituted acetylenes though novel is not without precedence since the synthesis of tetraphenylthiophene by diphenylacetylene using freshly prepared nickel sulfide containing a little excess of sulfur as catalyst led to the isolation of a phenylsubstituted dithiolene complex $[Ni(S_2C_2(C_6H_5)_2)_2]$.[16] Here the formation of the dithiolene complex is proposed to be due to the presence of small amounts of a short-lived nickel tetrasulfide species.

The vibrational spectral data of the complexes are given in Table 2. The IR spectral data of $[Ni(S_4)_2]^{2-}$ agrees well with that reported by Müller and coworkers.[12] The IR spectrum of $[Ni(CS_4)_2]^{2-}$

shows the characteristic absorptions of the coordinated perthiocarbonato group. Recently a band at 905 cm^{-1} in the IR spectrum of $[Ni(CS_4)_2]^{-2}$ has been assigned to the C=S vibration.[15] An earlier report[17] assigns this vibration to a peak at 1035 cm^{-1}. In our IR spectrum we observe three strong bands in the region 1030–900 cm^{-1} and a medium intensity band at 855 cm^{-1}. We tentatively assign these bands to C=S vibrations. The vibrations due to S–S and Ni–S modes appear in the lower region and it is difficult to assign them accurately.

A detailed normal coordinate analysis of nickel dithiolene complexes is reported in the literature.[18] In this series $[Ni(S_2C_2R_2)_2]^n$ ($n = 0, -1, -2$) the perturbed C=C stretching frequency is a rough measure of the C=C bond strength as it couples very little with other modes. In a series of mononegative ions the C=C stretching frequency would be mainly dependent on the substituent group on the acetylenic carbon atoms. When R = COC_6H_5 the C=C stretching frequency is found to be about 60 cm^{-1} less than when R = $COOCH_3$. A lower ν(C=C) in the $-COC_6H_5$ substituted complex indicates a better π-electron delocalization than that in the $-COOCH_3$ substituted dithiolene complex. For comparison some of the data reported for similar complexes are also listed in Table 2.

The electronic spectral data of the complexes are given in Table 3. The solid state electronic spectrum of $[Ni(S_4)_2]^{2-}$ and the solution spectrum of $[Ni(CS_4)_2]^{2-}$ agree well with the reported data of these complexes.[12,17] The characteristic features of the electronic spectra of the monoanionic complexes are the intense absorptions in the visible and near infrared region. These bands are not of *d–d* type but have their origin in some sort of charge transfer. Extensive studies on the electronic spectra of nickel dithiolene complexes have been carried out and the assignments of electronic bands for similar systems are available in the literature.[19]

The monoanionic dithiolene compounds give ESR signals at room temperature in the solid state. The interesting feature of these ESR spectra is the considerable anisotropy of the g-tensor. The observed ESR parameters along with the magnetic moment values are presented in Table 4. Using extended Hückel MO calculations Schlapfer and Nakamoto[18] have calculated the electron density of metal character in the highest occupied molecular orbital for some of the monoanionic nickel dithiolene complexes. The results obtained by them are shown in Table 4. It can be seen that the percent metal character of the HOMO depends markedly on the substituent group present on the dithiolene moiety. A comparison of the percent metal character of the HOMO and the $\langle g \rangle$ values suggests that the percent metal character of the HOMO increases roughly with an increase in the $\langle g \rangle$ value. The complexes isolated in this study have the highest $\langle g \rangle$ values compared to the other compounds listed in Table 3.

Recently, the presence of nickel as Ni(III) (ESR active) has been demonstrated in several hydrogenases.[21] The donor atom in the nickel containing hydrogenases has been found to be sulfur.[22] These enzymes give rhombic ESR signals similar to that

of the dithiolene complexes described here but the anisotropy is more pronounced and the $\langle g \rangle$ values are quite high.[23] Nonetheless, the formation of ESR active, stable dithiolene complexes of nickel at normal conditions suggests that this could well be the starting point to synthesize model systems of the nickel containing hydrogenase.

Abstract—The formation constants of the complexes formed between H^+, Cu^{2+}, Ni^{2+}, Co^{2+} and Zn^{2+} and *N*-isobutyroyl-L-lysine (NIBL) [$H_2A^+ = (CH_3)_2CHCONH(CH_2)_4CH(NH_3^+)COOH$] have been determined by potentiometry at 25.0°C and $I = 0.1$ mol dm^{-3} $NaClO_4$. Titration curves of this ligand in the presence of a metal ion did not reveal appreciable complexing in acidic media. At intermediate pH values, after neutralization of the carboxyl group, the presence of the metal ion induces a lowering of the pH value, indicating complex formation. The detection of the species and the determination of the corresponding formation constants has been made with the aid of the MUCOMP refinement program. It has shown that the following species are present in solution: CuA^+, CuA_2, NiA^+, NiA_2, CoA^+, CoA_2, ZnA^+ and ZnA_2. These complexes are likely to be N, O chelates of the glycine type. The cumulative and the stepwise formation constants follow the Irving–Williams series. No evidence was found for the deprotonation of the amide group.

The formation constants of the complexes formed between copper(II) and the polymeric analog of NIBL, poly(*N*-methacryloyl-L-lysine) were determined in the same way. For this purpose, it was necessary to consider as the ligand a hypothetical molecule made up of two repeat units. The results obtained are in good agreement with those of spectroscopic measurements.

We are currently investigating the complex properties of optically active hydrosoluble polymers derived from natural amino acids. These polymers have –C–NH–CH(R)COOH as their side chain where R depends on the nature of the amino acid used for the synthesis. Up to now, polymers derived from alanine ($R = CH_3$), glutamic acid [$R = (CH_2)_2(COOH)$], aspartic acid ($R = CH_2COOH$), asparagine ($R = CH_2CONH_2$) and lysine [$R = (CH_2)_4NH_2$] have been studied.[1–5] As is well known, the ionization and complexing properties of a polymeric ligand are very different from those of a small molecule because the electrostatic interactions between the neighbouring ionizable groups strongly influence all the thermodynamic parameters such as the p*K* values.[6] Thus, to have a best knowledge of the behaviour of these polymers we were led to study low molecular weight compounds considered as models. The present paper reports results obtained with *N*-ε-isobutyroyl-L-lysine $(CH_3)_2CHCONH(CH_2)_4CH(NH_3^+)COOH$ (NIBL), which is the analog of the repeat unit of poly(*N*-ε-methacryloyl-L-lysine) (PNML),[4] using a potentiometric technique. The stability constants of the complexes formed with Cu(II), Ni(II), Co(II) and Zn(II) are compared with those of the lysine (from which NIBL is derived) and glycine complexes.

In a second part of this work, is reported the tentative determination of the formation constants

* Author to whom correspondence should be addressed.

of the complexes of copper(II) with the polymer PNML.

EXPERIMENTAL

Samples

N-ε-isobutyroyl-L-lysine (NIBL) was synthesized by a Schotten Bauman reaction between isobutyroyl chloride and the ε-amino group of L-lysine, the α-amino and carboxyl group being protected by a complex with copper. Details of the experimental procedure will be found elsewhere.[4] NIBL was purified by column chromatography using *n*-butanol as eluant. NIBL was characterized by its rotatory power ($[\alpha]_{546}^{20} = +9.2°$ in water). IR spectroscopy (amide I: 1660 cm^{-1}; amide II: 1525 cm^{-1}; NH: 3300 cm^{-1}; COOH: 1720 cm^{-1}), NMR spectroscopy and elemental analysis. (Found: C, 47.3; H, 8.3; N, 11.0; Cl, 14.2. Calc. for $C_{10}H_{20}N_2O_3$, HCl: C, 47.5; H, 8.3; N, 11.1; Cl, 14.1%.)

Poly(*N*-methacryloyl-L-lysine) (PNML) was prepared by free radical polymerization of *N*-methacryloyl-L-lysine and purified according to a procedure described elsewhere.[4]

Measurements and calculations

The potentiometric data (added volume of sodium hydroxide, pH of the solution) were collected using the automated titration system described elsewhere.[7] Added volumes and pH were measured to a precision of 10^{-4} cm^3 and 10^{-3} pH unit respectively. The studies were carried out at 25.0°C in a 0.10 mol dm^{-3} sodium perchlorate medium and under purified nitrogen. The glass electrode was standardized in the concentration scale with perchloric acid in the presence of 0.10 mol dm^{-3} sodium perchlorate.

Titrations of perchloric acid (2×10^{-3} mol dm^{-3}) with sodium hydroxide (0.25 mol dm^{-3}) were periodically performed in order to check—by using the MUPROT program—the parameters of the measuring cell (zero shift, sensitivity), the ionic product of water as well as the characteristic figures of the titrant (total concentration of the sodium ion and of the carbonate). The carbon dioxide evolution coefficient was fixed at 3×10^{-4}, the liquid junction coefficients remaining always negligible.

Protonation constants for the free ligands were obtained from titrations of the ligands (2×10^{-3} mol dm^{-3}) in the presence of perchloric acid.

The stability constants for the metal complexes were computed from titrations in which the metal: ligand: perchloric acid ratios were 1:1:1, 0.5:1:1, 0.2:1:1, for NIBL and lysine and 0.05:1:1, 0.06:1:1, 0.1:1:1 and 0.2:1:1 for PNML.

The titrations were discontinued when precipitation took place, i.e. when the pH readings became unstable, rejection of such points being also possible during the refinement process on the basis of anomalous residuals. Thus the following maximum pH ranges were used for calculations with Cu(II), Ni(II), Co(II) and Zn(II), respectively: 2.79–10.93; 2.81–10.86; 2.81–9.73; 2.80–11.10. For NIBL and lysine, the data were processed as in earlier studies by use of the MUPROT and MUCOMP multiparametric refinement programs.[7,8] As hydrolysis constants for the metal, the following values were introduced: $Cu_2(OH)_2^{2+}$, $\log \beta_{qj0} = -10.7$; $CoOH^+$: −9.8; $NiOH^+$: −9.3; $ZnOH^+$: −9.8.[9,10]

Besides the stability constants, other parameters such as the total concentration of the ligand, the excess of the strong acid, were simultaneously refined in order to compensate systematic errors. That possibility was evidently used with great care.

RESULTS AND DISCUSSION

The protonation constants of the ligand NIBL are first compared with those of lysine and glycine (Table 1) ($t = 25°C$ and $I = 0.1$ mol dm^{-3} $NaClO_4$).

Table 1. Protonation constants of lysine, NIBL and glycine at 25°C and $I = 0.1$ mol dm^{-3}. Standard deviation (1σ values) are given in parentheses

	Lysine	NIBL	Glycine
$\log K_1$	10.67[a]	9.42(1)[a]	9.56[e]

[a] 0.1 mol dm^{-3} KNO_3, Ref. 11.
[b] Ref. 12.
[c] 0.2 mol dm^{-3} KCl, Ref. 13.
[d] 0.1 mol dm^{-3} $NaClO_4$, this work.
[e] 0.1 mol dm^{-3} $NaClO_4$, Ref. 14.
[f] 0.1 mol dm^{-3} $NaClO_4$, Ref. 15.
[g] 0.15 mol dm^{-3} $NaClO_4$, $t = 37°C$, Ref. 16.

Our values for the protonation constants of lysine in 0.1 mol dm^{-3} $NaClO_4$ are in very good agreement with those previously reported by Brookes and Pettit in 0.1 mol dm^{-3} KNO_3.[11] For NIBL, the protonation constants are much closer to those of glycine than those of lysine. This is due to the absence of the ε-amino group which, in lysine, competes with the α-amino group for the uptake of a proton. At 25°C, the pK of the α-amino group in NIBL is significantly lower than in glycine. This may be due to the presence of an amide group in the molecule, which is known to have an acidifying influence.[17]

Titrations in the presence of metal ion were carried out with [ligand]/[metal] molar ratios ranging from $R = 1$–5.

Figure 1 shows typical titration curves of NIBL in the absence of metal and with Cu(II), Ni(II), Zn(II) and Co(II). The lowering of the pH decreases from copper to cobalt indicating decreasing stability constants for the complexes. The stability constants values are reported in Table 2 as overall formation constants $\beta_{qjp} = [M_qH_jA_p]/[M]^q[H]^j[A]^p$, together with values for lysine and glycine. Various models were fitted to the data and the models selected and reported in Table 2 were those giving for each ligand–metal system, the best statistical fit, consistent with chemical logic.

For lysine, our results for copper, nickel and cobalt are in reasonable agreement with those of Refs 11 and 13 taking into account the difference in the nature of the medium.

Nevertheless the $CuHA_2$ complex was found to be about one log unit more stable in 0.1 mol dm^{-3} $NaClO_4$ than in other media.

With nickel, the MH_2A_3 and MA complexes which were assumed by Brookes and Pettit[11] were not found to improve the refinement of the data.

For the lysine–cobalt system, the MH_2A_3 complex which was tentatively assumed in Ref. 11 was rejected in the calculation.

Table 2 also gives values for the lysine–zinc system for which the MHA, MH_2A_2, MHA_2 and MA_2 complexes were found with stability constants intermediate between those of the nickel and cobalt complexes. The ornithine–zinc parent system was recently investigated by Nair *et al.*[20] who found the following set of complexes: MHA, MA and MH_2A_2. Similar differences between the sets of complexes were found for the copper complexes of ornithine and lysine[11] and are related to the lower values of the protonation constants of ornithine compared to lysine.[11]

For NIBL, the titration data were conveniently explained with only two complexes, namely MA and MA_2, for the four metal ions under study. The stability constants decrease from glycine to lysine and NIBL especially for the nickel and cobalt complexes. This is undoubtedly an effect of steric hindrance due to the additional $COCH(CH_3)_2$ group in NIBL compared to lysine.

The stepwise formation constant ($\log K^{A}_{102}$) for the addition of the second ligand:

$$MA + A \rightarrow MA_2 \qquad (1)$$

is given by:

$$\log K^{A}_{102} = \log \beta_{102} - \log \beta_{101}. \qquad (2)$$

The values are 6.80, 4.29, 3.12 and 3.40 for copper, nickel, cobalt and zinc, respectively. They are always lower than the corresponding $\log \beta_{101}$

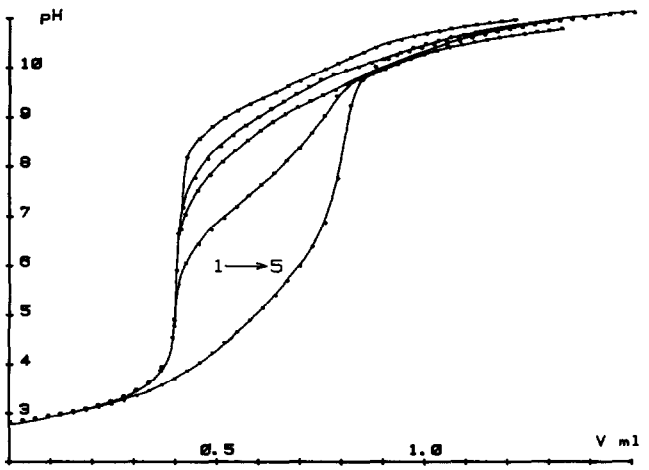

Fig. 1. Titration curves of NIBL and NIBL–metal mixtures in 0.1 mol dm^{-3} $NaClO_4$, 25°C: 1, NIBL; 2, NIBL–Co, $R = 5$; 3, NIBL–Zn, $R = 5$; 4, NIBL–Ni, $R = 2$; 5, NIBL–Cu, $R = 2$.

values, which means that the coordination of the second ligand to the metal is more difficult than the binding of the first one.

Both the cumulative and stepwise formation constants are in accordance with the Irving–Williams series: Co < Ni < Cu > Zn.[21]

From the comparison between NIBL and glycine, it is clear that the complexes formed by NIBL with metal ions are five-membered ring chelates made up of the amino acid extremity. These glycine-like chelates with N, O donor atoms were confirmed by a spectroscopic study using electronic spectroscopy, circular dichroïsm and electron paramagnetic resonance.[4]

Characteristic ratios may be used to compare the affinity of the ligand A for the metal and the proton:[22] $\log \beta_{101}/\log \beta_{011}$ (Table 3).

Values for NIBL and glycine are very close which confirms that the mode of bonding is similar.

The possible role played by the amide group of NIBL has not yet been discussed. In similar molecules such as dipeptides, which also contain an amino and a peptide group, the CuA complex which first appears is a five-membered chelate involving the terminal NH_2 group and the carbonyl of the amide group. In Gly–gly, for example, the complex has a $\log \beta$ value equal to 5.60.[23–25] In NIBL, a similar complex involving the carbonyl group would be a ten membered chelate ring, much less stable and thus with a $\log \beta$ value much lower than 5.6, which is not the case ($\log \beta = 8.00$). In addition, the second step in the case of Gly–gly, is the deprotonation of the amide group with formation of a $CuH_{-1}A$ complex ($\log \beta = 1.50$[20–22]) which has not

Table 3. Characteristic ratios for complexation and acidity constants

Co	0.45	0.48	0.73	0.73
Zn	0.52	—	0.70	—

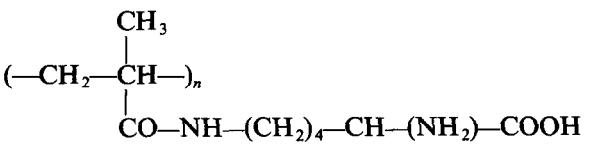
[a] From Refs 15 and 18.

been evidenced for NIBL. In this case, the five-membered chelate ring between the α-amino and carboxyl groups is largely favoured. Nevertheless, the following relationship:

$$\log \beta_{101} = 2 \log \beta_{010} - 10.7$$

which was established for a number of peptides with a glycine in the N terminal position,[26,27] holds for the CuA complex of NIBL. This indicates that the stability of this complex depends mostly on the basicity of the amino groups as for peptides.

Figure 2 shows the titration curves of the polymeric analog of NIBL, PNML, in the presence of copper.



[Ligand]/[metal] ratios ranging from 5 to 20 were used in this case because precipitation of the complexes readily occurred at lower values. With $R = 5$, only the 18 first points of the titration curve were used for calculation. For the same reason, titration curves of PNML in the presence of nickel could not be processed.

Figure 2 shows a large decrease of the pH in the presence of copper, indicating strong complex formation.

In a first step, an attempt was made to calculate the acidity constants of the amino and carboxyl groups of PNML, considered as a simple ligand, and using the concentration C of the repeat unit, whose value was kept constant in the refinement process. In this case the agreement between the calculated curve and the experimental data was rather bad, especially in the high pH range. As said in the introduction, this is due to strong electrostatic interactions between charges of the same sign beared by the polymer chain, with the consequence that pK values are not unique as for the model molecule NIBL.

Thus, in a second step, PNML was considered as a ligand made up of two repeat units, each one being characterized by a different set of two pK values. In that case a fixed concentration $C/2$ was used to take into account the "dimeric" nature of the ligand. Then a satisfactory agreement was found between experimental and calculated data, showing that the polyelectrolyte effect may be well represented, for PNML, by the use of only four acidity constants. The following pK values were found: $pK_1 = 9.47$ and $pK_2 = 10.95$ for the amino groups. For NIBL, $pK = 9.42$ which is very close to pK_1. The somewhat higher value for pK_2 reflects the electrostatic interactions. For the carboxyl groups $pK_3 = 2.88$ ($pK = 2.40$ for NIBL). The pK_4 value is too low to be conveniently refined

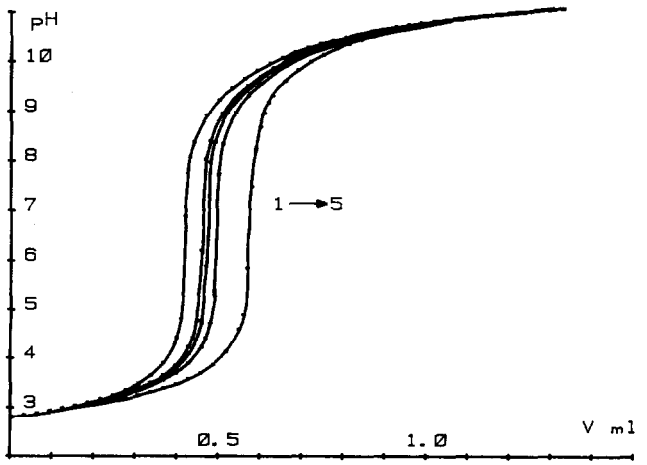


Fig. 2. Titration curves of PNML and PNML–Cu mixtures: 1, PNML; 2, PNML–Cu, $R = 20$; 3, PNML–Cu, $R = 15$; 4, PNML–Cu, $R = 10$; 5, PNML–Cu, $R = 5$.

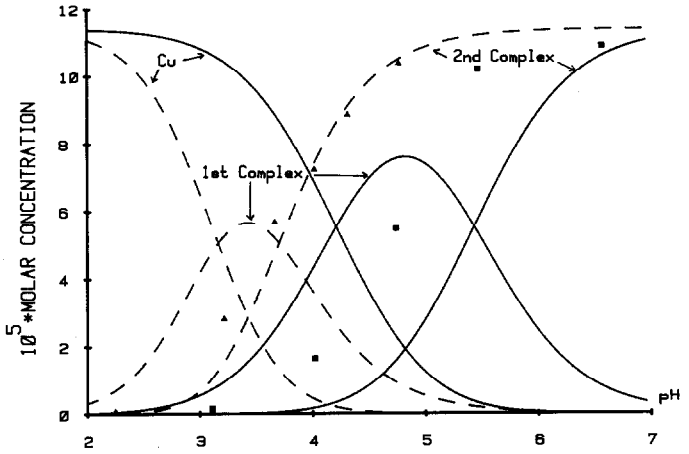

Fig. 3. Species distribution curves for NIBL–Cu and PNML–Cu mixtures, $R = 15$. Full line: NIBL; dotted line PNML. Points are concentration values calculated from circular dichroïsm measurements[4] for the second complex: (■) NIBL; (▲) PNML.

($pK_4 < -\log C/2$). We can consider that this carboxyl group is fully ionized in this concentration range. Thus only three acidity constants are necessary to simulate the titration behaviour of PNML.

This result is not surprising. In fact, this means that, for a given function of repeat unit, the successive elementary deprotonations are controlled only by statistical factors and are equally distributed around the given p*K*s.[28]

In the next step were calculated the formation constants of the PNML–Cu complexes using the MUCOMP program. Two $MA_{0.5}$ and MA complexes (which are the analogs of the MA and MA_2 complexes of NIBL) were found with formation constants equal to 8.68(4) and 16.77(3), respectively.

Using the formation constants of the PNML–Cu and NIBL–Cu complexes, the distribution curves of the species as a function of pH were plotted with the aid of the COMSOL program (Fig. 3). With PNML the first complex is formed at a pH lower than with NIBL and to a lower extent. The second complex forms about 1.5 pH units earlier with PNML than with NIBL. As shown in a previous work[4] this results from the accumulation of the complexing sites along the polymer chain which affects the entropy change of the complexation. The distribution curves obtained from potentiometry (Fig. 3) are in rather good agreement with data obtained from circular dichroïsm measurements[4] (especially for the second complex) if it is considered that the two approaches of the complex formation are very different.

The agreement is fairly good at high pH, i.e. in the domain of formation of the second complex. This suggests that the discrepancy observed at lower pH could result from the contribution of the first complex to the circular dichroïsm.

To our knowledge, this work is the first report on the determination of polyelectrolyte–metal complex formation constants using multiparametric refinement programs. Work is now in progress to extend this approach to other kinds of polyelectrolytes.

COMMUNICATION

A KINETIC STUDY OF THE OXIDATION OF HYDROXYLAMINE BY OCTACYANOTUNGSTATE(V)

ABRAHAM J. VAN WYK,* C. ROBERT DENNIS,† JOHANN G. LEIPOLDT and STEPHEN S. BASSON

Chemistry Department, University of the Orange Free State, Bloemfontein 9300, Republic of South Africa

(*Received* 28 *July* 1986; *accepted* 4 *September* 1986)

Abstract—The kinetics of the oxidation of hydroxylamine by octacyanotungstate(V) ions has been studied over a wide pH range. The reaction is first-order in both oxidant and reductant. The kinetically determined dissociation constants, $K_{a1} = 2.5 \pm 0.5 \times 10^{-6}$ M and $K_{a2} = 3.2 \pm 8.0 \times 10^{-14}$ M, are in agreement with values obtained from the literature.

The reaction of hydroxylamine with a variety of oxidizing agents has been studied.[1] Various oxidation products, i.e. NH_3, $H_2N_2O_2$, N_2 and N_2O, have been reported. These studies were performed in acidic solution (pH 5.6 to 2.5 M H^+) and the reactions were first-order in both oxidant and hydroxylamine.

Autoxidation of hydroxylamine in alkaline solutions was studied by Hughes and co-workers.[2] A deprotonated hydroxylamine species (NH_2O^-) and its acid dissociation constant were reported. Peroxonitrite (ONO_2^-) was formed as an oxidation product, but rapid oxidation with a further hydroxylamine ion yielded nitrite and nitroxyl (NO^-) ions.

The oxidation of hydroxylamine[3] by $Fe(CN)_6^{3-}$ in a weak acidic medium proceeds via an intermediate radical, NH_2O, which is formed by oxidation of NH_2OH. N_2 was detected as the main reaction product. The observed hydrogen ion effect was attributed to acid dissociation of the protonated hydroxylamine species, NH_3OH^+.

The oxidation of hydroxylamine by $W(CN)_8^{3-}$ was performed as part of a research project on the redox properties of the cyano complexes of Mo, W and Fe. Although the oxidation of hydroxylamine in acidic solution is well-studied, very little is known about the reaction in alkaline medium. For this reason the present study was performed over a wide pH range to include results of the alkaline oxidation of hydroxylamine.

EXPERIMENTAL

$Cs_3W(CN)_8 \cdot 2H_2O$ was prepared as described by Leipoldt *et al.*,[4,5] and was used as a primary standard[6] after recrystallization. Hydroxylammonium chloride (Merck *pro analisi*) was used as source of hydroxylamine. The hydroxylammonium chloride solution was neutralized with sodium hydroxide. This solution was renewed daily. All other reagents used were analytical-grade and redistilled water was used throughout.

Kinetic measurements were made in both alkaline and acidic media using Britton–Robinson[7] buffer mixtures or sodium hydroxide solutions at a constant ionic strength. Rate data were obtained by monitoring the decrease in $[W(CN)_8^{3-}]$ on a Durrum D-110 spectrophotometer (faster runs) and a Pye–Unicam SP 1700 spectrophotometer (slower runs) at 357 nm.

Experiments to identify reaction products at pH ~ 6 and $[OH^-] \sim 0.05$ M were carried out by comparing the normal O_2:N_2 ratio of the atmosphere directly above a hydroxylamine solution with the atmosphere resulting from a reaction mixture in a stoppered flask, on a Packard model

472 gas chromatograph. A significant increase in N_2 was detected. Calculations proved that this increase was equal to the stoichiometric amount of N_2 generated by the reaction between $W(CN)_8^{3-}$ and hydroxylamine.

RESULTS AND DISCUSSION

Pseudo-first-order plots of log $[W(CN)_8^{3-}]$ vs time were linear for at least two half-lives. Results in Table 1 show that the reaction is first-order in both oxidant and reductant in a weakly acidic as well as in an alkaline medium. Adding $W(CN)_8^{4-}$ to the reaction mixture caused a decrease in the reaction rate in the acidic medium, but no significant effect was observed in the alkaline medium. This result is indicative of an equilibrium in the reaction pathway in an acidic medium.

Kinetic measurements over a wide pH range (Fig. 1) show the pH dependence of the reaction. These results clearly show two dissociation constants which indicates that three hydroxylamine species are present over the observed pH range. The equilibria [eqns (1) and (2)]

$$NH_3OH^+ \overset{K_{a1}}{\rightleftharpoons} NH_2OH + H^+, \quad (1)$$

$$NH_2OH \overset{K_{a2}}{\rightleftharpoons} NH_2O^- + H^+ \quad (2)$$

are thus operative and the relative reactivities of the

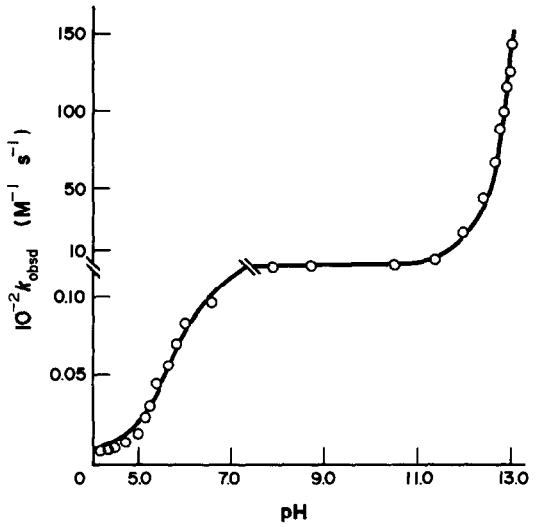

Fig. 1. pH dependence of the oxidation of hydroxylamine by $W(CN)_8^{3-}$: $[W(CN)_8^{3-}] = 5 \times 10^{-4}$ M, $[NH_2OH] = 5 \times 10^{-3}$ M, $\mu = 0.1$ M (NaCl), $T = 25°C$. The solid curve is the computer fit.

species are in the order $NH_3OH^+ < NH_2OH \ll NH_2O^-$.

The product study has shown N_2 to be a reaction product. From this and the observed kinetic results, a reaction mechanism (Scheme 1) is proposed. The oxidation of hydroxylamine in acidic medium proceeds via the $NH_2O^{\cdot}$ radical, which decomposes to N_2 and H_2O. The $NH_2O^{\cdot}$ radical was reported earlier by Gutch and Waters.[8]

$$
\begin{array}{lcl}
NH_3OH^+ + W(CN)_8^{3-} & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & W(CN)_8^{4-} + NH_2O^{\cdot} + 2H^+ \\
\Big\| K_{a1} & & \\
NH_2OH + W(CN)_8^{3-} & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & W(CN)_8^{4-} + NH_2O^{\cdot} + H^+ \\
\Big\| K_{a2} & & \\
NH_2O^- + W(CN)_8^{3-} & \xrightarrow{k_3} & W(CN)_8^{4-} + \tfrac{1}{2}N_2 + H_2O
\end{array}
$$

Scheme 1.

From the reaction mechanism, the following rate law is obtained:

$$\frac{-d[W(CN)_8^{3-}]}{dt} = \frac{k_1[H^+]^2 + k_2K_{a1}[H^+] + k_3K_{a1}K_{a2}}{[H^+]^2 + K_{a1}[H^+] + K_{a1}K_{a2}} [W(CN)_8^{3-}][NH_3OH^+]_T. \quad (3)$$

A non-linear least-squares fit of the data in Fig. 1 to the rate law (3) yielded $k_1 = 2 \pm 1 \times 10^{-2}\,M^{-1}s^{-1}$, $k_2 = 12 \pm 4\,M^{-1}s^{-1}$, $k_3 = 8 \pm 2 \times 10^4\,M^{-1}s^{-1}$, $K_{a1} = 2.5 \pm 0.5 \times 10^{-6}$ M ($pK_a = 5.6$), and $K_{a2} = 3.2 \pm 0.8 \times 10^{-14}$ M ($pK_{a2} = 13.5$) under the approximation that $[H^+] = 10^{-pH}$. The obtained pK_a values are in very good agreement with literature values, i.e. $pK_{a1} = 5.82$[9] and $pK_{a2} = 13.7$.[2]

REACTIONS OF M–M BONDED DINUCLEAR ZIRCONIUM(III) COMPLEXES WITH VICINAL DIHALOALKANES AND OLEFINS: A NEW TYPE OF METAL–OLEFIN COMPLEX

F. ALBERT COTTON* and PIOTR A. KIBALA

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 28 *August* 1986; *accepted* 16 *September* 1986)

Abstract—The reaction of $Zr_2X_6(PR_3)_4$ compounds with *vic*-dihalides or with olefins gives $Zr_2X_6(PR_3)_4(C_2R_4)$ compounds in which the mid-point of the olefin lies between the two Zr atoms, providing an unprecedented type of metal–olefin complex.

Dinuclear complexes of types **I** and **II** in which there are usually metal–metal bonds[1] are numerous and have been studied from many points of view. Those of type **I** formed by niobium(III) and tantalum(III), which contain M=M double bonds have proved to be extremely useful starting materials for synthesizing a variety of compounds of these elements.[2] We are conducting studies to extend the applicability of this approach to other elements, especially by oxidative addition reactions. We report here some results with zirconium(III) compounds of type **II** that contain Zr—Zr single bonds wherein they readily undergo clean and unusual reactions with vicinal dihaloalkanes and olefins.

Our first observations were unplanned. When attempting to employ 1,2-$C_2H_4Cl_2$ as a solvent for the bromo analog of $Zr_2Cl_6(PEt_3)_4$,[3] we noted that the solution spontaneously and rapidly changed color from green to orange. A red crystalline product (**1**) was isolated from the reaction mixture. $Zr_2Cl_6(PEt_3)_4$ undergoes a similar reaction with $ClCH_2CH_2Cl$ to produce yellow solutions from which an orange crystalline product (**2**) could be isolated. Both compounds were characterized crystallographically† and were shown to be of the general type $Zr_2X_6(PR_3)_4(CH_2CH_2)$, where X = Cl or Br, and R = Et. The characteristic feature of both molecules is an ethylene bridge perpendicular to the Zr–Zr axis. Figure 1 shows an ORTEP drawing of a $Zr_2X_6P_4(CH_2CH_2)$ fragment and Table 1 lists selected bond distances and angles for $Zr_2Cl_6(PEt_3)_4(CH_2CH_2)$ (**1**) and $Zr_2Br_6(PEt_3)_4(CH_2CH_2)$ (**2**).

With the above results in hand we naturally wondered if $Zr_2X_6(PR_3)_4$ species would react directly with olefins to yield compounds **1** and **2** and similar ones. On reexamining Ref. 3, we found that reactions of ethylene and propene with $Zr_2Cl_6(PEt_3)_4$ had already been reported; however, no crystallographic work had been done and structures with Zr—C σ-bonds were proposed.‡ We have been able to obtain the compound formulated

in Ref. 3 as $(Et_3P)_2Cl_3ZrCH_2CH_2Zr(PEt)_2Cl_3$ in crystalline form and we find that it is identical to our compound **2**.

The reaction of $Zr_2X_6(PR_3)_4$ compounds with 1,2-$C_2H_4Cl_2$ (and other vicinal dihalides) is now under detailed study. Evidence now available suggests that two molecules of $Zr_2X_6(PR_3)_4$ react with 1,2-$C_2R_4X'_2$ to produce $[ZrX_3(PR_3)_2]_2$ $C_2R_4 + 2ZrX_3X'(PR_3)_2$.

Molecular-orbital (MO) calculations by the Fenske–Hall method[5] have been carried out to elucidate the bonding in the M_2-(μ_2-η^4-olefin) unit. To our knowledge this type of metal–olefin interaction has not previously been recognized to exist and has not, therefore, been considered from a theoretical point of view. If the molecule is considered to be assembled from two $ZrX_3(PR_3)_2$ units and the $H_2C{=}CH_2$ molecule, we can envision that two major contributions to the bonding will arise. The π-orbital of C_2H_4 and its pair of electrons can interact with a pair of σ-type orbitals on the two Zr atoms. The calculations show that this contribution is spread over a number of b_{1u} MOs rather than being clearly identifiable in any one. Overlap between suitable $d\pi$ orbitals (or $d\pi$–$p\pi$ hybrids) on the metal atoms with the π^*-orbital of C_2H_4, and the population of the resulting b_{2g} bonding orbital by two electrons [nominally the unpaired electrons on the $ZrX_3(PR_3)_2$ fragments] should provide a second important contribution. The calculation shows that this contribution can be clearly identified as the HOMO. Since the calculation shows a very large HOMO to LUMO gap, we are inclined to believe that analogs to these molecules in which there are more electrons may not be obtainable.

SYNERGISTIC EFFECTS IN EXTRACTION SUBSTRATES—AN APPLICATION OF THE CONE-PACKING MODEL TO THE SOLVENT EXTRACTION OF URANYL IONS

TANG BER-LIN, YU ZHI-HUI, GUO AO-LING, SUN PENG-NIAN, FENG XI-ZHAN and LI XING-FU*

(*Received* 25 *November* 1985; *accepted after revision* 22 *September* 1986)

Abstract—Synergistic extraction in mixed substrates has been predicted according to the cone-packing model and confirmed in the uranyl extraction with TBP in mixed solutions of ammonium chloride and sodium acetate. The molecular structure of $UO_2(CH_3COO)Cl(dmf)_2$ (dmf = *N*,*N*-dimethylformamide) confirmed the suggested extraction mechanism.

Although "coordination saturation" is a much used idea in solvent extraction, it is quite a confused concept in that one could understand it as saturation with respect either to coordination number or to coordination space. From our treatment of more than 500 molecular structures of lanthanide and actinide compounds, we have found that the latter offers the best explanation of the observed behaviour in this field.[1–5]

The packing saturation rule summarized in our previous paper[5] was also applied to the solvent extraction of the actinides and lanthanides in order to predict the extracted complexes.[6] In this communication we report the prediction and experimental confirmation of synergistic extraction of the uranyl ion in mixed aqueous substrates by applying the cone-packing model.

So far interest in synergistic extraction has been concentrated in the following ternary system:

$$\text{substrate} + \text{extractant}_1 + \text{extractant}_2.$$

An enhanced extraction efficiency in the mixed extraction substrates has been claimed[7–11] but the mechanism was not reported. We expected that synergism would also be shown in the following system:

$$\text{substrate}_1 + \text{substrate}_2 + \text{extractant},$$

and chose the UO_2^{2+}–NH_4Cl–$Na(CH_3COO)$–CH_3COOH–TBP system to test this assumption. It is clear from Fig. 1 that the complex $UO_2(CH_3COO)Cl(TBP)_2$ (I) has the most favourable packing compared to the other possible complexes, $UO_2Cl_2(TBP)_2$ (II), $UO_2Cl_2(TBP)_3$ (III), $UO_2(CH_3COO)_2TBP$ (IV), and $UO_2(CH_3COO)_2(TBP)_2$ (V). It is therefore expected that a higher extraction efficiency should coincide with the formation of the more stable compound (I).

As shown in Fig. 2, a synergistic effect was found with an acetate:chloride ratio of *ca* 1:3 which shifts

O5···U = 2.353(14) Å, O6···U = 2.363(17) Å,
Cl···U = 2.678(6) Å, Cl···U···O6 = 81.3(5)°,
Cl···U···O5 = 79.6(5)°, O3···U···O5 = 74.3(6)°, and
O4···U···O6 = 87.2(9)°.

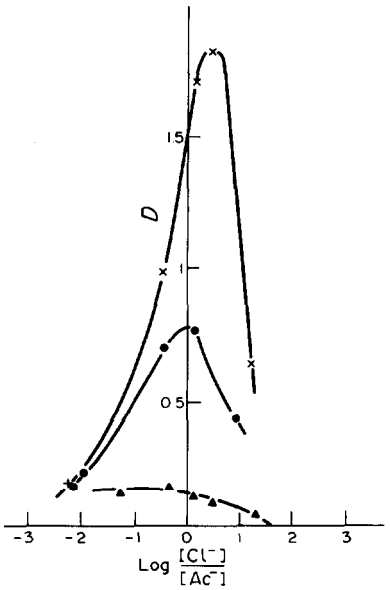

Fig. 2. Uranyl extraction by mixed substrates of different total concentrations: (×) 2.0 N, (●) 1.0 N, and (▲) 0.2 N. $UO_2^{2+} = 9.94 \times 10^{-4}$ mol dm^{-3}.

only slightly on changing the total concentration of the mixed substrates from 2.0 to 0.2 N, but remains constant on varying the uranyl ion concentration. The extracted complex was found to be mainly $UO_2(CH_3COO)Cl(TBP)_2$ by the slope method from which the values of $\log D - \log C$ are 1.91, 1.00 and 1.05, respectively, for TBP, acetate and chloride. By analysing the uranyl ion and chloride concentrations in the organic phase it was found that $[UO_2^{2+}]/[Cl^-]$ fluctuates in the range 0.893–1.23 when the $[Cl^-]:[CH_3COO^-]$ ratio in the aqueous phase was changed from 1:9 to 9:1. The synergistic effect is most marked in the pH range 2.5–3.5 and decreases at lower pH. A similar effect was found with other extractants and other diluents.

A structural study of the mixed-ligand complexes of this type is still in progress.

We have prepared and characterized new compounds $UO_2(CH_3COO)Cl(L)_2$ (L = triphenylphosphine oxide, tributylphosphine oxide, hexamethylphosphoramide or dimethylformamide) and have determined the molecular structure of $UO_2(CH_3COO)Cl(dmf)_2$ (Fig. 3), which confirms our expectation that the extracted complexes are genuine compounds rather than mixtures of uranyl chloride and uranyl acetate complexes.

(*Received* 4 *July* 1986; *accepted* 27 *October* 1986)

Abstract—The substitution reactions with ethylenediamine of the bidentato-*O,O* ligand of (bidentato-*O,O*)bis(ethylenediamine)cobalt(III) complex have been studied in a weakly alkaline aqueous solution in the presence of tris(2,2′-bipyridine)ruthenium(II) complex under photoirradiation. The reaction was catalyzed by the photoexcited ruthenium(II) complex. Enhanced generation of the photoexcited ruthenium(II) complex and acceleration of the reaction of the bidentato-*O,N* ligand of (bidentato-*O,N*)bis(ethylenediamine)cobalt(III) complex were noticed when the optically active isomer of the ruthenium(II) complex was irradiated by the corresponding circularly polarized light.

It has been reported that the ligand substitution reaction of glycinato ligand in bis(ethylenediamine)glycinatocobalt(III), $[Co(gly)(en)_2]^{2+}$, with ethylenediamine does not proceed at room temperature (25°C) but does proceed at an elevated temperature (60–70°C)[1] or in the presence of triplet state excited tris(2,2′-bipyridine)ruthenium(II), $*[Ru(bpy)_3]^{2+}$, even at room temperature.[2] The $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction mechanism has been explained in terms of labilization of $[Co(gly)(en)_2]^{2+}$ by a charge-transfer process between $*[Ru(bpy)_3]^{2+}$ and $[Co(gly)(en)_2]^{2+}$.[2]

Further investigation of the role of $*[Ru(bpy)_3]^{2+}$ on the ligand substitution reaction of carbonatobis(ethylenediamine)cobalt(III), $[Co(CO_3)(en)_2]^{+}$, and bis(ethylenediamine)oxalatocobalt(III), $[Co(ox)(en)_2]^{+}$, with ethylenediamine suggested that the mechanism is general for the (bidentato-*O,O* and -*O,N*) bis (ethylenediamine) cobalt(III) complexes. Furthermore, it was found that the catalytic role of $*[Ru(bpy)_3]^{2+}$ could be enhanced for $[Co(gly)(en)_2]^{2+}$ by using the optically active isomer of $[Ru(bpy)_3]^{2+}$, and by exciting with irradiation by the corresponding circularly polarized light. The present article relates to these investigations.

EXPERIMENTAL

$[Co(CO_3)(en)_2]Cl$ and $[Co(ox)(en)_2]Cl \cdot H_2O$ were prepared and resolved into optically active isomers according to procedures given in the literature.[3,4] All other complexes and reagents used have been described elsewhere.[2]

The $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction was followed by procedures given in a

†Author to whom correspondence should be addressed.

previous paper.[2] In addition, excitation of $[Ru(bpy)_3]^{2+}$ at 452 nm by irradiation by left and right circularly polarized light was made by using Polaroid Circular Polarizers, Nos HNCP37L-4 and HNCP37R-4, which were attached in front of the sample holder of the photoirradiation system.[2] Other experimental procedures, including fluorescence quenching of $*[Ru(bpy)_3]^{2+}$, determination of hydroxide ion concentration etc., have been carried out as described elsewhere.[1,2]

RESULTS AND DISCUSSION

Investigation by liquid chromatography [SP-Sephadex C-25 column (Na^+ form); eluant, 0.05 mol dm^{-3} aqueous NaCl] of the photoirradiation reaction solution {initial conditions: 1.00×10^{-2} mol dm^{-3} $[Co(CO_3)(en)_2]^+$, 1.00×10^{-3} mol dm^{-3} $[Ru(bpy)_3]^{2+}$, 2.00 mol dm^{-3} ethylenediamine, pH 12.0 (buffered), room temperature (25°C)}, revealed that $[Co(CO_3)(en)_2]^+$ changed uniquely to $[Co(en)_3]^{3+}$. The amount of $[Co(CO_3)(en)_2]^+$ was decreased linearly with increasing photoirradiation time. Furthermore, no evidence was noticed of the formation of $[Co(en)_3]^{3+}$ in the absence of $[Ru(bpy)_3]^{2+}$. When $[Co(ox)(en)_2]^+$ was used in place of $[Co(CO_3)(en)_2]^+$, a stoichiometric change of $[Co(ox)(en)_2]^+$ to $[Co(en)_3]^{3+}$ by $*[Ru(bpy)_3]^{2+}$ was also found. However, the relation between the decreased amount of $[Co(ox)(en)_2]^+$ and the photoirradiation time [cf. Fig. 1 (for CD data), curves 5 and 6] showed a deviation from linearity. This deviation can be ascribed to the photodecomposition process of $[Co(ox)(en)_2]^+$ (cf. Fig. 1, curve 7).† Hence it is deduced that the ligand substitution reaction of $[Co(bidentato\text{-}O,O)(en)_2]^+$ with ethylenediamine is catalyzed by $*[Ru(bpy)_3]^{2+}$, as in the case of $[Co(gly)(en)_2]^{2+}$.[2]

Stern–Volmer plots were taken at 25°C by monitoring fluorescence intensities at 607 nm of 1.00×10^{-3} mol dm^{-3} $[Ru(bpy)_3]^{2+}$ in relation to concentration (0–2.00×10^{-2} mol dm^{-3}) of $[Co(bidentato\text{-}O,O)(en)_2]^+$. Linear relations with an intercept of unity were obtained for $[Co(CO_3)(en)_2]^+$ and $[Co(ox)(en)_2]^+$ with Stern–Volmer constants of 0.54×10^2 and 0.50×10^2 mol^{-1} dm^3, which can be converted by applying a lifetime of $*[Ru(bpy)_3]^{2+}$ in water at 25°C of 0.6 μs[6,7] to quenching rate constants (k_q) of 0.90×10^8 and 0.83×10^8 mol^{-1} dm^3 s^{-1}, respectively. These data compare well with the rate constant of $[Co(gly)(en)_2]^{2+}$ (1.25×10^8 mol^{-1} dm^3 s^{-1}),[2] corresponding to a diffusion-controlled, outer-sphere charge-transfer between $*[Ru(bpy)_3]^{2+}$ and $[Co(gly)(en)_2]^{2+}$. It should be noted that the Stern–Volmer constant decreases slightly in the following order; $[Co(gly)(en)_2]^{2+} > [Co(CO_3)(en)_2]^+ > [Co(ox)(en)_2]^+$.

The yield for the $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction of $[Co(bidentato\text{-}O,O)(en)_2]^+$ with ethylenediamine against $*[Ru(bpy)_3]^{2+}$ generated, Φ^{sub} $\{= (-d[[Co(bidentato\text{-}O,O)(en)_2]^+]/dt)/I_a\Phi^o$, where $I_a\Phi^o$ corresponds to the formation rate of $*[Ru(bpy)_3]^{2+}\}$,[2] was determined on both racemates as well as optically active isomers, and the data are summarized in Table 1. The yield does not depend on the stereochemistries of both the ruthenium(II) and the cobalt(III) complexes; the values are about the same magnitude with, however, a slight decrease in the following order; $[Co(gly)(en)_2]^{2+}$,[2] $> [Co(CO_3)(en)_2]^+ \fallingdotseq [Co(ox)(en)_2]^+$.

From the evidence given above, it is concluded that the mechanism of the $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction of $[Co(bidentato\text{-}O,O)(en)_2]^+$ with ethylenediamine is the same as that of $[Co(gly)(en)_2]^{2+}$.[2]

According to the discussion above, there remains an interesting point left unsolved on the role of circularly polarized light on the generation of $*[Ru(bpy)_3]^{2+}$. The $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction was followed under irradiation by left or right circularly polarized light at 452 nm of the optically active isomers of both $[Ru(bpy)_3]^{2+}$ and $[Co(bidentato\text{-}O,O)(en)_2]^+$ as well as $[Co(gly)(en)_2]^{2+}$ (cf. Fig. 1). Figure 1 demonstrates that $[Co(gly)(en)_2]^{2+}$ clearly shows the effect of irradiation by circularly polarized light; the rate of the decrease in $[Co(gly)(en)_2]^{2+}$ is enhanced by irradiation by right circularly polarized light on a solution containing $\Delta\text{-}(-)_{589}\text{-}[Ru(bpy)_3]^{2+}$ irrespective of the optical isomerism of $[Co(gly)(en)_2]^{2+}$. This effect can be explained in terms of an enhanced excitation of $\Delta\text{-}(-)_{589}\text{-}[Ru(bpy)_3]^{2+}$ by right circularly polarized light because this isomer shows a negative CD sign at 452 nm. Furthermore, this finding supports our conclusion on the mechanism of the $*[Ru(bpy)_3]^{2+}$-catalyzed ligand substitution reaction of $[Co(gly)(en)_2]^{2+}$,[2] that the overall rate of the reaction is governed by the photoexcitation step of $[Ru(bpy)_3]^{2+}$. We could not obtain any definite indication of the irradiation effect of circularly polarized light on $[Co(bidentato\text{-}O,O)(en)_2]^+$ within our experimental uncertainties. The reason is not clear at present, but we can safely state that the effect may be less pronounced $\{[Co(CO_3)(en)_2]^+\}$ or may be influenced by the

†$[Co(ox)(en)_2]^+$ has been reported not to racemize on photoirradiation.[5]

Excitation wavelength of circularly polarized light (nm), 452. Wavelength of CD intensity measurement (nm), 509 $\{[Co(gly)(en)_2]^{2+}\}$, 520 $\{[Co(ox)(en)_2]^+\}$, and 530 $\{[Co(CO_3)(en)_2]^+\}$. Notation is as follows:

	$[Co(gly)(en)_2]^{2+}$		$[Co(ox)(en)_2]^+$	$[Co(CO_3)(en)_2]^+$
	Δ-$(-)_{589}$-	Λ-$(+)_{589}$-	Λ-$(+)_{589}$-	Λ-$(+)_{589}$-
Right CPL	1	2	5	9
Left CPL	3	4	6	8

CPL = circularly polarized light. Δ-$(-)_{589}$-$[Ru(bpy)_3]^{2+}$ was used throughout the runs. Curve 7 is a blank run for Λ-$(+)_{589}$-$[Co(ox)(en)_2]^+$ in the absence of Δ-$(-)_{589}$-$[Ru(bpy)_3]^{2+}$.

Table 1. Yield for ligand substitution reaction against $*[Ru(bpy)_3]^{2+}$ generated as determined by the circular dichroism spectral method at 25°C

	$\Phi^{sub\,a}$

UNUSUAL MERCURY–PHOSPHORUS COUPLING CONSTANTS IN THE MERCURY(II) TRIPHOSPHINE COMPLEXES $[Hg(\eta^2\text{-LL})(\eta^1\text{-dppm})]^{2+}$ (LL = dppe OR dppp)*

(*Received* 11 *April* 1986; *accepted* 23 *October* 1986)

Abstract—The asymmetric complexes $[Hg(LL)(LL')]^{2+}$ (LL and LL' = dppm, dppe or dppp, LL ≠ LL') are formed in an equilibrium mixture with the corresponding symmetric compounds from $[Hg(Me_2SO)_6](O_3SCF_3)_2$ and the corresponding diphosphines. The bonding mode of dppe and dppp in the mixed complexes is chelating bidentate. The dppm ligands are monodentate and are involved in fast intramolecular exchange of the coordinated phosphorus atoms by the free phosphorus atoms. The mercury triphosphine complexes show unusual Hg–P coupling constants which are explained by the different *s*-character of the ligand–Hg bonds as a result of the fixed geometry of the chelate ligands differing from the ideal geometry of tricoordinate mercury(II).

Anomalous metal–phosphorus coupling constants have been observed when the actual coordination geometry of a metal differs from its ideal geometry.[1]
