An unexpected property of the copolymers was their increased solubility in several organic solvents, those having 20% or more of the comonomer II being soluble in acetone and xylene. Probably for this reason the differences in crystallinity between copolymers and homopolymers was not as great when crystallinity was induced by soaking in acetone, though in this case also the copolymer did show a lower crystallization than the homopolymers. It was possible to measure the crystalline melting points of several copolymers and these were shown to fall with increasing comonomer content. At 15% of II the melting point was reduced by about 30°C.

As might be expected from the above, tensile experiments on films of copolymers containing appreciable amounts of II, carried out in organic solvents suggested that they were more solvent-sensitive than the homopolymer.

Glass transition temperature of copolymers

The effect of introducing II on the glass transition temperature of the copolycarbonates was not very large. Nevertheless the comonomer did have a significant effect in reducing T_g whether measured on the d.s.c. or from the high

temperature relaxation peak of the Rheovibron (using a cast film). With low comonomer concentrations the Rheovibron measurements gave higher values of T_g than those obtained by the d.s.c. (*Figure 6*) a result which was reasonable since the Rheovibron measurements were made at 11 Hz whereas the d.s.c. experiments were extrapolated to zero heating rate. However, the Rheovibron results also seemed to be more sensitive to the presence of comonomer and gave lower

Figure 7 Effect of annealing below T_g on the tensile yield stress of synthetic polycarbonate and the 15% copolymer (- - - - -). □, 110°; △, 120°; ○, 130°; X, 140°C

Tensile properties

Tensile experiments were carried out on films 0.5—1.5 mm thick. These were cast from 20% methylene chloride solution on glass plates and progressively dried out, first at room temperature for 12 h, then at 35°C for 5 h and finally at 80°C in vacuum. This temperature was chosen because it had been reported that annealing effects as measured mechanically were small below 80°C[8].

Tensile test-pieces were cut from the films according to BS 2782 (1970) Fig 301.12, Method 301K, and tested on an Instron tester under standard conditions (23 ± 1°C; 50 ± 2% r.h.).

The results which are shown on *Table 2* are in line with the observations on T_g. Increasing the comonomer leads to a small reduction in yield stress and to an increase in elongation at break. Molecular weight has been separately shown to have only a minimum effect on yield stress but it does effect elongation at break. Only polymers having $\overline{M}_n > 27\,000$ exhibited necking along the whole length of the test-piece before fracture.

More interest attaches to the effect of annealing on tensile properties, since polycarbonates are known to become more brittle when annealed[8,9]. However, in studying annealing effects allowance might be necessary for differences in T_g since the most sensitive annealing temperatures might be lower for the copolymers than for the homopolymer. However, it will be seen from *Figure 7* that synthetic polycarbonate and the 15% copolymer show the same differences in annealing response over a wide range of temperatures. At every temperature the homopolymer shows a much greater increase in yield stress than the copolymer.

The effect of copolymer composition may therefore be conveniently illustrated by annealing a series of materials for a standard time; e.g. 130°C for 48 h. The results can then be represented in terms of the relative increase in yield stress, $\Delta\sigma/\sigma_0$, due to the treatment, plotted against composition (*Figure 8*). It will be seen that even small quantities of the comonomer have a substantial effect on the magnitude of the annealing changes.

Study of annealing effects by d.s.c.

The influence of annealing in causing an endothermic peak at T_g in the differential scanning calorimeter has been known for some time[6,7,27]. These peaks therefore offer an alternative means of studying annealing effects to the measurement of yield stress. Again we studied similar materials to those used in the previous section and in *Figures 9a* and *9b* we show the annealing behaviour of a homo-BPA polycarbonate compared with a 15% copolymer. The results
Figure 8 Relationship between copolymer composition and the relative change in yield stress due to annealing (heated at 130°C for 48 h)

values of T_g at higher monomer concentrations. The reason for this is not known. On the other hand, the observed reduction in T_g with increased amounts of II could be ascribed to the greater frequency of flexible linkages along the chain.
Figure 9 Effect of annealing time on d.s.c. peak height for poly-carbonates. (a) 15% copolymer; (b) synthetic polycarbonate. □, 110°; △, 120°; ○, 130°; X, 140°C
Figure 10 Effect of the fluorinated comonomer on the d.s.c. peak height developed by heating at 130°C. Time of heating, 48 h

obtained are analogous to these observed with yield stress. In every case the copolymer is much less affected by annealing than the homopolymer and the effect of comonomer content under constant annealing conditions may also be readily demonstrated (*Figure 10*).

Thus the introduction of the comonomer also reduces the effects due to annealing as measured by d.s.c.
Figure 11 Dynamic mechanical measurements on polycarbonate homopolymer and copolymers. (a) Homopolymer, $\overline{M}_v$ 80 000; (b) 15% copolymer; (c) 50% copolymer

Dynamic mechanical properties

Dynamic measurements were carried out by means of a Rheovibron dynamic viscoelastometer using films cast from a 10% solution in 1,2-dichloroethane and dried out in vacuum for 24 h at 80°C.

Three examples of the curves obtained are shown in *Figure 11,* where typical results are given for the synthetic homopolymer, and the 15% and 50% copolymers. Briefly the results obtained may be summarized as follows.

(1) The main α or glass transition peak remains sharp for all the materials used, suggesting a reasonably random copolymer structure. It moves to a lower temperature with increasing comonomer content (as previously stated).

(2) Two low temperature (β) peaks are observed with the pure polycarbonate and with those copolymers which contain only small quantities of II. With 50% of II, however, only one low temperature peak is observed. Two peaks have not always been observed with polycarbonate[9,28] but Illers and Breuer[29] observed a broad loss peak which they ascribed to these overlapping peaks at −40, −100, and −150°C (1 Hz) while Le Grand and Erhardt[30] found two n.m.r. loss peaks at −150°C and −50°C (at 2×10^4 Hz) which might well correspond with our results.

(3) The two peaks respond differently to the introduction of comonomer. The position of the low temperature peak, starting at −110°C for pure polycarbonate, rises steadily to −75°C with the 50% copolymer. On the other hand, the position of the −10°C peak does not vary significantly with comonomer content, but disappears completely when the level of II is raised to 50%.

While we do not propose to comment on the different behaviour of the two peaks we may note that the loss of specificity (broad peak) associated with the 50% copolymer may well correspond with a low degree of structural regularity in the glassy state.

Sorption of water vapour by atactic and isotactic poly (methyl methacrylate)

Z. Miyagi and K. Tanaka
Department of Chemistry, Faculty of Science, Science University of Tokyo, Tokyo, Japan
(Received 5 August 1974)

For the purpose of studying the relation between the stereoregularity and the sorption properties of atactic (a-PMMA) and isotactic (i-PMMA) poly(methyl methacrylate) samples, the isotherms for the sorption of water vapour by these polymers were determined. The glass transition temperatures, T_g and the densities of both PMMA samples were also measured under different conditions of moisture content. The amount of water vapour sorbed by i-PMMA was found, in this study, to be greater than that by a-PMMA. This is rather peculiar when we consider that the former has a high crystallinity (76%) and the latter is non-crystalline in nature. It was concluded that water vapour is sorbed by a-PMMA by a mechanism whereby the water molecules sorbed, fill pre-existing sites (polar groups) and spaces occupied by microvoids or free volumes in the polymer without causing any swelling in the latter; and that the extra sorption of water vapour by i-PMMA was due to a mechanism by which the water molecules sorbed cause the polymer to swell, and thus increase its sorption capacity.

INTRODUCTION

The present work was undertaken to study the effects of stereoregularity on the water vapour sorption properties of poly(methyl methacrylate) (PMMA) samples. It is well known that the sorption properties of polymeric materials for the vapours of various solvents depend not only on the chemical structures of the polymers, but also on their higher-order structures, and there are numerous reports[1,2] on the effects of crystallinity on the water vapour sorption properties of polymers. Formerly, it was assumed that the sorption occurred only in the non-crystalline part of the sorbent and that the crystalline part did not have any effect on this. However, it has been reported recently that water molecules sorbed by poly(vinyl alcohol)[3] and nylon-6[4] cause changes in the lattice constants of the crystals, and also that a meaningful relationship does not necessarily exist between an increase in the degree of crystallinity and a decrease in the amount of organic vapours sorbed by polyethylene[5], whose degree of crystallinity has been increased by elongation and heat treatment.

Thus, the sorption properties of polymers are influenced in a complicated way, by their chemical structures and physical properties. Moreover, differences in the stereoregularity of polymers cause differences in their physical properties. However, since no specific discussion on the relationship between the stereoregularity and the sorption properties of polymers had so far been reported, we studied this relationship by measuring the amount of water vapour sorbed by atactic (a-) and isotactic (i-) PMMA samples. The changes in the T_g and in the densities of both samples, with changes in the moisture content of the polymers, were also determined.

EXPERIMENTAL

Materials and methods

a-PMMA($\overline{M}_v = 1.10 \times 10^5$) manufactured by Sumitomo Chemical Co. and i-PMMA ($\overline{M}_v = 6.01 \times 10^5$) synthesized

by the authors were used as samples. The a-PMMA was purified and prepared as follows: it was dissolved in 5 wt % acetone, precipitated in methanol. decanted and collected by filtration, a procedure which was repeated 4 times. It was then dried under reduced pressure, and films were prepared by casting the polymer from a 10 wt % benzene solution onto glass sheets. i-PMMA was synthesized and refined by the method that had been reported previously by Watanabe[6]. The conditions for polymerization were as follows: Grignard reagent with isobutyl bromide as the base was used as the catalyst, the molar ratios of monomer: solvent(toluene) and catalyst: monomer were 4.70×10^{-1} and 1.88×10^{-2}, respectively, and the temperature was 0°C. The films of i-PMMA were prepared in a similar manner as the a-PMMA ones, from a 3–5 wt % benzene solution of the polymer. The film thickness of both a- and i-PMMA samples was 0.08–0.1 mm, and these samples were vacuum-dried for 50 days at 10^{-5} mmHg and stored in sealed glass tubes. The moisture content of the samples for T_g and density measurements were adjusted by allowing the sample to stand in the vapour of saturated solutions of various salts. The samples for the T_g study were sealed in aluminium pans to prevent evaporation during measurement.

Sorption measurement

Measurements of the amount of water vapour sorbed by both a- and i-PMMA samples were carried out on about 300 mg of the samples by the gravimetric method using the usual quartz spiral balance. Standard drying of the samples was carried out for 4 days at 10^{-6} mmHg and 35°C. The sensitivity of the quartz spiral balance was 1.0523 mm/mg at 30°C. Since amount of water vapour sorbed by polymers depends greatly on temperature, the whole sorption apparatus was made of double tubes, and the temperature was kept constant by circulating thermostatically controlled water.

Table 1 Characteristics of both a- and i-PMMA samples

Samples	M_v x 10^{-5}	Densities (g/cm³) 20°C	Densities (g/cm³) 30°C	Crystal-linity (%)	Iso-tacticity (%)
a-PMMA	1.10	1.163	1.158	–	–
i-PMMA	6.01	1.224	1.223	76	99
Figure 1 Intensity of X-ray diffraction of PMMA samples: A, i-PMMA; B, a-PMMA

T_g and density measurements

The T_g and densities of a- and i-PMMA samples were measured under different conditions of moisture. The T_g was measured with a Perkin–Elmer Model DSC-1b differential scanning calorimeter. The rate of temperature rise was 8°C/min. Density measurements were carried out rapidly at 20°C and 30°C, by the density-gradient tube method, using zinc chloride and methanol.

Determination of isotacticity

The isotacticity was determined by the i.r. method. As i-PMMA shows an absorption at 757 cm⁻¹ that was not found in a-PMMA, the absorbancy ratio D_{749}/D_{757} was calculated from the absorbancies at 749 cm⁻¹ and 757 cm⁻¹, and the isotacticity was determined from the calibration curve previously reported by Watanabe[7].

RESULTS AND DISCUSSION

The characteristics of both a- and i-PMMA samples are listed in *Table 1*. As shown in *Table 1*, the isotacticity of i-PMMA is 99%. Consequently, it is a suitable substance for studying the effects of stereoregularity on the sorption properties of a polymer. A clear difference in degree of crystallinity between a- and i-PMMA samples can be seen from the densities listed in *Table 1* and from the results of X-ray diffraction shown in *Figure 1*. a-PMMA is composed almost entirely of non-crystalline substance, whereas a considerable portion has crystallized in i-PMMA. The degree of crystallinity of i-PMMA, calculated from the densities[8-10], is 76%.

Sorption isotherms

The isotherms for the sorption of water vapour by a- and i-PMMA samples at 30°C are shown in *Figure 2*. It can be seen from *Figure 2* that the amount of water vapour sorbed

by i-PMMA with a crystallinity of 76% was greater than that sorbed by non-crystalline a-PMMA. This is contrary to previous thinking that 'increase in the degree of crystallinity of polymers causes decrease in the amount of water vapour sorbed by them'. In order to elucidate this singular phenomenon in a- and i-PMMA samples resulting from the difference in their chemical structure, the BET theory[11] was applied to the isotherms shown in *Figure 2*. This does not mean that the isotherms necessarily satisfy the BET theory, but it is convenient for studying the mechanism of sorption with respect chiefly to the point at which the observed amount of water vapour sorbed deviates from the theoretical value. The results are shown in *Figure 3*. The BET theory is expressed by the following equation:

$$\frac{x}{a(1-x)} = \frac{1}{a_0 c} + \frac{(c-1)x}{a_0 c} \tag{1}$$

where a is the weight of the sorbate in g sorbed/g of polymer, a_0 is the weight of the sorbate sorbed to form a monomolecular layer, x is the relative vapour pressure and c is a constant related to the heat of sorption.

As shown in *Figure 3*, BET plots of the isotherms are linear in a narrow range of lower relative vapour pressures (RVP), but deviate from straight lines with increase in RVP, as in water vapour sorption by other polymeric materials[12,13]. However, BET plots for water vapour sorption of PMMA samples is different from those other polymeric
Figure 2 Sorption isotherms of PMMA samples at 30°C: ●, a-PMMA; ○, i-PMMA
Figure 3 BET plots of the isotherms of *Figure 2*: ●, a-PMMA; ○, i-PMMA

Table 2 BET constants of both a- and i-PMMA samples

Samples	a_0 (mg/g)	x_0 (%)	n_0	n_0^*	E (kcal/mol)
a-PMMA	4.42	38.8	40.6	40.6	0.520
i-PMMA	3.17	16.9	56.8	13.4	1.850

a_0 = weight of sorbate sorbed to form a monomolecular layer
x_0 = relative vapour pressure corresponding to a_0
n_0 = number of sorption sites occupied by one molecule of the sorbate in a monomolecular layer
n_0^* = value corrected in n_0 for crystallinity
E = heat of sorption

materials, because BET plots for water vapour sorption of a- and i-PMMA samples show that the deviations from straight lines are mutually in the opposite directions to those suggested by the theory. The deviation of BET plot from the theoretical values for sorption in the a-PMMA/water vapour system is negative[13] (the observed *a* values are much smaller than those predicted by the theory), whereas the i-PMMA/water vapour system shows a positive deviation (the observed *a* values are much larger than those predicted by the theory). This suggests that there is a clear difference between the mechanisms of water vapour sorption by a- and i-PMMA samples. That is, the sorption capacity of a-PMMA is restricted, while that of i-PMMA is increased during the sorption process. This is considered in further detail by assuming that sorption occurs by two mechanisms[12]: adsorption of the Langmuir type and by dissolution. The amount of water vapour sorbed by adsorption of the Langmuir type, is represented by the a_0 value in the BET constants listed in *Table 2*. It is clear from *Table 2* and *Figure 2* that the amount of water vapour sorbed by a-PMMA by adsorption of the Langmuir type is greater than that sorbed by i-PMMA, despite the fact that the amount of water vapour sorbed by i-PMMA is greater than that sorbed by a-PMMA. This indicates that the dissolution mechanism corresponding to the increase of sorption capacity makes a large contribution in water vapour sorption by i-PMMA, and that the adsorption mechanism, in which an increase of sorption capacity is not expected, greatly affects the water vapour sorption of a-PMMA.

T_g and density

To obtain further information on such difference between the mechanisms of water vapour sorption of a- and

i-PMMA samples, the changes in T_g and densities of both samples with changes in moisture content in the polymers were determined. The results are shown in *Figure 4* and *Figure 5*, respectively. The tendency for T_g to decrease, with increase in moisture content in both a- and i-PMMA samples, can be seen. The T_g of i-PMMA drops to below $30°C$ near an *a* value of 0.44 wt % ($RVP = 28\%$), where the
Figure 4 Variations of T_g of PMMA samples as a function of *RVP*: ●, a-PMMA; ○, i-PMMA
Figure 5 Variation of density of PMMA samples as a function of *RVP*: ●, a-PMMA; ○, i-PMMA

BET plot shows a positive deviation from the straight line expected by the theory, i.e. it becomes lower than the temperature of sorption measurement above a RVP value of 28%. Therefore the motion of the polymer chain, which had been fixed, rises above 28% RVP and the sorption capacity increases in i-PMMA. Consequently, the amount of water vapour sorbed in i-PMMA is much larger than that predicted by the BET theory, and the BET plot shows a positive deviation from the theoretical value, as shown in *Figure 3*. No decrease in the T_g of a-PMMA below 50°C was observed within the range measured. As the measurement of the amount of water vapour sorbed by a-PMMA was consequently carried out in conditions in which the molecular motion of the main chain of the polymer was in a fixed state, the amount of water vapour sorbed by a-PMMA was much smaller than that predicted by the BET theory and the BET plot shows a negative deviation from the theoretical value, as shown in *Figure 3*.

When the water molecules sorbed by PMMA samples cause swelling in a polymer, its density should decrease correspondingly with the moisture content, when we consider that the density of water (0.9998 g/cm^3 at 30°C) is smaller than that of a- and i-PMMA samples, 1.158 and 1.223 g/cm^3 at 30°C, respectively. Moreover, when the water molecules cause no swelling, but merely fill the spaces where there are microvids or free volumes in the polymer, the density should increase corresponding to the moisture content. As shown in *Figure 5*, the density of a-PMMA increased over the entire range measured with increases in the moisture content, i.e., 0.58% over the dry sample density, with a water vapour sorption of 0.80 wt %. This shows that a-PMMA had hardly swelled at all over the entire range measured, and since the value of 0.22% is much smaller than the density increase estimate based on the amount of water added (i.e. the moisture content of 0.80 wt %), the difference of 0.22% between density increase and mositure content is explained reasonably, in terms of the sorption mechanism of water vapour by the pre-existing sites (polar groups) exposed on the surface. The density of i-PMMA showed a maximum in the vicinity of an a value of 0.44 wt % $(RVP = 28\%)$, and a decrease of 0.02% of the dry sample value with an increase of moisture content of 0.10 wt % from 0.44 wt % $(RVP = 28\%)$. This suggests that i-PMMA swelled above the RVP value of 28%.

From the discussion of the isotherms, T_g and density, it was concluded that water vapour had been sorbed by a-PMMA by a mechanism in which the water molecules sorbed fill the pre-existing sites (polar groups) and spaces occupied by microvoids or free volumes in the polymer, causing no swelling in the latter. The extra sorption of water vapour by i-PMMA, was concluded to have occurred by a mechanism whereby the water molecules sorbed caused swelling in the polymer, as well as increasing the sorption capacity of the polymer. Consequently, since the T_g of polymers generally increases with increase in the degree of crystallinity, the sorption properties of polymers may be said to be affected by the degree of crystallinity. However, the T_g of crystalline i-PMMA is lower than that of non-crystalline a-PMMA and the sorption capacity of the former is greater than that of the latter. Furthermore, it has been reported previously that the amount of water vapour sorbed by nylon-6[14] is different after heat treatment, even at the same degree of crystallinity. Accordingly, if the sorption properties of such singular polymers as PMMA, nylon-6, etc., are discussed concurrently, it should be taken that they are controlled by their T_g rather than their degree of crystallinity.

Pressure dependence of upper critical solution temperatures in the polystyrene – cyclohexane system

S. Saeki, N. Kuwahara, M. Nakata and M. Kaneko

Department of Polymer Science, Hokkaido University, Sapporo, Japan
(Received 5 August 1974; revised 11 September 1974)

The pressure dependence of the upper critical solution temperature $(dT/dp)_c$ in the polystyrene–cyclohexane system has been measured over the pressure range of 1 to 50 atm. The value of $(dT/dp)_c$ determined over the molecular weight (M_w) range of 3.7 x 10^4 to ~145 x 10^4 greatly depends on the molecular weight of polystyrene. The value of $(dT/dp)_c$ for a polystyrene solution of low molecular weight $(M_w = 3.7$ x $10^4)$ is positive (3.14 x 10^{-3} degree atm^{-1}), while the values are negative (-0.52 x 10^{-3} ~ -5.64 x 10^{-3} degree atm^{-1}) for solutions of polystyrene over the high molecular weight range of 11 x 10^4 to ~145 x 10^4. The Patterson–Delmas theory of the corresponding state and the newer Flory theory have been used to explain this behaviour.

INTRODUCTION

Thermodynamic phenomena such as phase separation behaviour at the upper critical solution temperature (*UCST*) and the lower critical solution temperature (*LCST*)[1–10], excess volume of mixing[11–18], concentration dependence of the χ parameter[11–17,19,20], and both endothermic and exothermic behaviour[5,21,22] have been extensively investigated in non-polar polymer solutions. The temperature dependence of polymer chain dimensions[23,24] in dilute polymer solutions has been correlated with the temperature dependence of χ_1: the polymer chain dimension attains a maximum in the vicinity of the minimum value of χ_1. The recent theories of polymer solution thermodynamics by Patterson[2,21,24–29] and Flory[17,30–32] successfully predict these phenomena. In these theories the polymer–solvent interaction parameter, χ_1, consists of a decreasing function of temperature from the contact interaction and an increasing function from the free volume or equation of state terms.

Systematic examinations have been carried out by introducing pressure as a thermodynamic variable on the second virial coefficient[33–35], the mean square end-to-end distance of polymer in dilute solution[33–35] and the upper and lower critical solution temperatures[36–39]. Determinations of the pressure dependence of the *UCST* and *LCST* are of great interest for investigation of the thermodynamic properties of the polymer solution and also for obtaining information about the third derivative of the chemical potential with respect to concentration[40].

The present work was done to supply the phase diagram in temperature –pressure–concentration space in the vicinity of the *UCST* in the polystyrene–cyclohexane system and to apply recent theories of polymer solution thermodynamics.

EXPERIMENTAL

Polystyrene samples were obtained from the Pressure Chemical Co. Characterization for samples of $M_w = 3.7$ x 10^4 to 67 x 10^4 has been described elsewhere[7–9]. A sample designated by 14b-3 was obtained by the solution fractionation described in detail elsewhere[7]. The 14b-3 fraction $M_w = 145$ x 10^4 and $M_w/M_n < 1.10$ was used in this work. Cyclohexane was reagent grade and was further purified before use. The solvent was treated over silica gel and fractionally distilled by use of a column[7–9]. The middle fraction was dried over phosphorus pentoxide and redistilled through the same column. The apparatus for determination of the cloud-point temperature under pressure consisted of three parts; a pressure reservoir made of stainless steel, a calibrated Bourdon-type pressure gauge of 45 cm diameter (Heise Co., to 50 kg/cm^2), and a pressure cell consisting of a brass block with a hole to hold the solution cell and two glass windows for passage of the He–Ne laser beam. The solution cell was sealed by the use of mercury. Compressed nitrogen gas was used as the pressure source.

Upper critical solution temperatures were estimated from cloud-point curves. Several solutions in cyclohexane, prepared from each sample in the concentration range 1 to ~22 wt %, were stirred for a day and sealed by pure mercury inside the solution cells. The cloud-point temperatures for the *UCST* were determined with an accuracy of ±0.005°C by the aid of the pattern of He–Ne laser beam, as described elsewhere[7]. The cloud-point temperatures obtained by cooling very slowly (0.0005° to ~0.001°C/ min) in a water bath controlled to ±0.002° agreed within ±0.005°C by the aid of the pattern of He–Ne laser beam, as very slowly (0.03 to ~0.05 atm/min).

RESULTS

Figures 1 to *4* show the cloud-point curves at different pressures for solutions of polystyrenes of $M_w = 3.7$ x 10^4 to ~145 x 10^4 in cyclohexane. Although the maximum point is not the critical point, the difference of the maximum point from the critical point should be quite small because of the small values of M_w/M_n for the four samples in this work[41,42].

The pressure dependence of the *UCST* $(dT/dp)_c$ for the
Figure 1 Temperature/weight fraction phase diagram for the polystyrene (M_W = 3.7 x 10^4)—cyclohexane system under various pressures: $\triangledown$, 1 atm; ▲, 10 atm; $\bigcirc$, 20 atm; ▼, 30 atm; $\triangle$, 40 atm; ●, 50 atm
Figure 2 Temperature/weight fraction phase diagram for the polystyrene (M_W = 11 x 10^4)—cyclohexane system under various pressures: $\triangledown$, 1 atm; ●, 50 atm

solutions is shown in *Figure 5* and the values of $(dT/dp)_c$ are collected in *Table 1*. The values of $(dT/dp)_c$ are positive for the polymer sample of M_W = 3.7 x 10^4, slightly negative for M_W = 11 x 10^4, and more negative for M_W = 67 x 10^4 and 145 x 10^4. Although the increase or decrease of the precipitation temperature in the pressure range of 50 atm is very small, it is detectable by the use of the optical determination of the cloud-point temperature. Since the meniscus between two coexisting phases appears in the polystyrene—cyclohexane system after lapse of half a day at a temperature 0.003°C lower than the temperature of a dramatic change of the pattern of a He—Ne laser beam passed through the solution cell, the cloud-point temperatures determined in this work are sufficiently reliable.

DISCUSSION

Ham *et al.*[37] have determined the precipitation temperatures of polystyrene solutions in cyclohexane as a function of pressure up to 400 atm. The values of $(dT/dp)_c$ estimated

from their data over the pressure range of 1 to 100 atm are 2.5 x 10^{-3} degree atm^{-1} for M_W = 26.7 x 10^4 and 3.1 x 10^{-3} degree atm^{-1} for M_W = 8.2 x 10^4. Their values are very different in sign and magnitude from our experimental values corresponding to M_W = 26.7 x 10^4 and 8.2 x 10^4. The difference should be attributed to the method for determination of cloud-point temperatures under pressure.

The Patterson[25—29] and Flory theories[17,30—32] of polymer solution thermodynamics predict the pressure dependence of the *UCST* and its variation with molecular weight of polymer. The χ_1 parameter obtained by Patterson *et al.*

and Flory *et al.* from the viewpoint of the corresponding state law is essentially the same expression except for the definition of the molecular parameters[3,26], and is expressed as a function of temperature and pressure. The equation of state in reduced form derived by Flory *et al.* is given by[30]:

$$\widetilde{P}\widetilde{V}/\widetilde{T} = (1 - \widetilde{V}^{-1/3})^{-1} - (\widetilde{V}\widetilde{T})^{-1} \tag{1}$$

By use of the van der Waals expression, $\widetilde{U} = -\widetilde{V}^{-1}$, for the dependence of the configurational energy on volume, the Patterson theory[25-28,35] gives:

$$\chi_1(P, T)/c_1 = -(\widetilde{U}_1(\widetilde{P}_1, \widetilde{T}_1)/\widetilde{T}_1)\nu^2 +$$

$$(\widetilde{C}_{p,1}(\widetilde{P}_1, \widetilde{T}_1)/2)(\tau + \pi\widetilde{\beta}\widetilde{P}_1/\widetilde{\alpha}\widetilde{T}_1)^2 \tag{2}$$

where

$$\widetilde{C}_{p,1}(\widetilde{P}_1, \widetilde{T}_1) = (1 - (2/3)\widetilde{V}_1^{-1/3}) -$$

$$2(1 - \widetilde{V}_1^{-1/3})/(\widetilde{P}_1\widetilde{V}_1^2 + 1) \tag{3}$$

and

$$\widetilde{\beta}\widetilde{P}_1/\widetilde{\alpha}\widetilde{T}_1 = \widetilde{P}_1\widetilde{V}_1^2/(\widetilde{P}_1\widetilde{V}_1^2 + 1) \tag{4}$$

The Flory theory[12,15-17,30-32] gives:

$$\chi_1 = (P_1^* V_1^*/\widetilde{V}_1 RT)(A^2\alpha_1 T/2 + Y_{12}) - V_1^* Q_{12}/R(s_1/s_2)^2 \tag{5}$$

where

$$A = (1 - T_1^*/T_2^*)(P_2^*/P_1^*) - (s_2/s_1)(X_{12}/P_1^*) \tag{6}$$

and

$$Y_{12} = (X_{12}/P_1^*)(s_2/s_1)^2 \tag{7}$$

In the Patterson theory, $-\widetilde{U}_1$ is the reduced vaporization energy of the solvent, $\widetilde{C}_{p,1}$ is the reduced configurational heat capacity of the solvent, and $\widetilde{\alpha}$ and $\widetilde{\beta}$ are respectively the reduced thermal expansion coefficient and the isothermal compressibility of the solvent. The ν^2 parameter is related to the difference of cohesive energy and size between the solvent molecule (1) and polymer segment (2). The τ parameter is related to the difference between the thermal expansion coefficient of the solvent (1) and the polymer (2) and is defined by:

$$\tau = 1 - T_1^*/T_2^* \tag{8}$$

where T_i^* is the characteristic temperature reduction parameter of the components (1) and (2). The π parameter is similarly related to the difference between the pressure reduction parameter of the components and is defined by:

$$\pi = P_1^*/P_2^* - 1 \tag{9}$$

The parameter c_1 is one-third the total number $(3c_1)$ of external degrees of freedom of the solvent molecule. In the Flory theory the parameter X_{12} measures the interchange energy on formation of contacts between unlike molecules, Q_{12} is analogously defined to represent the entropy arising from interchange of neighbouring molecules, and s_1 and s_2 denote the number of surface sites (or surface area) for segments of respective species, segments being of equal core volumes (V^*).

The pressure dependence of the critical solution temperature under the critical condition is expressed[40] by the ratio of second derivative of volume and enthalpy on concentration:

$$(dT/dp)_c = T(\partial^2 V/\partial\phi_2^2)_c/(\partial^2 H/\partial\phi_2^2)_c \tag{10}$$

where ϕ_2 is the segment fraction of polymer[12,17]. By assuming χ independent of concentration, equation (10) can be written as:

$$(dT/dp)_c = -(\partial\chi_1/\partial p)_T/(\partial\chi_1/\partial T)_p \tag{11}$$

Values of $(\partial^2 H/\partial\phi_2^2)_c$ are negative for the *UCST* corresponding to the endothermic condition and positive for the *LCST* corresponding to the exothermic condition. Rough estimations of $(dT/dp)_c$ have been carried out by the aid of the Patterson and Flory theories. The pressure coefficients of

14b-3	6.429	−8.99	−8.73	−2.47	−3.64	−3.53

χ_1 (equations 2 and 5) have been determined from the variation of volume with pressure at the critical solution temperature by use of equation (1). The values of $(\partial\chi_1/\partial T)$ at 1 atm have been estimated from the experimental values of the UCST over the molecular weight range of 3.7×10^4 to $\sim 145 \times 10^4$ and the critical values of χ_1:

$$\chi_1(\text{crit}) = (1/2)(1 + r^{-1/2})^2 \qquad (12)$$

where r is defined by the ratio of the molar volume reduction parameters (core volume), V_2^*/V_1^*[17]. The values of $(dT/dp)_c$ calculated by using these values of $(\partial\chi_1/\partial p)_{T_c}$ and $(\partial\chi_1/\partial T)$ at 1 atm are listed in *Table 2*, in which the pressure and temperature dependence of χ_1 are also included. The molecular parameters of the Flory theory obtained by using X_{12}, s_1/s_2, and the equation of state parameters[14] are given by $Y_{12} = 0.020\ 5$, $A^2 = 0.112\ 9$, and $c_1 = 1.14$, while the parameters of the Patterson theory are $\nu^2 = 0.0159$, $\tau^2 = 0.119$, and $c_1 = 1.01$; all these parameters are determined by comparison of experimental critical solution temperatures for the UCST and LCST with theory and the equation of state parameters[7]. A qualitative prediction of the experimental results is obtained by use of the Patterson and Flory theories, although the positive value for the solution of polystyrene of low molecular weight ($M_w = 3.7 \times 10^4$) is not predicted.

The expression proposed by Flory et al.[12−17] for the volume change on mixing in polymer solutions is given by:

$$\tilde{V}^E = \tilde{V} - \tilde{V}^0 \qquad (13)$$

and

$$\tilde{V}^0 = \phi_1 \tilde{V}_1 + \phi_2 \tilde{V}_2 \qquad (14)$$

where ϕ_i is the segment fraction of the component i. The value of $\tilde{V}$ for the solution is obtained by equation (1) at zero pressure. The characteristic temperature T^* of the solution is given by:

$$1/T^* = (\phi_1 P_1^*/T_1^* + \phi_2 P_2^*/T_2^*)/P^* \qquad (15)$$

and

$$P^* = \phi_1 P_1^* + \phi_2 P_2^* - \phi_1\theta_2 X_{12} \qquad (16)$$

where θ_2 is the site fraction of the polymer. The segment fraction and the site fraction for the polymer molecule (2) are defined by

$$\phi_2 = m_2 V_{sp;2}^*/(m_1 V_{sp;1}^* + m_2 V_{sp;2}^*) \qquad (17)$$

and

$$\theta_2 = (s_2/s_1)\phi_2/(\phi_1 + (s_2/s_1)\phi_2) \qquad (18)$$

where m_i is the mass of the component i and $V_{sp;i}^*$ is the characteristic reduction volume per gramme of the component i. The value of the excess volume for the polystyrene solution of $M_w = 3.7 \times 10^4$ at $12.25_1^\circ C$ and 16 wt % of polymer calculated by the Flory theory is $\tilde{V}^E/\tilde{V}^0 = -0.13 \times 10^{-2}$. The negative value is consistent with the prediction of a negative $(dT/dp)_c$.

The value of $(dT/dp)_c$ for $M_w = 3.7 \times 10^4$ is to be compared with the small value of the negative excess volume of mixing for the solution of polystyrene ($M_w = 5.1 \times 10^4$) in cyclohexane at 25°C obtained by Flory et al.[14]. The pressure dependence of the second virial coefficient $(\partial A_2/\partial p)$ in the polystyrene ($M_w = 10 \times 10^4$)–cyclohexane system obtained by Schulz-Lechner[34] is negative at 40°C and positive at 45° and 50°C over the pressure range of 1 to 400 atm. In the polystyrene–*trans*-decalin system[33,34] the values of $(\partial A_2/\partial p)$ are negative over temperature range of 15° to 35°C and slightly positive at 40°C. This behaviour of $(\partial A_2/\partial p)$ as a function of temperature can be related to the excess volume of mixing being positive at low temperature and being negative at high temperature[33,35]. Baba et al.[22] have recently observed the molecular weight dependence of the excess volume of mixing in the polystyrene–ethyl acetate system at 30°C. The excess volume of mixing is zero for solutions of polystyrene of $M_w = 0.21 \times 10^4 \sim 1.0 \times 10^4$ and negative, depending on concentration, for $M_w = 2.04 \times 10^4 \sim 67 \times 10^4$. In the light of these facts it is suggested that the value of the excess volume of mixing in the polystyrene–cyclohexane system changes sign depending both on the molecular weight of polystyrene and temperature.

Deformation mechanisms in polytetrafluoroethylene

Robert J. Young

Department of Engineering, University of Cambridge, Cambridge CB2 1PZ, UK
(Received 29 August 1974; revised 11 December 1974)

The deformation of isotropic and oriented polytetrafluoroethylene has been examined by wide-angle X-ray diffraction and electron microscopy. The deformation mechanisms which have been found to operate are $\{10\bar{1}0\}\langle0001\rangle$ chain direction slip and $\{10\bar{1}0\}\langle1\bar{2}10\rangle$ transverse slip. At $20°C$ the critical resolved shear stress for chain direction slip has been found to be about $2.5\ MN/m^2$ and that for transverse slip to be about $15\ MN/m^2$.

INTRODUCTION

Polytetrafluoroethylene (PTFE) normally crystallizes in the form of banded lamellae up to 1 μm thick and containing striations parallel to the chain direction[1]. The size of the banded lamellae has been found by Speerschneider and Li[2,3] to depend upon the crystallization conditions. They also found that when the banded material was deformed above $-70°C$ the striations tended to shear past each other whereas at lower temperatures deformation by kinking of the striations appeared to be more common[3].

The deformation of PTFE has also been studied by X-ray diffraction. Uniaxially oriented material has been found to have a texture with the chain axes, $\langle0001\rangle$ parallel to the draw direction[4]. The texture of rolled PTFE has been investigated by pole-figure analysis[5,6]. Hot-rolled PTFE has a simple texture with $\{10\bar{1}0\}$ in the plane of the sheet and $\langle0001\rangle$ parallel to the extension direction. McCrum and his coworkers[5,6] interpreted this texture in terms of chain direction slip on the closest-packed planes (i.e. $\{10\bar{1}0\}\langle0001\rangle$ slip). The crystal structures of PTFE and polyoxymethylene (POM) are similar in that both have molecules in a helical conformation and a hexagonal crystal structure. It is not surprising therefore that the texture of hot-rolled POM is similar to that of hot-rolled PTFE[5].

The texture of cold-rolled POM is rather complex[5-9]. Preedy and Wheeler[8] suggested that the difference in texture between the hot-rolled and cold-rolled material might be due to POM undergoing a phase transformation to an orthorhombic cell. Miles and Mills[9] found no evidence for a new phase in POM and suggested that the complex low temperature texture was probably due to the simultaneous occurrence of $\{10\bar{1}0\}\langle0001\rangle$ slip and $\{10\bar{1}0\}\langle1\bar{2}10\rangle$ slip. It is difficult to roll PTFE at room temperature and so little work has been done upon the structure of cold-rolled material. In this present work a technique has been used to obtain biaxially oriented PTFE at various temperatures by the use of a constrained compression die[10]. The texture of the oriented material has been interpreted in terms of deformation mechanisms. The constrained compression technique has been used to prepare oriented material with a well-defined texture which has then been used for further study of the individual deformation mechanisms.

DEFORMATION OF ISOTROPIC PTFE

The PTFE material used in this work was Fluon coarse dispersion polymer kindly supplied by ICI Ltd in the form of 6 mm thick sintered sheet. During fabrication, the material had been cooled slowly to produce the thick banded lamellae[1].

Experimental

Bars of PTFE were compressed at various temperatures between $-40°C$ and $220°C$ in the die illustrated schematically in *Figure 1* which is similar to the one used by Young et al.[10]. It had been modified to include electrical heaters which were able to hold the temperature constant to better than $±3°C$ up to $250°C$. When the material is compressed, the die allows the PTFE to extrude from the ends as the height is reduced but at the same time the sample is con-
Figure 1 The heated compression die used to prepare the oriented material. *X* is parallel to the compression direction, *Y* and *Z* are in the plane of the sheet with *Y* parallel to the extension direction
Figure 2 Electron micrographs of PTFE (a) before and (b)–(d) after deformation at different temperatures: (b) –40°; (c) 21°; (d) 70°C

strained to constant width. This produces a plane strain deformation similar to that of rolling but has the added advantage of not allowing any increase in width due to bulging[7].

In each case the sample was compressed to the maximum strain that could be tolerated before fracture intervened and the hot samples were quenched by water-cooling to room temperature at about 30°C/min.

Electron microscopy

Replicas of fracture surfaces of the PTFE samples were obtained before and after deformation and were examined in an electron microscope. The fracture surfaces were obtained by cleaving specimens in liquid nitrogen. Carbon replicas, shadowed by gold–palladium, were obtained using cellulose acetate as described by Young and Bowden[11] for HDPE.

An electron micrograph of a replica of a fracture surface of an undeformed sample is given in *Figure 2a*. The surface

consists of lamella crystals up to 1 μm thick. The striations within the crystals are parallel to the chain axes of the crystals[1] and approximately perpendicular to the surfaces of the lamellae. *Figure 2b* is a replica from a specimen compressed to a strain of 45% at –40°C. The section was taken in the plane strain plane with the X direction vertical and Y horizontal (*Figure 1*). In some of the crystals the striations appear to have sheared past each other and are no longer perpendicular to the surfaces of the lamellae. *Figure 2c* shows a similar specimen compressed at 21°C to a strain of 70%. In this case all the striations have tilted over sharply and in some cases crystals have started to break up. In the central area of the micrograph the broken crystals appear to have started to recrystallize and where this has happened the striations in the new crystals are approximately parallel to the extension direction (Y). *Figure 2d* is taken from a specimen compressed at 70°C to a strain of about 80%. In this case the original crystal structure is completely destroyed and a fibre structure produced.
Figure 3 Wide-angle X-ray diffraction patterns of PTFE deformed at three different temperatures. Patterns have been obtained with the beam parallel to *X, Z* and *Y* respectively

The behaviour outlined above is consistent with the model for the deformation of polyethylene and polypropylene by rolling or drawing put forward by Peterlin[12]. It is thought that first of all the molecules shear past each other within the crystals until they are aligned close to the extension direction. The crystals are then thought to start to break up and recrystallize such that the new crystals are all approximately transverse to the extension direction and the molecules are parallel to the extension direction. Previously most of the evidence for this model for deformation had been obtained by using indirect methods such as X-ray diffraction. The micrographs in *Figure 2* show clearly how this process takes place in PTFE on the molecular level.

X-ray diffraction

The X-ray diffraction patterns which were obtained at $25 \pm 2°C$ with the X-ray beams parallel to *X*, *Z* and *Y* for specimens deformed at $-40°$, $21°$ and $70°C$ are given in *Figure 3*.

The patterns obtained with the beam parallel to *X* and *Y* for specimens deformed at $-40°C$ show almost complete rings and are not very different from the pattern obtained from the undeformed structure. The pattern obtained with the beam parallel to *Z* is quite different showing a well-defined hexagonal pattern. The reflections in the inner ring are of the $\{10\bar{1}0\}$ type and the positions of the maxima correspond to 3 sets of $\{10\bar{1}0\}$ planes parallel to *Z* as illustrated in *Figure 4a*. One set is also parallel to *X*
Figure 4 Schematic diagrams of the texture in oriented PTFE. (a) Transverse texture obtained at -40°C; (b) normal texture obtained by hot rolling or compression orientation

and the other two are at $\pm 60^{\circ}$ to X.

For specimens deformed at higher temperatures the three diffraction patterns are found to change. In the pattern obtained with the beam parallel to X the inner rings start to intensify at the equator and become quite intense at 70°C. With the beam parallel to Z intensification on the equator also starts to occur at higher temperatures and the hexagonal symmetry found at -40°C starts to be destroyed. The intensification of these patterns about the equator is characteristic of molecular orientation when $(hkiO)$ reflections intensify perpendicular to the extension direction (Y). However, the pattern obtained with the beam parallel to Z at 70°C still has a maximum on the meridian of the $\{10\bar{1}0\}$ ring indicating the presence of $\{10\bar{1}0\}$ planes perpendicular to Y.

The patterns obtained with the beam parallel to Y do not show a great deal of orientation and do not change greatly as the temperature is raised. However, careful examination of the $\{10\bar{1}0\}$ ring in the specimen deformed at 70°C shows that there is a variation of intensity around the ring. There is intensification on the meridian and at $\pm 60^{\circ}$ to the meridian. Along with the other patterns obtained from the 70°C material this implies that the texture is made up of $\{10\bar{1}0\}$ planes in the ZY plane and also at $\pm 60^{\circ}$ to the ZY plane as illustrated schematically in *Figure 4b*. This is precisely the texture obtained by McCrum and coworkers[5,6] for hot-rolled PTFE.

INTERPRETATION OF TEXTURE IN TERMS OF DEFORMATION MECHANISMS

The interpretation of texture in deformed polymers in terms of deformation mechanisms has been discussed in detail by Bowden and Young[13] and essentially their approach will be used again here. The deformation mechanisms that have been suggested for PTFE are $\{10\bar{1}0\}$ $\langle 0001 \rangle$ chain direction slip[5,13] and $\{10\bar{1}0\}\langle 1\bar{2}10 \rangle$ transverse slip[13]. For both of these two mechanisms there are three slip systems, two of which are independent. In total, therefore, there are four independent slip systems for the PTFE crystal. It has been shown[14] that five independent slip systems are required to be able to operate before any polycrystalline material may undergo a general shape change. As PTFE can deform plastically without cracking, it must be concluded that shape changes are to some extent taken up by the amorphous material between the crystals[13].

Hot-oriented PTFE

The simplest texture of PTFE to interpret is that of hot rolled or hot compression-oriented material. The texture consists of $\{10\bar{1}0\}$ planes transverse to the compression direction (X) and $\langle 0001 \rangle$ chain axis parallel to the extension direction (Y). McCrum and coworkers[5,6] interpreted such a texture as being due to $\{10\bar{1}0\}\langle 0001 \rangle$ chain slip. Bowden and Young[13] showed that such a texture could not be produced by chain direction slip alone and went on to show that in order to produce such a texture during plane strain deformation, slip would have to take place on $\{10\bar{1}0\}$ in both $\langle 0001 \rangle$ and $\langle 1\bar{2}10 \rangle$ directions (i.e. transverse slip was needed as well).

Orientation at lower temperatures

The texture found by orienting PTFE at lower temperatures is more unusual than that found at higher temperatures. The amount of strain that can be produced before cracking is less at lower temperatures and this may account for some of the differences. *Figure 4a* gives a schematic illustration of the texture of compression-oriented PTFE deformed at -40°C. The chain axis $\langle 0001 \rangle$ is transverse to the extension direction and the $\{10\bar{1}0\}$ planes perpendicular to the extension direction (Y) and at $\pm 60^{\circ}$ to Y. In order to interpret this texture it is necessary to consider what the X-ray beam is sampling. For any given orientation of the X-ray beam the reflections on the diffraction pattern are from planes which are oriented at the Bragg angle to that beam. In polymers strong reflections are only normally obtained from low index planes. The spacing of the $\{10\bar{1}0\}$ planes in PTFE is 4.9 Å which using CuKα radiation leads to a Bragg angle of about 9°. This is within the limits of the spread of the texture that would be expected and so it may be assumed that for this analysis $\{10\bar{1}0\}$ planes giving rise to the $\{10\bar{1}0\}$ reflection are effectively parallel to the beam.

As there is no high degree of overall orientation at -40°C, it appears that the texture found in the pattern obtained with the beam parallel to Z may be due to the deformation of crystals which were oriented initially with their chain axes approximately parallel to Z. This transverse texture is probably due to slip within these crystals only. The chain axes of the crystals are perpendicular to the plane strain (XY) and so during deformation $\{10\bar{1}0\}$ $\langle 1\bar{2}10 \rangle$ transverse slip will be favoured. Because of the hexagonal symmetry of PTFE there are three possible slip systems at 60° to each other. Slip will take place on the
Figure 5 Illustration of the three different ways in which specimens were cut from the oriented sheets. (a) Specimen for shear on XY; (b) specimen for shear on YZ; (c) specimen for shear perpendicular to the molecular chains (Y)

$\{10\overline{1}0\}$ plane which experiences the highest resolved shear stress and the crystal rotates until this plane is at 60° to the compression direction (X). At this point another plane is also at 60° to X and slip then takes place on both of these planes simultaneously. This is known as *Duplex slip* and there is no further rotation of the crystal (see later). The texture found in the specimen compressed at $-40°$C is consistent with this type of deformation. At higher tem-

peratures and in specimens deformed to higher strains, crystals of all original orientations will have to deform to accommodate the strain. $\{10\overline{1}0\}\langle0001\rangle$ chain slip will then take place as well as transverse slip and the high temperature texture will be produced. However, even at 70°C there are still $\{10\overline{1}0\}$ planes perpendicular to Y due to Duplex slip in crystals which were originally oriented with their chain axes ($\langle0001\rangle$) parallel to Z.

Table 1 Measured values of θ_0, θ_1, e and bulging for specimens of oriented PTFE sheared in two different ways parallel to the chain direction (θ_1 has also been calculated using equation 1)

Mode	θ_0 (degrees)	θ_1 (degrees)	e (%)	θ_1 (calc.) (degrees)	Bulging (%)
Shear	17	38	26.7	45	21
on	36	47	22.5	51	3
XY	52	62	22.8	61	7
Shear	27	46	20.5	45	7
on	43	56	26.0	57	1
YZ	60	66	22.0	67	~0

DEFORMATION OF ORIENTED PTFE

The oriented material used in this section had been compressed as described in the experimental section to a strain of 83% which corresponds to a compression ratio of about 6. This material was similar to that compressed at 70°C with $\{10\overline{1}0\}$ planes parallel to and at ±60° to the plane of the sheet (YZ). The X-ray diffraction patterns of this material were more well-defined showing that deformation at higher temperatures produced a higher degree of orientation. No extra reflections were observed in the X-ray diffraction patterns after deformation so it was assumed that

Before

After

Figure 6 Wide-angle X-ray diffraction patterns obtained before and after deformation for specimens with $\theta_0 \sim 40°$. The compression direction is vertical and θ was measured using the innermost ($\{10\overline{1}0\}$) arcs. (a) Specimen sheared on XY (X-ray beam parallel to X); (b) specimen sheared on YZ (X-ray beam parallel to Z)

the PTFE crystals had not undergone a stress-induced phase change as in the case of deformed PE[10,15].

Shear parallel to the molecules

Specimens were cut from the oriented sheets at angles to the chain direction in two different ways as shown in *Figures 5a* and *5b*. They were then compressed between steel dies at various angles to the chain direction as described for PE by Young *et al.*[10] and deformation was found to take place principally by slip parallel to the chain direction. The angle between the chain direction and the compression direction has been defined as θ and for the two types of specimen samples were cut out at θ values of approximately $20°$, $40°$, and $60°$.

Stress—strain curves were obtained for each specimen and θ was measured before (θ_0) and after (θ_1) deformation using wide-angle X-ray diffraction and CuKα radiation. The measured values of θ_0 and θ_1 are given in *Table 1*. Pairs of X-ray diffraction patterns for the two types of specimens both with $\theta_0 \sim 40°$ are given in *Figure 6*. In all cases it was found that θ had increased after deformation which is consistent with the deformation having taken place by single slip parallel to c^{10}. For this type of deformation the relationship between θ_0 and θ_1 is given by[10]:

$$\frac{\cos \theta_1}{\cos \theta_0} = 1 - e \qquad (1)$$

where e is the specimen strain. Values of θ_1, calculated using this equation with the measured values of θ_0 and e are also given in *Table 1*. For shear on YZ it can be seen that the measured and calculated values of θ_1 agree to within one degree which shows that for this case, the deformation took place essentially by single slip parallel to the chain direction. For specimens sheared on XY this agreement was somewhat worse. The increase in specimen width due to bulging perpendicular to the compression direction was also greater. This shows that there was some deviation from plane strain deformation. Both of these observations show that in this orientation, the specimens deformed by other mechanisms as well as single slip parallel to the chain direction.

The stress—strain curves were converted into plots of stress against θ using equation (1). The curves for shear on XY are given in *Figure 7* and those for shear on YZ in *Figure 8*. In a previous paper[10] upon PE an attempt was made to interpret similar data in terms of slip parallel to c at a constant critical resolved shear stress, τ. The yield or flow stress σ is then given by the equation,

$$\sigma = \tau/\sin \theta \cos \theta \qquad (2)$$

This equation is plotted as broken lines in *Figures 7* and *8* fitted approximately to the yield stresses of each of the curves by choosing an appropriate value of τ. For shear upon XY (*Figure 7*) τ is 5 MN/m^2 and for shear upon YZ (*Figure 8*) τ is 2.5 MN/m^2. It may be noted that, although the yield points of the curves lie approximately upon the broken lines, after yield the curves rise steeply above them. This may be contrasted with similar investigations into the deformation of compression-oriented and annealed HDPE[10]. In this case, it was found that the oriented HDPE yielded and flowed at a constant critical resolved shear stress. However, compression-oriented HDPE which had not been annealed did show similar strain-hardening during plastic flow.
Figure 7 Plots of stress as a function of θ for specimens sheared on XY
Figure 8 Plots of stress as a function of θ for specimens sheared on YZ

Deformation mechanisms induced by shear parallel to the molecules

In the previous section it was shown that slip parallel to the molecules would take place upon both the XY and YZ planes. However, it was also shown that slip was easier upon YZ as there was a lower value of τ required, much less bulging (*Table 1*) and good agreement with equation (1). This gives a strong indication of the slip plane for the chain direction ($\langle 0001\rangle$) slip process. In the oriented PTFE that has been used there is a set of $\{10\bar{1}0\}$ planes in the plane of the sheet (YZ). Since slip is very much easier on the YZ plane, the slip plane with the lowest critical resolved shear stress must therefore be $\{10\bar{1}0\}$. The $\{10\bar{1}0\}$ planes are at $\pm 30°$ to the XY plane and so for slip to take place on $\{10\bar{1}0\}$ planes in a specimen sheared on XY, the stress needed for $\langle 0001\rangle$ slip is higher by a factor of $(\cos 30°)^{-1}$ (1.15). Since the measured ratio of the τ values is of the order of 2 and in some specimens there was considerable amounts of bulging (*Table 1*) any quantitative interpretations of this form of deformation would appear to be difficult.

Shear perpendicular to the molecules

Specimens were cut from the sheets of oriented PTFE as shown in *Figure 5c* so that they could be compressed in directions perpendicular to the molecular chains. They were compressed in uniaxial compression in a similar way
Figure 9 Stress—strain curves for specimens compressed in directions transverse to the chain axis (Y). A, Specimen compressed parallel to X; B, specimen compressed parallel to Z

to the compression of oriented and annealed HDPE described by Young and Bowden[15]. Two particular specimens were used. One was compressed parallel to X and the other parallel to Z. In both cases there was no measurable change in specimen length parallel to Y and so the deformation could be considered to be essentially plane strain. Plots of true stress against nominal strain were obtained for the two specimens and they are both given in *Figure 9*.

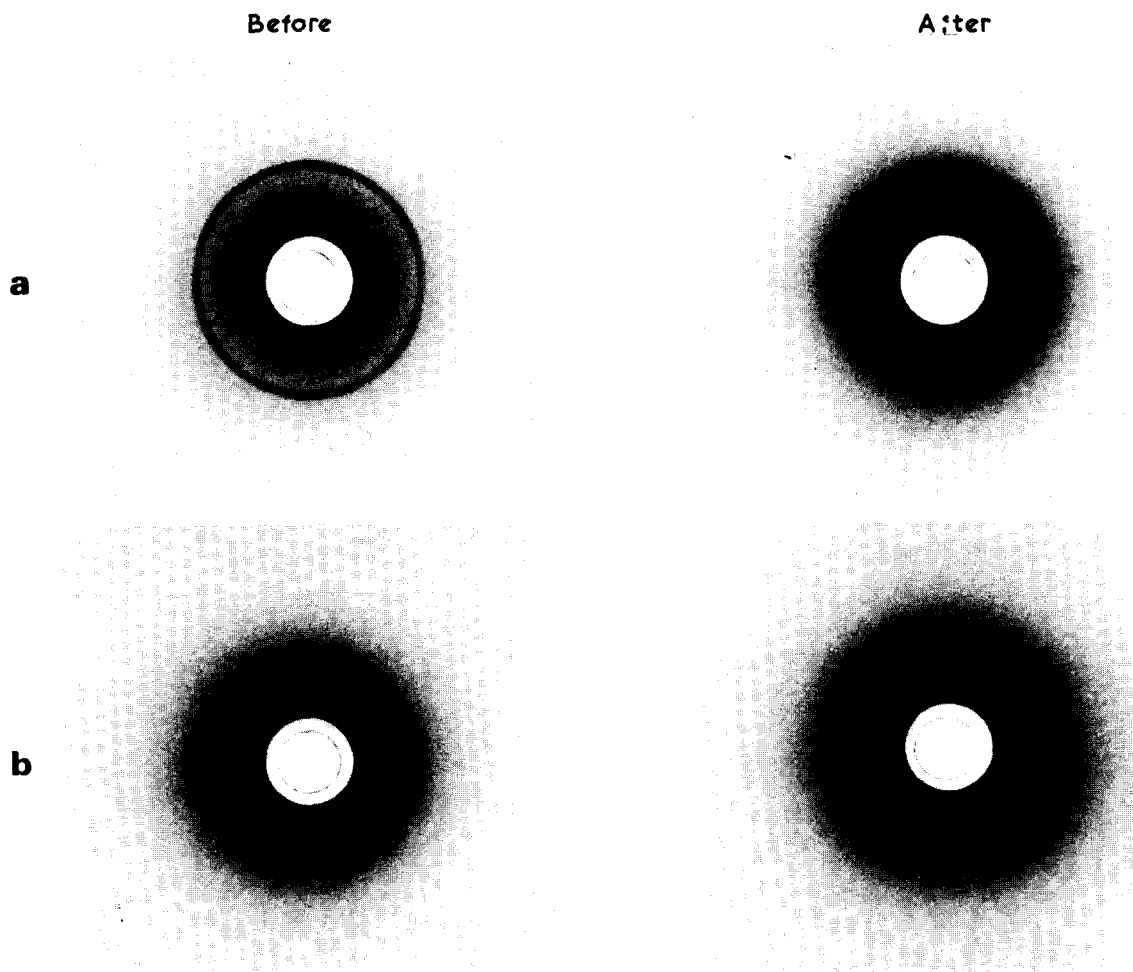
Wide-angle X-ray diffraction patterns were also obtained from each specimen before and after deformation and they are given in *Figure 10*. In each case the X-ray beam is parallel to Y and the compression direction is vertical. The first pair of diffraction patterns (*Figure 10a*) were obtained from the specimen compressed parallel to X. Before deformation, the pattern has hexagonal symmetry corresponding to $\{10\bar{1}0\}$ transverse to and at $\pm30°$ to the compression direction. After deformation, the pattern is less well-defined but careful examination of the $\{10\bar{1}0\}$ ring shows maxima corresponding to planes parallel to and at $\pm60°$ to the compression direction. The second pair of patterns (*Figure 10b*) are for the specimen compressed parallel to Z. The pattern obtained before deformation has hexagonal symmetry again and the $\{10\bar{1}0\}$ maxima correspond to planes parallel to and at $\pm60°$ to the compression direction. After deformation the pattern is less well-defined but the position of the maxima remains unchanged. This means that this time the $\{10\bar{1}0\}$ planes have not rotated during deformation but have remained stationary at $\pm60°$ to the compression direction.


Figure 10 Wide-angle X-ray diffraction patterns for the specimens used in *Figure 9* obtained with the beam parallel to Y. (a) Specimen compressed parallel to X; (b) specimen compressed parallel to Z

Deformation mechanisms induced by shear transverse to the molecules

From the X-ray diffraction patterns obtained in the previous section it is possible to determine the deformation mechanisms which were operating during transverse deformation. For both specimens the X-ray patterns obtained after deformation are identical with $\{10\bar{1}0\}$ planes parallel to and at ±60° to the compression direction.

The orientation of the unit cell for compression perpendicular to the chain direction and parallel to X is illustrated schematically in *Figure 11*. In this orientation $\{10\bar{1}0\}$ $\langle 1\bar{2}10\rangle$ transverse slip will take place on the $\{10\bar{1}0\}$ plane which experiences the highest resolved shear stress. i.e. one of the planes at 30° to the compression direction. The plane is rotated by the slip process and the resolved shear stress is continuously reduced until it reaches a minimum when the plane is at 45° to the compression direction. Any further rotation of the plane increases the resolved shear stress but slip continues until it is at 60° to the compression direction as it is still the plane which experiences the highest resolved shear stress. When the slip plane is at 60° to the compression direction, there is then another plane also at 60° to the compression direction (*Figure 11*). In this position any further rotation of the original slip plane reduces the angle of the second plane. This is a position of Duplex slip[16] since slip will take place simultaneously on the two $\{10\bar{1}0\}$ planes without any overall rotation of the crystal.

It is now possible to explain the stress–strain curves in *Figure 9* in terms of Duplex slip. For curve B the stress increases as the specimen is loaded until it reaches a constant value. In this specimen the $\{10\bar{1}0\}$ planes were originally at ±60° to the compression direction. The yield and flow stress in this orientation is 36 MN/m² and since there is no change in orientation during Duplex slip, there is no overall change in stress during flow. It must be noted that there is no apparent strain hardening as was found for chain direction slip. The critical resolved shear stress, τ, for $\{10\bar{1}0\}\langle 1\bar{2}10\rangle$ slip may be estimated from equation (2). In this case, the $\{10\bar{1}0\}$ slip planes are always at ±60° to the compression direction which means that θ equals 60°. The yield and flow stress for compression parallel to Z is about 36 MN/m² which gives a value of τ of about 15 MN/m² for $\{10\bar{1}0\}\langle 1\bar{2}10\rangle$ slip at 20°C. Curve A in *Figure 9* eventually settles at about 36 MN/m² at strains above 30% when the $\{10\bar{1}0\}$ slip planes have rotated to the position for Duplex slip to take place.

DISCUSSION AND CONCLUSIONS

The deformation mechanisms which have been found to operate in PTFE are $\{10\bar{1}0\}\langle0001\rangle$ chain slip and $\{10\bar{1}0\}$ $\langle 1\bar{2}10\rangle$ transverse slip. Both of these two mechanisms give rise to three slip systems, only two of which are independent. This gives a total of four independent slip systems. For an isotropic polycrystalline material to undergo a general shape change without cracking five independent slip systems must be able to operate[13,14]. However, the amorphous material between the crystals can accommodate the change in shape of the individual crystals and may therefore allow the material to undergo a general shape change without the necessity of five independent slip systems[13].

The critical resolved shear stress for $\{10\bar{1}0\}\langle0001\rangle$
Figure 11 A schematic diagram of the rotation of the hexagonal unit cell of PTFE by compression perpendicular to the chain direction. The slip planes are represented by broken lines

chain direction slip has been found to be about 2.5 MN/m² and that for $\{10\bar{1}0\}\langle 1\bar{2}10\rangle$ transverse slip to be about 15 MN/m². Chain direction slip also appears to show a large amount of strain hardening but transverse slip shows remarkably little.

Recent work[17] has shown that dislocations may be activated thermally during the deformation of HDPE by means of chain direction slip. The energy of a dislocation depends strongly upon the Burgers vector which for chain direction slip in PTFE is extremely large (19.5 Å). For this type of deformation to take place with such ease, slip must occur by means of partial dislocations or the rotation of molecules during deformation[18].

Notes to the Editor

Voiding in glass fibre reinforced thermoplastics mouldings

M. W. Darlington and G. R. Smith

Department of Materials, Cranfield Institute of Technology, Cranfield, Bedfordshire MK43 0AL, UK
(Received 16 December 1974)

INTRODUCTION

The tensile creep behaviour of short fibre reinforced thermo-plastics has been studied in these laboratories using highly accurate equipment in which all three orthogonal strains are measured simultaneously. This has enabled volume changes associated with voiding during uniaxial tensile creep to be calculated and these have been correlated with the incidence of permanent damage (in the form of deterioration in mechanical properties) resulting from the deformation of the fibre matrix system[1,2]. The detailed development of the voiding has not yet been studied.

The nature of these composites makes the preparation of well oriented (or indeed, perfectly random) and homogeneous samples extremely difficult, and the fibre orientation distribution in typical injection mouldings of these materials is usually complex and inhomogeneous. Nevertheless, a detailed characterization of the fibre orientation distribution and all other relevant features of the composite is essential if the mechanical data are to have any real significance. Some guidance on fibre orientation distributions in the above samples has been obtained by optical examination of surfaces cut in a variety of directions through the samples and polished using standard metallographic polishing techniques.

In preparation for an extension of the above studies to creep in liquid environments, a new batch of short glass fibre reinforced thermoplastics injection mouldings were obtained from a different source (referred to as moulder B) to that of the original batch (from moulder A). During an initial characterization of these mouldings a new feature became apparent. This took the form of a central white zone and was initially observed in the through-thickness cross-section of short glass fibre reinforced polypropylene (GFPP) edge-gated discs of nominal thickness 3 mm and 6 mm. On re-examination, a similar, though less marked and discontinuous, central white zone was noted in the cross-section of the GFPP 3 mm thick edge-gated discs previously supplied by moulder A. The appearance of the cross-section for the samples from moulder B is shown in *Figure 1*. The weight fraction of glass fibres was $28 \pm 1\%$ in all samples.

Although voids were known to occur in GFPP mouldings with thick sections, enquiries and a search of the literature produced no clear statement on the nature of the white zone, or even on the occurrence of voids, in the thinner sections. In view of the possible effects of voids on mechanical properties in air, and the proposed creep study in liquids, it was considered essential to examine the central white zone, with particular regard to any occurrence of voids.

A detailed determination of fibre content in the mouldings indicated little change through thickness, but the central white zone was found to have a lower density than the
Figure 1 Photograph of the cross-section of 3 mm and 6 mm thickness edge-gated discs of GFPP supplied by moulder B, showing the central white zone

surrounding regions. Subsequent optical examination of the 6 mm thick GFPP disc moulding indicated the existence of voids in the central white zone, large enough to be resolved by a low power stereo-optical microscope at a magnification of 60. It was considered that the occurrence of the narrow central white zone in the 3 mm thickness moulding should be an effect similar to that observed in the 6 mm mouldings, though occurring on a smaller scale. As stereo-optical microscopy provided no evidence of the existence of voids in the 3 mm thickness mouldings, scanning electron microscopy was employed in an attempt to locate such features in the central white region.

The surface preparation technique was that mentioned above for the determination of fibre orientation distributions. Although this surface preparation technique appears to be reasonably well established for the examination of glass fibre reinforced thermosets[3], and has been shown to be useful for fibre orientation distribution studies in short fibre reinforced thermoplastics. it does not appear to be readily acceptable for the study of features such as voids in the latter group of composite materials. The purpose of this note is therefore to establish the validity of the preparation technique for the study of voids and to report some of the interesting features observed in the central white

regions of some short glass fibre reinforced thermoplastics injection mouldings.

It is concluded that (1) the polishing technique is superior to microtome methods in this context and that (2) voids occur in all the mouldings examined, but that the scale of the effect changes substantially with mould thickness.

EXPERIMENTAL

Examination techniques have been refined from standard metallographic sectioning and polishing procedures in order to reduce to a minimum the number of spurious observations of surface features associated with polishing brittle glass fibres embedded in a flexible matrix. Sections were cut along planes parallel and orthogonal to the moulding surfaces from a number of glass fibre reinforced nylon (GF nylon) mouldings, as well as from those GFPP mouldings described above. These sections were then embedded in a cold curing mounting compound prior to progressive polishing on graded emery papers followed by polishing on five graded diamond wheels down to 0.25 μm. Examination of the polished surfaces for defects by reflection optical microscopy then preceded careful extraction of the sections from the embedding medium and remounting on metal studs. These remounted, polished specimens were then coated under vacuum with a gold/palladium alloy before examination by scanning electron microscopy.

RESULTS AND DISCUSSION

The most severe instance of voiding observed during this study was noted in a 12 mm square cross-section GF nylon-6,6 impact test bar provided by moulder A. Here holes clearly visible to the naked eye could be observed in the central white region. *Figure 2* presents a low magnification scanning electron micrograph of the central region of a cross-section plane cut and polished from this impact bar. In addition to the large voids visible by eye, a wide range of smaller size voids can also be seen in this micrograph. *Figure 3* then concentrates on the area around the largest void visible in
Figure 3 Detail of a large void appearing in the micrograph of *Figure 2*

Figure 2 and here it can be seen that void sizes range over at least two orders of magnitude (from approximately 1 mm across down to a few μm).

A similar pattern of voids has been observed in the central white region of 6 mm thickness GFPP edge-gated discs. In addition to the large voids described earlier for this material many smaller voids were visible at higher magnifications by scanning electron microscopy. The largest void sizes observed in the 6 mm GFPP disc (about 0.3 mm across) were far smaller than the large void visible in *Figures 2* and *3*. However, a wide range of void sizes was observed and the pattern of voiding in the central white region of the 6 mm thickness GFPP disc was quite similar to that observed in the GF nylon impact bar.

The incidence of a central white layer through the cross-section of 3 mm thickness GFPP edge-gated discs was far less developed than in the 6 mm GFPP disc moulding. However, this central white layer was easily observable in the 3 mm thickness disc supplied by moulder B. A wide void size range was noted in the central white zone of sections cut through the disc cross-section and in sections cut parallel to the moulding surface at half-thickness through the disc. The overall impression obtained was that void sizes in this 3 mm thickness disc (from 0.1 mm down to several μm) were smaller than those observed in the 6 mm disc provided by the same moulder.

It is worth noting that sections cut at half-thickness through the disc parallel to the mould surface were found preferable to sections through the disc cross-section for the observation of these smaller holes. As the plane of these 'half-thickness' sections was the plane in which most fibres lay (the fibre distribution in the central zone of these discs being generally aligned in the plane of the disc), damage occurring at polished fibre ends was thus minimized. Examination of sections cut parallel to the surface outside the central white layer of the specimens described above produced no detectable voids (i.e. features greater than 2 or 3 μm across).

Observation of voiding in the discontinuous and narrow central white layer of the 3 mm thickness GFPP disc produced by moulder A presented a greater problem. Sections

Figure 4 Voiding appearing in the central white layer of a GFPP 3 mm thickness edge-gated disc supplied by moulder A. (See text for detail of sectioning.)

cut parallel to the mould surface at half thickness invariably polished through the narrow white layer during preparation. To overcome this difficulty, a section was cut through this narrow central white layer at an angle to the plane of the disc. The section was cut near to the disc edge where this central white zone had become slightly more apparent in the disc cross-section.

Figure 4 presents a micrograph of this section from the GFPP 3 mm thickness disc produced by moulder A. It could be seen visually that this section had sliced through the narrow white layer and observations of this section at different magnifications under the scanning electron microscope showed that the site of the white layer coincided with the region in which the voids visible in *Figure 4* occurred. Again, a large size range of voids can be seen (from 0.05 mm across to a few μm). It should be noted that the edge visible in this micrograph is not a moulded disc edge, but a cut edge of the section examined.

Once again many sections cut parallel to the surface outside the white region in this edge-gated disc produced no voids of size greater than several μm. Indeed very few holes even in this size range were observed. This, and the observation of holes only in the white zone, is seen as support for the contention that the holes down to this size range are inherent in the moulding and not artefacts of the preparation process.

Figure 5 presents a micrograph of a small void observed in the white zone of the 3 mm GFPP disc from moulder B. This hole is approximately 5 μm across. It is thought that such a void represents the lower bound in size range which can be regarded as an inherent fault in the material when using this metallographic preparation technique. Below this size, problems of interpretation may arise due to surface damage caused by small glass particles.

Figure 5 may also be used to illustrate the nature of the general polished surface at high magnification. The polished surfaces produced in the manner described above have been found to be far superior to surfaces produced in

these laboratories by microtome techniques for the observation of voids in these composites. The polishing technique is also considered superior for the simpler problem of observing fibre orientation distributions.

Figure 6 concentrates on one of the voids visible near the cut edge shown in the micrograph of *Figure 4*. The slight effects of fibre damage and of rounding the edge of the void, both due to the polishing technique, can be observed in this micrograph.

It was possible with the void shown in *Figure 6* to scan down into the void, beyond the effects of polished edge-rounding, to observe the micro-structure of the void wall. This is depicted in *Figure 7*. It is interesting to compare
Figure 5 Small voids appearing in the central white region of the cross-section of a 3 mm thickness GFPP edge-gated disc supplied by moulder B
Figure 6 Detail of a large void which can be observed in the scanning electron micrograph of *Figure 4*

Figure 7 Scanning electron micrograph of the wall of the void shown in *Figure 6*

the fibrillar structure of this void wall with previously published[4] stereo and transmission electron micrographs of an unoriented polystyrene fracture surface in which the fibrillar structure of the fracture surface is of a similar nature to the structure observed on the void wall. Other small voids have also been observed with fibrillar material across the void suggesting that the void may have occurred as a craze parted and developed into a crack.

From this work it appears that wherever a white central

zone occurs in the cross-section of a glass fibre reinforced thermoplastic injection moulding, it is an example of the same phenomenon and involves voiding. The extent of this whitening phenomenon and the scale of voiding have been seen to be dependent on the thickness of the moulding and perhaps, more particularly, on moulding conditions.

Trends with thickness in different glass fibre reinforced thermoplastics are also worth noting. While a visible white zone and voids existed in 3 mm thickness GFPP mouldings, no whitening was observed in GF nylon mouldings of a similar thickness (though it should be noted, of different fibre length distribution). However, in thicker cross-section specimens the extent of voiding appeared more pronounced in GF nylon, though it was accompanied by a less extensive white region than appeared in similar thickness GFPP mouldings.

While this work has not endeavoured to clarify the origin of the white layer itself in these mouldings, it seems reasonable to suggest that the central white zone may arise as crazing occurs to relieve stresses created during cooling. The occurrence of this white zone may then precede the development of voids by some crazing and splitting mechanism through which built-in stress is further relieved.

(Received 17 December 1974)

INTRODUCTION

Calorimetric investigations have revealed that a number of crystalline polymers including polyethylene[1,2], polyoxymethylene[3], nylon[4], and poly(ethylene terephthalate)[5-8] may exhibit multiple melting peaks. This behaviour is closely tied to the thermal history of the samples and may arise from: (1) the presence of alternate crystal modifications; (2) molecular weight segregation accompanying crystallization; (3) variations in morphology; (4) orientation effects; or (5) melting, recrystallization and annealing processes taking place in the calorimeter. Identification of the specific causes of multiple melting in a particular polymer is an important aspect of its thermal characterization. We wish to report some recent calorimetric studies of multiple melting in poly(butylene terephthalate) (PBT), a polymer currently experiencing rapid growth as an injection mouldable engineering thermoplastic.

EXPERIMENTAL

PBT samples were supplied by the GE Plastics Division (Pittsfield, Mass.) and had intrinsic viscosities ranging from 1.21 to 1.53 dl/g. All thermal measurements were carried out in a Perkin-Elmer DSC-2 calorimeter. The samples were first melted in the calorimeter for 2 min at 250°C, recrystallized by slow cooling to room temperature. and then remelted. Wide angle X-ray diffraction measurements were made on a GE XRD-5 machine using CuKα radiation.

RESULTS

Since similar d.s.c. traces were obtained on all samples over the available molecular weight range only data for a sample having an intrinsic viscosity in hexafluoroisopropanol (HFIP) at 25°C of 1.31 dl/g are presented in this report. Crystallization exotherms for samples cooled at rates from

INTRODUCTION

Calorimetric investigations have revealed that a number of crystalline polymers including polyethylene[1,2], polyoxymethylene[3], nylon[4], and poly(ethylene terephthalate)[5-8] may exhibit multiple melting peaks. This behaviour is closely tied to the thermal history of the samples and may arise from: (1) the presence of alternate crystal modifications; (2) molecular weight segregation accompanying crystallization; (3) variations in morphology; (4) orientation effects; or (5) melting, recrystallization and annealing processes taking place in the calorimeter. Identification of the specific causes of multiple melting in a particular polymer is an important aspect of its thermal characterization. We wish to report some recent calorimetric studies of multiple melting in poly(butylene terephthalate) (PBT), a polymer currently experiencing rapid growth as an injection mouldable engineering thermoplastic.

EXPERIMENTAL

PBT samples were supplied by the GE Plastics Division (Pittsfield, Mass.) and had intrinsic viscosities ranging from 1.21 to 1.53 dl/g. All thermal measurements were carried out in a Perkin-Elmer DSC-2 calorimeter. The samples were first melted in the calorimeter for 2 min at 250°C, recrystallized by slow cooling to room temperature. and then remelted. Wide angle X-ray diffraction measurements were made on a GE XRD-5 machine using CuKα radiation.

RESULTS

Since similar d.s.c. traces were obtained on all samples over the available molecular weight range only data for a sample having an intrinsic viscosity in hexafluoroisopropanol (HFIP) at 25°C of 1.31 dl/g are presented in this report. Crystallization exotherms for samples cooled at rates from

Figure 1 Crystallization exotherms for PBT samples cooled at different rates. The traces are not normalized for differences in sample weight. Cooling rates: (a) 5; (b) 10; (c) 20; (d) 40°C/min

5 to 40°/min are reproduced in *Figure 1*. In each case only one peak was observed which was displaced downwards in temperature with increased cooling rate. The size of the crystallization exotherm was constant at 11.5 cal/g. Wide angle X-ray diffraction patterns obtained on these samples showed little variation in relative line intensity and could be indexed to the triclinic unit cell (α modification) proposed for PBT[9]. No secondary crystal modification was observed.

The corresponding melt endotherms for these samples taken at a scan rate of 20°C/min are presented in *Figure 2*. The average heat of fusion was approximately 12 cal/g indicating very little additional crystallization occurred during heating. In all cases a double melting peak was observed. With decreasing cooling rate the high temperature peak decreased in size but remained centred at 220–222°C. In contrast, the low temperature endotherm increased in size at the expense of the high melting peak and showed a small upward temperature shift from 205 to 216°C at lower cooling rates. The approximate fractions of the total melt endotherm under each peak are listed in *Table 1*.

Melt endotherms taken at scan rates from 5 to 80°C/min on samples cooled from the melt at 20°C/min and showing a single crystallization exotherm are shown in *Figure 3*. Double melting was again observed at all heating rates although at 5°C/min the low temperature peak was barely visible. As the heating rate was increased the low

temperature peak grew in size (see *Table 1*) and superheated approximately 8°C before disappearing as a shoulder on the high temperature peak at a heating rate of 80°C/min. The high temperature peak showed only a small temperature shift (220 to 223°C) over the range of heating rates. A small, very broad shoulder was seen to develop in the region of 190–200°C at the highest scan speed.

DISCUSSION

Our results suggest that multiple melting in PBT is most convincingly interpreted in terms of reorganization processes occurring during heating in the d.s.c. The variations in both the positions and relative heights of the two melting peaks with different cooling and heating schedules can be explained on this basis as follows.

Crystals which are formed at the highest cooling rate are inherently unstable and anneal on heating at 20°C/min only to melt under a single endotherm centred at 220°C. As the degree of supercooling is reduced and the time of crystallization is increased, crystals of increased perfection are formed. Since the rate of reorganization of these crystals is on the same time scale as the heating rate, melting begins to occur in preference to annealing and a low temperature peak appears in the d.s.c. trace. This peak continues to grow in size at the expense of the high melting peak as the original cooling rates are decreased and greater numbers of crystals which are resistant to reorganization are produced. In addition, the low temperature peak shows the expected upward displacement with increasing crystallization temperature[10] while little or no upward temperature shift of the high temperature is observed.

When the cooling rate is held constant and the heating rate is increased (see *Figure 3*) the low temperature peak again increases in size as less and less time is available for reorganization of the metastable crystals. The small, broad peak which appears at ~195°C at the highest heating rates is attributed to a limited number of crystals containing predominantly low molecular weight species which reorganize very quickly and are not seen at scan rates less than 40°C/min. A small percentage of such low molecular weight species has been observed in g.p.c. traces on this sample. The observed superheating of the low temperature peak at fast heating rates is sufficiently large to suggest that there is some entropic restriction imposed on the melting process as noted by other authors[11,12]. It is unlikely that such superheating is associated with chain extension since all crystallizations were carried out in the absence of shear at low pressures.

CONCLUSIONS

The results of our calorimetric studies on poly(butylene terephthalate) are in qualitative agreement with similar studies on poly(ethylene terephthalate)[6-8]. Of the two primary melt endotherms shown by PBT samples crystallized non-isothermally from the melt, only the lower temperature peak can be identified with crystals produced during the original cooling. Extrapolation of our heating rate data on samples crystallized by cooling at 20°C/min indicate that at heating rates above 200°C/min only the low temperature melting peak will be observed. The high temperature peak develops as a result of reorganization processes during heating and is not characteristic of the material in its room temperature state. There is no experimental evidence of a conversion from a high to low melting crystal form or for the presence of a secondary crystal modification.

On the structure of poly(α-methylstyrene): 3. ^{13}C n.m.r. spectra at 67.88 and at 90.51 MHz

In a previous paper we reported on the ^{13}C n.m.r. spectrum of polybutadiene at 67.88 MHz[1]. The extension of these investigations to copolymers of butadiene, α-methylstyrene and methacrylonitrile called for the study of the ^{13}C n.m.r. spectrum of poly(α-methylstyrene).

The first basic assignment of the ^{13}C n.m.r. spectrum of poly(α-methylstyrene) with natural abundant ^{13}C at 25.14 MHz has been performed by Inoue et al.[2]. However, recently developed spectrometers operating at frequencies of 67.88 MHz and 90.51 MHz are available. Outstanding features of these spectrometers equipped with superconducting magnets are improved resolution and increased sensitivity. For improved signal-to-noise ratio we used samples with natural abundant ^{13}C as well as ^{13}C enriched samples. Representative n.m.r. spectra are shown in *Figure 1*. The main resonance regions are assigned. The fine structure of the spectra is caused by configurational sequences because the monomer units due to their asymmetric carbon atom are inserted into the backbone chain in m (meso) and r (racemic) placements[8]. Except for the resonance region of the –CH$_3$ group each spectrum is sufficiently well resolved to reveal the stereochemical structure of the chain.

The starting point for assigning the ^{13}C n.m.r. spectrum is the independent determination of the stereochemical

Figure 1 ^{13}C n.m.r. spectra of poly(α-methylstyrene). (a) Sample with natural abundant ^{13}C; (b) and (c) ^{13}C enriched samples (10%); * indicates the position of enrichment; if not otherwise indicated ^{13}C frequency = 67.88 MHz

structure by ^{1}H n.m.r. spectroscopy[3-6]. In this way it is feasible to assign the ^{13}C spectrum by comparison of measured and calculated line intensities without further assumptions on the mechanism of the polyreaction forming the sample under study. Using Inoue's assignment[2] of the aromatic C$_4$ carbon the sequence distribution of our samples agrees well with Bernoullian statistics as listed in *Table 1*. Within experimental error this is confirmed by

$$\rho = 2 \cdot m \cdot r/mr \cong 1.0 [7].$$

The aromatic C$_1$ carbon appears to lowest field and is split into clearly resolved signals as shown in *Figure 2*. Within resolution of the spectrometer and the experimental error of curve fitting techniques these resonance lines are assigned to five subsequent monomer units in the backbone chain. Experimental peak intensities as well as intensities calculated from Bernoullian statistics including exact peak positions are listed in *Table 2*. The largest splitting by 22 Hz is observable for pentads with a central syndiotactic triad rr. This value decreases to 5 Hz for the heterotactic triad mr, whereas the splitting of the isotactic triad mm can be estimated by curve fitting to be smaller than 3 Hz. Thus the fine structure of the pentad mrrm and the relative broadening of the pentads mrrr and rrrr may be interpreted as an incomplete heptad structure. To a certain degree fine structure is observable for the heterotactic pentad rmrr. too. Therefore the same linewidth as for the pentads rrrr and mrrr has been used for curve fitting.

Contrary to the splitting of the aromatic C$_1$ carbon, only triads relating to the aromatic C$_2$, C$_3$ and C$_4$ carbons have been identified. The enlarged resonance spectrum of these

Figure 3 ^{13}C n.m.r. spectrum of poly(α-methyl styrene). Expanded resonance region of the aromatic C_2, C_3, and C_4 carbons

carbons is shown in *Figure 3*. Peak positions and intensities from ^{13}C and ^{1}H n.m.r. spectra are listed in *Table 3*. Measured and calculated values according to Bernoullian statistics are in good agreement. In the main the tendency continues that signals due to r placements appear to lower field. Pentad splitting, if any, is not observable.

The most complicated structure of the spectrum has been found in the resonance region of the methylene carbon. The spectrum offers the sterochemical information of four and six subsequent monomer units. The expanded spectrum is shown in *Figure 4*. *Table 4* contains the chemical shifts and the fractions of all identified tetrads and hexads. The splitting takes place in a puzzling way. Most of the hexads with a central m enchainment, e.g. mrmrm, rrmrm and rrmrr, are clearly resolved. On the other hand most hexads with a central r enchainment, e.g. rmrrm, mmrrr and mmrrm, are accumulated in a small resonance region at about 58 ppm. The assignment given in *Figure 4* is that from several alternatives which minimizes the least squares sum. Further on this assignment is based on the interpretation of the ^{13}C spectra from poly(α-methylstyrenes) with varying amount of r and m enchainments.

Extreme resolving power of a spectrometer operating at a frequency of 90.51 MHz is necessary for investigations of the resonance region of the non-protonated carbon. The enlarged spectrum including the assignment is shown in *Figure 5*. Chemical shift differences are very small as compared to the aromatic C_1. ^{13}C n.m.r. spectroscopy arrives at the limit of its capacity. Using a DuPont 310 curve resolver it is feasible to determine triad and pentad fractions. Measured and calculated values are listed in *Table 5*.

Despite line broadening and severe overlapping the assignment could be performed in analogy to the aromatic C_1.

As shown in spectra 2,3,4 and 5 ^{13}C n.m.r. spectroscopy at 67.88 MHz and 90.51 MHz is capable of yielding important and detailed stereochemical information of poly(α-methylstyrene). In principle the enchainment can be determined from six individual ^{13}C nuclei in four resonance regions. Peak positions as well as sequence fractions can be determined even if the splitting of the resonance region, e.g. of the non-protonated carbon, does not match that of the aromatic C_1 carbon.

Experimental

The poly(α-methylstyrenes) were polymerized by n-butyl lithium in tetrahydrofuran at temperatures between +25 and $-78°C$. The stereochemical structure of these samples was determined by ^1H n.m.r. spectroscopy using a Varian HR 220 at 220 MHz.

The proton decoupled ^{13}C n.m.r. spectra were obtained in $CDCl_3$ at $35°C$ using a Bruker Spectrospin HX 270 and HXS 360 operating at frequencies of 67.88 and 90.51 MHz,
Figure 5 ^{13}C n.m.r. spectrum of poly(α-methylstyrene) at 90.51 MHz. Expanded resonance region of the non-protonated carbon; ^{13}C enrichment 10%; upper trace: m = 0.203, r = 0.797; lower trace: m = 0.312, r = 0.688

respectively. Internal standard was octamethyltetrasiloxane (OMTS) = 0 ppm.

Simulations and quantitative analysis of the observed spectra were performed using a DuPont 310 curve resolver.

Structure and radical reactivities of vinyl monomers: copolymerization reactivities of alkyl vinyl ketones

Recently, vinyl ketones have frequently been used as comonomers for preparing photodegradative polymers[1]. However, systematic investigations on their radical copolymerization behaviour, especially their relationship between structure and reactivity, have been little attempted.

Since 1961, we have studied the radical copolymerization of vinyl monomers having a series of substituents in order to determine the effect of the substituent[2]. In a series of monomers, in which the substituents were conjugated with a reacting vinyl group, such as nuclear-substituted styrenes, the results show that their copolymerization reactivities were correlated by the generalized Hammett equation[2,3]:

$$\log(\text{rel. react.}) = \rho\sigma + \gamma E_R \qquad (1)$$

where σ and E_R are polar and resonance substituent constants, respectively, and ρ and γ are reaction constants. Equation (1) was found to be also applicable in a number of radical reactions of substituted compounds[2].

However, in a series of aliphatic monomers in which the reaction sites were not conjugated with the substituents, such as alkyl acrylates and methacrylates, their reactivities were expressed by the Taft equation[2,4]:

$$\log(\text{rel. react.}) = \rho^*\sigma^* + \delta E_s \qquad (2)$$

where σ^* and E_s are, respectively, polar and steric substituent constants, in which the corresponding methyl-substituted compound was taken as the standard, and ρ^* and δ are reaction constants. Equation (2) was also applied to a number of alkyl-substituted monomers[2].

Since alkyl vinyl ketones (RVK) in which the reacting vinyl group is a cross-conjugated system with the substituents, it is interesting to clarify the correlation between the reactivity and alkyl substituents. The present communication deals with the results of radical copolymerizations of RVK with styrene, and of the effect of alkyl substituents on their reactivities.

Six RVK monomers were prepared, and copolymerized with styrene (M_1) in bulk in the presence of α,α'-azobisisobutyronitrile (AIBN) at 60°C. The composition of the copolymers obtained was determined from their elemental analysis, and the monomer reactivity ratios (r_1 and r_2) were obtained by a curve-fitting method. The copolymerization parameters obtained are shown in *Table 1*.

As can be seen from this Table, the r_1 and r_2 values change somewhat with the alkyl substituents in RVK.

Table 1 Copolymerization parameters for the copolymerizations of RVK (M_2) with styrene (M_1) at 60°C[a]

RVK	R in RVK	r_1	r_2	Q_2[b]	e_2[b]
MVK	CH_3	0.27	0.40	1.12	0.69
EVK	C_2H_5	0.45	0.31	0.87	0.69
IPVK	$CH(CH_3)_2$	0.40	0.30	0.78	0.66
t-BVK	$C(CH_3)_3$	0.40	0.30	0.78	0.66
CMVK	CH_2Cl	0.13	0.52	2.07	0.84
PVK	C_6H_5	0.21	0.48	1.40	0.74

[a] Conditions: $M_1 + M_2 = 4$ ml; [AIBN] $= 3.5 \times 10^{-3}$ mol/l
[b] Calculated by assuming that Q_1 and e_1 for styrene are 1.0 and −0.8, respectively
Figure 1 Plots of $\log(1/r_1)$ (○), Q_2 (△) and e_2 (□) with σ^* constants of alkyl substituents of RVK in the copolymerization parameters of styrene (M_1)—RVK(M_2) system

Although the relative reactivities towards the polystyryl radical were applied to equation (1), an accurate correlation was not found, because the values of σ and E_R of the substituents in RVK used here were very close to each other.

Previously Yokota *et al.*[5,6] reported that the copolymerization reactivities of nuclear-substituted phenyl vinyl ketones were correlated by equation (1) in which $\rho = 0.34$ and $\gamma = 2.0$[5], indicating that both polar and resonance effects in this case are influenced by the reactivity.

However, when the reactivities of RVK used here were plotted with the σ^* constants in equation (2), a good linear relationship with $\rho^* = 0.40 \pm 0.05$ and $\delta = 0$ was observed as shown in *Figure 1*. In this case, only the polar effect of the alkyl substituents was seen to have an important influence on the reactivity. Similar results were observed in a number of alkyl-substituted monomers such as alkyl acrylates[7], alkyl thiolacrylates[8], alkyl methacrylates[9] and vinyl esters[10].

From *Table 1*, it was found that the Q and e values of RVK increase with increasing the σ^* constants of their alkyl substituents (*Figure 1*). This may indicate that both polar and resonance effects are generally affected by the reactivities of RVK. As pointed out in alkyl methacrylate studies[2,9], these effects are explained on the basis of u.v. and n.m.r.[10] data of RVK from the fact that polarization of the carbonyl group is increased by the electron-donating alkyl groups, and that the resonance of the reacting double bond with the carbonyl group is reduced, resulting in decreased reactivities of the RVK monomer.

From the results of copolymerizations of methyl vinyl ketone (MVK) with styrene in solvents it was also found that relative reactivities of MVK towards the polystyryl radical were found to increase with increasing E_T values of the solvents, and with decreasing energy differences in $n - \pi$ interaction determined from u.v. spectroscopy data. These results seem to support the above consideration.

Preparation of ultra-high modulus linear polyethylenes: effect of initial crystallization conditions

In previous publications[1-4] we have reported the cold drawing behaviour of linear polyethylene and the preparation of very stiff oriented samples by means of ultra-high draw ratio. The essence of the previous work was to show that the draw ratios achieved under standard drawing conditions were markedly dependent on the molecular weight and morphology of the initial polymer. It was also shown that under the standard procedures adopted, the room temperature value of the Young's modulus of the oriented polymer was related only to the draw ratio to a good approximation.

In the most recent publication on the drawing behaviour[4], it was also reported that the draw ratio was very time dependent for polymer of low and intermediate weight-average molecular weight, $\bar{M}_w$. It was emphasized that the isochronal draw ratio/$\bar{M}_w$ curves reported did not represent an absolute upper limit for the plastic deformation, but higher draw ratios could often be obtained by extending the drawing time. It appeared to be of particular interest to prepare a series of oriented samples, varying both initial morphology and drawing time, to determine whether the apparently unique relationship between Young's modulus and draw ratio still held.

We have recently undertaken a detailed comparison of the drawing behaviour and the modulus/draw ratio relationship over a wide range of molecular weights for two very different initial crystallization conditions. Although this extensive study is still being completed, we believe that there is one result which is worthy of immediate publication.

Figure 1 shows the room temperature Young's modulus as a function of draw ratio for Rigidex 50 grade linear polyethylene (BP Chemicals International Ltd).

As in the previous work, the Young's modulus is quoted at 0.1% strain and obtained from isochronal stress–strain curves constructed from the 10 sec creep response. The results are compared for two extreme initial morphologies, produced by the thermal treatments described in the previous papers. In one case the compression moulded sheets were quenched immediately into cold water, in the other case the sheets were slow cooled, at a rate of $7-9°C/min$ to $110°C$ and subsequently quenched.

The quenched polymer shows the typical banded spherulitic morphology whereas the slow cooled material shows a coarser structure with hardly recognisable spherulites[4]. In each case a range of draw ratios was produced by drawing at a constant rate (Instron cross-head speed of 10 cm/min on a 2 cm gauge length sample) at $75°C$ for different times. It can be seen that there is a unique relationship between the modulus and the draw ratio. There are some differences between the moduli achieved for a given draw ratio and those reported earlier but these

Figure 1 Room temperature Young's modulus as a function of draw ratio. △, Quenched immediately into water; ●, slow cooled and quenched

are only significant at the highest draw ratios (~30) where very small differences in the sample homogeneity and preparation become important.

We therefore conclude that there is a unique relationship between modulus and draw ratio irrespective of the initial morphology. Moreover, it has been found that both high draw and very high modulus can be achieved for samples with conventional spherulitic morphology by extending the draw times under appropriate drawing conditions. The morphology of the initial material, however, is very important in determining the detailed nature of the plastic deformation. This is of interest both in understanding the mechanisms of deformation and in the development of practical procedures for production of these high modulus materials[5]. It is intended to deal with these aspects in a future publication, when our present studies have been completed.

Preparation of ultra-high modulus linear polyethylenes: effect of initial crystallization conditions

In previous publications[1-4] we have reported the cold drawing behaviour of linear polyethylene and the preparation of very stiff oriented samples by means of ultra-high draw ratio. The essence of the previous work was to show that the draw ratios achieved under standard drawing conditions were markedly dependent on the molecular weight and morphology of the initial polymer. It was also shown that under the standard procedures adopted, the room temperature value of the Young's modulus of the oriented polymer was related only to the draw ratio to a good approximation.

In the most recent publication on the drawing behaviour[4], it was also reported that the draw ratio was very time dependent for polymer of low and intermediate weight-average molecular weight, $\bar{M}_w$. It was emphasized that the isochronal draw ratio/$\bar{M}_w$ curves reported did not represent an absolute upper limit for the plastic deformation, but higher draw ratios could often be obtained by extending the drawing time. It appeared to be of particular interest to prepare a series of oriented samples, varying both initial morphology and drawing time, to determine whether the apparently unique relationship between Young's modulus and draw ratio still held.

We have recently undertaken a detailed comparison of the drawing behaviour and the modulus/draw ratio relationship over a wide range of molecular weights for two very different initial crystallization conditions. Although this extensive study is still being completed, we believe that there is one result which is worthy of immediate publication.

Figure 1 shows the room temperature Young's modulus as a function of draw ratio for Rigidex 50 grade linear polyethylene (BP Chemicals International Ltd).

As in the previous work, the Young's modulus is quoted at 0.1% strain and obtained from isochronal stress–strain curves constructed from the 10 sec creep response. The results are compared for two extreme initial morphologies, produced by the thermal treatments described in the previous papers. In one case the compression moulded sheets were quenched immediately into cold water, in the other case the sheets were slow cooled, at a rate of $7-9°C/min$ to $110°C$ and subsequently quenched.

The quenched polymer shows the typical banded spherulitic morphology whereas the slow cooled material shows a coarser structure with hardly recognisable spherulites[4]. In each case a range of draw ratios was produced by drawing at a constant rate (Instron cross-head speed of $10 cm/min$ on a 2 cm gauge length sample) at $75°C$ for different times. It can be seen that there is a unique relationship between the modulus and the draw ratio. There are some differences between the moduli achieved for a given draw ratio and those reported earlier but these

Figure 1 Room temperature Young's modulus as a function of draw ratio. △, Quenched immediately into water; ●, slow cooled and quenched

are only significant at the highest draw ratios (~30) where very small differences in the sample homogeneity and preparation become important.

We therefore conclude that there is a unique relationship between modulus and draw ratio irrespective of the initial morphology. Moreover, it has been found that both high draw and very high modulus can be achieved for samples with conventional spherulitic morphology by extending the draw times under appropriate drawing conditions. The morphology of the initial material, however, is very important in determining the detailed nature of the plastic deformation. This is of interest both in understanding the mechanisms of deformation and in the development of practical procedures for production of these high modulus materials[5]. It is intended to deal with these aspects in a future publication, when our present studies have been completed.

Particle structure and fusion of suspension poly-(vinyl chloride)

Although it is known that incomplete fusion of resin granules results in anomalous flow effects during the extrusion of suspension PVC[1], the relation between these anomalies and resin granule morphology is not well understood. This situation exists partly because few details on the structure of suspension PVC granules are published in the literature.

The information which is available[2] does not fully emphasize the heterogeneous nature of the particles in a given PVC formulation. As an example *Figure 1* shows typical granules from a commercial suspension PVC as photographed with a scanning electron microscope. This particular PVC sample was manufactured by Norsk Hydro and had average molecular weights (determined by g.p.c.) of $\bar{M}_w$ = 128 000 and $\bar{M}_n$ = 56 000.

The granules in *Figure 1* are different in size, shape, surface characteristics, and porosity. Other photographs of granules from this sample show many different particle shapes and sizes ranging from 50 to 150 μm. Close-up views of small regions of the same granules (*Figures 2* and *3*) indicate a complex aggregate morphology with a multitude of particles of submicron size. For each granule the surface
Figure 1 Two typical suspension PVC granules with varied characteristics (scanning electron photomicrograph)
Figure 2 Close-up view of PVC granule A showing aggregate structure and complex particulate morphology (scanning electron photomicrograph)
Figure 3 Close-up view of PVC granule B showing complex particulate structure different from granule A (scanning electron photomicrograph)
Figure 4 Suspension PVC granules partly fused after heating at 190°C; note that basic particulate structure is still apparent (scanning electron photomicrograph)

texture and state of aggregation are different; it appears also that granule B is more porous than granule A.

Some granules from a portion of the same PVC sample which had been treated with 2.5 pph dibutyltin di-octylthioglycolate stabilizer were heated to 190°C for 4 min. In *Figure 4* we see that some fusion has occurred but the basic particulate structure is still present. *Figure 5* is a close-up of a partly 'melted' portion of a similar PVC granule. It is clear from this that the fusion of these suspension granules at a temperature in the normal processing range is not complete. The surface is heterogeneous with both particulate and smooth regions apparent. The appearance of the granules in *Figure 4* suggests that they are heterogeneous on the inside as well.

While pressure, shear, and increased temperature all will contribute to enhance fusion, preliminary studies on the same PVC extruded at 205°C indicate that a heterogeneous particulate morphology persists. Moreover, granules heated to 220°C in the same manner as those described in *Figure 4*
Figure 5 Close-up of a partly fused PVC granule surface; both particulate and smoother regions are apparent (scanning electron photomicrograph)

still retain their basic shapes and some of their original surface texture, although they appear a good deal smoother than those 'melted' at 190°C. 220°C is above normal processing temperatures for PVC.

If the basic granule morphology of a suspension PVC is heterogeneous we expect a considerable influence on fusion and the resulting morphology of the processed polymer.

Some of the PVC samples we have examined are less heterogeneous with uniform particle sizes and shapes. In these materials extrudate homogeneity may improve accordingly. At this point we have not determined whether this is true. However, our studies to obtain additional data on extrudate fusion are continuing.

Book Reviews

Functional monomers
Edited by R. H. Yocum and E. B. Nyquist
Marcel Dekker, New York, 1973, Vol 1, 715 pp.
$39.50; 1974, Vol 2, 817 pp. $46.50

In these two volumes, written and edited by six members of the Dow
Chemical Company staff, one obviously benefits from the technical
and information resources of a large organization, resulting in a
competent and comprehensive review. The title refers to monomers
which undergo addition polymerization and, which although gene-
rally used only in small amount in relation to other polymerizable
compounds, introduce into the final polymers groups capable of
further modification or reaction so as to provide specific properties
such as ability to crosslink, modified surface behaviour, or enhanced
solubility, adhesion or dye receptivity. Thus the subject is one which
will have appeal to a wide range of readers, many of whom are con-
cerned with preparation and polymerization or with macromolecular
design and behaviour to meet specific end-uses.

The chapters in both volumes show commendable uniformity in
treatment and include sections on synthesis, chemical reactions,
physical properties and polymerizability, technical applications and
some, but probably far from complete, commercial information
regarding suppliers and costs. Much of the information on structure,
synthesis and properties is summarized and presented in tabular
form, thus providing for quick review and reference. At the end of
each chapter there are many hundreds of references to the relevant
literature which serve to bring the subjects up to early 1970, although
as the editors indicate, in an area such as this where scientific and
technical advance is rapid, the books cannot be regarded as the last
word. However, they will obviate the need for much time-consum-
ing literature searching and for this reason alone could be welcomed.

In the first volume are four chapters dealing with acrylamide and
other α,β-unsaturated amides; reactive halogen-containing mono-
mers (but excluding for very obvious reasons vinyl and allyl halides
and chloroprene); hydroxy monomers such as hydroxyalkyl acrylic
esters, allyl alcohol, N-methylolacrylamides; and ethylene-, allyl-
and styrene-sulphonic acids and 2-sulphoethyl methacrylate. The
second volume comprises three chapters on reactive heterocyclic
monomers containing three, five and six-membered rings (thus cover-
ing compounds such as glycidyl methacrylate, allyl glycidyl ether,
vinyl oxazolidones and pyrazoles, vinylene carbonate, and unsatu-
rated dioxolanes – vinyl pyridine and maleic anhydride are more
adequately dealt with in later chapters); acidic monomers based on
maleic, fumaric, itaconic and crotonic acids; and basic monomers
such as the vinyl pyridines and aminoalkyl acrylates and methacry-
lates.

Apart from some omissions in the compounds covered, e.g.,
reactive vinyl esters like the chloroacetate, N-substituted maleimides
and vinyl propiolactone, the several types of functional monomer
are well represented and the more important ones considered very
fully. Particular aspects of preparation and manufacture, reactions,
polymerization behaviour, and properties receive detailed attention,
although discussion is generally based on the publications concerned
and there may be a lack of critical review of some of the references
or expert appraisal of some of the technical information, particularly
that based on patent disclosures.

Lay-out of the text, formulae and binding are good but the
printed format relies on photoreduced typescript of only moderate
contrast which compares unfavourably with conventional type.
Again, the numbering systems used for compounds, reactions and
references can lead to some confusion. There are some errors in the
typescript but these are generally of a minor nature. Author and
subject indexes are included although the latter seem to be quite
inadequate in view of the comprehensive nature of the work, and
fuller itemization would have been an advantage.

The volumes are, perhaps understandably, somewhat expensive
(together they amount to $86, equivalent to some £36) but to those
interested in the preparation, reactions and uses of the monomers
or in technical applications of derived polymers and copolymers,
they are a worthwhile investment, providing a well informed source
of information and means of rapid reference. Many academic and
industrial workers will find it useful to have access to these books.

R. J. W. Reynolds

Polymer spectroscopy
Edited by D. O. Hummel
Verlag Chemie, Weinheim, 1974, 401 pp. DM 125

The book is intended for practising chemists and spectroscopists
concerned with polymers in industry and in universities. Apart from
diffraction techniques, spectroscopic methods offer the main means
of elucidating the structures of polymers: these methods have been
brought together here. The chapter entitled Vibrational spectroscopy
is sub-divided into the contributions: Vibrational analysis of highly
ordered polymers by H. Tadokoro and M. Kobayashi; Applied infra-
red spectroscopy by D. O. Hummel; Raman spectroscopy by P. J.
Hendra; at 180 pages this is the longest chapter. The remaining
chapters are High resolution nuclear magnetic resonance spectros-
copy by E. Klesper and G. Sielaff (95 pages); Electron spin reso-
nance by H. Fisher, D. O. Hummel, H. D. Schüddemage and K.
Rübenacker (31 pages). The size of the articles is in direct propor-
tion to the importance and level of treatment given to the various
branches of spectroscopy. The book is well printed and bound and
it is profusely illustrated: there is a subject but not a name index.

The scientific literature is cluttered with spectroscopic compendia
claiming to give special insight into some topic but mainly they
represent well-documented basic material. This book, however,
rarely deviates from its intended purpose of describing the applica-
tions of spectroscopic methods to polymer systems. Thus the
reviewer can recommend the book to anyone interested in the struc-
tural aspects of polymers

L. H. Sutcliffe

Structured polymer properties
R. J. Samuels
John Wiley, New York, 1974, 251 pp. £10.60

This book aims to present a unified approach to the quantitative
correlation of crystalline polymer structure with both fabrication
and end use property behaviour, in such a way that it will be of
interest to polymer physicists, chemists and engineers as well as
advanced course students.

Following a short introductory chapter on the nature of crystal-
linity in polymers with special reference to polypropylene, a second
chapter is devoted to details of techniques used in the characteriza-
tion of polycrystalline polymer structure including those of wide
angle X-ray diffraction, sonic modulus, birefringence, infra-red
dichroism and small angle light scattering in the context of actual
application. The third chapter concerns structural interpretation of
the fabrication processes for polypropylene film and fibre formation.
The last chapter which precedes some concluding remarks deals with
the quantitative correlation of polymer structure with end-use pro-
perties, using polypropylene and poly(ethylene terephthalate) as
examples.

The overall impression of this book is that it is authoritative
reflecting a great deal of the author's personal experience as an indus-
trial and academic scientist. Indeed so much does the impression
come through, occasionally as in say, chapter 3 where coded refe-
rence to polymer samples used, one almost has the feeling of reading
an original paper. On the other hand, experimental details of tech-
nique provide an air of conviction from which the most casual
reader can only presume an expert acquaintance of the author with
his subject. Despite one or two minor irritations such as a suggestion
for further reading to a book still in preparation or a different type
face for the index compared with the main text, the book appears
to be remarkably free from errors and its easy style makes it most
readable.

The book is particulalry recommended to workers in the general
as well as specific field and to more advanced students. Other
readers may have some difficulty in appreciating the significance of
the account in the broader area of polymeric materials as a whole,
although after reading the book they would then be well armed to
seek this significance.

Specific refractive index increments of certain polysaccharide systems

C. T. Greenwood* and D. J. Hourston[†]
Department of Chemistry, University of Edinburgh, Edinburgh, UK
(Received 24 July 1974; revised 22 November 1974)

The specific refractive index increments of amylose, amylose acetate, amylopectin and glycogen in various aqueous and non-aqueous solvents have been determined. These were measured by the direct determination of deviation method.

INTRODUCTION

Experimentally determined values of specific refractive index increment (dn/dc) are presented for the starch polymers amylose and amylopectin and the very similar mammalian polymer, glycogen, in a variety of solvents. Huglin[1] has published a compilation of dn/dc data for a very wide variety of polymer systems.

EXPERIMENTAL

The differential refractometer used in this work was that designed by Brice and Hawler[2] and manufactured by the Brice–Phoenix Precision Instrument Corporation, Philadelphia, USA.

Initially calibration was attempted using solutions of anhydrous Na_2SO_4[3], but the hygroscopic nature of this salt made the preparation of accurate solutions by weighing difficult. For this reason Analar sucrose was used instead and proved very satisfactory. Calibration was performed using a range of concentrations of sucrose solutions (0.1–5.0 g/100 ml) at wavelengths of 546 and 436 nm. The refractive index increment for sucrose in water at 25°C and 546 nm wavelength was taken as 0.1430 ml/g[4] and the corresponding value at 436 nm as 0.1449 ml/g[3]. The calibration constants were checked by measuring the refractive index increments of two systems, polystyrene in toluene and Ludox (a commercially available colloidal silica) in a 0.05 M NaCl solution. The results were in very good agreement with literature values.

All measurements were made at 25 ± 0.01°C on solutions which had not been dialysed against the respective solvents. The results reported were generally found to be reproducible to within less than 1%.

Starch was isolated from potatoes (cv. Redskin) as previously described[5]. Fractionation was achieved by aqueous dispersion and the amylose was purified by recomplexing, three times, from hot aqueous n-butanol. The amylose/n-butanol complex was dehydrated by protracted stirring with n-butanol and finally dried in vacuum at 50°C. The

amylopectin was obtained by freeze-drying the residual aqueous dispersion.

Amylose isolated as above was acetylated according to the procedure of Higginbotham and Morrison[6].

The glycogen used was a commercial sample of oyster glycogen (Koch-Light Laboratories Ltd).

RESULTS AND DISCUSSION

Table 1 presents data for amylose, amylopectin and glycogen in aqueous solvents commonly used in hydrodynamic studies of these natural polymers, but it also includes dn/dc values for amylose acetate in nitromethane.

The value of the dn/dc for amylose acetate in nitromethane at 436 nm was found to be 0.0885 ml/g which agreed well with values of 0.0875 ml/g[7] and 0.0857 ml/g[8]. The former literature value was obtained at 30°C. At 546 nm the experimental value was in exact accord with literature data[9,10] which, however, were measured at 20°C.

Glycogen in water was found to have a dn/dc value of 0.153 ml/g at 436 nm which compared very well with the value reported by Burchard *et al.*[11] of 0.151 ml/g at 20°C.

Data for amylopectin and glycogen in a range of aqueous solvents are presented in *Table 2*. The solvents investigated were 1% aqueous sodium lauryl sulphate, 1% aqueous cetyltrimethyl ammonium bromide, 15% aqueous $MgCl_2$, 8 M urea and 8 M guanidine hydrochloride.

Tables 3 and *4* present a survey of literature values of dn/dc for amylose, amylopectin, their various derivatives and for glycogen.

Table 1 Specific refractive index increments of various polysaccharide systems

		dn/dc (ml/g)	
Polymer	Solvent	436 nm	546 nm

Cavity field for axially symmetric dielectrics

K. H. Lau and K. Young
Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong
(Received 11 November 1974)

A useful parameter for characterizing drawn polymers is the anisotropy, v, in the average molecular polarizability, α. We examine, for an axially symmetric dielectric, the relation of v to the experimentally measurable anisotropy, u, in the permittivity, ϵ. The relatively simple limit of negligible electronic polarizability is studied explicitly and the resulting mathematical problem of finding the cavity field in an axially symmetric dielectric is solved to second order in the anisotropy, u. Our result is compared to the *ad hoc* modifications of the isotropic Onsager equation previously used in the literature and it is found that these formulae give anisotropies that may be in error by up to 10%. This amounts to a few degrees in the equivalent angle for the orientation function.

INTRODUCTION

Dielectric measurements are useful for studying the microscopic structure of polymers possessing permanent dipole moments. Studies of dielectric absorption, in particular the anisotropy in the absorption, are often valuable in identifying the nature of the underlying relaxation processes. In cases where the geometrical relation between the molecular dipoles and the polymer chain is unambiguous, the measured anisotropy can be used to determine the orientation function for the chains.

In all such measurements, the experimental output is the permittivity, ϵ (real and imaginary parts as a function of temperature and frequency). This is to be confronted with models of microscopic structure, which predict (or attempt to relate to other quantities) the average molecular polarizability. If short range interactions are neglected, the polar contribution α to the average molecular polarizability can be obtained from the experimentally measured ϵ by Onsager's[1] equation:

$$\epsilon - n^2 = 4\pi N\alpha \left(\frac{3\epsilon}{2\epsilon + n^2} \right) \left(\frac{n^2 + 2}{3} \right)^2 \qquad (1)$$

Here N is the number of dipoles per unit volume and n^2 is the high frequency dielectric constant arising from electronic polarizability. For a dipole μ_0 completely free to rotate:

$$\alpha = \frac{\mu_0^2}{3kT} \qquad (2)$$

Onsager's equation (1) is derived for an isotropic substance whereas one's interest in using dielectric absorption as a tool in polymer science lies often in drawn polymers, which are of course anisotropic. Previous analyses of anisotropic data have either used the *ad hoc* prescription of replacing each quantity in equation (1) by principal

values, e.g.[2]:

$$\epsilon_{xx} - (n^2)_{xx} = 4\pi N\alpha_{xx} \left(\frac{3\epsilon_{xx}}{2\epsilon_{xx} + (n^2)_{xx}} \right) \left[\frac{(n^2)_{xx} + 2}{3} \right]^2 \qquad (3)$$

or assumed[3] that the factor:

$$\left(\frac{3\epsilon}{2\epsilon + n^2} \right) \left(\frac{n^2 + 2}{3} \right)^2$$

is isotropic, so that:

$$\epsilon_{xx} - (n^2)_{xx} = B\alpha_{xx} \qquad (4)$$

where B is a constant taken to be independent of draw ratio.

When the anisotropy itself is the object of interest, such *ad hoc* treatments as equations (3) or (4) make one somewhat uneasy especially in the absence of an estimate on the likely size of the error. Our purpose here is to consider the proper modification to Onsager's equation in the case of an anisotropic medium. Hopefully, this will lead to a theoretically more satisfactory framework for the analysis of anisotropic data. At the very least this will give an estimate of the error involved in previous treatments.

THE CAVITY FIELD

In order to focus on just one important aspect of the problem, we shall assume that the electronic polarizability can be ignored. Setting $n^2 = 1$ in equation (1), we get:

$$\epsilon - 1 = 4\pi N\alpha \left(\frac{3\epsilon}{2\epsilon + 1} \right) \qquad (5)$$

This is the formula to be generalized to the anisotropic case. The factor $3\epsilon/(2\epsilon + 1)$ is easily recognized as due to the so-

called cavity field. We do not mean to claim that $n^2 \approx 1$ is a particularly good approximation for most polymers. The purpose for neglecting $n^2 - 1$ is two-fold. First, we wish to address a relatively simple problem in order not to obscure the physics. Secondly, by comparing the results of the correct treatment with equations (3) and (4) in this limit, we shall get an idea of the size of the error in equations (3) and (4). A complete treatment including the electronic polarizability will be given elsewhere.

In an anisotropic medium, the average molecular polarizability will be represented by a tensor α_{ij} and the permittivity by ϵ_{ij}. These are defined as follows. The average polarization of an isolated molecule in an electric field G is:

$$\langle \mu_i \rangle = \alpha_{ij} G_j \qquad (6)$$

The induced polarization density in the dielectric medium in the presence of a macroscopic field $\vec{E}$ is:

$$P_i = \frac{1}{4\pi}(\epsilon_{ik} - \delta_{ik})E_k \qquad (7)$$

Now if there are N dipoles per unit volume, then:

$$P_i = N\langle \mu_i \rangle$$

hence,

$$(\epsilon_{ik} - \delta_{ik})E_k = 4\pi N \alpha_{ij} G_j \qquad (8)$$

The crux of the matter is that the field $\vec{G}$ available to orient a dipole is not the same as the macroscopic field, $\vec{E}$. The field $\vec{G}$ is the resultant field due to all external sources plus all induced dipole moments *except* that due to the dipole in question. (The argument is the same as the isotropic case, and details may be found in Onsager's paper[1].) Thus one is to imagine the dipole in question removed from the medium, leaving a hole. $\vec{G}$ is then the field at the centre of this hole when the field far away is $\vec{E}$. For this reason $\vec{G}$ is referred to as the cavity field. (Equivalently, one may remove a sphere containing many dipoles, but ignore the short range interaction among these dipoles. The mathematics is identical.)

For a linear dielectric, the relation between $\vec{G}$ and $\vec{E}$ must be of the form:

$$G_j = X_{jk}E_k \qquad (9)$$

so that equation (8) becomes:

$$\epsilon_{ik} - \delta_{ik} = 4\pi N \alpha_{ij} X_{jk} \qquad (10)$$

or in matrix notation ($\hat{\ }$ denotes a matrix)

$$\hat{\epsilon} - \hat{1} = 4\pi N \hat{\alpha} \hat{X} \qquad (11)$$

THE MATHEMATICAL PROBLEM

The problem is simply to calculate $\hat{X}$. If we treat the medium minus the cavity macroscopically, $\hat{X}$ will be a function of $\hat{\epsilon}$ only. Let the cavity be spherical, with radius R and let the electric field be given by $-\vec{\nabla}\psi(x)$ for $r < R$ and $-\vec{\nabla}\phi(x)$ for $r > R$. Gauss' law requires:

$$\nabla^2 \psi = 0 \qquad (12a)$$

$$\epsilon_{ij}\partial_i\partial_j\phi = 0 \qquad (12b)$$

The boundary condition at the origin is:

$$|\psi| < \infty \text{ as } r \to 0 \qquad (13)$$

and at infinity:

$$\phi \to -\vec{E} \cdot \vec{r} \text{ as } r \to \infty \qquad (14)$$

Across the boundary $r = R$, we must have:

$$\left. \begin{array}{l} \psi = \phi \\[1.2em] \dfrac{\partial \psi}{\partial r} = n_i(\epsilon_{ij}\partial_j\phi) \end{array} \right\} \text{ at } r = R \qquad \begin{array}{l}(15a) \\[1.2em] (15b)\end{array}$$

Here $\vec{n}$ is the unit outward normal. Equations (12)–(15) completely specify the problem. The cavity field G is then

$$\vec{G} = -\vec{\nabla}\psi \big|_{r=0} \qquad (16)$$

We now specialize to the case of axial symmetry, say about the z axis. This is the most common situation in polymers. The problem is not in principle more difficult for the general anisotropic case, but will be quite tedious in practice. It will be convenient to use the matrix:

$$\hat{\eta} = \begin{pmatrix} 1 & & \\ & 1 & \\ & & -2 \end{pmatrix}$$

in terms of which we may write:

$$\epsilon_{ij} = \epsilon(\delta_{ij} + u\eta_{ij}) \qquad (17)$$

where

$$\epsilon = 1/3 \, tr\epsilon_{ij} \qquad (18)$$

is the mean value (over the principal directions) of the permittivity and

$$u = \frac{\epsilon_{xx} - \epsilon_{zz}}{2\epsilon_{xx} + \epsilon_{zz}} \qquad (19)$$

measures the anisotropy in the tensor ϵ_{ij}. The potentials will now be expanded as a power series in u:

$$\psi = \Sigma u^n \psi_n$$

$$\phi = \Sigma u^n \phi_n \qquad (20)$$

Then equations (12)–(15) become:

$$\nabla^2 \psi_n = 0 \qquad (21a)$$

$$\nabla^2 \phi_n = D\phi_{n-1} \qquad D \equiv -(\partial_\perp^2 - 2\partial_z^2) \qquad (21b)$$

$$|\psi_n| < \infty \qquad \text{as } r \to 0 \qquad (22)$$

$$\phi_0 \to -\vec{E} \cdot \vec{r} \qquad \text{as } r \to \infty$$

$$\phi_n \to 0 \qquad \text{as } r \to \infty \quad n \geqslant 1 \qquad (23)$$

$$\psi_n = \phi_n \tag{24a}$$

$$\left. \begin{array}{c} \\ \\ \end{array} \right\} \text{ at } r = R$$

$$\frac{1}{\epsilon}\left(\frac{\partial \psi_n}{\partial r}\right) = \frac{\partial \phi_n}{\partial r} + D'\phi_{n-1} \tag{24b}$$

$$D' \equiv n_1 \partial_1 - 2n_z \partial_z$$

The zeroth order is nothing but the isotropic case and is trivial[4]. With the zero order solution, we compute $D\phi_0$ and $D'\phi_0$. These are the inhomogeneities 'driving' the next order. Physically $D\phi_0$ corresponds to an induced volume charge density while $D'\phi_0$ corresponds to a surface charge density. The next order can then be solved in a straightforward manner by separating variables in spherical coordinates.

We have carried the iteration to second order in u, with the result:

$$X_{ij} = \left(\frac{3\epsilon}{2\epsilon + 1}\right)\delta_{ij} + u\left\{\frac{3}{5}\left(\frac{\epsilon(3\epsilon + 2)}{(2\epsilon + 1)^2}\right)\eta_{ij}\right\} +$$

$$u^2\left\{\frac{6}{25}\left(\frac{\epsilon(9\epsilon^2 - 4\epsilon - 6)}{(2\epsilon + 1)^3}\right)\delta_{ij} + \right.$$

$$\left. \frac{3}{175}\left(\frac{\epsilon(-3\epsilon^2 + 26\epsilon + 12)}{(2\epsilon + 1)^3}\right)\eta_{ij}\right\} +$$

$$O(u^3) \tag{25}$$

The first term is the well-known isotropic result. It is convenient to write:

$$X_{ij} = X(\delta_{ij} + w\eta_{ij}) \tag{26}$$

where from equation (25):

$$X = \frac{3\epsilon}{2\epsilon + 1} + u^2\left\{\frac{6}{25}\left(\frac{\epsilon(9\epsilon^2 - 4\epsilon - 6)}{(2\epsilon + 1)^3}\right)\right\} + O(u^3)$$

$$w = u\left\{\frac{3\epsilon + 2}{5(2\epsilon + 1)}\right\} + u^2\left\{\frac{1}{175}\left(\frac{-3\epsilon^2 + 26\epsilon + 12)}{(2\epsilon + 1)^2}\right)\right\} +$$

$$O(u^3) \tag{27}$$

In the following we shall be concerned only with w. It will be convenient to use:

$$\bar{u} = \left(\frac{\epsilon}{\epsilon - 1}\right)u \tag{28}$$

which is the anisotropy in $\hat{\epsilon} - \hat{1}$:

$$\epsilon_{ij} - \delta_{ij} = (\epsilon - 1)(\delta_{ij} + \bar{u}\eta_{ij}) \tag{29}$$

In terms of $\bar{u}$, equation (27) is:

$$w = \bar{u}\left\{\frac{(\epsilon - 1)(3\epsilon + 2)}{5\epsilon(2\epsilon + 1)}\right\} +$$

$$\bar{u}^2\left\{\frac{1}{175}\frac{(\epsilon - 1)^2(-3\epsilon^2 + 26\epsilon + 12)}{\epsilon^2(2\epsilon + 1)^2}\right\} +$$

$$O(\bar{u}^3) \equiv \Sigma A_n(\epsilon)\bar{u}^n \tag{30}$$

Table 1 Coefficients for relating the anisotropy w of the cavity field factor X_{ij} to the anisotropy $\bar{u}$ in $\epsilon_{ij} - \delta_{ij}$: $w = \Sigma A_n(\epsilon)\bar{u}^n$

ϵ	A_1	$A_2 \times 10^3$
1	0	0
2	0.160	2.97
3	0.210	3.26
4	0.233	2.69
6	0.256	1.40
8	0.268	0.42
10	0.274	−0.20
∞	0.300	−4.29

Values of $A_1(\epsilon)$ and $A_2(\epsilon)$ are given in *Table 1*. It is evident that the expansion of w in terms of $\bar{u}$ is converging, and in fact the linear term will be sufficient for all practical purposes.

RELATION TO $\hat{\alpha}$ AND THE ORIENTATION FUNCTION

If equation (26) is substituted in equation (11), $\hat{\alpha}$ can be solved in terms of $\hat{\epsilon}$. It will be convenient to parameterize $\hat{\alpha}$ in the same way as $\hat{\epsilon}$ and $\hat{X}$:

$$\alpha_{ij} = \alpha(\delta_{ij} + v\eta_{ij}) \tag{31}$$

In general, v is the quantity desired. A little arithmetic yields:

$$v = \frac{\bar{u} - w}{1 - w - 2w\bar{u}} \tag{32}$$

and making the linear approximation for w as discussed in the last section:

$$v = \frac{(1 - A_1)\bar{u}}{1 - A_1\bar{u} - 2A_1\bar{u}^2} \tag{33}$$

It is useful to compare this with equation (3), which for $n^2 = 1$ reduces to:

$$\epsilon_{xx} - 1 = 4\pi N\alpha_{xx}\left(\frac{3\epsilon_{xx}}{2\epsilon_{xx} + 1}\right) \tag{34}$$

with a similar equation for the zz component. The resulting equation for v is:

$$\frac{1 + v}{1 - 2v} = \left(\frac{1 + \bar{u}}{1 - 2\bar{u}}\right)\left\{\frac{1 - 2\left(\frac{\epsilon - 1}{\epsilon}\right)\bar{u}}{1 + \left(\frac{\epsilon - 1}{\epsilon}\right)\bar{u}}\right\}\left\{\frac{1 + 2\left(\frac{\epsilon - 1}{2\epsilon + 1}\right)\bar{u}}{1 - 4\left(\frac{\epsilon - 1}{2\epsilon + 1}\right)\bar{u}}\right\} \tag{35}$$

Also, we compare our results with equation (4). For $n^2 = 1$, equation (4) reads:

$$\epsilon_{xx} - 1 = B\alpha_{xx} \tag{36}$$

with a similar equation for the zz component. This clearly leads to:

$$v = \bar{u} \tag{37}$$

For the same measured values of ϵ and $\bar{u}$, the three methods of analyses: equations (33), (35), (37) which we

shall label as (a), (b), (c) respectively, will lead to different values for v. To display this difference more graphically, it is best to consider the orientation function.

To be definite, we assume the following model[3]. The dipoles are perpendicular to the polymer chain and free to rotate in the plane normal to the chain. The angle between the chain and the z axis will be called θ. It can be shown that for such a model[3]:

$$\alpha_{xx} = K\left(\frac{1 + \langle\cos^2\theta\rangle}{4}\right)$$

$$\alpha_{zz} = K\left(\frac{1 - \langle\cos^2\theta\rangle}{2}\right) \tag{38}$$

where K is a constant. The anisotropy v is then:

$$v = \frac{1}{4}[-1 + 3\langle\cos^2\theta\rangle] \tag{39}$$

Incidentally this demonstrates the simple relation between v and the Hermans[5] orientation function:

$$f = [3\langle\cos^2\theta\rangle - 1]/2 \tag{40}$$

within this model. Solving for the mean angle:

$$\langle\cos^2\theta\rangle = (1 + 4v)/3 \tag{41}$$

An equivalent angle θ_0 can be defined by:

$$\cos^2\theta_0 = \langle\cos^2\theta\rangle \tag{42}$$

i.e. if the θ-distribution is sharp, it peaks at θ_0.

With these definitions in hand, we are ready to consider one numerical example. We take $\bar{u} = 1/3$. The values for v and θ_0 are computed according to the three formalisms and displayed as a function of ϵ in *Table 2*.

The discrepancy is a few degrees for θ_0, which is at the level of typical experimental errors. This will affect the details of data-fitting but not any qualitative conclusions.

It has been claimed[2] that equation (3) should be good for small anisotropy, since it is obtained from an isotropic formula. We should point out that this is not quite the

Table 2 Values of v and θ_0 computed by the three different formalism for $\bar{u} = 1/3$

ϵ	v			θ_0 (degrees)		
	(a)	(b)	(c)	(a)	(b)	(c)
1	0.333	0.333	0.333	28.1	28.1	28.1
2	0.307	0.314	0.333	30.5	29.9	28.1
3	0.298	0.288	0.333	31.3	32.2	28.1
4	0.294	0.313	0.333	31.6	29.9	28.1
5	0.289	0.317	0.333	32.0	29.6	28.1
8	0.287	0.319	0.333	32.2	29.4	28.1
10	0.286	0.321	0.333	32.3	29.2	28.1
∞	0.280	0.333	0.333	32.8	28.1	28.1

case. Equations (3) and (4) give exactly correct values of v for both zero and maximum anisotropy. This is best seen from equations (33), (35) and (37). All three equations have the property that $v = \bar{u}$ when $\bar{u} = 0$, $1/2$ or -1. Maximum discrepancy occurs at *intermediate* values of the anisotropy $\bar{u}$, though even for such values, the error is not very large.

CONCLUSION

The implication of the present analysis is simply that the error involved in using equation (3) or (4) is not very large, though for accurate work a correction should perhaps be made. The electronic polarizability, which has been neglected here, is expected to give an error of about the same order.

Ultrasonic studies of three fluoropolymers *

S. F. Kwan, F. C. Chen and C. L. Choy
Physics Department, The Chinese University of Hong Kong, Shatin, Hong Kong
(Received 9 September 1974)

The ultrasonic velocities and attenuations of poly(vinylidene fluoride), polytrifluoroethylene and poly-chlorotrifluoroethylene at 10 MHz from 170 to 300 K have been measured by the pulse echo-overlap and the pulse-height comparison methods, respectively. Discontinuities in the slopes of the velocity–temperature curves and concurrent sharp rises of attenuations were observed, and were identified with previously reported transitions. An analysis of the fractional changes in the corresponding temperature coefficients was made. The velocity data extrapolated to 0 K by Rao's rule were combined with presently available thermal data to yield the effective three-dimensional intermolecular force constants in the Tarasov model, and to confirm the existence of low-frequency vibrational modes contributing to the specific heat of polychlorotrifluoroethylene. The magnitude and temperature dependence of the elastic moduli and the Poisson ratio in relation to those of the velocities are also discussed.

INTRODUCTION

It has long been recognized[1] that the substitution of fluorine atoms for the hydrogen atoms in polyethylene may lead to a reduction of the intermolecular attraction. However, nearly all the ultrasonic studies[2-5] on fluorinated polyethylene concentrated on the relaxation regions and were not extended to sufficiently low temperatures to allow unambiguous evaluation of the intermolecular interaction. While in principle ultrasonic velocity measurements near 0 K should be used to calculate the intermolecular interaction, this is not really strictly necessary, because if one makes measurements at temperatures below the strong relaxation regions then the data can be extrapolated quite reliably to 0 K. The results so obtained are also useful for studying the acoustic contribution to the specific heat of polymers at low temperatures.

We have measured the ultrasonic velocities and attenuations at 10 MHz of three fluorine-containing polymers, poly(vinylidene fluoride) (PVF$_2$), polytrifluoroethylene (PVF$_3$) and polychlorotrifluoroethylene (PCTFE) between 170 and 300 K. From results of mechanical relaxation studies[6] down to 6 K, it appears that such linear crystalline polymers should not exhibit any mechanical relaxation at 10 MHz below 220 K. Our results can therefore be extrapolated to low temperatures with some confidence through the application of Rao's empirical formula[7], especially since the temperature dependence is already very weak at the lower end of our measurement range.

The extrapolated velocities can be understood in both the Debye[8] and the Tarasov model[9] of a solid, thus enabling us to evaluate the Tarasov three-dimensional spring constant of the polymers studied. At low temperatures the Debye model gives the specific heat of a substance as[8]:

$$C/T^3 = \frac{2\pi^2 k^4}{5\hbar^3 \rho} \frac{1}{\bar{v}^3} \tag{1}$$

---

where T, $\hbar$ and k have their usual meanings, ρ is the density, and $\bar{v}$ is the appropriate average velocity of sound at 0 K:

$$\frac{1}{\bar{v}^3} = \frac{1}{3}\left(\frac{1}{\bar{v}_L^3} + \frac{2}{\bar{v}_T^3}\right) \tag{2}$$

Both here and in the following the subscripts L and T refer to longitudinal and transverse elastic waves, respectively. The Debye temperature θ_D, which depends on the choice of the vibrating unit, is given by[10]:

$$\theta_D = \frac{\hbar}{k}\bar{v}\left(\frac{2\pi^2 Nn}{V}\right)^{1/3} \tag{3}$$

where N is the Avogadro number, V is the molar volume, n is the number of degrees of freedom per vibrating unit. For polymers it is customary to choose the repeating unit of the polymer chain as the vibrating unit[11]. For our samples, there are two backbone carbon atoms per repeating unit and in general six skeletal vibration modes are expected. However, the C–C stretching modes of these atoms are of high frequency[11] (about 10^3 cm^{-1}) and are not excited at low temperature, so that there are actually only four modes per repeating unit, $n = 4$. Combining equations (1) and (3) we therefore write the molar heat capacity as:

$$\frac{C}{T^3} = \frac{4\pi^4 Nnk}{5} \frac{1}{\theta_D^3} \tag{4}$$

In our case this model is unrealistic in that the polymer consists of many long-chain molecules capable of linear vibrations so it would not behave simply like a Debye solid. Tarasov[9] proposed a more realistic model by assuming its density of states to be a one-dimensional continuum arising from the vibration of individual chains superimposed on a three-dimensional continuum arising from interchain vibrations. Mathematically it is given by:

$$g(\omega) = \begin{cases} \dfrac{N'}{3\omega_1\omega_3^2} & (0 < \omega < \omega_3) \\[2ex] \dfrac{N'}{\omega_1} & (\omega_3 < \omega < \omega_1) \end{cases} \qquad (5)$$

where ω_1 and ω_3 are two characteristic cut-off frequencies and N' is the total number of states. The heat capacity for a single branch of acoustical vibration can then be shown to be:

$$\frac{C_a(T)}{R} = D(\theta_3, \theta_1, T)$$

$$= D_1\left(\frac{\theta_1}{T}\right) - \frac{\theta_3}{\theta_1}\left[D_1\left(\frac{\theta_3}{T_1}\right) - D_3\left(\frac{\theta_3}{T_1}\right)\right] \qquad (6)$$

where R is the gas constant, $\theta_i = \hbar\omega_i/k$, $(i = 1, 3)$ and the n-dimensional Debye function D_n is:

$$D_n(x) = \frac{n}{x^n} \int_0^x \frac{x^{n+1} e^x}{(e^x - 1)^2} dx \quad (n = 1,3) \qquad (7)$$

Suppose all acoustical branches have the same characteristic temperatures θ_3 and θ_1. The total acoustical heat capacity contributions is then:

$$C_a(T) = nRD(\theta_3, \theta_1, T) \qquad (8)$$

which at low temperatures ($T \ll \theta_3$) reduces to the Debye form:

$$\frac{C_a(T)}{T^3} = \frac{4\pi^4 Nnk}{5} \frac{1}{\theta_1\theta_3^2} \qquad (9)$$

Upon comparison of equations (4) and (9) we arrive at the relation $\theta_D^3 = \theta_1\theta_3^2$.

Through equations (2) and (3) the extrapolated results of our measurements lead to θ_D, which, together with the recently available data on θ_1[12], yield θ_3. To gauge the strength of the intra- and inter-molecular forces in the polymer, it is also useful to compute the effective one- and three-dimensional spring constants k_1 and k_3 defined as:

$$k_i = \bar{M}(k\theta_i/\hbar)^2 \quad (i = 1,3) \qquad (10)$$

where $\bar{M}$ is the average mass of the group of atoms associated with each carbon atom of the backbone.

It has been pointed out[13–17] that low-frequency Einstein modes of vibrations may contribute to the specific heats of amorphous materials at low temperature, so as to explain the excess of the calorimetrically determined specific heat over the acoustic contributions given by equation (1). Since thermal values for PCTFE became available recently[18], our results would also allow us a check on this assertion.

EXPERIMENTAL

The experimental techniques employed in this experiment are quite conventional, and have already been reported in detail[19], so only brief descriptions will be given here.

Sample preparation

The samples of PVF_2 and PCTFE were obtained from Cellomer Associates, Inc. and 3M Co., respectively. The sample of PVF_3 was supplied by Dr R. E. Florin of the National Bureau of Standards of the USA and was mildly crosslinked. They were formed into stocks by slow heating to above the melting point in a mould, pressing for 30 min and then being gradually cooled to room temperature. For PCTFE, sample stocks of four different crystallinities were obtained by quenching in ice water and by annealing for various lengths of time. Crystallinity was determined by the buoyancy method in water to an accuracy of 3–5%. However, the effect of crystallinity on the elastic moduli will be the subject of a separate paper, and the PCTFE data discussed here refer mostly to just one crystallinity (0.53), even though the rest of the PCTFE data do have some bearing on the problem of the excess specific heat discussed below.

After moulding the stocks were cut into thin discs of 1.3 cm diameter and between 2 to 8 mm thickness. The two surfaces of each disc were then ground parallel to within $2 \mu m/cm$ and polished flat.

Temperature control and measurement

The copper sample chamber containing the sample and transducers was suspended at the end of a long stainless-steel tube in the middle of a double-wall, separately evacuable cryostat, which in turn was immersed in liquid nitrogen. A copper–constantan thermocouple junction calibrated against a standard platinum resistance thermometer to an accuracy of 0.01 K and mounted next to the sample on the same plate served both as the temperature indicator and the sensor for temperature control. A five-digit differential voltmeter (Hewlett-Packard (HP) 740B) provided digital dialling of temperature settings and also supplied an amplified control signal to the automatic temperature controller (Artronix 5309 and 2202). The overall temperature stability and accuracy was better than 0.05 K.

Ultrasonic instrumentation

Radiofrequency (r.f.) elastic waves were produced in the sample disc by 10 MHz X- or Y-cut quartz transducers (supplied by the Valpey-Fisher Corporation) bonded to it by silicone oil (Edwards 704). The bond was quite satisfactory between 170 and 300 K (below 250 K for shear wave).

The repetition rate of the r.f. pulses was derived from a sine oscillator (HP 651B) and monitored on a 7-digit frequency counter (HP 5306B). The oscillator output was converted to the actual triggering pulses by a decade divider (Matec 122).which drived the r.f. pulse generator and detector (Matec 6000, with plug-in 950 and 960). A pulse comparator (Matec 666B) triggered by another pulse generator (HP 214A) provided r.f. pulses of calibrated amplitude variable in 0.1 dB steps over a range of 4 decades. The signals were viewed on an oscilloscope (HP 140A with plug-in 1421A and 1402A) with calibrated sweep and delay.

Measurements and systematic errors

Velocity measurements were made by the pulse echo-overlap technique[20,21], with a sensitivity of better than 0.1% and an accuracy estimated to be 0.5%. Attenuation measurements were made by pulse-height comparison of the successive echoes[22] with standard pulses. The results
Figure 1 Velocities (v_L, v_T) and attenuations (α_L, α_T) in PVF$_2$ as functions of temperature, T. - - -, T_d. $\bigcirc$, v_L; $\square$, v_T; $\bullet$, α_L; $\blacksquare$, α_T
Figure 2 Velocities and attenuations in PVF$_3$ as functions of temperature. Legend same as for *Figure 1*

have a much larger uncertainty, say 3–5%. The most important factors giving rise to errors are the bond effect and, in the case of attenuation, the width of the oscilloscope trace.

We have corrected for systematic errors wherever possible. The bond effect was eliminated by making measurements on PCTFE samples of several different thickness d and then plotting the attenuation coefficient and the echo transit-time in the sample against d. It turned out that the bond absorption was quite large for longitudinal wave (4.0 dB or 10–30%) but practically zero for transverse wave. The shortening of transit time due to the phase-shift at the sample–bond interface was comparatively small, but still amounted to 60 ns and 36 ns, or 1–3%, for longitudinal

and transverse waves, respectively. These effects were temperature independent to within experimental error. We assumed all bonds to be similar and applied the above corrections to all of our data.

The error arising from the thermal contraction of the sample discs could be readily corrected for by use of the volumetric data on PVF$_2$ and PCTFE available in literature[23,24], but this could not be done for PVF$_3$ owing to the lack of similar data. Diffraction in the sample disc could also be a source of error, but estimates by use of the Papadakis formula[25] showed that such effects were quite negligible.

RESULTS AND DISCUSSION

The corrected data of the ultrasonic velocities and attenuations of PVF$_2$, PVF$_3$ and PCTFE are summarized in *Figures 1, 2* and *3*.

Transition regions

It is apparent from the Figures that each velocity - temperature curve has a break at the point which we called the temperature of discontinuity, T_d.

In the two velocity curves of PVF$_2$ (*Figure 1*) the magnitudes of both slopes increase by a factor of about 3.7 over a 10 K interval around the break, whereas away from this region the slopes practically do not change over intervals as large as 50 K. Near the break there is apparently also a sudden rise in both of the absorption coefficients. It is natural to identify this break, which can be located at 232 K to within ±5 K, with the glass-transition temperature, T_g at 238 K reported in the volumetric measurement of Mandelkern *et al.*[23]. It was suggested by Wada[26] and Work[27] that because of strong dependence of the modulus on the specific volume one can always expect a break at the static glass-transition point irrespective of the characteristic frequency of the modulus. Subsequently many authors confirmed that the temperature where the break appears is independent of frequency, which may range from the
Figure 3 Velocities and attenuations in PCTFE as functions of temperature. Legend same as for *Figure 1*
Figure 4 Relative amplitude of the first transmitted pulse of longitudinal wave in PVF_2 as a function of temperature

static region[28] up to the MHz region[29]. In view of their results, our identification seems quite justified.

The dynamic relaxation peak corresponding to the above glass-transition point was observed at approximately 317 K (i.e. 85 K above T_d) in the curve of the relative attenuation (*Figure 4*), which is deduced from the amplitude of the first transmitted longitudinal ultrasonic signal in PVF_2. Since we were not able to observe the subsequent echoes in this measurement, there is, of course, some uncertainty in the interpretation of this curve, especially regarding the exact location of the peak. Nevertheless it does seem clear that the character of the peak and its approximate position (with an error of perhaps ±5 K) are quite beyond doubt. In particular, together with the dielectric data of Kabin *et al.*[30] and Nakagawa and Ishida[31], this 10 MHz peak at 317 K can be fitted reasonably well by the empirical formula of Williams, Landel and Ferry (WLF)[32] (*Figure 5*) if the considerable error in its position is taken into account.

The glass-transition point for PCTFE at 325 K[33] is above our measurement range and not observed. However, we did observe a slightly rounder break in the two velocity curves of PCTFE (*Figure 3*) at 230 ± 5 K, where both slopes change by a factor of 2 within an interval of 10 K. This could possibly be the same break at 223 K observed by Baccaredda and Butta[34] at a lower frequency range (4–16 kHz). Similar breaks below the glass-transition points of a number of polymers and at different frequencies had been previously reported by Wada *et al.*[35]. They discussed this problem in connection with their own observations in the 33 kHz to 1 MHz region, and suggested that the most probable mechanism of such 'secondary discontinuities' was the activation of the end-groups or side-group rotations. Since there are no side-groups in the polymers studied, the observed breaks are probably associated with the motion of a section of the backbone involving a few carbon atoms and correspond to the low-temperature peak at about 230 K observed in dynamical mechanical measurements at 1 Hz[36]. A sudden rise of the absorption curves of PCTFE is also observed around the

same temperature, but any relaxation peak which may correspond to it lies beyond our measurement range.

We also observed a break in the longitudinal velocity curve of PVF_3 (*Figure 2*) at about 230 K, with an accompanying sharp rise in the attenuation. This corresponds to the onset of motion also observed in nuclear magnetic resonance (n.m.r.) measurements[37] as a decrease in the linewidths of both the proton and fluorine resonance lines, and was attributed to the rotation of a few chain segments of the carbon backbone. Mechanical and dielectric relaxation measurements[38] at low frequencies also show an absorption peak near 230 K, which is presumably due to this limited motion.

Back in 1956 Work[27] attempted to explain the discontinuity in the temperature coefficient of the ultrasonic velocity data of poly(methyl methacrylate) and polystyrene in terms of the discontinuity in the expansion coefficient β through the following thermodynamic relation derived at constant frequency:

$$\left(\frac{\partial v}{\partial T}\right)_P + K\beta\left(\frac{\partial v}{\partial P}\right)_T = \left(\frac{\partial v}{\partial T}\right)_V \tag{11}$$

where v (i.e. v_L or v_T) and K (the bulk modulus) are functions of the frequency, temperature T and pressure P, but β and V (volume) depend on T and P only. It was argued that $(\partial v/\partial T)_V \sim 0$ well below the relaxation region, and for these two polymers this was indeed found to be the case. On the assumption that K and $(\partial v/\partial P)_T$ were continuous at T_d, the fractional change of $(\partial v/\partial T)_P$ should then be equal to that of β by virtue of equation (11). This was well borne out by the experimental data[27]. Following this suggestion, Wada *et al.*[35] verified the same equality for several other polymers at both glass and secondary transitions.
Figure 5 Plot of log τ against $1/T$ for PVF_2. $\tau = 1/2\pi f$, where f is the frequency of the measurements. ——, Theoretical curve computed from the WLF equation using the parameters given in ref 31. ●, dielectric loss data ϵ'' taken from ref 31; ▲, dielectric loss tangent data (tan δ) taken from ref 30; □, our ultrasonic data

However, the above theory is not applicable to the discontinuities observed in this experiment. In *Table 1* we have listed T_d, β and the temperature coefficient of velocity γ (defined as $(\partial v/\partial T)_P/v$) of the three polymers studied, the primed and unprimed quantities referring to values above and below T_d, respectively. β is computed from the volume–temperature curves of PVF_2[23] and $PCTFE$[24] but is omitted for PVF_3, for which no data exist. It is easily seen that β'/β is much smaller than γ'/γ, such that the discontinuity in β cannot possibly account for the discontinuity in γ completely. In fact, β and γ are related as follows:

$$\gamma = \frac{-\beta\rho}{v}\left(\frac{\partial v}{\partial\rho}\right)_P \tag{12}$$

While ρ and v are continuous, the discontinuities in both β and $(\partial v/\partial\rho)_P$ are expected to contribute to that of γ. To verify this point we compute $(\partial v/\partial\rho)_P$ from the velocity–density curve obtained by combining our data and the available volumetric[23,24] data, both of which have been measured at atmospheric pressure. The $\ln v$ vs. $\ln \rho$ curves for PCTFE as shown in *Figure 6* are straight lines with different slopes above and below T_d, and therefore can be represented by what is known as Rao's Rule[7]:

$$\ln v = A \ln \rho + B \tag{13}$$

where the constants A and B are different above and below T_d. Similar curves are also obtained for PVF_2. Combining equations (12) and (13) we arrive at the relation $\gamma = -\beta A$. *Table 1* shows the good agreement between γ'/γ and $(\beta'/\beta)(A'/A)$, bringing out the fact that the hitherto neglected factor A'/A is at least as important as β'/β in our

Figure 6 Plot of $\ln v$ vs. $\ln \rho$ for PCTFE. $\bigcirc$, v_L; $\square$, v_T

case. At secondary transitions where the change in β is small, A'/A may even become the dominant factor. The velocity measurement may then be a much more sensitive method for detecting such transitions than the volumetric measurement, PCTFE being a good example. The reason why γ'/γ simply equals β'/β for the several polymers investigated by Work[27] and Wada et al.[35] is not clear, but it may be connected with the fact that all these polymers are amorphous, whereas the ones we studied have considerable crystallinity.

From our data and those of Wada et al.[35] it also seems a general feature that the ratio γ'/γ is considerably larger at glass transitions than at secondary transitions, with typical values of 4 and 2, respectively. This ratio may therefore serve as a parameter for distinguishing between these two kinds of transitions. Under this criterion and other corroborative evidences[38] it is reasonable to assign the break in the velocity curve of PVF_3 at 230 K ($\gamma'/\gamma = 2.5$) as a secondary transition.

Intermolecular interaction

In addition to transitions one can also learn something about the specific heat and the effective intermolecular force constant of the polymers from our data extrapolated to 0 K by the use of equation (13) together with the available volumetric data on PVF_2[23] and $PCTFE$[24]. Since no such data are available for PVF_3, and the constant A does not seem to change much from PVF_2 to PCTFE, we simply use the average values of them for PVF_3. The values of v_L and v_T so extrapolated to 0 K lead to the values of the average velocity at 0 K, $\bar{v}$, and of C/T^3, θ_D, θ_3 and k_3 through equations (1)–(4), (9) and (10). The results are shown in *Table 2*, where the corresponding quantities for polyethylene (PE)[11] and polytetrafluoroethylene (PTFE)[17] are also listed for comparison.

Among the three polymers studied the only thermal determination of C/T^3 available in literature is that of PCTFE, which was reported by Reese and Tucker[18] to be 559 erg/K⁴ g for a sample of crystallinity 0.34*. In comparison, the corresponding acoustic value listed in *Table 2* is 314 erg/K⁴ g, which has been obtained by linearly extrapolating the C/T^3 values of our four PCTFE samples to the same crystallinity. The latter C/T^3 values are based on the measured values of both v_L and v_T for one sample but only on v_T for the other three samples, the fact that $v_L \sim 2v_T$ being used in the latter cases. The error involved in this approximation is probably quite small, since the $1/v_L^3$ term contributes only about 7% to $1/\bar{v}^3$ in equation (2). In any case this certainly would not affect our main conclusion, namely that the thermal value of C/T^3 for PCTFE exceeds the acoustic value by a sizable factor (1.7).

---

* This crystallinity seems too low for the commercial rod used in ref 18. However, this does not affect the conclusion stated below since the acoustic C/T^3 values range only from 320 to 386 erg/K g when the crystallinity increases from 0.4 to 0.75.

Figure 8 Longitudinal moduli of PVF$_2$ (■), PVF$_3$ (●) and PCTFE (▲) as functions of temperature

The existence of excess low-temperature specific heat in amorphous material was first pointed out by Anderson[10] and subsequently observed in various inorganic glasses[13,14] and polymers[15–17]. This implies there may be low-frequency modes in addition to the Debye acoustical vibrations. Rosenstock[39] suggested that the vibrating units contained in or adjacent to cavities present in disordered struc-

tures would only be weakly bound to the rest of the lattice, and might vibrate independently at low frequency.

As already mentioned, the three-dimensional force constant k_3 is a measure of the interchain van der Waals interaction. *Table 2* seems to show that the substitution of n hydrogen atoms by halogen atoms for two carbon atoms of PE does not have any substantial effect on this interaction for $n = 2$, since k_3 decreases only marginally when PE changes to PVF$_2$; but that a drastic effect is produced for $n = 3$ or 4, since k_3 decreases by a factor of 2 when PE changes to PVF$_3$, PTFE or PCTFE. Qualitatively this is probably due to the larger size of the halogen atoms, so that the substitution causes an increase in the effective intermolecular distance and a consequent weakening in the interaction. As a matter of fact, the polymer chains of PTFE and PCTFE are known to have a helical conformation with an outer halogenated sheath[1], which may be the cause of the considerable decrease in k_3 when n increases from 2 to 4. It is somewhat unexpected that the value for PVF$_3$ is slightly lower than even PCTFE and PCTFE, but this probably reflects only the crudeness of the Tarasov model and may not have any real physical significance.

We also note that the one-dimensional force constant k_1 is greater than k_3 by a factor of 10 to 20, which is quite understandable since the covalent bonds responsible for the intrachain interaction should be much stronger than the van der Waals force responsible for the interchain interaction.

Elastic moduli and the Poisson ratio

The shear modulus G, longitudinal modulus M and bulk modulus K are related to the velocities v_T and v_L of the transverse (T) and longitudinal (L) waves by[40]:

$$G = \rho v_T^2 \tag{15}$$

$$M = \rho v_L^2 \tag{16}$$

$$K = \rho v_T^2 \left(y^2 - \frac{4}{3} \right) \tag{17}$$

where $y = v_L/v_T$ and we have neglected factors of the form $(1 - \eta^2)/(1 + \eta^2)^2$ on the right of equations (15) and (16), since in our temperature range, which is below the relaxation regions, the quantity $\eta = v\alpha/\omega$ (α being the attenuation) is $\ll 1$ for both waves. The Poisson ratio σ can then be written as[40]:

$$\sigma = \frac{1}{2}\left(1 - \frac{1}{y^2 - 1}\right) \tag{18}$$

The three moduli and the Poisson ratios are shown in *Figures 7* to *10*. The moduli for PVF$_3$ and PCTFE are
Figure 9 Bulk moduli of PVF$_2$ (■), PVF$_3$ (●) and PCTFE (▲) as functions of temperature

Figure 10 Poisson ratios of PVF$_2$ (■), PVF$_3$ (●) and PCTFE (▲) as functions of temperature

approximately equal but are much smaller than those of PVF$_2$. This is a reflection of the decrease in k_3 when the number of halogen atoms per repeat unit increases from 2 to either 3 or 4.

The breaks at T_d are observed in all moduli. This is quite natural, since the temperature coefficients of the latter are, according to equations (15)–(17), simply twice the corresponding values of γ, the contribution of p and y being rather small. We note that y has the approximately constant value 2 for all three polymers throughout the temperature covered, including the transition regions. This means that the Poisson ratio σ should always be about 1/3, as is indeed the case. Actually σ does have a small temperature coefficient γ_σ which, as can be deduced from equation (18), should be roughly equal to $4/3(\gamma_L - \gamma_T)$, where γ_L and γ_T refer to the temperature coefficients of the velocities of longitudinal and transverse waves, respectively. In addition, σ is also observed to have breaks around T_d, which can be characterized by $\gamma'_\sigma/\gamma_\sigma$. This ratio (computed to be 4.7 and 2.4 and observed to be 5.0 and 3.0 for PVF$_2$ and PCTFE, respectively) is about the same as the γ'/γ characterizing the velocity curves, which is a consequence of γ'_T/γ_T and γ'_L/γ_L being approximately equal. However, these breaks were not observed in similar curves obtained by Wada *et al.*[35] for other polymers and at slightly lower frequencies, possibly owing to the difference in materials.

CONCLUSION

From the foregoing analysis it can be seen that ultrasonics is a precise and sensitive tool for studying transitions in polymers, especially the secondary transitions, where the effects in other static quantities may be quite small; it is also useful for studying the intermolecular forces, even though this is necessarily model dependent, and cannot be expected to reveal any fine details of the interaction.

In the future it would be interesting to study the γ'/γ ratio systematically for several polymers such as PE, PCTFE and poly(ethylene terephthalate), at all transitions and at different crystallinities, to confirm that it does take
on distinctively different values for different kinds of transitions, and to determine whether the contribution of β'/β indeed decreases with crystallinity. It may also be worthwhile to repeat the experiment for a different series of polymers, such as those resulting from the chlorination of PE, and see if the variation of the van der Waals force shows the same features as we have observed here.

A study of solvent motion in acetone – PMMA solutions using ^{13}C and ^1H spin-lattice relaxation measurements

Frank Heatley and J. H. Scrivens

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 2 September 1974)

The ^{13}C and ^1H spin-lattice relaxation times of acetone in solutions containing from 0 to 20% poly(methyl methacrylate) have been measured from $-55°C$ to $120°C$. The ^{13}C measurements show that except at low temperature and the higher polymer concentrations, solvent rotation is little affected by the presence of polymer molecules. By assuming that the ^{13}C relaxation time is entirely intramolecular in origin, and by progressive deuteration of the acetone, the ^1H relaxation time has been separated into intramolecular, acetone–acetone intermolecular and acetone–polymer intramolecular contributions. These results show that up to 10% of polymer or so does not affect solvent diffusion, but for 20% polymer, solvent diffusion is perceptibly slowed down, and the activation energy increased by 50%. The data give no indication of polymer conformational transitions in this temperature range, as suggested by others elsewhere, but this may be because of the very short-range sensitivity of n.m.r. measurements.

INTRODUCTION

For obvious reasons, the majority of investigations into molecular motion in polymer solutions have concentrated on the behaviour of the polymer molecules. A number. however, have been directed towards the motion of the solvent, since this often provides more useful interpretable information on polymer solvent interactions. Nuclear magnetic relaxation (n.m.r.) measurements have proved an important experimental technique[1-8] in this respect, especially ^1H relaxation times which are well-known to be sensitive to both intramolecular and intermolecular interactions. Some workers[1,5,6] have investigated preferential polymer solvation by one component of a poor solvent/good solvent mixture while others[2,3,8] have used various methods of separating the three principal contributions to solvent proton relaxation — intramolecular, solvent solvent intermolecular and solvent–polymer intermolecular — in order to distinguish the effect of the polymer on the solvent rotational and translational diffusion. This paper is of the second type, the system studied being acetone poly(methyl methacrylate) (PMMA). This system was chosen to complement an earlier study[3] along these lines of the benzene- PMMA system, and also because of a recent paper[9] suggesting a conformational transition of PMMA in acetone at about $35°C$. which may be reflected in the solvent motion. In this work, the intramolecular relaxation contributions were determined using ^{13}C n.m.r., the ^1H acetone-acetone contribution was determined by the usual deuterium replacement technique, and the acetone PMMA contribution to the ^1H acetone relaxation was then determined by difference.

EXPERIMENTAL

The polymer used in this work was a mainly syndiotactic sample of $M_n = 90\,000$, supplied by the Rubber and Plastics Research Association, Shrewsbury, England. The proton n.m.r. spectrum showed that the polymer was 70% syndiotactic. with random placement of diads. All samples were degassed and sealed *in vacuo* before use. ^{13}C T_1 measurements were made on a Varian Associates XL-100 Fourier Transform Spectrometer operating at 25.14 MHz. using the 'progressive saturation' technique[10]. ^1H T_1 measurements were made on a Varian Associates HA-100 Spectrometer using the adiabatic rapid passage with sampling method[12]. ^{13}C Nuclear Overhauser enhancement factors[11] (*NOEF*) were determined from the ratio of the intensity of the completely ^1H noise decoupled spectrum to the intensity with the decoupling field offset by 30 kHz on continuous wave operation. This procedure eliminated changes in sample temperature occurring on switching the decoupler on or off.

RESULTS AND DISCUSSION

Figures 1 and *2* show the variation of the spin-lattice relaxation time and *NOEF* of the methyl ^{13}C nucleus in acetone as a function of temperature for pure solvent and solutions containing 0.05, 0.1 and 0.2 weight fraction PMMA. In each case the acetone was actually a 2 : 1 mixture of CH_3COCH_3 and CD_3COCD_3, but since the intermolecular contribution to relaxation of protonated ^{13}C nuclei is insignificant[13]. the sources of the methyl ^{13}C relaxation are entirely intramolecular, and are determined by overall molecular plus internal rotation. For all four samples. the T_1 passes through a common maximum (within the experimental scatter) at $30°C$, and follows a common path on the high temperature side of the maximum. The occurrence of this maximum indicates the presence of two ^{13}C relaxation mechanisms, namely dipolar interaction with attached protons dominant at lower temperatures, and the spin-rotation mechanism dominant at higher temperatures. The
Figure 1 Variation of T_{1C} with temperature for the methyl carbon in pure acetone (○) and solutions of PMMA in acetone: □, 0.05; +, 0.1; ×, 0.2 wt fraction PMMA. T_{1C}(D) (△) and T_{1C}(SR) (▽) for pure acetone are also shown. For clarity, only a single curve (— — —) has been drawn for T_{1C} of pure acetone and the solutions of weight fraction 0.05 and 0.1

NOEF also shows this, gradually falling from its theoretical maximum of 2 at low temperatures as the temperature increases and the spin-rotation mechanism increases in efficiency[13]. The two contributions will be discussed more quantitatively below, for there are two noteworthy features of these results worth discussing at this point. First, the presence of up to 0.1 weight fraction polymer has very little effect at any temperature on either the magnitude or rate of change with temperature of the solvent relaxation time, but 0.2 weight fraction polymer has a marked effect on the low temperature behaviour, increasing the activation energy from 7.6 kJ/mol for pure solvent to 10.9 kJ/mol for the 0.2 weight fraction sample. Earlier measurements of the benzene PMMA system[3], and recent results for the methylene dichloride polystyrene system[8], both indicate very little effect on solvent rotational mobility of up to 40% polymer. However, both investigations were made at a constant temperature of 35°C. at which temperature in this study polymer concentration indeed has little effect. In benzene and methylene dichloride. the spin-rotation relaxation mechanism is small compared to that present in acetone, but extrapolation of the Arrhenius low temperature dependence of T_{1C} back to 35°C for pure solvent and the 0.2 weight fraction solution. reveals that this is approximately the temperature at which the plots cross. Thus the results shown here are consistent with earlier results at a single temperature. but from the temperature dependence it is clear that above a certain concentration, the polymer does influence solvent motion. Both benzene and acetone are good solvents for PMMA, so it is unlikely that the difference in behaviour may be explained by different polymer—solvent interactions.

Secondly, we note that the spin-rotation relaxation must arise from coupling with internal rotation of the methyl group and not overall rotation, otherwise the 0.2 weight fraction solution would differ in its high temperature relaxation times from the pure solvent, since the correlation times for the dipolar and spin-rotation mechanisms are inversely related[14]. Rotation of the methyl group will be determined entirely by intramolecular factors.

The dipolar and spin-rotation contributions may be obtained from the equations[11]:

$$T_{1C}(D) = \frac{2}{\eta} \cdot T_{1C} \tag{1}$$

and

$$\frac{1}{T_{1C}} = \frac{1}{T_{1C}(D)} + \frac{1}{T_{1C}(SR)} \tag{2}$$

where T_{1C} is the experimental ^{13}C relaxation time. and the suffixes (D) and (SR) are self-explanatory. η is the nuclear Overhauser enhancement factor[11]. *Figure 1* shows the contributions to T_{1C} for pure acetone. The polymer solutions may be treated similarly but the results do not add anything significant.

The observed acetone proton relaxation time (T_{1H}) arises from three sources intramolecular $[T_{1H}(\text{intra})]$, acetone acetone intermolecular interactions $[T_{1H}(a\ a)]$ and acetone polymer intermolecular interactions $[T_{1H}(a\ p)]$. which are related by:

$$\frac{1}{T_{1H}} = \frac{1}{T_{1H}(\text{intra})} + \frac{1}{T_{1H}(a\ a)} + \frac{1}{T_{1H}(a\text{-}p)} \tag{3}$$

$T_{1H}(\text{intra})$ may contain dipolar and spin-rotation terms as for T_{1C}. related by an equation similar to (2). $T_{1H}(a\ a)$ is easily isolated by substitution of CH_3COCH_3 by CD_3COCD_3 in the usual way[3]. If deuterated polymer were available. $T_{1H}(a\ p)$ could be measured likewise. but we have chosen to calculate $T_{1H}(\text{intra})$ from $T_{1C}(D)$ and then obtain $T_{1H}(a\ p)$ from equation (3) by difference. It was found experimentally from the temperature dependence of $T_{1H}(\text{intra})$ in pure acetone, that both dipolar and spin-rotation mechanisms operated for ^1H as well as ^{13}C relaxation at higher temperatures although $T_{1H}(\text{intra})$ did not
Figure 2 Variation of *NOEF* with temperature for the methyl carbon in pure acetone and solutions of PMMA in acetone. Symbols as in *Figure 1*

pass through a maximum so the spin-rotation mechanism is less significant. It is straightforward to calculate $T_{1H}(D)$ from $T_{1C}(D)$, as the relationship between them is strictly geometrical, but $T_{1H}(SR)$ and $T_{1C}(SR)$ depend on ^1H and ^{13}C spin-rotation coupling constants which are not simply related. $T_{1H}(SR)$ was therefore obtained from the difference between the experimental value of $T_{1H}(intra)$ and the calculated value of $T_{1H}(D)$ for pure acetone, and was assumed to be the same for all polymer concentrations by analogy with $T_{1C}(SR)$. This approximation is not serious, as it proved possible to derive reliable values of $T_{1H}(a\text{-}p)$ only at lower temperatures where $T_{1H}(SR)$ is insignificant. $T_{1H}(D)$ was calculated as follows.

In the extreme narrowing limit applicable to small mobile molecules, $T_{1C}(D)$ for a methyl carbon is given by[13]:

$$\frac{1}{T_{1C}(D)} = \frac{3\gamma_H^2\gamma_C^2\hbar^2}{r_{CH}^6} \cdot \tau_C \tag{4}$$

where $\gamma_{H,C}$ are the magnetogyric ratios of ^1H and ^{13}C nuclei respectively, r_{CH} is the internuclear distance and τ_C is a dipolar correlation time embracing overall rotation (possibly anisotropic) and internal motions. The corresponding expression for ^1H relaxation is:

$$\frac{1}{T_{1C}(D)} = \frac{3\gamma_H^2\hbar^2}{r_{HH}^6} \cdot \tau_H \tag{5}$$

τ_H is not necessarily equal to τ_C because of anistropic and/or internal rotation. To make the calculation of τ_H tractable. isotropic overall rotation has been assumed, it is suggested quite reasonably, since the moments of inertia of the acetone molecule about three perpendicular axes do not differ greatly. However, the barrier to methyl rotation in acetone is[15] only 3.4 kJ/mol, and methyl rotation is therefore rapid enough to have a significant influence on correlation times. The problem of calculating relaxation times for a system undergoing simultaneous overall and internal rotation has been considered by Woessner *et al.*[16] who give the following expression for the dipolar correlation time:

$$\tau = \frac{1}{4}\left\{\frac{(1-3\cos^2\Delta)^2}{6D_1} + \frac{(\sin^2 2\Delta + \sin^4\Delta)}{6D_1 + D}\right\} \tag{6}$$

where D_1 is the isotropic rotational diffusion constant. D is defined as[16]: $\cdot 3/2 \times$ the total rate of jumping of a methyl group from any of its three equivalent orientations'. and Δ is the angle between the internuclear vector and the axis of internal rotation. To obtain D, one may use the equation[17]:

$$Z = \frac{1}{2\pi}\left(\frac{f}{m}\right)^{1/2}\exp(-E^*/kT)$$

which gives the rate of passage Z of particles of mass m from a harmonic potential well of force constant f over a potential barrier E^*. Applying this to the case of a threefold internal rotation potential:

$$u(\phi) = \frac{1}{2}V_0(1-\cos 3\phi)$$

and changing m to the moment of inertia of the methyl top. one obtains:

$$D = \frac{9}{8\pi}\left(\frac{V_0}{I}\right)^{1/2}\exp(-V_0/kT)$$

For $V_0 = 3.4$ kJ/mol at $-55°C$, $D = 8.43 \times 10^{11}$ s^{-1}. Knowing the structure of acetone[18] ($r_{CH} = 0.1084$ nm, $r_{HH} = 0.1765$ nm, $\Delta_{CH} = 110.3°$, $\Delta_{HH} = 90°$), one may then apply equation (6) obtaining $\tau_H/\tau_C = 1.34$ and combine equations (4) and (5) to obtain $T_{1C}(D)/T_{1H}(D) = 1.14$. (A small correction has been applied to the equation for T_{1H} to take account of inter-methyl interactions.)

At $-55°C$, $T_{1C}(D)$ is 13.1 s for pure acetone, whence one calculates $T_{1H}(D) = 11.5$ s compared with the experimental value of 11.9 s for $T_{1H}(intra)$. At this temperature, both ^{13}C and ^1H relaxation are completely dipolar. and the excellent agreement between the calculated $T_{1H}(D)$ and $T_{1H}(intra)$ is substantial justification for the method. To gain exact correspondence between $T_{1H}(D)$ and $T_{1H}(intra)$ at these low temperatures, the relationship $T_{1C}(D)/T_{1H}(D) = 1.1$ has actually been used. With the aid of this equation one may then evaluate $T_{1H}(D)$ and $T_{1H}(SR)$ for pure acetone and hence $T_{1H}(a\text{-}p)$ for the polymer solutions. *Figures 3* and *4* show respectively the quantities $W_a \times T_{1H}(a\text{-}a)$ and $(W_p/0.05) \times T_{1H}(a\text{-}p)$ as a function of temperature for the same solutions as in *Figure 1*, where W_a and W_p are the weight fractions of acetone and polymer respectively. The purpose of multiplying $T_{1H}(a\text{-}a)$ by W_a and $T_{1H}(a\text{-}p)$ by $W_p/0.05$ is to eliminate the concentration dependence of intermolecular relaxation contributions, thus showing more clearly relative changes in solvent translational mobility. $T_1(a\text{-}a)$ is thus normalized to give the value one would expect for pure acetone if the translational mobility remained the same as in the polymer solution. and $T_1(a\text{-}p)$ is normalized to the value one would expect for a 5% polymer solution if the same happened.
Figure 3 Variation of $W_a \times T_{1H}(a-a)$ with temperature for pure acetone (□) and solutions of PMMA in acetone: +, 0.05; ×, 0.1; ○, 0.2 wt fraction PMMA. For clarity only one line has been drawn for pure acetone and the solutions of weight fraction 0.05 and 0.1
Figure 4 Variation of $(W_p/0.05) \times T_{1H}(\text{a}-\text{p})$ with temperature for the acetone protons in solutions of PMMA: □, 0.05; ×, 0.1; ○, 0.2 wt fraction PMMA. For clarity only one line has been drawn for the solutions of weight fraction 0.05 and 0.1

From these results, it is clear once again that the presence of up to 10% polymer has little effect on solvent or polymer translational mobility, but 20% polymer has a marked effect on the activation energy. For the pure solvent and polymer solutions of 0.05 and 0.1 weight fraction, the activation energies for $T_{1H}(\text{a}\ \text{a})$ and $T_{1H}(\text{a}-\text{p})$ are 10 and 15.5 kJ/mol respectively, rising to 14.5 and 22 kJ/mol respectively for the 0.2 weight fraction polymer solution. The hindrance to solvent rotation afforded by 20% polymer noted earlier is not unexpectedly also a hindrance to solvent diffusion. In the benzene- PMMA system[3], it was found that up to 35% polymer had little effect on solvent translation, at 35°C. As with the T_{1C} measurements described earlier, at this temperature in the present work there is relatively little variation of either $T_{1H}(\text{a}\ \text{a})$ or $T_{1H}(\text{a}\ \text{p})$ (extrapolated) with solution composition. The effect of the polymer on solvent motion is revealed most clearly by the temperature dependence of the relaxation contributions.

Because of the fairly sharp increase in the hindrance to solvent motion on going from 10% to 20% polymer, it is likely that the explanation lies in the formation of an entangled network rather than in the replacement of relatively weak solvent solvent contacts by stronger solvent polymer contacts which would be more gradual in their effect. It is also significant that the change in solvent

mobility occurs at a solvent/monomer molecular ratio of 7 : 1 (0.2 weight fraction polymer) at which point the immediate environment of a solvent molecule (i.e. the first and second solvation shells) begins to look less like pure solvent. There is evidence[19] that the motion of polymer chains is determined only by the very local viscosity of polymer solution, and this may also be true of solvent motion.

Finally, it is worth noting that there is no indication of any departure from Arrhenius temperature dependence of any relaxation contributions which might occur because of possible conformational transitions in the polymer chain. However, if the molecular motion is sensitive only to nearest and next-nearest neighbours, then a long-range change in polymer dimensions would not be detectable by the n.m.r. method.

Molecular motion in polyisobutylene and poly(propylene oxide) studied by ^{13}C nuclear magnetic relaxation

Frank Heatley
Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 2 September 1974)

The ^{13}C spin-lattice relaxation times of low molecular weight (up to 2500) samples of polyisobutylene and poly(propylene oxide) have been measured as a function of molecular weight, temperature and concentration in chloroform solution. For both polymers there is little dependence on molecular weight indicating a flexible conformation in the liquid state, but the relaxation time increases with increasing dilution in CHCl$_3$. The motion of the polymer backbone therefore depends on the micro-viscosity of the solution, rather than the bulk viscosity. In polyisobutylene the methyl re-orientation rate increases in parallel with the backbone re-orientation rate, showing that the two motions are interlinked. In poly(propylene oxide) the methyl re-orientation rate is independent of the backbone motion.

INTRODUCTION

In recent years ^{13}C n.m.r. relaxation measurements have supplemented the well-established ^{1}H n.m.r. technique as a means of investigating molecular motion in polymers. ^{13}C n.m.r., although much less sensitive than ^{1}H n.m.r. has a number of advantages, among which are: (i) when run under ^{1}H decoupled conditions, ^{13}C spectra consist of single lines for each type of carbon present, separated by chemical shifts an order of magnitude greater than ^{1}H chemical shifts; (ii) the relaxation times of protonated ^{13}C nuclei are determined entirely by dipolar interaction with the attached protons, provided the correlation time for the molecular motion is greater than 10^{-11} s, a condition which is fulfilled for polymers, even in dilute solution.

These advantages have been used by a number of workers[1-7], who have established for polymers in solution that (a) for a fixed monomer unit concentration and high molecular weight, ^{13}C T_1 values are independent of molecular weight for many vinyl polymers, indicating that the relaxation is controlled by internal motions of the polymer chain, which are rapid compared to overall rotation; (b) the correlation time for relaxation of backbone ^{13}C nuclei is typically 5×10^{-10} s at normal temperature; (c) the correlation time for relaxation of side-group ^{13}C nuclei may be the same as the backbone, e.g. polystyrene[1], indicating that internal rotation of the side-group is strongly hindered, or much shorter than the backbone, e.g. polypropylene[4], indicating rapid internal rotation of the side-group compared to motion of the polymer chain to which it is attached.

In this work, the ^{13}C relaxation in low molecular weight polyisobutylene (PIB) and poly(propylene oxide) (PPO), both in bulk and in solution in CHCl$_3$, has been investigated as a function of temperature, molecular weight and concentration, with particular attention being paid to the concentration and temperature dependence of the correlation times for backbone motion and internal rotation of the

methyl groups. One objective was to compare the barrier to methyl rotation with that obtained from neutron inelastic scattering[8].

EXPERIMENTAL

The PIB samples were provided by W. R. Grace Ltd, Port Talbot, Wales. Two samples were used, one of M_n = 900, with M_w/M_n = 1.8, and the other of M_n = 2900, with M_w/M_n = 3.0. The PPO samples were obtained from Waters Associates, Framingham, Mass., USA. Two samples were also used with M_n = 790 and 2020, both having $M_w/M_n <$ 1.1. All samples were viscous liquids.

^{13}C spin-lattice relaxation times were measured on a Varian Associates XL-100 Fourier Transform spectrometer operating at 25.14 MHz, using the standard $\pi - \pi/2$ pulse sequence.

RESULTS AND DISCUSSION

In both polymers, all ^{13}C resonances appeared as singlets, although there is the possibility of sequences of different tacticities in PPO. The peak positions, essentially unaffected by concentration, molecular weight or temperature are, in ppm downfield from TMS, 22.0, 74.0 and 76.0 for the CH$_3$, CH$_2$ and CH carbons in PPO, and 33.3, 40.0 and 61.9 for the CH$_3$, C and CH$_2$ carbons in PIB. In the bulk polymers, all peaks were broad, with a linewidth exceeding 20 Hz. The CH$_2$ in PIB was particularly broad, with a linewidth of 240 Hz. All peaks decreased markedly in width on dilution with CDCl$_3$ and/or raising the temperature, the CH$_2$ peak in PIB to the greatest extent.

The variation of the spin-lattice relaxation time of all protonated carbons with solution composition in CDCl$_3$ is shown in *Figures 1* and *2*, in the form of a plot of T_1 against the ratio of solvent molecules to monomer units.
Figure 1 Variation of ^{13}C T_1 values of PIB with concentration in CDCl$_3$. $\bigcirc$, M_n = 900, CH$_2$; $\triangle$, M_n = 900, CH$_3$; X, M_n = 2900, CH$_3$; $\square$, M_n = 2900, CH$_3$

The sample temperature was 30°C. The feature common to both polymers is a rapid rise in T_1 with the initial addition of CDCl$_3$ to the bulk polymer, and the attainment of a plateau in T_1 at a CDCl$_3$/monomer molecular ratio of about 5, corresponding to a polymer weight fraction of 0.1. At greater dilutions, T_1 is practically independent of polymer concentration and therefore of bulk sample viscosity, which may vary with concentration by an order of magnitude even for quite dilute polymer solutions. There is a slight variation of approximately 10% in T_1 between the samples of different M_n used here, which are of much lower molecular weight than those used previously. Again, however, this is much less than the factor of 2–3 by which the bulk viscosity changes. These results are in agreement with the independence of T_1 and molecular weight and polymer concentration in dilute solution observed by earlier workers[1,3]. However, the rapid rise in T_1 with initial addition of solvent is a novel feature which shows that the polymer motion is not independent of its environment. This observation suggests that although the polymer motion is not correlated with bulk sample viscosity, it does depend on the frictional forces exerted by the immediate environment of a polymer segment. Since the plateau in T_1 is reached at a CDCl$_3$/monomer molecular ratio of 5, the immediate environment in this case means the first solvation shell, i.e. enough solvent to separate the polymer molecules. Thus it seems that in these two polymers, and presumably others of a like flexibility, the chain segmental motion loses correlation in a short range. of the order of two or three monomer units possibly, otherwise T_1 would be dependent on molecular weight, and forces determining the segment re-orientation rate are not entirely intramolecular. but are controlled in part at least by the very local

viscosity of the segment. It is clear that the Gierer and Wirtz[9] 'microviscosity' theory of n.m.r. relaxation times, which takes the microscopic structure of liquids into account and which has been successfully applied to small molecules[10], is unable to account for polymer relaxation times, since it contains the inverse proportionality between T_1 and the bulk viscosity. Hill's theory[11] employing an inertial model and the concept of a 'mutual viscosity' may be applicable, but the theory requires a fairly precise knowledge of the solution structure, and there are severe problems in evaluating for a polymer solution some of the moments of inertia needed.

In both polymers the backbone and side-group carbon relaxation times parallel each other, but the side-group T_1 values are considerably longer, indicating the presence of internal methyl rotation which is comparable to the rate of segmental motion. Woessner et al.[12] have analysed theoretically the relaxation times of nuclei undergoing simultaneous overall and internal rotation and this formulation has been employed to separate the two motions in these polymers. This theory is based on the single correlation time description of overall motion, and may not be strictly applicable to polymers for which Schaefer[13] has shown that a distribution of correlation times is indicated by experimental fact. However, results obtained from Woessner's theory will not be qualitatively in error. Isotropic segmental motion has been assumed which may also lead to systematic quantitative error.

For isotropic diffusional re-orientation, the relaxation time of the ^{13}C nucleus in a CH$_n$ group which is relaxed by
Figure 2 Variation of ^{13}C T_1 values of PPO with concentration in CDCl$_3$. $\bigcirc$, M_n = 790, CH$_2$; X, M_n = 790, CH; $\triangle$, M_n = 790, CH$_3$; $\square$, M_n = 2020, CH$_2$; +, M_n = 2020, CH; $\triangledown$, M_n = 2020, CH$_3$

dipolar interaction with the protons is given by:

$$\frac{1}{T_1} = \frac{n\gamma_C^2\gamma_H^2\hbar^2}{10r_{CH}^6}\left\{\frac{\tau_1}{1 + (\omega_H - \omega_C)^2\tau_1^2} + \right.$$

$$\left.\frac{3\tau_1}{1 + \omega_C^2\tau_1^2} + \frac{6\tau_1}{1 + (\omega_H + \omega_C)^2\tau_1^2}\right\} \qquad (1)$$

where γ_C and γ_H are the magnetogyric ratios of ^{13}C and ^1H nuclei respectively, r_{CH} is the internuclear distance and ω_C and ω_H and the ^{13}C and ^1H resonance frequencies. τ_1 is the n.m.r. correlation time and is related to the rotational diffusion constant D_1 by: $\tau_1 = 1/6D_1$. In the presence of internal rotation about a three-fold potential barrier this equation becomes[12]:

$$\frac{1}{T_1} = \frac{n\gamma_C^2\gamma_H^2\hbar^2}{40r_{CH}^2}\left\{(1 - 3\cos^2\Delta)^2\left[\frac{\tau_1}{1 + (\omega_H - \omega_C)^2\tau_1^2} + \right.\right.$$

$$\left.\frac{3\tau_1}{1 + \omega_C^2\tau_1^2} + \frac{6\tau_1}{1 + (\omega_H + \omega_C)^2\tau_1^2}\right] +$$

$$3(\sin^2 2\Delta + \sin^4\Delta)\left[\frac{\tau_2}{1 + (\omega_H - \omega_C)^2\tau_2^2} + \right.$$

$$\left.\left.\frac{3\tau_2}{1 + \omega_C^2\tau_2^2} + \frac{6\tau_2}{1 + (\omega_H + \omega_C)^2\tau_2^2}\right]\right\} \qquad (2)$$

Δ is the angle between the C–H bond and the axis of internal rotation, and τ_2 is defined by: $\tau_2 = 1/(6D_1 + D_{int})$ where D_{int} is '3/2 x the total rate of jumping of a methyl group from any of its three equivalent orientations'[12]. When the extreme narrowing condition applies: $(\omega_H + \omega_C)^2\tau^2 \ll 1$ corresponding to $nT_1 > 150$ ms, these equations simplify considerably. This condition was fulfilled in all samples except the bulk polymers and more concentrated PIB solutions. To separate D_1 and D_{int}, D_1 was obtained from the relaxation time of the CH_2 carbon in PIB and the CH carbon in PPO, using equation (1). For a methyl group, $\Delta = \cos^{-1}(1/3)$, and this was then substituted, together with D_1, into equation (2) to obtain D_{int}. In both cases r_{CH} was assumed to be 0.11 nm.

The effect of dilution in $CDCl_3$ on D_1 and D_{int} is shown in *Figure 3* for the higher molecular weight samples. D_1 of course parallels the behaviour of the corresponding T_1 values shown in *Figures 1* and *2*. The significant feature is that for PIB the plot of D_{int} follows closely the plot of D_1, whereas for PPO, D_{int} is essentially independent of D_1. Also D_{int} for PPO is at least an order of magnitude greater than D_{int} for PIB. Two conclusions may be drawn: (1) the barrier to methyl rotation in PIB is greater than in PPO; and (2) the barrier in PIB depends on the environment, whereas the barrier in PPO does not. Examination of molecular models shows that PIB is indeed a good deal more sterically crowded than PPO, so much so in fact that steric repulsion of neighbouring methyl groups is so strong that the chain bonds must necessarily be forced out of the usually favoured staggered conformation by 20° or so. Even then, rotation of the methyl groups is still strongly hindered, and can proceed most freely by a co-operative process involving neighbouring methyls and motion about the chain bonds.

Thus the relationship between methyl and segmental rotation diffusion constants in PIB is simply a manifestation of the interdependence of the molecular potential barriers of the two processes. In PPO, on the other hand, the methyl groups are well separated, nor need they necessarily interfere with each other or with rotation about chain bonds. The rate of methyl rotation is thus determined solely by intramolecular factors, intermolecular effects being minimized by the three-fold symmetry.

Activation energies have been obtained for the temperature variation of D_1 and D_{int} for the bulk polymers and for solutions in $CDCl_3$ of polymer weight fraction 0.3, corresponding approximately to a $CDCl_3$/monomer molecular ratio of unity. The values obtained are listed in *Table 1*, together with values of the barrier obtained from torsional oscillation data provided by neutron inelastic scattering[8]. We note that in PPO, the activation energy for D_{int} is much less than that for D_1, and is independent of dilution with
Figure 3 Variation of D_1(○) and D_{int} (●) of PIB (——) and PPO (————) with concentration in $CDCl_3$. M_n: PIB = 2900; PPO = 2020

Table 1 Activation energies of D_1 and D_{int} for PIB and PPO

Sample		Activation energy (kJ/mol)		Barrier from neutron scattering[8] (kJ/mol)
		D_1	D_{int}	
PPO	bulk	27 ± 2	10.5 ± 2	13
	0.3 wt fraction in $CDCl_3$	21 ± 2	11 ± 2	
PIB	bulk	24 ± 2	25 ± 2	24
	0.3 wt fraction in $CDCl_3$	18 ± 2	18 ± 2	

CDCl$_3$, whereas in PIB the two activation energies are equal within experimental error, and both vary with polymer concentration. The activation energies for D_1 for both polymers are similar for the same concentration. There is excellent agreement between the activation energies for D_{int} and the methyl barrier from neutron scattering, although the results obtained here for PIB show that the assumption of no coupling between methyl torsion and other vibrational modes made in the neutron scattering experiment may not be even approximately valid.

Synthesis and properties of completely crystalline POM copolymers

M. Dröscher*, G. Lieser, H. Reimann and G. Wegner*†

Institut für Physikalische Chemie, Universität Mainz, D-65 Mainz, West Germany
(Received 8 November 1974)

Extended chain crystals of polyoxymethylene copolymers have been prepared by cationic copolymerization of trioxane and dioxolane. These crystals do not contain amorphous regions and behave like an ideal solid solution of $-CH_2CH_2O-$ units in the crystal of $-CH_2O-$ units up to a mole fraction of $x_{CH_2CH_2O} = 0.1$. Melting points, melting enthalpies, specific heat, density and lattice parameters were measured as a function of mole fraction up to $x_{CH_2CH_2O} = 0.2$. Comparison of the dependence of lattice parameters on mole fraction for the extended chain crystals and melt or solution crystallized copolymers indicates, that in the semi-crystalline samples the comonomer units are not distributed at random between amorphous and crystalline phase but the comonomer units are enriched in the amorphous phase.

INTRODUCTION

In their early work Staudinger and his coworkers showed that polymerization of formaldehyde or cyclic oligomers of formaldehyde give rise to highly crystalline polyoxymethylene (POM) by simultaneous polymerization and crystallization[1,2]. In a recent investigation[3] our group has demonstrated that true single crystals of POM can be obtained by cationic polymerization of trioxane in nitrobenzene. These crystals possess the well known hexagonal structure of POM crystals but differ greatly from the so-called solution grown 'single-crystals' of POM with regard to morphology, melting behaviour and degree of crystallinity. All relevant data on the formation and properties of these crystals[3] indicate that they may be called extended chain crystals according to the definition given by Wunderlich[4].

We now have studied the crystals of the copolymer which are formed during cationically induced copolymerization of trioxane and 1,3-dioxolane. Again, extended chain crystals of the copolymers are formed in which the comonomer $(-OCH_2CH_2-)$ units are distributed at random throughout the lattice of the $-CH_2O-$ units. It is interesting to look for the dependence of melting behaviour, density, specific heat and other characteristic data on the mole fraction of comonomer units, because these copolymer crystals do not contain amorphous regions. Thus, all effects are directly related to disturbances created by the comonomer units inside the POM crystal. Therefore, we believe to have found a system in which the thermodynamical properties of a copolymer crystal can be measured directly for the first time. So far only measurements on semi-crystalline copolymers were possible, which are obscured by the fact that the distribution of the comonomer units between the crystalline and amorphous phase is generally not known[5–7].

EXPERIMENTAL

Trioxane (m.p. $62°C$) was refluxed over sodium–potassium alloy for 48 h and then distilled under nitrogen prior to polymerization. 1,3-Dioxolane (b.p. $74.5°C$) was refluxed over $LiAlH_4$ for 48 h and then distilled under nitrogen prior to polymerization. Nitrobenzene was refluxed over P_2O_5 for 20 h and then fractionated *in vacuo*. Methylene chloride was stored over CaH_2 for several days, refluxed over $LiAlH_4$ for 48 h and then distilled under nitrogen.

For polymerization, a solution of trioxane in nitrobenzene or in dichloromethylene was transferred under an atmosphere of dry nitrogen into a 100 ml polymerization flask which was decontaminated from water by evacuating and heating with a torch. The flask was set in a thermostat at $30°C$. A solution of the catalyst ($BF_3 \cdot Et_2O$) in nitrobenzene or dichloromethylene was added by means of a syringe through a rubber stopper. Dioxolane was added in the same way. Total concentration of the monomers was varied between 1.8 and 4 mol/l and the concentration of the initiator was 1 mmol/l. After a period of several days polymerization was stopped by adding a solution of triethylamine in methanol in five-fold excess with regard to the initiator concentration.

The polymer crystals were carefully filtered without applying suction and were washed repeatedly with acetone. The polymer was dried *in vacuo* at room temperature. Molecular weight was determined by viscometry with hexafluoroacetone sesquihydrate as solvent according to the procedures described by Jaacks *et al.*[8] using the viscosity–molecular weight relationship for the homopolymer as a first approximation. Thermal data were measured with a Perkin-Elmer 1B differential scanning calorimeter (d.s.c.). A heating rate of $8°C/min$ was used in determination of melting points. Melting enthalpy was measured at heating rates of 16, 32 and $64°C/min$.

The composition of the copolymers was analysed by gas chromatography. 100 mg of the copolymer were reacted

at room temperature with 1 ml acetic anhydride and one drop of a 3.8 M solution of perchloric acid in acetic anhydride. After addition of 1,4-butanediol diacetate as an internal standard the concentration of the reaction products, formaldehyde diacetate and ethylene glycol diacetate, were determined with a Varian Aerograph 1700 gas chromatograph using a Porapak-P column of 1 m length.

Surface replicas for electron micrographs were obtained as described previously[3].

Lattice constants of the copolymer single crystals were determined by means of a Guinier camera with a precision monochromator using the powder method. Densities were determined in a density gradient consisting of mixtures of CCl_4 and n-hexane.

RESULTS AND DISCUSSION

The copolymerization of trioxane and 1,3-dioxolane is a reversible polyreaction in which the crystalline copolymer is in equilibrium with the dissolved monomers. Chain growth proceeds by two different reactions, namely 'normal' addition of the cyclic monomers onto cationically active chain ends presumable by an S_N2 reaction[9] and by insertion of the monomer into the chain folds of the lamellar crystals formed in the very beginning of the polymerization by a transacetalization mechanism[3]. In the closed polymerization system practically all the initiator stays alive over an extended period of time so that the copolymer crystals are allowed to reach their equilibrium composition and comparatively large sizes by the well known mechanism of crystal coarsening (Ostwald ripening)[3,10]. In other words. copolymer crystals grow under thermodynamically controlled conditions and contrary to crystallization of copolymers from solution or melt which is clearly controlled by kinetic factors[5,6].

Under our reaction conditions crystalline copolymers were obtained up to a mole fraction of $-CH_2CH_2O-$ units in the isolated copolymer of $x_{CH_2CH_2O} \leqslant 0.2$. Copolymers richer in $-CH_2CH_2O-$ units are soluble in the reaction medium and consequently could not be obtained as extended chain crystals. *Figures 1a* and *1b* show crystals containing 1.8 mol% $-CH_2CH_2O-$ units. Size and morphological features such as growth spirals are very similar to the crystals obtained in homopolymerization of trioxane[3]. The micrographs show the fracture surfaces of such copolymer crystals obtained by fracturing a slightly compressed cake of the crystals at liquid nitrogen temperature. The sample consists of lamellae with a rather small distribution in crystal thickness. Average crystal thickness is about 0.14 μm; some crystals are, however, as thick as 0.6 μm. As was shown previously[3], the polymer chains run perpendicular to the lamella surfaces. An average molecular weight of $M_n = 23\,000$ was determined from viscosity measurements corresponding to a length of about 0.15 μm, if one assumes an extended 9/5 POM helix. The molecular weights of all the polymers investigated in this work were in the range of 2×10^4 to 6×10^4. The comonomer units have to be distributed at random throughout these crystals, since it has been well established that random copolymers are formed in this copolymerization[11,12]. The randomness of comonomer distribution is indeed the key in the stabilization of technical polyacetal resins, prepared in a similar manner by bulk polymerization.

POM crystallizes as a 9/5 helix in a hexagonal unit cell[13,14]. The dependence of the lattice parameters on the

mole fraction of comonomer units is shown in *Figure 2*. The lattice is expanded in a lateral direction almost linearly with increasing content in comonomer units up to a mole fraction of about 0.1 and then remains nearly constant with further increase of $-CH_2CH_2O-$ units. The chain axis (c-axis) is contracted linearly up to $x_{CH_2CH_2O} = 0.1$ and then increases again. A correspondence between lattice parameters and concentration of comonomer units has already been demonstrated by Holdsworth and Fischer[14] using melt crystallized samples. However, melt or solution crystallized copolymers seem to behave differently as it is seen from *Figures 2a* and *2b*, if one just plots the observed lattice parameters against mole fraction of comonomer units. In reality a segregation occurs in the recrystallized samples leading to a higher concentration of the comonomer units in the amorphous phase as compared to the
Figure 1 Electron micrographs of fracture surfaces (replica) of a POM copolymer containing 1.8 mol % of CH_2CH_2O units
Figure 2 Unit cell spacings as a function of mole fraction of —CH_2CH_2O— units in crystals as polymerized (△), as crystallized from solution (□) and from the melt (○). Melt data according to Holdsworth and Fischer[14]

crystalline phase. This segregation was verified by a neutron scattering experiment using a copolymer in which the oxyethylene units were fully deuterated. A peak was observed in the low angle diffraction diagram with much higher intensity than the peak observed in the neutron low angle scattering diagram of a non-deuterated standard sample of POM copolymer with the same mole fraction of comonomer units. The diffraction peak is due to density differences in the non-deuterated sample and density differences plus concentration differences of CD_2 groups in the deuterated sample yielding a much higher scattering length density of the non-crystalline phase. From the diffraction angle the same long spacing was calculated as was observed with X-ray small angle scattering within the limits of error (~ 100 Å). Therefore, the deviation from the lattice parameters of pure POM with increasing content of comonomer units seems to be less for solution or melt crystallized samples because the crystalline phase contains actually considerably less comonomer units than the total polymer.

Figure 3 shows a plot of the experimentally observed density of the copolymers as polymerized against mole fraction of comonomer units. Density decreases linearly with increasing content of CH_2CH_2O units. A density of $\rho = 1.4670$ (g/cm^3) is observed directly for the homopolymer and $\rho = 1.476$ is extrapolated from the best fit of the line through all points which can be represented by:

$$\rho = 1.476 - 0.665 x_{CH_2CH_2O} \qquad (1)$$

On the other hand, a value of $\rho = 1.492$ g/cm^3 is reported by Uchida and Tadokoro as based on their determination

of unit cell parameters (X-ray density) and we derive a value of $\rho = 1.4857$ from our measurements shown in *Figures 2a* and *2b*. At present we cannot explain the difference in densities as measured by the density gradient and derived from X-ray data except by the assumption that the polymer contains voids which would not contribute to the wide angle scattering but would very much show up in density measurements. The discrepancy between the two values is less than 2% in any case. Recently Iguchi and coworkers[15] have reported density values as high as 1.494 to 1.50 g/cm^3 for crystals obtained by polymerization and crystallization of trioxane in cyclohexane. Unfortunately we were not able to obtain similar samples by the techniques described by these authors and we believe that the methods of density measurement used by them (floating and volume exclusion) are much more apt to experimental errors than X-ray determination of unit cell parameters and density gradient.

The melt behaviour of the extended chain copolymer crystals was measured by d.s.c. methods. The half-width of the melting peak is only $3-5°C$ at a heating rate of 8°C/min. The melting point $T_m(x)$ as defined by the maximum of melt-peak decreases at first considerably with increasing comonomer content, reaches a plateau between 10 and 20 mol % comonomer units and then decreases again very considerably. The complete melting diagram going from pure POM to pure polydioxolane is shown in *Figure 4*. The
Figure 3 Density as a function of mole fraction of —CH_2CH_2O— units for as-polymerized crystals
Figure 4 Melting point vs. mole fraction of —CH_2CH_2O units of crystals as-polymerized (△) and recrystallized from solution (○). — — —, according to the data of Wilski[20]
Figure 5 Heat of melting as a function of mole fraction of CH_2CH_2O units of crystals as-polymerized

region of extended chain crystals extends from pure POM to $x_{CH_2CH_2O}$ = 0.2. If the polymers are recrystallized from melt or solution the well known folded-chain crystals are formed which show a melting point depression of $5-18°C$ depending on the crystallite thickness and on the degree of segregation of the comonomer units between the crystalline and amorphous phase.

From the slope of the linear part of the melting point curve for extended chain crystals ($x_{CH_2CH_2O} < 0.1$) according to Eby[5] the defect enthalpy ΔH_D can be determined by:

$$T_m(x) = (1 - A \cdot x_{CH_2CH_2O})T_m(0)$$

$$= \left(1 - \frac{\Delta H_D}{\Delta H_m(0)} \cdot x_{CH_2CH_2O}\right) T_m(0) \qquad (2)$$

$$T_m(x) = (1 - 0.765 \cdot x_{CH_2CH_2O})458 \qquad (3)$$

where the terms with (0) refer to the pure POM crystal and ΔH_D is the defect enthalpy.

The change in melt enthalpy caused by introduction of comonomer units into the POM lattice is ΔH_D = 5.82 kJ/ mol of CH_2CH_2O units as derived from the experimentally observed equation (3) with $\Delta H_m(0)$ = 7.61 kJ/mol.

The enthalpy of melting as a function of comonomer units is shown in *Figure 5*. A similar dependence as already discussed for the melting points is observed. Since

we deal with fully crystalline copolymers, the curve describes the ideal enthalpies of melting as a function of comonomer units, which can be used in determination of the crystallinity of semi-crystalline copolymers by d.s.c. methods. The enthalpy of melting for the pure POM extended chain crystals is found to be 254 ± 4 J/g in excellent agreement with the value of 250 J/g reported in the literature[17-19].

A plot of the melting enthalpies per mole of CH_2O units against the mole fraction of the counits shows a linear function.

$$\Delta H_m(x) = \Delta H_m(0) - \Delta H_D x_{CH_2CH_2O}(x_{CH_2CH_2O} < 0.1)$$
$$\qquad (4)$$

$$\Delta H_m(x) = 7.52 - 7.5 x_{CH_2CH_2O} \qquad (5)$$

The slope gives the defect enthalpy ΔH_D = 7.5 kJ/mol of CH_2CH_2O units. The difference between the two values of ΔH_D found by melting point and melting enthalpies studies implies that the excess melting entropy is not zero as was assumed by Eby.

Mechanical and dielectric relaxations in polytrifluoroethylene

C. L. Choy, Y. K. Tse, S. M. Tsui and B. S. Hsu
Physics Department, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong
(Received 14 October 1974)

Molecular motions in polytrifluoroethylene are studied by dynamic mechanical and dielectric measurements. Two absorption peaks (α_a, β) have been observed in the frequency range from 3 Hz to 300 kHz and in the temperature range from $-150°$ to $130°C$. The molecular mechanisms for these absorptions are discussed, and the results are compared with ultrasonic, heat capacity and n.m.r. measurements. It is concluded that the α_a absorption located at $45°C$ (10 Hz) is associated with the large-scale motion of the main chains and the β absorption at $-35°C$ (10 Hz) is attributed to the limited motion of a few segments of the frozen main chains. In contrast to polychlorotrifluoro-ethylene the α_c absorption associated with crystalline regions has not been observed in polytrifluoro-ethylene. At high temperatures a steep rise in dielectric absorption is observed, which has been ascribed to a d.c. ionic conduction process.

INTRODUCTION

Numerous work has been carried out on the mechanical and dielectric relaxations in polychlorotrifluoroethylene (PCTFE)[1]. However, not a single study has been reported on the relaxations in polytrifluoroethylene (PVF$_3$) which differs from PCTFE only in that the chlorine atoms is substituted by a hydrogen atom. Recently, it has been found[2] that the ultrasonic velocity (10 MHz) in PVF$_3$ exhibits a change in slope at $-40°C$, which has been attributed to limited motion within the chain backbone. Similar change in slope at $40°C$ has also been observed in the heat capacity[3] but it is difficult to associate this change with any motion solely from the heat capacity data.

Dynamic mechanical[4,5] and dielectric[6] investigations of PCTFE reveal three loss peaks α_c, α_a and β which, at 1 Hz, are located at $140°$, $100°$ and $-40°C$ respectively. The small α_c peak is exhibited only by samples of the highest crystallinity and is connected with the occurrence of chain-folded lamellar spherulites. The α_a peak decreases in magnitude as the crystallinity increases and is associated with the glass transition at $52°C$ found by dilatometric measurements[7]. The relatively low activation energy of the β relaxation suggests that only a small number of segments of the chain backbone are involved in the motion. It would be interesting to make similar mechanical and dielectric relaxation measurements on PVF$_3$ so as to compare with the relaxations in PCTFE.

EXPERIMENTAL

The sample of PVF$_3$ was supplied in the form of coarse powder by Dr R. E. Florin of the National Bureau of Standards, (USA) and was mildly crosslinked. The powder was pressed into sheets at $160°C$ and slowly cooled to room temperature at a rate of $2°C/min$. In an attempt to prepare samples of different crystallinities, some samples were quenched either in air or in ice water. Cracks were found in these samples which were not used in our measurements.

The dynamical tensile modulus was measured with a viscoelastic spectrometer (Iwamoto Seisakusho Co. Ltd.) at 3, 10 and 100 Hz, between $-150°$ and $+100°C$. The samples had a thickness of 0.3 mm and lateral dimensions of 5 x 50 mm. The dielectric measurements were carried out with an Ando transformer ratio-arm bridge between $-110°$ and $+130°C$ from 30 Hz to 300 kHz. The details of the measurements have been described previously[8]. The samples were discs of diameter 2.7 cm and thickness 0.5 mm. Electrodes were applied by vacuum deposition of silver.

RESULTS AND DISCUSSION

Mechanical measurements

The tensile modulus E' and the mechanical loss tangent tan δ at 10 Hz are shown as functions of temperature in *Figures 1a* and *1b*. A predominant peak is observed at $45°C$. Because this peak is comparatively narrow and is associated with a large drop in E' within a narrow temperature range it is probably assoicated with the glass transition and is therefore denoted as the α_a transition. Unfortunately, we have not been able to prepare samples of different crystallinities to check this assignment and no dilatometric measurements have been carried out for this polymer. The only other corroborative evidence is the change in slope of the heat capacity at $40°C$ mentioned above[3]. In fact, there should be a jump in the heat capacity at the glass transition; probably because PVF$_3$ is a crystalline polymer the jump is so small that it exhibits only as a change in slope.

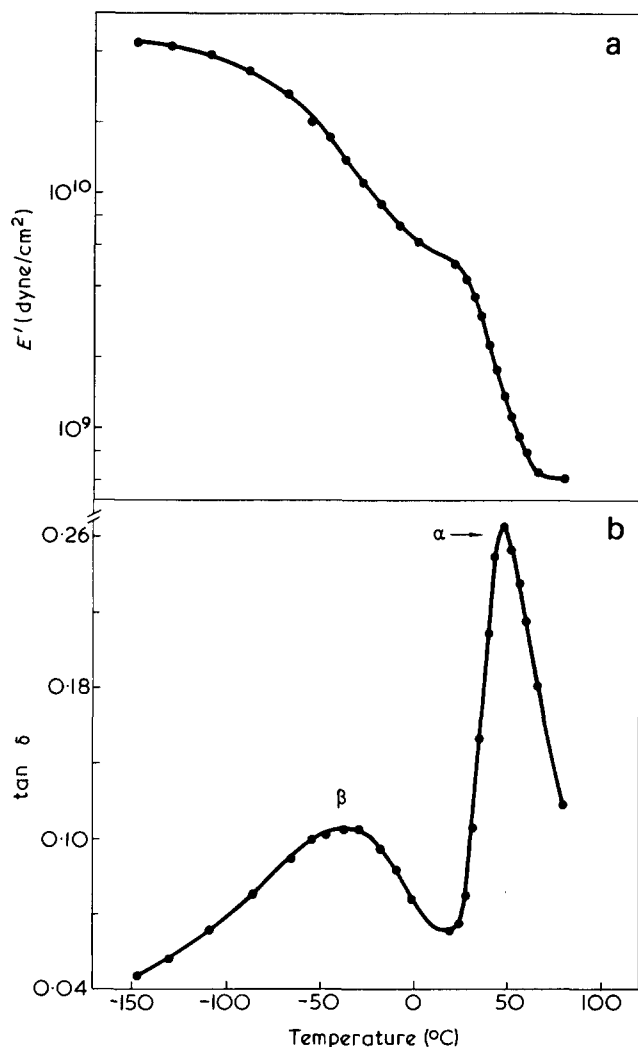
The low temperature peak at $-35°C$, assigned as the β relaxation, is probably due to the motion of a few segments in the carbon backbone. This motion had been observed as the narrowing of both the proton and fluorine resonance linewidths in nuclear magnetic resonance measurements[9]. Further evidence for the β relaxation is shown in the change in slope of the ultrasonic velocity curve at $-40°C$[2].


Figure 1 Temperature dependence of (a) tensile modulus, E' and (b) loss tangent tan δ at 10 Hz for polytrifluoroethylene

Figure 2 Temperature dependence of the dielectric loss ϵ'' at 300 Hz (■), 3 kHz (▲) and 100 kHz (●) for polytrifluoroethylene

Dielectric measurements

The dielectric losses ϵ'' at 300 Hz, 3 kHz and 100 kHz are plotted as functions of temperature in *Figure 2*. In contrast to the mechanical measurements the prominent peak in ϵ'' is the β relaxation which is located at $-40°C$ (30 Hz). The frequency dependence of the dielectric constant and loss in the β relaxation region is illustrated in *Figures 3* and *4*. From the Cole–Cole plots[10] of these data, the dielectric increment $\Delta\epsilon = \epsilon_R - \epsilon_U$ (ϵ_R and ϵ_U are the relaxed and unrelaxed dielectric constants) and the Cole–Cole distribution parameters $\bar{\beta}$ are obtained and shown in *Figure 5*. It is easily seen that $\Delta\epsilon$ for the β relaxation decreases as the temperature decreases. The broading of the loss peak with decreasing temperature is also represented as a decrease in the Cole–Cole distribution parameter.

Figure 2 also shows that for the lower frequencies (below 1 kHz) ϵ'' increases very steeply above 90°C and the α_q peak is almost covered by this absorption process. The α_q relaxation shows up as the shoulder in the ϵ'' curve at 300 Hz and a shallow maximum at 3 kHz. Above 3 kHz, there is considerable overlap between the α_q and β relaxations and at 100 kHz the α_q relaxation is completely covered by the tail of the β relaxation. The rise in ϵ'' at high temperatures is probably due to a d.c. ionic conduction mechanism because of the sharp increase with increasing temperature

and decreasing frequency. Similar contributions to ϵ'' have been observed in other halogen polymers such as poly(vinyl chloride)[11] and poly(vinyl fluoride)[12,13]. *Figure 6* shows the plots of ln ϵ'' at 30 and 300 Hz against 1/T, which are straight lines above 90°C, illustrating the fact that ϵ'' =
Figure 8 Plots of log *f* against 1/*T* for polytrifluoroethylene.
■, ●, Mechanical data; ▼, ▲, dielectric data

$A\sigma/f^1$ (where A is a constant, σ the d.c. conductivity, f the frequency) increases exponentially with temperature. Below 90°C the data points lie above the straight lines indicating the existence of the α_a relaxation. Using straight lines similar to those in *Figure 6* the ϵ'' values due to d.c. ionic conduction are extrapolated to lower temperatures for the data obtained from 30 Hz to 3 kHz. Curve I in *Figure 7* is an example of this extrapolation for the ϵ'' data at 300 Hz. Curve II is obtained by subtracting curve I from the experimental data (curve III) and reveals the α_a relaxation peak. From curve II the temperature at which ϵ'' exhibits a maximum is obtained and used in the log *f* against 1/*T* plot in *Figure 8*.

Activation energies

From *Figure 6* the activation energy of the ionic conduction process is found to be 13 kcal/mol. For PCTFE,

the corresponding energies obtained from direct d.c. conductivity measurements are 5 and 32 kcal/mol, respectively, in the glassy and rubbery state[24]. The log *f* against 1/*T* plots for both the α_a and β relaxations are shown in *Figure 8*. From the slopes of these curves the activation energies of the α_a and β relaxations are found to be 60 and 24 kcal/mol, respectively. The relatively large activation energy for the α_a relaxation confirms our assignment that it is associated with the large scale motion of the glass transition. Although the log *f* versus 1/*T* plot for this relaxation should obey the WLF equation[15], it seems to be linear in the limited temperature region (40–70°C) and thus the activation energy is independent of temperature. This is in contrast to the corresponding relaxation in PCTFE where the activation energy decreases from 67 kcal/mol at 90°C to 34 kcal/mol at 120°C[6]. The activation energy for the limited motion of the main chain in the β relaxation is slightly higher than the corresponding energies of 13.5 (crystallinity = 1) to 17.4 (crystallinity = 0) kcal/mol for PCTFE[6].

In conclusion, both the α_a and β relaxations are observed in PVF$_3$ and have activation energies similar to those of PCTFE. The β relaxation occurs at nearly the same temperature as that of PCTFE but the α_a relaxation occurs at 55°C lower. The α_c relaxation associated with crystalline regions has not been observed.

Conformation of poly(ethylene oxide) in the solid state, melt and solution measured by Raman scattering

J. Maxfield and I. W. Shepherd

Physics Department, University of Manchester, Manchester M13 9PL, UK
(Received 16 July 1974; revised 8 October 1974)

The Raman spectrum of poly(ethylene oxide) (PEO) $\overline{M}_w$ = 3 x 10^6 and 6 x 10^3 has been measured in bulk as a function of temperature and in aqueous and chloroform solution as a function of solvent concentration. The spectral features are assigned to particular isomeric configurations and the changes on melting are found to be consistent with a helix-coil transition. In both solvents the ordered nature of the polymer is largely lost at a critical concentration, approximately 50% by weight; residual ordering in dilute aqueous solution is lost and the random coil configuration attained only above the melting temperature. The wavenumber change of the 862 cm^{-1} mode as a function of water concentration showed formation of a complex involving three water molecules and was consistent with a simple H-bonding model. The differences between the spectra in the two solvents are explained by this H-bonding. The results are in general agreement with n.m.r. work.

INTRODUCTION

The conformation of polymer molecules in solution has been a subject of interest over many years and several different experimental techniques have been used in the study[1-4]. Biopolymers in particular have been shown to take up ordered forms in aqueous solution and the stability of the ordering is generally critically dependent on the solution variables. Studies of biological molecules are clearly of great importance but the extremely complex nature of these makes detailed analysis very complicated. In this work we present detailed Raman studies on poly(ethylene oxide) (PEO) which we believe is an ideal molecule for solution studies. It is a synthetic molecule of great industrial importance and has been studied by several different techniques, which we review briefly below. Furthermore it displays some basic features of proteins and can be thought of as a simple model compound. The most important feature is that the monomer contains one hydrophobic region ($-CH_2-CH_2-$) and one hydrogen bonding site ($-O-$).

Raman spectroscopy has great potential in the study of polymer conformations, particularly in aqueous solution because the water spectrum is weak and does not obscure any of the polymer bands. The present paper examines the changes in the Raman spectrum between the crystalline phase and the melt and relates these to the breakdown of ordering. The differences in the spectra of solutions in water and chloroform are presented and discussed in terms of the hydrogen bonding of water to the polymer chain. The solution spectra are also compared with the melt spectrum. At all stages the deductions from the Raman data are compared with previous work, using other techniques, which is briefly reviewed below.

It is well established from X-ray analysis[5] that poly(ethylene oxide) crystallizes in a helical configuration, and spectroscopic studies[6,7] show that the symmetry is isomorphous with the factor group $D(4\pi/7)$. The helical form of this polymer is constructed with a succession of trans (CCOC), gauche (OCCO), and trans (COCC) conformers along the chain, with bond angles of 192°, 60° and 192° respectively[8]. The normal coordinate analysis for this system has been carried out on the basis of the 7_2 helix by Yoshihara et al.[6] and the calculated frequencies agree fairly well with the observed infra-red[9] and Raman[10] bands.

In aqueous solution the configuration of the PEO chain will be influenced by the hydrophobic nature of the interaction between the ethylene groups and the polar solvent molecules. Ultrasonic attenuation measurements[11] show that there is a single relaxation time in aqueous solution, which is attributed to a polymer/solvent interaction involving hydrogen bonding of the water molecules to oxygen atoms along the chain, modified by hydrophobic interactions within the polymer and by water clusters near the hydrophobic groups. The data also imply that a minimum molecular size of the solvent-macromolecule structure, of the order of 75 units, is required before cooperativity is displayed[12,13]. The requirement of a minimum molecular size has also been demonstrated in the case of the helix-coil transition in polypeptides[14].

Liu[15,16] has made an extensive study of PEO solution structures using n.m.r. techniques. The chemical shift of the ethylene protons was found to increase almost linearly with water concentration until a certain composition was reached (~50% by vol), after which it remained constant. The hydroxyl protons exhibited an almost analogous behaviour. These results indicate that there is a linear change in the average segmental environment of PEO until 50% concentration is reached, after which there is negligible segmental environment change. This behaviour corresponds to the formation of a hydrogen bonded complex containing approximately three water molecules per monomer unit. The ethylene proton chemical shift in chloroform solution was found to change linearly with solvent content over the entire concentration range. The hydroxyl proton behaviour

was quite different. The chemical shift was constant with increasing chloroform concentration until a particular value was reached (~40% by vol) and then fell off sharply. The ethylene proton chemical shifts show that without any specific interaction between the polymer and solvent, the segmental environment changes linearly with solvent content over the entire composition range. The hydroxyl proton behaviour is a measure of the strong molecular association through intermolecular hydrogen bonding. The sharp fall off is associated with the breakdown of this bonding on reaching a specific dilution.

The diffusion constant, D, of PEO has been measured as a function of concentration in D_2O solution by neutron scattering[17]. This parameter, which measures the local motions occurring over a number of monomer units, has been measured at several temperatures. At each temperature the behaviour is essentially the same, D decreases with increasing solvent content until approximately 1 molecule of D_2O per monomer unit has been added, after this point D starts to increase. So far measurements have only been made with up to 3 molecules of D_2O present. In an organic solvent, toluene-d_8, the diffusion constant increases rapidly as the solvent content is increased.

The Raman spectrum of crystalline PEO has been studied by several groups, notably by Yoshihara *et al.* in their analysis of the normal vibrations[6]. Koenig and Angood[18] have published spectra taken in both solution and melt. In the next section we shall present a more intensive study of solutions using Raman scattering methods, with the aim of investigating the structural changes suggested from the n.m.r., ultrasonic, and neutron scattering data of previous workers.

EXPERIMENTAL AND RESULTS

Method

The exciting source was an argon ion laser operating with a power of 800 mW in the 5145 Å line. The scattered light was analysed using a Cary 82 spectrometer. Two samples of PEO with molecular weights $\bar{M}_w$ = 3 x 10[6] and 6 x 10[3] were used in these experiments. The melting points were determined from differential thermal analysis to be 61.1 ± 0.2°C and 53.8 ± 0.5°C respectively. The sample cells were square and of spectroscopic quality. Temperatures above ambient were attained by wrapping heating wire and insulation round the cell leaving small areas free for the incident and scattered beams. The temperature was measured using a Comark electronic thermometer and was controlled to ±0.25°C.

Raman spectra of PEO in the crystalline and molten states

Raman spectra of pure PEO, $\bar{M}_w$ = 3 x 10[6], are shown in *Figure 1* at various temperatures above and below the melting temperature of 61.1°C. The various well resolved band splittings observed in the crystalline material (lower trace), e.g. at 846—860 cm^{-1}, are a result of the ordered helical conformation and disappear at the higher temperatures. The very weak band at 810 cm^{-1} is of particular interest, and has been assigned to the *trans* conformation of the (OCCO) grouping following the assignment of the 1R mode at 811 cm^{-1} [19,20]. In the crystal state most of the (OCCO) groups are in the *gauche* state and the low intensity of the 810 cm^{-1} mode is consistent with this assignment. Previous Raman workers[18] have assigned this mode to (OH) end groups or, rather ambiguously, as an 'amorphous'

band. However, our observations discussed below agree with the assignment from 1R measurements.

Changes in the spectrum caused by melting occur over a range of several degrees, owing to the distribution of chain lengths within the sample. The molten PEO spectrum is radically different from that of the crystalline material. Such changes are to be expected in going from a highly ordered state exhibiting considerable molecular symmetry to a disordered, essentially random structure. The loss of order is reflected in the disappearance of much of the band splitting observed in the solid state. There are also some frequency shifts of existing bands, and the appearance of new bands, which can be associated with the formation of new conformational structure in the melt. The frequencies of the Raman bands in both the crystalline and molten states are listed in *Table 1*, together with their probable assignments which are based on previous work[6,9,10].

In this study, the bands in the region 800 to 1100 cm^{-1} have been investigated in most detail. These bands arise from combinations of chain backbone modes, in particular the (C—O—C) stretching vibration, and the ethylene rocking modes and are most likely to be susceptible to hydrogen bonding effects. The changes in the remainder of the spectrum were considered to be relatively unimportant, being mainly attributable to the loss of crystalline order. The bands at 810, 846 and 884 cm^{-1} in the melt spectrum are all attributed to ethylene rocking vibrations. The 846 cm^{-1} band is at the same frequency as the crystalline band and hence is assigned to the *tgt* conformation. The 810 cm^{-1} band, as stated above is due to the *trans* conformation of the (OCCO) group. There are several possible structures for the (CCOCCOCC) sequence arising from rotations about the (C—O) and (C—C) bonds. The closeness of the methylene groups for the *gauche* conformation of the (C—O) bonds indicate that this state is highly unfavourable[21]; certainly this conformation will be distorted. The retention of the 846 cm^{-1} band in the melt also provides confirmation that the *trans* form is largely retained. In view of this, the 810 cm^{-1} band can be associated with the *ttt* conformational sequence. The band at 884 cm^{-1} is most probably due to *gauche* structures of the type *tgg* or *ggg*. The small intensity of this band is again consistent with the limitations on the *gauche* form of the (C—O) bond.

The doublet at 1065—1075 cm^{-1} in the crystalline state, attributed to $(COC)_s + r(CH_2)_a$ and $(COC)_s + r(CH_2)_s$ motions respectively, is lost in the melt, and a broad band
Figure 1 Raman spectra of PEO in the range 800—1500 cm^{-1} measured at various temperatures: A, 25.0°; B, 40.5°; C, 61.0°; D, 62.0°; E, 71.9°C. The sample had molecular weight $\bar{M}_w$ = 3 x 10[6] and melting point 61.1 ± 0.2°C

Table 1 Observed PEO Raman bands in the frequency range 800—1500 cm^{-1} for the crystalline structure, the melt and for aqueous and chloroform solutions. The assignments are based on the work of Yoshihara *et al.*[6]. The listed conformations refer to the (CCOC), (OCCO) and (COCC) groups. The conventional notations used are interpreted as follows. Band intensities: w (weak); m (moderate); s (strong). Band resolution: sh (sharp). Mode assignments: r (rocking); t (torsion); ν (stretching); ω (wagging). The assignment subscripts a and s refer the asymmetric and symmetric motions with respect to the 2-fold axis perpendicular to the helix axis and passing through the O atom or through the centre of the C—C bond

appears at 1043 cm^{-1}. This band is also due to a combination of *gauche* conformations, the frequency shift being at least partly a result of the breaking of intermolecular hydrogen bonds present in the helical configuration.

These data show that the *trans* to *gauche* ratios change on melting but at present there is no method of making a reliable quantitative experimental estimate to compare with the random coil ratios of 2.8 for (C—C) bonds and 7.3 for (C O) bonds[22].

Raman spectra of PEO in aqueous solution

The Raman spectra for several concentrations are shown in *Figure 2*. The frequencies of the dilute solution bands are given in *Table 1*, where they can be compared with the bands of the molten form. The region 1100 to 1550 cm^{-1} is very similar to that of the melt, except that the bands are slightly narrower which is to be expected at the lower temperature. The solution spectrum for the region 800 to 1100 cm^{-1} on the other hand shows considerable differences from the melt. The band at 1043 cm^{-1} in the melt is split into two bands, at 1041 and 1061 cm^{-1}, and the ethylene rocking mode at 846 cm^{-1} occurs at 851 cm^{-1} with an increased relative intensity.

The relatively low intensity of the 810 cm^{-1} band in dilute solution, compared with the melt spectrum, can be taken as an indication of the greater retention of the *tgt*

conformation of the helix. This fact is emphasized by the retained splitting of bands at 1280 cm^{-1}. The behaviour of the doublet at 846 and 862 cm^{-1} on dilution is quite complex. In the work of Koenig[18], it was reported that the splitting was lost, leaving only the band at 846 cm^{-1} in solution. Our results show that this is incorrect. It was found that the band at 862 cm^{-1} decreased in frequency with dilution, while the band at 846 cm^{-1} remained unchanged, until the composition reached 50% by volume, whereupon the two bands merged to form a hybrid band at 851 cm^{-1}. The band at 862 cm^{-1} in the solid state is attributed to a combination of a symmetric rocking motion of the ethylene groups, with a symmetric stretching involving the oxygen atom in the backbone chain. We would therefore expect this vibration to be sensitive to hydrophobic as well as hydrogen bonding interactions.

The major, large scale changes observed in these spectra follow the trends observed by Liu using n.m.r. The spectral changes, loss of ordered modes and appearance of new bands, occur as a smooth function of water concentration until 50% water content is reached. At this point the polymer—solvent structure is completely formed, and no further changes occur in the spectrum on further dilution. This behaviour is characterized by the behaviour of the 862 cm^{-1} band. In *Figure 3* the frequency of this band is plotted as a function of dilution in aqueous solution. There is a sharp fall in frequency with decreasing polymer
Figure 2 Raman spectra of PEO—water system in the range 800—1500 cm^{-1}. A, 33.5; B, 56.3; C, 66.7; D, 88.3; E, 100% polymer ($\bar{M}_w = 3 \times 10^6$)
Figure 3 Frequency of the PEO ethylene rocking mode plotted as a function of water concentration. The mode energy in the pure crystal state is 862 cm^{-1}
Figure 4 Raman spectra of PEO ($\overline{M}_W$ = 3 x 10⁶) in water solution measured above and below the melting temperature of 61.1°C. A, 83.9°C; B, 24.5°C

concentration until the composition reaches 50% water content, and then the frequency curve levels off, giving no further change with dilution. This trend is in direct agreement with the n.m.r. data of Liu, and provides further evidence for the formation of a hydrogen bonded water complex with a composition of three water molecules per repeat unit. The structure of this complex will be discussed later, but it is clear that the helical form is largely lost and the structure tends towards that of the molten state.

In *Figure 4*, the Raman spectra of a dilute aqueous solution (~30%) is shown for two temperatures above and below the melting point of the polymer. The high temperature spectrum is identical to that of the melt, the band at 810 cm⁻¹ is increased in intensity and the ethylene rocking mode occurs at 846 cm⁻¹. The cooperative structure of the low temperature solution is therefore destroyed at temperatures above the polymer melting point.

Raman spectra of PEO in chloroform solution

The PEO spectra in chloroform solution were studied for two reasons. The first was to observe the breakdown of the molecular association at a particular concentration and thus confirm the n.m.r. results. The second reason was to provide a non-polar solution 'reference' with which to compare the aqueous solution spectra. Spectra showing the variation with concentration in chloroform solution are given in *Figure 5*. The frequencies of the dilute solution bands are given in *Table 1* for comparison with the melt and dilute water solutions. In the region 1100 to 1500 cm⁻¹ the chloroform and aqueous solutions spectra are almost identical. Both spectra show more ordering than in the melt, although much less than the crystalline solid. The major differences from the aqueous solution spectra are for the ethylene stretching modes at ~1050 cm⁻¹ and the rocking modes around 850 cm⁻¹. The band at 810 cm⁻¹ is also much stronger in the chloroform solution and the relative intensity is comparable to that of the melt. This fact, together with other smaller differences, would point to there being slightly greater order in the aqueous than the chloroform solution.

The spectra of *Figure 5* show that the helical structure of the PEO is largely maintained in chloroform solution until the composition reaches 55% by weight solvent concentration. At this point there is a fairly sudden breakdown of the ordered structure and the spectrum takes the form

for the dilute solution structure. This behaviour is analogous to that observed with n.m.r. by Liu. The presence of strong intramolecular hydrogen bonds is sufficient to prevent the breakdown of the helix until a particular dilution is reached.

DISCUSSION

We have seen that the spectra of chloroform and aqueous solutions of PEO differ only in the region 800 to 1100 cm⁻¹ and it is on this region that we concentrate. In *Figure 3*, the frequency dependence of the 862 cm⁻¹ band on water concentration was shown. This band is a complex mode involving two motions: an ethylene rocking mode and a backbone stretching vibration. If the band had been associated solely with the backbone mode we would expect the presence of hydrogen bonded molecules at the oxygen atom to increase the frequency of the vibration, the exact opposite to the observed behaviour. (The apparent anomaly that the addition of a mass should increase the stretching frequency is explained by the fact that the additional mass is not fixed but is held by a comparatively weak force.) The effect of the bonded water on the rocking mode must therefore be critical. This motion will be affected by the hydrophobic interaction of the ethylene groups with the polar solvent. It is difficult to be very precise about this interaction, but we can make a few comments. First, it must act in such a way as to decrease the frequency, outweighing the effect of bonded water on the backbone vibration contribution. This type of behaviour has also been observed in polyamides[23] where again the pendant group motion is predominant. Secondly, such an interaction is likely to cause a perturbation of the electron cloud of the methylene groups. Such an interaction would be a smoothly varying function of water concentration until the stable polymer/solvent structure is formed, whereupon no further water molecules can enter the area of the polymer chain, and so we would expect no further change.

Such an explanation is compatible with the results of *Figure 3*, where we see a smoothly varying decrease in frequency up to 50% water content, followed by no further change.

The two bands at 1061 and 1041 cm⁻¹ in the aqueous solution are also combinations of ethylene rocking motions and (C–O–C) stretching vibrations for the *tgt* and *tgg* con-

figurations respectively. In the chloroform solution spectrum, these bands occur at 1055 and 1038 cm⁻¹, and we can infer a frequency increase between the non-polar and polar solvents. Such frequency shifts are qualitatively in agreement with the model of water forming hydrogen bonds onto the oxygen atom involved in the backbone stretching vibration. The relative intensities of these bands increase on dilution, until 50% water concentration is reached, exactly the behaviour outlined above. Finally, the potential energy distribution of the 1065 cm⁻¹ band contains a larger percentage of the backbone stretching vibration than does the 862 cm⁻¹ band, and it is reasonable to assume that this mode is dominant in this case. A simple calculation can be done to estimate the effect on the stretching vibration of the bonded water based on the models shown in *Figure 6*. For water single-bonded onto a backbone oxygen the estimated shift is about 5 cm⁻¹ which is in reasonable agreement with the differences between 1061 cm⁻¹ (H_2O) and 1055 cm⁻¹ ($CHCl_3$) and between 1041 cm⁻¹ (H_2O) and 1038 cm⁻¹ ($CHCl_3$). It seems probable, then, that the differences observed in these mode energies in the two solvents are due to simple hydrogen bonding of water molecules. The more complicated arrangement in which the water molecules form a crosslink by bonding to oxygens in neighbouring chains gives a frequency shift of the order of 10 cm⁻¹. This is much larger than the observed shifts and suggests that this form of bonding is unlikely in solution. Indeed this is borne out by simple observation; a predominance of such crosslinks would result in a gel, for which there is no evidence in low molecular weight samples. For high molecular weights, at low concentration, gel behaviour is observed but this is most probably due to entanglements.

CONCLUSIONS

From the data presented above we can confirm that the PEO molecule forms a hydrogen bonded complex in aqueous solution in which three water molecules are involved with one repeat unit. The helical structure of the crystal is lost in aqueous solution, as in the melt and

chloroform solution. In the melt, the structure would seem to move towards the random coil configuration with an increase in *trans* conformation of the (C–C) bond typified by the increase in the intensity of the 810 cm⁻¹ band. Both of the solution spectra, however, exhibit some retention of ordering. The band at ~1060 cm⁻¹ from the *tgt* conformation, for example, is present in both solutions but not in the melt. The difference between the chloroform and aqueous solution spectra can be explained by the hydrogen bonded water perturbing the ethylene rocking modes and the backbone stretching modes. There is, therefore, very little difference between the conformational structures for the two solutions. Finally, if the aqueous solution is taken above the melting point of the pure polymer, the spectrum becomes that of the melt. This would suggest that the hydrogen bonded structure is destroyed.

E.s.r. study of γ-irradiated isotactic and atactic polypropylene

Toshitami Ooi

Research Center, Mitsui Toatsu Chemicals Inc., Totsuka-ku, Yokohama-City, Japan

and Masami Shiotsubo, Yoshimasa Hama and Kenichi Shinohara

Science and Engineering Research Laboratory, Waseda University, Tokyo, Japan

An e.s.r. study of γ-irradiated isotactic (i-) and atactic (a-) polypropylene (PP) was carried out. Both the 17 line (or 9 line) spectrum for i-PP and the 6 line spectrum for a-PP are attributed to the tertiary carbon radical, $-CH_2-\dot{C}(CH_3)-CH_2-$. The difference in the hyperfine structure between the spectrum of i-PP and that of a-PP can be explained by different radical conformations owing to the stereoregularity. Hyperfine coupling and the radical conformation for the tertiary carbon radical in i- and a-PP were determined from the $\cos^2 \theta$ rule. It is shown that the δ methylene proton as well as the β methylene proton contribute to the slight anisotropy in the stretched sample. The spectral change from 9 lines to 17 lines with elevation of temperature, observed at low temperature in i-PP, could be explained by the hindered oscillation of the β methylene proton.

INTRODUCTION

Free radicals produced in irradiated polypropylene (PP) have been studied by many authors[1-7] using electron spin resonance (e.s.r.) spectroscopy. It seems, however, that the ultimate interpretation of the spectrum has not yet been obtained. It is well known that isotactic polypropylene (i-PP), γ-irradiated at room temperature, gives a well-resolved 17 line e.s.r. spectrum at room temperature. Fisher *et al.*[2] reported that this 17 line spectrum is due to $-CH(CH_3)-CH-C(CH_3)-CH-CH(CH_3)-$ radical, from experiments with oriented samples. Ayscough *et al.*[5], however, reported that the 17 line spectrum can be assigned to the tertiary carbon radical:

$$-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{C}}-\dot{C}(CH_3)-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{C}}-$$
which gives a hyperfine coupling constant of $a_0 = 21 \pm 1$, $a_1 = 9 \pm 0.6$, $a_2 = 43 \pm 2$, for the isotropic term in β methylene protons and $b_1 = \pm0.6 \pm 0.3$, $b_2 = \mp 1.0 \pm 0.3$ for the anisotropic term in β methylene protons, respectively. An e.s.r. study of γ-irradiated i-PP carried out by Iwasaki *et al.*[6] has shown that the 17 line spectrum appears as a 9 line spectrum by measurement at $-196°C$, and that when the sample is exposed to u.v. light for a short time this 9 line spectrum converts to a 4 line spectrum due to $-CH_2-CH(\dot{C}H_2)-CH_2-$ radical. The fact that this last radical gives a 4 line spectrum was also reported by Loy[3].

On the other hand, e.s.r. studies of γ-irradiated atactic (a-) PP have seldom been reported. It is expected that the difference of the stereoregularity between i- and a-PP affects the e.s.r. spectrum.

In the present investigation, an e.s.r. study of γ-irradiated i- and a-PP was carried out, and an attempt was made to explain the difference of the steric configuration, and to propose a possible radical structure giving such e.s.r. spectrum, simulating the spectrum with a computer.

EXPERIMENTAL

i-PP and a-PP (Mitsui Toatsu Chemicals Inc.) were purified by Soxhlet extraction. For experiments using anisotropic samples, sheets of i-PP stretched at 90°C to the extent of 500% after being extracted by ether were used. These samples were dried sufficiently and then sealed in a vacuum of about 10^{-4} mmHg. The sealed samples were irradiated to a dose of 0.5–1 Mrad by γ-rays from a ^{60}Co source at room temperature or at $-196°C$.

E.s.r. spectra were measured with an X-band spectrometer with 100 kHz field modulation. The microwave power was attenuated to a level sufficient to remove the effect of power saturation. The anisotropy of the spectrum was investigated by placing the stretched sample either parallel or perpendicular to the applied magnetic field.

Two different procedures were adopted in observing the e.s.r. spectra. In one the measurement was begun at $-196°C$ and the temperature was raised in steps to room temperature. In the other, the spectrum was observed at $-196°C$ after heat-treating the sample at various temperatures.

The simulation of the spectrum was made with JEC-6 spectrum computer manufactured by Japan Electron Optics Laboratory Co. Ltd.

RESULTS AND DISCUSSION

E.s.r. spectrum of i-PP

When the i-PP was irradiated by γ-rays at $-196°C$ and measured immediately at $-196°C$, e.s.r. spectra as shown in *Figure 1* were obtained. A sharp singlet observed at the centre of the spectrum in *Figure 1A* can be attributed to trapped electrons because it is subjected easily to power saturation and also it disappears by photobleaching with i.r. light. *Figure 1B* shows the e.s.r. spectrum obtained at $-196°C$ after the disappearance of the trapped electrons. This is similar to the spectrum reported by Iwasaki *et al.*[6].

Figure 1 First derivative e.s.r. spectra of i-PP γ-irradiated at −196°C: A, observed at −196°C immediately after irradiation; B, observed at −196°C after photobleaching with i.r. light; C, observed at −196°C after being kept at room temperature for 3 min

out at various temperatures, the e.s.r. spectra shown in *Figures 2A–2C* were obtained. The spectrum shown in *Figure 2A* shows 9 lines due to radical (II) but its resolution is better than that of *Figure 1C* which shows the spectrum due to the same radical. A well-resolved 17 line spectrum was obtained at room temperature as shown in *Figure 2C*. It is seen from *Figure 2B* that the 17 line spectrum makes its appearance already in the spectrum measured at −150°C, although its resolution is poor compared to that of the spectrum shown in *Figure 2C*.

E.s.r. spectrum of stretched i-PP

Figure 3 shows e.s.r. spectra obtained under various condition of measurement when the stretched i-PP was irradiated at room temperature by γ-rays. Between the spectra measured at $\theta = 0°$ and $90°$. θ being the angle between the direction of stretching and that of the applied magnetic field, slight differences can be found. When $\theta = 0°$ and measurement was carried out at room temperature. a well-resolved 17 line spectrum was observed. This 17 line spectrum made its appearance even for measurement at −196°C although the resolution of the spectrum is poor. When $\theta = 90°$, the spectrum obtained at room temperature seems to be made of 19 or 20 lines with poor resolution. This spectrum made its appearance by measurement at −150°C too but with poorer resolution. By measurement at the

Figure 2 First derivative e.s.r. spectra of i-PP γ-irradiated at −196°C and kept at room temperature for 2 days: A, observed at −196°C; B, observed at −150°C; C, observed at room temperature

When the sample was measured at −196°C after being kept at room temperature for 3 min, the spectrum shown in *Figure 1C* was obtained. Such change of the spectrum is due to the radical conversion indicated by Iwasaki *et al.*[6]:

$$-CH_2-CH(\dot{C}H_2)-CH_2- \cdots \rightarrow -CH_2-\dot{C}(CH_3)-CH_2- \quad (1)$$

$$(I) \qquad\qquad\qquad (II)$$

When a sample irradiated at −196°C was kept at room temperature for 2 days and the measurement was carried

still lower temperature of −196°C, a 9 line spectrum was observed instead of the 19 or 20 line spectrum. The overall spread of the spectrum was about 170 and 174 G for $\theta = 0°$ and $\ell = 90°$, respectively.

50 G

Figure 4 First derivative e.s.r. spectra of a-PP γ-irradiated at −196°C: A, observed at −196°C immediately after irradiation; B, observed at −196°C after photobleaching; C, observed at heat-treating the sample at −38°C for 3 min; D, observed at −133°C for the sample of C

E.s.r. spectrum of a-PP

E.s.r. spectra of a-PP irradiated by γ-rays at −196°C, then kept at various temperatures for 3 min, and measured at −196°C, are shown in *Figure 4*. The spectrum of *Figure 4A*, obtained at −196°C immediately after irradiation, is composed mainly of a broad quartet and a sharp singlet due to trapped electrons in the centre of the spectrum, although a weak peak is observed at both outskirts of the broad quartet. The maximum slope width of the sharp singlet is about 15 G which is not very different from that of polar materials. The broad quartet is similar to one observed at −196°C for γ-irradiated i-PP and is due to radical $(I)^{3,6}$.

On heat treatment, even at the low temperature of −160°C the sharp singlet due to trapped electrons disappears. The spectral intensity of the quartet decreases with elevation of the temperature of heat-treatment and a broad 6 line spectrum having average hyperfine splitting of 28 G appears. These subsequent heat-treatments not only cause the decrease of the intensity of the broad quartet but also that of the total intensity of the spectrum. Weak peaks observed at both outskirts of the spectrum obtained at −196°C, however, increase intensity with elevation of the temperature of heat-treatment. This fact together with the appearance of a 6 line spectrum on heat-treatment at higher temperature, shows that these two peaks belong to the 6 line spectrum.

Change of the 6 line spectrum to another spectrum could not be observed by measurement at or above −196°C, unlike the case of i-PP.

Origin of the 9 line and 17 line spectra, and the 6 line spectrum

As described above, when a sample of i-PP is irradiated by γ-rays at −196°C and then measured after being kept at room temperature, a 9 line spectrum is obtained at −196°C and a 17 line spectrum at room temperature. On the other hand, a 6 line spectrum is observed for a-PP irrespective of the temperature of measurement. The 9 line spectrum and the 17 line spectrum are attributed to the tertiary carbon radical (II) as shown in some previous reports[3,5,6].

It may be reasonable to suppose that the 6 line spectrum obtained for a-PP is also due to the tertiary carbon radical (II), because the e.s.r. spectrum obtained at −196°C after γ-irradiation at −196°C shows a broad quartet which is similar to the spectrum obtained for i-PP under the same condition. The 9 line spectrum observed for i-PP and the

Table 1 Hyperfine coupling constants and radical conformation for i-PP

H.f. coupling constant (G)		Conformational angle (degrees)		Radical conformation*
$\Delta H(CH_3)$	21.4			
$\Delta H(C-H_{\beta 1})$	39.6	θ_1	15.5	
$\Delta H(C-H_{\beta 2})$	15.1	θ_2	53.5	
$\Delta H(C-H_{\beta 3})$	42.1	θ_3	6.6	
$\Delta H(C-H_{\beta 4})$	9.1	θ_4	62.5	

6 line spectrum in a-PP can, therefore, be attributed to the same radical, which appeared through the radical conversion shown by equation (1) due to heat treatment. The difference of the hyperfine structure between the spectrum of i-PP and that of a-PP was supposed to arise from different radical conformations.

Hyperfine coupling and radical conformation of -CH₂-C(CH₃)-CH₂- radical

$-CH_2-C(CH_3)-CH_2-$ radical

It is assumed that the hyperfine splitting of β proton is given by the following $\cos^2 \theta$ rule[8]:

$$\Delta H(C-H_{\beta i}) = B\rho \cos^2 \theta_I \qquad (2)$$

Results obtained from analysis of the experimental spectrum and simulation of the spectrum by computer are summarized in *Table 1*.

In the case of i-PP, the hyperfine coupling constant due to a methyl proton is estimated to be 21.4 G since a methyl group rotates rapidly around the three-fold axis even at $-196°C$. Four protons belonging to two methylene groups give a different hyperfine coupling constant as shown in *Table 1* for i-PP. From these values of coupling constant, a value of 42.8 G is obtained for the constant $B\rho$. Such hyperfine coupling constants also lead to the computed

spectrum shown in *Figure 5*, which seems to represent the observed feature of e.s.r. spectra rather well. From the $\cos^2 \theta$ rule, the conformational angle θ_I are determined and they are also given in *Table 1*. The radical conformation shown in *Table 1* is slightly distorted from the original 3_1 helical conformation[9]. The different conformational angle obtained for four protons of two β methylenes may be attributed to a 3_1 helical structure of the trapping site of radical.

The hyperfine coupling constants for the a-PP are summarized in *Table 2*. The computed spectrum obtained from these coupling constants is shown by the solid curve in *Figure 6B*. The computed spectrum is different from the experimental curve in the spectral centre. Addition of a broad singlet shown by the broken line in *Figure 6B* to the computed spectrum leads to a spectrum which fits the experimental spectrum, shown in *Figure 6A* quite well. In the case of a-PP also, the conformational angle for two methylene groups is obtained, which is summarized in *Table 2* together with the radical conformation expected from these conformational angles.

When the methylene group (*Table 1*) is projected on the

Table 2 Hyperfine coupling constants and radical conformation for a-PP

H.f. coupling constant (G)		Conformational angle (degrees)	Radical conformation	
$\Delta H(CH_3)$	21.4			
$\Delta H(C-H_{\beta 1})$	1.8	θ_1 78.2		
$\Delta H(C-H_{\beta 2})$	30.0	θ_2 33.0		
$\Delta H(C-H_{\beta 3})$	30.0	θ_3 33.0		
$\Delta H(C-H_{\beta 4})$	1.8	θ_4 78.2		

plane perpendicular to the direction C_α–C_β, the angle between two projected C–H bonds is $111°$ for both i-PP and a-PP. This value deviates from that of $120°$ of the original helical structure. Such deviation of the projected bond angle was also reported in a paper by Ohnishi *et al.*[10] on their e.s.r. study of irradiated polyethylene. Similar deviation has also been observed in the e.s.r. study of low molecular weight organic compounds[8,11-15]. The different e.s.r. spectra in i-PP and in a-PP, i.e. a 17 line spectrum and a 9 line spectrum in the former and a 6 line spectrum in the latter, can thus be explained by assuming different conformations for the same kind of radical.

Temperature dependence of e.s.r. spectral shape

As described above, the e.s.r. spectrum in i-PP, observed as a 9 line spectrum at $-196°C$ changes into a 17 line spectrum at $-150°C$. The motional narrowing due to the motion of the polymer molecule cannot arise at such low temperatures, since the radical under consideration is produced in a crystalline region and also the temperature of $-150°C$ is far lower than the glass transition temperature of polypropylene. Ohnishi *et al.*[10] reported in their e.s.r. study of irradiated polyethylene that the spectral change of allylic radicals with temperature can be attributed to the motional narrowing caused by the hindered oscillation of the β methylene proton of the allylic radical. It seems possible to explain the spectral change of the tertial carbon radical $-CH_2-\overset{.}{C}(CH_3)-CH_2-$ from a 9 line spectrum to a 17 line spectrum observed in the present investigation, in a similar way. If the β methylene proton can oscillate by a small amplitude of $\Delta\theta$ around θ_i given in *Table 1* and if the frequency of oscillation becomes higher than the difference of the hyperfine coupling frequency at both positions, θ_i and $\theta_i + \Delta\theta$. by elevation of temperature, the hyperfine coupling constant is averaged to give the value determined by θ_i.

At a temperature below $-150°C$, the frequency of oscillation of β methylene proton becomes lower than the hyperfine coupling frequency. The width of each 17 line spectrum becomes broader and because of the overlap of lines the 17 line spectrum takes an appearance of a 9 line spectrum. Such change of the computed 17 line spectrum to a 9 line spectrum by broadening of the linewidth has also been ascertained by computation. This computed 9 line spectrum is shown in *Figure 5B*. The computed 9 line spectrum differs slightly from the observed spectrum. The difference is caused probably because the computation was carried out so that $\Delta\theta$ gives only the breadth to the spectral lines.

In the case of a-PP, change of the 6 line spectrum with elevation of temperature was not observed. This fact may be explained by taking the view that the oscillation of β methylene protons is taking place fairly rapidly even at $-196°C$ and that the irregular structure due to low tacticity makes the linewidth quite broad.

Anisotropic interaction in the stretched polymer

As seen above, the e.s.r. spectrum of the stretched i-PP shows a slight anisotropy. The tertial carbon radical, however, does not have an α proton. Ayscough *et al.*[5] suggested the possibility that the anisotropy is due to one of two β methylene protons. However, in the 3_1 helical structure of i-PP, it can be seen that one of the δ methylene protons exists near the α carbon. The distance between this δ

methylene proton and the carbon atom, estimated from the 3_1 helical structure, is about 1.8 Å. If $(3\cos^2\theta - 1)$ in the term of the anisotropic interaction is nearly equal to unity, the anisotropic hyperfine splitting turns out to be about 4.8 G from the distance of 1.8 Å. Other three δ carbon protons are situated far from the α carbon atom to give only a weak dipole–dipole interaction.

The value of 4.8 G due to the δ carbon proton is comparable to that of the dipole–dipole interaction of the β protons. The computation of the e.s.r. spectrum shows that the spectrum for $\theta = 90°$ in the stretched sample can be obtained by adding a splitting of 4–5 G to the spectrum of bulk sample. This fact suggests that the anisotropy of the spectrum observed at $\theta = 90°$ is attributed to the dipole–dipole interaction with the δ carbon proton rather than that with four protons of the β methylene which has both anisotropic and isotropic interaction. The slight change of the hyperfine coupling constant from that of the bulk sample, due to slight anisotropy of the β methylene proton, may mainly give rise to a broadening of the linewidth in the spectrum at $\theta = 90°$.

As for the spectrum observed at $\theta = 0°$, it can be obtained by a slight change of the hyperfine coupling constant due to β methylene protons; therefore, the anisotropic interaction contributing to this spectrum may be supposed to be caused by the β methylene protons rather than the δ methylene proton which is located in the position to make the value of $(3\cos^2\theta - 1)$ fairly small in such a case.

By measurement of the stretched sample at $-196°C$, a poorly resolved 17 line spectrum and 9 line spectrum were observed at $\theta = 0°$ and $\theta = 90°$, respectively. This may be attributed to the following reasons: as the 17 line spectrum observed at $\theta = 0°$ is well-resolved, it may still remain the 17 line spectrum even if the linewidth increases at $-196°C$, owing to the decrease of the oscillation frequency of the β methylene proton, though its resolution is made poorer. On the contrary, the poorly resolved spectrum observed at $\theta = 90°$ may convert to the 9 line spectrum by slight increase of the linewidth.

Association of stereoregular poly(methyl methacrylates): 2. Formation of stereocomplex in bulk

E. L. Feitsma, A. de Boer and G. Challa

Department of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands
(Received 17 September 1974; revised 18 December 1974)

Blends of isotactic and syndiotactic poly(methyl methacrylate) (i- and s-PMMA) are obtained by pre-cipitation from chloroform and acetone solutions. By differential scanning calorimetry and dynamic-mechanical measurements the formation of stereocomplexes from i- and s-PMMA in bulk is demon-strated. After annealing of the blends at 130–160°C a melting endotherm is detected and it is established by X-ray analysis that this endotherm is caused by formation of crystalline stereocomplex. The rate of complex formation is maximal at 140°C and the extent of complex formation is maxi-mal at an isotactic-rich composition. It appears that the difference in solvent history can be removed by heating to 240°C. The subsequent S-shaped course of glass transition temperature, T_g, with composition is explained by the occurrence of some complex formation during cooling from 240°C. Asymmetry and shift of the dynamic-mechanical damping curves after annealing are also explained by the formation of complexes. A mechanism is proposed with helical isotactic chains acting as nuclei for a fringed micelle type of complex formation.

INTRODUCTION

In previous papers it was reported[1-5] that complex forma-tion between isotactic and syndiotactic poly(methyl methacrylate) (i- and s-PMMA) can occur in suitable sol-vents, even at concentrations far below that with homo-geneous segmental distribution. Spěváček *et al.*[6] have shown by high resolution n.m.r. investigations that fixed structures are present in the complexes in solution. The physical pro-perties of isolated stereocomplexes are different from those of the composing components. The complexes are crystal-line, as shown by X-ray analysis[2] and their melting points are different from those of i- and s-PMMA[1].

As the solvents have different influence on complex formation, we divided them in three types: A, strongly complexing solvents; B, weakly complexing solvents; C, non-complexing solvents. This classification was clearly illustrat-ed in the course of reduced viscosity with composition of mixtures of i- and s-PMMA in different solvents[1]. The heats of complex formation of i- and s-PMMA in different solvents, as reported by Byros *et al.*[7] are also in agreement with this classification. Moreover, Buter *et al.*[8] had found that the effect of solvent on replica polymerization of methyl meth-acrylate (MMA) along stereoregular PMMA is in line with its complexing ability.

Pyrlik *et al.*[9] reported that complex formation occurred even in very concentrated (22.4%) solutions of i- and s-PMMA in *o*-xylene. At the same time we were interested to know whether i- and s-PMMA can associate not only in solution but also in bulk. Therefore, blends of i- and s-PMMA of different origins were subjected to calorimetric and dynamic-mechanical investigations.

EXPERIMENTAL

The polymers i- and s-PMMA were prepared according to known procedures[10,11]. The data of the used polymers are

Table 1 Data of used polymers

	Number	triads i-h-s	$[\eta]$ (dl/g)	$\bar{M}_v \times 10^{-3}$
i-PMMA	i MA-103	91 : 6 : 3	1.95	570
	i MA-107	91 : 6 : 3	1.99	600
s-PMMA	s MA-102	5 : 9 : 86	1.33	350
	s MA-106	4 : 8 : 88	1.37	370

compiled in *Table 1*. The tacticities of PMMA were measur-ed on 5% solutions in *o*-dichlorobenzene[12] at 160°C by 60 MHz n.m.r. spectroscopy with a Varian A-60 instrument. $[\eta]$ of the PMMA samples were determined in chloroform at 25°C. For the calculation of $\bar{M}_v$ we used the relation-ship[13]: $[\eta] = 4.8 \times 10^{-5} \bar{M}_v^{0.8}$.

Samples of i- and s-PMMA blends were prepared by mix-ing 1 wt% chloroform solutions of i MA-103 and s MA-102 in various ratios under continuous stirring. After 2 h the mixed solutions were precipitated in excess petroleum ether (b.p. 40–60°C) and the precipitates were dried at 40°C in vacuum for 5 days. In the same way blends were prepared from acetone solutions.

Glass transitions, T_g, and melting temperatures, T_m, were measured with a differential scanning calorimeter (Perkin-Elmer, DSC-1B) at a heating rate of 8°C/min. The beginning of the c_p jump was taken as T_g and the maximum of the melting endotherm as T_m.

Dynamic-mechanical measurements were performed on 7 x 0.7 x 0.3 cm bars with a torsion pendulum of Nonius/ TNO at a frequency of ~1 Hz in the temperature range 20–170°C. The samples were obtained by precipitation from i MA-107 and s MA-106 solutions in acetone and they were heated in a press for 10 min at 240°C. The bars were obtained by pressing the samples at 50 kg/cm² for 2 min at the same temperature. After fast cooling to 150°C the bars were cooled slowly down to room temperature

under pressure. From the damped oscillations loss moduli G'', storage moduli G' and loss tangents tan δ of the samples were calculated.

RESULTS

D.s.c. experiments

In *Figure 1* some characteristic thermograms are plotted for samples obtained from the non-complexing solvent chloroform, recorded after annealing at 140°C for 2 min in the d.s.c. An endotherm with a maximum of about 190°C is found for most of the blends. *Figure 2* shows the effect of annealing times at 140°C on the area of the endotherm for the 60 : 40 i-/s-PMMA composition. The endotherms in *Figures 1* and *2* indicate that complex formation of i- and s-PMMA in bulk can occur.

Annealing experiments were carried out for the whole composition range with 21 mg samples from chloroform at different temperatures of complex formation (T_c 130–170°C). In *Figure 3* the area of the endotherm at about 190°C as recorded by d.s.c. is plotted against composition after annealing at 140°C and 150°C for 4 and 40 h. The values measured after 2 min at 140°C (*Figure 1*) give a somewhat lower curve than those after 4 h. The extent of complex formation reaches an end-value after 40 h at 140°C. More than 75 h are needed at 130 and 150°C to reach the same end-value, whereas the rate of complex formation is almost zero at 170°C. Thus, it is clear that the rate of complex formation of i- and s-PMMA in bulk is maximal at about 140°C. Moreover, it appears from *Figure 3* that the complex formation curve shifts to lower s-PMMA content for increasing temperature and decreasing time of complex formation. Finally, it is evident that pure i-PMMA and pure s-PMMA do not crystallize at all under these conditions.

For the sake of completeness, *Figure 4* shows that there is a great resemblance between the X-ray diffractograms of an annealed sample from chloroform and that of stereocomplex crystallized from dilute solution in acetone. These diffractograms differ strongly from those of pure i- or s-PMMA[8]. So, the crystalline material in bulk consists of stereocomplexes of i- and s-PMMA indeed.

In *Figure 5* T_g and T_m are plotted against composition for mixtures obtained from the strongly complexing solvent acetone. The T_m of about 205°C originates from complexes, which were already formed in the acetone solutions[1]. Only at the left and right side of the composition range were T_g values detected.

T_g values measured after premelting for 2 min at 240°C

Figure 5 Glass transition temperatures (T_g) by d.s.c. of samples precipitated from acetone versus wt% s-PMMA. Melting temperatures (T_m) are also presented

in the d.s.c. are plotted against composition in *Figures 6* and *7* for blends from acetone and chloroform respectively. To indicate the width of the glass transition the end of the c_p jump is also presented. No endotherm is measured. It is clear that *Figures 6* and *7* are almost identical. Samples from the weakly complexing solvent toluene (type B solvent) demonstrate the same course.

Dynamic-mechanical measurements

In order to check the d.s.c. results dynamic-mechanical measurements were performed. In *Figure 8* tan δ is plotted against temperature for various compositions. After the measurements the bars were annealed at 140°C for 120 h. The effect of annealing is shown in *Figure 9*, where tan δ is plotted against temperature for some pairs of not-annealed and annealed bars. When the logarithm of the loss modulus

$(\log G'')$ is plotted against temperature a similar picture is obtained. It is seen from the curves in *Figure 9* that not all material is complexed after annealing for 120 h, not even for i-PMMA rich compositions although d.s.c. would not detect a glass transition anymore.

DISCUSSION

Acetone is a strongly complexing solvent and the melting endotherms of samples obtained from acetone originate

from stereocomplexes already formed in solution (*Figure 5*). The measured T_g at the left and right side of the composition range is probably caused by non-complexed excess i-PMMA and s-PMMA, respectively. The course of T_g with composition for samples from acetone becomes almost identical to that of samples from chloroform after premelting at 240°C (*Figures 6* and *7*). So, it can be concluded that the solvent history is removed by heating to 240°C. After such elimination of solvent history equal compositions become comparable with respect to complex formation irrespective of their origin.

From *Figures 1–4* it is evident that formation of crystalline complex takes place in bulk in the temperature range of 130–160°C with a maximum rate at 140°C.

Previous results[1] indicated that in very dilute solutions of type A solvents maximum complex formation occurs at an i/s ratio of 1 : 2 with $T_m = 210°C$ of the separated complex. At higher concentrations the i/s ratio tended to shift to higher values. In type B solvents (weakly complexing) maximum complex formation appears, even at low concentrations, at an i/s ratio of 1 : 1 with $T_m \simeq 200°C$. In line with this trend maximum complex formation in bulk always occurs at ratios below 1 : 1 (*Figure 3*) with $T_m \simeq 190°C$. Moreover, it follows from the area of the endotherms that the maximum amount of crystalline complex in the blends is almost two times lower than that of the complexes separated from acetone (see also *Figure 4*). So, complex formation in bulk is a less selective process than it is in dilute solution and probably yields smaller and less regular regions of complexed material.

Figure 2 suggests that it is quite possible that some complex is formed in the bulk just during cooling from 240°C in the d.s.c. although no distinct endotherm could be measured. Thus at low s-PMMA contents all s-PMMA chains may be locally fixed in complexes and the measured T_g values in *Figures 6* and *7* originate from non-complexed excess i-PMMA. At increasing s-PMMA content no longer can all s-PMMA chains be complexed during cooling. Hence complex formation gives rise to a distribution of local compositions of non-complexed material. This is demonstrated by a broadening of the glass transition in *Figures 6–8*. Above 50 wt% s-PMMA the rate of complex formation in bulk decreases strongly (*Figures 1* and *3*), which means that the composition of non-complexed material approaches the overall composition. At high s-PMMA contents no complex formation occurs at all and the glass transition corresponds to that of the overall composition.

Krause *et al.*[14] investigated dilatometrically the course of T_g with composition of i- and s-PMMA blends obtained

from chloroform. Examining their results it appears that the glass transitions are very broad. So it is quite possible that in those blends complex formation in bulk has taken place too.

Figure 9 shows clearly that annealing at 140°C produces an additional broadening of the glass transition towards higher temperatures. The largest effect is seen in the middle of the composition range, where complex formation is most pronounced (*Figure 3*). The shift towards higher temperatures may be partly due to stresses created in the amorphous regions as a result of formation of tie molecules between the complex crystallites. Moreover, we know from *Figure 2* that the endotherms sharpen during annealing, which points to improvement of complex crystallites. The complexed regions probably approach their optimum composition by further association of material in some stoichiometric ratio, which results in a larger asymmetry of the damping curve during longer annealing times. Since the optimum composition of complexes in bulk seems to be somewhat richer in i-PMMA (*Figure 3*), the non-complexed material tends to include more s-PMMA than corresponds with the overall composition. As s-PMMA has the highest T_g this compositional change yields a further shift of the damping curves towards higher temperatures.

Figure 3 showed that the complex formation is most fast at 140°C in i-PMMA rich compositions. Further, we know from *Figure 2* that more than half of the transformation takes place within 2 min. Since 140°C is near to the glass transition temperature of s-PMMA it is reasonable to assume that chain segments of i-PMMA form nuclei for complex formation, probably by attaining the favourable helix conformation[2,15]. Then chain segments of s-PMMA partly associate with the helices, initiating crystallization according to the fringed micelle model. This mechanism of molecular nucleation is supported by the observation that samples preheated to 300°C crystallize with the same rate as samples which have been preheated only 20°C above T_m.

If the number of crystallites was increasing in time, this
Figure 9 Effect of annealing on loss tangent, tan δ at about 1 Hz *versus* temperature for four i-/s-PMMA compositions. (a): ○, 80 : 20; △, 40 : 60; (b): ○, 60 : 40; △, 20 : 80; ●, ▲, after annealing for 120 h at 140°C
Figure 10 Effect of annealing on storage modulus (log G', N/m²) at 0.65 Hz *versus* temperature for two i-/s-PMMA compositions. ○, 80:20; △, 40:60; ●, ▲, after annealing for 120 h at 140°C

should result in a tighter network with a higher value of the storage modulus G' above the glass transition. However, *Figure 10* shows that the values of log G' interpolated to a fixed frequency of 0.65 Hz are practically the same for annealed and not-annealed bars. In our opinion this suggests that the main process taking place in bulk during annealing comprises growth of complex crystallites as

was first supposed by Pyrlik *et al.*[9] for stereocomplexes of i- and s-PMMA in concentrated solutions in *o*-xylene.

Kinetics of graft polymerization of styrene on cis-1,4-polybutadiene

P. Manaresi, V. Passalacqua and F. Pilati

Istituto Chimico, Facoltà di Ingegneria, Università di Bologna, Bologna, Italy
(Received 16 July 1974; revised 31 October 1974)

By measurements of polymerization rate, grafting efficiency and number-average molecular weight of free and grafted polystyrene, the α-dicumyl peroxide initiated polymerization of styrene on cis-1,4-polybutadiene at 100°C and at low extents of reaction was studied. The polymerization rate and the polystyrene molecular weights decreased with the rubber content of the solution. The grafting efficiency was found to be substantially independent of the peroxide concentration, but to increase with rubber content. A rigorous mathematical model of the reaction was developed, from which it has been possible to confirm the proposed mechanism and to establish the value of many kinetic constants.

INTRODUCTION

In previous papers[1-3] we have studied the dicumyl peroxide initiated graft polymerization of styrene with cis-1,4-polybutadiene, mainly by measurement of overall polymerization rates and grafting efficiencies. It has been possible to outline an initial reaction mechanism of direct attack by hydrogen abstraction of initiator radicals onto rubber, to derive a rate equation and to establish the value of a combined kinetic constant. Some approximations were introduced in the mathematical treatment, and chain transfer reactions, thermal initiation and termination between rubber radicals were neglected.

This paper deals with an experimental and theoretical extension of the previous work. A more rigorous mathematical treatment is developed with the aid of a computer, and the calculated values of polymerization rates, number-average degrees of polymerization of free and grafted polystyrene, and grafting efficiencies are compared with the experimental data. This was done to establish the complete initial reaction mechanism and to determine the values of the kinetic constants.

EXPERIMENTAL

Materials

cis-1,4-Polybutadiene used was Taktene 1202 S (Polysar Italiana SpA) (content: cis-1,4 = 96.1%; trans-1,4 = 2.1%; vinyl = 1.8% by i.r. analysis). Other characteristics were: $[\eta]^{30}$ = 2.2 dl/g in toluene; $\overline{M}_n$ = 90 000 (osmometry); gel content <0.1%. The polybutadiene was freed of antioxidants by repeated acetone extractions, and the disappearance of the u.v. band at 240–280 nm was verified.

Styrene was supplied by Montedison SpA, and had a styrene content >99.8%. The monomer was twice distilled under reduced pressure prior to use.

α-Dicumyl peroxide was supplied by Noury & Van der Lande, and was purified from two recrystallizations with ethanol.

Di-t-butyl hydroperoxide was obtained from Merck-Schuchardt and osmium tetroxide from Carlo Erba SpA.

The solvents benzene, toluene, chlorobenzene, methanol, methyl ethyl ketone, t-butyl alcohol and benzaldehyde were Carlo Erba reagent grade products.

Grafting reaction

Grafting was carried out in dilatometers, starting from styrene solutions of polybutadiene (2–9 wt %) containing α-dicumyl peroxide (0.1–0.3 wt %) as initiator. Dilatometers were filled under vacuum with repeatedly de-aerated solutions, and the polymerizations were carried out at 100.0 ± 0.1°C. Usually monomer conversion did not exceed 10%; only in a few cases have conversions up to 25% been purposely reached. Polymerization rates, after dilatometer calibration, were calculated from the initial slopes of the dilatometric plots. The crude polymerizate was precipitated in an excess of methanol, washed and then vacuum dried at 50°C and weighed. The extent of polymerization C (%) is given by:

$$C = \frac{100(A - R)}{100 - R}$$

where A is the amount (wt %) of gross polymer in the solution after the polymerization, and R is the polybutadiene (wt %) in the initial solution.

Separation of free polystyrene from grafted polystyrene

As described in previous papers, free polystyrene was separated from the gross polymer by repeated extractions with methyl ethyl ketone and subsequent centrifuging in order to get a better separation of the two phases. Grafting efficiency was calculated from the amount of polystyrene in the grafted fraction, determined by n.m.r. analysis of the CS_2 solution[4]. Grafting efficiency, E (%) is given by:

$$E = \frac{10^4 \times PR}{C(100 - P)(100 - R)}$$

where P is the polystyrene (wt %) in the grafted fraction.

Figure 1 Calculated curves and experimental data for overall polymerization rate. ○, thermal; ●, 0.00310; ■, 0.00620; ▲, 0.00930 mol/l of peroxide

concentration. The grafting efficiency increases with the rubber concentration and, at high rubber concentrations decreases strongly with increasing styrene conversion. The number-average degree of polymerization of free polystyrene is noticeably decreased in the presence of polybutadiene, and the magnitude of such effect is increasing with rubber concentration, at the same catalyst concentration. The number-average degree of polymerization of grafted polystyrene is slightly lower than that of free polystyrene at low rubber contents, but greatly increases with increasing rubber concentration. From such molecular weight data it is also evident that in the grafted fraction there exists some unreacted free rubber.

Therefore. it is likely that grafting occurs by initiator radical attack on polybutadiene as previously proposed, but the molecular weight data indicate that chain transfer processes cannot be neglected. The reaction mechanism previously proposed was therefore extended by introducing chain transfer with rubber and with monomer. termination between rubber radicals and. owing to the relatively high polymerization temperature, thermal initiation.

Therefore the mechanism proposed for low extents of reaction and low rubber concentrations is:

$$(1) \quad I \xrightarrow{K_d} 2\, I^{\bullet} \qquad\qquad \text{decomposition of initiator}$$

$$(2) \quad I^{\bullet} + M \xrightarrow{K_{i1}} M_1^{\bullet} \qquad\qquad \text{initiation}$$

$$(3) \quad 2\, M \xrightarrow{K_{th}} 2\, M_1^{\bullet} \qquad\qquad \text{thermal initiation}$$

$$(4) \quad I^{\bullet} + RH \xrightarrow{K_{i2}} IH + R^{\bullet} \qquad\qquad \text{attacking rubber}$$

$$(5) \quad R^{\bullet} + M \xrightarrow{K_{i3}} RM_1^{\bullet} \qquad\qquad \text{re-initiation}$$

$$(6) \quad M_1^{\bullet} + M \xrightarrow{K_p} M_2^{\bullet}$$
$$\qquad\quad M_n^{\bullet} + M \xrightarrow{K_p} M_{n+1}^{\bullet} \qquad\qquad \begin{array}{l}\text{propagation of}\\ \text{homopolymeriza-}\\ \text{tion}\end{array}$$

$$(7) \quad RM_1^{\bullet} + M \xrightarrow{K_p} RM_2^{\bullet}$$
$$\qquad\quad RM_n^{\bullet} + M \xrightarrow{K_p} RM_{n+1}^{\bullet} \qquad\qquad \begin{array}{l}\text{propagation of}\\ \text{graft}\\ \text{polymerization}\end{array}$$

$$(8) \quad M_n^{\bullet} + M \xrightarrow{K_{tM}} M_n + M_1^{\bullet}$$
$$\qquad\quad RM_n^{\bullet} + M \xrightarrow{K_{tM}} RM_n + M_1^{\bullet} \qquad\qquad \begin{array}{l}\text{chain transfers to}\\ \text{monomer}\end{array}$$

$$(9) \quad M_n^{\bullet} + RH \xrightarrow{K_{tR}} M_nH + R^{\bullet}$$
$$\qquad\quad RM_n^{\bullet} + RH \xrightarrow{K_{tR}} RM_nH + R^{\bullet} \qquad\qquad \begin{array}{l}\text{chain transfers}\\ \text{to rubber}\end{array}$$

$$(10) \quad M_n^{\bullet} + M_m^{\bullet} \xrightarrow{K_{t1}} M_{n+m}$$
$$\qquad\quad RM_n^{\bullet} + RM_m^{\bullet} \xrightarrow{K_{t1}} RM_{n+m}R$$
$$\qquad\quad RM_n^{\bullet} + M_m^{\bullet} \xrightarrow{K_{t1}} RM_{n+m} \qquad\qquad \text{terminations}$$

Degradation of rubber backbone

In order to obtain reliable molecular weight data for grafted polystyrene, it is necessary to make use of a degradation technique which leaves unaffected polystyrene grafts. The method proposed by Hubin[5] and Locatelli et al.[6] based on the polybutadiene degradation with hydroperoxides and OsO$_4$ in presence of benzaldehyde was employed.

Molecular weight determination

Number-average molecular weights of polystyrenes were determined by osmometry (toluene, 38°C) with a Mechrolab Model 502 high-speed membrane osmometer. Non-aqueous Schleicher and Schuell type 0-8 membranes were used. Data were taken at four or five different concentrations and graphical extrapolations were made of π/c *versus* c plots to zero concentration.

RESULTS AND TREATMENT OF DATA

In *Figure 1* the results pertaining to the initial rate of polymerization as a function of rubber and initiator concentrations are reported. The data indicate that the presence of cis-1,4-polybutadiene lowers the rate of styrene polymerization. This takes place regularly only up to a rubber concentration of about 8%, where the rate has a minimum value.

Table 1 summarizes the results obtained for the grafting efficiency and number-average degree of polymerization of free and grafted polystyrene. As may be seen, the grafting efficiency is slightly lower in the absence than in the presence of initiator, but is almost independent of initiator

Table 1 Grafting efficiency (E); number-average degree of polymerization of free and grafted polystyrene ($\bar{x}_{n,f}$; $\bar{x}_{n,g}$) (T = 100.0 ± 0.1°C)

where I is the peroxide, M is the monomer, RH is the polybutadiene, R* is the radical:

$$-CH_2 \diagdown \qquad \diagup {}^{\bullet}CH-$$
$$C{=}C$$
$$\diagup H \qquad \diagdown H$$

and RM* is a growing grafted styrene chain.

In this kinetic treatement we considered all the polystyrene radicals, free and grafted to be equally reactive. Owing to the high monomer concentration the peroxide efficiency was considered to be constant and was included in the constant K_d. An eventual effect of preferential solvation of polybutadiene by the peroxide[7] was also neglected, owing to the relatively high polymerization temperature. Besides for sake of simplicity we considered the thermal initiation to be second order with respect to monomer[8] with the formation of two monoradicals.

In order to calculate the overall polymerization rate the concentrations of radicals RM* and M* can be considered as a whole: $[M_{tot}^{\bullet}] = [RM^{\bullet}] + [M^{\bullet}]$.

Assuming that a stationary state exists for all radicals, the following equations are set up:

$$\frac{d[I^{\cdot}]}{dt} = 0 = 2K_d[I] - K_{i1}[I^{\cdot}][M] - K_{i2}[I^{\cdot}][RH] \qquad (1)$$

$$\frac{d[M_{tot}^{\cdot}]}{dt} = 0 = K_{i1}[I^{\cdot}][M] + 2K_{th}[M]^2 +$$

$$K_{i3}[R^{\cdot}][M] - K_{tR}[RH][M_{tot}^{\cdot}] -$$

$$2K_{t1}[M_{tot}^{\cdot}]^2 - K_{t2}[R^{\cdot}][M_{tot}^{\cdot}] \qquad (2)$$

$$\frac{d[R^{\cdot}]}{dt} = 0 = K_{i2}[I^{\cdot}][RH] + K_{tR}[RH][M_{tot}^{\cdot}] -$$

$$K_{i3}[R^{\cdot}][M] - K_{t2}[R^{\cdot}][M_{tot}^{\cdot}] -$$

$$2K_{t3}[R^{\cdot}]^2 \qquad (3)$$

From equation (1) it follows:

$$[I^{\cdot}] = \frac{2K_d[I]}{K_{i1}[M] + K_{i2}[RH]} \qquad (4)$$

By introducing equation (4) into equation (2), equation (5) follows:

$$[R^{\cdot}] = \frac{2[M_{tot}^{\cdot}]^2 + \dfrac{K_{tR}}{K_{t1}}[RH][M_{tot}^{\cdot}] - \dfrac{2K_{th}}{K_{t1}}[M]^2 - \dfrac{2K_d[I]}{K_{t1}\left(1 + \dfrac{K_{i2}}{K_{i1}}\dfrac{[RH]}{[M]}\right)}}{\dfrac{K_{i3}}{K_{t1}}[M] - \dfrac{K_{t2}}{K_{t1}}[M_{tot}^{\cdot}]} \qquad (5)$$

By introducing equations (4) and (5) into equation (3). and rationalizing, it is possible to obtain the equation:

$$[M_{tot}^{\cdot}]^4(1 - 4\theta) + [M_{tot}^{\cdot}]^3(1 - 4\theta)\gamma[RH] +$$

$$[M_{tot}^{\cdot}]^2 \left[\frac{8\theta\delta[I]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} + 8\theta J[M]^2 - \theta\gamma^2[RH]^2 - \right.$$

$$\left. J[M]^2 - \beta^2[M]^2 - \beta\gamma[RH][M] - \delta[I]\frac{\left(1 - \alpha\dfrac{[RH]}{[M]}\right)}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} \right] +$$

$$[M_{tot}^{\cdot}]\left[4\theta J\gamma[M]^2[RH] + \frac{4\theta\gamma\delta[RH][I]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} + \right.$$

$$\left. \frac{2\beta\alpha\delta[RH][I]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} \right] + \delta\beta^2[M]^2[I] + J\beta^2[M]^4 - 4\theta J^2[M]^4 -$$

$$\frac{4\theta\delta^2[I]^2}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)^2} - \frac{8\theta\delta J[M]^2[I]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)}$$

$$= 0 \qquad (6)$$

where

$$\theta = \frac{K_{t1}K_{t3}}{K_{t2}^2}; \quad J = \frac{K_{th}}{K_{t1}}; \quad \delta = \frac{K_d}{K_{t1}};$$

$$\beta = \frac{K_{i3}}{K_{t2}}; \quad \gamma = \frac{K_{tR}}{K_{t1}}; \quad \alpha = \frac{K_{i2}}{K_{i1}} \qquad (7)$$

From equation (6) it is possible to calculate, for fixed values of the kinetic constants, the concentration of $M_{tot}^{\cdot}$ and the overall polymerization rate $v_p = K_p[M][M_{tot}^{\cdot}]$.

In order to calculate number-average degrees of polymerization of free and grafted polystyrene and grafting efficiencies, the concentrations of radicals $M^{\cdot}$ and $RM^{\cdot}$ were separated in the calculus. Equation (2) pertaining to the stationary state for radicals $M_{tot}^{\cdot}$ becomes:

$$\frac{d[M^{\cdot}]}{dt} = 0 = K_{i1}[I^{\cdot}][M] + 2K_{th}[M]^2 +$$

$$K_{tM}[M][RM^{\cdot}] - K_{tR}[RH][M^{\cdot}] - 2K_{t1}[M^{\cdot}]^2 -$$

$$2K_{t1}[M^{\cdot}][RM^{\cdot}] - K_{t2}[R^{\cdot}][M^{\cdot}] \qquad (8)$$

$$\frac{d[RM^{\cdot}]}{dt} = 0 = K_{i3}[M][R^{\cdot}] - K_{tM}[M][RM^{\cdot}] -$$

$$K_{tR}[RH][RM^{\cdot}] - 2K_{t1}[RM^{\cdot}]^2 - 2K_{t1}[RM^{\cdot}][M^{\cdot}] -$$

$$K_{t2}[R^{\cdot}][RM^{\cdot}] \qquad (9)$$

By introducing (4) and (5) into equation (8), substituting $([M_{tot}^{\cdot}] - [M^{\cdot}])$ for $[RM^{\cdot}]$, it is possible to obtain an equation (eqn.10) for the concentration of radicals $M^{\cdot}$:

$$[M^{\cdot}] = \frac{\dfrac{2\beta\delta[I][M]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} + 2\beta J[M]^3 + \beta\epsilon[M]^2[M_{tot}^{\cdot}] - \dfrac{2\delta[I][M_{tot}^{\cdot}]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} - 2J[M]^2[M_{tot}^{\cdot}] - \epsilon[M][M_{tot}^{\cdot}]^2}{2\beta[M][M_{tot}^{\cdot}] - \epsilon[M][M_{tot}^{\cdot}] - \dfrac{2\delta[I]}{\left(1 + \alpha\dfrac{[RH]}{[M]}\right)} - 2J[M]^2 + \beta\epsilon[M]^2 + \beta\gamma[M][RH]} \qquad (10)$$

where

$$\epsilon = \frac{K_{tM}}{K_{t1}} = C_M \frac{K_p}{K_{t1}}$$

Now the number-average degree of polymerization of the growing polystyrene radicals (free and grafted), namely the kinetic chain length λ is given by:

$$\lambda = \frac{\text{rate of growth of polystyrene radicals}}{\text{rate of disappearance of polystyrene radicals}} ;$$

$$\lambda =$$

$$\frac{K_p [M] [M^{\cdot}_{tot}]}{2K_{t1}[M^{\cdot}_{tot}]^2 + K_{t2}[R^{\cdot}] [M^{\cdot}_{tot}] + K_{tM} [M] [M^{\cdot}_{tot}] + K_{tR} [RH] [M^{\cdot}_{tot}]} ;$$

$$\lambda = \frac{K_p[M]}{K_{t1} \left(2[M^{\cdot}_{tot}] + \dfrac{K_{t2}}{K_{t1}} [R^{\cdot}] + \epsilon[M] + \gamma[RH] \right)} \qquad (11)$$

where from equation (5):

$$\frac{K_{t2}}{K_{t1}} [R^{\cdot}] =$$

$$2[M^{\cdot}_{tot}]^2 + \gamma[RH] [M^{\cdot}_{tot}] - 2J[M]^2 - \frac{2\delta[I]}{\left(1 + \alpha \dfrac{[RH]}{[M]}\right)}$$
$$\overline{\rule{0pt}{2.2em}\beta[M] - [M^{\cdot}_{tot}]} \qquad (12)$$

The number-average degree of polymerization of free polystyrene $\bar{x}_{n,f}$ is evidently given by:

$$\bar{x}_{n,f} = \lambda \left(\frac{\text{number of polyradicals disappearing to form free polystyrene}}{\text{number of free polystyrene molecules formed}} \right)$$

and hence:

$$\bar{x}_{n,f} = \lambda \cdot \left[\frac{K_{tM} [M] [M^{\cdot}] + K_{tR} [RH] [M^{\cdot}] + 2K_{t1} [M^{\cdot}]^2}{K_{tM} [M] [M^{\cdot}] + K_{tR} [RH] [M^{\cdot}] + K_{t1} [M^{\cdot}]^2} \right] ;$$

$$\bar{x}_{n,f} = \lambda \cdot \left[1 + \frac{1}{1 + \epsilon \dfrac{[M]}{[M^{\cdot}]} + \gamma \dfrac{[RH]}{[M^{\cdot}]}} \right] \qquad (13)$$

Analogously the number-average degree of polymerization of grafted polystyrene $\bar{x}_{n,g}$ will given by equation (14):

$$\bar{x}_{n,g} = \lambda \left[\frac{K_{tM} [M] [RM^{\cdot}] + K_{tR} [RH] [RM^{\cdot}] + 2K_{t1} [RM^{\cdot}]^2 + 4K_{t1} [RM^{\cdot}] [M^{\cdot}] + K_{t2}[R^{\cdot}] [M^{\cdot}] + K_{t2}[R^{\cdot}] [RM^{\cdot}]}{K_{tM} [M] [RM^{\cdot}] + K_{tR} [RH] [RM^{\cdot}] + K_{t1} [RM^{\cdot}]^2 + 2K_{t1} [RM^{\cdot}] [M^{\cdot}] + K_{t2}[R^{\cdot}] [M^{\cdot}] + K_{t2}[R^{\cdot}] [RM^{\cdot}]} \right]$$

$$\bar{x}_{n,g} = \lambda \left[1 + \frac{1}{1 + \dfrac{\epsilon[M]}{[M^{\cdot}_{tot}] + [M^{\cdot}]} + \dfrac{\gamma[RH]}{[M^{\cdot}_{tot}] + [M^{\cdot}]} + \dfrac{K_{t2}[R^{\cdot}] [M^{\cdot}_{tot}]}{K_{t1}([M^{\cdot}_{tot}]^2 - [M^{\cdot}]^2)}} \right] \qquad (14)$$

The grafting efficiency, E (%) will evidently be given by:

$$E = 100 \times \frac{\text{moles of styrene grafted}}{\text{total moles of styrene polymerized}} ;$$

$$E = 100 \times \frac{K_p [M] [RM^{\cdot}] + 2\lambda K_{t1} [RM^{\cdot}] [M^{\cdot}] + \lambda K_{t2}[M^{\cdot}] [R^{\cdot}]}{K_p [M] [M^{\cdot}_{tot}]}$$

Substituting $([M^{\cdot}_{tot}] - [M^{\cdot}])$ for $[RM^{\cdot}]$, it follows:

$$E = 100 \left[1 - \frac{[M^{\cdot}]}{[M^{\cdot}_{tot}]} + \frac{\lambda[M^{\cdot}]}{\dfrac{K_p}{K_{t1}} [M] [M^{\cdot}_{tot}]} \left(\frac{K_{t2}}{K_{t1}} [R^{\cdot}] + \right. \right.$$
$$\left. \left. 2[M^{\cdot}_{tot}] - 2[M^{\cdot}] \right) \right] \qquad (15)$$

In equations (6) and (10)–(15) there are many kinetic constants, which were evaluated as follows:

$$\delta = \frac{K_d}{K_{t1}} \text{ and } J = \frac{K_{th}}{K_{t1}}$$

The constants have been obtained from the experimental data pertaining to the styrene polymerization ($[RH] = 0$), by plotting the square of the polymerization rate *versus* initiator concentration, from the equation:

$$\nu^2_{p,0} = \frac{K_d}{K_{t1}} K_p^2 [M]^2 [I] + \frac{K_{th}}{K_{t1}} K_p^2 [M]^4 \qquad (16)$$

A linear relationships was observed. By introducing for the propagation constant a value of $K_p = 1.67 \times 10^3$ sec^{-1} mol^{-1} l (at 100°C) obtained by a least squares plot of the literature data[9], the following values were obtained: $\delta = K_d/K_{t1} = 1.2 \times 10^{-14}$ mol/l; $J = K_{th}/K_{t1} = 2.8 \times 10^{-19}$. Analogously the constants $\epsilon = K_{tM}/K_{t1}$ and K_p/K_{t1} were evaluated from the data pertaining to the styrene polymerization by plotting $1/\bar{x}_{n,0}$ against the polymerization rate, following the equation:

$$\frac{1}{\bar{x}_{n,0}} = \frac{K_{t1}}{K_p^2 [M]^2} \nu_{p,0} + \frac{K_{tM}}{K_p} \qquad (17)$$

A linear relationships was observed, from which the following values were obtained: $K_{tM}/K_p = 2.0 \times 10^{-4}$; $K_{t1}/K_p^2 = 67.3$ sec mol l^{-1} and consequently: $\epsilon = K_{tM}/K_{t1} = 1.8 \times 10^{-9}$; $K_p/K_{t1} = 8.9 \times 10^{-6}$. For the constant $\alpha = K_{i2}/K_{i1}$ a fixed value of 2 was chosen, as approximately found in our previous studies*. Moreover, since the crosslinking

---

* The value in that case was about 1, because we considered in the calculus of [RH] the presence of two reactive hydrogens in each monomeric unit. In the present work, for reasons of homogeneity, the molecular weight of the unit was taken as equal to that of butadiene.

reaction, if present, is insignificant at low conversions (the grafted fraction is completely soluble), the constant θ = $K_{t1}K_{t3}/K_{t2}^2$ was assumed to be small, from 0 to 0.05. Now. by introducing into equations (6) and (10)–(15) fixed values of these kinetic constants, it was possible to calculate with the aid of a computer (for $[M_{tot}^{\bullet}]$ real, positive and >$[M^{\bullet}]$) values of v_p, $\bar{x}_{n,f}$, $\bar{x}_{n,g}$, E, for different values of β, γ and θ. By comparing calculated values with experimental ones, it was possible to obtain for the constants β and γ: $\beta = K_{i3}/K_{t2} = 3.0 \times 10^{-9}$; $\gamma = K_{tR}/K_{t1} = 1.0 \times 10^{-8}$. The value of θ between 0.0005 and 0.05 was seen to have only very little influence.

Calculated values of $[M_{tot}^{\bullet}]$, $[M^{\bullet}]$, v_p, $(K_{t2}/K_{t1})[R^{\bullet}]$,

$\bar{x}_{n,f}$, $\bar{x}_{n,g}$, λ and E are summarized in *Table 2*.

In *Figure 1* calculated curves of the polymerization rate are reported in comparison with experimental data. It appears that the agreement is good up to a rubber concentration of about 8% ([RH] = 1.25 mol/l).

In *Figure 2* calculated curves concerning $\bar{x}_{n,f}$ are compared with experimental data. The agreement is good enough, particularly at higher peroxide concentration.

The calculated values of $\bar{x}_{n,g}$ (*Table 2*) are slightly higher than those of $\bar{x}_{n,f}$; experimental and calculated $\bar{x}_{n,g}$ values are close together only at low rubber concentrations.

In *Figure 3* the calculated curve of E is reported; the experimental data are generally lower than the calculated ones, owing to the influence of the conversion.

DISCUSSION

Grafting of styrene on polybutadiene proceeds evidently by two ways: direct attack by hydrogen abstraction of

initiator radicals and chain transfer on the rubber.

While the first process is practically the sole one at low temperatures[10], the data reported here clearly demonstrate that at 100°C it is necessary to consider also chain transfer with polybutadiene.

Values evaluated for the kinetic constants are suitable or in agreement with literature data. Indeed the value for $\alpha = K_{i2}/K_{i1} = 2$ can be justified by the better resonance— stabilization of the allyl radicals with respect to the styryl ones, in agreement with the results of Fischer[11]. The low value of $\theta = K_{t1}K_{t3}/K_{t2}^2$ is also attributed to the stability of the allyl radical and to the steric hindrance for the cross-linking reaction. Analogously the value of the constant $\beta = K_{i3}/K_{t2} = 3.0 \times 10^{-9}$ is very low if compared with the ratio $K_p/K_{t1} = 8.9 \times 10^{-6}$; this again can be justified by the relative stability of the allyl radical $(K_{i3} < K_p)$.

The $K_p^2/K_{t1} = 1.48 \times 10^{-2}$ l mol^{-1} sec^{-1} value is in good agreement with that extrapolated at 100°C from the literature data[8]. From the value of $K_p = 1.67 \times 10^3$ l mol^{-1} sec^{-1}, it follows: $K_{t1} = 1.9 \times 10^8$ l mol^{-1} sec^{-1}; from the δ value. $\delta = K_d/K_{t1} = 1.2 \times 10^{-14}$ (mol/l), one obtains $K_d = 2.3 \times 10^{-6}$ sec^{-1}, in good agreement with values reported by several authors in different solvents[12,13].

From the constant $\epsilon = K_{tM}/K_{t1} = 1.8 \times 10^{-9}$, it follows $C_M = (K_{t1}/K_p)\epsilon = 2.0 \times 10^{-4}$. Such a value for the transfer constant to styrene is in excellent agreement with those in the literature[9]. After all, from the γ value: $\gamma = K_{tR}/K_{t1} = 1.0 \times 10^{-8}$ one obtains for the transfer constant to poly-butadiene: $C_R = (K_{t1}/K_p)\gamma = 1.1 \times 10^{-3}$, a value of the same order as that reported by Fischer[11] for some poly-butadienes at 110°C, by Minoura et al.[14] for the natural rubber at 50°C, and of those reported for unsaturated hydrocarbons[9]. When the polybutadiene concentration is very high (for instance 9%), a disagreement between experimental and calculated values appears, and molecular weights and grafting efficiencies become strongly dependent of the extent of reaction. This effect clearly is due to the phase separation, which arises for these rubber concentrations at very low styrene conversions (<1%). All the concentrations could be different in the two phases and, owing to the different medium viscosities, also the kinetic constants (particularly the termination constants and K_d) could be different and strongly conversion-dependent.

CONCLUSIONS

The development of a rigorous mathematical model has shown that the mechanism proposed for the initial stages of reaction is in complete agreement with experimental data, in the case of styrene solutions with low polybutadiene content. Deviations arising at high polybutadiene concentrations are related exclusively to the phase separation, which makes it impossible to study this reaction in an entirely homogeneous phase. It must be realized that the general reaction mechanism is still valid in each phase, provided one considers their different compositions and physical characteristics.

Kinetic studies of the free cationic polymerization of ethyl vinyl ether and isobutyl vinyl ether initiated by triphenylmethyl hexachloroantimonate

Y. J. Chung, J. M. Rooney, D. R. Squire and V. Stannett
Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27607, USA
(Received 18 October 1974)

The absolute rate constants for the cationic polymerization of ethyl and isobutyl vinyl ethers have been determined in methylene chloride solution. Under the conditions used, the polymerization proceeded by 'free ions'. Extremely rigorous drying procedures were used and the values obtained were somewhat higher than those reported in the literature. The values were in reasonable agreement with the 'free cation' values obtained by a combination of rate and conductivity measurements of bulk polymerizations, initiated with gamma radiation under 'super dry' conditions. The activation energies were also in good agreement.

INTRODUCTION

Cationic polymerization lags behind free radical and anionic polymerization in the extent of our understanding of the precise mechanisms involved and our knowledge of the absolute rate constants for the propagation termination and transfer reactions. The present status of the field has been well reviewed recently by Sigwalt[1]. A study of systems which proceed essentially by 'free' cations, not complicated by the presence of gegenions should add considerably to our knowledge. Cationic polymerization initiated by ionizing radiations is such a system and in the capable hands of Williams *et al.*[2] did indeed provide us with orders of magnitude for the propagation rate constants for a number of monomers. However, even when such rate studies are combined with electrical conductivity measurements. only approximate values can be obtained since a number of assumptions are involved concerning both the initiation and termination rates. The development of the stable carbenium ion salts which, in the correct solvent–monomer systems, give essentially instantaneous initiation and non-terminating polymerizations, has made it possible to measure rather accurately the absolute rate constants for a number of vinyl monomers. This work has been mainly carried out by Bawn and Ledwith and their coworkers and has been reviewed in detail recently by Ledwith[3].

In these laboratories, kinetic studies of radiation-induced cationic polymerization of a series of alkyl vinyl ethers have been carried out systematically under 'super dry' conditions to determine the relative reactivities of the series[4,5]. Under 'super dry' conditions, the radiation-induced polymerization occurs through 'free-cationic' propagation and in theory the polymerization follows a square-root dose-rate dependence. The apparent rate constant of the radiation-induced cationic polymerization of ethyl vinyl ether (EVE) was found to be somewhat smaller than that of isobutyl vinyl ether (IBVE) and there were alarming differences between the chemical and radiation propagation

rate constants[4]. To shed further light on the radiation-induced cationic polymerization of the vinyl ethers, it was decided to study chemically initiated cationic polymerization of EVE under experimental conditions such that propagation might occur through a free ion mechanism. Bawn *et al.*[6] have reported an excellent and detailed kinetic study of the 'free' cationic polymerization of IBVE in methylene chloride initiated by stable carbenium ion salts. Using concentrations low enough to permit virtually complete dissociation of these salts, they have obtained rate constants and the activation energy of propagation by free cations. In this paper some further kinetic studies of the cationic polymerization of isobutyl vinyl ether and ethyl vinyl ether have been conducted according to their well established approach. In particular the results of a study of the kinetics of the free cationic polymerization of ethyl vinyl ether initiated by triphenylmethyl hexachloroantimonate are presented. Isobutyl vinyl ether was studied briefly in order to check the procedures against those of Ledwith *et al.*

EXPERIMENTAL

At the beginning of the current series of experiments. methylene chloride was purified according to the procedure of Bawn *et al.*[6]. The solvent was washed with sulphuric acid, water and alkaline solution, dried over calcium, refluxed over calcium hydride, fractionated and degassed over calcium hydride. The solvent was then transferred to a 'scavenge' vessel containing triphenylmethyl hexachloroantimonate It was later found that reproducibility of rate constants and high conversions could also be obtained with simpler purification methods. Approximately 500 cm^3 of methylene chloride was stirred for 2 h over 75 cm^3 sulphuric acid, decanted and washed with water adjusted with KOH pellets to a pH of 8.5 (6 x 200 cm^3). After drying overnight on anhydrous $CaCl_2$, a first fraction of 350 cm^3 was

vacuum-distilled into a receiving flask from which it was poured into a scavenge vessel containing Ph_3CSbCl_6. Approximately 0.1 g of triphenylmethyl hexachloro-antimonate was added to 80–140 cm^3 of methylene chloride. The solution was then degassed through several freeze–thaw cycles under liquid nitrogen and sealed off at a pressure of less than 10^{-4} mmHg. The degassing was carried out in a flask equipped with a side-arm containing a break-seal, so the solvent vessel could be connected directly to a vacuum line for transfer to the reactor.

EVE and IBVE were both purified by techniques conventional in 'super dry' radiation polymerization studies[4,5]. About 200 cm^3 of the monomer were washed in water, adjusted with KOH to a pH of 8.5 and stored over KOH pellets for 24 h in a round-bottom flask. The monomer was then refluxed over fresh reagent grade sodium metal (J. T. Baker Chemical Co.) in a spinning band distillation column for 24 h. After refluxing, the middle fraction was collected in a receiving flask equipped with a side arm containing a break-seal. The flask containing pure monomer was attached to a vacuum line and degassed to 10^{-5} mmHg. The degassed monomer was then transferred to a sodium mirror flask *in vacuo* and stored for several days. When the sodium mirror disappeared, the monomer was transferred to a new flask, and the process was repeated until the condition of the monomer permitted the sodium mirror to remain intact. The resulting monomer was transferred in quantities of about 10 cm^3 to an ampoule containing anhydrous barium oxide which had been baked out overnight at 400°C and 10^{-5} mmHg. After several days, ~1 cm^3 of the monomer was transferred to an empty ampoule with a break-seal which had been baked out overnight at 480°C *in vacuo* and sealed off under high vacuum. This ampoule was attached directly to the vacuum line for transfer to the reactor.

Triphenylmethyl hexachloroantimonate was prepared as described by Bawn *et al.*[6]. All phials of initiator solution (triphenylmethyl hexachloroantimonate in methylene chloride) were prepared under a vacuum of less than 1 x 10^{-5} mmHg.

The progress of the polymerization reaction was followed by an adiabatic calorimetric technique using a system similar to that developed by Biddulph and Plesch[7]. A glass jacket enveloped the lower half of the reaction vessel. When evacuated, this jacket provided a region of negligible heat transfer during polymerization. The top of the reactor was equipped with a variable-speed stirrer, a thermocouple (copper—constantan) and a phial-breaking device. The shaft of the stirrer was sealed to the reactor by an O ring and Teflon bearings (Fisher Cat. No. 14-513-100). The copper–constantan thermocouple (250 mm diameter) leads were sheathed in Teflon to within 6.0 mm of the tip. A circular electromagnet was used to activate a phial-breaking rod. Phials of catalyst solution were held in place by fixed glass supports with space provided for two phials. The thermocouple was attached through an automatic reference junction compensator (Con-Ohmic Devices, Carle Place, NY) to a high speed recorder (Leeds & Northrup Speedomax XL-602) which was calibrated in mV with a potentiometer. The thermocouple voltage was virtually linear over the desired temperature range (usually 10°C), permitting direct readout of temperature *versus* time. The chart speed of the recorder during the polymerization reaction was 25.4 mm/sec. The response time of the recorder was 0.3 sec for a full-scale deflection and that of the thermocouple was less than 0.1 sec.

Procedure

Following the placement of an initiator phial in the phial holder, the two halves of the reaction vessel were sealed together with Apiezon Q compound. The entire vacuum line and the reactor were then subjected to mechanical pumping overnight. When the pressure had been reduced to less than 1 x 10^{-5} mmHg, the pumping valves were closed, and a measured amount of solvent (70–125 cm^3) was distilled into the vessel along with the monomer. When the temperature was stabilized at the desired level, the Dewar jacket was evacuated, the stirring speed increased and the recorder switched to maximum speed (25.4 mm/sec). The electromagnet was then activated and the catalyst phial was crushed. When the recorder indicated that the polymerization was complete, the stirrer was stopped and the entire calorimeter was opened to the atmosphere. A strong jet of methanol was used to quench the mixture. The thermocouple, stirrer and breaker were washed with benzene, the washings were added to the polymer solution and finally the solvent was evaporated slowly. Molecular weights of polymers were measured by using a vapour pressure osmometer (Hewlett-Packard Series 300).

RESULTS AND DISCUSSION

The upper curve (A) of *Figure 1* shows a typical plot of temperature rise during an experiment, and the lower curve (B) shows the temperature rise due to the heat of both breaking an initiator phial and mixing the initiator solution with solvent in the absence of monomer. The difference between the two curves corresponds to the temperature rise due to the heat of polymerization alone. Since it was found that adiabatic conditions held for the duration of the reaction, the maximum temperature rise could be equated to the polymerization yield which was usually well in excess of 90%. By equating the total temperature rise to the yield of polymerization, the concentration of mono-

Figure 2 Plot of log [M] vs. *t* during a typical experiment

mer was obtained as a function of time, and typical data are presented in *Table 1*. A plot of log [M] vs. time yields a straight line after a brief induction period as shown in *Figure 2*, indicating that the propagation reaction can be considered first order with respect to monomer concentration. Consequently, the concentration of the propagating species can be assumed to be constant under the experimental conditions. This assumption is substantiated by the results obtained from successive polymerization. After ~90% conversion of the monomer, a second equivalent amount of the same monomer was introduced *in situ* to the polymerization mixture and the observed rate of the second polymerization was similar to that of the first.

From the slope of the log [M] vs. *t* plot shown in *Figure 2*, the pseudo-first order rate constant was found to be 2.1. This value is equal to the rate constant of propagation (k_p) times the concentration of the propagating species. Assuming that all initiator molecules participated in initiating polymerization*, the propagation rate constant was calculated to be 9.2 x 10³ l mol⁻¹ sec⁻¹ at 15°C. All experimental data have been analysed similarly and results are presented in *Table 2*. The temperature quoted in *Table 2* is the initial temperature of the reaction mixture. An Arrhenius plot (*Figure 3*) of average values of log k_p vs. 1000/*T* gives rise to an activation energy of 9.9 kcal/mol from 25°C to +15°C.

Molecular weight measurements conducted on polymer samples prepared from more highly concentrated reaction mixtures gave evidence of extensive chain transfer reactions. Polymerization for which the original monomer and initiator concentrations were 0.7 mol/l and 2 x 10⁻⁴ mol/l respectively yielded polymers of an approximate molecular weight of 4000 at reaction temperatures of 0–25°C. The molecular weight theoretically possible under the given conditions is about 250 000. This prevalence of chain transfer in similar cationic systems has also been noted by Ledwith[3,6].

Table 3 presents the average propagation rate constants and activation energies for both isobutyl and ethyl vinyl ethers obtained in this work together with the literature values and the results obtained from radiation-induced polymerization studies. It can be seen that the rate constants for isobutyl vinyl ether are, indeed, consistantly higher than for ethyl vinyl ether but not by a large margin. The

---

* This assumption has been challenged recently, however, by Plesch[10]

reasons for this have been discussed by Ledwith[3][6]. With regard to the chemically initiated polymerization the k_p values from this study are consistently somewhat higher than the literature values. This is almost certainly due to the more rigorous drying conditions used. The activation energies and the k_p values are, however, in good agreement with the literature considering the experimental difficulties involved.

Considering now the results obtained with radiation initiation, it can be seen that the activation energies are in good agreement. The propagation rate constants are seen to be somewhat higher for the radiation polymerizations compared with chemical in the case of isobutyl vinyl ether and about half as large for the ethyl vinyl ether. Considering the assumptions made, however, with both initiating systems the agreement can be regarded as excellent. This removes one of the more vexing problems of free ion cationic polymerization as pointed out by Sigwalt[1]. Studies of cationic polymerization with free ions whether produced by stable carbenium ion salts or by radiation can be continued therefore with considerable confidence.

The structural and morphological characterization of a styrene—butadiene—styrene thermoelastic three-block copolymer (Kraton 1101) is reported together with the stress—strain properties of specimens prepared with different techniques (compression moulding, extrusion, solution casting). The influences of the extrusion and of the annealing treatment at high temperature on the morphology (and therefore on the stress—strain properties) are considered in detail because the structure of the specimen becomes particularly simple; it consists of polystyrene cylinders arranged along the extrusion direction and embedded into the rubbery matrix. The rods along the axis lead to a continuous polystyrene phase, so that the plugs exhibit the Mullins and hardening effects already observed for other copolymers. Films cast from toluene are also investigated; the rate of evaporation of the solvent shows a remarkable influence on the morphology of the material and, of course, on its physical properties. An explanation for the hardening effects at high values of deformation is also suggested, supported by optical birefringence measurements on compression moulded specimens after strain.

INTRODUCTION

The correlation between physical properties and composition of SXS three-block copolymers (S = styrene. X = butadiene or isoprene) has been widely studied. Some years ago[1-6] the influence of the amount of polystyrene was investigated in detail and the conclusion was reached that the glassy or rubber-like behaviour of the material depends on it. Nevertheless at that time no attempt was made to state the principles concerning the relationship between stress—strain behaviour and morphology; only the high values of the Young's modulus and the stress-softening effects which are often shown by the stress strain curves were explained assuming a polystyrene continuous phase whose weaker ties are progressively broken with increasing load.

It must be stressed that the physical properties of SXS three-block copolymers depend on the morphology which the material, owing to its polystyrene content, is able to assume in consequence of thermal or mechanical treatments carried on in the course of the specimen preparation[7].

Extrusion and annealing at high temperature have been considered in detail in our experiments. Copolymers with low amount of polystyrene (~10%) do not show any orientation of the domains after the extrusion; the annealing induces a 'polycrystalline type' structure and an arrangement of spherical domains in a body centred cubic lattice[8]. When higher amounts of polystyrene are considered (~25%). the polystyrene domains have a cylindrical shape[9] and are highly oriented along the axis by extrusion; the annealing treatment leads to a 'single crystal' with parallel and continuous rods, hexagonally packed in the rubbery matrix[10-12]. The stress strain plot of the former is similar to that of the ordinary vulcanized rubbers while the latter shows a large influence of the annealing treatment on the physical behaviour[7] as well as both stress-softening and hardening effects for low and high values of the deformation respectively.

On the other hand, the statement that the stress-softening was due to the breaking off of the weaker ties of the polystyrene continuous phase was always taken for granted as far as the experimental results could reasonably be assumed. Recently we have experimentally supported this hypothesis[13].

In this paper we report the molecular characteristics of another SBS copolymer, the influence of compression moulding, extrusion and annealing on its morphology and on the corresponding stress—strain behaviour; finally. when films cast from dilute solution are prepared, the effect of the solvent evaporation rate on the physical properties will be taken into consideration. The aim of the work is to find an explanation for the hardening effect which comes out at the highest values of the load and, beside this. to stress that the total amount of polystyrene in the copolymer is not the conclusive parameter defining the mechanical properties of the material but only the necessary starting point leading to specific morphologies on which the physical properties actually depend.

EXPERIMENTAL

Material and molecular characterization

The copolymer employed in our experiments was commercial Kraton 1101 supplied by Shell Co. It is a styrene-butadiene-styrene three-block copolymer whose molecular characterization, performed with techniques already described in detail elsewhere[8], gives the results summarized in *Table 1*; these are in good agreement with those previously reported by other authors[14,15].

The amount of polystyrene and the total molecular weight were higher than the corresponding K 1102 previously studied[7,9-12]; the polystyrene end blocks were longer and therefore the chain mobility was highly hindered.

The toluene used to cast the films was a commercial distilled product.

Methods

The copolymer was studied as supplied by the manufacturer, after extrusion and/or annealing, and as a film.

The extrusion was carried out at high temperature ($220°C$ and 9.7 kg/cm^2) and plugs of about 2 mm in diameter were obtained. The annealing was carried out under vacuum ($\simeq 10^{-3}$ mmHg) at $150-170°C$. Films were obtained either by die-casting at $110°C$ under slight pressure or from dilute solutions in toluene at $50°C$ on a mercury surface at two different evaporation rates (about 20 and 0.5 cm^3/h). These latter specimens were completely dried under vacuum at the same temperature; their thickness was about $0.2-0.4$ mm.

The morphological analysis was performed by electron microscopy on ultra-thin sections cut by low temperature ultramicrotomy[16]. The staining was obtained by exposing the sections to vapour of aqueous OsO$_4$ solutions at room temperature for several minutes; consequently in the electron micrographs the butadiene phase will appear dark and the styrene bright.

The stress—strain measurements were done by simple extension at room temperature ($\simeq 20°C$) and with a deformation rate of 10 mm/min. The stress. o (kg/cm^2) is defined by the ratio f/s_i, f being the load applied and s_i the original cross-section of the specimen; the extension ratio. α. is defined by $(\Delta L + L_i)/L_i$ where L_i is the original length of the sample and ΔL the deformation.

Compression moulded films were observed in polarized light in order to give evidence of anisotropy phenomena.

RESULTS AND DISCUSSION

Original copolymer

Figures 1 and *2* show the morphologies of the K 1101 original copolymer, as supplied by Shell and after an annealing treatment of about one month.

The original material does not show any regular morphology. *Figure 1* makes evident polystyrene domains of different size and shape (mainly circular and rod-like) together with large aggregates which can be due to small amounts of homopolymer in the copolymer[17].

Taking into account that the sections viewed in the electron microscope are about 500 Å thick and that the osmium tetroxide stains the whole thickness of the section. the micrograph of *Figure 1* does not allow us to draw any conclusion on the morphology of the original copolymer. We looked at the projection on the observation plane of the three-dimensional structure of the sample: therefore circular domains of polystyrene may appear from spheres or from the exact cross-sectional view of cylinders with orientation perpendicular to the cutting section; on the other
Figure 2   Electron micrograph of the K 1101 annealed under vacuum for one month at $150-170°C$. The arrow indicates crystal grains in which rod-like and hexagonally assembled circular polystyrene domains are present
Figure 3 Electron micrograph of a K 1101 extruded plug (diameter, 2 mm) cut along the extrusion axis (indicated by the arrow)

hand, streaks could be due either to a true rod-like structure or to the projection of spherical domains lying down on the same row but at different depths in the section[8]. The copolymer composition would suggest a rod-like polystyrene structure, characterized by very short cylinders randomly embedded in the rubbery matrix[18].

This hypothesis is supported by *Figure 2*, showing the equilibrium morphology that appears after one month of annealing at high temperature. Actually we can see crystal grains in which rod-like and hexagonally assembled circular polystyrene domains are present; it can be explained only if one assumes that the polystyrene end blocks supply regularly packed cylinders, variously oriented in adjacent regions of the cross-sectional plane of the specimen. The structure of the whole specimen is that one of a polycrystalline material.

Therefore we reach the conclusion that the original material is also characterized by rod-like polystyrene domains, as with the theoretical prediction of Inoue[19] and Meier[20].

Extruded and extruded-annealed specimens

Figures 3 and *4* show an extruded plug, cut along the extrusion direction, and an extruded-annealed specimen, sectioned both along and perpendicularly to the extrusion axis.

The polystyrene cylinders, which characterize the morphology of the original material, are arranged along the axis of the plug during the extrusion (*Figure 3*). By annealing it could reach the 'single crystal' structure completely similar to that obtained with the K 1102 copolymer[10-12], where hexagonally packed continuous rods of polystyrene are regularly embedded in the rubbery matrix[21]; a more regular distribution of the rod-like domains along the extrusion axis is observed (*Figure 4*) but the single crystal is more difficult to obtain in this case owing to the size of the molecular weight and to the length of the polystyrene end blocks, which highly reduce the macromolecular mobility.

The morphology of extruded and extruded-annealed

specimens is well defined and sufficiently simple, allowing us to give an interpretation of their mechanical properties (*Figures 5* and *6*) without any unreasonable assumption, on the basis of the older hypothesis[1-6].

(i) The high values of the Young's modulus (*Figures 5a* and *6*) are justified by the continuous polystyrene phase owing to the arrangement of polystyrene rods along the extrusion axis. It has been shown that the specimens are anisotropic; by stretching the plugs perpendicularly to the extrusion direction a rubber-like behaviour is produced[22].

(ii) The improvement of the phase separation due to the annealing treatment gives rise to a more regular and continuous distribution of the polystyrene cylinders in the rubbery matrix; therefore the annealed plugs are stiffer than the extruded ones (*Figures 5a* and *6*).
Figure 4 Electron micrographs of a K 1101 extruded and annealed plug (diameter, 2 mm; annealing time, 1 month). (a) Section parallel to the extrusion axis (indicated by the arrow); (b) section perpendicular to the plug axis
Figure 5 Simple extension stress—strain plots of extruded K 1101 copolymer. (a) First (●) and second (○) deformation run. Between the two successive deformations the specimen has been relaxed, at zero load, for 10 min; (b) consecutive stretching of the sample with the maximum deformation progressively increased
Figure 6 Stress—strain isotherms obtained with an extruded-annealed sample (annealing time, 1 week). ●, First run; ○, second run after 10 min of relaxation

(iii) The yield point (*Figures 5a* and *6*) is easily explained if one takes into account that the rods are not regularly assembled everywhere and do not have constant diameters (*Figures 3* and *4a*). Many dislocations are present and thin ties often link consecutive cylinders. These defects clearly act as points where the strength of the material is strongly

reduced; when the load becomes sufficiently high, a large number of interconnections between rods in a row can be suddenly broken and therefore a well defined yield point appears.

(iv) The stress-softening (*Figure 5b*) is another consequence of the tie breaks: by increasing the load the number of ties which are broken off becomes progressively larger and larger. We have recently experimentally supported this hypothesis[13], which also explains the difference between the first and the second stretching at low values of deformation.

Only the hardening effect, which appears at the higher strain values, is still unexplained.

Solution cast films

Figure 7 shows the morphologies of toluene cast films prepared at different solvent evaporation rates. The cor-
Figure 7 Electron micrographs of K 1101 films cast from toluene. (a) Fast evaporation; (b) slow evaporation. The sections are perpendicular to the film surface. Evaporation temperature = 50°C
Figure 8 Simple extension stress—strain plots of toluene cast K 1101 films. Fast evaporation: first (△) and second (▲) deformation run; slow evaporation: first (○) second (●) and third (X) deformation run. In both the experiments the storage time of the specimen at zero load is 10 min

responding stress strain curves are plotted in *Figures 8* and *9*.

It is well known[14,19,23-29] that both the thermodynamic power and the evaporation rate of the solvent influence the morphology of the film. *Figure 7* supports this conclusion as far as the evaporation rate is concerned, although the differences between films obtained with fast and slow rate of evaporation are not striking. The morphology of samples prepared at high rate do not show any regular arrangement of the polystyrene domains, which anyway seem to have a rod-like shape; on the contrary, the morphology of samples prepared at low evaporation rate is rather similar to that of the original annealed material (*Figure 2*) and leads to the same conclusion — a polycrystalline structure where cylinders are hexagonally packed in the rubbery matrix.

Our results cast some doubts on the conclusions of a previous paper[15], from which it follows that the morphology of a toluene cast film of K 1101 would be basically a simple cubic geometry of spherical domains. The disagreement between results obtained by electron microscopy and by low angle X-ray diffraction was already pointed out when films of the same copolymer were cast from mixtures

of tetrahydrofuran and methyl ethyl ketone[30,31]. We do not have any conclusive explanation for this. From the experimental point of view two parameters are able to modify the morphology of films cast from a well known solvent, i.e. the evaporation rate of the solvent itself and the annealing treatment carried on the dry film; in this case: (i) Brown *et al.*[15] do not give any data on the evaporation rate experimentally used in their experiments; nevertheless *Figure 7* shows clearly that the morphology of K 1101 toluene cast films is always characterized by polystyrene rods embedded in the rubbery matrix; (ii) Brown *et al.*[15] did not anneal their specimens at high temperatures which underlines the basic feature of the first order diffraction pattern remaining unaltered up to 130°C. leading to the conclusion that the structure does not change at all. Our experiments show that the equilibrium morphology, obtained after a long treatment at high temperature, is still characterized by polystyrene rods (*Figure 2*).

We therefore feel that perhaps the low angle X-ray diffraction results might be more critically considered. This topic has been recently reviewed by Krigbaum *et al.*[32].

The small differences between fast and slow evaporated films so far discussed also appear if the corresponding stress--strain curves are taken into consideration. The
Figure 9 Simple extension stress—strain plots of slowly evaporated toluene cast K 1101 films. ——, First deformation; — — —, second deformation after 10 min of relaxation at zero load; ▲, second deformation after 1 day of relaxation at zero load; ■, second deformation after 1 week of relaxation at zero load; △, third deformation after 10 min of relaxation of the sample (▲)

the sample, stored for 1 day between the first and second deformation, is strained again after only 10 min we obtain the same plot as obtained without any storage. The suggestion that the hardening effect at high strain values could have a kinetic explanation. We can reasonably assume that, when the load is removed, the recovery of the original structure needs a rather long time owing to the hindered mobility of the copolymer macromolecules; this also occurs when the original dimension of the specimen is apparently restored. Therefore if a deformation is followed immediately by another one, macromolecules that are still strained by the previous deformation run are stretched.

Compression moulded films

Figures 10 and *11* show sections of compression moulded films in the original state and after stretching. The corresponding stress—strain plots are reported in *Figure 12* and finally in *Figure 13* the films are observed in polarized light.

In the moulded film the polystyrene phase is embedded in the rubber as rod-like domains and no particular orientation of the cylinders is present, as is clearly seen from the comparison of the two orthogonal sections of *Figure 10*. The cylinders are oriented by the stretching and the original morphology is not immediately restored (*Figure 11*). At α = 4 the polystyrene cylinders are still rather long and oriented in the stretching direction more regularly than in the unstrained material (*Figure 10a*); when the deformation is larger (α = 8) the continuity of the polystyrene phase seems to be broken so that the cylinders are shorter. We believe that the orientation of the polystyrene cylinders needs an irreversible work which can give its contribution

Figure 10 Electron micrographs of a K 1101 compression moulded film. (a) Section parallel to the compression surface; (b) section perpendicular to the compression surface
Figure 11 Electron micrographs of die-casting films stretched and relaxed before cutting. Sections parallel to the compression surface. (a) α = 4; (b) α = 8

first deformations are not too different (*Figure 8*); the slowly evaporated sample does not show any well defined yield point and seems to be slightly more stiff. However, it is noteworthy that the stress—strain curves of the second deformation are exactly coincident; according to the current model this would correspond to the same number of tie breaks.

Figure 9 concerns the influence on the stress—strain curves of the storage time at zero load between following deformations. The complete irreversibility of the first mechanical response of the material appears quite clearly; even after one week of relaxation the softening at low deformation and the hardening at high strain are still present. The main result is nevertheless obtained by stretching a specimen three times after different relaxations; when

Figure 12 Stress—strain isotherms obtained with a die-casting film. □, First run; ■, second run, after 10 min; ●, third run after one week; ○, fourth run, 10 min after the third

to the softening effect together with the mechanism of breaking.

On the other hand, the hypothesis that the hardening process could be caused by macromolecules in stretched and oriented state at zero load seems to find further support in *Figure 13*. The distribution of the dark zones is related to the distribution of the force field and therefore to the degree of orientation in the sample. It is evident that, at the same value of the strain, in the second deformation we have a more regular distribution of isotropic zones parallel to the strain direction pointing towards a higher degree of orientation.

CONCLUSIONS

From the result it would seem that the polystyrene content of the copolymer is certainly an important parameter in order to define the morphology of the material bit nevertheless many different morphologies can be obtained from a copolymer as a result of mechanical and/or thermal treatment.

In addition, some experimental evidence indicates that the hardening effect, which appears when two successive deformations are carried out without storage at zero load between them, could have a kinetic explanation. The hindered mobility of the macromolecules of the copolymer does not allow the recovery of the starting conformation; chains which are still strained are stretched again and therefore higher loads are necessary to reach the same values of deformation.

Effect of temperature and frequency in fatigue of polymers

J. C. Radon and L. E. Culver

Department of Mechanical Engineering, Imperial College of Science and Technology, London SW7 2BX, UK

The effects of frequency and temperature on fatigue crack propagation rate in poly(methyl methacrylate) and polycarbonate have been studied using centrally notched plate specimens cycled in tension between constant stress intensity limits. Crack growth was monitored at frequencies between 0.1 Hz and 100 Hz and at temperatures between $-60°C$ and $40°C$. A linear relationship between the cyclic crack growth rate $d(2a)/dN$ and appropriate levels of toughness, K, has been proposed: $d(2a)/dN = A\phi^{\alpha}$, where $\phi = (\lambda - \lambda_{th})/(K^2_{1C} - K^2_{max})$, $\lambda = K^2_{max} - K^2_{min}$, λ_{th} is the threshold limit and A and α are constants. Also, the influence of mean stress intensity was briefly discussed.

INTRODUCTION

Polymeric materials are now frequently used by engineering designers wherever they can suitably replace more conventional materials. Some possible advantages are the favourable strength to weight ratio, good damping properties and wear resistance and the possibility of economic manufacture of intricately shaped components.

Thus, in recent years, with the continuous development of industrial plastics of improved mechanical properties, considerable interest has been created in their behaviour under monotonic and cyclic loading conditions. While static fracture has received by far the most attention, attempts to analyse specific fatigue failure processes, in particular those connected with the evaluation of crack growth rates, have been relatively scarce.

The study of crack propagation under cyclic loading aims to provide data in a form suitable for use in stress analysis and design. A great deal of fatigue research is now being directed towards a detailed investigation of the influence of environment, temperature, frequency and other factors on subcritical crack growth from the initiation period up to the critical crack size. The development of linear elastic fracture mechanics (*LEFM*) concepts provided a promising approach to investigations of crack growth in statically loaded structures; stress intensity factors, K, are now known for a wide range of cracked configurations. Subsequent application of *LEFM* methods in cyclically loaded situations offered yet further possibilities for reliable evaluations of engineering materials. Recent work[1,2] provided some evidence that the *LEFM* approach may be conveniently used to describe the propagation of cracks under fatigue conditions in a range of polymers.

In the last ten years a number of fatigue crack growth 'laws' have been proposed and are fully described by Hoeppner and Krupp[3]. While some of the laws suggest that the critical parameter may be a function of stress or of strain, the majority are based on *LEFM* concepts. The basic and probably most widely known crack propagation equation, due to Paris, has been successfully applied to the analysis of cyclic crack growth in many materials for elastic

or, quasi-elastic situations:

$$d(2a)/dN = C_1(\Delta K)^m \tag{1}$$

where $2a$ is the crack length, N is the number of cycles, ΔK is the range of the stress intensity factor, $K = K_{max} - K_{min}$ and C_1, m are constants dependent on the material tested, the environment and the conditions of cyclic loading.

Recent results of a comprehensive programme of work on fatigue crack propagation at room temperature using a range of polymers[2] provided detailed information on the effects of the mean level, K_m, and the amplitude, ΔK, of the stress intensity factor; they led to a crack propagation model of the form:

$$d(2a)/dN = \beta\lambda^n \tag{2}$$

where $\lambda = K^2_{max} - K^2_{min} = 2\Delta K \cdot K_m$, and β and n are constants dependent upon the test conditions. Because of the encouraging correlation of the polymer results analysed by equation (2) with other published data, it was decided to apply the method for the evaluation of crack growth in tests similar to those in ref 2 but performed over a range of temperatures and frequencies. Preliminary tests indicated that this particular criterion could probably find a wider application. However, it should be mentioned that the tests[2] had been restricted to a comparatively narrow range of ΔK and in particular, cycling at very low values of K, usually described as region I, was not investigated in detail.

The purpose of the present paper is to report on a study of the effect of temperature between $-60°C$ and $+40°C$ and of frequencies between 0.1 Hz and 100 Hz in PMMA and PC under repeated tension fatigue. Some additional tests indicating the significance of mean stress intensity K_m and the threshold value ΔK_{th} are also discussed.

EXPERIMENTAL

The two polymers chosen for the present programme were poly(methyl methacrylate) (PMMA) and polycarbonate

(PC). It was shown previously[1] that PMMA (manufactured by ICI, UK) was a suitable material for fracture toughness studies and results on fatigue crack propagation with particular reference to the mean value of stress intensity K were reported. The fracture properties of polycarbonate of bisphenol A (Makrolon, manufactured by Bayer, Germany), available in the form of extruded sheets, are less well known than those of PMMA[4,5]. However, its increasing use in engineering applications results in the need for full information about its mechanical properties.

Specimens were made in the shape of 6.25 mm thick rectangular plates 180 x 300 mm for PC, and 350 x 400 mm for PMMA. Each was provided with a small central hole 6 mm diameter extended into a sharp crack 25 mm long. Notching procedure and other pertinent details were previously described in detail[1]. Two fatigue testing machines were used: a Dowty electrohydraulic machine suitable for higher frequencies and a hydraulic Denison T42C2 for tests at 0.1 Hz. Repeat tests performed on both machines confirmed that their stiffnesses were comparable and the repeatability of the results was within 5%.

The specimen, in self-aligning shackles, was assembled in an environmental chamber fixed to the machine crosshead. A refrigerator—heater unit (Haake, model KT32) provided temperature regulation ($\pm 0.5^\circ C$), the regime investigated in this programme being between $-60^\circ C$ and $+40^\circ C$ and the temperature was automatically recorded using a number of thermocouples attached to each side of the specimen close to the crack path. Each specimen was subjected to cyclic tension under selected maximum and minimum values of stress intensity factor K at the chosen temperature and frequency and the resulting crack growth was monitored using a cathetometer via narrow observation windows fitted on both sides of the chamber; this arrangement proved to be both simple and adequate.

The limits of the stress intensity range investigated and the maximum testing times were decided by reference to the calculated values of K for a centrally notched plate, according to the ASTM recommended procedure[6]. The highest level of K used in the cyclic tests was $0.8K_{1C}$. The plastic zone size corresponding to this K_{max}, calculated in the usual way, was very small when compared with the plate thickness (for both materials it was below 10^{-2} mm), thus plane strain conditions were assured. In the preliminary tests performed above $0.8K_{1C}$ a certain amount of cyclic creep was observed, but this was negligible at lower K levels. As expected, in tests at a low level of K_{max}, the crack growth rate $d(2a)/dN$ decreased considerably and $0.5K_{1C}$ was the lowest level of K_{max} investigated in detail. However, some tests were performed at still lower values of K_{max} (or ΔK) to establish whether crack growth would cease when cycling below a certain threshold stress intensity ΔK_{th}[7].

RESULTS AND DISCUSSION

Influence of temperature

Typical linear crack growth records obtained from the constant λ tests on PC at different temperatures but at constant frequency are shown in *Figure 1*. As the temperature was reduced from $27^\circ C$ to $-60^\circ C$ the crack growth rates decreased distinctly, the decrease amounting to 60% in the case of PC and 90% for PMMA. A comparable decrease was observed at other frequencies, as mentioned below.

Information on the effect of temperature on crack growth rate is scarce, but some results[8] report an increasing growth

rate $d(2a)/dN$ with temperature decreasing from $50^\circ C$ to $-10^\circ C$. The current tests have so far covered a temperature range between -60° and $40^\circ C$ and the first results obtained at 5 Hz on PMMA are included in *Figure 2*. It can be seen that the general tendency of all the tests is that of a decreasing crack growth with decreasing temperature. The crack growth rate also decreased with decreasing λ, the factor in

equation (2), and it appears that the influence of λ is dominant at higher temperatures, at least in PMMA. A similar trend, namely that of decreasing crack growth rate with decreasing temperature is shown in *Figure 3* on PC, although it should be noted that the observed change was relatively small.

Additional tests on PMMA at different temperatures and at various values of stress intensity factors are shown in *Figure 4*, where d(2a)/dN is plotted as a function of λ at 20 Hz. In the investigated region the relationships are essentially linear and have approximately the same slope. Other results obtained from tests on PMMA performed at the same value of ΔK but at two different temperatures, +27°C and $-60°$C are plotted in *Figure 5*. It can be seen that for a given frequency within the temperature range investigated the crack growth rates decreased noticeably with decreasing temperature.

The differences in the crack growth rates were larger as frequency decreased, but the slope remained unchanged. Additional tests at still lower temperatures will provide further insight into the changes of crack growth rates with

temperature and it is to be expected that the value of the slope may change also.

Influence of frequency

Tests were conducted on sheet specimens as before but at a range of frequencies, namely 5, 20 and 100 Hz. Tests at 0.1 Hz are now in progress, but frequencies below 0.1 Hz were not used because of excessively long testing times, while preliminary tests showed that frequencies above 100 Hz would lead to a considerable heat build-up in the specimen which would influence crack growth and finally result in a thermal failure of the material. Similarly, values of K_{max} were limited, as it became clear that fatigue crack growth at levels close to the critical K would be accompanied by a certain amount of creep damage. In all cyclic tests at constant K values the crack growth will include a component of cyclic creep, but preliminary tests at 21°C on PMMA confirmed that the contribution of cyclic creep would not become significant except at K_{max} levels greater than 0.93 MN/m$^{3/2}$. A similar limiting value of K_{max} was found for PC (1.0 MN/m$^{3/2}$) and tests were not performed at higher levels at 21°C. However, it was possible to increase slightly both limits in testing at lower temperatures and/or higher frequencies.

Data available on the effect of loading frequency on the fatigue crack growth rate even in metals are rather scarce. In general, only small changes in crack growth caused by frequency variation are recorded[9]. In some materials, such as mild steels, the evidence is inconclusive. However, in very strain-rate sensitive materials, such as polymers, changes in frequency may have a definite effect.

In a previous paper[10], tests performed at 21°C on PMMA showed an increasing crack growth rate with decreasing
Figure 5. Crack growth at various frequencies and temperatures for PMMA. $---$, $-60°$; $---$, +27°C. $\circ$, 5; $\square$, 20; $\triangle$, 100 Hz. $K_{max} = 0.66$ MN/m$^{3/2}$; $K_{min} = 0.22$ MN/m$^{3/2}$
Figure 6 Crack growth rate vs. λ at different frequencies and at 27°C for PMMA. ●, 5; ○, 20; ✕, 100 Hz

frequency and current tests at other temperatures confirm this tendency (*Figure 5*). The relationship between crack length and number of cycles at all frequencies was again linear, as has been similarly reported for metals[11]. Crack growth at high frequencies was extremely slow and decreased by one order of magnitude with frequency increasing from 5 to 100 Hz.

Constant temperature tests may provide an alternative insight into the cyclic process. Crack growth rates in PMMA at a range of frequencies but at constant temperatures are shown in *Figure 6*. These results indicate a considerable frequency dependence in the growth rates at higher temperatures, although distinctly smaller changes were observed at −60°C. At 27°C the crack growth rate at a frequency of 100 Hz was approximately two orders of magnitude lower than that observed in the tests at 5 Hz, but at −60°C this difference was not more than 50%. Preliminary tests performed on PC at higher than ambient temperatures showed that the crack growth rate may change only marginally with increasing frequency.

However, the results now available on PC (*Figure 3*) suggest that at temperatures below +25°C the situation reversed. Tests at yet higher temperatures may clarify this point. A slight increase in the crack growth rate appears to occur again below −60°C indicating that the minimum growth rate may occur at approximately −40°C.

In the tests discussed so far the crack growth rate and its dependence on ΔK was investigated using tensile cycling, i.e. $R = (K_{min}/K_{max}) = 0$. It should be recalled that in metals, such as steels and Al alloys, mean stress intensity, K_m, effects may become important. Also, it is known that the influence of K_m decreases with increasing toughness[9]. The behaviour of polymers under the conditions $R \neq 0$ is therefore of interest.

In a further series of tests, ΔK was maintained constant whilst K_m was varied under given temperature and frequency conditions. Again a linear relationship between the crack growth rate and number of load cycles similar to *Figure 1* was obtained, but the rate of increase of the crack growth was not proportional to K_m. These tests indicate

that both K_m and ΔK exert a distinct influence on the crack growth rates. *Figure 7* shows results obtained at 5 Hz and 21°C on PMMA in the tests at K_m equal to 0.27, 0.54 and 0.80 MN/m$^{3/2}$, compared with the basic growth rate curve for $R = 0$. It can be seen that the crack growth increases with increasing values of K_m. A similar behaviour could be expected at other frequencies and tests at 100 Hz; *Figure 8* confirms this. Comparable results are recorded for PC at $K_m = 0.85$ MN/m$^{3/2}$ and 5 Hz in *Figure 9*. As already mentioned, contrary to the behaviour observed on PMMA, the crack growth rate in PC increased with increasing frequency (20 Hz). Basic growth rate curves, $R = 0$, showing decreasing growth with increasing frequency in PMMA are shown in *Figure 10*; in all these graphs experimental points have been omitted for the sake of clarity.

As the results obtained in the present tests show some similarities with the previous data on polymers, obtained under comparable testing conditions (temperature, frequency, etc.), the use of equation (2) may again be appropriate. A logarithmic plot of the results (*Figure 11*) including those from the tests in which $R = 0$ show a family of fatigue crack growth curves converging into a single line at higher values of λ.

Fatigue crack growth curves can be divided into three parts. In region I crack initiation and primary crack growth, usually described as stage I (along primary slip planes) becomes more important with decreasing values of λ. At very low crack growth rates the factor λ is strongly dependent on K_m. The lower limit of region I represents fatigue thresholds. The existence of this critical range of stress intensity, below which crack propagation occurs either

which leads to a generalized equation:

$$\frac{d(2a)}{dN} = A\phi^{\alpha} \tag{5}$$

where

$$\phi = \frac{\lambda - \lambda_{th}}{K_{1C}^2 - K_{max}^2}$$

as indicated in *Figure 12*, $\alpha = 1.39$ and $A = 8.71 \times 10^{-6}$ cm/cycle.

CONCLUSIONS

1. In the investigated regime the cyclic crack growth rate decreases with decreasing temperature and increasing frequency.
2. Fatigue crack growth rate was found to be dependent upon the range of stress intensity factor ΔK and its mean value K_m.
3. Fatigue crack growth rate can be described as:

$$\frac{d(2a)}{dN} = A\phi^{\alpha}$$

where $\phi = (\lambda - \lambda_{th})/(K_{1C}^2 - K_{max}^2)$, $\lambda = K_{max}^2 - K_{min}^2$, λ_{th} is the threshold value of λ and A and α are constants.
4. The threshold stress intensity factor ΔK_{th} decreases with increasing K_m.

extremely slowly or may not occur at all, has been confirmed for some steels and Al alloys[7,9]. The existence of a threshold in the present polymeric materials is also indicated in *Figures 7, 8* and *9*, where the rapid fall in growth rates at low ΔK values would allow the threshold ΔK_{th} to be inferred at a rate of about 10^{-9} cm/cycle. The figures also show that ΔK_{th} decreases rapidly as K_m increases. This threshold value ΔK_{th} seems to be dependent on the basic material properties, but detailed information is not yet available[7].

The higher crack growth rate in region II can be described by basic equations such as equation (2). A yet faster growth rate is observed in region III culminating in a half-cycle loading when K_{max} reaches its critical value. In this region, static modes of fracture become more important with increasing levels of K_{max}.

The threshold value λ_{th} will influence crack growth in region I (*Figure 11*) which is highly dependent on K_m, whereas K_{1C} is the critical parameter at the instability point, region III. These two values provide the limiting conditions:

$$\left. \begin{array}{l} \lim_{\lambda \to \lambda_{th}} \dfrac{d(2a)}{dN} = 0 \\[2em] \lim_{K_{max} \to K_{1C}} \dfrac{d(2a)}{dN} = \infty \end{array} \right\} \tag{4}$$

Poly(oxybenzhydrylidene-1,4-phenylenemethylene)

D. Braun and U. Platzek

Deutsches Kunststoff-Institut, 61 Darmstadt, Schlossgartenstrasse 6R, West Germany
(Received 31 December 1974)

It is known that triphenylmethanol and benzyl alcohol
react readily with thionyl chloride or hydrogen chloride to
yield triphenylmethyl chloride and benzyl chloride respec-
tively[1]. Accordingly, reaction of diphenyl(4-hydroxymethyl-
phenyl)methanol (I), which contains the structure elements
of both the above alcohols with thionyl chloride, produces
a good yield of diphenyl(4-chloromethylphenyl)methyl
chloride (II). However, it is noteworthy that the reaction
of diol (I) with hydrogen chloride in benzene, results in
the formation of a polyether rather than the expected di-
chloride. The mode of formation and structure of this
polyether (IV) have become of particular interest to us.
The equations below illustrate the differences between the
two reactions:

HO—CH₂—⟨benzene⟩—C(Ph)(Ph)—OH

(I)

+ SOCl₂   + HCl

ClCH₂—⟨benzene⟩—C(Ph)(Ph)—Cl   HO—CH₂—⟨benzene⟩—C(Ph)(Ph)—Cl

(II)   (III)

| – HCl

[—O—CH₂—⟨benzene⟩—C(Ph)(Ph)—]ₙ

(IV)
Reaction of (I) with hydrogen chloride may proceed by
exchange of the hydroxyl group on the tertiary carbon
atom with the halogen. In this manner a phenyl analogue
of chlorhydrin (diphenyl(4-hydroxymethylphenyl)methyl
chloride) (III) is formed, which easily yields the correspond-
ing ether (IV) by splitting off hydrogen chloride.

In contrast to the above raction, the conversion of the
diol with thionyl chloride may possibly proceed via its ester
with chlorosulphinic acid[3]. However, Carré and Libermann
could not obtain the chlorosulphite intermediate with
either benzyl alcohol or triphenylmethanol and they
assumed the formation of the chloride to be a direct reac-
tion[4]. In the conversion of the diol (I) with thionyl chloride,
hydrogen chloride is also formed and owing to this a small
amount of polyether is obtained as a byproduct.

The structure of the polyether was confirmed by infra-
red (i.r.) spectrometry and nuclear magnetic resonance
(n.m.r.) spectrometry. The i.r. spectrum displayed very
strong ether group vibrations at 1070 and 1090 cm⁻¹ (tri-
phenylmethyl methyl ether 1077 and 1089 cm⁻¹)[3], whereas
the n.m.r. spectrum (*Figure 1*), shows absorptions due to
aromatic protons between $\tau = 2.1$ and 3.1 ppm and due to
the oxymethylene group at $\tau = 5.85$ ppm. As expected,
hydroxyl groups could not be detected.

The end groups of the polyethers deserve particular con-
sideration. In the i.r. spectrum there is a carbonyl absorp-
tion at 1705 cm⁻¹ which can be attributed to an aromatic
aldehyde. The aldehyde proton can be easily detected in
the n.m.r. spectrum at $\tau = 0.16$ ppm. Moreover, the spec-
trum contains signals due to methine protons from tri-
phenylmethane end groups at $\tau = 4.6$ ppm, and due to
chloromethylene end groups at $\tau = 5.6$ ppm.

It is known that triphenylmethyl ethyl ether, in the
presence of hydrogen chloride, decomposes to triphenyl-
methane and acetaldehyde[6]. By analogy, during the forma-
tion of the polyether, triphenylmethane and benzaldehyde
end groups may be formed by the following reaction:

—OCH₂—⟨benzene⟩—C(Ph)(Ph)—   + HCl →   —OCH₂—⟨benzene⟩—C(Ph)(Ph)—H

+

O=C(H)—⟨benzene⟩—C(Ph)—
Such a degradation could be responsible for the osmometric
number-average molecular weight of the polyether (IV)
being only 890. This molecular weight corresponds to a
number-average degree of polymerization of 3.3.

The gel chromatogram of the polyether (IV) on Mercko-
gel 5000 in tetrahydrofuran (*Figure 2*), provides some indi-
cation of the molecular weight distribution. As in our
earlier publication on poly(1,4-phenylene-1,1-diaryl-
ethylene)[7], the fraction at $V_e = 246$ ml corresponds to the
monomer fraction; whilst that at $V_e = 200$ ml corresponds
to the dimer fraction etc.

From the chromatogram it is clear that molecules with
a degree of polymerization greater than 15 are present in
only minute quantities.

EXPERIMENTAL

Hydrogen chloride gas was passed through a solution of
diphenyl(4-hydroxymethylphenyl)methanol in dry benzene
(3.36 g in 50 ml), whereupon the solution became red in
colour. After 20 to 30 min the solvent was removed
under vacuum, leaving a glassy, light brown mass. This
substance was dissolved in methanol and precipitated in

Measurement of crystallinity of polyamide-6 by d.s.c.

G. Coppola, R. Filippini and B. Pallesi
Snia Viscosa, Centro Sperimentale F. Marinotti, 20031 Cesano Maderno, Milano, Italy
(Received 23 December 1974)

INTRODUCTION

The aim of this work was to provide a calibration plot for routine measurements of the degree of crystallinity of commercial polyamide-6 through enthalpies of fusion, ΔH_f, derived by differential scanning calorimetry (d.s.c.).

EXPERIMENTAL

Some commercial samples of polyamide-6 were moulded at different temperatures to films of 1 mm thickness, thus achieving various degrees of crystallinity (up to 50%). One totally amorphous sample was prepared by quenching in

liquid nitrogen (–196°C) after melting at 250°C. This sample did not show any crystallinity by observation under a polarizing microscope.

Degrees of crystallinity were calculated from the density values measured by a gradient column, using the well known equation:

$$C = \frac{d_x - d_a}{d_c - d_a} \cdot \frac{100 d_c}{d_x} \qquad (1)$$

were C is the percentage crystallinity, d_x, d_a and d_c are the densities of the sample, of the totally amorphous and totally crystalline polymer, respectively. The density of the quenched sample was 1.098 g/cm^3, in good agreement with published data[1].

ΔH_f values were measured, on samples of 20 mg each, by a Du Pont Model 900 thermal analyser equipped with a d.s.c. cell, at a temperature scanning speed of 30°C/min and under a nitrogen atmosphere. These conditions have been adopted in order to minimize sample crystallization during heating. For samples of low crystallinity, however, crystallization above T_g (glass temperature) is unavoidable; in these cases, the exothermic peak was always subtracted from the melting area.

RESULTS AND DISCUSSION

In order to derive C values from equation (1) we tentatively substitute the value of $d_c = 1.220$ g/cm^3; this is an average value of various published data[2–4] which are not in good agreement, however, since they range from 1.243 to 1.133 g/cm^3. By plotting ΔH_f against C, we obtain, nevertheless, not one but two straight lines; subsequent analysis by X-rays[5] showed that samples rich in α crystalline form gave one line, distinct from the other on which samples rich in γ form were allocated. This finding is in complete agreement with Illers' conclusions[1].

Since our object was to produce a simple calibration plot of C vs. ΔH_f to be used for samples (films, monofilaments, etc.) where density measurements are difficult, the existence of two lines complicates the whole matter, requiring X-ray analysis of each sample in order to determine the crystalline form. We have therefore plotted in *Figure 1* only the values concerning those samples in which one of the two forms (α or γ) was prevailing; in equation (1) two d_c values were used: 1.235 for α crystals and 1.190 for γ crystals, which are averages of published data[4–6].

By the least squares method we calculated the single
Figure 2 Corrected calibration curve considering the amorphous crystallization after T_g

upper line shown in *Figure 1*. We assumed that ΔH_f values for α and γ forms are practically identical; with this assumption the plot is valid whatever the crystal composition of any sample. *Figure 1* shows that the calibration line does not pass through the origin but cuts the ordinate axis at a value of $\Delta H_f = 5.20$ cal/g. This same observation was made by Illers[1], who explained it by assuming the existence of some ordered structures in the amorphous phase. This is probably true for their samples, which were quenched, after melting, in carbon tetrachloride at 0°C. Our samples, quenched at a much lower temperature, suggest a better explanation, i.e. to assume a slow crystallization of the sample during heating in the calorimeter. Polyamides-6 can easily crystallize owing to their low T_g values. Crystallization is known to occur immediately above T_g and is put into evidence by an exothermic peak but the phenomenon probably takes place even after this peak, until the polymer melts; this is not easily shown being included in the base line. This effect produces values of ΔH_f which are 20–30% higher than those expected from the crystallinity of the original samples. Since, however, ΔH_f values have been correlated with degrees of crystallinity measured by density values, the plot of *Figure 1* is still good for the purpose we wanted.

As an indication of the correctness of our hypothesis, we can assume that the amount of crystallinity introduced into the sample on heating is proportional to the original amorphous content; by multiplying this value for 5.2 cal/g and subtracting this quantity from the measured ΔH_f, we obtain a new line, shown in *Figure 2*, which passes through the origin.

A new catalytic system for the polymerization of THF

H. W. Siesler* and B. Tittle

Department of Chemistry, University of the Witwatersrand, Jan Smuts Avenue, Johannesburg, South Africa
(Received 23 December 1974)

INTRODUCTION

The polymerization of tetrahydrofuran (THF) with various catalytic systems has been studied by many workers[1-4]. THF polymerizes by a cationic mechanism with the initial formation of an oxonium ion and successive nucleophilic attack of monomer oxygen on the carbon atom in α-position to the positive oxygen[5]. The influence of various catalysts, solvents and reaction temperatures on the physical and chemical properties of polytetrahydrofuran (PTHF) has been discussed in numerous publications[6-8].

Here we wish to report the preparation and the results obtained in THF polymerization by a so far unreported catalyst system.

A literature report[9] indicates that phosphorus tricyanide, $P(CN)_3$, when isolated from the reaction mixture of phosphorus trichloride, $P(Cl)_3$, with silver cyanide, AgCN, in acetonitrile is initially white and that on standing the product changes from white through yellow to orange. These authors[9] state that the colour change did not affect the reactions of $P(CN)_3$ which they were studying. We find that $P(CN)_3$ in this orange–yellow form is an active catalyst for the bulk polymerization of THF to high molecular weight products. Although the exact nature of the catalyst species has not yet been illucidated, we have demonstrated that the change from white to orange form only occurs in the solid state when residual acetonitrile is present.

$P(CN)_3$ has been shown to exist as a dimer in acetonitrile solution[10]. Although acetonitrile is tenaciously retained by $P(CN)_3$ on isolation, no definite stoichiometry could be detected and sublimation or prolonged evacuation will remove the last traces of solvent. $P(CN)_3$ purified by vacuum sublimation and shown by mass spectrometry not to contain acetonitrile does not catalyse the polymerization and no change on standing in a sealed vessel to the active form occurs. Similarly complete removal of acetonitrile under high vacuum when isolating $P(CN)_3$ produces a product which does not revert to the orange active form. On prolonged exposure to the atmosphere a brown product is obtained which, even in the presence of residual acetonitrile, does not act as catalyst in the polymerization reaction and is the result of hydrolysis of the $P(CN)_3$.

In view of the uncertainty in the elemental analysis results owing to the hygroscopic nature of the catalyst we do not attempt to propose a mechanism and the nature of the ions involved in the initiation step of the polymerization. Notwithstanding this uncertainty in the exact composition of the catalyst system it can be derived from our observations that residual acetonitrile is a necessary cocatalyst.

EXPERIMENTAL

Preparation of catalyst

$P(CN)_3$ was prepared by adding 5 g of $P(Cl)_3$ in 20 ml acetonitrile (dried over P_2O_5 and distilled) to 15 g of AgCN

vigorously stirred in 200 ml of acetonitrile under dry nitrogen. After 2 h at room temperature the product was filtered under nitrogen and the acetonitrile was removed on a rotary evaporator with a bath temperature of 45°C. When a solid residue was obtained, air was admitted and the flask stoppered. On standing for 24 h the change from white to orange form occurred. This product was used in the polymerization studies.

Preparation of polymer

Previous to its use in the polymerization reaction THF (predried over KOH) was distilled from sodium and collected over molecular sieve. To 4 ml (~50 mmol) THF approximately 0.1 g of the above-mentioned catalyst was added and the mixture was shaken at room temperature. Within a few minutes the yellow colour of the solution intensified and concomitantly the viscosity increased until the original solution solidified to a transparent yellow–brown solid after about 1 h. After standing for 2 days the reaction mixture was dissolved in 100 ml THF and the polymer was precipitated by adding this solution dropwise to 1 l of ice-cold water in a high speed blender. The polymer precipitated as white rubbery solid which accumulated mainly on the stirrer blades.

The dissolution and precipitation operations were repeated and the yield of white tough product, finally dried in the vacuum oven at 25°C for 48 h varied between 43 and 54% in different experiments.

CHARACTERIZATION OF THE POLYMER

The intrinsic viscosity $[\eta]$ determined in chlorobenzene as solvent at 30°C scattered between 0.75 and 1.0 dl/g for products obtained in a series of 6 experiments. In a previous paper Makletsova *et al.* have published their results of viscosity and light scattering studies on PTHF[11]. Applying their relationship between the intrinsic viscosity (measured in methyl ethyl ketone and chlorobenzene solutions respectively) and molecular weight $\bar{M}_w$ of PTHF:
$[\eta] = 2.1 \times 10^{-3} M^{0.5}$, we derive molecular weights ranging from 130 000 to 230 000 in our products. The elemental analysis of the polymer (*Table 1*) is in good agreement with the theoretical values for PTHF. A thermogram of the polymer by differential scanning calorimetry showed an endotherm at the crystalline melting point between 37 and 44°C. For the i.r. spectroscopic investigation 40 mg of polymer were dissolved in 5 ml dry benzene and part of the solution was spread evenly on a KBr disc. The solvent was evaporated in a vacuum oven at 50°C for 48 h. The i.r. spectra of the sample recorded at 50°C and after recrystallization for a week at 20°C were identical to those of amorphous and crystalline PTHF[12].

Table 1 Elemental analysis of PTHF, $[(CH_2)_4{-}O]_n$

	C (%)	H (%)	O (%)
Exp.	66.3	11.2	22.3
Calc.	66.7	11.1	22.2

* Present address: Bayer AG, Werk Dormagen, Postfach 1140 D 4047 Dormagen, West Germany.

In conclusion we may say that experimental evidence proves that application of the catalyst under investigation yields crystalline high molecular weight products in the bulk polymerization of THF at room temperature.

Observations of craze structure in bisphenol A polycarbonate

During the course of work concerned with the effect of crazes on the quality of performance of polycarbonate material, it became desirable to be able to examine the structure of a craze. This letter describes the means by which this has been achieved.

Many techniques have been used to study craze structure in glassy polymers. A popular and useful technique has been transmission electron microscopy of thin films, sections, or replicas from bulk specimens. Good examples of the use of these techniques have been described by Kambour[1], and Beahan et al.[2]. The transmission electron microscope used in their work enables high magnifications to be obtained (~250 000 x), but requires a lot of sample preparation and restricts the type of specimen which can be observed. The scanning electron microscope (stereoscan) enables thick specimens of crazed polymer to be observed without sectioning or replication. The specimen merely needs to be coated with a thin conducting metal layer to prevent it charging in the electron beam. However, although the crazes can be seen, the detailed structure within the craze is often obscured. A typical craze observed by this method is seen in *Figure 1a*. In the work now reported

Figure 2 Craze shown in *Figure 1b* but with application of stress to the specimen (4100x)

the specimen has been fractured in a brittle manner across the crazing, at right angles to the direction of craze growth. This enables the structure through the depth of the crazes to be examined.

The crazes examined to data by this method have been formed by the action of ethanol and n-propanol on polycarbonate specimens under stress. Large crazes were grown in specimens cut from compression-moulded sheet (thickness 0.8 mm), by the application of tensile stress in a bench-mounted jig, and the chosen environment. The specimens were then notched with a sharp blade, cooled to liquid nitrogen temperatures, and fractured perpendicular to the craze growth direction by rapid flexure. The sample thus obtained was then mounted on a straining device fitted to a stereoscan stub, coated with a thin metal film, and the exposed craze cross-section examined in the stereoscan.

Figure 1b shows a craze formed by the action of n-propanol under a strain of ~2.0% (part of the original specimen surface is also shown). The craze exhibits V-shaped bridging with a central discontinuity. It is probable that
Figure 3 Craze shown in *Figures 1b* and *2* after strain removal (4100x)
Figure 4 Typical craze in bisphenol A polycarbonate formed by action of ethyl alcohol (1640x)
Figure 5 About 4% strain applied to the specimen seen in *Figure 4*. (a) 1640x; (b) 4100x

some details have been modified by the fracture process, and by relaxation of the craze structure. However, the general appearance of the material would correspond to that found in the craze interior prior to fracture. This craze is about 8 μm in width and the fibrils are 0.2–0.5 μm thick. *Figure 2* shows this craze upon the application of stress to the specimen. The overall strain on the specimen was 2–3%, and the craze has increased in width by about 10%, hence the craze material is seen to elongate more than the bulk; this agrees with previous work[3]. The structure gives the appearance of having been pulled taut, and cracks have started to form; these are probably caused by the action of the electron beam. *Figure 3* shows the craze in *Figures 1b* and *2* after strain removal. The structure has clearly been severely affected, and the craze has narrowed somewhat (~5%) compared to the original.

Figure 4 shows a craze formed in ethanol under similar conditions to the previous example. The structure, however, appears to be of a considerably different form, and

the craze is also somewhat wider at ~17 μm. The fibrils appear to be more densely packed, more extended, and there is a prominent ridge of material running down the craze. Additionally, there appear to be smaller fibrils connecting the transverse structure in a similar way to that observed by Beahan *et al.*[2]. Applying strain to this craze, as before, produced little effect at first. Under similar conditions as applied to the craze in *Figure 2*, the only observable change was a very slight widening of the craze. On applying further strain (to the limit of the device used — about 4%) some breakdown of the structure was observed as shown in *Figures 5a* and *5b*. It appears that the material in the ridge has undergone some kind of tearing; the thin fibrils do not seem to be much affected. The bulk material surrounding the craze also seems to have been torn, perhaps illustrating the strength of this type of craze.

Thus it is seen that this technique enables craze structure to be observed with the minimum of sample preparation, and preliminary observations of the effects of strain so far

carried out show that different craze structures can have very different physical properties.

Book Reviews

Blood compatible synthetic polymers: an introduction
S. D. Bruck
C. C. Thomas, Springfield, 1974, 131 pp. $9.75

The field of biomedical polymers is receiving increasing attention from workers in medical engineering and Dr Bruck has set out to provide a short introductory guide for people of all disciplines, be they physicians, engineers, life or materials scientists involved in the development and use of devices which come into direct contact with blood. What it is that makes some synthetic materials more tolerated by the living environment than others is still the subject of much speculation and consequently this monograph deals only briefly with its principal subject matter, giving a summary of the more promising materials found to date which demonstrate a degree of biocompatibility with blood while discussing the attributes mainly associated with a material's surface which might be responsible for the effect.

Understandably the bulk of the text is taken up with a review of polymeric materials and their many chemical, physical and mechanical properties. The emphasis here is on a direct comparison between synthetic and naturally-occurring macromolecules and on those properties which render the former suitable for use in biomedical applications and which might have a bearing on the various theories of blood compatibility.

Additionally, the author has contributed a useful presentation on the composition of blood and its working environment. This serves to highlight the many vital factors which can either influence or be influenced by the presence of a foreign material. For example, the influence of chemical, physical and mechanical action on the blood's defensive mechanisms are exemplified in relation to the blood coagulation pathways.

The current rate of advance in biomaterials science is such that one can anticipate the appearance of a more comprehensive treatise in the near future. This relatively inexpensive book provides a useful insight into the present state of the art and as the performance requirements expected of synthetic biomaterials increase it will serve to encourage the move from intuitive selection towards the synthesis of macromolecules designed to exist at the interface between a device and both the cellular and non-cellular components of blood.

It must be remembered, however, that while efforts have been made to relate blood compatibility of material to the composition of of that material, the final analysis must take account of the application and the physical form.

Polymer—plastics technology and engineering
Edited by Louis Naturman
Marcel Dekker, New York, Vol 2, 1974. 262 pp. $25.50

In order to better reflect the broadening of its subject matter in years to come, particularly in the polymer processing and application fields, the *Journal of Macromolecular Science (D: Reviews in Polymer Technology)* has changed its title to *Polymer — Plastics Technology and Engineering*, it being intended that a series of publications be arranged, on the basis of two issues per volume, providing timely intensive reviews of the state of the art in various branches of polymer technology and engineering.

Volume 2 presents papers on controlled u.v. degradation of plastics, metal plating of polymeric surfaces, fracture of polymers and polyblends, cationic coupling agents for thermoplastics, drilling of multi-layer printed boards, review of properties of polycarbonate resins, pressure sensitive adhesives, and impact behaviour of polymeric foams.

This particular volume in the series, in terms of its value to research and development workers, is difficult to assess there being wide variation in standards between individual authors. For instance the chapter on controlled u.v. degradation contains important open literature and patent material not previously published in a collected form. An example would be the key additives used to promote controlled polymer degradation namely, and unexpectedly, dibutyl dithiocarbonate salts, iron stearate, are listed alongside known polymer pro-oxidants based on copper, manganese, cobalt, and chromium salts. Such and similar data are undoubtedly very useful to newcomers and experienced workers. In like category are the chapters on drilling of multi-layer printed circuit boards, metal plating, pressure sensitive adhesives, and these alone would possibly justify the volume to specialized readers. Against these benefits some of the other chapters, listed above, have in various forms, featured elsewhere in the new voluminous polymer technology literature.

These criticisms may, of course, diminish as the series grows, the reviewer recognizing the considerably editorial problems initially in attracting new technology material written to adequate scientific standards. Change there should be if the present aims of intensive timely reviews are to be realized and, given such improvements, this series would find a place in the libraries and reference rooms of most research and tertiary educational institutions concerned with polymer technology.

Book binding, paper, printing and type-setting are of adequate quality and the price normal by present day standards for what

Polymer—plastics technology and engineering
Edited by Louis Naturman
Marcel Dekker, New York, Vol 2, 1974. 262 pp. $25.50

In order to better reflect the broadening of its subject matter in years to come, particularly in the polymer processing and application fields, the *Journal of Macromolecular Science (D: Reviews in Polymer Technology)* has changed its title to *Polymer — Plastics Technology and Engineering*, it being intended that a series of publications be arranged, on the basis of two issues per volume, providing timely intensive reviews of the state of the art in various branches of polymer technology and engineering.

Volume 2 presents papers on controlled u.v. degradation of plastics, metal plating of polymeric surfaces, fracture of polymers and polyblends, cationic coupling agents for thermoplastics, drilling of multi-layer printed boards, review of properties of polycarbonate resins, pressure sensitive adhesives, and impact behaviour of polymeric foams.

This particular volume in the series, in terms of its value to research and development workers, is difficult to assess there being wide variation in standards between individual authors. For instance the chapter on controlled u.v. degradation contains important open literature and patent material not previously published in a collected form. An example would be the key additives used to promote controlled polymer degradation namely, and unexpectedly, dibutyl dithiocarbonate salts, iron stearate, are listed alongside known polymer pro-oxidants based on copper, manganese, cobalt, and chromium salts. Such and similar data are undoubtedly very useful to newcomers and experienced workers. In like category are the chapters on drilling of multi-layer printed circuit boards, metal plating, pressure sensitive adhesives, and these alone would possibly justify the volume to specialized readers. Against these benefits some of the other chapters, listed above, have in various forms, featured elsewhere in the new voluminous polymer technology literature.

These criticisms may, of course, diminish as the series grows, the reviewer recognizing the considerably editorial problems initially in attracting new technology material written to adequate scientific standards. Change there should be if the present aims of intensive timely reviews are to be realized and, given such improvements, this series would find a place in the libraries and reference rooms of most research and tertiary educational institutions concerned with polymer technology.

Book binding, paper, printing and type-setting are of adequate quality and the price normal by present day standards for what

must be a limited and specialized market. Somewhat brief author and subject indexes are provided and regretfully but expectedly as this is a USA publication, imperial units predominate. This volume could usefully be referred by both chemists, physicists and engineers the writing style being suitable for most technically orientated people from diverse backgrounds.

C. Hepburn

Hot melt adhesives: manufacture and application
M. J. Satriana
Noyes Data Corporation, Park Ridge, NJ, 1974, $36.00

This review of the US Patent literature relevant to the field of interest accurately described in the title immediately wins the heart of anyone who has had to try to extract the important information from an official patent document. The author has done an expert job in transposing such documents into a text comprehensible to the adhesives technologist for whom one presumes the book is primarily intended. The reader is left in little doubt that Mr Satriana, like the other Noyes Data Corporation authors, is well versed in this art.

It is believed that anyone in the adhesives industry should have access to this book since it succeeds in achieving one of the objectives in the foreword in describing a very wide area of available hot melt adhesive technology which should stimulate ideas in the reader and lead to technological transfer between the diverse industries which use adhesives.

The patents described cover such a wide field of adhesive use that one hesitates to make too general comments, but extrapolating from familiar fields then the book gives the impression of a vast store of adhesives technology which has not been made use of practically.

The book is well produced and is intended to earn its keep; however, the small print does not suit lengthy periods of reading for any, but the most accommodating eyes.

The book is expensive since one would have thought that the production processes claimed to have been chosen to give rapid publication (and no doubt responsible for the print style) might have been expected to have resulted in a lower cost production. However, if one accounts for the time saved in reading lengthy patent documents then the book is well worth its price to the busy technologist.

No claim is made for the degree of coverage achieved by the book and its performance in this respect is difficult to judge but the reviewer is aware of a number of patents in his own field which have not been referred to.

I would recommend any adhesives technologist to read this book whether he is involved directly in hot melts or not, but I do feel that the book would be of increased value if the extensive contents list had been supplemented by an alphabetical subject index.

Conference Announcement

Canadian High Polymer Forum

Hamilton, Ont., 20–22 August 1975

The 18th Canadian High Polymer Forum will be held at McMaster University, Hamilton, Ontario from 20 to 22 August 1975 and will cover all aspects of polymer science. It will be sponsored by the Macromolecular Science Division of the Canadian Chemical Society and the Division of Polymer Chemistry of the ACS. Further details may be obtained from Dr J. Prud'homme, Secretary-Treasurer 18th Canadian High Polymer Forum, Department of Chemistry, University of Montreal, PO Box 6210, Montreal, Quebec, Canada.

Mechanical properties of polymers and composites
Lawrence E. Nielsen
Marcel Dekker, New York, 1974. Vol 1: 255 pp. $24.50. Vol 2: 231 pp. $28.75

This book is one of the few truly comprehensive accounts of mechanical properties of polymers and composites. In addition, it includes elements of current research ideas and activities. It is intended for both the non-specialist scientist who may require a grasp of properties for engineering design and for the polymer scientist embarking on a detailed investigation of some particular aspect. Both these aims are satisfied, although the non-specialist will gain more from the material selection and concise description than the potential specialist who might suffer from an absence of critical account. (The specialist, however, will benefit enormously from the many thousands of well indexed literature references.)

The contents of the book are intended to cover the general mechanical behaviour of polymers to both environmental and structural factors, together with a broad account of composite properties. These aims are achieved, especially as there are chapters on mechanical tests and polymer transitions, elastic moduli, creep and stress relaxation, dynamic mechanical properties, stress–strain behaviour and strength, particulate-filled polymers, fibre-filled composites and other composites and other mechanical properties. In addition each chapter includes a useful summary and a section on problems (without answers).

The writing style is lively and lucid, although the print presentation is poor. The book is in two volumes and can only be recommended as a whole, particularly as several helpful appendixes and the author and subject indexes only appear in the second volume. The cost of the complete book is over £20. This is a formidable cost but on balance the book is good value for money, mainly because the eminent Nielsen has cleverly and creatively compiled the right material.

D. R. Moore

Injection moulding of rubber
M. A. Wheelans
Newnes–Butterworths, London, 1974, 241 pp. £6.75

The start of the book is somewhat disappointing since the first chapter is a comprehensive review of the history of injection moulding comprising some 208 references! However, it is not long before the practical knowledge of the author and the resources of MRPRA become evident. The effects of various machine parameters are detailed and this is followed by a chapter on rubber compound design: the comment might here be made that a certain bias towards natural rubber can be detected. Examples of injection moulding are given complete with photographs in many cases, and details of machines and machine settings. A short but very practical troubleshooting guide follows and the book concludes with a chapter on the economics of injection moulding, incorporating criticisms of previous authors on this complex subject.

The book is well written and the reviewer's interest was revived once the first chapter was over and the more practical aspects were being described. The typescript can best be denoted as 'imitation typewritten characters' which are not easy to read, and unfortunately the notes beneath some of the tables tend to merge with the text. Examples of this are to be found on pp 83, 101 and 169. Nine items of errata were supplied with the book, and apart from a misprint in the last full paragraph of p 7 and the omission of a reference (41) to Geschwind on p 74, the reviewer did not find any other mistakes. The index appears to be adequate to enable the reader to refer quickly to important passages.

It is a pity, however, that the author has not included some of the recently published work on thermosetting resins and thermoplastics with regard to processing variables and mould design. This work is very relevant to the injection moulding of rubbers and mention of it would have helped the reader to appreciate that in many ways the processing behaviour of rubber is not so different from that of plastics, with which he may be more familiar. With this exception, the book is a very complete guide to the subject and can safely be recommended to students of rubber technology, experienced rubber technologists and engineers, even those of the latter category who have not previously been involved in the production of rubber articles. The binding is attractive and the book is well worth the price for the information it contains.

Blood compatible synthetic polymers: an introduction
S. D. Bruck
C. C. Thomas, Springfield, 1974, 131 pp. $9.75

The field of biomedical polymers is receiving increasing attention from workers in medical engineering and Dr Bruck has set out to provide a short introductory guide for people of all disciplines, be they physicians, engineers, life or materials scientists involved in the development and use of devices which come into direct contact with blood. What it is that makes some synthetic materials more tolerated by the living environment than others is still the subject of much speculation and consequently this monograph deals only briefly with its principal subject matter, giving a summary of the more promising materials found to date which demonstrate a degree of biocompatibility with blood while discussing the attributes mainly associated with a material's surface which might be responsible for the effect.

Understandably the bulk of the text is taken up with a review of polymeric materials and their many chemical, physical and mechanical properties. The emphasis here is on a direct comparison between synthetic and naturally-occurring macromolecules and on those properties which render the former suitable for use in biomedical applications and which might have a bearing on the various theories of blood compatibility.

Additionally, the author has contributed a useful presentation on the composition of blood and its working environment. This serves to highlight the many vital factors which can either influence or be influenced by the presence of a foreign material. For example, the influence of chemical, physical and mechanical action on the blood's defensive mechanisms are exemplified in relation to the blood coagulation pathways.

The current rate of advance in biomaterials science is such that one can anticipate the appearance of a more comprehensive treatise in the near future. This relatively inexpensive book provides a useful insight into the present state of the art and as the performance requirements expected of synthetic biomaterials increase it will serve to encourage the move from intuitive selection towards the synthesis of macromolecules designed to exist at the interface between a device and both the cellular and non-cellular components of blood.

It must be remembered, however, that while efforts have been made to relate blood compatibility of material to the composition of of that material, the final analysis must take account of the application and the physical form.

Polymer–plastics technology and engineering
Edited by Louis Naturman
Marcel Dekker, New York, Vol 2, 1974. 262 pp. $25.50

In order to better reflect the broadening of its subject matter in years to come, particularly in the polymer processing and application fields, the *Journal of Macromolecular Science (D: Reviews in Polymer Technology)* has changed its title to *Polymer – Plastics Technology and Engineering*, it being intended that a series of publications be arranged, on the basis of two issues per volume, providing timely intensive reviews of the state of the art in various branches of polymer technology and engineering.

Volume 2 presents papers on controlled u.v. degradation of plastics, metal plating of polymeric surfaces, fracture of polymers and polyblends, cationic coupling agents for thermoplastics, drilling of multi-layer printed boards, review of properties of polycarbonate resins, pressure sensitive adhesives, and impact behaviour of polymeric foams.

This particular volume in the series, in terms of its value to research and development workers, is difficult to assess there being wide variation in standards between individual authors. For instance the chapter on controlled u.v. degradation contains important open literature and patent material not previously published in a collected form. An example would be the key additives used to promote controlled polymer degradation namely, and unexpectedly, dibutyl dithiocarbonate salts, iron stearate, are listed alongside known polymer pro-oxidants based on copper, manganese, cobalt, and chromium salts. Such and similar data are undoubtedly very useful to newcomers and experienced workers. In like category are the chapters on drilling of multi-layer printed circuit boards, metal plating, pressure sensitive adhesives, and these alone would possibly justify the volume to specialized readers. Against these benefits some of the other chapters, listed above, have in various forms, featured elsewhere in the new voluminous polymer technology literature.

These criticisms may, of course, diminish as the series grows, the reviewer recognizing the considerably editorial problems initially in attracting new technology material written to adequate scientific standards. Change there should be if the present aims of intensive timely reviews are to be realized and, given such improvements, this series would find a place in the libraries and reference rooms of most research and tertiary educational institutions concerned with polymer technology.

Book binding, paper, printing and type-setting are of adequate quality and the price normal by present day standards for what

must be a limited and specialized market. Somewhat brief author and subject indexes are provided and regretfully but expectedly as this is a USA publication, imperial units predominate. This volume could usefully be referred by both chemists, physicists and engineers the writing style being suitable for most technically orientated people from diverse backgrounds.

C. Hepburn

Hot melt adhesives: manufacture and application
M. J. Satriana
Noyes Data Corporation, Park Ridge, NJ, 1974, $36.00

This review of the US Patent literature relevant to the field of interest accurately described in the title immediately wins the heart of anyone who has had to try to extract the important information from an official patent document. The author has done an expert job in transposing such documents into a text comprehensible to the adhesives technologist for whom one presumes the book is primarily intended. The reader is left in little doubt that Mr Satriana, like the other Noyes Data Corporation authors, is well versed in this art.

It is believed that anyone in the adhesives industry should have access to this book since it succeeds in achieving one of the objectives in the foreword in describing a very wide area of available hot melt adhesive technology which should stimulate ideas in the reader and lead to technological transfer between the diverse industries which use adhesives.

The patents described cover such a wide field of adhesive use that one hesitates to make too general comments, but extrapolating from familiar fields then the book gives the impression of a vast store of adhesives technology which has not been made use of practically.

The book is well produced and is intended to earn its keep; however, the small print does not suit lengthy periods of reading for any, but the most accommodating eyes.

The book is expensive since one would have thought that the production processes claimed to have been chosen to give rapid publication (and no doubt responsible for the print style) might have been expected to have resulted in a lower cost production. However, if one accounts for the time saved in reading lengthy patent documents then the book is well worth its price to the busy technologist.

No claim is made for the degree of coverage achieved by the book and its performance in this respect is difficult to judge but the reviewer is aware of a number of patents in his own field which have not been referred to.

I would recommend any adhesives technologist to read this book whether he is involved directly in hot melts or not, but I do feel that the book would be of increased value if the extensive contents list had been supplemented by an alphabetical subject index.

D. Pettit

Mechanical properties of polymers and composites
Lawrence E. Nielsen
Marcel Dekker, New York, 1974. Vol 1: 255 pp. $24.50. Vol 2: 231 pp. $28.75

This book is one of the few truly comprehensive accounts of mechanical properties of polymers and composites. In addition, it includes elements of current research ideas and activities. It is intended for both the non-specialist scientist who may require a grasp of properties for engineering design and for the polymer scientist embarking on a detailed investigation of some particular aspect. Both these aims are satisfied, although the non-specialist will gain more from the material selection and concise description than the potential specialist who might suffer from an absence of critical account. (The specialist, however, will benefit enormously from the many thousands of well indexed literature references.)

The contents of the book are intended to cover the general mechanical behaviour of polymers to both environmental and structural factors, together with a broad account of composite properties. These aims are achieved, especially as there are chapters on mechanical tests and polymer transitions, elastic moduli, creep and stress relaxation, dynamic mechanical properties, stress—strain behaviour and strength, particulate-filled polymers, fibre-filled composites and other composites and other mechanical properties. In addition each chapter includes a useful summary and a section on problems (without answers).

The writing style is lively and lucid, although the print presentation is poor. The book is in two volumes and can only be recommended as a whole, particularly as several helpful appendixes and the author and subject indexes only appear in the second volume. The cost of the complete book is over £20. This is a formidable cost but on balance the book is good value for money, mainly because the eminent Nielsen has cleverly and creatively compiled the right material.

D. R. Moore

Injection moulding of rubber
M. A. Wheelans
Newnes—Butterworths, London, 1974, 241 pp. £6.75

The start of the book is somewhat disappointing since the first chapter is a comprehensive review of the history of injection moulding comprising some 208 references! However, it is not long before the practical knowledge of the author and the resources of MRPRA become evident. The effects of various machine parameters are detailed and this is followed by a chapter on rubber compound design: the comment might here be made that a certain bias towards natural rubber can be detected. Examples of injection moulding are given complete with photographs in many cases, and details of machines and machine settings. A short but very practical troubleshooting guide follows and the book concludes with a chapter on the economics of injection moulding, incorporating criticisms of previous authors on this complex subject.

The book is well written and the reviewer's interest was revived once the first chapter was over and the more practical aspects were being described. The typescript can best be denoted as 'imitation typewritten characters' which are not easy to read, and unfortunately the notes beneath some of the tables tend to merge with the text. Examples of this are to be found on pp 83, 101 and 169. Nine items of errata were supplied with the book, and apart from a misprint in the last full paragraph of p 7 and the omission of a reference (41) to Geschwind on p 74, the reviewer did not find any other mistakes. The index appears to be adequate to enable the reader to refer quickly to important passages.

It is a pity, however, that the author has not included some of the recently published work on thermosetting resins and thermoplastics with regard to processing variables and mould design. This work is very relevant to the injection moulding of rubbers and mention of it would have helped the reader to appreciate that in many ways the processing behaviour of rubber is not so different from that of plastics, with which he may be more familiar. With this exception, the book is a very complete guide to the subject and can safely be recommended to students of rubber technology, experienced rubber technologists and engineers, even those of the latter category who have not previously been involved in the production of rubber articles. The binding is attractive and the book is well worth the price for the information it contains.

S. H. Morrell

Gel permeation chromatography: universal calibration for rigid rod and random coil polymers

J. V. Dawkins* and Malcolm Hemming†

ICI Corporate Laboratory, The Heath, Runcorn, Cheshire, WA7 4QE, UK
(Received 27 June 1974; revised 11 November 1974)

The g.p.c. behaviour of poly(γ-benzyl-L-glutamate) (PBLG) samples, polystyrene standards and poly(2-vinyl pyridine) has been examined in *N,N*-dimethylacetamide (DMA) at 80°C. Solution viscosity measurements show that DMA is a good solvent for the flexible random coil polystyrene and that it promotes a helical rigid-rod shaped PBLG. Comparison of polystyrene and poly(2-vinyl pyridine) confirms that polystyrene separates strictly according to steric exclusion and that polymer/ gel interactions are not involved. A PBLG calibration curve predicted from the polystyrene calibration by the $[\eta]M$ universal calibration procedure was used to calculate average molecular weight and M_{peak} data from the PBLG chromatograms. The calculated $\overline{M}_v$ values are in good agreement with experimental data. Plots of log $[\eta]M_{peak}$ against retention volume for PBLG and polystyrene were coincident. These results suggest that the product $[\eta]M$ is a valid universal calibration parameter for PBLG and polystyrene which have significantly different shapes. Comparison of theoretical equations relating the diameter of polystyrene hydrodynamic spheres to the half-length of PBLG helices suggests that the parallel-plane model may be a useful mathematical representation of pore geometry.

INTRODUCTION

Column chromatography separations with porous cross-linked organic gels are now of major importance in characterizing natural and synthetic polymers[1]. The dependence of retention volume V_R on solute size may be represented by the standard chromatography equation

$$V_R = V_0 + K_D V_i \tag{1}$$

where V_0 is the volume of mobile phase (interstitial volume) and V_i is the volume of stationary phase (volume of solvent within gel pores). The distribution coefficient K_D determines the fraction of V_i accessible to a solute of given size. The dependence of K_D on solute size and the pore size distribution may be calculated assuming a steric exclusion separation mechanism which is controlled by the loss in conformational entropy when a solute transfers from the mobile phase to a pore. Theoretical expressions for K_D have been given in terms of the mean external length for rigid biopolymers[2] and in terms of the radius of gyration for random coil polymers[3]. Experimental observations have suggested that the separation is determined by the hydrodynamic volume of the solute. Thus, the separation of globular proteins in aqueous solution can be predicted from the Stokes radii of rigid spheres[4], whilst the separation of linear and branched homopolymers and copolymers in tetrahydrofuran is predicted by representing these random coils as impermeable hydrodynamic spheres[5].

In order to rationalize theory and experiment, separations with polymers having different shapes are required, since hydrodynamic behaviour, as judged by dilute solution viscosity[6], is markedly influenced by solute geometry. Gel permeation chromatography (g.p.c.) with crosslinked polystyrene gels was developed for separations of synthetic polymers in organic solvents[7]. Very few synthetic high polymers have non-spherical conformations in organic media but poly(γ-benzyl-L-glutamate) (PBLG) exists as an α-helix in the solid state and retains a rigid rod conformation when dissolved in some organic solvents, e.g. *N,N*-dimethylformamide (DMF) and *m*-cresol. However, the choice of solvent is exceedingly critical. Thus, very polar solvents disrupt the helix-stabilizing intramolecular hydrogen bonds, whilst solvents less polar than DMF do not prevent intermolecular PBLG association[6].

Grubisic *et al.*[8] compared the g.p.c. separation of PBLG samples and polystyrene (PS) standards in DMF with crosslinked polystyrene gels. They suggested that both polymers fell on the same curve of log $[\eta]M$ versus V_R, where $[\eta]$ is intrinsic viscosity and M is molecular weight. However, their PBLG samples had relatively broad molecular weight distributions with the ratio of the weight-average to number-average molecular weight $\overline{M}_w/\overline{M}_n$ lying between 1.3 and 1.6. Therefore, the PBLG values of $[\eta]M$ will depend on the average molecular weight chosen. Furthermore, subsequent g.p.c. studies[9-11] have suggested that DMF is not entirely satisfactory for PS separations on crosslinked polystyrene gel, because V_R is higher than expected from a steric exclusion mechanism. This behaviour is due to solute–gel interactions which influence the separation of PS in poor and theta solvents with crosslinked polystyrene gels[12,13]. Then, V_R is given by

$$V_R = V_0 + K_D K_p V_i \tag{2}$$

where K_p is a distribution coefficient representing the retardation of PS in the stationary phase due to solute–gel interactions ($K_p > 1.0$). PS separates solely by steric exclusion ($K_p = 1.0$) only when the exponent α in the Mark–Houwink equation:

$$[\eta] = KM^\alpha \qquad (3)$$

exceeds 0.65. PS in DMF over the temperature range 20–80°C has α values in the range 0.60–0.64[9–11,14–17]. Although Grubisic et al.[8] did not specify their g.p.c. separation temperature, it is unlikely to be above 80°C.

In this paper the relationship between $\log[\eta]M$ and V_R is reported for g.p.c. separations of PBLG samples and PS standards in N,N-dimethylacetamide (DMA) with cross-linked polystyrene gels at 80°C. The results are related to the solute size dependence of K_D in equation (1). Particular attention has been paid to the following points. The molecular weight at the peak of a gel permeation chromatogram (M_{peak}) for PBLG samples was calculated by the procedure developed by Frank et al.[18,19]. In order to demonstrate the absence of solute–gel interactions, g.p.c. separations of poly(2-vinyl pyridine) (PVP) and PS were compared (PVP is a random coil polymer having a similar molecular size to PS and a similar polarity to PBLG and DMA). Dilute solution viscosity measurements were performed in order to show that DMA is a good solvent for PS ($\alpha = 0.68$) at 80°C, that high molecular weight PBLG has a rigid rod conformation ($\alpha = 1.75$) in DMA, and that PBLG does not associate in DMA (Huggins constant, $k' \sim 0.5$).

BACKGROUND TO SOLUTION VISCOSITY

The dilute solution viscosity behaviour of macromolecules may be represented by the Einstein–Simha equation:

$$[\eta] = \gamma \frac{NV_h}{M} \qquad (4)$$

where V_h is the hydrodynamic volume, N is Avogadro's number whilst $[\eta]$ (dl/g) and M are as defined previously. The Simha parameter γ is constant (0.025) for spheres but varies with the molecular weight of non-spherical macromolecules. For a prolate ellipsoid having axial ratio $p = a/b$, where a and b are respectively the semi-major and semi-minor axes, the increase in the value of γ with augmenting p has been derived by Simha[20] and expressed graphically by Tanford[21]. For small values of p the graph is curved but for p greater than about 50 (corresponding to PBLG molecular weights greater than approximately 10^5), γ and (a/b) are linearly related by:

$$\gamma = 0.14\left(\frac{a}{b}\right)^{1.8} \qquad (5)$$

In order to convert equation (4) into a form suitable for cylindrical rigid rods[6], the volume ($4\pi ab^2/3$) and length ($2a$) of a prolate ellipsoid are equated respectively with the volume ($\pi d^2 L/4$) and length (L) of a cylinder having diameter d. Substituting in equation (4) gives:

$$[\eta] = 4.58 \times 10^{22} d^{0.2} L^{2.8} \frac{1}{M} \qquad (6)$$

Then replacing L by Mh/m, where h is the length per repeat unit of molecular weight m, and remembering that d is constant for a homologous series of cylindrical molecules leads to:

$$[\eta] = K'M^{\alpha'} \qquad (7)$$

This equation resembles the Mark–Houwink viscosity relationship (3), but the value of the exponent α' (1.8) is much larger than for spherical macromolecules ($\alpha = 0.5$ to 0.8). Also the constant K' for rigid rods is fundamentally different from and numerically smaller than K values for spheres. The form of equation (4) for random coil polymers is:

$$[\eta] = 0.025N \; \frac{4\pi}{3}\left(\frac{D}{2}\right)^3 \frac{1}{M} \qquad (8)$$

where D is the diameter of the rigid equivalent hydrodynamic sphere which increases solution viscosity by the same amount as the flexible random coil.

It has been shown[22–24] that the dilute solution viscosity behaviour of high molecular weight PBLG ($M > 5 \times 10^4$) in solvents of suitable polarity follows equation (7) with $\alpha' = 1.7$. This suggests that the rigid cylindrical α-helix, characteristic of the solid state[25,26] persists in solution. For PBLG molecular weights lower than 5×10^4, α' gradually decreases towards 0.8 as predicted by Simha[20] and Tanford[21].

EXPERIMENTAL

Materials

The narrow distribution PS standards were supplied by Pressure Chemical Company, Pittsburgh. The M_{peak} values in *Table 1* are those recommended by Waters Associates except in the case of PS 10, for which a $\bar{M}_n$ value obtained by vapour pressure osmometry is preferred[10,27,28]. The $\bar{M}_w$ and polydispersity $\bar{M}_w/\bar{M}_n$ data in *Table 2* were given by the supplier.

The PBLG samples were used as supplied by Miles–Yeda Ltd, Rehovot, Israel. The viscosity average molecular weights, $\bar{M}_v$, in *Table 3* were calculated from the supplier's DMF (25°C) intrinsic viscosities. The intrinsic viscosity molecular weight relations given by Fujita et al.[23] and Spach et al.[24] were used for the calculations in preference to the

a Supplier's values

earlier relationships of Doty *et al.*[22] which would give lower $\bar{M}_v$ values.

The narrow distribution PVP samples were prepared at the ICI Corporate Laboratory, Runcorn, by Dr D. Brown using an anionic method[29]. Disodium α-methylstyrene tetramer initiator was formed in tetrahydrofuran at room temperature and the polymerization was performed at –80°C in the same solvent. The $\bar{M}_n$ and $\bar{M}_w$ values in *Table 4* were measured with a Mechrolab membrane osmometer (methyl ethyl ketone, 37°C) and a Sofica light-scattering instrument (chloroform, 30°C) respectively.

The DMA, 99% pure, was supplied by Honeywell and Stein, and was degassed at 120°C to remove water and other low boiling point impurities.

Gel permeation chromatography

The g.p.c. measurements were obtained with a Waters Associates model 200 gel permeation chromatograph at ICI Organics Division, Blackley, Manchester. The PBLG and PVP data were obtained with different column sets, designated D and F respectively. Both sets comprised five Waters Associates Styragel columns, 10^5, 10^5, 10^4, 10^3 and 10^3 Å, which were calibrated with the PS standards. The eluent flow rate was 1 ml/min, and the concentrations of PS, PVP and PBLG solutions were 0.25, 0.17 and 0.50% respectively. Peak retention volumes for PBLG chromatograms recorded with 1.00, 0.70, 0.50 and 0.25% solutions of sample D95 agreed to within ±0.2 count, indicating the absence of PBLG concentration effects. The toluene plate counts of 450 ppf, obtained by injecting a 1% (w/v) solution for 15 sec, were rather low. However, PS polydispersities (*Table 2*) calculated[30] from chromatograms indicate a low degree of broadening. This suggests that the plate counts are anomalously low, probably owing to the inclusion of two 10^3 Å columns in each set.

Peak retention volume data for PS, PVP and PBLG are shown in *Tables 1, 4* and *5* respectively. Average molecular weights and polydispersities were calculated from

chromatograms by the method of Pickett *et al.*[30]. Values of M_{peak} for PVP fractions and PBLG samples ($\bar{M}_w/\bar{M}_n >$ 1.3) and corresponding values of the constants A and B in the calibration equation:

$$\log M = A - BV_R \tag{9}$$

were obtained by the method of Frank *et al.*[18,19]. Details are given in the results section.

Solution viscosity

Viscosities were measured with two Ubbelohde suspended level dilution viscometers having 12 cm capillaries of diameter 0.3 and 0.5 mm. The flow times for DMA in the two viscometers were 380 and 114 sec respectively, and kinetic energy corrections are therefore not significant. The wider bore viscometer was used for all of the measurements except for those on standards PS7, PS8 and PS10. The ratio of radius to length was such that shearing stresses were very low, and orientation of PBLG was avoided. The solution concentrations were corrected for solvent expansion from room temperature to 80°C. Data at four or five concentrations, giving relative viscosities in the range 1.1 to 1.9, were extrapolated linearly to infinite dilution by Huggins and Kraemer plots giving [η] and the Huggins constant k' and Kraemer constant k''.

Values for k' for PS were in the range 0.3 to 0.4 and the sums of k' and k'' were 0.50 ± 0.02. The [η] values in *Table 1* are shown as a double logarithmic plot against peak molecular weight in *Figure 1*. This plot is well represented by:

$$[\eta]_{DMA}^{30} = 1.4 \times 10^{-4} M^{0.68} \tag{10}$$

The exponent in this equation is typical of a flexible random coil polymer in a good solvent.

For PBLG values for k' shown in *Table 3* are in the range 0.5 to 0.6 whilst values for k'' were about 0.01. Such k' and k'' values are typical of PBLG in a helicogenic solvent and suggest that the macromolecules are not associated[6]. A double logarithmic plot of $[\eta]_{DMA}^{80}$ (*Table 3*) against $\bar{M}_v$ (DMF, 25°C) is shown in *Figure 2*. For molecular weights greater than 5×10^4, the data obey the typical rigid rod relation:

$$[\eta]_{DMA}^{80} = 2.2 \times 10^{-9} \bar{M}_v^{1.75} \tag{11}$$

and suggest that samples D95 and C100 have sufficiently large p values for equation (7) to be valid. For lower mole-

RESULTS AND DISCUSSION

Effect of eluent power and polarity

Results discussed elsewhere[12,13] suggest that interactions between PS and crosslinked polystyrene gel can occur when the solubility parameter, δ for the eluent is greater than that for PS. In the present case, δ (DMA) is 10.8 and δ (PS) is 9.1[31] and therefore it is necessary to confirm that, when DMA (80°C) eluent is used, PS is fractionated according to steric exclusion only. Thus, PS has been compared with PVP for which δ is approximately 10.5. These two polymers have similar unperturbed dimensions, $(L_0^2/M)^{1/2}(PS) = 0.67$ Å [31] whilst $(L_0^2/M)^{1/2}(PVP) = 0.66$ Å [31,32]. Solution viscosity determinations show that DMF is a good solvent for PVP $(\alpha = 0.69)$[17] and it is assumed that polymer/solvent interactions will be similar in DMA.

The PS calibration curve for column set F, shown in *Figure 3*, was used to calculate $\bar{M}_w$ and $\bar{M}_w/\bar{M}_n$ values for PS and PVP chromatograms. The PS values in *Table 2* are in good agreement with the experimental values confirming the absence of the unsymmetrical broadening phenomena which accompany solute/gel interaction effects[12,13]. Also, the PVP results in *Table 4* are in good agreement with the experimental values, reflecting the similarities in PS and PVP unperturbed dimensions and suggesting that the separation of PS in DMA (80°C) is controlled by steric exclusion only. The M_{peak} values for PVP shown in *Table 4* were calculated from the chromatograms using the experimental $\bar{M}_n$ and $\bar{M}_w$ values. For both samples the values of calibration constants A and B were 25.3 and 0.71 respectively. The PVP M_{peak} values are plotted against corresponding peak retention volumes in *Figure 3*. The two points are coincident with the PS curve.

Universal calibration for PBLG

If the product $[\eta]M$ is a valid universal calibration parameter for the rigid-rod molecule PBLG and the random coil
Figure 3 Molecular weight calibration plot for column set F with *N,N*-dimethylacetamide at 80°C; ○, M_{peak} polystyrene standards; □, M_{peak} poly(2-vinyl pyridine) samples

PS, then at a given retention volume:

$$[\eta]M(\text{PS}) = [\eta]M(\text{PBLG}) \tag{13}$$

Substituting equations (3) and (7) for PS and PBLG respectively gives:

$$K(\text{PS})M^{1+\alpha(\text{PS})} = K'(\text{PBLG})M^{1+\alpha'(\text{PBLG})} \tag{14}$$

Taking logarithms and rearranging leads to:

$$\log M(\text{PBLG}) = \frac{1 + \alpha(\text{PS})}{1 + \alpha'(\text{PBLG})} \log M(\text{PS}) +$$

$$\frac{1}{1 + \alpha'(\text{PBLG})} \log \frac{K(\text{PS})}{K'(\text{PBLG})} \tag{15}$$

This equation should predict a valid PBLG molecular weight calibration from a PS calibration curve. Alternatively, plots of log $[\eta]M_{peak}$ against appropriate PS and PBLG retention volumes should be coincident.

The PS calibration curve for column set D, shown in *Figure 4*, was used to calculate average molecular weight and polydispersity data from the PS chromatograms. The results in *Table 2* are in good agreement with the accepted values and with the data obtained with column set F, indicating that PS was separated according to equation (1).

A PBLG molecular weight calibration was derived from the PS curve in *Figure 4* by substituting into equation (15) the DMA (80°C) intrinsic viscosity relations (10) for PS and (11) for PBLG ($M > 5 \times 10^4$). For lower PBLG molecular weights, equation (15) was modified to accommodate K' and α' values for PBLG in relation (12). The complete PBLG calibration curve, shown as a broken line in *Figure 4*, was used to calculate average molecular weight and polydispersity data from the PBLG chromatograms. The results are shown in *Table 5*. The viscosity average molecular weights for the three highest molecular weight samples were

calculated with a Mark–Houwink exponent of 1.75, whilst 0.84 was used for sample A89. For all of the samples, the calculated $\bar{M}_v$ values are in very good agreement with the experimental ones. This suggests that the PBLG calibration predicted from equation (15) is valid, and is also consistent with the very small degree of broadening. The calculated polydispersities for the PBLG samples, particularly D95 and C100, indicate that precise calculation of M_{peak} is necessary before assignment to peak retention volumes. M_{peak} values were calculated[18,19] from experimental viscosity average molecular weight values and g.p.c. number-average molecular weights. The results are shown in *Table 5*, which also contains values of constants A and B and $[\eta]M_{peak}$ data. The PBLG M_{peak} values are plotted against peak retention volume in *Figure 4* and are in very good agreement with the calibration curve predicted from equation (15). Semi-logarithmic plots of $[\eta]M_{peak}$ against peak retention volume for PBLG and PS are also coincident (*Figure 5*).

The results for PBLG in DMA (80°C) therefore show that the g.p.c. separation of rigid-rod molecules (at 1 ml/min) may be represented by the viscometric size parameter $[\eta]M$ and that equation (15) is applicable to such systems. This suggests that at normal flow rates, the g.p.c. separation is an equilibrium-controlled distribution of macromolecules of differing size between the mobile phase and stationary phase ($K_p = 1$). Therefore, PBLG in DMA at 80°C is not influenced by solute–gel interaction effects ($K_p > 1$) which affect the separation of some polyamides in phenol-type solvents[33].

Separation mechanism

Retention volumes may be related to the distribution coefficient K_D by equation (1). Giddings *et al.*[2] applied

25.75	678	485	1.49	0.22
26.90	410	318	1.29	0.28
Figure 6 Theoretical variation of distribution coefficient K_D with the ratio of rod half-length to sphere diameter for parallel plane pore model

statistical mechanics to the distribution of rigid particles, including spheres and rods, in several idealized pore structures. They derived the variation of K_D with the diameter D of spheres and with the half-length $L/2$ of rods for a variety of pore shapes, including random planes, spherical cavities and parallel planes. The relations for random planes predict that at a given value of K_D, and consequently at a given retention volume, D and $L/2$ are equal. For spherical cavities D is predicted to be greater than $L/2$ at a given K_D, whilst for parallel planes D is expected to be smaller than $L/2$.

The PBLG and PS results were used to assess the suitability of these simple pore models for representing g.p.c. behaviour. The half-lengths $L/2$ at M_{peak} for the two high molecular weight PBLG samples were calculated from $L = Mh/m$ using $m = 219$ and $h = 1.3$ Å [23]. Corresponding values of D for PS at the same V_R were calculated from equation (8) assuming a rigid hydrodynamic sphere. The resulting values of $L/2$ and D are shown in *Table 6*.

Of the three pore models under consideration, only the parallel plane shape predicts a relationship between $L/2$ and D consistent with that found experimentally. The theoretical variation of K_D and $L/2D$ is shown in *Figure 6*. Values of K_D from this graph were substituted in equation (1) together with the corresponding retention volumes. Solving the simultaneous equations gives a value of 21.5 counts for V_0 and 19.0 counts for V_i. The value of V_0 is in reasonable agreement with the upper exclusion limit. The sum of the V_0 and V_i values, 40.5, is in very good agreement with the experimental retention volume, 41.0, for toluene. It would therefore appear that the parallel plane model is a useful mathematical representation of pore geometry. This is consistent with Casassa's observation[3] that the data of Moore and Arrington[34], for PS, porous glass and a binary theta-solvent, are in good agreement with the parallel plane or 'slab' model.

Light scattering Rayleigh linewidth measurements on some dextran solutions

D. B. Sellen

Astbury Department of Biophysics, University of Leeds, Leeds LS2 9JT, UK
(Received 20 November 1974)

Light scattering Rayleigh linewidth measurements have been made upon eight fractions of dextran from *Leuconostoc mesenteroides* B512 with molecular weights ranging from 10 to 500 kg/mol and the relationship $D_{20} = 2.25 \times 10^{-4} M^{-0.45}$ (D in mm^2/s, M in kg/mol) was established. No concentration dependence of diffusion constant was detected within experimental error (±3%). The measurements were corrected for the polydispersity of the fractions. The results are compared with diffusion constants obtained by conventional techniques and with viscosity data.

INTRODUCTION

Investigation of the spectra of light scattered from macromolecular solutions is now an established technique for the determination of translational diffusion constants[1-7]. The most convenient method of making these measurements is by means of the optical homodyne technique in which the power spectrum of a photoelectric signal is investigated. In recent years it has been found advantageous to do this by obtaining the autocorrelation function by use of a suitable computer[4,5,7]. The present paper describes some experiments of this type upon eight fractions of dextran with molecular weights ranging from 10 to 500 kg/mol.

EXPERIMENTAL

Dextran is a branched polymer of D-glucopyranose with $\alpha(1 \to 6)$ linkages in the main and side chains and $\alpha(1 \to 3)$ linkages at the branch points. The dextrans used in this work were commercial samples (Pharmacia Fine Chemicals, Uppsala, Sweden) consisting of fractions of material synthesized from sucrose by the bacterial species *Leuconostoc mesenteroides* strain B512. Dextran produced in this way has a number of branch points equal approximately to 5% of the degree of polymerization[8,9].

Both conventional light scattering measurements and light scattering Rayleigh linewidth measurements were made on all the samples. The same solutions were used for both types of measurement, the solvent being glass distilled water. Solutions were clarified by centrifuging for 1 h at 20 000 × g and passing through a 1.2 μm Millipore filter directly into the light scattering cell.

Conventional light scattering measurements were made with the Aminco (American Instrument Co. Inc., Silver Spring, Maryland, USA) apparatus. The light scattering Rayleigh linewidth apparatus and its operation have already been described[6,7]. Where spectral broadening is due to translational diffusion alone the autocorrelation function of the photoelectric signal resulting from light scattered from a polydisperse solution of macromolecules is given by:

$$\phi(\tau) = \frac{c^2\gamma^2}{2} \left[\Sigma_n I_n \exp(-K^2 D_n \tau)\right]^2 \qquad (1)$$

c is the overall photosensitivity of the detecting system and γ a coherence factor depending upon the geometry of the optics[6]. τ is the autocorrelation delay time, I_n the scattered intensity from that component having diffusion constant D_n and:

$$K = \frac{4\pi}{\lambda} \sin \theta/2 \qquad (2)$$

where λ is the wavelength *in the solution* and θ the angle of scatter.

RESULTS AND DISCUSSION

The results are summarized in *Table 1*. With the exception of the T20 sample (the results for this sample will be discussed later) the weight-average molecular weights agree within experimental error with the gel filtration data supplied with the samples. There was no dissymmetry of scatter except in the case of the T500 sample where the dissymmetry indicated a Z-average polar radius of gyration of 26 ± 5 nm. The refractive index increment was measured in a Rayleigh differential refractometer and found to be 0.148 ± 0.001 ml/g; no variation was detected with wavelength within the visible region.

Equation (1) shows that if $\ln\phi(\tau)$ is plotted against τ the slope of the graph at $\tau = 0$ is $-2K^2 D_z$ where D_z is the Z-average diffusion constant[7]. When the degree of polydispersity is not high enough for the autocorrelation function to differ significantly from a single exponential this graph will be a straight line of slope $-2K^2 D_z$. However, in the present work some of the samples had a high enough degree of polydispersity for this not to be the case and *Figure 1* shows the autocorrelation function at various angles of scatter for the T500 sample. As predicted theoretically the data all lie on the same curve[6,7]. The exponential fit at shorter values of τ yields D_z.

Figure 2 shows diffusion constant as a function of concentration for three of the samples. No concentration dependence was detected.

Figure 3 shows a double logarithmic plot of diffusion constant as a function of molecular weight. The diffusion

Table 1 Summary of results

Fraction	M_W (kg/mol)		Second virial coefficient $\times 10^4$ (mol m^3 kg^{-2}) by light scattering	M_W/M_n*	M_D/M_W	$D_{20} \times 10^5$ (mm^2/s) by light scattering
	Gel filtration*	Light scattering

Figure 2 Diffusion constant as a function of concentration for three dextran fractions: (a) T10; (b) T70; (c) T500. Measurements were made in distilled water
Figure 3 Diffusion constant as a function of molecular weight (kg/mol) for dextran. The open squares indicate the limits of error and the shaded squares represent the data corrected for polydispersity. ---, Variation predicted from viscosity data (see text)

constants were corrected from room temperature to 20°C assuming the validity of the Stokes—Einstein equation. The plot is approximately a straight line, i.e.

$$D = AM^{-\alpha} \tag{3}$$

It is necessary, however, to consider the polydispersity of the samples. The Z-average diffusion constant corresponds to a molecular weight M_D given by[7]:

$$M_D = \left[\frac{\Sigma_i N_i M_i^2}{\Sigma_i N_i M_i^{2-\alpha}} \right]^{1/\alpha} \tag{4}$$

N_i is the number of molecules having molecular weight M_i. In the case of a Shulz—Zimm distribution[10]:

$$M_D = \frac{M_w}{1+\alpha} \left[\frac{\Gamma(a+2)}{\Gamma(a+2-\alpha)} \right]^{1/\alpha} \tag{5}$$

where

$$a = 1/(r-1) \tag{6}$$

and

$$r = M_w/M_n \tag{7}$$

The gel filtration data supplied with the samples do in fact indicate distributions approximately equivalent to the
Figure 4 (a) Autocorrelation function for the T20 sample (*Table 1*) which contains a high molecular weight impurity (see text). ●, 60°; ○, 90° C. (b) Graph to find the diffusion constant for the low molecular weight component (see text)

Shulz–Zimm function. Values of M_D were accordingly calculated taking values of r from the gel filtration data and using an approximate value of α taken from the uncorrected light scattering data. *Figure 3* shows that data corrected in this way lie on a straight line within experimental error. In principle the true value of α should be found by successive approximations, i.e. recorrecting the data using the corrected value of α. In this case however further corrections do not materially alter the values of M_D.

Conventional light scattering measurements on the T20 sample yielded, after centrifugation at 40 000 x g for 2 h, a weight-average molecular weight of 40 kg/mol and a Z-average polar radius of gyration of 30 nm, the result depending upon the time and speed of centrifugation. These two figures are clearly inconsistent with each other for a single dextran fraction and the dissymmetry must arise from a small amount of high molecular weight impurity. *Figure 4a* shows a logarithmic plot of the autocorrelation function for this sample. At long times this becomes a straight line yielding a Z-average diffusion constant for the high molecular weight component of 4.3×10^{-6} mm^2/s. The Z-average diffusion constant of the low molecular weight component may be found from the autocorrelation function at shorter times if use is made of the extrapolated straight line. The following procedure, which is justified by equation (1), was adopted. At each value of τ the antilogarithm of one-half of the ordinate corresponding to the autocorrelation function and the extrapolated straight line were taken. These two values were then subtracted and the logarithm of the result plotted against τ to yield a straight line of slope $-K^2 D_z/2.3$ (*Figure 4b*). This value of D_z is shown in *Table 1* and *Figure 3*. The intercept of the extrapolated straight line at $\tau = 0$ indicates that the high molecular weight component accounts for approximately 50% of the scattered intensity, whilst the molecular size as indicated by the diffusion constant of this component suggests that it accounts for only a very small proportion of the total concentration. Thus the true molecular weight of the dextran fraction in this case is one-half of the measured value i.e. 20 kg/mol. This agrees with the gel filtration data. It must be emphasized that in general the results for a two-component system can only be analysed in this way if the two diffusion constants are different by an order of magnitude or more, and the polydispersity of the high molecular weight component is low enough for the log $\phi(\tau)$ plot to be a straight line at longer times.

From *Figure 3* the values $\alpha = 0.45$ and $A = 2.25 \times 10^{-4}$ are obtained. The diffusion constants of dextrans of the type investigated here have also been investigated using conventional techniques by Granath[11] and by Ingelman and Halling[12]. The results presented here agree within experimental error with those of the earlier authors for molecular weights above 70 kg/mol. At lower molecular weights the results using conventional techniques are higher. Granath's value of diffusion constant for a molecular weight of 11.2 kg/mol (determined by the sedimentation velocity method) is 8.8×10^{-5} mm^2/s and his results lie in a straight line with $\alpha = 0.50$. Granath made measurements in phosphate buffer. Measurements were therefore repated on the T10 sample with 0.05 M phosphate buffer (pH = 7) as solvent. The values of diffusion constant and weight-average molecular weight so obtained were the same within experimental error as those found from measurements in distilled water. (Measurements were also similarly repeated on the T20 sample but a high molecular weight impurity was still observed.) It was not possible to make light scattering measurements on the T10 sample at a concentration below 1%. This does not explain the discrepancy, however, as Granath did not detect any concentration dependence. There is also the possibility that the T10 sample contained some large aggregates. Whereas these would not materially affect conventional diffusion measurements, it has been shown that, in the case of light scattering measurements, the effect of a small number of large aggregates is to increase the weight-average molecular weight and decrease the Z-average diffusion constant in equal proportions[13]. The aggregates would have to contribute some 25% of the scattered intensity to account for the discrepancy. This is difficult to reconcile with the fact that gel filtration and light scattering measurements yielded the same weight average molecular weight, unless of course the gel filtration calibration for low molecular weights depended upon light scattering measurements on a sample similar to the T10 sample investigated in this work. The presence of a small amount of high molecular weight impurity in the T10 sample still remains a possibility therefore, although in this case the aggregates would have to be small enough in size so as not to produce a dissymmetry of scatter.

It is of interest to compare the results of diffusion constant measurements with those of intrinsic viscosity. The latter are usually analysed in terms of the Mark–Houwink equation:

$$[\eta] = BM^\beta \tag{8}$$

For *any* theoretical model involving an equivalent hydrodynamic sphere in which the hydrodynamic diameters for translation and shear are assumed to be *proportional* to each other[14]:

$$3\alpha = \beta + 1 \tag{9}$$

Granath obtained $\beta = 0.43$ which yields $\alpha = 0.477$. If the hydrodynamic diameter for translation and shear are assumed to be *identical* then:

$$A = \frac{kT}{3\pi\eta}\left(\frac{2.5\pi N_0}{6B}\right)^{1/3} \tag{10}$$

where the symbols have their usual meaning. The variation of diffusion constant with molecular weight predicted in

this way from Granath's viscosity data is shown by the broken line in *Figure 3*. The agreement with the diffusion data is somewhat better than that obtained for unbranched polymers where the measured diffusion constant is usually some 20% lower[14].

CONCLUSION

Diffusion constants of dextran fractions obtained by light scattering Rayleigh linewidth measurements are in good agreement with those obtained by conventional techniques for molecular weights above 70 kg/mol. For lower molecular weights diffusion constants are obtained which are lower than those obtained by conventional techniques. The possible presence of high molecular weight impurities might wholly or partly explain this discrepancy. The diffusion constant/molecular weight relationship obtained from light scattering measurements is:

$$D_{20} = 2.25 \times 10^{-4} M^{-0.45}$$

This is in fair agreement with the variation predicted from viscosity data. There is no concentration dependence of

diffusion constant within experimental error ($\pm 3\%$).

Transitions of a series of regularly alternating linear polyesteramides

C. Borri, E. Sorta and L. Zotteri

Laboratori Ricerche Polimeri, Snamprogetti, 20097 San Donato Milanese, Milano, Italy
(Received 14 October 1974; revised 1 April 1975)

The systematic detection of the relaxations of a series of regularly alternating linear polyesteramides, based on terephthalic acid, was effected using dynamic-mechanical, thermal and thermomechanical means, thus making it possible to support certain hypotheses as to the attribution of the motions involved in these relaxations. Sufficient data were collected to allow firm prediction of the glass transitions of homologous or similar polymers and copolymers.

INTRODUCTION

A series of polymers of the following types were synthesized in the Fibre Department of Snamprogetti:
with various x and y^1 values conventionally referred to with the symbols xNTy. The rheological properties of melt 12NT6[2] and the thermodynamics of such melting[3], determined both experimentally and by means of statistical mechanics calculations, have already been studied.

In carrying out this work, an attempt was made to establish and ascertain the nature of the transition of the polymers under examination, by dynamic-mechanical, thermal and thermomechanical tests. The criteria adopted in order to specify which particular molecular motion or structural defect has brought about the process of relaxation are those typical of other spectroscopic techniques, i.e., based on the comparison of polymer spectra which differ in the monomeric unit, and in the case of one polymer, the comparison of the spectrum of samples with different thermal or thermomechanical history.

EXPERIMENTAL

Samples

Circular-section fibres of three polyesteramides (6NT6, 12NT6, 12NT12) were prepared for the forced vibration dynamic-mechanical tests by means of spinning under optimum conditions.

For each type of polymer, three different thermomechanical histories (see *Table 1*) were taken into consideration: (A) thread as spun (lowest degree of crystallinity compatible to a process on a semi-industrial level); (B) thread as spun and then annealed; and (C) drawn and subsequently annealed thread. The samples marked B were obtained by means of a thermal treatment is a stove for 15 min under a pre-tension of 5.75×10^5 N/m^2 at different temperatures (see *Table 1*). The samples marked C were drawn on pin and plate at

temperatures of 150° and 80°C respectively with a drawing ratio of 1:5.2 and taken up at rate of 50 m/min.

Subsequently, the samples were treated in the stove in the same way as for samples B, with a pre-tension of 5.75×10^6 N/m^2.

The films for the Rheovibron viscoelastometer tests were obtained by means of evaporation of trifluoroacetic acid solutions and were then annealed in a stove (see *Table 1*).

The samples for the thermal analysis tests were subjected to suitable quenching in order to make their crystallinity so low that a net peak of cold crystallization was observed under thermal analysis.

The wt % crystallinity C_x was determined for each sample, from the relative density as measured in a gradient tube. The following values of ρ_a and ρ_c were used to define C_x respectively:

	6NT6	12NT6	12NT12
ρ_a (g/cm^3)	1.1875	1.135	1.100
ρ_c (g/cm^3)	1.314	1.251	1.210

The relative amorphous density values were obtained from the dilatometric data of Manzini *et al.*[3].

The 100% crystallinity density data were obtained through the determination of the elementary cell of RX spectrum of the fibre in a cylindrical chamber[4]. Orientation indexes for the fibres were obtained from the birefringence

expressed as: $\Delta n = R_0/D$ where Δn is the difference in refractive index parallel and perpendicular to the axis of the fibre, R_0 is the retardation of the light and D is the thickness of the sample.

Dynamic-mechanical tests

The dynamic-mechanical tests were carried out both by means of forced resonance vibration techniques[5], and by means of a Rheovibron dynamic viscoelastometer (Toyo Instruments Co. Ltd).

The cell for the forced vibrations was slightly modified to allow a range of temperatures from $-150°$ to $250°C$. With this apparatus, the frequency depends on the modulus and is not therefore constant through the temperature range. Some constant frequency recordings (110 Hz) were taken using a Rheovibron Dynamic Viscoelastometer.

A heating speed of approximately $1°C/min$ was chosen for both dynamic-mechanical measurements.

Thermal and thermomechanical analyses

The d.s.c. standard cell and Du Pont 941 Thermo Mechanical Analyzer (t.m.a.) connected to the Du Pont 900 console was used. A heating speed of $10°C/min$ was chosen for the d.s.c. measurements and a heating speed of $5°C/min$ for t.m.a. measurements.

RESULTS

Figures 1 to *4* show the dynamic-mechanical behaviour of the polyesteramides under examination. The dynamic-mechanical data relating to α, β and γ relaxations are summarized in *Tables 2* and *3*.
Figure 3 Plot of tan δ and E/E_{20} *versus* temperature for 12NT12 (100 < ν < 400 Hz). —·—, Sample A; ———, sample B; —— sample C

It was not possible to complete the spectrum on the low crystallinity sample (samples A) since at such temperatures cold crystallization occurs.

Thermal and thermomechanical data of the quenched samples are reported in *Table 4* where T_t (t.m.a.) and T_t (d.s.c.) are the transition temperatures measured by means of t.m.a. and d.s.c. techniques, T_{cc} is the temperature at the maximum point of the cold crystallization peak and T_m is the temperature of the maximum point of the melting peak.

Since the specific heat represents a property which is thermodynamically related to the volume there should be a correspondence between the transition temperatures measured using the d.s.c. and t.m.a. techniques. The dif-

ferences are therefore due to operative variables. Differences of this degree were found by Miller[6] using the same instrument.

DISCUSSION
α-Relaxation

There are considerable similarities between the glass transition of the poly(methylene terephthalates)[7] and the α-relaxation of the polymers under examination. In fact, the transition is dominant in both series of polymers. Moreover, T_α, temperature corresponding to the maximum point of tan δ (see *Table 2*) and T_t (see *Table 4*) decrease as the number of methylenes increases in a manner roughly parallel to the melting point as observed in the case of the poly(methylene terephthalates). This fact indicates that similar enthalpic and entropic factors act upon the melting point and the α-relaxation. It is accepted that the same parameters which influence the glass transition (T_g) also influence the melting point[8]. Moreover, the α-relaxations shift to higher temperatures as crystallinity and orientation increase.

In the case of samples having a similar thermomechanical history, the tan δ value at the maximum point of the peak (tan δ)$_{max}$ is almost constant in the series of polyesteramides examined. These facts support the hypothesis that the α-relaxation is due to movements of the entire chain and is not limited to certain groups. Crystallization was not observed at temperatures below T_t. It would seem to us that there is sufficient evidence to affirm that the α-relaxation is the glass transition for the polymers under examination.

Some observations may also be made in accordance with the logical scheme of properties and structures by means of comparison with data concerning 'related' polymers. If the amide links of the 6NT6 are replaced with ester links poly(hexamethylene terephthalate) chain is formed; meanwhile if the ester links are replaced with amide links the poly(hexamethylene terephthalamide) chain is formed. From other[7] dynamic-mechanical data relating to a sample of poly(hexamethylene terephthalate), an α-relaxation at 45°C at a frequency of 165 Hz results. This result should

be comparable to our spectrum of sample B of the 6NT6 (T_α at 120°C and at 140 Hz). It may therefore be observed that the introduction of alternating amide links brings about an increase of ~75°C of the glass transition. The thermal analysis verifies that the glass transition of a sample of poly(hexamethylene terephthalate)[9] (T_m = 152°C) falls to ~0°C whilst that of 6NT6 measured by means of the same techniques rises to 59°C.

There are no data available concerning poly(hexamethylene terephthalamide) but the dynamic-mechanical properties of its higher homologue, poly(heptamethylene terephthalamide)[10] are available. The dynamic-mechanical spectrum of the poly(heptamethylene terephthalmide) shows that the total introduction of amide links leads to a further and considerable increase in the temperature of the relaxation to ~200°C at 1000 Hz. Butta[10] records also a T_g obtained by means of thermal analysis at 177°C. In any case, more precise comparison is not possible since the above-mentioned paper does not specify the thermomechanical history of the sample. Unlike the polyesteramides, the poly(heptamethylene terephthalamide) shows, however, a distinct shoulder at ~100°C connected with the aromatic parts of the chain. In the case of polyesteramides, this relaxation is not recorded as it is preceded by the micro-Brownian motion of the entire chain.

β-Relaxation

For each polymer the β relaxation peak moves towards higher temperatures in the sequence A, B and C; this fact can be more distinctly observed for the 6NT6 rather than the 12NT6 whilst it tends to disappear in the 12NT12. The intensity of the peaks decrease in relation to the increase of the crystallinity. The irregularity observed for the oriented samples, the intensity of which is slightly higher than that of sample B, is probably due to the difference between the morphological nature of the crystals formed during drawing and annealing and therefore has a different

effect on the movements of the amorphous part. The frequency differences corresponding to the maximum point of the peak are not such as to invalidate the qualitative value of the observations made. All such observations support the hypothesis that the β relaxation occurs in the amorphous part.

The comparison between samples of different polymers is more difficult since the diverse degree of crystallinity and water content must be taken into consideration because the water absorption depends on the crystallinity and polar group content. With the data at our disposal the absorption of water decreases in proportion to an increase in the crystallinity as in the case of aliphatic polyamides and therefore, in the biphase approximation, it may be affirmed that the water is absorbed by the amorphous region. Our samples were not dried before the tests; in each case and for each type of polymer, the absorption of water was less than 1.6% at 66% r.h. and therefore was less than the absorption of some aliphatic polyamides (e.g. nylon-6 and nylon-6,6). By reason of the low water content, the absorption remains nearly independent of the density of the chain polar groups. The comparison of the intensity of the β relaxations with similar degrees of crystallinity (see *Figures 4* and *5*) shows that the relaxation mechanism finds its origin in polar groups in the amorphous part.

γ-Relaxation

The γ-relaxation in the polyesteramides under examination occurs approximately at the same temperature and frequency as the γ-peak of aliphatic polyamides[11], partly aromatic polyamides[10] and polyethylene[11]. This similarity enables the designation of the γ-relaxation in polyamides to the movements of the CH_2 units between the amide links. This interpretation is considered valid also in the case of the γ-relaxation of the polyesteramides, emphasis being laid on the fact that the movements of the CH_2 units is predominant in the relaxation mechanism since the phenomenon is more intense in the 12NT12 as compared to the 12NT6 and to the 6NT6 (see *Figure 4*).

CONCLUSIONS

The results of this research can serve to predict the glass transitions in polymers having a similar structure. There is evidence both on the effect of the variation of the number of CH_2 units and of the effect of the introduction of a greater number of amide links. Therefore it is possible to approximately predict the glass transition temperature of a polymer of the $xNTy$ type with varying x and y and of other alternating polyesteramides obtained by means of the polycondensation of a glycol with a diester, which contains more than two preformed amide links.

Conformational properties of poly(alkene sulphone)s in solution: 1. Relation between the dielectric properties in solution and the structure of the repeat unit

A. H. Fawcett and K. J. Ivin

Department of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, UK
(Received 19 September 1974; revised 13 December 1974)

A survey of the available evidence shows that the central C—C bonds in β-disulphones and polysulphones have a mainly *trans,* and sometimes an exclusively *trans,* conformation.

Calculations of the coulombic interactions in the 27 possible conformational sequences in $-SO_2CH_2CH_2SO_2-$ show that certain sequences having *gauche* C—C bonds are unlikely to be significantly populated. Others such as (t, g^-, g^+) and (g^-, g^-, g^+) involve a certain amount of steric interaction but are likely to be comparable in energy with those having a *trans* C—C bond. One alkyl substituent or two at the same carbon atom eliminates some but not all of the accessible sequences having a *gauche* C—C bond. Substituents at both carbon atoms cause such strong steric interactions that only *trans* C—C bonds are allowed. It is shown how such considerations account satisfactorily for the two types of dielectric behaviour of poly(alkene sulphone)s in solution.

Preliminary experiments indicate that poly(norbornene sulphone), unlike polysulphones of other 1,2-disubstituted alkenes, does have a permanent dipole because of the inability of adjacent C—S bonds to take up anti-parallel positions.

A close resemblance is noted between the conformation about the main-chain C—C bond in poly(cyclohexene sulphone) and that about the main-chain C—C bond in poly(but-2-ene sulphone) in its most stable configuration.

INTRODUCTION

The dielectric behaviour of six poly(alkene sulphone)s in solution has been reported[1-3]. The polymers fall into two distinct groups: group A in which the alkene unit is hex-1-ene or 2-methylpent-1-ene; and group B in which the alkene unit is but-2-ene, hex-2-ene, cyclohexene or cyclopentene. Members of group A show a dispersion in the range 10^3–10^6 Hz and the critical frequency is strongly dependent on molecular weight[1,2], indicating relaxation by overall motion of the molecule. Members of group B show no dispersion in the range 10^2–10^7 Hz, indicating zero dipole moment. The essential difference between the two groups of polymers is thought to reside in the proportion of *gauche* conformations taken up by the main-chain C—C bonds. The zero dipole moment for group B implies that all the main-chain C—C bonds are in the *trans* conformation, while the finite dipole moment for group A implies that at least a proportion of the main-chain C—C bonds are in a *gauche* conformation at any one time.

The purpose of the present paper is first, to summarize the available evidence concerning conformations about C—C bonds in β-disulphones and polysulphones, and also about C—S bonds in sulphones; second, to consider the factors which operate to determine the conformational populations in sulphones and polysulphones, and to examine the importance of coulombic interactions between adjacent sulphone groups; and third, to consider the relationships between the structures of polymers in group B.

CONFORMATIONS IN SULPHONES

Apart from the dielectric evidence on the polysulphones in solution there are five pieces of information concerning the conformation of the central C—C bonds in β-disulphones and polysulphones.

First, the magnitude of one of the vicinal coupling constants (~9.5 Hz) in the ^1H n.m.r. spectrum of poly(propene sulphone)[4] indicates a preference for the *trans* conformation about the main-chain C—C bond, as in poly(propene sulphide)[5].

Second, for $Pr^nSO_2CH_2CH_2SO_2Pr^n$ in the polar solvent dimethyl sulphoxide-d_6 the ^{13}C side band of the ^1H n.m.r. spectrum of the central protons indicates a preference for the *trans* C—C conformation[6]; the enthalpy difference is estimated to be about 6 kJ/mol in favour of the *trans* conformation[7].

Third, $Pr^nSO_2CH_2CH_2SO_2Pr^n$ in the solid state obeys the rule of mutual exclusion for the Raman and infra-red bands, showing that it has a centre of symmetry[8]. Intermolecular forces in the crystal thus assist to ensure that all the central C—C bonds adopt a *trans* conformation.

Fourth, the dipole moments of $Pr^nSO_2CH_2CH_2SO_2Pr^n$ and $Pr^nSO_2CHMeCH_2SO_2Pr^n$ in dioxane solution are both 3.6 D[7], which is not equal to any of the values which would be expected (0, 5.8 or 8.2 D) were any one of the 27 possible conformations of the S—C—C—S bonds exclusively adopted. In both of these molecules there must be present in the moderately polar solvent dioxane several conforma-

S—C bond   C—C bond   C—S bond
Figure 1   Rotational states about the three bonds in
−SO$_2$−CH$_2$−CH$_2$−SO$_2$−

tions of comparable enthalpy.

Fifth, in the ^{13}C−$\{^1$H$\}$ n.m.r. spectrum of poly(but-2-ene sulphone), the two chemical shifts observed for the methyl carbon are consistent with an all-*trans* conformation for the main chain C—C bond and two alternative relative configurations about adjacent main-chain carbon atoms[9]; also see final section.

Thus all the evidence indicates a substantial preference for the *trans* conformation of the central C—C bonds in β-disulphones and polysulphones. However, *gauche* conformations are significant in some molecules and their energies must then lie fairly close to those for the *trans* conformation.

We may note in passing that in compounds of the type RSO$_2$CH$_2$−CH$_2$CH$_3$ the temperature dependence of the n.m.r. spectra again indicates a preferred *trans* conformation, the *gauche* conformations about the α–β C—C bond having an excess enthalpy of the order of 4 kJ/mol (R = CH$_2$CH$_2$SO$_2$Pr^n, Me, Pr^n, Bu^t, OH)[7,10].

Knowledge of the potential energy function for rotation about C—S bonds in sulphone is limited to the determination of the barrier height to internal rotation in dimethyl sulphone. This has been estimated from third law arguments to be 14 kJ/mol, assuming a three-well cosine function[11]. Substituents at the carbon atom may be expected to remove the symmetry of the energy function but without affecting the angular positions of the minima.

FACTORS CONTRIBUTING TO THE POTENTIAL FUNCTIONS FOR ROTATION ABOUT THE MAIN-CHAIN BONDS

Since we are dealing with main-chain atoms that are each bonded to four other atoms, we assume that the potential function for rotation about each of the main-chain bonds will show three minima, situated to a first approximation at dihedral angles of 0, $2\pi/3$ and $-2\pi/3$ and corresponding to conformational states t, g^+, g^-. The rotational states of the three bonds in a repeat unit are depicted in *Figure 1*. We may expect the energies of the minima and their dihed-

ral angle positions to be affected by steric repulsions, dispersion attractions and dipole—dipole interactions.

Sulphones have relatively large dipole moments[2] so that dipole—dipole interactions between two sulphone groups separated by two carbon atoms may be quite large. Thus, taking each dipole as 4.4 D and representing it as a pair of electronic charges separated by 100 pm, a pair of parallel dipoles separated by 400 pm in a medium of relative permittivity 2 is calculated to have an energy 17 kJ/mol in excess of that for a pair of anti-parallel dipoles at the same distance. This is considerably more than RT so that the orientation of each dipole in the chain will be strongly correlated with those of its neighbours. More detailed calculations of the coulombic interactions are described below and we then go on to consider how the situation is modified by the introduction of substituents.

CALCULATIONS OF COULOMBIC INTERACTION ENERGIES BETWEEN ADJACENT SULPHONE GROUPS IN THE STRUCTURE −SO$_2$CH$_2$CH$_2$SO$_2$−

It is assumed that the rotational states are as shown in *Figure 1*, the bond lengths being taken as: C−S, 180 pm; C−C, 154 pm; and S−O, 144 pm, in accordance with published data[12]. The dipole moments of n-propyl and isopropyl sulphones[2] in benzene have a mean value of 4.42 D. In calculating coulombic interactions between adjacent sulphone groups we have assumed that each dipole may be represented by charges of 8.87 × 10^{-20}C and 17.74 × 10^{-20}C located on the oxygen and sulphur atoms respectively.

The total coulombic energy E_c arising from the interaction of adjacent sulphone groups in the 27 possible sequences of conformations has been calculated from:

$$E_c = \sum_i \sum_j (q_i q_j / 4\pi r_{ij} \epsilon_r \epsilon_o) \tag{1}$$

and the results are shown in *Table 1*. q_i and q_j are the charges associated with the interacting atoms i and j on different sulphone groups separated by a distance r_{ij} calculated from the geometry of the system. ϵ_r is the relative permittivity of the medium, taken as 2.0 (close to the value of dioxane and benzene) and ϵ_o is the permittivity of a vacuum. It is likely that the true value of ϵ_r is less than 2.0 when the interacting atoms are very close together. It may also be affected by specific solvent interactions, as will be shown in another paper[17].

It will be seen from *Table 1* that there are in fact only nine distinct values of E_c; sequences with the same value of E_c bear a structural relationship to each other through simple symmetry operations. It may also be seen that when the C—C bond has a *gauche* conformation, there is a larger range of energies than when the C—C bond has the *trans* conformation. This is because the sulphone groups are brought closer together in the former case so that

Figure 2 Conformational sequences in $-SO_2-CH_2-CH_2-SO_2-$:
(a) (t, g^-, t); (b) (t, g^-, g^+); (c) (g^-, g^-, g^+)

neighbouring dipoles are then more strongly correlated in orientation.

In *Figure 2* we show three different sequences in which the C–C bonds have a *gauche* conformation: *Figure 2a* illustrates one (t, g^-, t) which is typical of the high energy sequences, while the others are examples of lower energy $(t, g^-, g^+), (g^-, g^-, g^+)$. In the first case two oxygen atoms of adjacent sulphone groups are brought very close together, and the repulsive contribution to E_c from this pair of atoms is probably underestimated by the use of the value

of 2.0 for ϵ_r. Even neglecting this factor, sequences of high energy (>25 kJ/mol) in *Table 1* are not likely to be appreciably populated, and can be eliminated from further consideration. The sequences of real interest to the present discussion are therefore those with the C–C *gauche* conformation which have energies such as those of the sequences shown in *Figures 2b* and *2c*, together with those with C–C *trans* conformations. The uncertainties in the calculations mean that one cannot be sure of the actual relative energies of these conformational sequences; some light will be thrown on this problem in the next paper[17]

STERIC FACTORS AND EFFECT OF SUBSTITUENTS

If we examine the 'low energy' sequences depicted in *Figures 2b* and *2c* in more detail we find that the interatomic distance between C_4 and the nearest oxygen atom to it attached to S_1 is only 171 pm, which is considerably less than the sum of the van der Waals radii of an oxygen atom doubly bonded to a sulphur atom (140 pm) and a methylene group (200 pm)[13]. This would cause a considerable repulsive force, which will, however, be relieved by a relatively small change in the dihedral angles and perhaps by some change in the bond angles[14]. From the different laws of force of coulombic interaction on the one hand and steric repulsion on the other, small changes in the angles may relieve steric strain in the segment under consideration, while not greatly changing coulombic energies. Thus *gauche* states of the C–C bonds in the polymers may be significantly populated. The states of the bond can still be designated g^+ and g^-, though it is likely that the minima will occur at dihedral angles somewhat different from $2\pi/3$ and $-2\pi/3$; the C–S bond rotational minima may likewise be displaced from the 'ideal' dihedral angles. Such distortion will be less significant when the C–C bond has the *trans* conformation.

Next we consider the effect of replacing the hydrogen atoms by one or two alkyl groups on the same carbon atom. Poly(2-methylpent-1-ene sulphone) and poly(hex-1-ene sulphone) are known to have a head-to-tail structure[15] so that we may place the alkyl substituent(s) on C_1 and C_3 in *Figures 2b* and *2c*. It can be seen that this will not greatly affect the conformational energy. The sequences (t, g^-, g^+) and (g^-, g^-, g^+) are thus accessible in the sense of not having much higher energies than certain other sequences; likewise the symmetry-related sequences (t, g^+, g^-) and (g^+, g^+, g^-) are also accessible. If, however, we place the alkyl substituents on C_2 and C_4 in *Figures 2b* and *2c*, an additional and severe steric hindrance arises between the alkyl group(s) on C_4 and the oxygen of the adjacent sulphone group; the sequences $(t, g^-, g^+), (g^-, g^-, g^+), (t, g^+, g^-)$ and (g^+, g^+, g^-) are then inaccessible. This is equivalent to demonstrating that with substituents on C_1 and C_3 the symmetry-related sequences $(g^+, g^-, t), (g^+, g^-, g^-), (g^-, g^+, t)$, and (g^-, g^+, g^+) are inaccessible. Thus with one or two substituents on the same carbon atom, the number of accessible sequences having a *gauche* C–C bond is more limited.

Coming now to the case of one substituent on each main-chain carbon atom we may predict from the above considerations that all the sequences with *gauche* C–C (main chain) conformations will be of high energy as a result of steric effects, leaving only the *trans* C–C conformations significantly populated. The zero dipole moment in poly(but-2-ene sulphone) is thus accounted for, as well as the ^{13}C chemical shifts of the methyl carbons (see next section).

Figure 3 (a) Structure about the main-chain C—C bond of poly(but-2-ene sulphone) in its most stable configuration (and conformation); (b) structure about the main-chain C—C bond of poly(but-2-ene sulphone) for its less stable configuration; cf (a); (c) structure about the main-chain C—C bond of poly(cyclohexene sulphone) in its most stable conformation; (d) unit of poly(norbornene sulphone)

Summarizing the above arguments, the population of main-chain *gauche* C—C states may be expected to decrease through the series:

$$-SO_2CH_2-CH_2SO_2- > -SO_2CH_2-CR_1R_2SO_2- >$$
$$\text{(one of } R_1R_2 \text{ can be H)}$$

$$-SO_2CHR_1-CHR_2SO_2- \text{ (zero)}$$
$$(R_1R_2 \text{ both alkyl})$$

The experimental observations on disulphones and polysulphones summarized at the beginning of this paper can be understood in terms of this conformational analysis.

It should be noted that those matrix schemes of Flory[16], which express Markov correlations of bond conformations over pairs of bonds by use of statistical weight matrices of order $r \times r$ (r is the number of rotational states per bond), will not be adequate to account for vector properties of the polysulphones in group A (see introduction), where correlation over three bonds is clearly important. However, the all-*trans* conformation of the main-chain C—C bond for the group B polymers is a simplification which allows the method to be applied[17] without recourse to the use of statistical weight matrices of order $r^2 \times r^2$ and a more elaborate generator matrix formulation.

COMPARISON OF CONFORMATIONS IN POLYSULPHONES OF 1,2-DISUBSTITUTED ALKENES

The $^{13}C-\{^1H\}$ n.m.r. spectrum of poly(but-2-ene sulphone) indicates that the most stable configuration is formed as a result of *trans*-addition to *cis*-but-2-ene[10]. This information, coupled with the known *trans* conformation of the main-chain C—C bond[3], means that the structure is as shown in *Figure 3a*. The methyl groups are thus all in a *gauche* position relative to one another. In such circumstances the chemical shift is expected to be upfield from that of the methyl carbon in poly(propene sulphone) by about 3—4 ppm (γ-effect)[18], as is indeed the case. *Trans* addition to

trans-but-2-ene is observed to occur to some extent when the polymer is made at very low temperature and the resulting structure is as shown in *Figure 3b*. Here the methyl groups are all in a *trans* position relative to one another so that the γ-effect will be absent. In accordance with this the chemical shift for the methyl group is 3 ppm downfield from that for the structure in *Figure 3a*. It is worth noting that the structure of the more stable configuration, shown in *Figure 3a*, is analogous to that of poly(cyclohexene sulphone)[3], shown in *Figure 3c*. Poly(cyclopentene sulphone) also shows no dielectric dispersion in solution[3], which again indicates *trans* addition to the double bond of cyclopentene, with the C—S bonds distorted into near anti-parallel positions.

The question arises as to whether poly(norborn-2-ene sulphone) would have a net dipole moment, and therefore a dielectric dispersion. The structure of this polymer is shown in *Figure 3d* and no matter whether the sulphone groups are attached to the bridged ring system at the positions shown, or in another way, it is impossible for the components of the sulphone dipoles along the C—S bonds to cancel. Preliminary experiments on an unfractionated sample of this polymer in benzene solution showed that there was a dielectric loss in the region 10^2 to 10^7 Hz, as expected[19]. An attempted fractionation using dioxane/acetone as the solvent/non-solvent system gave a sample ($[\eta] = 17.2$ cm^3/g in benzene) which showed two dispersion regions in this frequency range. This appears to have been caused by a bimodal distribution in the sample, as indicated by gel permeation chromatography[20], rather than by the operation of two relaxation mechanisms. Thus it appears that poly(norborn-2-ene sulphone) exhibits group A behaviour. Further work is planned.

Conformational properties of poly(alkene sulphone)s in solution: 2. A rotational isomeric state study of the poly(cyclohexene sulphone) chain

A. H. Fawcett and K. J. Ivin

Department of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, UK
(Received 19 September 1974; revised 13 December 1974)

The rotational isomeric states model, coupled with the Flory matrix method, was applied to the calculation of the unperturbed mean-square end-to-end distance in poly(cyclohexene sulphone) as a function of several parameters. The calculations were performed for atactic, isotactic and syndiotactic chains; the tacticity arises from the two possible ways, D and L, in which the rings can be attached to the main chain, assuming that the C–C bonds are all in the t conformation, as indicated by dielectric measurements. One of the three conformations about each C–S bond is strongly hindered and was given zero statistical weight whereas the other two were assigned weights determined by second-order effects, operating over three or more consecutive bonds, and dependent on the chirality of the rings and the coulombic interactions between adjacent dipoles.

The calculations for the atactic model, in which a Monte Carlo procedure was used to generate the chain, were found to agree with experiment only if the parameter α was given a value of 5 or greater. This parameter is determined by the relative orientation of successive sulphone dipoles and was expected to have a value less than unity. It appears that specific solvation effects help to stabilize (t, g) and (g, t) C–S–C bond pairs relative to t, t. Other parameters are not so important.

The calculations for the isotactic and syndiotactic models show interesting features, particularly for certain limiting conditions when cyclic or helical structures are generated. For these models there is a greater sensitivity to the various parameters than in the atactic case.

INTRODUCTION

It was shown in Part 1[1] that neighbouring sulphone dipoles in poly(olefin sulphones) are likely to be correlated in orientation by dipole–dipole interactions. From the absence of a dielectric dispersion in the range 10^2 to 2×10^8 Hz in solutions of poly(cyclohexene sulphone) it was deduced that the sulphone groups attached to each cyclohexene ring take up a 1,2-diaxial configuration[2]. There are therefore in effect only two axes of rotation between each pair of neighbouring dipoles, since of the three main-chain bonds between the sulphone groups one (the C–C bond) adopts solely the *trans* conformation with respect to the main chain. The simple matrix scheme of Flory[3], which allows the expression of second order Markov correlations of bond rotation, may thus be applied to this polymer to include explicitly the dipole–dipole interactions, without further elaboration to express third-order correlations[3].

There are two distinguishable ways of substituting the chair form of the cyclohexane ring with 1,2-diaxial substituents. For this study we arbitrarily define the D and L forms as those depicted in *Figure 1*. The existence of these two chiral forms of the repeat unit allows the possibility of tacticity in the chain. Proceeding along such a chain the D and L units may be distributed randomly (atactic polymer), or they may occur alternately (syndiotactic polymer), or each unit may have the same chirality as the previous one (isotactic polymer). The results of the calculations will be independent of our arbitrary labelling of the chiral centres.

In this paper the influence of dipole–dipole correlation and tacticity upon the characteristic dimensions of the polymer is studied. The $^{13}\text{C}-\{^1\text{H}\}$ n.m.r. spectrum of poly(cyclohexene sulphone) made by the radical copolymerization of cyclohexene and sulphur dioxide shows two peaks of equal area for the main chain carbon[4], which indicates an atactic structure, as was also deduced for poly(propene sulphone) made in the same way[5] The properties of the rotational isomeric state model of the atactic chain considered in this paper may thus be compared with experimental data on the atactic polymer and an assessment
Figure 1 The two chiral forms of 1,2-diaxially substituted cyclohexane rings, L and D, as defined in the text

made of the reliability of the calculations of dipole—dipole correlations, made in Part 1.

EXPERIMENTAL VALUES OF THE CHARACTERISTIC DIMENSION

The characteristic dimensions of the polymer have been determined at 25°C in two solvent systems[2], although not under θ-conditions. K_θ was obtained from viscosity measurements made in the good solvent benzene by the Stockmayer—Fixman[6] and the Inagaki—Suzuki—Kurata methods[7], and had a mean value of $(5.4 \pm 0.4) \times 10^{-2}$ cm³/g The Stockmayer—Fixman plot of the viscosity measurements obtained with the poor solvent system dioxane—cyclohexane (59:41% v/v) gave $K_\theta = (5.56 \pm 0.06) \times 10^{-2}$ cm³/g. Since there is no rotation about the C—C main chain bond, $\langle R^2 \rangle/z$, the mean-square end-to-end distance per repeat unit is a more significant quantity than the characteristic ratio $(\langle R^2 \rangle/n(l^2)_{av})$. It is obtained from:

$$K_\theta = \frac{[\eta]_\theta}{M_n^{1/2}} = \frac{\Phi}{q}\left[\frac{\langle R^2 \rangle}{z M_0}\right]^{3/2} \tag{1}$$

where Φ is Flory's θ constant[8], z is the number of repeat units in the chain, M_0 is the weight of a mole of repeat units, q is a polydispersity factor[9] equal to $(M_w/M_n)^{1.5}$. Φ was given the value 2.6×10^{23} g⁻¹, from theoretical[10] and experimental determinations[11], and (M_w/M_n) was assumed the same as that (1.13 ± 0.02) estimated for poly(hex-1-ene sulphone)[12] fractions obtained by similar fractionation techniques. The value of $\langle R^2 \rangle/z$ so obtained from the dioxane/cyclohexane results, 59 $(\pm 2) \times 10^{-20}$ m² (repeat unit)⁻¹, was taken to represent the chain dimensions in benzene also.

ROTATIONAL ISOMERIC STATE CALCULATION

Rotational isomeric state treatments of polymer chains relate a mean-square moment characteristic of a polymeric molecule to: (i) moments associated with individual bonds; (ii) the bond angles and dihedral angles of each rotational state; and (iii) statistical factors which express the relative probabilities of the various possible configurations at each bond. It is well established that these statistical factors should not only express the form of the rotational potential about each bond, but should also include the influence of the rotational states of the neighbouring bonds[3]. A method has been developed for performing such calculations in a convenient manner[13], which also allows the expression of tactic effects in the proper way. The present calculations were based upon equation (2), which is taken from the paper by Flory and Jernigan[14],

$$\langle M^2 \rangle/n(m^2)_{av} = 1 + \left(\frac{2}{Zn(m^2)_{av}}\right)|J^t00\ldots0|G_1^{n-1}\begin{vmatrix} 0 \\ \cdot \\ \cdot \\ \cdot \\ J \otimes m_n \\ J \end{vmatrix} \tag{2}$$

in which n is the number of bonds in the chain, M is the molecular moment, m is the bond moment vector, J is the $r \times 1$ column matrix with all elements unity, and J^t is its transpose. r is the number of rotational states for the bonds, G_1^{n-1} is the product $G_1 G_2 \ldots G_{n-1}$ (the serial pro-

duct), G_i is a function[14] of U_i, m_i and $T_i(\phi_1) \ldots T_i(\phi_r)$, $\otimes$ indicates the direct matrix product, $U_i = [u_{pq}]_i$, the statistical weight matrix for bond i, $u_{pq} = \exp\{-(\epsilon_{(i,p)} + \epsilon_{(i,p;i-1,q)})/kT\}$, $\epsilon_{(i,p)}$ is the energy to promote the bond i to the pth state, $\epsilon_{(i,p;i-1,q)}$ is the energy of the interaction which occurs when the bond $(i-1)$ is then promoted to the qth state. $T_i(\theta,\phi_s)$ is the matrix to transform orthogonally from the coordinate system of bond $(i+1)$ to that of bond i, which has the rotational angle ϕ_s. θ is the angle between the two bond vectors, Z is the partition function $J^t U_1 U_2 \ldots U_{n-1} J$.

The definition of the element u_{pq} of the statistical weight matrix in terms of simple Boltzmann factors[15] carries the assumption, which may not be strictly valid, that the conformational entropy differences are zero.

TRANSFORMATION MATRICES

A segment of the main chain is shown in *Figure 2*. The three bonds S—C, C—C and C—S are labelled as vectors **a**, **v** and **w**, and are all shown in the *trans* conformation. In our calculations the virtual bond **b**, equal to **v** + **w**, replaces the two real bonds **v** and **w**; this may be done because **v** is fixed in conformation. Bond lengths used were those employed in Part 1, and tetrahedral bond angles were assumed. The four right-handed coordinate systems shown in *Figure 2* follow the usual conventions[3].

$T_a(\chi, \phi_a)$ is simply given by:

$$T_a(\chi, \phi_a) = \begin{vmatrix} \cos\chi & \sin\chi & 0 \\ \sin\chi\cos\phi_a & -\cos\chi\cos\phi_a & \sin\phi_a \\ \sin\chi\sin\phi_a & -\cos\chi\sin\phi_a & -\cos\phi_a \end{vmatrix} \tag{3}$$

but because **w**, the second axis of internal rotation in the repeat unit, does not coincide with the second bond vector **b**, the transformation matrix $T_b(\theta_\phi, \phi_b)$ is formulated as the product of three successive transformations: $T_w(\psi, \phi_w)$, which has the same form as $T_a(\chi, \phi_a)$, and transforms to system **w**; and two further transformations $T(\delta)$ and $T(\pi)$, respectively given by:

$$T(\delta) = \begin{vmatrix} \cos\delta & -\sin\delta & 0 \\ \sin\delta & \cos\delta & 0 \\ 0 & 0 & 1 \end{vmatrix} \tag{4}$$

and

$$T(\pi) = \begin{vmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{vmatrix} \tag{5}$$
Figure 2 Coordinate systems of the repeat unit of poly(cyclohexene sulphone)
Figure 3 Rotational states t, g^+ and g^- of the C—S bond **w** attached to an L-ring

which describe successive rotations to transform from system **w** to system **b**. Thus:

$$T_b(\theta_\phi, \phi_b) = T_w(\psi, \phi_w)T(\delta)T(\pi) \qquad (6)$$

(The subscript in θ_ϕ is used because the angle between bonds **b** and **a**' depends upon the conformation adopted by bond **w**, and thus upon ϕ_w).

STATISTICAL WEIGHT PARAMETERS

First order effects

In considering first order effects in poly(cyclohexene sulphone) we have to deal with rotation about only one type of bond, namely the C—S bond. Conclusions concerning first order effects for the C—S bond may be applied equally to the neighbouring S—C bond. *Figure 3* shows the rotational states of the C—S bond **w** attached to an L-ring. The t state is that in which the main-chain bonds are in the planar zig-zag configuration.

In the t and g^- states an oxygen atom is located above the ring, whereas in the g^+ state a carbon atom, to which is attached a hydrogen and two other carbon atoms (part of the next ring, not shown), is in this position. In order to assess the relative importance of these three states we may compare the internuclear distances with the sums of the appropriate van der Waals radii.

For the g^+ state the carbon atom above the ring will be in close proximity to the two axial hydrogen atoms shown, which each form part of a methylene group. The distance between the carbon nucleus above the ring and the carbon nuclei to which these axial hydrogens are attached is 283 pm, which is appreciably less than twice the van der Waals radius of a methylene group (400 pm). In reality the sum of the van der Waals radii for the interacting groups will be substantially greater than this since the carbon atom above the ring is in fact part of a methine group in a substituted cyclohexane ring. Turning now to the t and g^- states the distance between the oxygen nucleus above the ring and the carbon nuclei of the ring methylene groups is 273 pm, which is again somewhat less than the sum of the individual van der Waals radii for a methylene group and

an oxygen atom (340 pm). However, in this case there is likely to be an attractive force arising from the dipole induced in the C—H bonds by the neighbouring S—O dipole, thereby decreasing the effective van der Waals radii. Such an effect appears to operate in poly(trimethylene oxide) where there is an attractive interaction[16] between oxygen atoms and methylene groups at a separation of 290 pm.

Thus there are strong reasons for believing that the t and g^- states will be greatly preferred over the g^+ state. We therefore assign statistical weights of 1, 0 and 1 to the t, g^+ and g^- states respectively, for an L-ring. The corresponding weights for a D-ring are 1, 1 and 0 respectively. Second order effects, considered in the next section, modify this otherwise very simple situation.

Second order effects

Here we have two things to consider. First, the effect of the rotational states of bond **w** on those of the subsequent bond **a** (the direction of the chain is defined in *Figure 2*); and second, the effect of the rotational states of bond **a** on those of the subsequent bond **w**. In both cases steric effects arise which depend on the chirality of the rings in the neighbourhood of the bond; but coulombic interaction between adjacent dipoles arises only in the second case, and is independent of the chirality of the rings.

Correlation parameters for bond **a**. The interactions associated with the (**w**, **a**) bond pair depend on the chirality of the two rings adjacent to the bonds and on the conformations about each bond. There are four possibilities so far as the chirality is concerned, namely DD, LD, DL, LL, and three possibilities for the conformations about each of the two bonds, although, as discussed earlier, one of these for each bond may be assumed to have zero weight. In deciding what parameters to introduce at this stage we therefore need to examine $4 \times 2 \times 2 = 16$ possible structures. Of these, four are depicted in *Figure 4a* and four in *Figure 4b*, the other eight being mirror images of these. It should be noted that sulphur atoms are attached to each ring *either* at S_L *or* S_D, the chirality of the ring then being denoted by the subscript. It will be seen that four structures summarized in *Figure 4a* have the same steric interactions but arise from four different combinations of configuration and conformation as listed in *Table 1*; likewise
Figure 4 Representation of eight of the sixteen accessible structures in relation to bond a. On each ring only one of the two positions labelled S_D and S_L is actually occupied by a sulphur atom; if the sulphur is attached at S_D the ring has D-chirality, similarly for S_L. (a) depicts four of the combinations and (b) the other four as listed in *Table 1*

4	L	g^-	t	D	1
5	D	g^+	t	L	1
6	D	t	g^+	L	1
7	D	g^+	g^+	D	σ
8	D	t	t	D	1

for the four structures summarized in *Figure 4b*. The eight mirror-image structures may be derived from those listed in *Table 1* by exchanging L and D, and g^+ and g^-.

For the structures shown in *Figure 4a* there are two possible interactions to consider, that between the two hydrogens labelled H_i and that between the pair labelled H_j. For

a tetrahedral lattice the internuclear distance for each pair of atoms is 132 pm, which will give rise to a severe steric repulsion. From Hendrickson's data[17] we may estimate the repulsion energy at this distance to be in excess of 36 kJ/mol. It is likely that the H_j interaction will be relieved by a small twist from the tetrahedral lattice, but the H_i interaction will be less easily accommodated. For the structures shown in *Figure 4b*, there may be much smaller interactions between pairs of hydrogen atoms H_k and H_l, their internuclear distance on a tetrahedral lattice being 214 pm. To take account of this difference between the two groups of structures we introduce the parameter f as the statistical weight of the structures shown in *Figure 4a* relative to those shown in *Figure 4b*. f is expected to be very much smaller than 1.

Let us now examine the more highly populated structures shown in *Figure 4b* and their four mirror images in more detail. They form four pairs in which the chirality of the rings is fixed but the two bonds w and a have a different sequence of conformations. Combination 3 is the reverse of combination 5, which is the mirror image of combination 4. Combinations 3 and 4 may therefore be assigned equal weights of unity; likewise for combinations 5 and 6. However, combinations 1 and 2, and also 7 and 8 may have different weights and we introduce the parameter σ as indicated in *Table 2* to take account of this possibility. Examination of *Figure 4b* shows that in combination 7 alternate sulphone groups, labelled S_D and S_D, are brought closer together than in combination 1 (which is the mirror image of combination 8) where the alternate sulphone groups are labelled S_L and S_L. There is, however, no steric interaction and we may expect σ to be close to unity.

The statistical weight matrices for bond a are summarized in *Table 3*. If, as the above arguments suggest, f is zero, and σ is unity it is apparent that (w, a) bond pairs are limited to very few possibilities, namely the eight shown in *Table 2* which will be restricted still further if the chain is isotactic or syndiotactic. For example if successive rings have D chirality and bond w has t conformation then bond a

must also have t conformation. This absolute determinance is an important feature of the model of which use is made in the next section.

Correlation parameters for bond **w**. Here we consider how the rotational state of bond **w** is affected by that of bond **a** which precedes it in the chain, and which lies on the other side of a cyclohexane ring. Three possible sequences are shown in *Figure 5*. We shall not for the moment consider the dispositions of the chain before C_a or beyond C_w, but simply recall that the conformations of the bonds immediately outside this segment are exactly determined as summarized in *Table 2*.

The first point to note is that as the conformations in the (**a**, **w**) bond pair vary, so does the relative orientation of the two sulphone dipoles. *Figure 5a* shows the all-*trans* conformational sequence (on an L-ring), which is taken as the reference state so far as coulombic interactions of the sulphone dipoles are concerned. When either bond **a** or bond **w** is converted to the g^- state, as for example in *Figure 5b*, the sulphone dipoles take up a relative orientation which we will define as an α-interaction, characterized by a statistical weight of α. When both bonds **a** and **w** are in the g^- state, as in *Figure 5c*, there is a different relative orientation of the dipoles, and we give this arrangement a statistical weight of γ. As previously concluded when examining first order effects, g^+ states of bonds attached

to an L-ring may be assigned a statistical weight of zero. For bonds attached to D-rings, it is the g^- states of the bonds which have zero statistical weight and the α and γ interactions then correspond to the (**a**, **w**) bond pairs (t, g^+) or (g^+, t), and (g^+, g^+) respectively. The calculations in Part 1 show that the excess energies associated with α and γ ($\epsilon_\alpha = -kT\ln\alpha$; $\epsilon_\gamma = -kT\ln\gamma$) might be expected to be of the order of 5 and 9 kJ/mol respectively. This would suggest that $1 > \alpha > \gamma$. However, the assumption of a constant relative permittivity of the medium and the neglect of specific solvent effects could well upset this order and we have therefore not restricted the values of ϵ_α and ϵ_γ in the calculations.

One further type of interaction can be taken into account as a result of the severe restriction of available conformational sequences. If one examines sequences of three rings there are 8 possible combinations of chiralities coupled with four possible conformational sequences of the four bonds (two **a** and two **w**). Of these 32 arrangements, models show that in two ($Dg^+g^+Dg^+g^+D$ and its mirror image) there is severe overlap at the ends of the sequence. Account of this has been taken by introducing an additional parameter ω in the statistical weight matrix for the **w** bond.

The statistical weight matrices for bond **w** are summarized in *Table 4*.

THE COMPUTER PROGRAM

Equation (2) was computer-programed in Algol 60 to perform the calculations, $\langle R^2 \rangle/z$ being subsequently obtained using the relationship $n(l^2)_{av}/z = a^2 + b^2 = 10.7 \times 10^{-20}$ m^2 (cf *Figure 2*). *Table 5* contains the **U** matrices deduced for the rotatable bonds of the repeat units of the tactic polymers. The rotational states there shown with zero weights were excluded from the calculations, reducing the problem in effect to a 2-state model, with a consequently smaller requirement of computer time. For the atactic chain the random sequence of ring chiralities was simulated by a Monte Carlo technique[13], 400 or 800 chemical repeat

units being generated. Matrix squaring was then used to find a limiting value of $\langle R^2 \rangle/z$. The standard deviation of the mean characteristic dimensions of several such Monte Carlo chains was taken as an indication of the reliability of the simulation process.

RESULTS OF CALCULATIONS AND DISCUSSION

We give first the results for the atactic chain since here we can make a direct comparison with experiment. The results for the isotactic and syndiotactic chains show some interesting features which may have a wider bearing than on the particular polymer under consideration.

Atactic chain

A preliminary calculation was made using the following values, based on the earlier discussion: $f = 0$, $\sigma = 1$, $\omega = 0$, $\epsilon_\alpha = 5.1$ kJ/mol ($\alpha = 0.13$ at 25°C), $\epsilon_\gamma = 9.0$ kJ/mol ($\gamma = 0.026$). This gave $\langle R^2 \rangle/z = (211 \pm 33) \times 10^{-20}$ m^2 (repeat unit)$^{-1}$ which is nearly four times the experimental value. Since the discrepancy is most likely to stem from an incorrect estimation of α and γ (the coulombic parameters) these were varied first in order to discover what values were necessary to bring the calculated values into line with experiment.

Figure 6a shows that there is marked dependence of $\langle R^2 \rangle/z$ on ϵ_α for all values of ϵ_γ used. The important thing to notice is that the calculated values of $\langle R^2 \rangle/z$ lie in the region of the experimental value only for values of ϵ_α more negative than -4.0 kJ/mol ($\alpha \geqslant 5.0$). The dependence on ϵ_γ in this region is only slight, as shown in *Figure 6b*. We have also tested the effect of making f and ω finite, and of allowing σ to depart from unity. The results are shown

in the form of plots of $\langle R^2 \rangle/z$ against the appropriate ϵ value in *Figures 7a, 7b* and *7c*. It will be seen that in the regions close to $f = 0$ (high ϵ_α), $\omega = 0$ (high ϵ_ω), and $\sigma = 1$ ($\epsilon_\sigma = 0$) there is no significant dependence of $\langle R^2 \rangle/z$ upon any of these parameters taken singly.

Thus the most important parameter, so far as the atactic chain is concerned, is α and, unexpectedly this has to be assigned a value considerably greater than unity in order to obtain agreement with experiment. We must now consider what this means in physical terms and how it can be explained. α is the statistical weight of (**a**, **w**) bond pairs which have one t and one g conformation, relative to those in which both are t. This means that although in the polymer chain all the C–S bond dipoles cancel for both types of bond pair (since the C–C bonds are always t) the adjacent sulphone groups prefer to take up a non-parallel arrangement in benzene or in dioxane/cyclohexane mixtures despite the fact that simple coulombic considerations suggest that such an arrangement should have the higher energy. The difference in coulombic energies is changed in magnitude but not in sign if a different value of the relative permittivity of the medium is used in the calculation. In order to account for a value of α greater than 1 it is necessary to postulate a differential solvation effect,
Figure 6 Atactic chain. (a) Dependence of $\langle R^2 \rangle/z$ on ϵ_α for values of ϵ_γ equal to 10.5 (○), 0 (△), and -10.5 (□) kJ/mol, and taking $f = \omega = 0$, $\sigma = 1$. in which the solvent tends to stabilize the (t, g) or (g, t) bond pair relative to the t, t bond pair. Such an effect has indeed been observed with small molecules such as 1,2-dichloroethane[18] where both benzene and dioxane have been found to solvate the *gauche* form preferentially; likewise for 1,2-dibromoethane in benzene[19]. In the second case it has

been estimated that the g form is stabilized by this effect to the extent of 1.7 kJ/mol. Other things being equal, this effect will be proportional to the square of the moment of the dipole interacting with the solvent (regarding the effect as arising from a dipole-induced dipole attraction). The sulphone dipole is more than twice as big as the C—Cl and C—Br bond dipoles, so that an effect of the order of 8 kJ/mol in the present system is not unreasonable and will reconcile the value of α deduced from the chain dimensions with that estimated from simple coulombic interactions. The presence of the cyclohexane ring to one side of the chain contour may also be a factor assisting differential solvation of the (t, g) and (t, t) states. It may be noted that differential solvation is also believed to be an important factor in the interpretation of solvent effects on n.m.r. chemical shifts[20], end-to-end distances[21] and mean-square dipole moments per repeat unit in polysulphones[22].

In an earlier paper[2] we noted that the free rotation parameter, $(\langle R^2\rangle/\langle R_f^2\rangle)^{1/2}$, had a value of 1.24, $\langle R_f^2\rangle$ being derived on the basis of two freely rotating C—S bonds per repeat unit. It was concluded that the energy levels for the three conformations about the C—S bonds were close together. The present, more refined, treatment shows that this is not correct; the number of available conformational sequences is much more restricted and the fact that $(\langle R^2\rangle/\langle R_f^2\rangle)^{1/2}$ is close to unity is fortuitous.

Isotactic chain

In the calculations for the isotactic chain the parameters γ and ω always occur as a product (see *Table 5*) so that we may treat $\gamma\omega$ as a single variable. Plots of $\langle R^2\rangle/z$ against ϵ_α, ϵ_σ and $(\epsilon_\gamma + \epsilon_\omega)$ are shown in *Figures 8a, 8b* and *8c* respectively.

Comparison with *Figures 6* and *7* show that there is a marked difference in the nature of the curves for the atactic and isotactic chains. For the isotactic chains the calculated characteristic ratio is very sensitive not only to the value of α but also to the values of σ and $\gamma\omega$. However, it may be noted that the minima of many of the curves lie close to the experimental value for the atactic chain. The much greater dependence of $\langle R^2\rangle/z$ upon any one parameter is a consequence of the much stronger correlations imposed by the tacticity of the chain. This means that on the rising parts of the curves there is a strong tendency towards helix formation and it is necessary to go to very high values of z before a limiting value of $\langle R^2\rangle/z$ is reached. For example in *Figure 8b*, at the minimum in curve C, the limit was reached within 0.02 m² (repeat unit)$^{-1}$ at $z = 2050$, whereas for the point at $\epsilon_\sigma = 12.6$ kJ/mol the limit was only reached at $z = 130\,000$.

Syndiotactic chain

For this model, two parameters, α and γ, have been varied, f being taken as zero (see *Table 5*). The calculated values of $\langle R^2\rangle/z$ are plotted in *Figures 9a* and *9b*. When either α or γ is zero an extreme type of behaviour is exhibited. Let us consider these in turn.

(1). $\alpha > \gamma = 0$. This corresponds to the right-hand side of *Figure 9b*. Under these conditions, the four *rotatable* bonds in the repeat unit have the sequence (g^-, t, g^+, t), in the limit of large z. The chemical repeat unit then has two bonds in the *trans* conformation, and the third in a *gauche* conformation. *Gauche* conformations along the chain have alternate sign, and the chain describes a ring. This is why the limiting value of $\langle R^2\rangle/z$ is zero for all finite values of α.

(2). $\gamma > \alpha = 0$. This corresponds to the right-hand side of *Figure 9a*. Two sequences of conformations for the repeat unit are equally probable under these circumstances. These are (g^-, g^-, t, t) and (t, t, g^+, g^+), and their repetition generates respectively right-handed and left-handed helices, for which $\langle R^2 \rangle/z \propto z$ and has no limit. The two helices cease to be mutually exclusive if the condition $\alpha = 0$ is relaxed. As α increases relative to γ, the points along the chain at which transitions between the two helix forms occur come closer and closer together, until eventually the random coil form of the chain is obtained.

The convergence of $\langle R^2 \rangle/z$ to the limiting value in a variety of polymers has been found to be from below[14,23]. With certain values of α and γ, when conditions are close to those which lead to the chain describing a ring, it was found that the limiting value of $\langle R^2 \rangle/z$ was approached from above. This type of convergence arises from the quasi-ring structure of the polymer.

A consequence of the form of the statistical weight matrices is that a set of values of ϵ_α and ϵ_γ exist for each value of $\langle R^2 \rangle/z$. It was found that for each set there was relationship between ϵ_α and ϵ_γ of the form $\epsilon_\gamma = 2\epsilon_\alpha +$ constant.

CONCLUSIONS

The main conclusion from this work is that, for the atactic polymer, the parameter α unexpectedly has a value greater

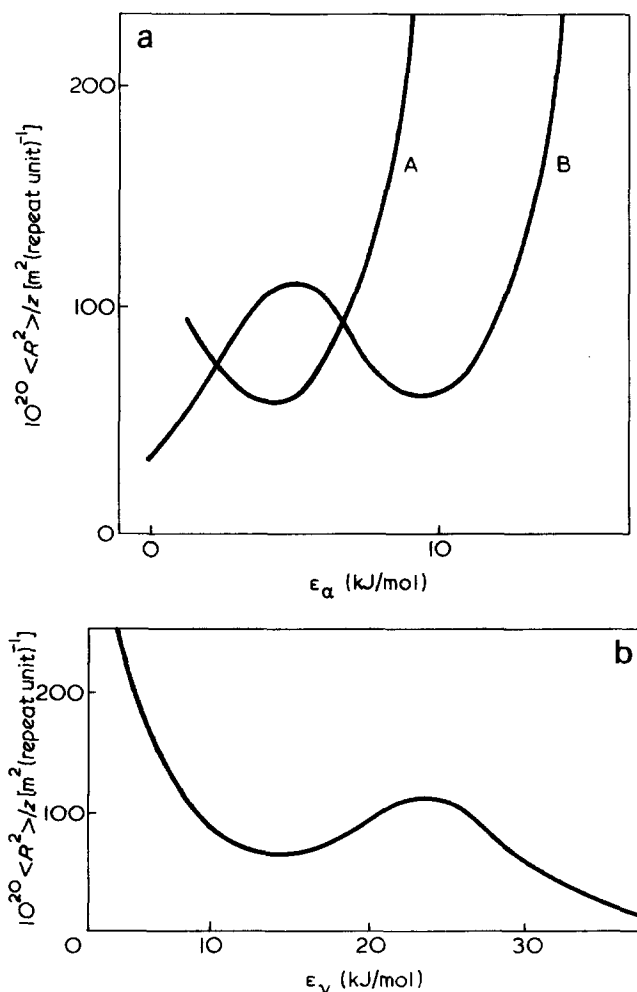
Figure 8 Isotactic chain. (a) Dependence of $\langle R^2 \rangle/z$ on ϵ_α for values of $(\epsilon_\gamma + \epsilon_\omega)$ of (A) −6.3, (B) −2.1, (C) 8.4 kJ/mol; with $\sigma = 1$, $f = 0$. (b) Dependence of $\langle R^2 \rangle/z$ on ϵ_σ for values of (A) $\epsilon_\gamma + \epsilon_\omega = \epsilon_\alpha = 0$, (B) $\epsilon_\gamma + \epsilon_\omega = -\epsilon_\alpha = 4.2$, (C) $\epsilon_\gamma + \epsilon_\omega = \epsilon_\alpha = -4.2$, (D) $\epsilon_\gamma + \epsilon_\omega = \epsilon_\alpha = -8.4$ kJ/mol; with $\sigma = 1$, $f = 0$. (c) Dependence of $\langle R^2 \rangle/z$ on $(\epsilon_\gamma + \epsilon_\omega)$ for values of ϵ_α of (A) −8.4, (B) −4.2, (C) 2.1 kJ/mol; with $\sigma = 1$, $f = 0$


Figure 9 Syndiotactic chain. (a) Dependence of $\langle R^2 \rangle/z$ on ϵ_α for values of ϵ_γ equal to (A) 10.5, (B) 21 kJ/mol, with $f = 0$. (b) Dependence of $\langle R^2 \rangle/z$ on ϵ_γ for $\epsilon_\alpha = 6.3$ kJ/mol, $f = 0$

than unity, perhaps even bigger than 5, whereas a simple treatment in terms of coulombic interactions between adjacent dipoles would have suggested a value less than unity. It thus appears that specific solvation effects help to stabilize (t, g) and (g, t) states for C—S—C bond pairs in poly(cyclohexene sulphone).

For the isotactic and syndiotactic models the value of $\langle R^2 \rangle / z$ is much more sensitive to the various parameters than in the atactic case and a marked dependence of the solution properties of such polymers on solvent is to be expected.

Study of molecular packing density in boundary layers of some polymers

Yuri S. Lipatov, E. G. Moisya and G. M. Semenovich
Institute of Macromolecular Chemistry, Academy of Sciences of the Ukrainian SSR, 252160, Kiev 160, USSR
(Received 9 September 1974; revised 11 November 1974)

Packing density of macromolecules of some amorphous polymers, poly(methyl methacrylate), polystyrene and polydimethylsiloxane, in boundary layers formed at the solid—polymer interface, was studied by a 'molecular probe' technique. It was shown that the boundary layers of the above polymers have a complex structure composed of regions with different densities of molecular packing: a surface region of thickness 2 to 4 μm, and a transient and loosely-packed region of thickness of the order of 30 to 60 μm. It was established that both the structure and the thickness of boundary layers for each of the polymers depends both on polymer chain flexibility, and on cohesion energy density of a polymer.

INTRODUCTION

Current interest in the phenomena occurring at the solid—polymer phase interface is readily explained by their role in the properties of filled polymers. Experimental data accumulated during recent years leads one to conclude that in the vicinity of the polymer—solid interface a boundary layer is formed, the properties of which markedly differ from those of polymer in bulk[1-4]. Physico-chemical investigations of the layer have shown that the polymer—solid interaction results in the net decrease of segmental mobility of macromolecules near the interface, and may lead in some cases to the shift of glass transition temperature of a polymeric matrix and/or change of molecular packing density in the latter. However, studies of packing density in filled polymers in different laboratories have given seemingly discordant results. For example, experimental data obtained by methods which permit the estimation of the overall effect of a solid—polymer interface on the properties of a filled polymer, suggest[1] that packing efficiency of macromolecules in filled systems is worse than that in pure samples. This was attributed by some authors[1] to the loosening of molecular packing in boundary layers. On the other hand, investigation of properties of very thin polymeric films on various fillers reported by Nesterov and Lipatov[5] indicates that boundary layers have a rather complex structure and that the packing density change with distance from the filler surface is not smooth.

The purpose of the present paper is to study the packing density of macromolecules near the polymer—solid interface as a function of chain flexibility, cohesion energy density (*CED*) of a polymer and energetic properties of a filler surface. We have chosen for this study polystyrene (PS), poly(methyl methacrylate) (PMMA) and polydimethylsiloxane (PDMS). As shown in *Table 1*, the first two polymers have similar values of a flexibility parameter σ^*, while their *CED*'s are different, and the last two (PS and

PDMS) possess approximately equal *CED* values, but markedly different σ[3,6]. This choice allows us to elucidate the contribution of polymer chain flexibility and its energetic interaction with the substrate to the change of packing density at the solid—polymer interface.

EXPERIMENTAL

We used in this study the 'molecular probe' (MP) technique[7-10] which is especially suitable for estimation of magnitude of the packing density change in polymeric matrix under various environmental conditions. This information is provided by measurements of the magnitude of the absorption spectral shifts, $\Delta\nu$, or luminescence spectra of impurity molecules dissolved in a matrix polymer with respect to the spectra of these molecules in the 'free' state (vapour). Since the magnitude of spectral shifts for 'probe' molecules in non-polar or weakly polar media exhibits quadratic dependence on the density of a medium, the equation for a molecular packing density change in polymer boundary layers with respect to polymer density in the bulk phase[10] is:

$$\frac{\rho_{boundary}^2}{\rho_{bulk}^2} = \frac{\Delta\nu_{boundary}}{\Delta\nu_{bulk}} \tag{1}$$

where $\rho_{boundary}$ and ρ_{bulk} are polymer 'apparent' densities in boundary layers and in the bulk, $\Delta\nu_{boundary}$ is the difference $\nu_{vapour} - \nu_{boundary}$, and $\Delta\nu_{bulk}$ is the difference $\nu_{vapour} - \nu_{bulk}$, $\nu_{boundary}$ and ν_{bulk} are band positions for a

* $\hat{\sigma} = \langle r^2 \rangle_0 / \langle r^2 \rangle_f$, where $\langle r^2 \rangle_0$ and $\langle r^2 \rangle_f$ are mean-square end-to-end dimensions of an 'unperturbed' macromolecule and of a model freely rotating chain respectively.

pure electron transition or a position of one band of vibrational electronic sequence in spectra of absorption or luminescence of probe molecules, incorporated into the boundary layers or bulk phase respectively, and ν_{vapour} is the position of the same band in the vapour spectrum of the impurity molecules. Having determined experimentally the values $\nu_{boundary}$ and ν_{bulk} and knowing ν_{vapour}, we may estimate the deviation of packing density in the boundary layers from that in the bulk phase from equation (1). In this work change of packing density of macromolecules in the boundary layers was estimated from the shift of position of $(\nu_{00} + 2 \times 1405)$ cm^{-1} band of luminescence spectra of anthracene probe molecules which are in a molecularly dispersed state in studied polymers.

Luminescence spectra of anthracene molecules in polymeric matrices were recorded at the liquid nitrogen temperature (77 K) using the spectrometer model DFS-12. Luminescence was excited with a high pressure mercury lamp model DRS-500 equipped with a glass filter λ_{max} = 365 nm. Since both excitement and recording spectra were effected from the substrate side, the latter had to satisfy the following requirements: (i) the substrates had to have different surface energies (see above); (ii) they should be transparent in the u.v. region. These requirements seemed to be met by the fused silica and Teflon polymer. Prior to use the fused silica slides were annealed at 600°C for 1.5 to 2 hours, while Teflon films were carefully washed with the same solvents which were used for casting of polymer samples. The following polymers with a rather narrow molecular weight distribution were used: atactic PS of high purity (product of Waters Associates Co., USA) with $\bar{M}_w$ = 867 000 and $\bar{M}_n$ = 773 000; atactic PMMA (product of suspension polymerization supplied by Miss N. Averbakh, Dzerzhinsk) with the 'viscosity-average' molecular weight (chloroform, 25°C) 590 000, which was obtained by a step-by-step precipitation fractionation in acetone—water and subsequent solvent evaporation; and commercial sample of PDMS (trademark SKT, supplied by Dr Yu. Godovsky, Moscow) with the viscosity molecular weight 237 000 purified by a double precipitation. It is pertinent to note that sudden quenching of PDMS in liquid nitrogen virtually excludes any possibility of its crystallization, so that it forms a glass below its glass transition temperature[11]. This means that all the data obtained in the present work refer to glassy polymers. Films from the above polymers were cast from 'good' solvents (chloroform, dichloroethane and benzene for PMMA, PS and PDMS respectively) on a substrate. All solvents used were carefully purified, dried and fractionally distilled according to standard methods[12]. To insure the homogeneous distribution of impurity molecules in the solution, an amount of anthracene corresponding to desired concentration in polymer was added to a solvent before a polymer. The polymer concentration in solution was always 0.2 g/100 ml. Polymer films were formed at room temperature on the substrates and then dried in a vacuum oven to a constant weight. The thickness of the polymer films on the substrates remained constant, while the thickness of the layer from which the information was obtained was varied by changing the concentration of impure probe molecules in the range from 10^{-2} to 10^{-4} g/g. This method allowed us to follow the packing density change in the polymer matrix at different distances from the substrate, since all other conditions being equal, the higher the concentration of probe molecules in a matrix, the lower the depth of penetration of exciting radiation into the polymer surface layers. Hence, we obtain information on the density of an environmental phase of impurity molecules which refers only to those polymer layers which are in the immediate vicinity of a solid surface. On the other hand, when the probe molecules concentration is low, the radiation penetrates to greater depth (Lambert—Beer law), and we obtain information on the density of the medium in the more distant layers, the thickness of which is greater, the lower the concentration of impurity molecules in a polymer. Using eight different anthracene concentrations (see *Figure 1*) we calculated from a knowledge of the absorptive characteristics of anthracene[13], the dependence of an 'apparent' polymer layer thickness on impurity concentration. The experimental error (i.e. resolution of an adjacent weak band on the wing of a principal luminescence band) is about 10%, and therefore our calculations were limited to those thicknesses corresponding to a 90% absorption at a given concentration. Noticeable differences between impurity molecules spectra in surface layers and in the bulk or in the loosely packed regions would imply that the former might be superimposed on the latter. This effect, however, should not be taken into account because transition from higher concentrations (10^{-2} g/g) to the lower ones is accompanied by a rather large decrease of relative intensity of probe molecules in the surface layers, and will not exceed about 10% at a concentration of 10^{-3} (10% on the band wing will be close to the experimental accuracy limit), while at a concentration of 10^{-4} g/g it will drop to only 1% with respect to the overall intensity of anthracene spectra.

RESULTS AND DISCUSSION

The observed changes in the position of fluorescence spectra of probe molecules at different concentrations of the latter are shown in *Figure 1*. The ordinate shows the values of the ratio $\rho_{boundary}/\rho_{bulk}$ (in %) calculated from the experimental values of spectral shifts of impurity molecules and the abscissa log C from which the thickness of the surface layer was calculated.

It can be seen that increase of packing density of macromolecules in the immediate vicinity of the solid surface is a common feature for all polymers and substrates used. Since this effect is observed both for high energy, as well as low energy solid surfaces, it seems reasonable to propose that the orientation of macromolecules under the influence of the solid is dominating[14]. The corresponding packing density increment for this surface layer with respect to the bulk polymer for the three polymers amounts to 3 to 5%. Comparison of the influence of high energy and low energy substrates on the packing density of macromolecules in the surface layers shows that the difference was most pronounced for PMMA, which has a high *CED* value (132 cal/cm^3) and rather stiff chain (σ = 2.14), somewhat less for PS which has similar chain stiffness but lower *CED*, whereas for PDMS which possesses the lowest values of σ and *CED*, the nature of the substrate plays a rather minor role. This comparison alone shows that the mode of molecular packing in the polymer boundary layers depends significantly on values of σ and *CED*. Moreover, the whole spectrum of changes of packing density (i.e., quantitative differences between packing densities in boundary layers and in the bulk, thickness of the layer where structural rearrangement due to the solid surface effect is still observed, and differences between effects of a high energy and low energy solids, etc.) was also most noticeable for PMMA with the high *CED* and σ, while it was the least for PDMS with
Figure 1 Change of packing density of macromolecules in boundary layers as function of the distance from the polymer—solid interface. (a) PDMS; (b) PS; (c) PMMA; —, boundary layers on fused silica; - - -, those on Teflon

minimum values of *CED* and σ, PS exhibiting an intermediate effect. Structural rearrangement in the surface layers of films cast on Teflon was limited to formation of a densified surface layer with thicknesses of 2 to 3 μm for PDMS and 3 to 4 μm for PS and PMMA. In the more remote regions for the most flexible polymer (PDMS) the orienting effect of both high energy and low energy substrates virtually disappears and the packing density at distances of more than 3 μm from the solid corresponds to that for a bulk polymer. In the case of PMMA and PS the structure of the layer formed on the high energy substrate (fused silica) is rather complex: here the regions in the immediate vicinity of interface that show an enhanced packing density are followed presumably by regions where packing density is close to that in the bulk ('transient' layers), after which packing of macromolecules becomes looser than in the bulk ('loosely-packed' regions). The thickness

of the boundary layers on the high energy substrate where the change of molecular packing density compared to that of the bulk phase is still observed, was estimated as 30 μm for PS and 60 μm for PMMA.

CONCLUSIONS

The results indicate that the surface layers have a complex structure. The layer nearest to the solid exhibits enhanced packing density of macromolecules as compared with the bulk, and this can be tentatively attributed to the orienting effect of the solid surface. At larger distances from the solid the orientation induced by a substrate surface greatly weakens, especially in the case of low energy solids and/or polymers with high chain flexibility and low cohesion energy density, the effect being more pronounced the lower the flexibility parameter, σ. For polymers with stiffer chains and stronger interactions with a substrate, however, such structural changes are far more evident. In this case and for films cast on a high energy substrate the 'transient' layer is followed by a 'loosely-packed' region with the packing density lower than that for bulk polymer. This effect is observable in the more remote regions, the higher the *CED* of the polymer.

Effect of pressure on the formation of poly(methyl methacrylate) glasses

Colin Price
Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 8 December 1974)

Poly(methyl methacrylate) (PMMA) glasses were formed by cooling from the fluid state at constant pressures in the range 0.1—295 MN/m² and then decompressing at 20°C. The densities of the glasses determined at 30°C and atmospheric pressure were found to increase with increasing cooling pressure; for the highest cooling pressure investigated the percentage densification was 1.43. Heats of solution of the PMMA glasses in toluene were measured at 30°C using a Calvet microcalorimeter. The results showed that for cooling pressures up to 70 MN/m² the enthalpy of the glasses remained approximately constant, but increased progressively over the upper part of the range covered. The results for PMMA glasses were compared quantitatively with results obtained earlier for polystyrene glasses. Using hole energies determined by Smith and assuming that rotational isomerism became frozen in at the glass transition, conformational contributions of 0.13 and 0.07 J g⁻¹ K⁻¹ were calculated for PMMA and polystyrene respectively.

INTRODUCTION

Tammann and Jenckel[1] showed that formation of organic glasses by cooling from the fluid state at elevated pressures leads to samples which are more dense (at say 20°C and 0.1 MN/m²) than those formed by cooling at atmospheric pressure. Some years later Shishkin[2] carried out a lengthy investigation of the densification process for a range of glass forming substances including poly(methyl methacrylate), polystyrene, phenolphthalein and boron trioxide. From the results it was possible to conclude that densification was a general phenomenon for glass forming substances and that it was not merely an artifact associated with the method of transmitting the pressure. Shishkin's interpretation of the effect was that the substances had been artificially moved down their supercooled fluid curves and therefore were in a state closer to thermodynamic equilibrium than glasses formed by conventional cooling methods.

Renewed attention has been given in recent years to the effect of conditions of formation on the properties of organic glasses and in particular of the effect of pressure[3–7]. A thermodynamic analysis carried out by Gee[6] for temperatures and pressures up to 126°C and 125 MN/m² respectively indicated that densification of a polystyrene sample by means of a temperature/pressure cycle had very little influence on the enthalpy of the sample as determined at 20°C and atmospheric pressure. Calorimetric studies[8–10] on polystyrene glasses confirmed this somewhat surprising result and further showed that if higher pressures and temperatures were used in the cycle the enthalpy actually increased with densification.

In the present study an investigation is reported of the effect of densification on the enthalpy of poly(methyl methacrylate) glasses and the results are compared with those obtained earlier for polystyrene.

EXPERIMENTAL

Poly(methyl methacrylate) (PMMA)

The polymer was prepared by free-radical polymerization and separated into three fractions by liquid—liquid separation using benzene/iso-octane as the solvent/non-solvent mixture. The investigation was carried out on the middle fraction; the weight-average molecular weight of this fraction determined by light scattering was 180 000, and the $\bar{M}_w/\bar{M}_n$ from gel permeation chromatography was 1.6. The material was compression moulded into sheets ~3 mm in thickness. Residual water was removed by maintaining the samples at a temperature of 112°C for several days. Until required for study the sheets were stored in a desiccator at room temperature.

High-pressure equipment

A pressurized reservoir fed oil into the low-pressure end of a high compression pump. The pump, which was an air-driven reciprocating pump manufactured by Pressure Products Inc., could generate pressures up to 1000 MN/m² and these were transmitted to a pressure vessel containing the sample using a hydrocarbon oil as the hydrostatic fluid. Pressures were measured by means of a calibrated Astra pressure gauge. The dimensions of the internal cylindrical cavity of the pressure vessel were 1.9 cm (diam.) and 15.2 cm (length). Inside the pressure vessel, samples (pieces cut from the sheets) were kept within a stainless-steel container filled with mercury; the mercury transmitted the hydrostatic pressure to the samples but prevented any contact of the samples with the oil. An electrically heated jacket permitted the pressure vessel to be thermostated to ±0.2°C. An outer water jacket facilitated cooling at lower temperatures. Temperatures were measured using thermocouples inserted into the base of the vessel.

Densification procedure

The polymer was heated at a constant pressure to a temperature T_x above the ordinary glass transition temperature (105°C). The pressure was then built up over a period of 15 min to a value P_a which was insufficient to bring about glass formation at T_x. Maintaining the pressure constant the system was then cooled down at ~1 K/min to 20°C. At this stage the applied pressure was released and the polymer was recovered and stored in a desiccator at —5°C. This

Figure 1 Experimental assembly of the microcalorimeter cell

recorder assembly (Sefram Verispot galvanometer, projection lantern, and photodyne spot-follower).

During the course of an experiment the recorder deflection Δ was measured as a function of time. The thermal power, W, developed in the 'laboratory' cell (relative to the 'reference' cell) at time t was given by

$$W = (p/g)\Delta + \tau(p/g)(d\Delta/dt) + Pi(1 - iI^{-1}) \qquad (1)$$

where (p/g), τ, P and I are calibration constants and i is the applied Peltier current. Thus the quantity of heat emitted by the cell contents between times t_1 and t_2 was given by:

$$q = (p/g) \int_{t_1}^{t_2} \Delta dt + \tau(p/g) \int_{\Delta_1}^{\Delta_2} d\Delta + \sum_{j=1}^{j=n} Pi_j(1 - i_j I^{-1})(t)_j \qquad (2)$$

In the heat of solution measurements, the second term on the righthand side of equation (2) was zero, since experiments were started and ended on the same base line (i.e. $\Delta_1 = \Delta_2 = 0$). The first term was determined from the area under the recorder curve and the third term from the times $(t)_j$ for which each Peltier current i_j was applied.

The experimental assembly within the 'laboratory' cell (G) is shown schematically in *Figure 1*. In a mixing experiment the glass rod (L) was depressed by means of brass push rod (B) attached to a microsyringe head until the Teflon stopper (P) was forced out of the roof of the cell. The sample (S) then dropped into the solvent (X), toluene, contained in the inner glass cell (K). To facilitate mixing the sample was prevented from falling straight to the bottom of the cell by means of a copper wire (W). Forcing out the Teflon stopper inevitably generated a small quantity of heat near the roof of the cell; it was possible to compensate for this small effect by setting up a reference system in which the sample was replaced by a piece of Pyrex glass.

Each experimental run was conducted as follows: the 'laboratory' and 'reference' cells were first loaded and inserted in position by means of the Teflon tubes (R). When the base-line had stabilized, the two push rods were screwed down simultaneously by turning each micrometer screw approximately six turns. During the mixing process the deflection of the recorder was kept as small as possible by means of the Peltier effect; normally, it was possible to compensate for about 90% of the total heat output. The complete mixing experiment usually took about 4 h.

procedure was repeated for different values of P_a up to 295 MN/m². (The constant pressure used in the initial heating part of the cycle was $\sim P_a/3$.) The densities of the glasses were determined by a flotation method at 30°C using the mixture of non-solvents utilized by Kimmel and Uhlmann[11]. The observed percentage densifications were checked dilatometrically for the glasses to be used later in the heat of solution studies. In this procedure mercury was used as the dilatometric fluid, and the change in volume of the sample brought about by annealing at 115°C overnight was determined at 30°C.

Microcalorimetry

A detailed description of the theory, construction, calibration and operation of the Calvet microcalorimeter may be found elsewhere[12]. Briefly the instrument consisted of an aluminium heat sink containing two cavities into which fitted twin cylindrical cells (referred to as 'laboratory' and 'reference' cells). The twin cells, 1.7 cm (diam.) and 8.5 cm (length), were constructed of stainless steel and were held on Teflon tubes (R) via screw threaded Teflon plugs (N) (see *Figure 1*). The temperature of the aluminium block was controlled to ±0.001 K. In each cavity a thermopile (496 copper/constantan thermocouples) was interposed between cell and metallic block. Either a quarter or three-quarters of the thermocouples in the pile surrounding the 'laboratory' cell could be used to generate the compensating Peltier effect. The remaining thermocouples were connected in opposition to their counterparts surrounding the 'reference' cell, and the net output from these fed to a

RESULTS AND DISCUSSION

In *Figure 2* the percentage density increase of the PMMA at 1 atm pressure and 30°C is plotted against the pressure (P_a) applied during the cooling part of the temperature/pressure cycle. The density of a PMMA glass formed by cooling from 120°C under 1 atm pressure at a rate of 1 K/min was taken as the reference ($\rho = 1.184_0$). As observed previously for polymeric glasses[2,5,9], the densification produced by a given pressure increment falls off with increasing pressure. For the highest cooling pressure investigated, $P_a = 295$ MN/m², the percentage densification was 1.43. Allowing for the somewhat different molecular weight characteristics of the samples, the percentage densifications obtained in the present study are in fair agreement with those obtained by Shishkin for PMMA[2].

It has been argued[13,14] that if a single ordering parameter was sufficient to describe the excess thermodynamic pro-
Figure 2 Percentage increase in density of PMMA glasses determined at 30°C and atmospheric pressure as a function of the pressure applied during cooling from the fluid state

perties of the fluid state over those of the glassy state then the following relationships would hold:

$$dT_g/dP = \Delta K/\Delta a \tag{3}$$

$$dT_g/dP = TV\Delta a/\Delta C_p \tag{4}$$

where ΔK, Δa and ΔC_p are the discontinuities in the compressibility, the thermal expansion coefficient and the heat capacity at the transition, and dT_g/dP is the dependence of the glass transition temperature on pressure. Even if this description does not hold, Goldstein[4] has suggested that if the transition occurs at a constant value of the excess volume V_e, equation (3) should apply, whilst if the transition occurs at a constant value of the excess entropy or the excess enthalpy, equation (4) should apply. From assessments[4,6] of the available data it appears that $dT_g/dP < \Delta K/\Delta a$, whilst $dT_g/dP \simeq TV\Delta a/\Delta C_p$. The densification phenomenon can be accounted for on a thermodynamic basis in terms of the inequality attached to the first of these relationships. Following the line of argument put forward by Beuche[3] let us consider the two processes (a) and (b) shown in *Table 1*.

The fractional changes in volume which occur during the processes are

$$\Delta V_a/V = a_f[(T_g)_p - (T_g)_0] + K_g P \tag{5}$$

and

$$\Delta V_b/V = K_f P + a_g[(T_g)_p - (T_g)_0] \tag{6}$$

where a_f and a_g are the coefficients of expansion and K_f and K_g the compressibilities of the polymer in the fluid and glassy states respectively. Hence,

$$(\Delta V_a - \Delta V_b)/V = \Delta a[(T_g)_p - (T_g)_0] - \Delta K P \tag{7}$$

Since it has been shown that $\Delta a[(T_g)_p - (T_g)_0] < \Delta K P$ the sample produced by process (a) should be denser than that

produced by process (b). It should be noted, however, that the validity of this simple argument rests on the assumption that it is possible to ignore relaxation effects (i.e. it is possible to establish time-independent values of a_g and K_g for all the conditions of interest). If further we assume that densification has no influence on the values of a_g and K_g, equation (7) will provide us with a rough estimate of the percentage densification expected from the temperature/pressure cycle used in the present study. Setting[6] $\Delta K = 1.23 \times 10^{-4}$ MN^{-1} m^2, $\Delta a = 2.95 \times 10^{-4}$ K^{-1} and $dT_g/dP = 0.23$ K MN^{-1} m^2 we obtain $(\Delta V_a - \Delta V_b)/V = -1.63 \times 10^{-2}$ for glasses formed by cooling at $P = 295$ MN/m^2 which corresponds to a percentage densification of 1.65 (cf 1.43, *Figure 2*). The discrepancy between the calculated and observed values is not serious in view of the assumptions made; better agreement would be obtained by taking account of the temperature and pressure dependence of Δa and ΔK, but this refinement was not felt worthwhile in view of the general uncertainty posed by relaxation effects.

Heats of solutions ΔH_s of the PMMA glasses in the solvent, toluene, at $P = 1$ atm and $T = 30°$C are recorded in *Table 2*; the final concentration of each solution was 0.01 g/cm^3. For the purpose of discussion the dissolution process can be considered to take place in two stages:

$$\text{glass} \rightarrow \text{hypothetical fluid}$$

$$\text{hypothetical fluid} + \text{solvent} \rightarrow \text{solution}$$

Hence we have $\Delta H_s = (H_f - H_g) + \Delta H_{sf}$, where H_g and H_f are the enthalpies of the glass and hypothetical fluid respectively and ΔH_{sf} is the enthalpy change on dissolution of

Figure 3 Dependence of the enthalpy of PMMA glasses on the pressure applied during cooling from the fluid state

the hypothetical fluid. The first contribution, $(H_f - H_g)$, is large and exothermic due in part to a substantial volume relaxation and is responsible for the large exothermic heat of solution on dissolution of the glass; the second contribution, ΔH_{sf}, is much smaller than the first and may be slightly endothermic. The difference in enthalpy between any two glasses is obtained by taking the negative difference of their heats of solution. Relative enthalpies of densified PMMA glasses calculated in this way are given in *Table 2*; again a PMMA glass cooled from 120°C under 1 atm pressure at a rate of 1 K/min was taken as the reference material.

In *Figure 3* the difference in enthalpy between densified and reference glasses (ΔH_d) is plotted against the pressure (P_a) at which the densified glass was cooled from the fluid state. Over the lower part of the pressure range (up to 70 MN/m^2) the enthalpy is seen to be approximately independent of volume. The result is similar to that first observed by Allen *et al.*[8] for polystyrene and later verified by Ichihara *et al.*[10]. With further increase in densification however there is a significant increase in enthalpy. A similar trend was observed by Price *et al.*[9] on studying polystyrene over an extended pressure range. In disagreement with the present results, Kimmel and Uhlmann[11,15] using a d.s.c. method found that the enthalpy of PMMA decreased on densification. Since the percentage densifications were very similar to those obtained in this work, it is difficult to account for the discrepancy. It may be associated in some way with the fact that they used a Bridgeman anvil device in their temperature/pressure cycles, whereas here hydrostatic pressures were used.

The calorimetric results obtained for polystyrene in previous studies and those reported for PMMA in this paper are inconsistent with the suggestion[2] that densified glasses are closer to thermodynamic equilibrium than ordinary glasses, since if a substance was artificially moved down its supercooled-fluid curve its enthalpy would be expected to fall. The results imply that for pressures up to 70 MN/m^2, T_g occurs at an approximately constant value of the excess enthalpy, but that on going to higher pressures T_g occurs at progressively increasing values of this function.

Let us now consider the factors which will govern the relative enthalpies of the glasses. Within the framework of free-volume theories the total volume of a liquid is considered to be divided into a part 'occupied' by the molecular segments and a 'free volume' which is shared communal-

ly and distributed in the form of disconnected holes[16-18] Each hole is characterized by its molar volume, v_h, and the molar excess energy, e_h; for PMMA and polystyrene, e_h/v_h = 400 and 350 J/cm^3 respectively[19]. In a liquid the holes and phonons associated with the liquid matrix are in thermal equilibrium. A glass may be distinguished from a liquid in that the free volume is independent of temperature, and continual redistribution of free volume no longer occurs. If the densification phenomenon observed in the present studies was associated solely with a reduction of frozen-in free volume, the enthalpy of a densified glass would be lower than that of the reference glass by $\Delta H_v \simeq (e_h/v_h)$ $(\rho_r^{-1} - \rho_d^{-1})$. Since as shown in *Figure 3* the enthalpy does not fall in this way, there must be some compensation factor involved, ΔH_c, having a value of $\Delta H_d + \Delta H_v$. As suggested previously[6,8] the conformational energy of the chains is a possible source of this compensation factor. Rotational isomerism will be frozen-in at a temperature in the region of T_g, so that the magnitude of the compensation factor will be a function of the temperature of glass formation. In *Figure 4*, ΔH_c is plotted against $[(T_g)_p - (T_g)_0]$ for PMMA and polystyrene; the results for polystyrene were determined from data given in ref 9. In calculating the effect of pressure on T_g, dT_g/dP was taken as 0.23 K MN^{-1} m^2 for PMMA and 0.31 K MN^{-1} m^2 for polystyrene. Using the method of least squares to establish the best linear plots passing through the origin, the conformational contributions of PMMA and polystyrene were calculated to be 0.12_9 and 0.07_1 J g^{-1} K^{-1} respectively.

It is possible, however, that 'internal strain' within the densified glass may be responsible for part of the compensation factor. On removing the pressure at the end of the cycle the volume will increase in a manner which is consistent with the minimizing of the free energy of the system within the limits imposed by the restricted translational motion of the molecules. Depending on the volume change involved, some 'internal strain' such as distortion of main-chain bond angles could be introduced during this process. This would make a positive contribution to the
Figure 4 Dependence of the compensation enthalpy ΔH_c of PMMA (O) and of polystyrene (+) on $(T_g)_p - (T_g)_0$

compensation energy and would lead to a lower estimated value for the conformational contribution arising from freezing-in of rotational isomerism.

Catalytic action of metallic salts in autoxidation and polymerization: 11. Polymerization of methacrylic acid esters with sodium hexanitrocobaltate in methanol–water

Zenjiro Osawa, Hitoshi Kanazawa, Yuji Kuwako and Yoshitaka Ogiwara
Department of Polymer Chemistry, Faculty of Engineering, Gunma University, Kiryu City, Gunma 376, Japan
(Received 26 March 1973; revised 2 September 1974)

The polymerization of a series of methacrylic acid esters (methyl, ethyl, isopropyl and n-butyl) with sodium hexanitrocobaltate, $Na_3[Co(NO_2)_6]$ was carried out in a methanol–water mixed solvent. The homogeneity of the polymerization system was dependent on the composition of the mixed solvent and greatly affected the rate of the polymerization. A maximum rate was obtained at approximately equimolar fractions of methanol and water in the polymerization of methyl methacrylate. The effect of bulkiness of ester groups on the polymerizability of each monomer was indistinguishable in the mixed solvent system. Kinetic study of the polymerization of methyl methacrylate in a mixed solvent of about an equimolar fraction of methanol and water gave the following polymerization equation: $R_p = k[I]^{1/2}[M]^2$, and an apparent activation energy of 10.6 kcal/mol. The copolymerization of methyl methacrylate and styrene with the initiator suggested that polymerization proceeded via a radical mechanism. The possibility of a certain interaction between initiator, solvent and monomer in the initial stage of the polymerization is discussed on the basis of the kinetic data, properties of oligomers of methyl methacrylate, spectroscopic and other data.

INTRODUCTION

This paper discusses the polymerization of methacrylic acid esters (methyl, ethyl, isopropyl and n-butyl) with sodium hexanitrocobaltate, $Na_3[Co(NO_2)_6]$, in various alcohol–water mixed solvents and the initiation mechanism.

Extensive studies have been made on the vinyl polymerization of methyl methacrylate with metal salts or metal chelates[1-9], and it has been reported that a few cobalt (III) complexes could initiate the polymerization of vinyl monomers in an aqueous medium[10-14]. In a previous paper[15] of this study we reported that sodium hexanitrocobaltate could initiate the polymerization of methyl methacrylate in mixed solvent of acetone and water. By further study we found that the same initiator could polymerize methyl methacrylate in a methanol–water mixed solvent much faster than in an acetone–water solvent. We have now carried out a kinetic study on the polymerization of methyl methacrylate with $Na_3[Co(NO_2)_6]$ in about an equimolar fraction of water and methanol and here discuss the possibility of a certain interaction between initiator, solvent and monomer in the initial stage of the polymerization.

EXPERIMENTAL

Materials

Sodium hexanitrocobaltate $Na_3[Co(NO_2)_6]$ was prepared according to a literature method[16], from reagent grade sodium nitrite and cobalt nitrate $Co(NO_3)_2 \cdot 6H_2O$, and was identified by its infra-red spectra[17]. Purification of monomers and solvents was performed in the usual manner[18].

Polymerization

Kinetic studies were carried out in a simple dilatometer and rapid preparative polymerizations in a glass tube under nitrogen. The polymerization products were treated in the usual manner[19]. For the oligomeric materials, the contents of a glass tube were poured into a large amount of water and the precipitates were purified by precipitation from acetone into water. The polymerization conditions are shown in the Figure captions.

Characterization of polymers and oligomers

Molecular weights of the polymers were measured viscometrically in benzene solution at 25°C with the aid of the intrinsic viscosity molecular weight relationship of Fox *et al.*[20]. Oligomers were characterized by i.r. spectral analysis, elemental analysis and determination of molecular weight by a vapour pressure method. Ultra-violet spectroscopic measurements were made with a Hitachi double beam type spectrometer.

RESULTS AND DISCUSSION

Dependence of conversion on solvent composition

The relationships between conversion of methacrylic acid ester monomers and molar fraction of water in alcohol-water mixed solvents are shown in *Figures 1* and *2*. As shown in *Figures 1* and *2*, homogeneity of the polymerization system at the initial stage is greatly affected by mole fractions of water and alcohols, and the conversion of each monomer is extremely dependent on the homogeneity of the system. In general, homogeneous systems give higher conversion than heterogeneous ones. The effect of bulki-

ness of the ester group on the polymerizability of each monomer is, therefore, indistinguishable in these mixed solvent systems. In the case of methyl methacrylate a maximum conversion is observed at about an equimolar fraction of water and methanol. The following kinetic study was, therefore, made in a mixed solvent of 0.49 mole fraction of water.

Kinetic study

The dependence of the polymerization rate, R_p, on the concentration of initiator and monomer was examined at very low conversion and in homogeneous solutions. Usually time—conversion curves were approximately linear for 50 min, and during this time the degree of polymerization was almost constant and no appreciable increase in the degree of polymerization was observed thereafter.

The overall rates of polymerization, R_p, were calculated from the initial linear time—conversion curves, and it was found that the rate was proportional to the square root of the initiator concentration and to the square of mono-mer concentration, respectively. The plots of the overall rate of polymerization obtained against the product of the square root of initiator concentration and the square of monomer concentration are clearly linear (see *Figure 3*). Accordingly, the polymerization rate equation can be expressed as follows:

$$R_p = k[I]^{1/2}[M]^2$$

Figure 3 Plot of R_p against $[I]^{1/2}[M]^2$. Polymerization conditions for dependence on initiator concentration: [M] = 3.51 mol/l; [I] = 1.55 x 10^{-4} to 7.74 x 10^{-4} mol/l; total solvent = 10 ml (3 ml H_2O and 7 ml MeOH); temperature = 50°C; for dependence on monomer concentration: [I] = 6.19 x 10^{-4} mol/l; [M] = 1.17 to 3.51 mol/l; total solvent = 10 ml (3 ml H_2O and 7 ml MeOH); temperature = 50°C
Figure 4 Radical copolymerization curve of methyl methacrylate with styrene. Polymerization conditions: [I] = 8.26×10^{-4} mol/l; total monomer = 5 ml (MMA and St); solvent = 7 ml (2 ml H_2O and 5 ml MeOH, corresponding to 0.47 fraction of water); time = 3 h; temperature = 50°C

The dependence of the polymerization rate on temperature was examined between 40° and 60°C. An Arrhenius plot was linear over the temperature range 40 to 60°C and gave an activation energy of 10.6 kcal/mol.

The degree of polymerization ranged from ~1400 to 5800 and decreased with increasing initiator concentration and increased with increasing monomer concentration.

In order to elucidate whether the polymerization proceeded via a radical mechanism, copolymerization of methyl methacrylate and styrene with $Na_3[Co(NO_2)_6]$ was carried out. The copolymerization curve shown in *Figure 4* is apparently the same as that obtained by a conventional radical copolymerization. The polymerization of this system was also inhibited by conventional inhibitors such as hydroquinone and diphenylpicrylhydrazyl (DPPH). These results indicate that the polymerization proceeds via a radical mechanism.

Furthermore, we also confirmed that the overall rate of polymerization of methyl methacrylate with a conventional radical initiator, azobisisobutyronitrile (AIBN), in the same methanol—water mixed solvent was proportional to the first power of monomer concentration.

The dependence of the polymerization rate on the square of monomer concentration suggests the participation of monomer in the initiation reaction. In order to examine the initiation mechanism, oligomeric materials were prepared and were characterized by their molecular weight, i.r. spectra, and elemental analyses. The i.r. spectra of the oligomers and the polymers are shown in *Figure 5* and clearly show the presence of nitro groups, namely two peaks at 1560 cm^{-1} due to C—NO_2 and 1650 cm^{-1} due to N—O, whereas those of the polymers indicate the presence of the nitrogen groups only in minor amounts. The nitrogen content of the oligomers was measured and compared with their average molecular weights determined by a vapour pressure method. The results obtained are summarized in *Table 1*. Since the nitrogen content of the oligomers observed was almost equal to that of the calculated one, the oligomers presumably contain two nitro groups at

both ends of the molecule. If the oligomers contain two nitro groups, possible termination reactions may be recombination of growing oligomer radicals themselves, recombination of chain radicals with primary radicals, and chain transfer of chain radicals to the initiator.

Baysal and Tobolsky[22] suggested a well known kinetic scheme for vinyl polymerization with an initiator, and proposed that the following equation could be used to estimate the chain transfer reaction in solution polymerization:

$$1/\bar{P}_n = C_M + C_I[I]/[M] + C_S[S]/[M] + R_p\delta^2/[M]^2$$

where $\bar{P}_n$ = the number-average degree of polymerization, C_M, C_I, C_S = chain transfer constants for monomer, initiator, and solvent, respectively, [I], [M], [S] = concentrations of initiator, monomer, and solvent, respectively, R_p = overall rate of polymerization, δ^2 = a constant and equal to $(2k_{td} + k_{tc})/k_p^2$, and k_{td}, k_{tc}, k_p = rate constants of termination by disproportionation, termination by recombination and rate constant of propagation. Recently, Potnis and Deshpande[23,24] presented a comprehensive kinetic study of the polymerization of vinyl acetate using the Baysel and Tobolsky method. The same treatment was, therefore, made in order to examine the possibility of chain transfer reaction to initiator in this polymerization system. The relationship between $1/\bar{P}_n$ and $R_p/[M]^2$ is shown in *Figure 6*. From *Figure 6*, δ^2 was estimated to be 0.57 x 10^2. The relationship between $(1/\bar{P}_n - R_p\delta^2/[M]^2)$ and $[I]/[M]$ is shown in *Figure 7*. The slope of the linear curve shown in *Figure 7* is almost zero ($C_I = 0$). Therefore, the results indicate that no chain transfer to initiator is present in the polymerization system.

* Assumed that one oligomer molecule contains two NO_2 groups Polymerization conditions: [I] = 2.45×10^{-2} mol/l; [M] = 3.06 mol/l; solvent = 7 ml (2 ml H_2O and 5 ml MeOH); time = 30 min; temperature = 47°C (for exp.1), 40°C (for exp.2)
Figure 6 Relationship between $1/\bar{P}_n$ and $R_p/[M]^2$. Polymerization conditions: $[M]$ = 3.51 mol/l; $[I]$ = 1.55 x 10^{-4} to 7.74 x 10^{-4} mol/l; $[S]$ = 10.8 mol/l; MeOH—H$_2$O mixed solvent (0.49 molar fraction of water); time = 1 h; temperature = 50°C
Figure 7 Relationship between $(1/\bar{P}_n - R_p\delta^2/[M]^2)$ and $[I]/[M]$. Polymerization conditions are the same as in *Figure 6*

The other two possibilities for termination are recombination of oligomer radicals themselves and recombination of oligomer radicals with primary radicals. However, it is well known that termination in methyl methacrylate polymerization is normally predominantly by disproportionation. Thus, the more probable termination to produce oligomers containing two NO$_2$ groups in one molecule seems to be recombination of chain radicals with primary radicals.

Spectrophotometry

The aforementioned dependence of the polymerization rate on the square of monomer concentration implies the participation of monomer in the initiation process. Spectroscopic measurements seem to give some information for the elucidation of the initiation mechanism. An aqueous solution of Na$_3$[Co(NO$_2$)$_6$] shows four absorption peaks in the visible and u.v. regions, namely, 240, 280, 360 and 470 nm. Among them the absorption peak at 360 nm is the clearest and decays with slight blue shift. Based on these facts, the u.v. spectra of the initiator in water and in a methanol—water mixed solvent in the presence and absence of monomer were measured at 20° and 50°C. The decay of the absorption peak at 360 nm is shown in *Figure 8*. This apparently shows that the decay of the

absorption peak at 360 nm is fairly fast in water and the addition of methanol and monomer enhance further the rate of decay. Furthermore, the rate of decay of the absorption is substantially increased with the rise of temperature and at 50°C the peak at 360 nm becomes almost constant within 10 min. No evidence of the formation of a complex between initiator and monomer was observed by spectrophotometry. However, these results may indicate that the initiator changes to other active species by the partial replacement of ligand with solvent, and that the primary radicals may be generated by the interaction of the active species and monomer. In other words, the results suggest the presence of a certain interaction between initiator, solvent and monomer at the beginning of the polymerization.

To confirm the assumption of the interaction, the effect of standing time of the initiator in the mixed solvent on conversion was examined. After the addition of mixed solvent of methanol—water into a glass tube containing the initiator, the solution was kept at 50°C for various times and then polymerization was started by adding monomer. By the treatment of the initiator with solvent, the rate of polymerization was decreased remarkably. For example, after 1 h standing the rate of polymerization became almost half the rate observed when all components were added together, and after 24 hours standing no polymer was obtained, during 3.5 h polymerization. The kinetic treatment was, of course, made without prior standing of the initiator in solvent, and the rates of polymerization were calculated by the use of the initial linear time—conversion curves. Thus, the active species formed by the interaction of the initiator and solvent or monomer should be sufficiently unchanged to allow one to assume a stationary state in the polymerization system.

The results mentioned above may imply the presence of a certain interaction between initiator, solvent and monomer in the initial stage of the polymerization. However, the polymerization mechanism of the examined system is fairly complex and various elementary reactions may be considered.

Low temperature internal friction in some poly(α-olefins)

M. Pineri
*Centre d'Etudes Nucléaires de Grenoble, Département de Recherche Fondamentale, BP 85, 38041
Grenoble Cédex, France*
(Received 6 December 1974; revised 11 February 1975)

1 Hz internal friction experiments have been carried out using a torsion pendulum. The temperature
range was between 4 and 100K. The existence of a very low temperature δ peak has been studied in
poly(α-olefins)

$$-CH_2-CH-$$
$$|$$
$$(CH_2)_n$$
$$|$$
$$CH_3$$
where n = 0–3. Polyethylenes have been studied in the same way. Evidence has been given for the
existence of a low temperature peak coming from the presence of nitrogen or air. After purification
we obtained $\Delta W/W$ against temperature curves without a δ peak for polyethylene and polypropylene
samples. Evidence has been given for the existence of such δ peaks in polypentene and polyhexene.
A possible mechanism involving the rotation of the alkyl group is proposed.

INTRODUCTION

Frequency spectra of chain motions define the dynamical
physical properties of polymers. During the last ten years
many experiments have been carried out in this field. Di-
electric measurements, nuclear magnetic resonance experi-
ments, dynamic mechanical techniques and more recently
incoherent inelastic neutron scattering spectroscopy have
given much information about molecular motion[1–7].

This paper considers the δ type processes which occur at
low temperatures (below 100K) when using 1 Hz dynamic
mechanical techniques. Many experiments have been car-
ried out between liquid helium and nitrogen tempera-
tures[8–19]. Yet many questions are still unsolved as far as
we are concerned with the interpretation of this δ peak.
When the temperature is lowered, molecular motions are
more and more frozen in. At very low temperatures only
very local motions are possible, such as methyl rotation.
Many polymers containing pendant methyl groups, PMMA,
polypropylene, polybutene, have been studied. Relaxation
peaks appeared in some polymers.

It has been proposed that methyl group rotation is the
mechanism responsible for the existence of this peak. Yet
this explanation is not consistent with experiments per-
formed with polybutene (no δ peak) and poly(vinyl
chloride) (one peak at 20K). Another inconsistency arises
from the position of the peak compared to the value of the
barrier of potential ($\sim$2 kcal). Quantum mechanical tun-
nelling as suggested by Eisenberg[11] can explain this last
inconsistency.

Another explanation for the very low temperature
peaks in semi-crystalline polymers has been advanced by
some authors[8–10]. Motions of dislocation jogs and their
interactions with specific conformational kink defects
would produce δ maxima.

Our purpose of the present study is to review the influ-
ence of the size of the side group in polymers such as:

$$-CH_2-CH-$$
$$|$$
$$(CH_2)_n$$
$$|$$
$$CH_3$$
where n is 0–3. In addition we have used polyethylene as
a reference. If δ peaks arise from methyl rotation we must
have such a peak in polyhexene, polypentene, polybutene
and polypropylene. The position of this peak must stay at
the same temperature. The amplitude of the maximum
must change with the relative number of methyl groups.

EXPERIMENTAL

Procedure

A 1 Hz torsion pendulum was used for the experiments
described in this paper. It consists of an inverted free
oscillating apparatus which has been previously described[20].
We plot against temperature the values:

$$\Delta W/W = 1 - \exp\left(-\frac{2}{n}\ln\theta_o/\theta_n\right)$$

and

$$G_T/G_4 = P_4^2/P_T^2$$

where θ_o and θ_n are the amplitudes of the oscillations o
and n. P_T is the period of the decrease at temperature T.
Figure 1 1 Hz $\Delta W/W$ (x) and G/G_4 (□) against temperature curves for a polyethylene

When the damping is low, as in the case of our experiments, we have:

$$\frac{\Delta W}{W} \simeq 2\delta \simeq 2\pi Q^{-1}$$

Materials

Six different commercial types of polyethylene have been studied. The density varies from 0.9 for the most branched polyethylene to 0.97 for the most linear.

Polypropylene, polybutene, polypentene and polyhexene were synthesized in the laboratory of 'Cinetique chimique macromoleculaire' by Dr Guyot.

The characterization of the different samples which have been studied was carried out in the Laboratoire de Chimie Macromoléculaire de l'Université Claude Bernard Lyon I. Infra-red spectroscopy, X-ray diffraction experiments, differential enthalpic analysis and density measurements were done on the different polymers.

The polymorphism of polybutene (I, II and III), polypentene (I and II), polypropylene (α, β and γ) and polyhexene has been taken into account.

Using quenching and annealing treatments the influence of crystallinity has been studied in these polymers.

Different catalytic systems were used in order to have polymers of different tacticity and of different molecular weights.

No important difference has been observed when changing these parameters in a polymer in the low temperature range studied. For this reason we will speak of a polymer without considering the different values which define it.

All the samples were prepared by compression moulding into sheets 0.5 mm thick. Differential enthalpic experiments have been performed so as to define the heat of fusion and the onset of melting temperature for each specimen.

RESULTS

Figure 1 shows the curve of $\Delta W/W$ against temperature for a polyethylene. We can see a peak, the maximum of which is located at 50K for 1 Hz experiments. We have obtained such a peak in many experiments studying specimens of polybutene, polypentene, polyhexene, nylon, etc. This peak is characterized by a very quick decrease in the high temperature side. The amplitude of the maximum seemed to change in a hazardous manner.

In the same way we have obtained such a peak in experiments with graphite to define the origin of this peak. When having an entry of air or nitrogen we have observed such a peak while nothing appears with oxygen. For 1 Hz experiments the peak appears at 60K with air and 54K with nitrogen: *Figure 2* shows the different curves.

From these last experiments we can conclude that the peak shown in *Figure 1* is connected with a presence of nitrogen. We suppose that the formation of a very thin coat of solid nitrogen on the specimen has occurred. Internal friction damping comes from this coat.

Such a peak was no longer observed when we used the following procedure. After the sample had been mounted in the pendulum chamber, the entire system was evacuated to 10^{-2} mmHg overnight. Purified helium gas was introduced to give 15 mmHg pressure. Purification of helium was achieved by adsorbing O_2, N_2, H_2O molecules on a synthetic zeolite molecular sieve. The chilling of the molecular sieve to liquid nitrogen temperature was accomplished by plunging the trap in liquid nitrogen. Thus when the δ peaks are studied, we must pay particular attention to the purity of the exchange gas and to the quality of the initial vacuum.

Figure 3 shows the curves of $\Delta W/W$ against temperature for a polyethylene; G_T/G_4 is similarly plotted. It is seen that we have a continuous increase in $\Delta W/W$ beginning from 4K. This increase corresponds to the γ peak, the maximum of which is located between 123 and 153 K depending on the percentage of CH_3 in the polyethylene. For all the
Figure 2 1 Hz Q^{-1} against temperature curves for nuclear graphite without exchange gas (...) and with oxygen (---), with nitrogen (—·—·) and air (——) as exchange gases
Figure 3 1 Hz ΔW/W (X) and **G/G₄** (□) against temperature curves for a polyethylene after purification of the exchange gas
Figure 4 1 Hz ΔW/W (X) and **G/G₄** (□) against temperature curves for a polypropylene specimen

polyethylene specimens we have studied, no δ peak has been seen.

Figure 4 shows the same curves obtained for a polypropylene sample. The increase in $\Delta W/W$ values is not very important between 4 and 80K. The decrease in the values of G_T/G_4 is uniform in this range of temperatures. *Figure 5*

shows the curves of $\Delta W/W$ and G_T/G_4 for the polybutene specimen. No important change in the curves appears when we change the phase (I, II or III) or the crystallinity.

Figure 6 shows the same curves obtained for the poly-pentene specimen. In the same way no change has appeared when we change the phase or crystallinity. The important increase of the $\Delta W/W$ value between 20 and 80K is con-
Figure 5 1 Hz ΔW/W (X) and **G/G₄** (□) against temperature curves for a polybutene specimen
Figure 6 1 Hz ΔW/W (X) and **G/G₄** (□) against temperature curves for a polypentene specimen
Figure 7 1 Hz $\Delta W/W$ ($\times$) and G/G_4 ($\square$) against temperature curves for a polyhexane specimen

nected with the γ peak. We have the superposition of a δ peak as shown by an inflection point at ~34K.

Figure 7 shows the same curves for polyhexene. The range of temperatures is between 4 and 210K. The γ peak has its maximum at 120K. The large increase in the $\Delta W/W$ value from 180K is associated with the β peak corresponding to the glass temperature. An important decrease in the modulus is associated with these peaks. Evidence of the existence of a δ peak, superimposed to the low temperature side of the γ peak, is given by the change of slope in the $\Delta W/W$ against temperature curve.

Another kind of experiment has been carried out, similar to that recently made by Papir and Baer[8,9]. We start with a linear polyethylene which as previously seen gives no evidence of a δ peak. The specimen is annealed for 2 h at 128°C, being submitted *in situ* to a 660 g/cm² tension. After cooling at 4K we obtain the curve shown in *Figure 8*. A new peak centred at 35K appears. When annealing in the same way but without tension, we do not obtain this peak. With polypropylene we have not obtained a peak when annealing with tension or not.

DISCUSSION

First, we wish to demonstrate that classical rotation of methyl groups cannot give a maximum in dynamic mechanical experiments.

Let us consider such a chain:

$$-CH-$$
$$|$$
$$CRH_2$$

which gives the Newman representation and the potential curve of *Figure 9*.

If n_1 = the number of CRH_2 groups with R in position number 1 or 2, E_1 = the energy of CRH_2 in such a position,

n_2 = the number of CRH_2 groups with R in number 3 position, E_2 = the energy of CRH_2 in such a position, we have $n = n_1 + n_2$ (total numbers of CRH_2). Therefore the total energy is:

$$E_0 = n_1 E_1 + n_2 E_2$$

$$n = n_1 + n_2$$

$$\frac{n_1}{n_2} = \exp(V/KT)$$

which gives:

$$E_0 = \frac{n}{1 + \exp(V/KT)}\left[\exp\left(\frac{V}{KT}E_1 + E_2\right)\right]$$
Figure 8 1 Hz $\Delta W/W$ ($\times$) and G/G_4 ($\square$) against temperature curves for a polyethylene after annealing for 2 h at 128°C. A 660 g/cm² tension was maintained during the annealing

$$-\!\!-\!\!-CH-\!\!-\!\!-$$
$$|$$
$$CRH_2$$
Figure 9 Potential barrier associated to the rotation of alkyl groups
Figure 10 60 Hz $\Delta W/W$ against temperature curve for a poly-pentene specimen

If now at a given time t we have a deformation, we will change the value $V \rightarrow V'$. Therefore, we have two consequencies:

(1) We will change the energies: $E_1 \rightarrow E_1'$ and $E_2 \rightarrow E_2'$. This change is instantaneous. The energy of the system becomes:

$$E_0 = \frac{n}{1 + \exp V/KT} \left[\exp \left(\frac{V}{KT} E_1' + E_2' \right) \right]$$

(2) We will change the populations. Since this last change is not instantaneous, it will depend on the value of V_0 and KT. The new energy will be for $t \rightarrow \infty$:

$$E_0' = \frac{n}{1 + \exp V'/KT} \left[\exp \left(\frac{V'}{KT} E_1' + E_2' \right) \right]$$

If the deformation is periodic:

$$V' = V + a \sin \omega t$$

Such a system will give a loss of energy, the maximum of which will be for $\omega \tau \simeq 1$ where ω is the frequency of oscillation:

$$\tau = \frac{1}{2K \exp(V_0/KT)}$$

If now R = H (methyl group rotation), for the deformation there will be an instantaneous change of the CH_3 energy. But there will be no change of this energy by rotation because of the identity of the H groups. No peak in internal friction experiments can appear in that case.

The problem to be discussed now is are there δ peaks in polyethylene, polypropylene, polybutene, polypentene, and polyhexene? If such a peak appears, what is the mechanism involved?

From our experimental results we can draw the following conclusions: no δ peak appears in polyethylene and polypropylene samples, and there is a δ peak superimposed on the low temperature side of the γ peak in polypentene and polyhexene specimens. An internal friction experiment carried out at a frequency of 60 Hz in *Figure 10* gives more evidence of the presence of a δ peak in a polypentene specimen.

We are unable to draw a conclusion about the presence or absence of such a peak in polybutene.

It seems now impossible to separate the γ and δ contributions in the $\Delta W/W$ curve since we do not know the exact mechanisms which are involved in the relaxation peaks. We can only obtain qualitative information about the existence or non-existence of a δ process if we plot $\Delta W/W$ (*Figure 6*) or G'' (*Figure 11*) against temperature. Only experiments at higher frequencies are perhaps able to give such a separation.

What is now the mechanism which is able to give a δ peak? Methyl rotation was proposed to explain such a peak. As we have seen classical rotation is unable to give such a peak and there is no evidence of maximum in polypropylene. Inelastic tunnelling as proposed by Eisenberg[11,12] is a possibility to explain a very low temperature peak (~6K) in PMMA.

Classical rotation of a CRH_2 group in polybutene, polypentene, and polyhexene is able to take into account the presence of a low temperature peak.

If we suppose an Arrhenius law, $v = v_\infty \exp(W/KT)$, for the rotation of the alkyl group we can define the energy activation W from the position of the maximum. We must take an arbitrary value for v_∞. In polypentene and polyhexene the maximum of the δ peak is located around 40K. With $V_\infty = 10^{13}$ we obtain $W \approx 2$ kcal which is relatively low compared to the values defined for the rotation of small molecules.

Polyhexene is an amorphous polymer, polypentene is a semi-crystalline one. Therefore it is impossible to propose a mechanism involving defects and dislocations in the crystalline phase to explain the δ peak.

The aim of this paper is not to discuss the interpretation for the γ peak. However, we can state that the γ peak in polyhexene (amorphous) must be connected to the motions of the backbone involving side groups. In the same
Figure 11 1 Hz G' (——) and G'' (· · ·) against temperature curves for a polypentene specimen

way an important part of the γ peak in polypentene and polybutene must correspond to the same mechanism.

CONCLUSIONS

A low temperature peak associated with nitrogen or air disappears after purification. No evidence of a δ peak has been given in polyethylene and polypropylene samples. In polypentene and polyhexene strong evidence of such a peak has been seen. As for polybutene it is very difficult to draw any conclusions from 1 Hz experiments.

The mechanism involved in this δ process must be side group motion. Rotation of ethyl, propyl and butyl side groups are able to give an internal friction peak. Mechanisms involving defects in a crystalline part must be eliminated because of the amorphous character of the polyhexene. However, the activation energy of ~2 kcal which is found for the δ process seems to be low compared to the energies usually found for this type of motion.

Polymerization of methyl methacrylate by tri-n-butylborane in the presence of amino acid esters*

Kuniharu Kojima, Susumu Iwabuchi, Yuichi Moriya and Masako Yoshikuni

Department of Applied Chemistry, Faculty of Engineering, Chiba University, Chiba 280, Japan
(Received 7 October 1974)

The polymerization of methyl methacrylate by tri-n-butylborane in the presence of amino acid esters was investigated. The binary systems of tri-n-butylborane and amino esters were found to be more effective for initiating the polymerization than tri-n-butylborane alone. Co-catalytic effects of amino acid esters were in the order: tyrosinate > glutamate > aspartate ≫ phenyl alaninate > serinate > gly-cinate. The rate of polymerization in a mixture of dimethylsulphoxide and toluene was proportional to the square root of the concentration of the initiator system, to the monomer concentration, and to the concentration of dimethylsulphoxide in the solvent. The overall energy of activation was esti-mated to be 4.6 kcal/mol for the tri-n-butylborane/methyl tyrosinate system. Copolymerization curves gave a typical free-radical character.

INTRODUCTION

It is known that alkylboranes can initiate the polymeriza-tion of vinyl monomers in the presence of oxygen[1,2]. Both organic and metal peroxides show co-catalytic effects on the alkylborane-initiated polymerization[3,4]. Previous investi-gations of the polymerization and copolymerization of vinyl monomers by tri-n-butylborane[5-8] showed that nitrogen-containing compounds (e.g. pyridine[5] and its derivatives[6]) and alkyl halides (e.g. butyl iodide[7]) exhibit co-catalytic effects. Furthermore, the polymerization of methyl meth-acrylate by tri-n-butylborane was found to be accelerated in the presence of silk[8]. In order to clarify this, the poly-merization of methyl methacrylate by tri-n-butylborane was studied in the present work in the presence of methyl esters of amino acids which contain structural units of silk.

EXPERIMENTAL

Materials

The monomers and solvents used were purified by distil-lation. Tri-n-butylborane (TBB) was prepared from boron trifluoride etherate and n-butyl bromide by a Grignard reaction. TBB was distilled under nitrogen in a dry box and stored in a sealed glass ampoule (b.p. 111–112°C at 25 mmHg)[9]. Methyl esters of amino acids were prepared in accordance with the method of Fischer[10]. The esters so obtained were identified by means of i.r. spectroscopy and m.p. or b.p.

Polymerization procedure

To a mixture of 10 ml (3.7 mol/l) of methyl methacrylate (MMA) and a given amount of the esters in solvent (di-methylsulphoxide and/or toluene) the TBB was added quickly by means of a microsyringe. The mixture was poured into a 20 ml dilatometer or a tapered glass tube

(capacity about 40 ml) and was immersed in a thermo-stated bath at 25°C. After a specified time, the mixture was poured into 200 ml of methanol, the precipitate was filtered, washed with methanol, and dried *in vacuo* at 40°C to constant weight.

Measurements

Intrinsic viscosities of the polymers were determined at 25°C in chloroform with a modified Ubbelohde visco-meter and average molecular weights were calculated from[11]:

$$[\eta] = 0.48 \times 10^{-4} \cdot M_n^{0.8} \quad (dl/g; 25°C).$$

Dilatometry showed that the rate of polymerization was of pseudo first-order at the initial stage of reaction and the rates of polymerization and the rate constants reported in this paper were calculated as a reaction of first-order.

RESULTS AND DISCUSSION

Co-catalytic effects of various amino acid esters

Polymerizations of methyl methacrylate (MMA) by tri-n-butylborane (TBB) were carried out in dimethyl-sulphoxide (DMSO) and/or toluene in the presence of methyl esters of amino acids. The results (*Table 1*) show that methyl tyrosinate (MeTyr), dimethyl glutamate (DMGlu), and dimethyl aspartate (DMAsp) promoted, while methyl phenylalaninate (MePhe), methyl serinate (MeSer), and methyl glycinate (MeGly) retarded the poly-merization. The co-catalytic effects of the esters were in the order: MeTyr > DMGlu > DMAsp ≫ MePhe > MeSer > MeGly.

Effects of the molar ratios of the esters on the rate of polymerization

In order to investigate the optimum catalytic activity of the TBB/amino acid ester systems, polymerizations were

performed in DMSO and toluene, at varying concentrations of amino acid ester and constant concentration of TBB. The results plotted in *Figure 1* show the rate of polymerization was a maximum near 0.5 for the TBB/MeTyr system.

Effects of initiator concentration

The dependence of the rate of polymerization in initiator concentration was studied at varying initiator concen-

trations and constant molar ratios of [TBB]/[ester] (*Table 2*). The plots of R_p against [initiator] was non-linear and the extrapolation of [TBB—MeTyr] to $R_p = 0$ gave a value of about 1.6 x 10^{-3} mol/l. This means that no polymerization could occur at this concentration and lower. When this amount of the initiator system was added to a solution of MMA in DMSO under the same conditions, no polymerization in fact was observed. Therefore, the effective initiator concentration ([I]$_{eff}$) was assumed to be the concentration of the added initiator system ([I]) — the critical initiator concentration ([I]$_c$ = 1.6 x 10^{-3} mol/l). The log of the rate of polymerization (R_p) was plotted against the log of the effective initiator concentration ([I]$_{eff}$) (*Figure 2*). The plot was linear and the rate was found to be proportional to the square root of [I]$_{eff}$.

Effects of initial monomer concentrations

Polymerizations were performed, at initial monomer concentrations from 1.87 to 7.5 ml/l and constant initiator concentration. The plot of the rate of polymerization against the initial monomer concentration was non-linear i.e. the rate was assumed to depend on [DMSO]. The plot of R_p/[MMA] against [DMSO] (*Figure 3*) was linear and
Figure 2 Plots of the rate of polymerization vs. the effective initiator concentration, [I]$_{eff}$. [MMA] = 3.75 mol/l; solvent = DMSO; temperature = 25°C
Figure 3 Solvent effects on the rate of polymerization. [TBB] = 8.0 x 10^{-3} mol/l; [MeTyr] = 4.0 x 10^{-3} mol/l; temperature = 25°C

thus $R_p/$[MMA] $\propto$ [DMSO]. In order to keep the solvent effects constant, polymerizations were repeated using a constant amount of DMSO (5 ml), to which MMA and toluene were added to bring the total volume up to 25 ml. As can be seen from *Figure 4*, the rate of polymerization was found to be proportional to the initial monomer concentration. The above results show that: $R_p = k \cdot [\text{I}]_{\text{eff}}^{1/2} \cdot$ [MMA] $\cdot$ [DMSO].

Temperature dependence of rate constants

The plots of rate constants (R_p) against reciprocals of temperatures $(1/T)$ gave the overall energy of activation of 4.6 kcal/mol for the TBB–MeTyr system in DMSO (*Figure 5*). The corresponding activation energy of the polymerization of acrylonitrile by TBB in tetrahydrofuran is 3.8 kcal/mol[12], that of MMA by the TBB–methyl nicotinate system 4 kcal/mol[6], and that of vinyl chloride by triethylborane 8.23 kcal/mol[13].

Reaction mechanism

The polymerization of vinyl monomers by alkylboranes in the presence of oxygen or electron donors is known to proceed via a free-radical mechanism[14-18]. In order to elucidate the reaction mechanism of the polymerization of MMA by the TBB/amino acid ester systems, MMA and styrene were copolymerized by TBB in the presence of MeTyr in DMSO. *Figure 6* shows the copolymerization curve; this was found to be of the typical free-radical mechanism[19]. Monomer reactivity ratios of MMA (M_1) and styrene (M_2) were $r_1 = 0.42$ and $r_2 = 0.46$ for the TBB–MeTyr system. The result agrees closely with those for the typical free-radical copolymerization of MMA and styrene within experimental errors ($r_1 = 0.42$ and $r_2 = 0.54$)[20].

Borsini and Cipolla[21] found that the alkylborane-initiated polymerization of vinyl chloride is accelerated by electron-donating solvents, such as ether and pyridine, and they assumed the formation of the complex of alkylborane and these donors. We previously showed that the electron-donating property of hydrophilic groups, such as amino and hydroxyl groups, plays an important role in the polymerization and copolymerization of vinyl monomers by TBB[5-8,22-26]. Analogously, the amino acid esters seems to act as electron donors.

The following reaction mechanism, similar to that previously suggested for the polymerization of MMA by TBB/

Figure 5 Arrhenius plots for the systems MeTyr/TBB and DMGlu/TBB. [TBB] = 8.0×10^{-3} mol/l; [MeTyr] = 4.0×10^{-3} mol/l; [DMGlu] = 8.0×10^{-3} mol/l; solvent = mixtures of DMSO (5 ml) and toluene

pyridine system[5] or by the TBB/alkyl halide system[7] is proposed:

TBB + amino acid ester $\rightleftharpoons$ complex $\longrightarrow$
free radicals $\longrightarrow$ initiation

Further studies on the polymerization of vinyl monomers in the presence of polymeric model compounds for silk (e.g. synthetic polypeptides) are now in progress.

and M. Fontanille
Laboratoire de Recherches sur les Macromolécules de l'Université Paris-Nord, Place du 8 Mai 1945, 93206 Saint-Denis, France
(Received 12 December 1974)

The kinetics of the propagation reaction for the polymerization of butadiene initiated by cumyl potassium in tetrahydrofuran solution at several temperatures have been studied. Kinetic data and electrolytic behaviour indicate that polybutadienyl free ions assume the whole of the propagation reaction. At $0°C$, the respective rate constants for ion-pairs and free ions are $1 \ l \ mol^{-1} \ s^{-1}$ and $4.8 \times 10^4 \ l \ mol^{-1} \ s^{-1}$ respectively. The ionic dissociation constant is $7.8 \times 10^{-9} \ mol/l$. The activation energy of the propagation reaction for free ions is 6.5 kcal/mol.

INTRODUCTION

The kinetics of anionic polymerization of dienes initiated by organo-alkali derivatives in polar solvents such as tetrahydrofuran (THF) are difficult to study owing to the very low stability of active centres propagating the polymerization.

Medvedev and coworkers[1,2] measured overall rate constants for the propagation of butadiene in THF solution, for several alkali cations associated with carbanionic end groups, at temperatures between $-96°C$ and $+10°C$. These authors deduced from their experimental data a very small influence of free ions on overall reactivity, especially in the case of species associated to Li^+ and Na^+ cations. These conclusions are surprising if compared to results obtained by Bywater and Worsfold[3] who studied the kinetics of isoprene polymerization initiated by n-BuLi in THF solution. The measurement of homopolymerization rate constants and the determination of dissociation constants from ion-pairs to free ions showed the preponderence of free ions over ion-pairs in the kinetic scheme. Their relative concentration is low, but their reactivity is much higher than the reactivity of ion-pairs.

THF is an aprotic solvent having a dissociating power high enough to show the influence of free ions. We have chosen K^+ as counter-ion because its compounds have a stability higher than those of species associated with Na^+ and Li^+ [4].

EXPERIMENTAL

Purification of solvent, monomer and initiator were carried out in all-sealed high vacuum apparatus as described in previous papers[5]. Polymerizations were carried out in an adiabatic calorimeter similar to the one used by Sigwalt *et al.*[6] for kinetic studies of cationic polymerizations. This sealed apparatus (shown in *Figure 1*) also permits operation at any temperature lower than room temperature.

Cumyl potassium was used as initiator and was prepared by direct reaction of methyl cumyl ether on a potassium mirror, washed with hexane over sintered glass, dissolved in THF and filtered.

The introduction of the initiator solution into the calorimeter was made from a side storage vessel. A breaking-bulb system was used to introduce the monomer into the initiator solution.

As butadiene has a low boiling point, we verified that under vacuum and between $-80°$ and $0°C$, more than 95% of the monomer is in the THF solution. At higher temperatures, monomer concentration in the gas phase is not
Figure 1 Polymerization apparatus. 1, U.v. cell; 2, vacuum; 3, bulb containing the monomer; 4, thermoregulation; 5, thermistor

negligible but with this technique, it is not possible to operate at a temperature higher than 0°C.

Initiation is very rapid, and the active centre concentration was assumed equal to initiator concentration (see later). The variation of the concentration of active centres was followed with a u.v. spectrometer in a low-temperature cell as previously described[7].

RESULTS AND DISCUSSION

We have shown that the stability of active species is very dependent on their concentration and on temperature. Indeed, as shown in *Figure 2*, it is possible to follow the transformation from polybutadienyl initial species to 'isomerized' species by using a high concentration (2×10^{-2} M) of active centres, whereas at a low concentration (10^{-4} M), the isomerization is fast above −20°C. In that case, the overall transformation cannot be followed by spectrophotometry. The isomerization corresponds to a disappearance of the initial absorption maximum ($\lambda_{max} = 315$ nm) and to the appearance of 3 peaks at 220, 285 and 385 nm. A satisfactory scheme was proposed by Hay and McCabe[8] for analogous conditions:

$$\text{\textasciitilde}\text{CH--CH}_2\text{--CH}^-, \text{Li}^+(\text{TMEDA})_2 + {}^-\text{CH=CH--} \rightarrow$$
$$\begin{array}{cc} | & | \\ \text{CH} & \text{CH} \\ \| & \| \\ \text{CH}_2 & \text{CH}_2 \end{array}$$

$$\text{\textasciitilde}\text{CH--CH=CH} + {}^-\text{CH}_2\text{--CH}^-, \text{Li}^+(\text{TMEDA})_2 \rightarrow$$
$$\begin{array}{ccc} | & | & | \\ \text{CH} & \text{CH} & \\ \| & \| & \\ \text{CH}_2 & \text{CH}_2 & \end{array}$$

$$\text{Li}^+(\text{TMEDA})_2$$

$$^-\text{CH}_2\text{--CH}_2\text{--} + {}^-\text{C}^-\text{--CH=CH}$$
$$\begin{array}{cc} | & | \\ \text{CH} & \text{CH} \\ \| & \| \\ \text{CH}_2 & \text{CH}_2 \end{array}$$
Moreover, several polymerizations initiated by cumyl potassium have shown that isomerization phenomena are faster when the temperature is increased, the general behaviour remaining similar.

Nevertheless, several observations permit us to conclude that the stability of propagating species is such that their concentration may be considered as constant during the propagation step. The study of spectra realized at room temperature about 2 min after the polymerization was achieved, shows that at least 50% of active species still exist in the system. One can estimate that active centres destroyed during the propagation step is less than 3%.

This estimation was corroborated by the fact that no important modification of electrolytic behaviour (see *Figure 3*) or of the reaction kinetics (see *Figure 4*, $\log(M_0/M) = f(t)$ is a straight line) are observed during the reaction.

Kinetic measurements

We have verified for each temperature that the order in monomer is equal to unity. Homopolymerizations were

realized between 0° and –13°C. At temperatures lower than –13°C, polymerization rates are too slow to obtain a satisfactory adiabaticity of the system.

Kinetic results given in *Table 1*, show an important variation of the overall rate constants with the concentration in active centres. This behaviour can be ascribed to the existence of an equilibrium between two types of active centres with different reactivities. Addition of potassium tetraphenylboride to the solution displaces this equilibrium and this permits us to conclude that as in the case of styrene, electrolytic dissociation of ion-pairs into free ions determines the kinetic behaviour.

$$\text{vvv but}^-, \text{K}^+ \overset{K_D}{\rightleftharpoons} \text{vvv but}^- + \text{K}^+$$
The rate of polymerization can be represented by the following kinetic law:

$$V_p = k_p [\text{C}] [\text{M}]$$

where [M] = monomer concentration, [C] = concentration of active centres, k_p = overall rate constant, but k_p varies

with [C][9]:

$$k_p = k_p(\pm) + k_p(-) \left(\frac{K_D}{[\text{C}]}\right)^{1/2}$$

where $k_p(\pm)$ and $k_p(-)$ are the absolute rate constants for propagation upon ion-pairs and free ions respectively, and K_D the ion-pairs dissociation constant.

Extrapolations of $k_p = f([\text{C}]^{-1/2})$ (*Figure 5*) at several temperatures, show that the dependence of propagation rate constants upon ion-pairs are close to zero.

The dissociation constants K_D cannot be measured by conductimetry with the experimental conditions used as the transformation of the active centres is fast. It was necessary to use the effect of an electrolyte possessing a common cation (potassium tetraphenylboride) upon the kinetics of the propagation reaction. With added electrolyte the overall rate constant[10] is given by:

$$k_p = k_p(\pm) + k_p(-) \cdot \frac{K_D}{[\text{K}^+]}$$

Figure 6 shows that extrapolations of straight lines $k_p = f([\text{K}^+]^{-1})$ correspond to very low values for absolute rate constants for polybutadienyl potassium ion-pairs ($k_p(\pm) \sim$ 1 l mol⁻¹ s⁻¹). The exact values are difficult to estimate.

For concentration in active centres higher than 10^{-3} M, the heat evolution from the propagation reaction is disturbed by the initiation reaction. Moreover the least squares method shows that in all cases the extrapolations of $k_p = f([\text{K}^+]^{-1})$ give ion-pairs absolute rate constants close to unity. These results are in agreement with those obtained for electrochemically initiated polymerization by Funt and Hornoff[11], for polybutadienyl sodium ion-pairs at –10°C ($k_p(\pm) = 1.15$ l mol⁻¹ s⁻¹). *Table 2* shows that the free

–13	11.0	26000	<1
Figure 7 Determination of the activation energy upon free ions

The slope of the straight line $\ln k_p(-) = f(1/T)$ (*Figure 7*) gives a value for the activation energy for the propagation reaction by free ions: $E(-) = 6.5$ kcal/mol. This value is near those observed for 2-vinylpyridine ($E(-) = 6.5$ kcal/mol) and styrene ($E(-) = 5.9$ kcal/mol) anionic polymerizations in THF. We were not able to measure with sufficient precision the activation energy for the propagation by ion-pairs, because the exact value of the corresponding absolute rate constants are difficult to estimate.

ions assume practically the whole of the propagation process. Their relative concentration is low, but their reactivity is much higher than that of ion-pairs.

(Received 23 October 1974)

The phenomenon of specific fibrillation from melts of polymer mixtures is considered (using mixtures of polyoxymethylene with copolyamide as an example) when, in contrast to conventional fibre spinning methods, a complex thread consisting of hundreds of thousands of ultrafine fibrils oriented along the extrusion axis is obtained as a result of compressing the melt mixture through a single orifice (or upon extension of one stream of the polymer melt mixture). Here we deal with a radically new process of fibrillation of one of the polymers of the mixture (under the effect of the rheological forces at the capillary inlet) in the matrix of the other, when the number of the filaments in the thread is not determined by the number of the orifices in the die.

After solvent extraction (from the solidified extrudate) of the polymer forming the matrix the other component remains as a bundle of fine fibrils less than 1 μm in diameter. The microstructure of mixture extrudates depends on the rheological properties of the melt, the mixture composition, the conditions of mixing and extrusion. Capillary viscometry methods have revealed a drastic difference in the viscoelastic properties of melt mixtures as compared with the separate components.

INTRODUCTION

As a rule, polymers in mixtures are thermodynamically incompatible. However, in spite of the multiphase structure of polymer systems, the polymers considerably affect each other as a result of mixing, and this is manifested in a radical change of their fine and supermolecular structure, thermodynamic and physicomechanical properties. Owing to this, mixing of polymers is an efficient method for modifying their properties and obtaining products with pre-assigned new properties[1,2]. Thus, we have demonstrated the possibility of obtaining ultrafine fibrils and thin films by extruding melts of mixtures of thermodynamically incompatible polymers differing in crystallization rate, degree of crystallinity, or melting point, as well as melts of mixtures of crystallizable and amorphous polymers[3]. At present this problem is given some attention, mainly in the patent literature[4]. It should be noted that the production of fine synthetic fibres (of diameter less than 1 μm) is extremely important and urgent. Such fibres are used in the production of filters for high-precision purifications (entrapment of particles 0.01 to 0.001 μm in size)[5], high-quality materials, etc. Conventional methods for spinning (from polymer melts and solutions) can produce fibres of 10 to 15 μm diameter. The spinning of fibres, even of such a small diameter, involves great difficulties and requires intricate equipment.

Of particular importance are the problems of reinforcing polymer products with ultrafine fibrils. It was shown[3,6] that ultrafine synthetic fibrils can be obtained by extruding (or extending) melts of polymer mixtures of various nature: polyoxymethylene—copolyamides; polyoxymethy-

lene—homopolyamides; polyoxymethylene—polystyrene; polyoxymethylene—copolymers of ethylene and vinyl acetate (and other copolymers of ethylene); polyesters—polyamides; polyolefins—copolyamides; polyolefins—polyesters; polyamides—copolymers of ethylene, etc. The most significant results were obtained on mixtures of polyoxymethylene (POM) with copolyamides (CPA).

Since the phenomenon of specific fibrillation under review depends on rheological factors and results from the compression (by any method) of a melt of a polymer mixture through a duct, the present work investigates the viscous properties of melts of POM—CPA mixtures over a wide range of shear stresses, as well as the effect of the flow regimes on the microstructure of extrudates.

EXPERIMENTAL

The objects under investigation were mixtures of a copolymer of formaldehyde with 2% of 1,3-dioxalane (POM) and a mixed copolyamide (CPA), which is a copolymer of caprolactam (44%), hexamethylene adipate (37%) and hexamethylene sebacate (19%). The characteristics of the polymers were reported earlier[7].

The content of CPA in the mixtures varied from 0 to 100 wt %. The properties and microstructure of the extrudates of mixtures with a POM/CPA ratio of 60 : 40, 30 : 70, 20 : 80 were thoroughly investigated; they were selected on the basis of the results of Tsebrenko *et al.*[8] according to which these compositions showed the most pronounced change in the thermodynamic and structural properties of the polymers in the mixture as compared with the

8	3.000	79.7	26.6		

* Capillary with $L/D = 1.0$ was used with the aim of assessing the effect of L/D on the microstructure of mixture extrudates

initial components. For the other mixtures, the viscosity—composition relationships in the shear stress range of $(0.89-5.76) \times 10^4$ N/m² were obtained. The polymers were mixed as described previously[3]. The viscous properties of the melts of the indicated systems were investigated on constant-pressure capillary viscometers at temperatures of 170, 190 and 210°C.

The capillary dimensions and the shear stress (τ) and rate ($\dot{\gamma}$) range are given in *Table 1*.

The experimental data were treated by the conventional procedure, so that τ and $\dot{\gamma}$ were determined on the capillary wall. The root mean square of the arithmetical mean in determination of viscosity (η) and ($\dot{\gamma}$) was ±5% (with 95% confidence).

The formed extrudate structure (obtained under definite conditions) was observed in thin transverse or longitudinal sections with the aid of a polarization microscope. To obtain sections, a piece of extrudate, 1 mm long, was dipped in epoxy resin in a gelatine capsule and held in a thermostat for 48 h until solidified. With the aid of a piezoelectric ultramicrotome UMTP-2, sections of 10–15 μm thickness were obtained. The sections were inspected (in polarized light) under a microscope (magnification 57–420x) and photographed. The copolyamide was entirely dark (almost in all cases) in the microscope field of vision, the structural formations of the polyoxymethylene being very prominent against its background. In addition. the fibre bundles obtained after the polyamide was washed from the extrudate and distributed in the immersion liquid were investigated visually under a microscope. The copolyamide was extracted in a Soxhlet apparatus with ethyl alcohol at a temperature of 75°C. The time of removal of CPA depends on the size and the conditions under which the extrudate is obtained. The i.r. spectra of the ultrafine fibres were recorded on a UR-10 spectrometer with the use of NaCl/LiF prisms.

RESULTS

Viscous properties

Some authors[9-11] indicate the specific features of the properties of melts of polymer mixtures, which are hard to predict, knowing the viscosity and the elastic properties of the separate components. This also refers to the POM—CPA mixtures investigated in the present work. Having relatively close values of melt viscosities, POM and CPA form, on mixing, systems which differ drastically from the initial polymers as regards the viscous properties of their melts (*Figure 1*). It can be seen from *Figure 1* that the nature of the curve $\eta = f$ (composition) depends on the

shear stress: at $\tau < 6.30 \times 10^4$ N/m², the curves lie above the viscosities of POM and CPA. In the shear stress regions above 6.30×10^4 N/m² the nature of the viscosity—composition relationship changes radically; the curves lie below the viscosities of the POM and CPA melts and they have a minimum in the region of 80% concentration of the copolyamide. Besides, at high shear stresses for melt mixtures, the viscosity anomaly is very pronounced. Thus, if in the range of τ from 1.2×10^4 to 3.2×10^5 N/m² the viscosities of the POM and CPA melts decrease about three times, for 60 : 40, 30 : 70, 20 : 80 mixtures POM/CPA, they decrease 17.6 and 38 times, respectively. In this respect the flow behaviour of the mixtures are like certain filled polymers[14,15]. The behaviour of these POM—CPA melt mixtures is probably connected, primarily, with the change of the phase state, shape, size and nature of distribution of the POM regions in the mixture melt, and this (as will be shown below) is supported by the results of the investigation into the microstructure of extrudates of mixtures obtained at high shear stresses.

Proceeding from the temperature dependence of the melt viscosity of the systems investigated we calculated the values of the apparent activation energy of the viscous flow E, which proved to be 12–15 kcal/mol. This means
Figure 1 Dependence of viscosity of POM/CPA melt on composition at 190°C. Shear stress: A, 1.27; B, 3.93; C, 5.44; D, 6.30; E, 12.59; F, 19.52; G, 31.62 × 10⁻⁵ dyne/cm²
Figure 2 Electron photomicrograph of longitudinal section (a) and photomicrograph of longitudinal section (b) of POM/CPA extrudate

that in the temperature range from 190 to 210°C (when both polymers are in the fluid state) the fluidity of the mixtures is determined by the copolyamide (E_{CPA} = 12--15 kcal/mol, E_{POM} = 7--9 kcal/mol).

For POM/CPA melts, the pressure losses at the capillary inlet are small — the inlet corrections are equal to one radius at low shear stresses and two or three radii at high τ. However, in flowing through a capillary, melt mixtures, unlike the initial polymers, manifest three-to-four-fold swelling of the melt stream after it leaves the capillary (with the exception of specimens obtained at 170°C). With an increase in the degree of dispersity of the initial POM powder the swelling increases. Thus, for instance, if the average diameter of the POM powder particles is 2 μm, the issuing stream of the POM—CPA melt swells to about ten

times the capillary diameter and has a milky-white colour.

The above features of the viscoelastic properties of POM—CPA melts are due, primarily, to the above-described phenomenon of specific fibrillation, and this confirms the results of the investigation into the microstructure of mixture extrudates.

Extrudate microstructure

At a temperature of 170°C (i.e. below the melting point t_m of POM), composition mixtures of 60 : 40, 30 : 70, 20 : 80 POM/CPA are capable of flowing, but no fibres are then formed. The swelling of the stream leaving the capillary is insignificant and therefore difficult to record. After extraction of the CPA from the extrudate, the POM remains in powder form. Ultrafine polyoxymethylene fibres can be obtained only at temperatures above melting point of POM, t_m (*Figure 2*). An analysis of sections and washed fibre bundles (freed from CPA) has shown that with an increase in melt temperature the degree of dispersion of the POM in the extrudate increases (in the sense of reduced fibril diameter and increased number of the fibrils), and a more uniform fibril bundle is obtained, both from the point of view of fibril diameter distribution and the presence of balls, short fibrils, and films. The principal cause of this is evidently a reduction in melt viscosity with increasing melt temperature, which facilitates deformation of the POM particles in the direction of flow.

The shear stress strongly affects the microstructure of mixture extrudates. As τ increases, the average diameter of the POM fibres decreases (from 3 μm) at τ = 3.9 x 10^4 N/m^2 to values beyond the resolution of optical microscopes at $\tau > 10^5$ N/m^2; layer-like arrangement of the POM fibrils is observed, the layers being located closer to the capillary wall. The extrudate centre is impoverished in POM and the fibrils it contains are practically unobservable with an optical microscope (*Figure 3*). After the CPA is removed from such an extrudate, a set of concentric ultrafine fibrous tubes (films) remains with a small number of fibrils between them.

A similar 'telescopic' distribution of one polymer in the melt of the other (with the components being incompatible) was observed by Walczak[14] on polypropylene with an addition of poly(ethylene oxybenzoate) and by White et al.[15], and Han and Yu[9] for polyolefin—polystyrene mixtures. On short capillaries, the concentricity of the extrudate structure is less pronounced (and is practically nil, for L/D = 1), probably because the melt remains in the
Figure 3 Photomicrograph of longitudinal section of extrudate of POM + 70% CPA mixture obtained at τ = 3.2 x 10^6 dyne/cm^2
Figure 4 Effect of cooling conditions on microstructure of extrudate of POM + 70% CPA mixture. Temperature of extrudate reception: (a) +20°; (b) —40°C

capillary for only a short time. The shear stresses at which the extrudate has a 'telescopic' structure correspond to the region of sharp viscosity anomaly on the flow curves of the mixture melts. The aggregation of POM into tubular films is probably the main reason for the drastic increase in mixture fluidity.

If mixture extrudates are received, not in an air medium at —20°C, but in a dry ice—acetone mixture (—40°C), it is possible to considerably suppress the swelling of the stream and to fix the structure formed in the flow in the capillary.

An analysis of sections (and washed fibrils) has shown a strong influence of the cooling conditions (and hence of the swelling) of the extrudate on its microstructure. size, and the nature of distribution of the POM fibrils (*Figure 4*).

It is also possible to considerably restrict the adverse effect of stream swelling on the structure of the formed extrudate by die drawing (i.e. receiving the issuing stream at a constant rate). Here, the average diameter of the POM fibres decreases and the uniformity of the diameter distribution of the fibrils greatly improves (*Figure 5*); already on 1000% extension of the spinneret draw ratio 90% of all the fibres have a diameter of 1 μm. Extension

also results in a certain additional orientation of the POM fibres formed in the copolyamide matrix. It should be particularly emphasized, however, that fibrils obtained with a free flow of the melt from the capillary (i.e. practically without spinneret extension or with its negative value) prove to be well oriented in the direction of the extrusion axis. All this is clearly confirmed by X-ray analysis and by the infra-red dichroism method (*Figure 6*): thus, for instance, the dichroic ratio of the bands in the region of 1385 cm^{-1} is 1.60.

Experimental data indicate a qualitative difference in the process of fibrillation for 60 : 40, 30 : 70, 20 : 80 POM/CPA mixtures. With decreasing content of the high-crystalline component (POM) the uniformity and homogeneity of the fibrils improves, their diameter decreases and their number increase considerably. This is in good agreement with the data of Bakeyev *et al.*[16], according to which for most of the mixtures of incompatible polymers a decrease in the content of the higher-crystalline component in mixtures results in a gradual increase in its degree of dispersity and a decrease in scattering of the particle size.

Thus, the microstructure of extrudates depends on the composition of the mixture, the geometric dimensions of the capillary, and the conditions of flow and reception of the melt stream leaving the capillary.

DISCUSSION

The numerous experimental results obtained by us in investigating the properties of melts and solutions of poly-
Figure 5 Differential curves of distribution of ultrafine POM fibrils obtained from extrudate of POM + 80% CPA mixture. Die extension: A, 200; B, 500; C, 1000%

Figure 6 I.r. spectra of ultrafine POM fibrils in polarized light parallel (— — —) and perpendicular (———) to fibre axis

mer mixtures indicate that fibrillation in the systems at hand is achieved, not after the melt leaves the die (i.e. not in the stage of stream solidification), but in the inlet zone of the capillary with a considerable longitudinal rate gradient. This constitutes the specificity of such fibrillation. Thus, when using capillaries with $L/D \leqslant 1$ (i.e. actually dies), extrudates with extremely uniform ultrafine POM fibrils (in the absence of spinneret extension) were obtained.

Proceeding from the available experimental data, the mechanism of specific fibrillation can be visualized as follows.

A melt of two polymers, under certain conditions of mixture preparation and melting, is a heterogeneous system in which the dispersion medium is, for instance, copolyamide, and the dispersed phase, polyoxymethylene. The polymer melts under consideration are not homogeneous. It can be assumed that POM (at temperatures relatively close to its melting point) is in a liquid-crystalline state[17] in the melt mixture and therefore differs from the copolyamide in its viscoelastic characteristics. In the inlet zone of the capillary the POM droplets elongate mainly under the effect of extension, with the formation of ultrafine fibrils oriented along the extrusion axis. Here, directed crystallization of POM may occur under the influence of tensile and shear forces. Indeed, it is known from the literature[18] that the extremely high crystallization rate of POM and the absence of the latent period of crystallization are due to the small difference in the structure of the liquid and crystalline phases (the molecules in the melt have the same spiral conformation as in the crystal), and the presence of highly ordered melt regions. Therefore

shear or extension (even of low intensity) may initiate crystallization of POM, as has actually been observed for a number of other polymers[19,20]. Moreover, Mikhailov and Nedkov[21] have shown that on cooling of the melt POM crystallizes (at $t > 160°C$) with the formation of plastic crystals (this should be considered as a phase transition), and then, on further cooling, the plastic crystals transform to solid ones. Under the effect of shear and extension, directed crystallization of POM may be initiated in the form of such plastic crystals even at the investigated spinning temperatures (190°C), and this must yield fibrils of infinite length, given the appropriate component ratios and flow conditions. It is due to such directed crystallization in the capillary that POM fibrils acquire a considerable orientation (*Figure 6*) immediately after leaving the capillary.

The presence of ultrafine crystallized POM fibrils in a flowing melt explains the observed peculiarities of the viscous and elastic properties of POM—CPA melts. Indeed, the viscosity of such a highly filled (virtually reinforced) system must be much higher than the viscosity of the initial components, which is actually the case at $\tau < 6.3 \times 10^4$ N/m^2. The directed flow of streamlets and crystallization of POM in the form of ultrafine fibrils is also associated with enormous swelling of the stream on leaving the capillary. In connection with the above it is necessary to mention the work[22] where increased swelling of the extrudate (by a factor of 2.5) of polyethylene or polystyrene was observed on addition of small fractions of 1% of long flexible fibrils of Teflon to the melt.

No swelling was observed for POM/CPA extrudates obtained at 170°C (i.e. when a suspension of the POM powder in the CPA melt was present). A change in the phase state of POM must also increase the swelling. Thus, according to the data of Southern et al.[23], the beginning of crystallization of polyethylene when flowing through a capillary coincided with strong swelling of the stream leaving the capillary.

The drastic decrease in mixture melt viscosity is probably due to the change in the nature of distribution of the POM fibrils along the capillary radius; the fibrils are thrust towards the capillary wall with the formation of tubular films, the central part of the flow being enriched in CPA (*Figure 3*). In the rheological sense the behaviour of the systems investigated is similar to the behaviour of a flow of filled polymers[12,13].

Direct experimental results indicate that the microstructure obtained in a flow through a capillary undergoes considerable changes in the swelling zone (*Figure 4*): 'telescopicity' of the distribution of the POM fibres is observed, the latter aggregating into tubular films; the fraction of short fibrils and balls increases. Han and Yu have also shown experimentally[9] that in the course of cooling of extrudates of polyolefin—polystyrene mixtures on leaving the capillary, their structure changes, and this is accompanied by the rupture of the regions of the dispersed phase elongated in the direction of the flow, with the formation of drops.

The phenomenon of specific fibrillation from polymer melt mixtures is of interest not only from the point of view of obtaining a new type of fibrous material and mastering the spinning of a complex thread or yarn through a single orifice, but also from the point of view of the theory of processing of mixtures, and methods of fibrillation of one of the polymers in the mass of the other with the formation of reinforced materials.

Some basic aspects of flame resistance of polymeric materials

D. W. van Krevelen

Akzo Research and Engineering bv, Arnhem, The Netherlands
(Received 27 November 1974; revised 27 January 1975)

For a better insight into flame resistance and flame extinction it is useful to split the combustion process into its constituent elements. It then appears that the thermal decomposition is the first link in a series of reactions and therefore a better understanding of this decomposition is a prerequisite. Further, it is found that the amount of char and the amount of incombustible gases that may be formed in thermal decomposition are very important quantitative measures of flame resistance. For a large number of model substances the char residue upon pyrolysis has been determined. The residue is found to be very clearly related to the chemical structure of the polymer, so much so that the amount of char can be predicted from the structure. Finally, it has been demonstrated that there is a very significant relation between the pyrolysis residue (%) and the (limiting) oxygen index.

INTRODUCTION

Never before has there been such interest in the problem of the flammability of materials, now that we are faced with the imminent introduction of stringent legislation.

People have always been accustomed to the presence and use of flammable matter in the form of, for instance, building, clothing and auxiliary materials. But the problem at issue has become acute because of the present-day phenomenon of people crowding in confined spaces (sometimes of great height), such as blocks of flats, office buildings, department stores, hospitals and jumbo jets, with all the hazards this implies.

The point to be considered here in particular may, in short, be formulated as follows: is it possible to predict the degree of flammability of a polymeric material on the basis of its chemical structure?

As index of the flame resistance (ignition and flame propagation) we have chosen the (limiting) oxygen index OI value[1]. This limiting OI is the minimum fraction of oxygen in an oxygen–nitrogen mixture that is just sufficient to maintain combustion (after ignition) of the material. *Table 1* gives the OI values for a number of polymeric materials. A material must be considered flammable as long as the OI value $\leqslant 0.26$.

ESSENTIALS OF FLAMMABILITY AND FLAME RETARDANCE

What happens in broad outline when a material burns is schematically indicated in *Figure 1*[2]. Fundamentally there are two consecutive chemical processes — decomposition and combustion — connected by ignition and thermal feedback. Primarily the material decomposes (pyrolysis), which requires heat. The decomposition products are combusted, during which heat is generated. This heat is (partly) used to support the decomposition. An ignition mechanism is essential. Of great importance are the heat effects Q_1 and Q_2 as well as the available area, A, for exchange of heat and matter. To be flame-resistant a material should have a high Q_1 value, a low Q_2 value and

a low A value. Q_2 will be low if only small amounts of combustible gases develop in the pyrolysis, for instance, because the material chars considerably and mainly splits off carbon dioxide and water. The residue of pyrolysis (or the sum of this residue and the weight of carbon dioxide

and water formed by pyrolysis) may be used as a measure of the non-flammability.

This is proved by the fact that there is a significant correlation[3] between the char residue (*CR*) and the oxygen index of polymers, as is shown in *Figure 2**. This linear relationship can be represented by:

$$OI \times 100 = 17.5 + 0.4CR \qquad (1)$$

where *CR* is the char residue in wt % at 850°C. In view of this interesting correlation it seemed useful to make an elaborate investigation into the relation between the residue of pyrolysis and the constitution of polymers.

ESSENTIALS OF PYROLYTIC DECOMPOSITION

Thermal decomposition of a non-volatile organic material is accompanied with the phenomena illustrated schematically in *Figure 3*[3]. The pyrolysis generally proceeds in two stages: a primary decomposition in the range 350° to 550°C; in this stage there will often be softening of the material and formation of tar mist. Very often a residue of pyrolysis (semicoke) is obtained; this, however, does not happen in the pyrolysis of fully aliphatic polymers which are free from halogen and —OH groups.

Softening need not occur either, provided that the starting substance is strongly crosslinked or contains reactive dehydrogenating groups (—OH, =OH, halide). Basically the decomposition of the polymeric starting material into tar and gas on the one hand and char on the other is a disproportionation reaction which leads to hydrogen-enriched and hydrogen-poor fragments.

Above 550°C there will often be a second pyrolysis stage; primary char of the first stage will then be carbonized into a final char residue with attendant formation of a gas very rich in hydrogen. This second pyrolysis stage terminates in the range of 800° to 1000°C.

This scheme of pyrolysis as just described, or variants of it, will be recurrently encountered. This mechanism of pyrolysis is considered in the light of pyrolysis experiments with different series of model substances. For the purpose of comparison (some materials are highly heat resistant!) a pyrolysis temperature of 850°C is selected in all cases.

---

* This correlation is not valid for halogen-containing polymers. This is a direct consequence of the fact that halogen radicals are combustion inhibitors and therefore influence the interaction between pyrolysis and ignition.

INVESTIGATION INTO THE PYROLYSIS OF MODEL SUBSTANCES

Aliphatic and cyclo-aliphatic polymers

Table 2 summarizes the pyrolysis results for these substances on the basis of our own measurements. In general, aliphatic and cyclo-aliphatic polymers do not give any residue on pyrolysis. This even applies to substances such as polystyrene and poly(vinyl carbazole), although they have an aromatic or heterocyclic side group linked to an aliphatic chain. This absence of a pyrolysis residue is due to the high hydrogen content of these polymers, as a result of which the entire decomposition product can be disproportionated into volatile substances.

There are, however, a number of exceptions, viz. those polymers that contain free —OH groups and those that contain halogen or cyanide groups. The —OH-containing polymers are found to yield a small char residue when they contain the group —CHOH— [cellulose, poly(vinyl alcohol)]. The halogen-containing polymers are a special class. Some of them form a small char residue, others none at all. That these polymers are non-flammable is partly to be attributed to the splitting off of non-combustible gases such as HCl, HF and C_2F_4, which seal the surface of the material from the combustion air.

The —CN-containing polymer polyacrylonitrile must be considered an exception in that it readily cyclizes and therefore does give a char residue; but on the other hand, it gives off much flammable gas, so that it is not flame resistant.

Polymers of the $(-ArCH_2-)_n$ type with variable Ar group

Polymers of this type have been prepared by Wolfs *et al.*[5] and also subjected to pyrolysis experiments. The object then was to unravel the mechanism of pyrolysis from coal to coke by means of model substances. The polymers were prepared by reacting the respective aromatic hydrocarbons with formaldehyde in the form of paraformaldehyde, using nitrobenzene as solvent and anhydrous zinc chloride (dissolved in glacial acetic acid) as condensation catalyst. The reaction temperature was about 110°C, the reaction time about 24 h. The paraformaldehyde used was radioactive, so that from the measured value of the

Figure 5 Char residue as a function of parameter b. ●, Anthracene; ×, phenanthrene; □, pyrene

radiation intensity of the purified polymer the exact number of $-CH_2-$ bridges per aromatic unit, b, could be determined. The parameter b was varied from about 0.6 to about 1.5.

Figure 4 indicates the structure of the polymers and the variation of the aromatic unit (Ar). The thermal behaviour of the polymers was in accordance with expectation. As long as $b \leqslant 1$, the polymers were soluble and fusible. If $b \leqslant 0.5$ (dimer), total volatilization becomes possible without giving a char residue, since then the boiling point is sufficiently low ($<350°C$).

With b higher than 1, so that crosslinking occurs, softening will take place merely as a result of thermal decomposition, when also a high degree of swelling is observed. This swelling decreases with increasing value of b; at $b > 1.3$ softening and swelling no longer take place. *Figure 5* shows the percentages of char residue. By following the decomposition with thermogravimetric and elemental analysis and radiology, it was possible to unravel the mechanism of this pyrolysis. The results of this investigation led to the following conclusions: (1) with the type $(-ArCH_2-)_n$ polymer the division between the primary and secondary stages of the pyrolysis is very sharp (selective). Below $550°C$ all tar is formed, but hardly any gas; above this temperature there is only gas evolution; (2) the radioactive carbon fraction which is left in the primary residue (semi-coke) at $500°C$ is equal to that in the starting material; the carbon in the CH_2 bridges consequently is not split off selectively; (3) in each structural unit the amount of hydrogen left at $550°C$ in the residue is exactly equal to the amount of aromatic hydrogen in the starting material, so that hydrogen splits off selectively; (4) in the secondary pyrolysis all the (originally aromatic) hydrogen is removed, but only little carbon. Quantitative interpretation of the results of these experiments is possible with the aid of the rough and somewhat idealized reaction scheme shown in *Figure 6*.

Additional experiments have shown that when the Ar group concentration becomes large, i.e. when it contains more than about 25 C atoms, the entire Ar group is left in the residue and only the CH_2 bridges are cracked.

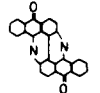
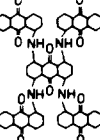
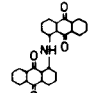
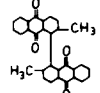
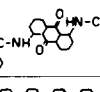
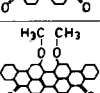
reacting with H atoms and therefore give rise to post condensation (crosslinking). The plastic range in the decomposition is consequently strongly narrowed and swelling will hardly occur. The char residue is higher than in the case of the non-substituted aromatic units.


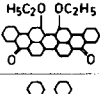


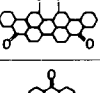


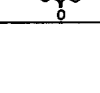


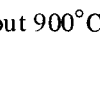












Polymers of the $[-Ar(X)Y-]_n$ type (with variable $-Y-$)

A number of representatives of this type of polymer, where Y is a varying bridge structure, have been prepared and investigated by Wolfs et al.[5]. *Table 4* gives the data of Wolfs as well as results of recent measurements carried out with commercial polymers at the author's laboratory. Both the group X and the bridge structure Y appear to have considerable influence on the amount of char residue. In general, CH_2 bridges reduce the char residue; this residue is also decreased by side groups of the alkyl type but increased by side groups of the OH type.

Condensed aromatic model substances containing multiring systems

Some years ago Riley and coworkers[6] carried out pyrolysis experiments with dyes built up of highly condensed aromatic systems, derivatives of anthrone and benzanthrone. Although these are not polymeric substances, the volatility upon heating (without decomposition) is nil, so that for our purpose they are particularly useful. *Table 5* gives the results of the experiments, from which the following conclusions arise: (a) during pyrolysis alkoxy groups as well as alkyl groups split off entirely; (b) phenyl groups and phenoxy groups also split off entirely; phenyl groups contribute to a very small extent to the formation of char

Polymers of the $[-Ar(X)CH_2-]_n$ type (with variable X)

A second type of polymers prepared by Wolfs et al.[5] is that of substituted aromatic units linked by CH_2 bridges. Some results are listed in *Table 3*. The nature of the functional group X appears to have considerable influence on the results of the pyrolysis. Roughly, 3 types of functional groups may be distinguished. (a) X = $-CH_3$, (-alkyl, $-C_6H_5$): the division between primary and secondary pyrolysis is less sharp here, and formation of tar is accompanied by the production of gas. In the disproportionation alkyl hydrogen as well as the CH_2 bridge hydrogen are used. (b) X = $-OCH_3$, $-O$-alkyl: in the primary pyrolysis the entire alkoxy group appears to split off, these polymers behaving similarly to those of the series $(ArCH_2-)_n$. (c) X = $-OH$, $(-Cl, -Br, =O)$: these groups are capable of

residue; (c) at about 900°C oxygen and nitrogen have largely split off.

Heterocyclic polymers of the $[-Het(X)Y-]_n$ *type*

A fair amount of data on these classes of substances is to be found in the literature[7-11]. The available data are listed in *Tables 6—8*. Further analysis shows that the general rules found for the previously mentioned classes of substances also apply here.

CONCLUSIONS FROM EXPERIMENTS WITH MODEL SUBSTANCES

Careful analysis of all experimental data indicated that during pyrolysis all the functional groups making up a polymer behave very regularly. Each functional group in principle contributes to the residue of pyrolysis in its own characteristic way. Some corrections must be made as a result of the disproportioning mechanism, which is primarily influenced by the non-aromatic hydrogen. This means that the char-forming tendency of a polymer is an additive property which may be calculated from group contributions. The char-forming tendency *(CFT)* is quantified here as the amount of char per structural unit of the

Carbon	100	100	57.5	57.5	56—64

polymer divided by 12 (the atomic weight of carbon); in other words: the amount of C equivalents in the char per structural unit of the polymer.

Table 9 shows the group contributions to the *CFT* per structural unit. For all the polymers investigated the char residue was calculated by means of the formula:

$$CR = 1200 \left\{ \sum_i (CFT)_i \right\} / M \qquad (2)$$

where M is the molecular weight per structural unit.

Figure 7 shows the comparison between calculated and experimental values and the result is really satisfactory for a complex process like thermal decomposition. For about 100 polymers investigated the mean deviation is ±3.5%.

RELATION BETWEEN FLAME RESISTANCE AND CHAR RESIDUE

Since the CR value can be calculated with the aid of *Table 9*, it is interesting to see which (calculated) OI values result from these (calculated) CR values when use is made of the combination of the derived formulae (1) and (2). The

results are shown in *Table 10* (halogen-containing polymers have not been included) and the result is fairly satisfactory.

It may therefore be concluded that, in the absence of factual information, the flame resistance of a polymer can be assessed fairly accurately on the basis of its chemical structure alone.

Notes to the Editor

Phosphoryl chloride as an initiator for the cationic polymerization of vinyl monomers

Mukul Biswas and Prashant K. Mishra
Department of Chemistry, Indian Institute of Technology, Kharagpur 721302, India
(Received 23 December 1974; revised 18 March 1975)

INTRODUCTION

There is no information on the ability of $POCl_3$ to initiate, as an aprotonic acid, the polymerization of vinyl monomers except some brief reports by Biswas and coworkers[1,2]. The kinetic and the mechanistic aspects of the $POCl_3$ initiated polymerizations of monomers such as α-methylstyrene, and the nitrogen substituted vinyls have since been explored. The purpose of this note is to focus, in the light of these results, the pertinent characteristics, monomer specificity and the inherent limitations of this initiator.

EXPERIMENTAL

Materials

Monomers such as α-methylstyrene (General Chemical and Pharmaceutical Co. Ltd, Sudbury, UK) and N-vinyl-pyrrolidone (Badische Aniline and Soda Fabrik, West Germany) were purified, fractionated and distilled by recommended procedures.

Solvents, all of analytical grades, were purified by standard methods.

Riedel, analytical grade, $POCl_3$ was treated following the procedure of Gutmann *et al.*[3].

Polymerization

The polymerizations were followed dilatometrically *in vacuo*, at 5°, 10° and 25°C in the case of α-methylstyrene (in benzene and nitrobenzene) and at 30°C, in the case of N-vinylpyrrolidone (in methylene chloride).

Molecular weights were determined cryoscopically in benzene. Elemental analyses for such elements as P and Cl were made by standard procedures.

RESULTS AND DISCUSSION

Salient features of $POCl_3$ initiated polymerization of α-methylstyrene

The polymerizations proceed without any induction period and never go to 100% conversion. The polymerization order, in benzene, with respect to $[POCl_3]$ varying from 0.2—0.5 mol/l is unity (over three monomer concentrations studied, 2—4 mol/l) and does not change with temperature.

For polymerizations conducted in mixtures of benzene and nitrobenzene of known dielectric constants (2.3—36)[4,5], both the rate and the molecular weight increase linearly[5] with the dielectric constant. This feature is apparently consistent with a cationic mechanism[4,5].

At constant $[POCl_3]$, the polymerization is first order with respect to α-methylstyrene at 25°C. However, this order rises to 1.5 at 10°C and to 1.7 at 5°C. Similar features have been reported in the polymerization of this monomer by other aprotonic acids such as $SnCl_4$[6] and $BF_3.Et_2O$[7] and imply that termination is more significant at higher temperatures compared to propagation.

The cationic nature of the $POCl_3$ initiated polymerization of α-methylstyrene is further endorsed[5] by the observed decrease of both the rate and the degree of polymerization, $\bar{P}_n$ (6×10^{-5} mol l^{-1} s^{-1}; 13.7 — control) in the presence of $\sim 5 \times 10^{-5}$ mol/l of bases such as n-butylamine (4.6×10^{-5} mol l^{-1} s^{-1}; 12.7), di-s-butylamine (3.5×10^{-5} mol l^{-1} s^{-1}; 12.4), ammonia (2.8×10^{-5} mol l^{-1} s^{-1}; 10.1) and thiophene (4.9×10^{-5} mol l^{-1} s^{-1}; 9.1).

For polymerizations performed in benzene with [α-methylstyrene] = 3 and $[POCl_3]$ = 0.3 mol/l, the rate and $\bar{P}_n$ (6×10^{-5} mol l^{-1} s^{-1}; 13.7) are independent of added water upto $\sim 1.8 \times 10^{-2}$ mol/l of the latter (6×10^{-5} mol l^{-1} s^{-1}; 14.4). At $[H_2O]$ = 2.6×10^{-2} mol/l, they rise to maximum values (21×10^{-5} mol l^{-1} s^{-1}; 17.3) and subsequently exhibit a fall (10.5×10^{-5} mol l^{-1} s^{-1}; 15.7) at $[H_2O]$ = 2.8×10^{-2} mol/l. These features do not exactly comply with what is usually observed in a typical water cocatalysis where the rate in fact tends to decrease with decreasing $[H_2O]$ to practically zero value[8,9] rather than attain a limiting value as in the present case. This may be considered to be a rather typical feature for this system signifying that the presence of water is probably not important for the initiation, which is therefore suggested to involve a direct interaction between the monomer and the initiator:

$$
\begin{array}{c}
CH_3 \\
| \\
CH_2{=}C \quad + POCl_3 \;\longrightarrow\; Cl_2OP{-}CH_2{-}\overset{+}{\underset{|}{C}}{-}CH_3Cl^- \\
| \\
Ph \qquad\qquad\qquad\qquad Ph
\end{array}
$$

This is endorsed by the results of elemental analysis indicating the presence of one P and two Cl atoms per molecule. For polymers with $\bar{M}_n$ = 1448 and 1366, the % P and % Cl values are 2.25(2.14), 4.98(4.90) and 2.36(2.27) and 5.01(5.20) respectively, the figures in parenthesis being the theoretical values.

Molecular weights

The major limitation of using $POCl_3$ as an initiator appears to be the low molecular weights of the resultant polymers, although even lower ranges of molecular weights have been reported for the polymerization of this monomer by $SnCl_4$[6] and $BF_3.Et_2O$[7]. The maximum $\bar{P}_n$, obtained with [α-methylstyrene] = 4 and $[POCl_3]$ = 0.5 mol/l in benzene is 25(5°C) which decreases to $\sim 15(25°C)$. $\bar{P}_n$ is independent of $[POCl_3]$ but varies linearly with [α-methylstyrene] following the equation $\bar{P}_n = 2 + K[M]$ in agreement with the polymerization behaviour of this monomer with other aprotonic acids[6,7].

Monomer specificity

A few comments may be made in conclusion on the monomer specificity of this initiator. $POCl_3$, under these conditions, fails to polymerize styrene but initiates, in a comparatively lower concentration range (10^{-4} to 10^{-3}

mol/l), the polymerization of nitrogen vinyl monomers such as N-vinylcarbazole (10^{-1} mol/l) or N-vinylpyrrolidone (1−2 mol/l). The general kinetic and related features of the polymerization of N-vinylpyrrolidone by $POCl_3$ in methylene chloride include the first order dependence of the rate on [$POCl_3$] and [N-vinylpyrrolidone], its retardation in presence of basic additives and H_2O, and the independence of $\bar{P}_n$ on both [$POCl_3$] and [N-vinylpyrrolidone] which incidentally are similar to those reported for the polymerization of N-vinylcarbazole by $AsCl_3$[5], or $SOCl_2$[10]. However, the molecular weights of these polymers are extremely low ($\bar{P}_n = 8$) which limits the use of this initiator.

Chitosan gel: a novel polysaccharide gel

Shigehiro Hirano, Sumiyo Kondo and Yasuo Ohe
Department of Agricultural Biochemistry, Tottori University, Tottori 680, Japan
(Received 24 February 1975)

Chitosan[1], (1→4)-2-amino-2-deoxy-β-D-glucopyranan is found in some micro-organisms[2] and is readily prepared from naturally abundant chitin by de-N-acetylation with alkali[3].

In this communication, we wish to report that chitosan, in solution in dilute acetic acid, readily undergoes partial acetylation with acetic anhydride to afford a novel polysaccharide gel.

Chitin was prepared by the conventional procedure from shells of crub, *Chinoecetes opilio*, and its de-N-acetylation was carried out with 40% $NaOH$[4] in the presence of 1% $NaBH_4$ to produce an almost completely de-N-acetylated product, chitosan, $[\alpha]_D^{15} - 3.1°$ (c 1.3, 50% formic acid), $-10.5°$ (c 1.3, 10% acetic acid).

Chitosan (500 mg) was dissolved in 25 ml of 10% acetic acid by shaking at room temperature[5]. To the solution was added 12.5 ml of acetic anhydride. The excess acetic anhydride added is important to the gel formation and is considered to be used for the acetylation of both amino and hydroxyl groups present in chitosan as well as for the reaction with water. The mixture was kept at room temperature for about 30 min to afford a rigidly solidified gel to the whole solution in a flask or even in a Visking cellulose tube. The solidified gel was kept at room temperature overnight and then suspended in a large volume (about 2 l) of distilled water, which was changed several times, at room temperature for three days or dialysed against running water. This treatment exchanged free acetic acid present in the gel for water and removed unreacted chitosan as its acetate salt which is soluble in dilute acid. Thus, the chitosan gel free of acetic acid was obtained by filtration in about 31.4 g yield. The gel was colourless, transparent and rigid, and gave no smell of acetic acid and almost no taste. The gel was soluble in formic acid but insoluble in water, 50% formic acid, 10% acetic acid, alcohols and acetone. The gel in a test tube did not melt by heating over a flame and could be sliced with a knife without destruction.

In order to examine its components, the gel was lyophilized or dehydrated in a large volume of acetone, and the product was further dried over P_2O_5 *in vacuo* at 110°C for 3 h to afford an amorphous product in 470−540 mg yield, $[\alpha]_D^{15} - 1.4°$ (c 0.72, formic acid). Calculated for $[C_{10}H_{14}NO_5(OH)_{0.6}(OCOCH_3)_{0.4} \cdot 0.7H_2O]_n$: C, 47.22; H, 6.31; N, 5.09%. Found: C, 47.75; H, 6.65; N, 5.47%. I.r. (KBr), 3250−3450 (OH, NH), 1730 and 1240 (C=O in OAC), 1650 (C=O in NAC), 1040 cm^{-1} (C−O−C). N.m.r. ($^2HCOO^2H$) δ (ppm, sodium 2,2,3,3-tetradeutereo-3-(trimethylsilyl)propionate as an internal standard), 6.00−3.00(methine and methylene), 2.13(N- and O-acetate-methyl). The ratio of (N- and O-acetate-methyl)/(methine and methylene) = 0.89 was found, and this value corresponds to a degree of substitution = 2.36 per monosaccharide residue. The dried gel was soluble in formic acid and 50% resorcinol but insoluble in other solvents examined. The solubility is similar to that of a peracetylated chitin prepared with acetic anhydride by passing dry HCl[6].

On the basis of these data, it is concluded that the novel polysaccharide gel is a chitosan hydrate which is partly acetylated to a degree of substitution = 2.36 per monosaccharide residue. Mechanism of the gel formation is under investigation. However, a molecular aggregation is considered to occur with frameworks that are crosslinked by micelles among chitosan chains. This is similar to the formation of cellulose gels through chemical modification of the polymer[7,8].

Inverse isotope effect on the rate of polymerization of deuterated methyl methacrylate

There are relatively few reports on the effect of deuterium substitution on rate of free radical polymerizations. Allyl[$1 - {}^2H_2$] acetate polymerizes 2–3 times faster than allyl acetate owing to a primary kinetic isotope effect on the rate of degradative chain-transfer termination step[1]. Styrene [$\alpha - {}^2H$] also shows a small inverse isotope effect[2-4]. Conflicting results have been reported for styrene [$\beta - {}^2H_2$] where there is either no effect[5,6] or a small inverse isotope effect[2-4]. In the latter case the effect was ascribed to a secondary deuterium isotope effect on the propagation step. We report here the preliminary results of a radiochemical investigation of the polymerization of methyl methacrylate [${}^2H_5$] [$CD_2 = C(CD_3)CO_2CH_3$].

Polymerizations ($\sim$10% conversion) were conducted in bulk in evacuated sealed tubes or dilatometers at 60°C using ${}^{14}C$-azoisobutyronitrile as initiator. The results, obtained as described previously[7], are recorded in Table 1. The overall rate constant, k, for polymerization of the deuterated monomer is $\sim$36% greater than that of the undeuterated monomer and the isotope effect $k_H/k_D = 0.73$. The increased rates of polymerization are also reflected in the higher molecular weights of the deuterated polymers.

Since $k = k_p (fk_d/k_t)^{1/2}$, where k_p, k_d and k_t are the velocity constants for propagation, initiator decomposition and termination and f is the initiator efficiency it follows that any one or all of the constants might have been affected by deuterium substitution. By making the reasonable assumption that k_d was not affected it was shown by

Table 1 Polymerization of methyl methacrylate and methyl methacrylate [${}^2H_5$] in bulk at 60°C*

Exp.	Monomer	$[I]_0$ x 10^3 (mol/l)	k x 10^4 (mol$^{-1/2}$ l$^{1/2}$ sec^{-1})	$\bar{M}_n$ x 10^{-5}	n

	Mean values		4.19 ± 0.04		1.52 ± 0.02

* $[I]_0$ = initial initiator concentration; $k = R_p/[M]_0[I]_0^{1/2}$ where R_p = rate of polymerization measured gravimetrically and $[M]_0$ = initial monomer concentration; $\bar{M}_n$ = number average molecular weight determined osmotically; n = number of initiator fragments per polymer molecule

radiochemical assay that the rates of initiation, R_i, and hence values of f, were identical within the limits of experimental error. Chain transfer to monomer can also be neglected in these systems. Thus, the isotope effect must be associated with either the propagation or the termination reaction.

Secondary inverse isotope effects have been observed when free radicals add to carbon double bonds. Addition of methyl or trifluoromethyl radicals to deuterated olefins gives rise to inverse isotope effects of about 3% per deuterium atom at 65°C[8]. An isotope effect of 0.94–0.90 was observed for the addition of methyl radicals to styrene [$\alpha,\beta - {}^2H_3$][9] and the effect of deuterium substitution on styrene polymerization at 60°C can be accounted for by an inverse effect on the propagation reaction of about 5% per atom of deuterium[2]. However, the value of $k_H/k_D = 0.73$ reported here seems rather large to be accounted for solely in terms of an inverse secondary effect on the propagation reaction, particularly as only two hydrogens are involved in the change from sp^2 to sp^3 hybridization.

The termination reaction is clearly affected since the value of n, the number of initiator fragments per polymer molecule is increased from 1.27 to 1.52 by deuteration. These values correspond to 42% and 68% combination of polymer radicals. This may be interpreted as an isotope effect on hydrogen transfer during termination by disproportionation which would explain all the results reported in the Table. The ratio of the velocity constants for termination by disproportionation may then be calculated as $k_{td,H}/k_{td,D} = 2.93$ which is about right for a hydrogen transfer reaction having a low activation energy. This in turn could be taken as clear evidence that the combination and disproportionation reactions proceed by way of different transition states.

The work with styrene[2] cannot be explained by the above mechanism, however, since polystyrene radicals terminate solely by combination. Thus, it seems possible that in the case of methyl methacrylate both k_p and k_t may be affected by deuterium substitution and it will be necessary to examine these constants individually to further delineate the system.

Book Reviews

The chemistry of organolithium compounds
B. J. Wakefield
Pergamon Press, Oxford, 1974. 335 pp. £10.20

The author aimed to write an account which is comprehensive, though not exhaustive. The selection of examples from more recent full papers, which give experimental details, rather than from preliminary communications or older work, was also a stated aim. This is perfectly reasonable in view of the available reviews covering the literature into the mid-fifties. The author admits some bias in the selection of examples and perhaps some readers may find too great an emphasis on, for example, the chemistry of perhalogeno-organolithium reagents. On the other hand, the selection of examples within such terms of reference does add a personal touch and a reasonable number of references are to papers published in 1972.

The book is divided into four parts. Two short chapters are devoted to the constitution and the preparation of organolithium compounds. The majority of the book is, in the reviewer's opinion, quite properly devoted to organic and organometallic synthesis. The book is clearly aimed at researchers in industrial and university laboratories and as such delineates the most important preparative and synthetic applications of these versatile reagents.

The book is well produced and is so free from proof-reading errors that a positive effort had to be made to detect any. The majority of the structural formulae are very clear but certain of the *schemes* are less clear and do not use a consistent method of indicating bonds (see for example *scheme* 9.1 on p 124). The book is relatively easy to use but I should have preferred the references to have been present as a footnote on individual pages or alternatively collected at the end of the whole book.

These minor criticisms do not detract from the general usefulness of the book which should find a place in all chemical libraries. It is unfortunate that the price will probably result in the book not finding its way onto many individual bookshelves, particularly since there has been a 20% increase in price since it was originally published less than a year ago.

H. Heaney

Reviews in macromolecular chemistry, Volume 11
Edited by G. B. Butler, F. O'Driscoll and M. Shen
Marcel Dekker, New York, 1974. 373 pp. $29.50

At first sight, the prospect of reading six lengthy articles on unconnected topics in polymer science appears a daunting one. It is therefore a pleasure to report that in the event this particular volume proved both interesting and rewarding. The standard of presentation is uniformly high and the exposition is pitched at a level which requires no more than a reasonable general knowledge of the physics and chemistry of polymers.

The first article in this book by S. Wu provides a comprehensive survey of Interfacial and surface tensions of polymers. It is clear that the present state of the state does not embrace much definitive theory, but this review covers the published work in the area in a very satisfactory fashion. The next topic, Mixing in polymer reactors by E. B. Nauman, is an unfamiliar one to this reviewer. In complete contrast to the previous article, the behaviour is discussed from the outset in terms of basic equations originated by Danckwerts and others. The whole discussion is developed in a systematic manner, always keeping in touch with the theoretical models. This article is followed by a very well written account of modern theories of polymer crystallization by I. C. Sanchez. The review is very much up-to-date in discussing the author's own theories (in collaboration with E. A. Di Marzio), comparing and contrasting these theories with those of Lauritzen and Hoffman, Frank and Tosi, Price and Lauritzen, Di Marzio and Passaglia.

The articles by Nauman and Sanchez rely on formal mathematical exposition and are comparatively short (~35 pages). In complete contrast the next article by G. L. Wilkes forms a comprehensive account of some 110 pages on Rheo-optical methods and their application to polymeric solids. This is an extremely valuable review, with much to stimulate anyone who is interested in structure/property relationships in solid polymers.

A rather shorter article, on the thermal decomposition of poly(vinyl chloride), covers new ground for this reviewer, but Z. Mayer must be congratulated on the clarity of this exposition. He makes out the case for thermal dehydrochlorination of PVC proceeding by non-radical mechanism, discusses the catalytic effect of free hydrogen chloride, and generally shows how ideas have changed dramatically in the subject over recent years. The final article in this volume is an account of the Thermodynamics of copolymerization by H. Sawada. This is a straightforward account of comparatively simple theories.

In conclusion, it can be seen that the articles in this volume range from informal reviews of experimental research to formal expositions of recent theoretical developments. There is something for most polymer scientists, written at a uniformly good standard, so that the book can be warmly recommended for any library where the subject of polymer science is to be included.

Conference Announcement

Plastics in Medicine and Surgery

Glasgow, 24–25 September 1975

This conference, organized by the Plastics and Rubber Institute, will be held at the University of Strathclyde, Glasgow on 24 and 25 September 1975. Thirty one contributions will cover aspects including implantable materials, artificial organs and assist devices and design, safety and standards. Further details and registration forms are available from Mr J. N. Ratcliffe, Plastics and Rubber Institute, 11 Hobart Place, London SW1W 0HL, UK.

Conference Announcement

Polymer Rheology and Plastics Processing

Loughborough, 16–19 September 1975

An international conference on polymer rheology and plastics processing, sponsored by the British Society of Rheology and the Plastics and Rubber Institute, will be held at Loughborough University from 16 to 19 September 1975. Over 30 contributions from industrial and academic workers are scheduled, with four sessions on principles and properties, three on plasticization and processing and one on attitudes to research in polymer rheology and plastics processing in industry and universities. The final day will consider shaping flows. Further information and registration forms are available from Miss S. Keeble, Plastics and Rubber Institute, 11 Hobart Place, London SW1W 0HL, UK.

Texture of elastin gels

R. B. Beevers

Belvoir Research Laboratory, 160 Chatham Road, Eastwood, New South Wales, 2122, Australia
(Received 7 April 1975)

Elastin gels which show a filamentous texture have been observed when an elastin fraction was swollen in buffer solutions between pH 5.85 and 8.16. This fraction, previously completely soluble in aqueous solutions, had been obtained during the hydrolysis of bovine *ligamentum nuchae* and stored for over three years at about 3°C. The diameter of the filaments was about 2 μm and microscopic examination showed that the texture of the gel depended on the protein concentration, pH and the ionic strength of the buffer solution used to cause swelling. Amino acid analysis of this protein fraction showed a slightly higher proportion of lysine and it is considered that the gel is the result of the reformation of a few lysinonorleucine and/or desmosine crosslinkages recreating an insoluble elastin matrix.

INTRODUCTION

Elastin may be isolated from bovine *ligamentum nuchae* by extraction at neutrality followed by periods of autoclaving in distilled water[1]. The insoluble elastin can then be degraded by reflux with oxalic acid to yield a soluble product (M_n = 70 000, Partridge method[2]).

There have been a number of reports of attempts to reconstitute an insoluble form of elastin from this soluble product. For example, Wood[3] obtained elastomeric gels by heating elastin solutions to form a coacervated phase which was then collected and these experiments may readily be repeated. A limited amount of success also has been achieved in the reconstitution of elastin through the addition of synthetic heparinoids to elastin solutions[4]. The gels obtained by these methods have elastic properties but show no structural features even when examined under the electron microscope.

As part of a detailed study of the solution properties of soluble elastin[5], bovine elastin obtained from a 1.5 year old ox was solubilized by the Partridge method. However, instead of following the usual procedure and pooling the solubilized elastin as it was produced, each of the five stages of reflux were separately treated dialysing the elastin obtained against water and then freeze-drying. These fractions were completely re-soluble in water and have remained so except for the fourth fraction. This fraction was found to contain some insoluble material after about 15 months storage at 3°C although initially completely re-soluble. At the time the insoluble component was discarded without further examination. Two years later, when further solution studies were contemplated, it was found that this elastin fraction had become almost completely insoluble. Microscopic examination of the water-swollen gel revealed a filamentous texture. A report is given here of the result of a more detailed examination of the elastin gel texture.

GEL TEXTURE

Mixtures of elastin (fourth fraction) were prepared with 0.05 M sodium formate buffer at pH 8.16 and had nominal concentrations in the range 6 to 98 mg dry protein/g. The mixtures were equilibrated at room temperature and then part of the gel was transferred by pipette to an excavated cell in a microscope slide and sealed with a coverslip. Each cell usually contained a portion of liquid to maintain equilibrium conditions of swelling. Examination of the gels under a polarizing microscope showed no indication of birefringent structures within the gel.

At the lowest protein concentration the general appearance of the gel was of a coarse grained texture similar to that which may be observed in elastin gels prepared by the method of Wood[3]. In the latter case the gel comprises a conglomerate of spherical coacervate particles which have sedimented to form a layer. At a high protein concentration, as shown in *Figure 1*, the gel comprises an amorphous granular base together with a distinctly filamentous component.

Examination of microphotographs of elastin gels prepared with increasing protein concentration reveals changes in the texture which strongly suggest the development of a filamentous structure, the final stage being shown in *Figure 1*. It was found that when gels were prepared at a lower pH filaments were obtained at a lower protein concentration. An example of the gel filaments prepared at pH 5.85 is shown in *Figure 2*. Further reduction in pH reversed this trend and no filaments could be found at pH 4.50. The boundaries to the development of filaments with respect to pH, protein concentration and temperature still remain to be clarified.

A comparison of the filamentous texture in gels prepared at pH 5.85 and 8.16 reveals a number of differences. For example, it was found that at the lower pH the gel consisted entirely of filaments and no amorphous gel component could be detected. Well developed branched structures were common and a typical example is shown in *Figure 2*. More detailed examination showed that at the lower pH there was an increase in the number of branches per unit length of filament and generally the branches were shorter in length.

Further it was observed that in gels prepared at pH 8.16 more than one type of filament could be detected. The prominent filament shown crossing the field in *Figure 1* was only found in small numbers. Some internal structure could be discerned and appears to be of a random, globular type. Also shown in *Figure 1*, close to this filament, is another distinct type occurring in small numbers and which have a characteristic 'I' cross-spacing at roughly regular intervals along the length of the filament. These two types are roughly 2-3 times the width of those forming the major
Figure 1 Microphotograph of part of an elastin gel swollen in 0.05 M sodium formate buffer at pH 8.16 and with a protein concentration of 95 mg dry protein/g. The bar indicates 0.1 mm

part of the gel. As far as can be judged the various types of filament exist independently.

A feature of the microphotographs of gels equilibrated at pH 5.85 is the large number of small particles in the surrounding protein solution. These particles often cluster in the region of the filaments as shown at the bottom of *Figure 2*. A possible explanation is that the particles are nuclei from which the filaments grow by accretion. Examination of gel filament at higher magnifications shows there to be some evidence for this view. This may also explain the absence of optical anisotropy in the filaments.

DIAMETER OF THE FILAMENTS

Measurement of filament diameter (Φ) was made with a calibrated micrometer eyepiece assuming the filaments to be of circular cross-section. In each gel a large number of filaments were measured and the mean filament diameter could be determined to $\pm 0.3~\mu m$. At pH 8.16 the distribution diagram of the filament diameters was skewed as a result of the presence of a small number of filaments of different type and significantly larger diameter.

An examination has been made of the effect of change of pH and ionic strength of the buffer solution on filament diameter. Preparatory to this work, part of an elastin solution containing gel was transferred to Visking tubing and dialysed against conductivity water. Fragments of filamentous gel were then transferred by pipette to tubes containing buffer solution of known pH and ionic strength. After equilibration for several days at 20°C small fragments of gel were then transferred to microscope slide cells for measurement of filament diameter with the results shown in *Figure 3b*. Adjustment to the ionic strength was made with KCl. Swelling measurements made on adult bovine *ligamentum nuchae* elastin by Jackson *et al.*[6] are reproduced in *Figure 3a* for comparison where w_s is the weight of water taken up by 1 g of dry ligament.

The two sets of data show an interesting correlation with a maximum at about pH 8 although the proportionate changes are not the same. Below pH 7, however, the swelling behaviour shows opposite trends. Differences here may be expected since quite severe hydrolysis conditions have been used to obtain the elastin fraction from the original insoluble bovine ligament. The ability to make use of the gel filaments in this manner demonstrates that they have a reasonable degree of coherence and are not simply an aggregation of particles.

ORIGIN OF THE GEL

The elastin gel filaments show many of the features exhibited by *in vivo* bovine *ligamentum nuchae* elastin that is, a fibrous texture with branching of the fibres[7] and an unordered molecular structure as detected by X-rays[8]. It has been found that X-ray scattering from wet gel filaments

mounted in Lindemann glass specimen tubes is similar to that obtained from water-swollen bovine ligament (results to be reported shortly).

The reason for the development of insolubility in this elastin fraction has not yet been established. Amino acid analysis has shown that the fractions are all similar in composition with no major differences. There is a small decrease in the amounts of valine and a slight but progressive increase in alanine, phenylalanine and lysinonorleucine with increase in fraction number. It has been found that the fourth fraction has a slightly larger amount of lysine than the other fractions and this permits a possible explanation for the development of insolubility.

It is now well established that there is a decrease in lysine during the development of foetal elastin the lysine residues becoming incorporated into desmosine and/or lysinonorleucine crosslinkages, the elastin becoming an insoluble protein[9]. The slight excess of lysine in this elastin fraction, determined shortly after preparation and whilst still completely water-soluble, would indicate that there may be a formation or reformation of the same type of crosslinkages. Only a few crosslinkages would be necessary to create an insoluble network structure and it may be that the observation of the gel texture is the most sensitive determinant of the presence of these cross-bridges.

Thermodynamic properties of concentrated poly(γ-benzyl-L-glutamate) solutions

K. Kubo and K. Ogino

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Tokyo, Japan
(Received 21 October 1974; revised 7 February 1975)

Solvent activities for the poly(γ-benzyl-L-glutamate)–chloroform system were obtained in the concentration range of 20 to 100 vol % polymer at 30°C by isothermal distillation and vapour pressure measurements. The results were combined with osmotic pressure data reported previously and were compared with the existing theories for solutions of rodlike molecules. Coexistence of two phases was not found. The data could be explained by the Flory theory, as modified by Wee and Miller, in a low or intermediate concentration range, and could be explained by the Flory–Leonard model at high concentrations.

INTRODUCTION

It is known that poly(γ-benzyl-L-glutamate) (PBLG) exists in the form of the rodlike, α-helical conformation in *N,N*-dimethylformamide (DMF) and chloroform. Below a limiting concentration (A-point) the solutions are isotropic, while above another concentration (B-point) they are anisotropic. The coexistence of these isotropic and anisotropic phases is observed in an intermediate concentration range.

Flory[1] proposed a theory of equilibrium properties for solutions of rodlike molecules based on a lattice theory. The important result of this treatment was that the phase separation arises from the contribution of entropy as a consequence of an asymmetric shape of the molecules. The enthalpy term in the free energy of mixing of the polymer and solvent was assumed to be of the van Laar type and to be characterized by a thermodynamic interaction parameter χ. A phase diagram for χ and composition was obtained for the stiff polymer–solvent system.

Robinson *et al.*[2] found the A- and B-points for PBLG solutions in methylene chloride and dioxane using a polarizing microscope. The dependence of the concentrations of these points on the axial ratio was semi-quantitatively explained by Flory's theory, provided the χ is sufficiently small or negative. Nakajima *et al.*[3] obtained the phase diagram from the observation of turbidity for the three component system, PBLG/DMF/poor solvent, in which the increase of the poor solvent content caused an increase in the thermodynamic parameter. Wee and Miller[4] determined the temperature–composition phase diagram for PBLG solutions in DMF from n.m.r. spectroscopy measurements. These phase diagrams were similar to those predicted by Flory's theory. Because the relation between χ and the poor solvent content or temperature was unfortunately not given in these experiments, an ambiguity for the propriety of the Flory model for rodlike molecules still remains.

Only limited thermodynamic studies have been made on the application of the Flory model. The results of vapour sorption studies for PBLG and poly(β-benzyl-L-aspartate) solutions at high polymer concentrations by Flory and Leonard[5] could not be explained by the Flory model, but could be explained by assuming that mixing of solvent with flexible side chains dominates the thermodynamic behaviour at high concentrations. Rai and Miller[6] obtained similar results for the PBLG–DMF system at high concentrations. They also showed that the results could be explained by the Wee–Miller theory, in which modification of Flory's lattice theory to allow for side chain flexibility had been made, i.e. the flexible side chains were assumed to be attached to a rigid main-chain backbone.

Osmotic pressure studies were recently reported for PBLG solutions in chloroform and ethylene dichloride in the concentration range of 2 to 15 vol % polymer at 29°C[7]. Because the measured osmotic pressures were a monotonic function of concentration, no phase boundaries were found. The value of χ was found to be 0.44–0.47 in the isotropic phase. In view of this large value of χ, it was concluded that the system cannot be treated without regarding net attraction between solute molecules.

In this paper determination of solvent activities for the PBLG–chloroform system are reported in the concentration range of 20 to 100 vol % polymer at 30°C. The solvent activities were determined from vapour pressure and isothermal distillation. The results are combined with those obtained by osmotic pressure measurements, and are compared with the existing theories.

EXPERIMENTAL

Materials

PBLG (M_n = 98 000) was the same as that used in the previous work, and its axial ratio was 45. Chloroform was dried over $CaCl_2$ and then distilled. Triphenylmethane (TPM), used as a reference solute for the isothermal distillation, was purified by recrystallization from ethanol, and was vacuum dried for more than 24 h.

Vapour pressure

Vapour pressure measurements were performed by two independent sets of apparatus, with different manometers. The basic part of the apparatus is a manometer, a chamber for housing a quartz spring balance, and a tube for storing pure solvent after vacuum-distillation. Direct and indirect vapour pressures were measured by a Bourdon gauge (60–100 vol % polymer) and by a U tube manometer (50–70 vol % polymer). The chamber, in the former, or together

with the tube, in the latter, was immersed in a bath ($30 \pm 0.02°C$), and the other parts of the system accessible to solvent vapour, including the manometer, were maintained at a slightly higher temperature ($+0.3°C$) above that of the bath to prevent condensation of solvent. Dried PBLG film, after weighing (40–50 mg), was placed on a quartz pan, suspended from the calibrated spring which was housed in the chamber. Solvent was admitted to the chamber and the manometer from the tube using a high-vacuum Teflon stopcock, and the resulting pressure was measured by the manometer, after evacuation to 10^{-4} mmHg through a vacuum line. The increase in weight owing to sorption of solvent by the polymer was observed from the elongation of the spring. Sorption equilibrium was usually attained within 6 h except at relatively high solvent concentration, where 24 h was generally necessary. The data were taken randomly by increasing or decreasing vapour pressure. The volume fraction was obtained assuming no volume change on mixing. The specific volume of PBLG was taken as 0.787 cm^3/g[5]. Prior to the isothermal distillation measurements, the activity coefficient of chloroform was determined using solutions of the standard solute (TPM) by the U tube method.

Isothermal distillation

Isothermal distillation was performed in the concentration range of 20 to 50 vol % polymer at $30°C$. The diagram of a glass vacuum desiccator is shown in *Figure 1*. The PBLG (0.5–1.0 g) was weighed in fibrous form at the beginning of the experiment. Two weighing bottles, A and B were put on a glass plate, and their lids were placed above the bottles. Polymer solution was set in one bottle, and a reference solution of TPM in chloroform was placed in the second bottle. All joints, C, D, and E were sealed with

mercury, and the desiccator was evacuated through a high vacuum Teflon stopcock F. The desiccator was then immersed in a bath at $30 \pm 0.01°C$. To take out the weighing bottles, the stopcock was opened, and the joints, C and D were removed. After the weighing bottles were quickly covered, the desiccator was opened. The volume fraction was obtained by weighing using the same assumption as was made in the vapour pressure measurements.

Isothermal distillation between polymer solutions whose initial concentrations were different by about 20 vol % polymer was performed. These concentrations coincided within the experimental error for the run after seven days. Therefore, we assumed that this was a sufficient condition for attainment of equilibrium for isothermal distillation.

RESULTS

Vapour pressure

Results for solvent activities are given in *Table 1*.

Vapour pressure depression for the reference solution of TPM in chloroform is plotted as a function of solute x_2 in *Figure 2*. The broken line represents Raoult's law. The

solvent activity coefficient $\gamma_1 = a_1/x_1$ was calculated from the vapour pressure depression, ΔP, by:

$$\gamma_1 = (1 - \Delta P/P_1^0)/(1 - x_2) \tag{1}$$

where P_1^0 is the vapour pressure over the pure solvent, a_1 the solvent activity, and x_1 the mole fraction of the solvent. These values are plotted as $(\gamma_1 - 1)/x_2^2$ versus x_2 in *Figure 3*. The expression for the activity coefficient of chloroform in TPM from this plot is:

$$\gamma_1 = 1 - 0.668x_2^2 - 0.273x_2^3 \tag{2}$$

Isothermal distillation

Results for isothermal distillation are summarized in *Table 2*. The second column lists the mole fraction of TPM in chloroform at equilibrium. The solvent activities listed in the third column were calculated using equations (1) and (2).

DISCUSSION

The thermodynamic properties of the PBLG–chloroform system over the entire concentration range could be obtained by combining the isothermal distillation and vapour pressure data with osmotic pressure data reported previously[7]. Although it is difficult to choose a function which describes the entire behaviour of the activity for a wide concentration range, we can satisfy this criterion by choosing a function, $\ln a_1/\ln v_1$, which was first used by Krigbaum and Geymer[8]. Here, a_1 and v_1 are the activity and the volume fraction of the solvent, respectively. The function $\ln a_1/\ln v_1$ obtained from three different types of measurements is plotted in *Figure 4* against volume fraction of polymer, v_2. At infinite dilution this function must approach a constant value $1/X$, where X is the ratio of the molar volume of polymer

Vertical broken lines indicate calculated positions of phase boundaries

to that of solvent. At the other limit of concentration the function must approach unity. Although the osmotic pressure and isothermal distillation data do not overlap perfectly, *Figure 4* shows that the two sets of data complement each other. The A-point for the PBLG (axial ratio 85)/chloroform system was found to be $v_2 \approx 0.065 - 0.070$[7], and the B-point should exist at a somewhat higher concentration. If the bisphasic region existed, this function $\ln a_1/\ln v_1$ must decrease with increasing concentration within this region. The existence of certain phase boundaries is not seen in the Figure.

In Flory's lattice theory of rodlike molecules, the thermodynamic properties are represented as follows. Activity of solvent a_1 and of polymer a_2 for the isotropic phase are:

$$\ln a_1 = \ln(1 - v_2) + \{(r - 1)/r\}v_2 + \chi v_2^2 \tag{3}$$

$$\ln a_2 = \ln(v_2/r) + (r - 1)v_2 - \ln r^2 + \chi r(1 - v_2)^2 \tag{4}$$

and those for the anisotropic phase are:

$$\ln a_1 = \ln(1 - v_2) + \{(y - 1)/r\}v_2 + 2/y + \chi v_2^2 \tag{5}$$

$$\ln a_2 = \ln(v_2/r) + (y - 1)v_2 + 2 - \ln y^2 + \chi r(1 - v_2)^2 \tag{6}$$

where v_2 is the volume fraction of the polymer, r the axial ratio of the polymer, and y a disorientation index, determined using the following equation:

$$v_2 = \{r/(r - y)\}\{1 - \exp(-2/y)\} \tag{7}$$

At high concentrations, where $y = 1$ (i.e. perfect alignment of rodlike molecules prevails at equilibrium) the activity of solvent is given by the expression for a solution with ideal entropy of mixing:

$$\ln a_1 = \ln x_1 + \chi v_2^2 \tag{8}$$

where x_1 is the mole fraction of solvent.

In *Figure 4*, $\ln a_1 / \ln v_1$ *versus* v_2 calculated from equations (3)–(8) for $\chi = 0$ with $r = 45$ and 948.8* is plotted.

From the general features of these curves, the discrepancy between the predicted values and experimental data cannot be removed by adjusting the value of r. The experimental curve may be aligned with a curve obtained by assuming a large value of χ, but Flory's theory predicted that the system with a large value of χ must be biphasic at extremely low concentration. It must also have a large concentration difference between the two phases in equilibrium, so our results cannot be accounted for by such an assumption.

Flory and Leonard[5] measured vapour pressures for PBLG—pyridine, PBLG—ethylene dichloride, and poly(β-benzyl-L-aspartate)/chloroform in the concentration range of 60 to 100 vol % polymer. They found that their data could not be fitted with the results predicted by Flory. To take account of this discrepancy, the mixing of solvent with flexible side chains of polymer was considered and the arrangement of main chains was assumed to be fixed where the volume fraction of solvent was small. Their data were compared with the following expression:

$$\ln a_1 = \ln(1 - v_2') + v_2' + \chi_s(v_2')^2 \tag{9}$$

where v_2' is the volume fraction of the side chains calculated on the basis of mixing being confined to the side chains,

---

* This value given for r corresponds to the value of X for this system.
Figure 5 Curves of $\ln a_1$ vs. v_2 calculated from Wee—Miller theory with $\chi = 0$. A, $x = 110$ and $a = 110$; B, $x = 110$ and $a = 0$. Vertical broken lines indicate positions of phase boundaries

and χ_s is the interaction parameter related to the side chain and solvent. The v_2' is given by:

$$v_2'/(1 - v_2') = (M_s/M_u)\{v_2/(1 - v_2)\} \tag{10}$$

where M_s and M_u are the molecular weights of the side chain and of the entire peptide unit. The data of Flory and Leonard were found to fit equation (9) reasonably, below the concentration of 10–15 vol % solvent, if χ_s for PBLG-pyridine, PBLG—ethylene dichloride, and poly(β-benzyl-L-aspartate)/chloroform were assumed as 0.35, 0.2, and 0, respectively. In *Figure 4*, $\ln a_1 / \ln v_1$ *versus* v_2 calculated from equations (9) and (10) with $\chi_s = -0.2$ is shown. Reasonable agreement is found between the predicted and experimental results above $v_2 \approx 0.6$. Rai and Miller[6] reported similar results obtained by vapour pressure measurements for the PBLG–DMF system in the concentration range of 70–100 vol % polymer. The experimental results were explained by equations (9) and (10) with $\chi_s = 0.6$. They also showed that these results can be explained by Flory's lattice theory, as modified by Wee and Miller. In this theory, polymer chain was assumed to be composed of rigid main chain and flexible side chains. A partition function for the system, in which the main chains were partly oriented about an axis, was derived on the basis of a lattice model as in the original Flory model. However, we did not adopt the Wee—Miller theory for explaining the present experimental results at high concentrations, because the assumption that arrangement of main chains is affected by dilution would not be reasonable at high concentrations.

We considered that the Wee—Miller theory for polymer molecules composed of rigid main chains and flexible side chains does not apply at high concentrations, but rather at low or intermediate concentrations. This has been briefly mentioned in a report by Rai and Miller[6] and is discussed in some detail below.

Activities of solvent and polymer for the isotropic phase are:

$$\ln a_1 = \ln(1 - v_2) + [(x + a - 1)/(x + a)]v_2 + \chi v_2^2 \tag{11}$$

$$\ln a_2 = \ln[v_2/(x + a)] + (x + a - 1)v_2 - \ln x^2 + \chi(x + a)(1 - v_2)^2 \tag{12}$$

and those of for the anisotropic phase are:

$$\ln a_1 = \ln(1 - v_2) + [(y + a - 1)/(x + a)]v_2 + 2/y + \chi v_2^2 \tag{13}$$

$$\ln a_2 = \ln[v_2/(x + a)] + (y + a - 1)v_2 + 2 - \ln y^2 + 2a/y + \chi(x + a)(1 - v_2)^2 \tag{14}$$

where x is the axial ratio of the main chain, a the number of segments of side chains per main chain, and y the disorientation index. The value of y is given by the expression:

$$v_2 = \{(x + a)/(x - y)\}\{(1 - \exp(-2/y)\} \tag{15}$$

These equations lead back to equations (3)–(7) in the case of $a = 0$. Solvent activities for the system with $x = 110$ and $\chi = 0$ calculated from equations (11)–(15) are shown in *Figure 5* in the cases of $a = 0$ and 110. The difference

between solvent activities for isotropic and anisotropic phases in the latter case is much smaller than that for the former. The concentrations of the A- and B-points are given as $v_2 = 0.073$ and 0.112 for $a = 0$, and $v_2 = 0.165$ and 0.174 for $a = 110$.

The segments of main chain and of side chain, and the solvent molecules to be occupied on a lattice site must be primarily limited to the same size on the basis of the lattice model. In order to allow the theory to be applied to actual solutions, we take x and a as adjustable parameters. Because the value of the function $\ln a_1/\ln v_1$ must approach $1/X$ at infinite dilution, it is reasonable to take the ratios of the molar volume of main chain and of side chains per main chain to the molar volume of solvent as x and a. The curve of $\ln a_1/\ln v_1$ *versus* v_2 calculated from equations (11)–(15) with $x = 242.6, a = 706.2$, and $\chi = 0.46$ is shown in *Figure 4*. The behaviour of solvent activities fits reasonably for the experimental data below $v_2 \approx 0.4$. The concentrations of the A- and B-points given as $v_2 = 0.153$ and 0.164 would be respectively higher than those observed using a polarizing microscope. This is, perhaps, due to the fact that the PBLG–chloroform system is not perfectly within the limitations of applicability of the lattice model in choosing values for x and a. The fact that the phase boundaries were not found from the thermodynamic measurements may be because the biphasic region was too narrow and the difference between the activities for the isotropic and anisotropic states was too small to be detected experimentally (see *Figures 4* and *5*).

The parameter χ, characterizing the enthalpy term in equations (11)–(14), is approximately given by the following expression, provided that the interaction between main chain and side chain is omitted:

$$\chi = [x/(x + a)]\chi_m + [a/(x + a)]\chi_s \tag{16}$$

where χ_m is the interaction parameter between the main chain and the solvent, and χ_s is the parameter related to the side chain. If χ, χ_s, and x/a are respectively taken as 0.46, -0.2, and 0.344, the value of χ_m is given as 2.4 from equation (16). The distinct and very large value of χ_m is due to the strength of the net attractive forces, perhaps resulting from the interaction between the large dipole moments of the main chains. We can deduce from these observations that the solubility of PBLG molecules can be attributed to the compatibility between the side chain and the solvent.

Thermodynamic studies of solid polyethers: 5. Crystalline–amorphous interfacial thermal properties*

Mitsuru Ikeda[†], Hiroshi Suga and Syuzo Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, Japan
(Received 17 June 1974; revised 10 February 1975)

The influence of the crystalline–amorphous interface on the bulk melting phenomena of poly(ethylene oxide) and poly(octamethylene oxide) was studied. For this purpose, heats of solution of various kinds of specimens prepared by precise heat treatment were measured at various temperatures with an isoperibol calorimeter. The crystallinity and the lamellar thickness were determined by dilatometric and small-angle X-ray scattering methods, respectively. Melting points of each sample were determined using a differential scanning calorimeter. The thermodynamic quantities obtained were correlated by theoretical consideration, so that the effects of crystalline–amorphous interfacial thermal properties on bulk quantities such as heat of fusion were derived.

INTRODUCTION

The nature of the surfaces of folded-chain crystals of solid high polymers has been the subject of intensive study in recent years. There are two methods of investigation in general. One of them is the kinetic approach. Hoffman and Lauritzen[1] have determined the surface free energy of folded-chain crystals by studying the kinetics of the crystallization of polymers. The other is based on thermodynamic considerations[2,3]. The investigation by Fisher and Hinrichsen[2] is a typical example.

As is well known, a crystalline high polymer is considered as consisting of crystallites embedded in an amorphous region. This model is widely supported by measurements of density[4], small-angle X-ray scattering[5], broadline n.m.r.[6] and of etching phenomena[4]. We have adopted this kind of model for the analysis of the surface-excess thermodynamic functions.

The present study aims to elucidate the effect of the nature of interface on the bulk properties such as melting phenomena, etc. Dynamic techniques such as differential scanning calorimetry may be useful for semi-quantitative discussion, but for more precise estimation of the free energy of the interface it is desirable to obtain accurate data under static conditions. In this respect, we have employed another technique to determine heats of fusion, through the determination of heats of solution with a precision solution calorimeter.

Table 1 Viscosity-average molecular weight (M_η), number-average molecular weight (M_n) and the ratio of the weight-average to the number-average molecular weight (M_w/M_n) of three PEO samples

Sample	M_η	M_n	M_w/M_n
I	1.29×10^3	1.52×10^3	1.13
II	7.80×10^3	6.84×10^3	1.11
III	2.02×10^4	1.96×10^4	1.18

We have determined thermodynamic quantities for characterized samples of poly(ethylene oxide) (PEO) and poly(octamethylene oxide) (POMO), since their crystal and molecular structures have been studied very precisely by Tadokoro et al.[7,8].

EXPERIMENTAL

Preparation and characterization of samples

Poly(ethylene oxide). Of three samples employed for the present research, sample I (PEO 1500) and sample II (PEO 6000) were obtained from Wako Junyaku Co. Ltd, sample III (PEO 20 000) being obtained from Union Carbide Co. Ltd.

They were recrystallized by precipitation of chloroform solution (Wako special grade) with petroleum ether (Wako special grade) at ice-bath temperature and then dried under high vacuum (10^{-3} N/m^2) for a week at room temperature.

The molecular weight distribution and number-average molecular weight of the samples were determined by use of gel permeation chromatography (g.p.c.). The g.p.c. analysis of sample I was carried out in tetrahydrofuran (THF) solution at 35°C, by means of a Shimadzu GPC packed with crosslinked polystyrene–divinylbenzene gel. Samples II and III were treated in dimethylacetamide solution at 80°C using Bio-Glass 200 (Bio-Rad Lab. Co. Ltd) as the packing. For the determination of M_η values of these samples the viscosities of their benzene solution were measured at 25°C. In this case the following equation[9] was employed:

$$[\eta] = 3.97 \times 10^{-4} M_\eta^{0.686} \tag{1}$$

The results are listed in *Table 1*.

Four samples of sample III, prepared under different annealing conditions, were used for the measurements of heat of solution, lamellar thickness, and degree of crystallinity. They were crystallized from the melts at the constant temperatures of 28°, 42°, 50° and 55°C, respectively. These samples are called hereafter samples I', II', III' and IV', respectively.

As PEO is very hygroscopic, special care was taken to isolate the sample from open air by handling in a dry-box.

Poly(octamethylene oxide). The monomer n-octa-methylene glycol was purified by repeated recrystallization from an acetone solution of a commercial sample (Nakarai Chemical Co. Ltd) by precipitation with ethyl ether. Polymerization was then performed in a special reaction tube which was designed by Rhoad and Flory[10]. After a small amount of concentrated sulphuric acid and (C₂H₅)OBF₃ (Nakarai Co. special grade) had been introduced into the tube, it was evacuated and degassed. The mixture was then heated up and polymerized in the temperature region 160°–210°C under a constant stream of dry nitrogen gas. The product was purified by repeated precipitation from benzene solution with methanol and finally dried in vacuum $(10^{-3}\ N/m^2)$ at 30° to 50°C for a week.

The molecular weight distribution and number-average molecular weight of POMO were determined by Yoshida *et al.*[11]. Based on this result the average molecular weight was evaluated to be ~7000. POMO exists in two crystalline forms. Although the chain conformation is planar zigzag in both forms, their packing in the unit cell differs. In this study, PTHF-type prepared by cooling the molten sample was used[8]. Four kinds of sample with different annealing conditions were prepared for the purpose mentioned above. They were crystallized from the melts at the constant temperatures of 30°, 40°, 50° and 60°C. These samples are called hereafter samples I′, II′, III′ and IV′, respectively. All the procedures of handling the samples were carried out in a dry-box as described above.

Heat of solution

The heat of solution was measured by making use of an isoperibol-type precision calorimeter, LKB 8700–1. This calorimeter was calibrated by measuring the heat of solution of tris(methyl hydroxy)amino methane in 0.1 N HCl solution and the inaccuracy was found to be 0.01%. The amount of sample used in each measurement was about 500 mg which was dissolved in 100 cm³ water.

The heats of solution in water for each of samples I, II, and III of PEO were measured at 20°, 25° and 30°C. In every case two kinds of sample, quenched or annealed, were investigated. For the quenching treatment each sample was dried under high vacuum $(10^{-4}\ N/m^2)$ for 30 min at 350 K and then immersed directly into liquid nitrogen. On the other hand, an annealed sample was prepared by a slow cooling (0.4 K/h) down to room temperature. For samples I′, II′, III′ and IV′ of PEO, the measurements of the heats of solution in water were carried out at 25°C.
Figure 1 Reading of dilatometer of PEO at different temperatures. A, Sample I′; B, sample II′; C, sample III′; D, sample IV′

The heats of solution of POMO (sample I′) in benzene were measured at 25°, 30° and 35°C. The heats of solution in benzene for samples I′, II′, III′ and IV′ of POMO were also measured at 35°C.

Dilatometry

After complete degassing of the melts (347 K) of each sample the volume changes on crystallization were measured with a dilatometer. An ordinary dilatometer made of glass was used with a cathetometer (to ±0.01 mm). The degree of crystallinity of each sample was determined using the method by Skoulios *et al.*[12–14].

Small-angle X-ray scattering

The measurement of small-angle X-ray scattering was carried out by using a Rigaku Denki RU-3HM. Small-angle X-ray diffraction photographs for samples I′, II′, III′ and IV′ of PEO were obtained at 25°C. The exposure time was about 24 h for each measurement. For the samples of POMO, the measurements were made at 20°C. These data were analysed by use of a photometer. The lamellar thickness of the samples was determined according to the method of Fisher and Hinrichsen[2].

Melting point determination

The melting points of all the samples were measured by use of a DSC-model 1B (Perkin–Elmer).

RESULTS AND DISCUSSION

Poly(ethylene oxide)

Determination of the degree of crystallinity. The degree of crystallinity of sample III was determined using the data of the dilatometric study described in the previous section. The relationship between the reading of dilatometer and the time elapsed immediately after dipping the sample into the water-bath is illustrated in *Figure 1*. Each curve consists of two parts: the initial drop of the reading corresponding to the process of crystallization from the melt at a definite temperature, and the second drop expressing the thermal contraction which takes place on cooling the sample from the crystallization temperature down to the final temperature, 25°C.

For the determination of the degree of crystallinity, the following relations proposed by Skoulios *et al.*[12–14] were adopted:

$$\tau(t) = [V(t) - V_1(t)] / [V_c(t) - V_1(t)] \qquad (2)$$

where $\tau(t)$ is the degree of crystallinity of the sample at $t°C$, V the specific volume of crystalline polymer and V_c and V_l, the specific volume of the crystalline as well as the amorphous regions on the assumption that the specific volume of the amorphous region is equal to that in the supercooled liquid state.

In the present case, the degrees of crystallinity were calculated by adopting the following numerical data: $V_c(25°C)$ = 0.810 4 cm³/g[7], $V_c(t_c)$ = 0.810 4 + 1.5 × $10^{-4}(t_c - 25)$[13]; $V_l(25°C)$ = 0.886 0 cm³/g and $V_l(t_c)$ = 0.886 0 + 7.0 × $10^{-4}(t_c - 25)$. The degrees of crystallinity based on these values are given in *Table 2*.

Heat of solution. In *Figure 2*, the dissolution curve into pure water of sample II at 25°C is shown. It is interesting to note here that the first process is endothermic, which is followed by a subsequent exothermic one. Presumably, the

former corresponds to a swelling effect, while the latter to a dissolving one. In order to analyse this mechanism in more detail, the dissolution curve of the same sample into a saturated aqueous solution of PEO at 25°C was measured. The result is shown in *Figure 3*. In this case we observe only the first abrupt rise of the temperature. This fact supports the above-mentioned interpretation, since no dissolution should occur in this case. The value of the heat of swelling amounts to 3.36 kJ/mol monomer unit. In the following experiments with PEO, 100 cm³ water were always used as the solvent. In such experiments the process of swelling and dissolution takes place simultaneously.

The dissolution curves of sample II in chloroform and benzene at 25°C are shown in *Figure 4*. After the swelling process was over, the exothermic process was observed in chloroform, while in benzene we could not observe any such tendency, and a monotonous approach to equilibrium was observed. The much slower process of dissolution in the cases of benzene and chloroform in comparison with that of water makes it impossible to determine the exact heat of solution from these data. However, we can observe the total effect due to the simultaneous swelling and dissolution processes. As a result, we can point out the important fact that at 25°C there appears to be an exothermic process in polar solvents but not in non-polar solvents.

To investigate the temperature dependence of the heat of solution in water in more detail than the results reported by Nakayama[15] and Lakhanpal *et al.*[16], we studied the heat of solution at various temperatures (20°, 25° and 30°C) for samples I, II and III, each of which had undergone two kinds of treatment, annealing and quenching. These results are given in *Table 3* and *Figure 5*. The experimental error was estimated to be ~±0.2–0.4%. As is shown in *Figure 5*, the heats of solution for all the samples shift from the exothermic side to the endothermic one with increasing tem-

perature. It is rather difficult to find out the systematic influence of the molecular weight on the heat of solution from these results, because the curves also reflect the influence of the degree of crystallinity on the heat of solution.

In order to illustrate this, we measured the heat of solution into water at 25°C for the samples of sample III with various degrees of crystallinity. These results are listed in *Table 2* and illustrated in *Figure 6*. This curve indicates that the heat of solution of this sample of PEO in water at 25°C becomes zero at a degree of crystallinity of about 86.7%.

Determination of lamellar thickness of folded-chain crystal. Small-angle X-ray diffraction patterns were taken for the samples which were recrystallized from the melt at crystallization temperatures of 28°, 42°, 50° and 55°C. To analyse these diffraction patterns, we referred to the collagen crystal[17] as a standard substance. Since the polymer crystal contains the amorphous region, a true lamellar thickness is obtained by taking into account the degree of crystallinity on the basis of Fisher's method[2]. This relates the lamellar thickness, L, to the crystallinity, $\tau(t)$, and the length of long period, l, obtained by the small-angle X-ray scattering method by:

$$L = \tau(t) \times l \tag{3}$$

The relationship between lamellar thickness and crystallization temperature obtained is illustrated in *Figure 7* and

Table 3 Values of the heats of solution of PEO samples measured at different temperatures

Figure 6 Heat of solution of PEO (samples I′, II′, III′ and IV′) in water at 25°C plotted against crystallinity
Figure 7 Lamellar thickness (25°C) of PEO plotted against crystallization temperatures for samples I′, II′, III′ and IV′

Table 2. As is shown from these results, the lamellar thickness increases with the crystallization temperature appreciably around 45°C. This fact indicates that the lamellar thickness is determined mainly during the period of crystal growth. The sharp change mentioned above seems to agree fairly well with the result of Skoulios *et al.*[14] and also is consistent with the theory of Lindenmeyer[18]. After the completion of our study we have noted the new results of Booth *et al.*[19] and Spegt[20]. The former investigated the change of the melting point as well as the interfacial free energies with the variation of molecular weight mainly for low molecular weight specimens, while the latter investigated the effect of variation of molecular weight on the lamellar structure. According to the latter's results it may be concluded that our sample corresponds to his sample H-20000.

Estimation of the melting point of an assumed ideal crystal. Melting points of samples I′, II′, III′ and IV′ were measured by using a Perkin—Elmer DSC 1B. The curve of melting points vs. reciprocal lamellar thickness is shown in *Figure 8*, in which we can see a linear relationship. This fact seems to reflect a continuous change in the lamellar thickness of our sample as was mentioned in the previous

section. If this assumption is correct, the melting point of an ideal crystal which consists of infinite extended-chain polymer may be estimated by extrapolating to $L^{-1} = 0$ and found to be 341.8 K.

Poly(octamethylene oxide)

Determination of the degree of crystallinity. The degrees of crystallinity for four samples (samples I′, II′, III′ and IV′) of POMO were determined in the same way as in PEO and the results are shown in *Figure 9*. In this case the final temperature was 30°C. In the calculation of the degree of crystallinity, the density of the crystalline part of POMO was found to be $d(25°C) = 1.03$ g/cm^3 from the X-ray diffraction data measured by Tadokoro *et al.*[8]. In addition, the following data were employed: $V_c(25°C) = 0.970\,9$ cm^3/g, $V_c(t_c) = 0.977\,0 \times [1 + 1.48 \times 10^{-3}(t_c - 30)]$[21], $V_l(30°C) = 1.191\,6$ cm^3/g and $V_l(t_c) = 1.191\,6 \times [1 + 7.53 \times (t_c - 30)]$. The degree of crystallinity data obtained are listed in *Table 4*.

Heat of solution. Measurements of the heat of solution into benzene for the samples recrystallized from the melts at 30°, 40°, 50° and 60°C, were carried out at 35°C. Below 35°C, the solubility and the rate of dissolution decreases markedly. Here, we can observe heat data as given in *Table 4* in which the experimental error was found to be ±2%. The heats of solution of sample I′ were measured at 25°, 30° and 35°C: their values were found to be 19.74, 22.07 and 24.30 kJ/mol monomer unit respectively.

Determination of lamellar thickness of folded-chain crystal. The small-angle X-ray diffraction photographs for the samples recrystallized from the melts were taken at crystallization temperatures of 30°, 40°, 50° and 60°C. As in the case of PEO, a change of diffraction patterns was observed. The experimental results of lamellar thickness are given in *Table 4*.

Estimation of melting point of an assumed ideal crystal. The corresponding procedure to the case of PEO (see *Figure 8*) was carried out and the melting point of an assumed

ideal crystal was obtained as 347 K. This result is compatible with that obtained by Yoshida *et al.*[11] (347 K) who determined it by use of an adiabatic calorimeter.

Interfacial enthalpy and enthalpy of fusion of folded-chain lamellar crystal

As was mentioned in the introduction, the main purpose of the present work is to determine the interfacial enthalpy of the two crystalline polymers, based on the measurement of the heats of solution as well as the crystallinities of the samples.

In this respect, the first step was to derive the relationship between the heat of solution and the interfacial enthalpy. By using the equation suggested by Fisher[2], the observed molar heat of fusion can be expressed as follows:

$$\Delta H_m^{ob} = \tau(t) \times \{\Delta H_m^{\infty} - (2V_c H^{\sigma}/L)\} \qquad (4)$$

where ΔH_m^{ob} is the observed molar heat of fusion of polymer per monomer unit, ΔH_m^{∞} is the molar heat of fusion for the ideal crystal which is made up with the perfect crystalline part of infinitely extended-chain, H^{σ} is the molar interfacial enthalpy of folded-chain crystal, V_c is the molar volume, $\tau(t)$ is the degree of crystallinity at t°C and L is the lamellar thickness of folded-chain crystal.

Assuming the additivity of the molar enthalpies of crystalline and amorphous regions, the observed molar heat of solution, ΔH_{sol}^{ob} at t°C is given by:

$$\Delta H_{sol}^{ob} = \tau(t) \times \Delta H_{sol}(cryst) + \{1 - \tau(t)\} \times$$
$$\Delta H_{sol}(amorph) \qquad (5)$$

where $\Delta H_{sol}(cryst)$ is the molar heat of solution at t°C for the crystalline part and $\Delta H_{sol}(amorph)$ is the molar heat of solution at t°C for the amorphous region of the partly crystalline polymer. By setting

$$\Delta H_{sol}(cryst) = H(sol) - H(cryst) \qquad (6)$$

$$\Delta H_{sol}(amorph) = H(sol) - H(liq) \qquad (7)$$

and substituting equations (6) and (7) into equation (5), we obtain:

$$\Delta H_{sol}^{ob} = \tau(t) \times [H(liq) - H(cryst)] + \Delta H_{sol}(amorph) \quad (8)$$

where $H(liq)$ and $H(cryst)$ are the enthalpies at t°C of liquid and crystalline regions of high polymer, respectively.

Then, we obtain the following approximate equations from equations (4) and (8):

$$\Delta H_{sol}^{ob} = \tau(t) \times [\Delta H_m^{\infty} - (2V_c H^{\sigma}/L)] +$$
$$\Delta H_{sol}(amorph) \qquad (9)$$

Table 5   Various thermodynamic data obtained from our experiments

Sample		ΔH_m^∞ (kJ/mol monomer unit)	ΔS_m^∞ (J/K per bond)	T_m^∞ (K)	$H^\sigma \times 10^{-7}$ (J/cm^2)	$G^\sigma \times 10^{-7}$ (J/cm^2)	$S^\sigma \times 10^{-7}$ (J/cm^2)
PEO	our data (25°C)	9.41 ± 1.05	9.11	341.8	104 ± 27	97.7	0.018 4
POMO	our data (30°C)	29.85 ± 1.30	9.70	347.1	80.8 ± 23	73.4	0.021 3

$$\Delta H_{sol}^{ob} - \Delta H_{sol}(\text{amorph}) = \tau(t) \times [\Delta H_m^\infty -$$
$$(2V_c H^\sigma/L)] \qquad (10)$$

From equation (9), we obtain the following equation by taking the difference of the ΔH_{sol}^{ob} of different samples:

$$[(\Delta H_{sol}^{ob})_i - (\Delta H_{sol}^{ob})_j = \Delta H_m^\infty [(\tau(t))_i - (\tau(t))_j] -$$
$$2V_c H^\sigma \{[(\tau(t))_i/L_i] - [(\tau(t))_j/L_j]\} \qquad (11)$$

where we assume that ΔH_m^∞ and H^σ are constant for ith and jth different samples, since we have employed rather high molecular weight polymers which have average lamellar thicknesses as was described in the preceding section*. In this way, we can eliminate $\Delta H_{sol}(\text{amorph})$ which is not measurable, and we are in a position to evaluate a kind of averaged ΔH_m^∞ and H^σ from the ΔH_{sol}^{ob} data by means of the method of least squares.

Substituting our experimental results into this equation, the interfacial enthalpy and the enthalpy of fusion of PEO and POMO were evaluated. The results obtained correspond to 25°C for PEO and to 30°C for POMO. The enthalpies of fusion obtained are converted to those at T_m^∞ by use of the C_p data of Beaumont *et al.*[23]. The final values are shown in *Table 5*.

Now, we proceed to the discussion of the significance of these values for PEO. If the interfacial term in equation (4) is neglected the ΔH_m^∞ of PEO will have an unreasonably large value of 13.30 ± 7.37 kJ/mol monomer unit with large probable error. This result suggests strongly that we should take the interfacial enthalpy into consideration. As far as we are aware the derivation of the enthalpy of fusion of ideal PEO crystals has been carried out either by the measurement of heat capacity[23] or by use of the method of the depression[24] of melting point for samples with different crystallinities. However, the former gives the enthalpy of fusion of folded-chain crystalline polymer with 100% crystallinity, not of the perfectly extended ideal crystal. So, the effect of the interfacial region is not taken into account. The latter method is rather inaccurate owing to the difficulty of accurate determination of the melting point. The value in this study corresponds to that of a perfect extended-chain crystal excluding the effect of interfacial enthalpy.

Skoulios *et al.* reported[13] the interfacial Gibbs energy of 74 × 10^{-7} J/cm^2 by using an enthalpy of fusion of 8.28 kJ/mol monomer unit estimated by Mandelkern and Flory[25]. In general it seems to be important in the case of a high

polymer that we should adopt a physical property for the definitely characterized specimen. In this respect, the data of Skoulios *et al.* are not so reliable, since the value of ΔH_m^∞ adopted for their calculation is taken from a different sample employed by Mandelkern and Flory. In passing it may be added here that after the completion of our study Maron and Filisko[26] reported the enthalpy of fusion for PEO (M_n = 6000) as 242 ± 1.7 J/g by the measurement of heat of solution in water.

The enthalpy of fusion and interfacial enthalpy of POMO crystal consisting of infinitely extended-chain were calculated in the same way. The results are also shown in *Table 5*. Little is known about the enthalpy of fusion of POMO, except for the value of 29.7 kJ/mol monomer unit which was estimated by Yoshida *et al.*[11] from the measurement of heat capacity and which agrees approximately with our result of 29.85 ± 1.30 kJ/mol monomer unit.

This fact indicates that the effect of folding on the enthalpy of fusion and melting point seems to be rather small for the POMO samples employed.

Interfacial entropy

The thermodynamic relation suggested by Flory[24] follows:

$$T_m^{ob} = T_m^\infty [1 - (2G^\sigma V_c/\Delta H_m L)] \qquad (12)$$

The combination of this equation with equation (4) and the following thermodynamic relation:

$$S^\sigma = [(H^\sigma - G^\sigma)/T_m^\infty] \qquad (13)$$

gives the interfacial entropy S^σ. Here we have used our data on H^σ and T_m^∞ given above. The results are as follows: $S^\sigma = 0.184 \times 10^{-7}$ and $0.021\,3 \times 10^{-7}$ J/cm^2, for PEO and POMO, respectively.

Entropy of fusion

The entropy of fusion of the ideal crystal is evaluated by the relation of $\Delta S_m^\infty = \Delta H_m^\infty/T_m^\infty$ and $\Delta S_m^\infty = 9.24$ and 9.84 J/K per bond for PEO and POMO, respectively.

Mixing enthalpies of PEO and POMO

From equation (10), $\Delta H_{sol}(\text{amorph})$, which is equal to the mixing enthalpy of the supercooled liquid of polymer with the solvent, is obtained by using the data of ΔH_m^∞, H^σ and L of solid high polymer obtained in the present study. *Figure 10* shows the $\Delta H_{sol}(\text{amorph})$ vs. t_c curve for PEO and POMO which were derived by substituting experimental values of the degree of crystallinity and the lamellar thickness into equation (10). We obtained the following data: $\Delta H_{sol}(\text{amorph}) = -7.11 \pm 0.42$ and 5.46 ± 0.27 kJ/mol monomer unit for PEO and POMO, respectively.

---

* In contrast with our case Afifi-Effat and Hay[21] studied the case of low molecular weight samples and found an apparent variation of G^σ with the lamellar thickness. Booth *et al.*[22] proposed a new formula for the relation between melting point and lamellar thickness for this kind of sample.
Figure 10   Mixing enthalpies vs. crystallization temperatures.
○, POMO; ●, PEO

CONCLUSION

In the present study it has been shown that the interfacial enthalpy of PEO makes a significant contribution to the total magnitude of the enthalpy of fusion. The dependencies of the heats of solution of PEO and POMO on temperature and degree of crystallinity were determined. The mixing enthalpies of these materials were also estimated experimentally. It was found to be reasonable that the additivity of the heats of solution of the crystalline and the amorphous regions holds in derivation of the heat of solution of real high polymer solid.

Thermal degradation of poly(diethyl vinylphosphonate) and its copolymer

Norihiro Inagaki, Kiyoshi Goto and Kakuji Katsuura
Polymer Chemistry Section, Faculty of Engineering, Shizuoka University, Hamamatsu 432, Japan
(Received 15 January 1975)

Thermal degradation of poly(diethyl vinylphosphonate) and diethyl vinylphosphonate/vinyl alcohol copolymer was investigated using thermogravimetry, infra-red spectroscopy and g.c.–mass spectrometry. For poly(diethyl vinylphosphonate), little chain scission occurred and the high stability may be attributed to P—O—P crosslinkages between phsophonate units. With the diethyl vinylphosphonate/vinyl alcohol copolymer, the presence of hydroxyl groups in the polymer chains inhibited the formation of the P—O—P crosslinkages. The main degradation products from the copolymer were aldehydes having the general formula $HC(O)(CH=CH)_n-CH_3$ and methyl ketones having the formula $H_3CC(O)(CH=CH)_n-CH_3$ and $CH_3C(O)(CH=CH)_n-CH=CH_2$, where $n = 1, 2, 3$. The introduction of phosphonate unit into poly(vinyl alcohol) is less effective than that of phosphate unit in enhancement of thermal stability.

INTRODUCTION

This paper reports an investigation of the effect of phosphonate units incorporated in poly(vinyl alcohol) on its thermal degradation.

The flame-proofing effect of phosphorus-containing polymers is dependent on the constitution of the phosphorus components. For example, Sander and Steininger[1] reported that the flame resistance of polymers of unsaturated phosphonates was higher than that of unsaturated phosphates, and this was ascribed to their different thermal stabilities. However, the flame resistance of polymers containing functional groups cannot be explained solely on the basis of their thermal stabilities. Thermal reactions induced by the interaction of functional groups with phosphorus residues need to be taken into account. For example, a relationship between the flame-proofing effect of cellulose and the induced reactions have been recognized[2].

In a previous paper[3] on the action of phosphate unit in poly(vinyl alcohol) on thermal degradation, it was shown that the introduction of phosphate units accelerated dehydration and inhibited the scission of polymer chains. This inhibition was due to the formation of conjugated double bonds in the polymer chains by the *cis-β*-elimination of the phosphorus ester groups.

Simple phosphonates are well known to be more stable than phosphates[4] and the elimination of phosphonate groups to give olefins rarely occurs[5]. The comparison of the thermal degradation of poly(vinyl alcohol) containing phosphonate units with that of phosphate units is therefore of interest.

EXPERIMENTAL

Materials

Diethyl vinylphosphonate was prepared from triethyl phosphite and 1,2-dibromoethane according to the method of Kosolapoff[6]. The product was identified by i.r. and n.m.r. spectroscopy[7–9]. Vinyl acetate was purified by distillation under nitrogen atmosphere before use. Azobisisobutyronitrile (AIBN) was recrystallized from ethanol solution. Other chemicals were analytical grade commercial materials and were used without further purification.

Polymerization

The homopolymerization was carried out by heating the degassed monomer containing 0.01 mol% AIBN in a sealed glass tube at 70°C for 200 h. The polymer was dissolved in benzene and precipitated with petroleum ether. This process was repeated three times.

The copolymer of vinyl alcohol and vinylphosphonate was prepared by alkaline hydrolysis of vinyl acetate/diethyl vinylphosphonate copolymer, according to the procedure of Tsuda and Yamashita[10]. The monomer reactivity ratio for the copolymerization at 70°C was estimated to be 1.3 and 0.73 for vinyl acetate and diethyl vinylphosphonate, respectively.

Thermogravimetry

Samples (10 mg) were placed in the quartz pan provided with a Rigaku–Denki thermogravimetric analyser. All analyses were carried out in vacuum (10^{-4} mmHg) at a programmed rate of 1.5°C/min.

Analysis of degradated products

Polymers contained in a Pyrex tube connected to a liquid nitrogen trap, were pyrolysed at a prescribed temperature for 1 h in vacuum. The infra-red (i.r.) spectra of the residual products were examined as a KBr disc using a Nihon–Bunko spectrophotometer IRA-1.

The oily products condensed in the trap were analysed by g.c.–mass spectrometry using a Nihon–Denshi GC–Mass spectrometer JMS-07. A separation column (3 mm i.d. × 2 m) containing 25 wt % of poly(ethylene glycol) 4000 coated on C-22(30–60 mesh) was used. The column was heated in a temperature range from room temperature to 150°C.

RESULTS AND DISCUSSION

Thermogravimetry (t.g.)

The thermogravimetric curves (*Figure 1*) showed that the thermal degradation of poly(diethyl vinylphosphonate) proceeded in two stages: (a) in the temperature range from 220° to 250°C, with weight loss of 34.3%. This was followed by a thermally pseudo-stable stage up to 430°C; (b) in

Figure 1 T.g. curves of poly(diethyl vinylphosphonate) and its copolymer. A, poly(vinyl alcohol); B, poly(diethyl vinylphosphonate); C, copolymer I; D, copolymer II; E, copolymer III

Table 1 Sequence distributions of diethyl vinylphosphonate/vinyl alcohol copolymer

Copolymer	Vinyl-phosphonate unit (mol%)	Sequence distribution (mol%)			Threshold temperature (°C)	Residue at 450°C (%)
		A–A	A–B	B–B		
I	71.2	1	47	52	245	48.1
II	42.2	34	42	24	140	45.5
III	21.9	59	33	8	135	30.2
IV	7.16				140	22.4

the temperature range from 430° to 470°C, with weight loss of 17.7%. Compared with polyolefins such as polyethylene and polypropylene, poly(diethyl vinylphosphonate) retains high thermal stability. It is suggested that the phosphonate unit in the side-chains contributes to the higher stability.

It was previously reported that the introduction of the phosphate unit into poly(vinyl alcohol) inhibited the scission of polymer chains and that a thermally stable polymer was formed[3]. In order to elucidate this effect three kinds of vinyl alcohol [A] /diethyl vinylphosphonate [B] copolymers were used and their sequence distributions[11] calculated from monomer reactivity ratio are summarized in *Table 1*. All three copolymers have nearly equivalent amounts of A–B unit. For copolymer I, A–A unit is negligible; the amount of A–B and B–B units is equivalent. For copolymer II, three units, namely, A–A, A–B and B–B, are present. Copolymer III is rich in A–A and poor in B–B.

As shown in *Figure 1*, all copolymers were degraded at a lower temperature (135–140°C) than the corresponding homopolymer. The thermally pseudo-stable stage could not be observed except in the case of copolymer I. These results indicate that the presence of A–B units in the polymer chains accelerates the degradation and that the presence of B–B units disturbs the formation of the thermally pseudo-stable stage. The amount of residue after complete degradation (at 450°C) increased with increasing content of phosphonate unit. There is no clear correlation between the residual amount and the sequence distribution.

The thermogravimetric behaviour is different from that of phosphate-containing poly(vinyl alcohol)[3]. The introduction of phosphonate unit into poly(vinyl alcohol) is less favourable than that of phosphate unit in inhibition of chain-scission.

I.r. spectrum of residual product

Poke and Cohen[12] reported that an ethoxy group was incorporated in polymer chains when vinylphosphonates were homopolymerized in the presence of peroxide ini-

tiator. Although the homopolymerization in this work was carried out by using AIBN instead of peroxide, the polymer exhibited absorption at 1090 cm^{-1}, indicating the presence of the ethoxy group in the polymer chains.

Changes in the i.r. spectrum of poly(diethyl vinylphosphonate) on heating are shown in *Figure 2*. In the first degradation stage of the polymer, the absorption bands at 1150, 1090, 1040 and 1020 cm^{-1} attributable to P–O–C$_2$H$_5$ groups disappeared. Two new bands appeared at 1080 and 900 cm^{-1}, assigned to be P–OH and terminal vinyl groups, respectively. From the above results the following reaction mechanism is suggested.

1. Elimination of ethyl ester group

2. Chain scission at the ethoxy group incorporated in polymer chains

Figure 2 I.r. spectra of poly(diethyl vinylphosphonate) residue. A, original; B, degraded at 250°C; C, degraded at 350°C; D, degraded at 450°C; E, degraded at 530°C

Figure 3 I.r. spectra of copolymer I residue. A, original; B, degraded at 250°C; C, degraded at 300°C; D, degraded at 350°C; E, degraded at 450°C

The suggestions were supported by the pyrolysis–gas chromatographic results which showed that only ethylene was the evolved product in the first stage degradation. In the second stage the absorption band of OH groups disappeared and a new band assigned to be P–O–P groups appeared at 975 and 955 cm^{-1}. The absorption of the phosphoryl groups shifted to the lower frequency at 1120 cm^{-1}. Weak absorptions at 1700(C=O) and 1600 cm^{-1} (C=C) were observed and the strong absorption of P–C groups (at 720 cm^{-1}) remained up to 530°C where the degradation was complete. The above results show that intra- and/or inter-molecular P–O–P crosslinkage is possible.
The elimination via a five-membered ring intermediate[5] occurs infrequently, although this polymer has an available β-hydrogen atom.

The i.r. spectra of copolymers I and III on heating are shown in *Figures 3* and *4*, respectively. Since the changes of bands attributed to the poly(vinyl alcohol) part of the copolymer were identical with the results[3] reported previously only other spectral changes are discussed here. In the first degradation step all the bands attributed to P–O–C₂H₅ group disappeared and absorption bands at 1050 and 1720 cm^{-1} appeared. The former absorption was assigned to the vinyl ester group and the latter to the

carbonyl group. In the second degradation stage a small amount of P–O–P crosslinked structure was formed, especially for copolymer III. A large amount of P–OH group (at 1080 cm^{-1}) and C–OH group (at 1430 cm^{-1}) remained after the complete degradation. The conjugated double bond group (at 1600 cm^{-1}) was less intense in absorption. The comparison between poly(diethyl vinylphosphonate) and the phosphonate copolymers shows that the formation of a P–O–P crosslinking structure is inhibited by the incorporation of a vinyl alcohol unit in polymer chains and that the phosphonate copolymer is more subject to chain scission at a vinyl alcohol unit than the phosphate copolymer.

Analysis of oily product

Poly(diethyl vinylphosphonate) on pyrolysis gave only trace amounts of oily products. The main products were ethylene and water, indicating that chain scission rarely occurs.

G.c.–mass spectrometric results presented in *Table 2* for the large yield of oily products from copolymer IV, showed the presence of unsaturated carbonyl compounds. No phosphorus compounds were detected. Tsuchiya and Sumi[13] reported that the main products from poly(vinyl
Figure 4 I.r. spectra of copolymer III residue. A, original; B, degraded at 250°C; C, degraded at 320°C; D, degraded at 400°C

Table 2 Oily degradation products (wt%) on heating at 500°C. Copolymer IV, 1 g; Oily products, 154 mg

$CH_2=CHCH=CHC(O)CH_3$	18.0

alcohol) were aldehydes having the general formula $HC(O)(CH=CH)_n-CH_3$ and methyl ketones having the formula $H_3CC(O)(CH=CH)_n-CH_3$, where $n = 1, 2, 3$, etc. In addition to these carbonyl compounds, methyl ketones having the formula $CH_3C(O)(CH=CH)_n-CH=CH_2$, $n = 1, 2, 3$, were main products from the phosphonate copolymer. The comparison with the phosphate copolymer[3] reported previously shows that the introduction of phosphonate unit in polymer chain is uneffective in inhibition of chain scission.

Small angle neutron and X-ray scattering by poly(methyl methacrylate) chains

D. Y. Yoon and P. J. Flory

Department of Chemistry, Stanford University, Stanford, California 94305, USA
(Received 20 February 1975)

The intensity of radiation scattering by poly(methyl methacrylate) (PMMA) chains is computed as a function of scattering angle over the range $0 < \mu = (4\pi/\lambda) \sin (\vartheta/2) < 0.3$ Å^{-1}, on the basis of a realistic rotational isomeric state model. The scattering functions $F_x(\mu)$, corresponding to $I\mu^2$, are developed for chains of x units in terms of the even moments $\langle r_{ij}^{2p} \rangle$ of the separation distance between pairs of the monomer units i and j. Whereas the theoretical scattering function $F_x(\mu)$ for isotactic PMMA increases monotonically with μ, for predominantly syndiotactic PMMA it exhibits a maximum at $\mu \approx 0.05$ Å^{-1}. This is in agreement with experimental results on small angle neutron and X-ray scattering by PMMA (in bulk and in solution, respectively). The appearance of the maximum in $F_x(\mu)$, heretofore considered anomalous, is shown to be a direct consequence of the preference of racemic diads of PMMA for the *trans, trans* conformation and of the inequality of the skeletal bond angles at $-CH_2-$ and at the doubly substituted C^α.

INTRODUCTION

Radiation scattering by polymer chains provides a preferred method for investigating their configurations both in solution and in the bulk state. In particular, small angle scattering of neutrons has received special attention recently as a means for direct determination of configurational characteristics of polymer chains in the absence of diluent. A wealth of experimental results[1-5] gathered within the past three years demonstrates beyond question that the radii of gyration of poly(methyl methacrylate) (PMMA), polystyrene and polymethylene, in either the glassy or the amorphous states, conform within close limits to their values in dilute solution in theta solvents. The dependences of the radii of gyration on chain length confirm the adherence to ideal behaviour, without perturbation of the configuration either by interactions with neighbouring chains or by effects of excluded volume[6]. For small magnitudes of the wave vector $\mu = (4\pi/\lambda) \sin (\vartheta/2) < 0.03$ Å^{-1}, the scattering function $P(\mu)$ expressing the ratio of scattered intensity at angle ϑ to that at zero angle follows the Debye equation[7]:

$$P(\mu) = (2/\nu^2)(\nu - 1 + e^{-\nu}) \qquad (1)$$

where ν is defined according to[8]:

$$\nu = \mu^2 \langle s^2 \rangle \qquad (2)$$

$\langle s^2 \rangle$ being the mean-square radius of gyration.

The Debye equation (1) rests on two assumptions[7]: (i) that the mean-square distance $\langle r_{ij}^2 \rangle$ between units i and j is proportional to the number $t = |i - j|$ of units separating these scattering centres; and (ii) that the distribution function $W(r_{ij})$ for vector r_{ij} is Gaussian (rather, that the Fourier transform of $W(r_{ij})$ is Gaussian[7]). These assumptions hold for small values of μ where the pairs of units that contribute significantly to $P(\mu)$ are far apart in sequence along the chain. At larger scattering angles such that $\mu > \sim 0.03$ Å^{-1}, the intensity depends increasingly on correlations between units separated by shorter sequences. Conditions (i) and (ii) are not then fulfilled, and departures from the Debye equation may be expected.

The discrepancies that may be encountered upon extending the Debye equation to larger values of the scattering wave vector are demonstrated most strikingly in the results of Kirste and coworkers on the small angle neutron[1,2] and X-ray[9,10] scattering by PMMA. For both syndiotactic and atactic PMMA they observed that $I\mu^2$, where I is the scattered intensity, passes through a maximum at $\mu \approx 0.1$ Å^{-1}, instead of increasing monotonically with μ as is usually observed for most other polymers[4,5]. These unusual deviations from the Debye equation have been attributed variously to helical sequences, or to ordered regions in the case of the bulk polymers investigated by neutron scattering.

In this communication we show that the abnormalities observed in the scattering functions for PMMA are consistent with the random-coiled configurations peculiar to predominantly syndiotactic PMMA chains. The configurational characteristics of relatively short sequences within long chain molecules of the isotactic, syndiotactic, and atactic PMMA are examined, and their contributions to the scattering functions are evaluated.

SCATTERING THEORY

The scattering function for a system of independent molecules oriented at random is given with full generality by[7,11]:

$$P(\mu) = (x + 1)^{-2} \sum_{i,j} G_{ij}(\mu) \qquad (3)$$

where

$$G_{ij}(\mu) = \langle (\mu r_{ij})^{-1} \sin (\mu r_{ij}) \rangle \qquad (4)$$

and r_{ij} is the distance between the groups i and j; the angled brackets denote the statistical mechanical average over all configurations of the chain. The function $G_{ij}(\mu)$, which is the Fourier transform of the distribution function $W(r_{ij})$, may be expressed as a series in the even moments of r_{ij} in the following manner developed by Nagai[12]:

$$G_{ij}(\mu) = \exp(-\mu^2 \langle r_{ij}^2 \rangle/6)[1 + g_{2;ij}(\mu^2 \langle r_{ij}^2 \rangle/3) +$$

$$g_{4;ij}(\mu^2 \langle r_{ij}^2 \rangle/3)^2 + g_{6;ij}(\mu^2 \langle r_{ij}^2 \rangle/3)^3 \ldots] \qquad (5)$$

where

$$g_{2;ij} = 0$$

$$g_{4;ij} = -2^{-3}[1 - 3\langle r_{ij}^4 \rangle/5\langle r_{ij}^2 \rangle^2]$$

$$g_{6;ij} = -2^{-4}[(1 - 3\langle r_{ij}^4 \rangle/5\langle r_{ij}^2 \rangle^2) - \frac{1}{3}(1 - 9\langle r_{ij}^6 \rangle/35\langle r_{ij}^2 \rangle^3)]$$

$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad (6)$$

$$g_{8;ij} = -2^{-6}[(1 - 3\langle r_{ij}^4 \rangle/5\langle r_{ij}^2 \rangle^2) - \frac{2}{3}(1 - 9\langle r_{ij}^6 \rangle/35\langle r_{ij}^2 \rangle^3) + \frac{1}{6}(1 - 3\langle r_{ij}^8 \rangle/35\langle r_{ij}^2 \rangle^4)]$$

etc.[13].

In this paper we identify the scattering group with the repeating unit:

$$\begin{array}{c} CH_3 \\ | \\ -CH_2-C- \\ | \\ COOCH_3 \end{array}$$
For sufficiently long chains, it is legitimate to replace all moments $\langle r_{ij}^{2p} \rangle$ for which $|i - j| = t$ by $\langle r_t^{2p} \rangle$ without regard for the location of the sequence of t units within the chain. When 'end effects' may thus be neglected, it is preferable to use the scattering function defined as follows:

$$F_x(\mu) = (x + 1)\mu^2 P(\mu)$$

where x is the number of units in the chain. With the introduction of equations (3)–(6), this expression simplifies to:

$$F_x(\mu) = \mu^2 + 2\mu^2(x + 1)^{-1} \sum_{t=1}^{x} (x + 1 - t) \times$$

$$\exp(-\mu^2 \langle r_t^2 \rangle/6)[1 + g_{4;t}(\mu^2 \langle r_t^2 \rangle/3)^2 +$$

$$g_{6;t}(\mu^2 \langle r_t^2 \rangle/3)^3 + \ldots] \quad (7)$$

ROTATIONAL STATES AND STATISTICAL WEIGHTS

A detailed investigation of the conformational energies of PMMA diads has been reported in a recent paper[14]. The C–C bond was assigned the length $l = 1.53$ Å. The supplements of the skeletal bond angles at the CH_2 group and at the substituted carbon (C^α) were concluded to be $\theta' = 58°$ and $\theta'' = 70°$, respectively. Well-defined minima were identified at bond rotations ϕ approximating $0°$ and $120°$, the latter being measured in the sense depending on the chirality of the bond, as previously defined[15]. These two

states, *trans(t)* and *gauche(g)*, are the only ones of significance in PMMA[14]. The energy in the vicinity of the $\bar{g}$ state at $\phi = -120°$ is excessive owing to severe steric interactions involving the planar ester group[14]. Hence, the required statistical weight matrices are of order 2 × 2. They take the form[14]:

$$\mathbf{U}' = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \end{bmatrix} \qquad (8)$$

$$\mathbf{U}''_m = \begin{bmatrix} 1 \\ \alpha \end{bmatrix} \begin{bmatrix} \alpha \\ \alpha^2/\beta \end{bmatrix} \qquad (9)$$

$$\mathbf{U}''_r = \begin{bmatrix} \beta \\ \alpha \end{bmatrix} \begin{bmatrix} \alpha \\ \alpha^2/\beta \end{bmatrix} \qquad (10)$$

for the pair of bonds flanking C^α, for the pair of bonds of a meso diad, and for those of a racemic diad, respectively. Rotational states are indexed in the order t, g on rows and columns of these matrices. Adjustment of the statistical weights calculated from the conformational energies as required to achieve reasonable agreement with experimental measurements of chain dimensions yields[14]:

$$\alpha = 1.6 \exp(-1100/RT)$$

$$\beta = 1.4 \exp(600/RT) \qquad\qquad (11)$$

NUMERICAL CALCULATIONS

The disubstituted carbon atom C^α was treated as the point scatterer representing the repeating unit in the calculations presented in this communication. (Calculations carried out using more realistic approximations offering refinements for larger values of μ will be presented in a paper now in preparation[16].) Accordingly, r_t was measured from the C^α of the first unit to the C^α of the tth unit of the sequence. The even moments $\langle r_t^{2p} \rangle$ with $p = 1, 2, 3$ and 4 were computed for chains of t units centred within a longer chain of $100 + t + 100$ units; i.e., terminal sequences of 100 units were appended at each end of the t-unit sequence to which r_t refers. The calculations were carried out using matrix generation methods[7,17]. The range $t = 2$ to 200 was covered by direct calculation for all of the moments with $p = 1$ to 4 for the stereoregular isotactic and syndiotactic PMMA chains. The calculations refer to the unperturbed state, usually denoted by a subscript 0, which is here omitted for simplicity.

Values of the ratios $\langle r_t^4 \rangle/\langle r_t^2 \rangle^2$, $\langle r_t^6 \rangle/\langle r_t^2 \rangle^3$ and $\langle r_t^8 \rangle/\langle r_t^2 \rangle^4$ required for the evaluation of $g_{2;t}$, etc., reflect characteristics of the distribution function $W(\mathbf{r}_t)$. They reach limiting values of $5/3$, $35/9$ and $35/3$, respectively, as t increases indefinitely, these being the values for a Gaussian distribution of the vector $\mathbf{r}_t$. These ratios for $200 < t < \infty$ are readily evaluated with high accuracy by extrapolation from the calculations for $t \leqslant 200$.

Calculations were carried out also for 'atactic' PMMA chains in which the average fraction w_m of meso diads is 0.20. This composition corresponds approximately to PMMA prepared in the conventional manner using a free radical initiator at elevated temperatures[18]. Chains were generated by Monte Carlo methods, the distribution of meso and racemic diads being Bernoullian. The sequence of t

units was embedded between terminal sequences of 100 'atactic' units each, in the same manner as for the stereoregular chains.

Evaluation of $\langle r_t^6 \rangle$ and $\langle r_t^8 \rangle$ by the Monte Carlo methods necessary for generation of atactic chains would require excessive computing time. Accordingly, we have employed the 'equivalent freely jointed' model chain as a basis for estimating their higher moments[†]. For the model chain composed of n^* freely jointed bonds[7],

$$\langle r^4 \rangle / \langle r^2 \rangle^2 = \frac{5}{3} - \frac{2}{3n^*} \qquad (12)$$

$$\langle r^6 \rangle / \langle r^2 \rangle^3 = \frac{35}{9} - \frac{14}{3n^*} + \frac{16}{9n^{*2}} \qquad (13)$$

$$\langle r^8 \rangle / \langle r^2 \rangle^4 = \frac{35}{3} - \frac{28}{n^*} + \frac{404}{15n^{*2}} - \frac{48}{5n^{*3}} \qquad (14)$$

From the given value of $\langle r_t^4 \rangle / \langle r_t^2 \rangle^2$ for the atactic chain of t monomer units, the number of equivalent freely jointed bonds, n^*, is obtained from equation (12). Then $\langle r_t^6 \rangle / \langle r_t^2 \rangle^3$ and $\langle r_t^8 \rangle / \langle r_t^2 \rangle^4$ are evaluated by inserting n^* into equations (13) and (14).

The validity of this approximate method was tested by comparing the exact calculations for isotactic and syndiotactic chains with the values of $\langle r_t^6 \rangle / \langle r_t^2 \rangle^3$ and $\langle r_t^8 \rangle / \langle r_t^2 \rangle^4$ obtained from equations (12)–(14). Agreement is within 15%. Although the indirect method is subject to some inaccuracy, it nevertheless affords a practicable approximation.

RESULTS

In *Figure 1* the characteristic ratio $C_n = \langle r_t^2 \rangle / 2tl^2$, where $n = 2t$ denotes the number of bonds, is plotted against $1/t$ for isotactic, syndiotactic and atactic PMMA. The passage of C_n through a maximum at $t \approx 15$ for the syndiotactic and atactic PMMA is the most striking result of these calculations. It is in marked contrast to the behaviour of C_n for most other polymers[7] and for isotactic PMMA as well.

[†] The present method resembles superficially the one applied recently to the moments of polymethylene chains[19]. The method of ref 19 differs, however, in taking account of the persistance vector and in the normalization transformation applied to render the distribution spherically symmetric.
Figure 1 Characteristic ratio, $C_n = \langle r_t^2 \rangle / 2tl^2$, for PMMA sequences of t repeating units situated within a very long chain plotted against $1/t$. ——, a-PMMA; —·—·—, s-PMMA; ————, i-PMMA
Figure 2 Scattering function, $F_x(\mu)$ plotted against μ for PMMA chains consisting of $x = 1000$ monomer units. Calculations were carried out according to equation (7) truncated at g_8. ——, a-PMMA; —·—·—, s-PMMA; ————, i-PMMA

This unusual variation of C_n with chain length arises from the inequality of the two skeletal bond angles in PMMA ($\theta'' = 70°$, $\theta' = 58°$) in conjunction with the predominance of the $|tt|$ conformation for racemic diads. The energy of $|tt|$ state for this diad is lower than that of $|gt|$ by 1700 cal/mol; for the meso diad this difference is 1100 cal/mol. The average length of sequences over which $|tt|$ states are perpetuated, as calculated according to well established methods[7], is about nine units for syndiotactic PMMA. For isotactic PMMA it is only about three units.

The scattering functions $F_x(\mu)$ obtained from equation (7) are presented in *Figure 2* over the range $0 < \mu < 0.3$ Å^{-1} for PMMA chains of 1000 monomer units. The series expansion of $F_x(\mu)$ was truncated at g_8. As stated above, values of $\langle r_t^2 \rangle$, $\langle r_t^4 \rangle / \langle r_t^2 \rangle^2$, etc. for $t > 200$ were obtained by extrapolation. It is to be noted that $F_x(\mu)$ is equivalent to the quantity $I\mu^2$ frequently plotted as a function of μ in the presentation of experimental results.

The scattering function $F_x(\mu)$ for isotactic PMMA increases monotonically with μ, rapidly at first and then more slowly as μ increases further. For syndiotactic and atactic PMMA, however, $F_x(\mu)$ passes through a maximum at $\mu \approx 0.05$ Å^{-1} and a minimum at $\mu \approx 0.18$ Å^{-1}. The maximum in $F_x(\mu)$ is directly related to the maximum observed in the characteristic ratio shown in *Figure 1*. This connection follows from the fact that the variation of $\langle r_t^2 \rangle$ with t is a major factor in determining $F_x(\mu)$ [see equation (7)].

These features of the variation of $F_x(\mu)$, or $I\mu^2$, with μ and their dependence on the stereochemical configuration of PMMA are in satisfactory qualitative agreement with the experimental results of small angle neutron and X-ray scattering as reported by Kirste *et al.*[1,2,9,10], as will be apparent from comparison of *Figure 3* with *Figure 2*. However, the agreement is by no means quantitative[†]. Improvement in

---

[†] Neither acetone nor benzene is a theta solvent for PMMA. Hence, in these solvents, the configurations of the chains are perturbed by excluded volume effects. These effects should be small in the range of main interest here, i.e., for $\mu > 0.03$ Å^{-1}, where the principal contributions come from sequences much shorter than the molecular chain length $x \approx 1000$.
Figure 3 Experimental results on the relative values of $I\mu^2$ plotted against μ^2: ——, neutron scattering by a-PMMA in the bulk ($w_m = 0.2$, $M_w = 250\,000$); ——-, X-ray scattering by s-PMMA in acetone (independent of M_w for $M_w > 10\,000$; ————, X-ray scattering by i-PMMA in benzene ($M_w = 275\,000$)

this regard appears to require refinement of the present treatment in two respects as follows: (i) the series expansion of $F_x(\mu)$ in equation (7) is not satisfactorily convergent when truncated at g_8. Terms of higher order g_{10}, g_{12}, etc. are required for $\mu > 0.05$; (ii) the representation of the monomer unit as a point scatterer located at the C^α atom is subject to error for larger value of μ, i.e., for $\mu > 0.2$. This is especially important in small angle neutron scattering by the deuterated polymer in a protonated host. The locus of the scattering is situated at the CD_3 groups;

these groups are separated from the C^α atom by appreciable distances.

Improvement of the present theoretical calculations through measures designed to overcome those inadequacies are in progress. Results of the newer calculations together with similar computations on other polymers will be published in the near future.

Heat capacity of linear high polymers

K. C. Wong, F. C. Chen and C. L. Choy
Department of Physics, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong
(Received 18 November 1974; revised 14 January 1975)

The molar heat capacity of a 45:55% copolymer of ethylene and tetrafluoroethylene has been measured from 80 to 340 K by the use of an adiabatic calorimeter, to an accuracy of 0.3%. The results are found to be in close agreement with values calculated from the known optical lines of related polymers and the Tarasov model; they are also analysed together with the available data on polyethylene and four other fluoropolymers, showing that the principle of additivity for heat capacities is generally valid to within 2%. The logical relations between these two phenomenological frameworks and their resultant implication on the effective one-dimensional force constant of the carbon backbone are discussed at some length.

INTRODUCTION

Two fairly successful phenomenological frameworks are at present available for analysing the heat capacities of linear high polymers. The temperature dependence of the heat capacity can be understood in the Tarasov model[1], which treats the acoustical modes of a polymer like those of a one-dimensional continuum superimposed on a three-dimensional continuum. The relation among different polymers, on the other hand, roughly obeys the principle of additivity proposed by Wunderlich and Jones[2], who found that the heat capacity of a particular polymer in the temperature range from 60 K up to the glass-transition point is approximately the linear combination of the contributions from its various segments.

It is mainly for the sake of the further verification of these two frameworks that we measured the heat capacity of a 45:55% copolymer of ethylene and tetrafluoroethylene (TFE), in the range 80 to 340 K. The results obtained turned out to be in good agreement with both frameworks: in the temperature range 80–200 K the acoustical contribution predicted by the Tarasov model together with the optical contribution are in close agreement with experimental data, even though above 200 K a definite discrepancy similar to those observed in previous works[3–6] appears between the two. As for the principle of additivity, the straightforward superposition of the observed heat capacities of polyethylene (PE)[7] and polytetrafluoroethylene (PTFE)[8] in 45:55% proportions is also found to fit the data extremely well up to the first-order transition point of PTFE at 270 K. This analysis can be extended to include the recently available data[5] on three other fluoropolymers: poly(vinyl fluoride) (PVF), poly(vinylidene fluoride) (PVF$_2$) and polytrifluoroethylene (PVF$_3$). Only three distinct 'segments' CH$_2$, CHF and CF$_2$ are involved in the six polymers named, and their values can be easily deduced by least-squares fit to the data. The linear combinations of these 'segmental' heat capacities again agree with all the data throughout the appropriate temperature ranges, bearing out the basic validity of the principle of additivity.

While the general agreement of these two models with our result is gratifying, it also raises a question: what are the logical and physical connections between these two models, if any? We are only able to give partial and tentative answers to this question, mainly because neither model is sufficiently refined and rigorous to allow a meaningful detailed analysis.

EXPERIMENTAL

The TFE sample used in this experiment was kindly provided by Dr M. Ragazzini of Montecatini Edison, SpA at Milan, and reported to contain 55 mol% of tetrafluoroethylene. This copolymer is known[9–11] to have a high melting temperature (516–545 K), and to be highly alternating between the two monomers, the degree of alternation generally exceeding 90% for the case of equimolar composition such as ours.

The sample stock came in the form of fine powder, 52 g of which were used without further preparation in an adiabatic calorimeter. The measurement of heat capacity at constant pressure, C_p, was made in the temperature range 80–340 K, to an accuracy of about 0.3%. Since experimental details have already been reported in previous papers[4,5], they will not be repeated here.

RESULTS AND DISCUSSIONS

The smoothed data of our measurements on the molar heat capacity C_p of TFE at constant pressure are given in *Table 1* and shown in *Figure 1*. We define a repeat unit of the copolymer as consisting of two chain atoms, so that the corresponding effective molecular weight is the sum of the atomic weights of two carbon atoms, 45% of two hydrogen atoms and 55% of two fluorine atoms, that is, 67.64.

Comparison with the Tarasov model

The analysis of our results in the framework of the Tarasov model[1] closely parallels several previous works of the same nature[4,5,7], the notations and basic assumptions of which are adopted below without detailed explanations. Since no spectroscopic data on TFE are available, the optical contributions to the heat capacity at constant volume C_v is estimated by a linear combination of the optical contributions calculated from the known spectral lines of PE[12] and PTFE[13], with weight factors 0.45 and 0.55, respectively. For each of these two polymer segments there are seven optical lines, including the stretching mode of the carbon chain, making a total of 14 lines. The acoustical contribution is calculated from the well-known Tarasov function[1]. For convenience in computation, we have used a polynomial (and, for large argument, another closed analytical form) to approximate this function to within 0.05% (Appendix A). As in refs 4, 5 and 7, only four acoustical modes with identical characteristic parameters

θ_1 and θ_3 are assigned to each repeat unit, because the two stretching modes have already been included in the optical contribution. Furthermore, in our temperature range the Tarasov function is practically independent of the parameter θ_3, so it is set arbitrarily at 100 K, about midway between the values for PE (147 K) and PTFE (58 K). It was then found that the optimum value for the variable parameter θ_1 is 360 K, for which the sum of the optical and the acoustical contributions fit the experimental data to within 2% from 90 to 200 K (Curves I, II and III of *Figure 1*).

As in previous calculations[4,5,7], the prediction falls below the data at higher temperatures, and naturally we ascribe the discrepancy to the difference between C_p and C_v. While the correction term $C_p - C_v$ does explain similar discrepancies quite satisfactorily in the cases of PVF and PCTFE[6] and, to a lesser extent, in that of PE[3], its effect on our data is not so clear. We evaluate $C_p - C_v$ by the well-known formula $\beta^2 VT/K$, where the expansivity β, molar volume V and isothermal compressibility K can all be estimated from the available data[14] on the specific volume v of TFE gathered by static measurements at different temperatures and pressures. Unfortunately, this term overcompensates for the discrepancy and seems to have too small a temperature dependence (*Figure 1*), which, however, may only be due to the experimental error in v.

The principle of additivity

The principle of additivity[2] can be applied to our data in a particularly simple manner: the linear combination of the

heat capacity data of PE[7] and PTFE[8] available in the literature with the respective coefficients 0.45 and 0.55 should match the TFE data. As shown by the broken curve in *Figure 1*, there is indeed close agreement (<2%) between the two up to 270 K, at which point the transition effect of PTFE begins to set in, and additivity is no longer valid. The relatively poor agreement at below 100 K is probably due to experimental uncertainty.

However, we can subject the principle of additivity to a much more stringent test by analysing our results together with the data on PE[7], PTFE[8], and the recently available data on the following series of fluoropolymers: PVF, PVF$_2$, PVF$_3$[5] and PCTFE[4]. Only three distinct segments CH$_2$, CHF and CF$_2$ are involved in the first six polymers, and one extra segment CFCl is involved in PCTFE. Additivity amounts to the following seven approximate equations:

$$PE \simeq 2x \tag{1}$$

$$PTFE \simeq 2y \tag{2}$$

$$TFE \simeq 0.9x + 1.1y \tag{3}$$

$$PVF \simeq x + z \tag{4}$$

$$PVF_2 \simeq x + y \tag{5}$$

$$PVF_3 \simeq y + z \tag{6}$$

$$\text{PCTFE} \simeq y + w \qquad (7)$$

where the left-hand sides refer to the heat capacities of the respective polymers named, and x, y, z and w on the right-hand sides refer to the additive contributions of the CH_2. CF_2, CHF and CFCl segments, respectively.

The segmental contributions x, y and z can be determined by least-squares fit to the six heat capacities on the left of equations (1)–(6) at each temperature. and w is then obtained directly from equation (7) (*Table 2*). Values of the first six heat capacities predicted from the segmental values so determined are shown in *Figure 2*, where it is seen that there is very close agreement between calculation and data for PE, TFE, PVF and PVF_3 up to 350 K and for PVF_2 and PTFE up to their respective transition points at 220 and 260 K. As a matter of fact, if we disregard points above these two transition points then the fit is better than 2% for all six polymers from 80 to 340 K except for a few points near 80 K, and the average error for all 142 points is less than 1%. The success of such a three-parameter fit to six independently observed quantities is a clear indication of the validity of the principle of additivity, and gives us confidence that the segmental values tabulated in *Table 2* should be a reliable basis for predicting heat capacities of other related polymers.

Additivity may in fact be valid above or around the glass-transition point provided the associated jump in C_p is small or diffused. Such seems to be the case for PE (*Figure 2*), which probably has a crystallinity-dependent double glass-transition between 190 and 280 K [15-17], and possibly also for PTFE (*Figure 2*), which may have a 'lower' glass-transition at 223 K [16]. Similarly contributions to C_p

[a] Heat capacities in this column are obtained by subtracting values of the CF_2 segment from the observed values of PCTFE
[b] Values of segmental heat capacities below 230 K are obtained by least squares fit to the observed values of PE, PTFE, TFE, PVF, PVF_2 and PVF_3. At 230 K and above the observed values of PVF_2 are not used in the fit
[c] At 270 K and above the values of PTFE are not used in the fit
Figure 2 Heat capacities of PE and five fluoropolymers vs. temperature. Solid lines are obtained from appropriate linear combinations of the fitted segmental contributions. Observed data points: ■, PE; □, PVF; ▼, TFE; ○, PVF_2; ●, PVF_3; △, PTFE. T_d. transition points. The scale for TFE has been shifted

arising from possible subglass transitions at low temperature are usually limited to only a few per cent and, what is more important, are rather featureless as well[17], so that they are not expected to affect the Tarasov model (except perhaps the numerical value of θ_1) or the principle of additivity in any significant manner.

Connection between the Tarasov model and additivity

Since both the Tarasov model and the principle of additivity are in good agreement with data, at least for the series of fluoropolymers being studied, it is natural to ask whether any relation can be established between these two models, or, in other words, whether one model can be derived from the other. We limit our attention to the region in which additivity is expected to be valid, that is from about 60 K up to the transition point of any particular polymer.

The Tarasov model consists of two terms, of which the optical contribution is clearly additive in the sense of equations (1)–(7) on physical grounds. This is precisely the principle one makes use of in estimating the optical contribution where direct spectroscopic data are not available. If the total contribution to C_v is additive as postulated then clearly the second term, i.e. the acoustical contribution, must also be additive. In a particularly simple case such as TFE this means, for an entire range of temperature T,

$$D_1\left(\frac{\theta_C}{T}\right) = \alpha D_1\left(\frac{\theta_A}{T}\right) + \beta D_1\left(\frac{\theta_B}{T}\right) \quad (\alpha + \beta = 1) \qquad (8)$$

where θ_A, θ_B and θ_C refer to the θ_1-values of PE, PTFE and TFE, respectively; α and β refer to the molar fractions of PE and PTFE, respectively; and we have approximated the

Tarasov function by $D_1(\theta_1/T)$ in the region where additivity is valid, i.e., above 60 K.

Mathematically equation (8) puts a constraint on the permissible form of $D_1(x)$; it can be shown (Appendix B) that, contrary to the known analytic form of $D_1(x)$, this equation implies it must have either one of the following forms:

$$r + sx^p$$

or

$$r + s\ln x \qquad (9)$$

where $x = \theta/T$ and r, s and p are constants. However, this contradiction is not disastrous, since, after all, equation (8) is but an approximate relation correct to, say, 3 or 5%. One can actually approximate the known form of $D_1(x)$ to within 2% by the simple linear form:

$$D_1(x) \simeq 1.06551 - 0.08846x \qquad (10)$$

in the interval $0.5 \leqslant x \leqslant 7$, which already covers all the T and θ_1 ranges of interest (*Figure 3*). It is therefore possible to reconcile D_1 with equation (8) by choosing $p = 1$ in the first form of equation (9). ($p = 0.9$ gives an even bet-
Figure 3 $NRD_1(\theta_1/T)$ vs. T, showing the approximate additivity of acoustical contributions as given by D_1. I, $\theta_1 = 515$ K, $N = 2$; II, $\theta_1 = 260$ K, $N = 2$; III, $\theta_1 = 0.45$ (515 K) + 0.55 (260 K) = 374.75 K, $N = 4$. ——, Exact D_1; ----, corresponding approximations linear in x; · · · ·, sum of I and II (solid lines), with weight factors 0.9 and 1.1, respectively. Note that, by construction, broken line III is an exact sum of dashed lines I and II, with weight factors 0.9 and 1.1, respectively

Table 3 Additivity of θ_1

| Polymer | θ_1 (K) | | |
	Fitted values[a]	Calculated[b,c] values	Deviation (%)
PE	515	503	−2.4
PVF	430	432	+0.5
PVF$_2$	357	377	+5.0
TFE	360	364	+1.0
PVF$_3$	308	306	−0.7
PTFE	260	250	−4.0

[a] Obtained by direct fittings of the Tarasov model to the experimental heat capacities. The values for PE and PTFE are obtained by our own fitting of the published data[7,8] and differ slightly from the corresponding published values[7,18]; the rest are taken from refs 4 and 5
[b] A least-squares fit yields the segmental values $\theta_x = 251.5$ K, $\theta_y = 125.0$ K and $\theta_z = 180.5$ K, from which the θ_1 values in this column are calculated through equations (1)−(6)
[c] From equation (7) and θ_1 (PCTFE) = 235 K one can also deduce the segmental value $\theta_w = 110$ K for the CFCl segment

ter fit, but $p = 1$ is more convenient.)

So in the region where the difference between C_p and C_v is negligible[4,5,7] (60 K $< T <$ 200 K) the principle of additivity as applied to C_p can be understood as a consequence of the separate additivity of the optical and the acoustical contributions, the latter being approximately valid by virtue of the mathematical form of $D_1(x)$.

But from 200 K up the difference $C_p - C_v$ becomes appreciable. Rewriting this term in the form $(\beta^2 v/K)MT$, where M is the molecular weight and other symbols bear the same meanings as before, we see that it would also be roughly additive if the factor $\beta^2 v/K$ is approximately the same for different polymers. Using the specific volume data available in the literature[14], this factor is estimated to vary by about ±20% at 300 K for the six polymers we have studied. Since $C_p - C_v$ accounts for no more than 15−20% of the total heat capacity, the variation in $\beta^2 v/K$ would introduce at most 3−4% error in the additivity of C_p, which thus can again be understood as a consequence of the rough additivity of its individual components. Nevertheless, it is still quite surprising that C_p is additive to within 2%, whereas the individual components are expected to be additive to within 2−4% only. Whether this is merely due to fortuitous circumstances, or deeper reasons are involved, we cannot say.

Connection between θ_1, the mass, and the force constant

A simple and immediate consequence of equation (10) and the additivity of C_p is that the one-dimensional Debye temperature θ_1 should also be additive. In other words, we can replace the heat capacities on the left of equations (1)−(6) by the corresponding experimentally determined θ_1 values of the respective polymers, carry out a least-squares fit to determine the three 'segmental' θ_1 values: $\theta_x, \theta_y, \theta_z$, and then calculate a set of predicted θ_1. The results are given in *Table 3*, where we see that the agreement between data and prediction is fair (<5%), especially in view of the fact that several successive approximations are involved in this prediction and $D_1(x)$ is not really very sensitive to θ_1.

It remains for us to point out that such a linear relation among the various θ_1 is inconsistent with the general impression[4,5,7] that the effective one-dimensional force constant k_1 of the carbon chain is the same throughout the series of polymers we study. By definition k_1 is propor-

tional to $M\theta_1^2$, M being the molecular weight of a repeat unit. Since M is additive the constancy of k_1 would imply that $1/\theta_1^2$ is also additive, or according to equation (9) that D_1 could be approximated by the form $r + s/x^2$. Unfortunately such an approximation involves on the average a 20% error and is clearly much inferior to the linear approximation. It does not seem to us that this inconsistency can be resolved within the phenomenological frameworks we are working in, since a 2–3% approximation is involved in each logical step, and any deduction involving several steps is always expected to have 5–10% uncertainty.

CONCLUSION

From the foregoing analysis it is clear that the Tarasov model and the principle of additivity are both valid and consistent with each other to within the degree of precision usually expected (about 2%), even though the surprisingly close fit of the predictions of additivity in regions where $C_p - C_v$ is appreciable certainly needs further clarification. Similarly, it remains to be seen whether the Tarasov model is also generally valid at higher temperatures after the $C_p - C_v$ correction is made, preferably by using the more accurately determinable ultrasonic data. On the other hand, it may not be meaningful to ask whether the effective one-dimensional force constant k_1 is indeed the same for different polymers, unless a reasonable and unambiguous definition of 'equality' can first be agreed upon. In any case, one should now be able to apply these two frameworks to other polymers and copolymers with increased confidence, and it would be interesting to see, for instance, whether other polymer series with different backbones are equally amenable to this line of investigation.

APPENDIX A

For computational purposes it is much more convenient to approximate the one- and three-dimensional Debye functions $D_1(x)$ and $D_3(x)$ by close analytical forms rather than relying on the defining integrals or tabulated values. The following approximations are good to within 0.05% of the published tabulations[7], and should suffice for most practical purposes.

$$D_n(x) \equiv \frac{n}{x^n} \int_0^x \frac{y^{n+1} e^y}{(e^y - 1)^2} dy \qquad n = 1, 2, 3, \ldots \quad (A1)$$

$$D_1(x) \simeq \sum_{n=0}^{5} a_n x^n \qquad 0 \leqslant x \leqslant 7$$

$$\simeq [A - (x^2 + 2x + 2)e^{-x}]/x, \ 7 < x \qquad (A2)$$

where $A = 3.28987$, $a_0 = 0.99980522$, $a_1 = 0.00387191$, $a_2 = -0.03452752$, $a_3 = 0.00394121$, $a_4 = 0.00000410$, $a_5 = -0.00001401$.

$$D_3(x) \simeq \sum_{n=0}^{6} b_n x^n \qquad 0 \leqslant x \leqslant 6.2$$

$$\simeq 3[B - (x^4 + 4x^3 + 12x^2 + 24x + 24)e^{-x}]/x^3$$

$$6.2 < x \qquad (A3)$$

where $B = 25.97576$, $b_0 = 0.99993481$, $b_1 = 0.00122983$, $b_2 = -0.05209779$, $b_3 = 0.00074816$, $b_4 = 0.00218456$, $b_5 = -0.00032884$, $b_6 = 0.00001496$

APPENDIX B

Let us define $\theta_A/T = x$, $\theta_B/\theta_A = \lambda$, $\theta_C/\theta_A = \eta$ and specialize to the case $\alpha = \beta = 1/2$. Then equation (10) can be written as

$$f(\eta x) = 1/2 [f(x) + f(\lambda x)] \qquad (B1)$$

where η is a function of λ, but not x, and D_1 has been replaced by a general function f. We now look for the most general f consistent with this equation.

Let $e^v = x$, $e^g = \eta$, $e^y = \lambda$ and $F(v) = f(x) = f(e^v)$, so that equation (B1) takes on the form

$$F(v + g) = 1/2 [F(v) + F(v + y)] \qquad (B2)$$

where $g = g(y)$. If we make a Taylor's expansion of F at v and also of g at $y = 0$, and equate the coefficients of powers of y, then with the reasonable assumption $g(0) = 0$ we obtain for the first two powers $g'(0) = 1/2$ and $F''(v) = 4g''(0)F'(v)$. If $g''(0) \neq 0$ then the latter equation leads to $F = C_1 \exp(4g''(0)v) + C_2$, or the form $f = C_1 x^p + C_2$. If $g''(0) = 0$ then one obtains $F = C_1 v + C_2$ or $f = C_1 \ln x + C_2$. Clearly all functions satisfying equation (B1) necessarily belong to one of these two forms. Since it is easy to verify that these functions do indeed satisfy equation (B1), they must be the only solutions of that equation, and the proof is complete. Extension of the proof to other values of α along the same lines is trivial.

An anionically prepared flexible adhesive: 1: Synthesis

A. V. Cunliffe, M. B. Huglin*, P. J. Pearce and D. H. Richards

*Explosives Research and Development Establishment, Ministry of Defence, Waltham Abbey, Essex EN9 1BP, UK*
(Received 6 February 1975)

A method is described whereby epoxides based on a diglycidyl ether of bisphenol A (DGEBA) may be flexibilized by reaction with dienes such as butadiene or isoprene (M). The process requires the reaction of a tetrahydrofuran solution of DGEBA and diene with excess alkali metal, and the initial step is that of formation of diene dianion which homopropagates until terminated by DGEBA. The isolated product consists of a mixture of unreacted DGEBA and modified DGEBA. Preliminary tests indicate that this mixture exhibits adhesive properties superior to that of the original epoxide.

INTRODUCTION

Epoxy resins have a wide and increasing use in industry owing to their unique combination of properties. They and their curing agents are generally liquids which are easily processable and systems may be selected which will effect cures at temperatures ranging from ambient to 200°C. The absence of volatile by-products and low shrinkage during cure results in good moulding characteristics, and the minimization of internal stresses gives the thermoset excellent mechanical properties. Further, the cured resins possess good electrical insulation and outstanding chemical resistance, and they have high adhesive strengths due mainly to the generation of polar hydroxyl groups during cure. It is this last property which is the subject of this series of papers.

By far the most commonly used epoxy resins are those derived from bisphenol A by reaction with epichlorhydrin. The simplest diepoxide formed in this process is the diglycidyl ether (I):

(I)
and the work to be described involves the flexibilization of commercial resins such as Araldite MY 750 or Epikote 828 in which this compound predominates. Although these materials are used as adhesives, they suffer from a lack of flexibility, and hence reduced shear strength and low peel, when cured with conventional 'small molecule' reagents. The epoxide contents of the resins are high and curing leads to a densely crosslinked structure so that this, plus the presence of rigid aromatic groups in the chain, results in severe restriction of segmental motion and thus to low flexibility. Improvements in flexibility can be obtained by incorporating long chain aliphatic compounds into the resin before cure; these may either remain unreacted during cure when they act as plasticizers, or they may be linked

chemically into the system by the cure process when they may be described as flexibilizers.

An alternative but hitherto relatively unexplored approach is to devise reactions which will modify the epoxide resin itself such that the product, whilst remaining a diepoxide, will be more flexible, and accordingly will, hopefully, exhibit shear strengths superior to the original material on curing with conventional reagents. It seemed that techniques which we had been developing to synthesize novel anionic condensation copolymers[1,2] could be adapted to prepare such flexibilized adhesives. These methods are modifications of the 'living' polymer systems developed by Szwarc *et al.* in which a suitable monomer (M), such as styrene, butadiene, isoprene etc., is reacted in tetrahydrofuran (THF) with alkali metal in the presence of a linking agent. Alkyl dihalides (RX$_2$) constitute a class of linking agents which were extensively examined and shown to react in a manner illustrated by the following reaction sequence:

$$2M + 2Na \rightarrow Na^{+-}M_2^-Na^+ \quad (1)$$

$$Na^{+-}M_2^-Na^+ + (n-2)M \rightarrow Na^{+-}M_n^-Na^+ \quad (2)$$

$$Na^{+-}M_n^-Na^+ + RX_2 \rightarrow [-M_n-R-] + 2NaX \quad (3)$$
The initial step is a surface reaction with the alkali metal to form a dimer dianion which then diffuses away, reacting with more monomer until the carbanionic ends are terminated by a metathetical reaction with the dihalide to form a copolymer. It has been shown by n.m.r. spectroscopy[2] and by model compound synthesis[3] (using the equivalent monohalide HRX) that when the molar ratio of monomer to dihalide is 2:1, a regular copolymer is formed where greater than 90% of the repeat units have $n = 2$.

Difunctional epoxides constitute another class of compounds which react with vinyl and diene monomers in an analogous way. Both diepoxides and halo-epoxides have yielded polyalcohols under these conditions[4]. It is well known that the epoxide group is subject to additive nucleophilic attack at the α-carbon atom[5,6], and so the generation of oligomeric dianions *in situ* results in the formation of alcoholate groups along the growing polymer chain, viz:

---

* Department of Chemistry and Applied Chemistry, University of Salford, Salford, M5 4WT, UK.

$$Na^+ \ ^-M_n \ Na^+ + CH_2—CH—R—CH—CH_2 \ \xrightarrow{H^+}$$

$$\left[\ —M_n—CH_2—\underset{\overset{|}{OH}}{CH}—R—\underset{\overset{|}{OH}}{CH}—CH_2— \ \right] \quad (4)$$
Thus, if these reactions were carried out in the presence of an excess amount of diepoxide, modified diepoxides (II) should be produced which possess a central oligomeric unit as shown in equation (5):

$$Na^+ \ ^-M_n \ Na^+ + \underset{(excess)}{CH_2—CH—R—CH—CH_2} \ \xrightarrow{H^+}$$

$$CH_2—CH—R—\underset{\overset{|}{OH}}{CH}—CH_2—M_n—CH_2—\underset{\overset{|}{OH}}{CH}—R—CH—CH_2 \quad (5)$$

$$(II)$$
Thus, by using diene as monomer, the rubbery central block should result in a significant flexibilization of the resin whilst retaining epoxide groups which would have a reactivity to curing agents very similar to that of the parent material.

This paper describes the synthesis and preliminary evaluation of such a material. Part 2[7] deals with a more detailed study of the effect of reaction variables on the structure of the product, and Part 3[8] describes tests carried out to evaluate the adhesive properties of a selected flexibilized epoxide as compared with those of the unmodified starting material. The whole process is the subject of a patent application[9].
Figure 1 'Spiked' flask used in the synthesis

EXPERIMENTAL

Materials

15 mm diameter sodium pellets (BDH Ltd) were washed with low boiling petroleum ether under a blanket of dry nitrogen, extruded into wire or cut into thin slices.

Tetrahydrofuran (THF) was first dried over molecular sieves and then treated, under dry nitrogen, with a solution of sodium naphthalene in THF until a permanent green colour characteristic of the complex remained to indicate complete drying. The solvent was subsequently distilled, stored over fresh sodium wire and used within two days.

The diepoxide was a diglycidyl ether of bisphenol A (DGEBA) supplied as either MY750 (Ciba—Geigy) or Epikote 828 (Shell) and used without further purification. These two materials were found to be of very similar composition and were used indiscriminately.

Butadiene was collected by condensation from a cylinder into a graduated container after passage through molecular sieves. Isoprene was used freshly distilled from powdered calcium hydride.

Apparatus

Gas—liquid chromatography (g.l.c.) was performed with the aid of a Pye series 104 chromatograph. 7 ft columns were used with Chromosorb 80/100 mesh support coated with 2½% OV17 silicone oil. Separations were effected using a temperature programme in the range 100 to 300°C at 8°C/min.

N.m.r. spectra were recorded on a Jeol PS-100 100 MHz spectrometer using approximately 10% solutions in deuterochloroform with tetramethylsilane as internal standard. Details of the analytical procedures employed are fully described in Part 2[7].

Mild steel lap joints, which had been prepared in a manner described in Part 3[8], were tested with a Monsanto Type E tensometer. Loading was applied at a constant crosshead speed of 0.2 in/min and continued until failure occurred.

Synthetic method

Conventional laboratory scale glass apparatus was used for the synthesis, with one important exception. Because of the problem of gel formation (see below) which initially appeared on the surface of the sodium metal, thereby causing the reaction rate to decline and eventually to cease, it was necessary to devise methods to overcome this difficulty. Two approaches were considered: first, the reaction flask was filled to about 50% capacity with glass beads of 6 mm diameter before introduction of the reagents. The beads had a 'ball mill' effect when agitated with a powerful stirrer, and caused a constant abrading of the metal surface. Despite the success of this method it had several drawbacks. The relatively large amount of beads required for optimum gel removal resulted in a considerable diminution of the available reaction volume. Furthermore, constant stirring rates were difficult to achieve and the risk of flask breakage was a potential fire hazard.

The second method involved modifying the glass reaction flask by forming a series of indentations projecting inwardly as spikes (*Figure 1*). When the reactants were stirred, the sodium slices repeatedly collided with the spikes and efficient cleaning of the surface resulted. A comparison of the product obtained from the two methods showed little difference in the epoxide content of the final product (*Table 1*) and so the 'spiked' flask procedure was adopted as standard for all further preparations.

The reaction was slightly exothermic but was maintained at $0 \pm 1°C$ with the aid of a Thermo-watch and Jack-o-matic manufactured by Instruments for Research and Industry.

The reaction between isoprene and DGEBA in equimolar proportions is typical of the procedure; the ratio may be changed over a wide range or butadiene substituted for isoprene without changing appreciably the method outlined here.

A glass, multinecked, spiked, flanged flask of 2 litres capacity was charged with 1000 ml THF containing 280 g (0.8 mol) of DGEBA. It was cooled and maintained at $0°C$ whilst purified nitrogen was bubbled through to maintain an inert atmosphere. With constant stirring a twofold molar excess, 37 g (1.6 mol), of sliced sodium metal was added followed by 54.4 g (0.8 mol) isoprene. The nitrogen flow was then stopped and the vessel was sealed. Following a short induction period, the sodium metal surface became yellow thus indicating that the reaction had started. After about 4 h the reaction mixture had become fairly viscous with signs of gel formation, and the metal surface had reverted to a dull grey. A few millilitres of methanol were then added to disperse the gel and to lower the viscosity, and the excess sodium was removed by coarse filtration to yield a clear orange-brown solution.

Most of the solvent was removed on a rotary film evaporator after which the residue was hydrolysed. Saturated brine was used to effect hydrolysis as this produced a better phase separation than water alone. The organic layer was extracted with ether and again shaken with aliquots of brine until the washings were neutral. Finally, the ether extract was dried over anhydrous magnesium sulphate filtered, and evaporated under vacuum to yield 300 g (87% yield) of product.

The freshly prepared modified resin is opaque, and on standing separates slowly into two layers, the top being very viscous and rubbery. The separation time is a few days at ambient temperature but may be accelerated to a matter of hours by warming to $50°C$. The upper layer may be peeled off by careful manipulation with a spatula, or removed by accurate breaking of the container at the interface. Reblending is best achieved by mixing the two phases at $40-50°C$.

Numerous procedures are available for the determination of epoxide content[10]. In this work a rapid, highly reproducible method of titration with a very sharp end point was used which has been developed by Jay[11] and by Dijkstra and Dahmen[12]. The epoxide content has been described using a variety of units; in this series of papers the results are given in equiv./kg.

RESULTS AND DISCUSSION

The reproducibility of the process was evaluated from the epoxide contents and the yields of materials produced in a series of experiments involving equimolar proportions of isoprene and DGEBA under a variety of conditions. Analyses were carried out immediately after isolating the materials and before any effective separation of the two phases could occur. The results are given in *Table 1*.

It appears that the reaction is insensitive to the changes effected in the experiments listed; neither the scale of reaction, the type of vessel, nor the form of the sodium metal seems to affect significantly the yield of product or its epoxide content. The former averages out over the thirteen experiments at 85% with a standard deviation of 5.5% whilst the latter averages at 3.74 with a 4.5% standard deviation. Considering the heterogeneous nature of the process, this reproducibility can be considered as good.

Reaction characteristics and mechanism

The reaction between dienes, excess epoxide and alkali metal may be carried out under a variety of conditions, but the following characteristics are invariably observed: (1) during the reaction the alkali metal assumes a silvery yellow coloration, and at low stirring rates yellow striations are seen to diffuse from the metal into the bulk of the solution where they are eliminated; (2) the rate of reaction is very sensitive to the rate of stirring; (3) as the reaction proceeds, the viscosity of the solution increases until gel is formed and the stirring can only be maintained with difficulty; (4) after the reaction is complete, the alkali metal takes on a matt appearance, and the gel is easily dispersed by adding small quantities of a protonating agent such as methanol; (5) the product isolated is an opaque material which can vary in colour from a pale yellow to a light orange-brown. On standing for a few days this material separates into two layers. The top layer is rubbery, opaque and viscous whereas the bottom is almost clear with a viscosity comparable to that of the original DGEBA.

These observations are important in elucidating the reactions occurring in the system and will be used, with evidence obtained from related experiments, to deduce the mechanistics of the processes involved.

Previous work, which has concerned the reaction of styrene or its derivatives with alkali metal in the presence of alkyl dihalides, has shown that it is the monomer which is adsorbed preferentially on to the alkali metal surface to form the dimer dianion, and that this subsequently desorbs and reacts with alkyl dihalide to form copolymer[3]. This dimer dianion is observed by the red coloration appearing on the metal surface and diffusing into the bulk solution. In a similar way, reactions of butadiene with alkali metal in the presence of dihalides[13], monohalides[14] or monoepoxides[15] have all been initiated by the diene dimer dianion and all exhibit the yellow-orange coloration characteristic of the diene dicarbanion. Thus the observation that similar coloration occurs in the present system is strong evidence for preferred reaction of diene monomer with the metal to form the initiating diene dianion. Experiments carried out where the monomer was omitted and a THF solution of the epoxide was allowed to stand in contact with sodium metal showed no significant reaction in the time span required for the present synthesis.

Table 1 Batch reproducibility of product prepared from equimolar quantities of DGEBA and isoprene

Scale (mol)	Apparatus	Sodium form	Yield (%)	Epoxide value
0.40	Flask and glass balls	Slices	—	3.44
0.40	Flask and glass balls	Thin wire	82	3.86
0.40	Flask and glass balls	Thin wire	87	3.64
0.85	Flask and glass balls	Slices	—	3.70
0.40	Flask and glass balls	Thick wire	79	3.47

The dependence of the reaction rate on the rate of stirring is a characteristic of a diffusion controlled reaction and is a common feature of these systems[3] regardless of the nature of the linking or terminating agent. The rate-determining step appears to be the formation or desorption of the dimer dianion and, as this is obviously controlled by the surface area of metal present, the rate of reaction is also sensitive to the particle size of the metal at constant weight.

When the dimer dianion is generated and diffuses into the solution, it can propagate until both ends are terminated by reaction with epoxide groups as illustrated by equations (1), (2) and (5). However, the structure of the diene units of which the central oligomeric blocks are composed must now be considered, as must the possibility of forming compounds of structure III:

$$\underset{CH_2}{\overset{O}{\diagup\!\!\!\diagup}}CHR\overset{OH}{\underset{|}{CH}}CH_2M_p CH_2\overset{OH}{\underset{|}{CH}}R\overset{OH}{\underset{|}{CH}}CH_2M_q CH_2\overset{OH}{\underset{|}{CH}}RCH\overset{O}{\diagdown\!\!\!\diagdown}CH_2$$

(III)

where both ends of a diepoxide have reacted with growing oligomers.

It is well established that lithium-dienyl ion pairs exist in good cation solvating solvents such as THF as π-allyl complexes[16] (IV) where the negative charge is delocalized over the last three carbon atoms. However, in inert solvents such as benzene, hexane etc., tight complexes of structure V predominate.

$$\underset{\text{www}CH_2\ Li^+\ CH_2}{\overset{CH\!=\!\!=\!CH}{\diagup\quad\diagdown}}$$

(IV)

$$\text{www}CH_2-CH\!=\!\!=\!CH-CH_2^-\ Li^+$$

(V)

Undoubtedly a similar situation holds with sodium as cation, although this case is not so well documented. The structure of the propagating end is of prime importance in determining the architecture of the resulting polymer. Thus polybutadienes prepared in inert solvents have a high 1,4-content, as is to be expected from the complex V, whereas the materials prepared in good solvents such as THF possess very high 1,2-structure (90% with Li^+ and 80% with Na^+)[17,18]. A similar picture emerges with isoprene where again very high vinyl structure (1,2- and 3,4-) is obtained in THF solutions (75% with Li^+ and 100% with Na^+)[18].

An average of about 45% vinyl structure was obtained by n.m.r. analysis of the materials modified with equimolar butadiene[7]. Although this figure is high relative to that observed in polymerizations in inert solvents, it is also significantly lower than that obtained for conventional homopolymerization in THF. The situation in the present study is more complicated than that obtaining in normal polymerization and an exact parallelism need not arise. This may be illustrated by reference to earlier but related work[15].

In that study, the relative concentrations of the variously structured dimer diols prepared by treating butadiene with alkali metal in the presence of alkyl monoepoxides were determined by g.l.c. If one does not distinguish between the *cis*- and *trans*-isomers of the 1,4-adduct, then three structural isomers may be obtained, namely the 1,2/1,2-dimer (VI), the 1,2/1,4-dimer (VII) and the 1,4/1,4-dimer (VIII).

$$HO-CH-CH_2-CH-CH_2-CH_2-CH-CH_2-CH-OH$$

with R, CH=CH₂, CH=CH₂, R substituents

(VI)

$$HO-CH-CH_2-CH-CH_2-CH_2-CH=CH-CH_2-CH_2-CH-OH$$

with R, CH=CH₂, R substituents

(VII)

$$HO-CH-CH_2-CH_2-CH=CH-CH_2-CH_2-CH=CH-CH_2-CH_2-CH-OH$$

with R, R substituents

(VIII)

If zero order statistics applied and each end of the dimer reacted in a manner unaffected by the fate of the other then, given that the probability of 1,2-addition to the epoxide were p, the ratios VI:VII:VIII would be in the proportions $p^2:2p(1-p):(1-p)^2$. This simple picture was found not to hold, and the results indicated that if one of the anionic ends reacted to form a 1,2-linkage then the probability of the other end reacting in the 1,4-mode was enhanced. This was explained as a drive to minimize electrostatic repulsion between the alcoholate ion and the carbanion by maximizing charge separation.

The same reasoning may be applied in the present work where at equimolar reagent ratios the average degree of polymerization of the diene oligomeric units is about 6[7]. It is to be expected that the addition of the first one or two monomer units to the butadiene dianion would also result in preferred 1,4-structure. Further, it is also established that the termination reaction of an isolated carbanionic end with an epoxide group occurs with only about a 40% probability of vinyl formation[15]. As the initiation and termination steps contribute significantly to the structural characteristics of these short chain oligomers these observations explain qualitatively the lower vinyl content of the diene oligomeric moieties connecting the DGEBA residues.

The work using monoepoxides[15] also confirmed the assumption made in posing structures VI to VIII that attack of the epoxide by butadiene carbanions occurs exclusively at the terminal carbon atom, because only secondary alcohols were identified in the dimeric product.

The evaluation of an average degree of polymerization of about 6 in systems involving equimolar ratios of diene and diepoxide[7] means that only about 17% of the total epoxide groups in the system are consumed by this process. Thus, if the reaction were completely homogeneous and the epoxide moieties reacted on a randomly statistical basis, the proportion of diepoxide having reacted at both ends to form structures of type III would be very small indeed ($\sim$1%). However, the present system is heterogeneous and diffusion controlled so that the reaction between the diepoxide and the growing oligomer occurs primarily at an interface close to the metal surface. This means that an epoxide molecule which has penetrated this reaction zone has an enhanced possibility that both of its epoxide groups will have reacted before it can diffuse away into the bulk of the solution. Thus the formation of the more complex structures of type III, although statistically remote in homogeneous systems, could be significant in these diffusion controlled circumstances and must be borne in mind.

A further complication in the simple reaction picture presented is that the alkoxide ions generated during the process can themselves initiate the homo-oligomerization

of the epoxide. Fortunately the basicity of the alkoxide ion is very much less than that of the carbanion so that the initiation step must be considerably slower. Nevertheless the concentration of alkoxide ion increases as the reaction proceeds so that its effect towards the end of the reaction could become significant.

To see whether homopolymerization of DGEBA by alkoxide ions occurs under these experimental conditions, the following experiment was carried out. A 0.25 M solution of the sodium salt of heneicosanol-11 (IX):

$$CH_3(CH_2)_9-CHOH-(CH_2)_9CH_3$$
$$(IX)$$
in THF was prepared by titrating a 20% excess of the alcohol with the calculated amount of sodium naphthalene in THF, and sufficient DGEBA was then dissolved in the solution to give a concentration of 1 M. A suitable hydro-carbon was then added as a marker and the solution was stirred under nitrogen for 5 h at 0°C. Samples removed before and after reaction, and subjected to g.l.c. analysis after acidification, showed that none of the heneicosanol-11 had been consumed. As the concentration and conditions of the experiment had been planned to duplicate as far as possible those obtaining in the flexibilization reaction, this result is a strong indication that negligible homopolymerization of DGEBA occurs in this system.

It is a feature of this reaction, and of other systems involving epoxy compounds, that the solution becomes more viscous as reaction proceeds until finally gelling may occur. This phenomenon is not observed when the epoxides are replaced by reagents such as alkyl halides which are capable of metathetical reaction with the carbanions to produce electrically neutral molecules. Thus the gelling must be directly related to the formation of alkoxide–alkali metal ion pairs. This effect has been noticed previously when 'living' polystyrene has been terminated with ethylene oxide[19,20], and has been ascribed to the formation of ion pair agglomerates which act as pseudo crosslinks and consequently produce a polymeric network which results in a gel. This hypothesis is supported by the observation that only small quantities of a suitable proton donor are required to destroy the gel by hydrolysing the alkoxide ion pairs. It is also significant that when monofunctional 'living' polymers are terminated with ethylene oxide, no gelling occurs but only an increase in viscosity because in this situation no network can result. Thus gelling appears as a direct consequence of the reactions being carried out and, although many additives have been tried in order to

minimize this effect in the present study, no significant improvement has as yet been achieved.

Preliminary evaluation

The lap joint shear strengths of the re-blended DGEBA resin modified with an equimolar quantity of isoprene were compared with those obtained with unmodified DGEBA using a number of different curing agents. Details of the experimental techniques and the curing cycles are given in Part 3. *Table 2* lists the results obtained using mild steel strips at ambient temperatures; the average shear strength of four replicates are listed together with the maximum value obtained, to give some indication of the spread of results. The results clearly show that the flexibilized material possesses significantly superior shear properties to the unmodified epoxide regardless of the cure system employed.

These preliminary results, therefore, confirm that this technique can produce materials with enhanced adhesive properties. It was therefore decided to study the reaction system and its products in more detail and these investigations are reported in Part 2[7]. When the reaction parameters were thus optimized, the resulting modified material was subjected to the more comprehensive series of physical tests described in Part 3[8].

Explosives Research and Development Establishment, Ministry of Defence, Waltham Abbey, Essex EN9 1BP, UK
(Received 6 February 1975)

The previously described reaction whereby epoxides based on a diglycidyl ether of bisphenol A (DGEBA) may be flexibilized by reaction with dienes such as butadiene or isoprene (M) is studied in more detail. The process transforms a proportion of the DGEBA into a modified DGEBA structure and the relative amounts of these components in the product have been examined as a function of reagent molar ratios. Similarly the effect of reaction parameters on the degree of polymerization, n, of the diene moiety has been studied and the behaviour of isoprene compared with that of butadiene. The reaction product separates out into two phases on prolonged standing and the composition of these phases has been estimated. The upper layer has been shown to consist principally of modified material and the lower principally of DGEBA, although fractionation of the modified material occurs between the phases.

INTRODUCTION

In Part 1[1] it was shown that commercial epoxides based on bisphenol A and comprised principally of molecules of structure (I):

(I)
could be flexibilized by reacting tetrahydrofuran (THF) solutions of mixture of the epoxide and of dienes, such as isoprene or butadiene, with excess sodium metal. Flexibilization was established as occurring via reactions represented schematically as follows:

$$2M + 2Na \longrightarrow Na^+ {}^-M_2{}^- Na^+ \quad (1)$$

$$Na^+ {}^-M_2{}^- Na^+ + (n-2)M \longrightarrow Na^+ {}^-M_n{}^- Na^+ \quad (2)$$

(II)
Thus the diene (M) reacts preferentially with the alkali metal to form a diene dianion which diffuses away from the surface and propagates further before reacting with the excess diepoxide present in the system. Under these conditions new diepoxides (II) are formed which contain a central oligomeric unit of diene in the molecule. It was shown that after standing for a few days the isolated material separated into two phases, the upper being opaque and rubbery and the lower having a consistency and appearance approximating to those of the starting material (I).

* Department of Chemistry and Applied Chemistry, University of Salford, Salford M5 4WT, UK.

The modified epoxide, produced from isoprene at a reactant molar ratio of unity, when reblended and mixed with a variety of curing agents exhibited in all cases significantly improved lap shear strengths on comparison with the original diepoxide (DGEBA).

This paper examines the structure of the product in greater detail and studies the effect of changing the epoxide to diene ratio on the nature of the material produced.

EXPERIMENTAL

The materials used were prepared and purified in the manner described in Part 1. The synthetic method and product isolation techniques are also given in detail in that publication and will therefore not be repeated here.

Gel permeation chromatography (g.p.c.) was carried out using a Waters Associates model ALC 100 chromatograph with a differential refractometer as detector. Five columns, each 5 ft × 0.375 in diameter were packed with Styrogel of porosity 2000–700 AU, 5000–2000 AU, 2000–700 AU, 700–350 AU and 350–150 AU respectively. An operating pressure of 4.8 MN/m² (700 lbf/in²) was used to give a flow rate of 0.85 ml/min. ¹H n.m.r. spectra were recorded on a Jeol PS-100 100 MHz spectrometer using approximately 10% solutions in deuterochloroform with tetramethylsilane as internal standard.

RESULTS AND DISCUSSION

N.m.r. spectra

The spectrum of unmodified DGEBA is shown in *Figure 1a*. The characteristic four line pattern at about 3τ arises from the two pairs of aromatic protons in each aromatic ring. Also prominent is the sharp singlet at 8.1τ due to the methyl peaks. Absorptions due to the $-OCH_2-$ groups can be found at 6.0τ whilst those due to the $-CH-$ and $-CH_2-$ groups of the epoxide ring occur at 7.0τ and 7.8τ respectively.

Figure 1b represents a typical spectrum obtained from the top layer of the product given by reaction of equimolar quantities of DGEBA and isoprene, and *Figure 1c*

shows the spectrum characteristic of the lower layer of this product. In addition to the peaks described for DGEBA, *Figure 1b* also possesses a characteristic pattern in the 4.5τ to 5.5τ region due to the aliphatic resonances of the isoprene units. The relatively complicated pattern arises because there are several types of alkylenic protons in the 1,2-, 1,4- and 3,4-isomeric forms. Similarly, the spectrum shows several broad absorptions in the 8.0τ to 9.0τ range due to the aliphatic isoprenyl groups. These peaks are also in evidence in the spectrum of the lower layer shown in *Figure 1c*, but to a much lower extent.

From a quantitative standpoint the most straightforward measurement to be obtained from the n.m.r. spectrum is the ratio of the aromatic peaks to the remainder. Since the aromatic peaks arise only from the DGEBA units, this ratio can be used to calculate the relative amounts of DGEBA to isoprene present in the sample (see Appendix).

Similar spectra are obtained when butadiene is used as monomer. In the alkylene region characteristic patterns

Figure 1 100 MHz [1]H n.m.r. spectra of: (a) unmodified DGEBA; (b) DGEBA modified with equimolar isoprene — top layer; (c) DGEBA modified with equimolar isoprene — bottom layer

are obtained due to the $-CH=CH-$ and $-CH=CH_2$ groups which absorb at about 4.7τ, and to the $-CH=CH_2$ hydrogens at 5.0τ. Broad aliphatic resonances also occur at 8.0τ and 8.7τ and are due to the $-CH_2-CH=CH-$ and the $-CH_2-CH-$ hydrogens respectively. The proportion of 1,2-units (p) can be calculated from the easily derived relationship $p = (4 - 2a)/(a + 1)$, where a = ratio of aliphatic to alkylenic hydrogens in the butadiene units.

Bulk material

Table 1 in Part 1 shows that the epoxide value of the resin, originally at 5.2 equiv./kg had been reduced by reaction with equimolar amounts of isoprene to an average of 3.74 equiv./kg with a standard deviation of 4.5%. If the initial assumption be made that the reaction is quantitative, and that no loss of product due to fractionation factors has occurred during the work-up stage, then the molar ratio of the components in the product mixture, r, is the same as that of the reactants, r_0. On this basis, application of equations (A2) and (A3) (see Appendix) to these data enables the mole fraction of adduct formed, p_0, and the number-average chain length of the diene oligomers, n_0, to be estimated. Despite the obvious inaccuracy in the assumption of quantitative conversion and isolation, it is instructive to apply these equations to the average value of the epoxide content previously obtained assuming $r = 1$. These give a value of $n_0 = 6.5$, and the percentage of DGEBA converted to adduct as 30%. Since the standard deviation of the results is 4.5%, this allows 'n_0' to vary between 5.2 and 8.6, and the percentage conversion to have limits of 23% and 38%. Thus calculations of 'n_0' and 'p_0' by this method are very sensitive to the accuracy of the epoxide determination, and so can safely be used only to give semi-quantitative indications of any trends in the process.

Although fractionation at the work-up stage may invalidate the absolute figures given above, the spread in the calculated results is probably still significant since any deviations due to this effect will probably be similar in the circumstances where reproducibility is being examined. However, when the reagent composition is changed this need no longer apply and an independent assessment of the molar ratio in the product is necessary. This is carried out by [1]H n.m.r. spectroscopy prior to phase separation of the material.

A series of reactions were carried out using isoprene as monomer where the molar ratio of isoprene to DGEBA was varied from 0.5 to 2.5. The products were then isolated and both the molar ratios and the epoxide contents of the bulk materials were evaluated before phase separation
Table 1 Analysis of total product obtained from reaction of DGEBA and diene at various molar ratios of diene to DGEBA

Monomer	Starting molar ratio				Spectroscopic molar ratio			
	r_0	$f(E)$	p_0	n_0	a	r	p	n

	2.0	0.675	0.134	14.9	3.07	1.72	0.160	10.7
	3.0	0.605	0.139	21.6	3.62	2.52	0.178	14.3

occurred. The former values were calculated using equations (A8) and (A9). A similar series of preparations and analyses was also carried out with butadiene as monomer. Equations (A10) and (A9) were employed in the spectroscopic analysis of these materials.

The results from both these series of modified epoxides are given in *Table 1* where, for purposes of comparison, calculations of the percentage modified material and of the average chain length of its diene component were carried out using values of the molar ratio derived from the initial mix (r_0) and from the spectroscopic analyses (r).

It can be seen that the relative quantity of either diene found in the isolated material is less than that introduced in the reagent mixture, and that this trend becomes more pronounced as the starting ratio increases. Agreement at ratios near unity is relatively close so that use of the initial reagent ratio in the reproducibility calculations mentioned previously should be reasonably sound. However, with butadiene using either method of calculation, the chain length increases with the reagent ratio although its degree does not match that of the reagents. Thus, increase in the diene proportion not only increases the degree of polymerization but also the number of chains initiated. Isoprene is less sensitive to reagent ratio and change is principally reflected in the number of chains formed rather than their length.

The average chain lengths of the butadiene moieties are significantly greater than those of isoprene under identical conditions. Furthermore, the rate of increase of chain length with reagent ratio is larger for butadiene so that the values for the two monomers diverge as the reagent ratio increases. These observations are consistent with the fact that the rate constant of anionic propagation in THF of butadiene is greater than that of isoprene.

Phase separated materials

The opaque bulk material gradually separates into two layers until, after about one week the viscous rubbery top layer may be physically removed.

The separated layers of products from a series of different syntheses were examined by g.p.c. and were subsequent-

ly analysed for epoxide content, and by n.m.r. spectroscopy. The g.p.c. traces of starting material and of the products from reactions involving equimolar proportions of either diene and DGEBA are shown in *Figure 2*. The DGEBA trace shows a main peak characteristic of material of structure I having a molecular weight of 340, and a minor peak at higher molecular weight which is almost certainly the derivative:

(III)
This has a molecular weight of 624 and, as the average molecular weight of the material is given as 384, this would require 15.5% by wt of the commercial DEGBA to consist of III, which is roughly in accord with the relative areas.

The traces of the upper and lower layers both show the presence of DGEBA and the modified material, although their relative abundances are very different. This means that the modified material has a significant solubility in DGEBA and *vice versa* and/or that the separation process is not complete. The transparency and comparatively low viscosity of the bottom layer suggest that solubility is the reason for the presence of modified material in this phase, whereas the opacity and high viscosity of the upper layer indicate that kinetic factors could be important in determining its composition.

The shapes of the traces of the modified material in both layers show that there is a high dispersity of chain lengths of the diene segments, although it is possible that the broadness reflects the formation of appreciable quantities of 'dimers' of structure IV (see Part 1)[1]:

(IV)
It is interesting and significant to note that the maximum in the trace of the modified material from the upper layer is at a higher molecular weight than that of the lower layer. Thus some fractionation of the modified material has occurred on separation. It is to be expected that those molecules containing the smallest diene oligomers would be most compatible with, and hence most soluble in, DGEBA and this appears to be confirmed.

A point of significance to the spectroscopic analysis described in the Appendix is whether the relative proportions of structures I and III in each phase have changed as a result of fractionation between the layers. Nothing conclusive may be derived from examination of the g.p.c. traces other than that any changes which have occurred are not large. It has therefore been assumed that the relative ratios of structures I and III have been maintained and are as recorded for unmodified DGEBA, although it is realized that this assumption introduces a further uncertainty in the results calculated by this method.

A more quantitative analysis of the g.p.c. traces is difficult because of the variation in the refractive index of the components of the layers with the size of the diene oligomeric units contained therein.

The weights of accurately known volumes of the upper and lower phases were determined for the products of isoprene and DGEBA reactions carried out at various reagent molar ratios. The resultant densities were shown to be

	3.0			0.50	0.220				

* $y_0 = y/(y + z)$ = mole fraction of modified material in top layer
$\dagger$ $(x - y)_0 = (x - y)/(1 - y - z)$ = mole fraction of modified material in bottom layer

insensitive to this parameter and to average at 0.96 and 1.11 g/ml respectively. These values compare with a density of 1.16 g/ml found for unreacted DGEBA. Although these results are not sufficiently accurate to serve as the basis of a quantitative analysis of phase compositions, the observation that the density of the bottom layer is slightly lower than that of pure DGEBA is explained by the observed solubility of the less dense modified material in this phase.

The volume fraction of top layer obtained in the separated product is very dependent on the molar ratio of starting materials; for example, the measured volume fraction increases from 0.10 to 0.50 as the molar ratio of isoprene to DGEBA rises from 0.5 to 2.5, and the rate of increase is roughly proportional to the change in reagent ratio (*Table 2*). Thus the epoxide equivalent of the top layer is relatively insensitive to the ratio of reactants and the change is principally reflected in the amount of modified material formed.

If one assumes that the upper and lower layers consist exclusively of modified epoxide and unreacted DGEBA respectively, then the epoxide content and volume fraction of the upper phase will be given by equations (A11) and (A13). This assumption is clearly justified from the foregoing observations but, nevertheless, the discrepancies between those values calculated on this basis and those observed highlight the significance of 'solubility' effect. The results are recorded in *Table 2* using the data obtained from the n.m.r. analysis given in *Table 1*. Inspection of *Table 2* leads to the following conclusions: (a) the calculated volume fractions of top layer are significantly larger than those observed, especially at low r_0; (b) the epoxide content of the bottom layer is appreciably lower than the value of 5.2 required if it were unreacted DGEBA only; (c) the epoxide content of the top layer is closer to, although

consistently lower than, the calculated value. These observations may be interpreted on the basis of mutual solubility of the two components in the system; particularly that of the modified material in DGEBA. If, however, the solubility of the modified epoxide were independent of molecular weight, the epoxide content of the top layer could not be lower than that calculated as is in fact obtained. This last observation can be explained only on the basis of a preferential solubility of the lower molecular weight component of the modified material in DGEBA, leaving the top layer with a distribution weighted towards the high molecular weight end, and hence with an epoxide number lower than that predicted.

The weight fraction of modified layer may be derived from the observed epoxide numbers by use of equation (A19) and converted into volume fraction via equation (A21). The results of these calculations are given in *Table 3* and shown to be in good agreement with those measured (*Table 2*). Further, the total mole fraction of both modified epoxide and DGEBA molecules in the top layer may be derived from equation (A20) and the results are listed in *Table 3*. The relative amounts of these two species cannot be determined without recourse to further compositional data. These were obtained for the isoprene modified series by n.m.r. analysis of the separated layers and the use of equation (A8). The degree of polymerization of the isoprene moieties in the top phase, n_T, and in the bottom phase, n_B, were derived in this way and are quoted in *Table 3*. It is clear that some of the values of n_T and n_B are inconsistent with those of n in *Table 1* since n should lie between these two extremes. It is easily shown, however, that the values of n_T are more accurate than n_B because n_B is very sensitive to small changes in $f(E)_B$ and

a_B since the amount of modified material in the bottom layer is small. Thus, the absolute values of n_B show a large scatter, although it is evident that n_B is always significantly less than n_T indicating that fractionation of the modified epoxide has occurred between the two phases.

These results may in turn be used in equations (A14) and (A15) to calculate the relative proportions of modified material and DGEBA in each phase. The values obtained are given in *Table 3* and despite wide variation, indicate that there is about 10 mol % of DGEBA in the top layer and a similar quantity of modified material in the bottom layer.

Lastly, it is necessary to consider the assumptions inherent in the analysis. First, it has had to be assumed that the ratio of compounds I and III, determined for the starting material, has been maintained in the composition of each of the phases. This is clearly an approximation as it has been shown that fractionation occurs on separation and the derivatives of these structures should be similarly affected under these circumstances. Secondly, the presence of dimers of structure IV has not been considered. If n in the calculations be regarded as the number-average degree of polymerization between DGEBA residues regardless of whether the epoxide groups in those residues have totally or partly reacted, then its values will be unchanged by the presence of structure IV. By the same token, however, this means that the analysis cannot be used to assess the importance of structure IV in the composition of the final products.

APPENDIX

Overall composition of the reaction product

If the molar ratio, r, of diene to total DGEBA present in the isolated product, whether as unreacted diepoxide or as ligand, be known then the average chain length of the diene moieties, n, and the mole fraction of unreacted DGEBA may be calculated from the epoxide content.

Let the overall reaction be represented by the equation:
where M = diene monomer of molecular weight m.

If the mole fraction of DGEBA converted into adduct = $2p_0$ then mole fraction of adduct relative to original DGEBA = p_0 and the total number of moles is reduced to $1 - p_0$. Therefore, mole fraction of DGEBA in product = $(1 - 2p_0)/(1 - p_0)$, and of adduct = $p_0/(1 - p_0)$.

The molecular weight of the commercial DGEBA used = 384, and, ignoring the molecular weight contribution of the —OH hydrogens in the product, the molecular weight of the adduct = $2 \times 384 + mn_0 = 768 + mn_0$ (n_0 = degree of polymerization of diene units assuming complete conversion). This approximation introduces an error well within

that of the determination of the epoxide content, and can therefore be applied where such figures are used. It is not permissible under other circumstances, as will be seen when the n.m.r. spectroscopic results are considered.

The epoxide content of DGEBA is given by $E_0 = 2000/384$ equiv./kg and the epoxide content of the product is similarly given by:

$$E^1 = \frac{2000(1 - p_0)}{(1 - 2p_0)384 + p_0(768 + mn_0)}$$

Thus:

$$\frac{E^1}{E_0} = f(E) = \frac{1 - p_0}{1 + (m/384)n_0 p_0} \qquad (A1)$$

If it be assumed that all reactants are retained in the product then we have $n_0 p_0 = r_0$, where r_0 = molar ratio of isoprene to DGEBA introduced into the reaction so that equation (A1) becomes:

$$f(E) = \frac{1 - p_0}{1 + (m/384)r_0} \qquad (A2)$$

or

$$n_0 = \frac{r_0}{1 - [1 + (m/384)r_0]f(E)} \qquad (A3)$$

and, for isoprene:

$$n_0 = \frac{r_0}{1 - [1 + 0.177r_0]f(E)} \qquad (A4)$$

Without the assumption of quantitative reaction and isolation, the product composition can be estimated by combining the epoxide value with the results of n.m.r. analysis.

Under these circumstances, if the mole fraction of modified epoxide in the product = x, the epoxide number is given by:

$$E^1 = \frac{2000}{(1 - x)384 + x(768 + mn)}$$

from which

$$f(E) = \frac{1}{1 + [1 + (mn/384)]x} \qquad (A5)$$

which, for isoprene, gives:

$$f(E) = \frac{1}{1 + (1 + 0.177n)x} \qquad (A6)$$

As the n.m.r. analysis gives the ratio of aliphatic to aromatic hydrogens, the composition of the DGEBA and of the modified material must be considered in more detail.

G.p.c. measurements have shown commercial DGEBA to consist of a mixture of structures I and III and calculation from the average molecular weight of 384 gives the mole fraction of III = 0.155. The best model to use to describe the starting material is therefore structure V:
Thus the aliphatic to aromatic hydrogen ratio of V is given by:

$$\left(\frac{Al}{Ar}\right)_{DGEBA} = \frac{16 + 12 \times 0.155}{8 + 8 \times 0.155} = 1.93$$

If we assume that the relative concentrations of I and III in the isolated product are identical with those in DGEBA, then V may be considered as undergoing the reaction with diene. Thus, including the hydrogens of the OH groups produced by the reaction, the aliphatic to aromatic hydrogen ratio in the isoprene modified product is now given by

$$\left(\frac{Al}{Ar}\right)_{Mixture} = a =$$

$$\frac{[2 \times (17 + 12 \times 0.155) + 8n]x + (16 + 12 \times 0.155)(1 - x)}{2 \times (8 + 8 \times 0.155)x + (8 + 8 \times 0.155)(1 - x)} =$$

$$\frac{1.93 + (2.15 + 0.866n)x}{1 + x} \tag{A7}$$

Equations (A6) and (A7) may now be combined to evaluate n:

$$n = \frac{a - 2.15 + 0.22f(E)}{0.866[1 - f(E)] - 0.177(a - 1.93)f(E)} \tag{A8}$$

Knowing n, x may be evaluated from equation (A6), whence an *apparent* conversion fraction p may be calculated from the relationship $p = x/(1 + x)$. Finally, the molar ratio (r) of diene to total DGEBA (unreacted or as ligand) can be derived from the equation:

$$np = r \tag{A9}$$

In an identical way an equation analogous to equation (A8) for the butadiene modified system may be derived:

$$n = \frac{a - 2.15 + 0.22f(E)}{0.65[1 - f(E)] - 0.146(a - 1.93)f(E)} \tag{A10}$$

Analysis of separated layers

Ignoring again the contribution to the molecular weight of the −OH hydrogen in the product, the epoxide content of the modified material is given by:

$$E = \frac{2000}{768 + mn} \tag{A11}$$

and it may be readily shown that the weight fraction of the modified epoxide is given by:

$$w_0 = \cfrac{1}{1 + \cfrac{1 - x}{x\left(2 + \cfrac{mn}{384}\right)}} \tag{A12}$$

and that its volume fraction is given by:

$$v_0 = \cfrac{1}{1 + \cfrac{D(1 - x)}{dx\left(2 + \cfrac{mn}{384}\right)}} \tag{A13}$$

where D = density of modified epoxide, and d = density of DGEBA.

Assume that the two components are mutually soluble and that fractionation has occurred between the two phases.

If the top phase contains y and z mole fractions of modified material and DGEBA respectively, then the bottom phase is composed of $(x - y)$ and $(1 - x - z)$ mole fractions of these components. Finally, if n_T and n_B are the average degree of polymerization of the diene moieties in the top and bottom phase respectively, and E_T and E_B be their epoxide number, then the following relationships may be derived for isoprene:

$$f(E_T) = \frac{E_T}{E_0} = \frac{y + z}{z + (2 + 0.177n_T)y} \tag{A14}$$

$$f(E_B) = \frac{E_B}{E_0} = \frac{1 - (y + z)}{(1 - x - z) + (2 + 0.177n_B)(x - y)} \tag{A15}$$

$$nx = n_T y + n_B(x - y) \tag{A16}$$

and

$$f(E) = wf(E_T) + (1 - w)f(E_B) \tag{A17}$$

where w = weight fraction of top layer. The weight fraction w may also be derived from the relationship:

$$w = \frac{(768 + mn_T)y + 384z}{(768 + mn_T)y + 384z + (768 + mn_B)(x - y) + (1 - x - z)384}$$

which, by use of equation (A16) may be simplified to:

$$w = \frac{(2 + 0.177n_T)y + z}{1 + (1 + 0.177n)x}$$

Again, using equations (A6) and (A14) this reduces to:

$$w = (y + z)\frac{f(E)}{f(E_T)} \tag{A18}$$

but from equation (A17):

$$w = \frac{f(E_B) - f(E)}{f(E_B) - f(E_T)} \tag{A19}$$

so that

$$y + z = \frac{f(E_T)[f(E_B) - f(E)]}{f(E)[f(E_B) - f(E_T)]} \tag{A20}$$

Thus the weight fraction w may be derived via equation (A19) from the epoxide numbers of the phases and may be related to the experimentally determined volume fraction by the equation:

$$v = \frac{1}{1 + [(1 - w)/w](D/d)} \tag{A21}$$

An anionically prepared flexible adhesive: 3. Physical testing

A. V. Cunliffe, M. B. Huglin*, P. J. Pearce and D. H. Richards
Explosives Research and Development Establishment, Ministry of Defence, Waltham Abbey, Essex EN9 1BP, UK
(Received 6 February 1975)

The physical properties of flexibilized epoxides produced by reaction of a diglycidyl ether of bisphenol A with dienes are examined and the reaction conditions necessary to produce materials giving maximum lap shear strengths are determined. It is shown that these optimum conditions occur when equimolar proportions of isoprene and bisphenol A based epoxides are reacted together with excess sodium metal. Tests carried out which involve ageing at elevated temperature, and exposure to adverse environmental conditions show that the improvements in lap shear strengths observed on flexibilization are retained under these adverse conditions.

INTRODUCTION

Part 1[1] of this series of papers describes a process by which conventional diepoxides based on a diglycidyl ether of bisphenol A (DGEBA) can be flexibilized by reaction with a diene and excess alkali metal. The chemistry of the reaction is fully covered in the paper, but the process may be represented as a transformation of a proportion of the starting material from the structure represented schematically as I to the flexibilized form II, where M_n represents an oligomeric diene unit of length n.
The isolated material separates on standing for a few days into two layers. The upper component, which is opaque and rubbery, has been shown to be composed principally of the modified epoxide II, whilst the lower layer consists predominantly of the unreacted starting material I. In Part 2[2] it was established that the volume fraction of the modified layer was directly dependent on the molar ratio of the diene to epoxide in the reaction whilst the diene oligomeric chain length was relatively insensitive to this change; for example, with isoprene as monomer, the average chain length n only changed from 5.6 to 8.6 over a five-fold increase in isoprene concentration.

Preliminary lap shear strength measurements on the product obtained from an equimolar isoprene—epoxide reagent mixture, reblended and mixed with a variety of curing agents, indicated that in all cases significant improvements in strength were obtained over the similarly mixed unmodified material[1].

This communication describes experiments carried out to establish whether isoprene or butadiene modified epoxide exhibits the better adhesive properties, and to decide

on the proportion of top to bottom layer which on blending results in the maximum synergism. The material with the optimum adhesive strength having been selected, there follows a discussion of the results of physical tests carried out under a variety of experimental conditions on lap joints bonded together by this adhesive.

EXPERIMENTAL

The experimental details relating to the purification of reagents and the synthesis and isolation of the flexibilized epoxides have been described in Part 1[1] and will not be repeated here.

Test method for adhesive shear strength using lap joints

This method is based on test specification ASTM D1002–64[3] which is universally accepted for lap shear examination.

Test specimens were prepared from metal sheets of 0.064 in gauge, cut into 4 in × 1 in strips. Immediately prior to use they were cleaned and dried carefully by a process which was dependent on the substrate. Two metals were used in this work, aluminium coated aluminium alloy (BS 2L73 specification) and mild steel; in both cases the surface was degreased in trichloroethylene vapour before further treatment.

The aluminium specimens were chemically etched by immersion for 30 min at 60–65°C in an agitated chromic acid solution, washed in tap water followed by distilled water and dried at 60°C. The acid solution was prepared by dissolving 5 parts chromium trioxide and 15 parts by wt concentrated sulphuric acid (s.g. 1.84) in 80 parts water.

A phosphate treatment recommended for etching the mild steel strips failed to give good reproducibility under test, but consistent results were obtained with pressure impact abrasion using alumina of 180–220 mesh, and this latter technique was adopted for mild steel strips throughout.

The cleaned strips were assembled in pairs and the adhesive, prepared by mixing resin and curing agent, was applied to a length across the end of each specimen sufficient to cover a space at least 0.25 in longer than the 0.5 in overlap required. The joints were then assembled, held rigidly under slight pressure and allowed to cure for the recommended period of time. Glue line thickness was controlled

* Department of Chemistry and Applied Chemistry, University of Salford, Salford M5 4WT, UK.

at 0.004 in by inserting into the joint two or three very short lengths of stainless-steel wire of this diameter during the joint assembly.

Testing was carried out using a Monsanto Type E tensometer adjusted to ensure that the breaking load of the specimen fell between 15 and 85% of full scale capacity. The joint was held by a suitable pair of self-aligning grips allowing the outer inch of each end to be firmly engaged. Loading was applied at a constant crosshead speed of 0.2 in/min and continued until failure occurred.

Curing systems and cycles employed

The proportion of curing agent added to the modified epoxides was the subject of experiment (*Table 2*) whereas the proportion added to the unmodified material (DGEBA) was that recommended by the manufacturers. The cure cycles employed were as described below unless otherwise specified in the text.

1. *Aliphatic primary amine:* triethylenetetramine (Ciba HY951). Cure cycle of 2 hours at 80°C.

2. *Aromatic amine:* 4,4'-diaminodiphenylmethane (Ciba HT972). Cure cycle of 2.5 hours at 100°C.

3. *Polyamide:* (Versamid 140). Cure cycle of 2 hours at 100°C.

4. *Anhydride:* hexahydrophthalic anhydride (Ciba HT907). Cure cycle of 2 hours at 120°C followed by 2 hours at 150°C.

5. *Catalytic:* borontrifluoride-ethylamine (Ciba HT973). Cure cycle of 3 hours at 120°C followed by 3 hours at 150°C.

Elevated temperature and environmental testing

In order to assess the performance of the modified resin under a variety of conditions, lap joints were assembled as described and subjected to the four tests given below. Unmodified DGEBA was used throughout as a standard for comparison.

Ageing at elevated temperatures. Lap joint specimens were treated at temperatures in the range 150–250°C in thermostatically controlled ovens and periodically sampled. Lap shear measurements were carried out at room temperature and the results were plotted as a function of time.

Lap shear measurements at elevated temperature. For this test the tensometer was fitted with a thermostatically controlled oven which totally enclosed the grips and lap joint. The test specimen was heated from ambient to the required temperature at a rate of 6 to 10°C/min and held for 15 min before application of the load.

Test at 96% r.h. for 1000 h at 43°C. These conditions, taken from Ministry of Defence specification D.T.D. 5577[4], were achieved by placing the specimens over a saturated solution of sodium sulphate in a desiccator and storing in a thermostatically controlled oven. Lapshear measurements

were then carried out at room temperature after 1000 h exposure.

Exposure to de-icing fluid for 1000 h at 43°C. This test, especially important to the aeronautical industry, is carried out by totally immersing the specimens in a mixture of water and methanol (56:44 parts by wt) in an enclosed cylinder heated in an oven at 43°C. Lap shear measurements were carried out at room temperature after a 1000 h exposure.

RESULTS AND DISCUSSION

Product composition

Preliminary tests with the product from the reaction of equimolar quantities of DGEBA (structure I) and isoprene with excess sodium had shown superior adhesive properties to DGEBA with a variety of curing agents. Two points were still to be resolved before a more detailed examination of properties could be launched: (a) whether isoprene or butadiene produces the better adhesive; and (b) which blend of top to bottom layer results in the optimum adhesive properties.

The former problem was investigated by carrying out comparative tests on the lap shear strengths of the products of reactions between equimolar quantities of each diene and DGEBA. Triethylene tetramine (TETA) was chosen as curing agent and blended with both of the modified resins and with DGEBA in stoichiometric proportions based on the determined epoxide content of the materials. The cure cycle employed was 1.5 h at 80°C followed by a postcure of 1 h at 250°C. The results of lap joint tests on these materials are given in *Table 1* where the average of four replicates are listed together with the maximum value obtained to give a measure of the dispersity of the results.

These results indicate that flexibilization to this degree gives a significant improvement in lap shear strength in both cases, but that the isoprene modified material gives higher values than the butadiene system. It was therefore decided to concentrate further investigation on isoprene based materials. This choice has the added advantages that: (a) during the synthesis the induction period before onset of reaction is usually very short for isoprene whereas an induction period in excess of 0.5 h has been observed with butadiene; (b) isoprene, being liquid at ambient temperature, is more convenient to purify and manipulate than butadiene; (c) the degree of polymerization of the isoprene moieties in the modified material is less sensitive to changes in the initial molar ratio of the reagents than is butadiene[2]. Thus experiments may be carried out to maximize the amount of upper layer without drastically affecting its composition. This is relevant to the question of determining the layer ratio necessary to optimise the shear strength.

This problem of maximizing the shear strength of the isoprene modified material was approached in the following way. The top layer of an equimolar preparation was removed and re-blended with various amounts of bottom layer and of DGEBA. Six mild steel lap joint specimens were prepared at each composition using triethylene tetramine (TETA) as the curing agent and with the curing cycle described above. The average lap shear strengths are given as a function of percentage top layer in *Figure 1*. The maximum in both sets of blends occurs at about 20% top layer, although the shear strength at this point is significantly lower if pure DGEBA is used. This last observation

Table 1 Comparison of the shear strengths of isoprene modified and butadiene modified epoxide resin (TETA cured with cycle of 1.5 h at 80°C followed by 1 h at 250°C)

Resin	Lap shear strength (MN/m^2)	
	Av.	Max.
DGEBA	24.5	25.1
1:1 isoprene–DGEBA	33.9	35.7
1:1 butadiene–DGEBA	30.2	31.6

could be due to the absence of low molecular weight modified epoxide in the pure DGEBA which would increase compatibility between the phases, thus ensuring on cure a maximum transmission of stresses to the rubbery micelles. However, the important observation is that maximum synergism occurs with the system containing 20% top layer. This is close to the proportion obtained in the reaction of equimolar quantities of isoprene and DGEBA and it was decided, therefore, that a further and more comprehensive examination of the adhesive properties of the product of this reaction would be carried out.

Mild steel substrate

The physical properties of cured resins are to a large degree determined by the curing agent employed; hence it is clearly of importance to evaluate the properties of the iso-prene modified material with a number of cures. Five
Figure 1 Maximization of shear strength by blending. O, Top layer/bottom layer; △, top layer/DGEBA

different curing systems were chosen to represent the wide variety available, namely, aliphatic amine, aromatic amine, polyamide, anhydride and catalytic. These were blended with the modified resin in various proportions to determine which resulted in the optimum shear strengths; DGEBA was used as a control with the hardner ratio recommended by the manufacturers. Eight replicates were tested for each variation and the results are given in *Table 2*. Particularly marked gains in performance were obtained with the aliphatic amine and anhydride cure systems, with 104% and 73% improvements over DGEBA recorded. It is also of interest to note that even when a flexible polyamide is used further gain in strength can be obtained by using the flexibilized epoxide, the resulting lap shear strengths being the highest recorded with any of the cure systems employed.

Thus, having established that the modified epoxy resin exhibits superior adhesive properties to those of DGEBA under ambient conditions, it is now necessary to consider whether these improvements are retained under a variety of adverse environmental conditions. The first of these to be considered is the effect of ageing at elevated temperature on lap shear strengths.

Effect of ageing on shear strength

Tests were carried out at 150°, 200° and 250°C; TETA was used as curing agent at all three temperatures whilst specimens cured with aromatic amine and anhydride were treated in parallel at 250°C. All curing agents were used at concentrations for optimum shear strength as determined in *Table 2*. Testing was carried out in quadruplicate, and the averaged results were plotted against time as shown in *Figures 2* to *6*.

Table 2 Determination of curing agent concentration for maximum shear strength with mild steel substrate (optimum curing agent concentration underlined)

Curing system	Resin	Curing agent (pph)	Lap shear strength (MN/m²)		Maximum improvement (%)

	Modified	8	15.6	17.0	
	Unmodified	3	17.5	18.3	

It is seen that a postcure strength increase is frequently observed with one or both of the resins. This is almost certainly caused by the reaction of last traces of curing agent leading to a more complete network structure with consequent increase in strength, as it occurs primarily with the systems cured at low temperature with aliphatic amine. The modified resin may also crosslink further through its unsaturation and, since the postcure effect is generally more marked with the modified resin, both reactions could well occur simultaneously.

More importantly, however, it is clear that at all temperatures and with each of the curing agents used the improvement in shear strength is maintained throughout the useful life span of the resin despite the potential instability present at the aliphatic double bonds. In fact, these double
Figure 2 Effect of temperature on shear strength for aliphatic amine cure at 150°C. O, Modified; □, unmodified
Figure 3 Effect of temperature on shear strength for aliphatic amine cure at 200°C. O, Modified; □, unmodified
Figure 4 Effect of temperature on shear strength for aliphatic amine cure at 250°C. O, Modified; □, unmodified

bonds might act as crosslinking sites at high temperatures and thus partly compensate for the thermally induced chain scission.

Finally, the aliphatic amine cured specimens which are unaffected at 150°C over a period of 1500 h have a useful life span of about 800 h at 200°C, but show rapid degradation at 250°C with a total useful life span of only about 13 h. This may be improved by replacing TETA with the more rigid aromatic amine or anhydride hardener. The former gave specimens which still retained a lap shear strength of 10 MN/m² after 20 h at 250°C whilst the latter averaged at 14 MN/m² after the same exposure period.

Environmental testing

One of the more important tests which evaluates the practical applicability of a material, and especially an adhesive, is that which assesses its ability to withstand conditions of high humidity. This is standardized for an adhesive by measuring the fall in shear strength after exposure to a relative humidity of 96% for 1000 h at 43°C. The results of such a test on the modified material and on DGEBA, expressed as the average of eight replicates, are contained in *Table 3*.

Both aliphatic and aromatic amine cured specimens, and those cured with polyamide gave significant drops in shear strengths averaging at about 17%. This is not unexpected as it is known that the curing process with nitrogen containing hardeners of these types gives bonds which are susceptible to hydrolysis. Hence, although these figures

are within most specifications, it indicates that these curing agents should be used with caution. On the other hand, very little change in strengths was observed when the resins

Table 3 Effect on lap shear strengths of exposure to 96% r.h. for 1000 h at 43°C

Curing system	Resin	Average lap shear strength (MN/m^2)		Change (%)
		Unexposed	Exposed	
Aliphatic	Unmodified	13.2	11.0	−16.7
amine	Modified	25.6	21.3	−16.8
Aromatic	Unmodified	15.6	12.8	−17.9
amine	Modified	21.9	16.7	−23.8
Polyamide	Unmodified	21.3	17.5	−17.9
	Modified	28.0	24.6	−12.1
Anhydride	Unmodified	15.9	16.7	+5.0
	Modified	29.4	28.1	−4.4
Catalytic	Unmodified	12.2	10.9	−10.7
	Modified	22.6	22.9	+1.3

Table 4 Comparison of lap shear strengths of isoprene modified and unmodified DGEBA using aluminium substrate

Curing system	Average lap shear strength (MN/m^2)		Improvement (%)
	Unmodified	Modified	
Aliphatic amine	16.7	24.8	49
Anhydride	19.0	31.8	67

were cured with anhydride or catalytically and it is evident that these would be preferred hardeners for use in circumstances where high humidity is expected.

Lastly, it is again observed that the improvements in shear strengths obtained by flexibilizing DGEBA are retained under the conditions of this test, and that the behaviour patterns of the modified and unmodified DGEBA are roughly parallel.

Aluminium coated aluminium alloy substrate

All the tests covered so far were carried out with mild steel testpieces. However, aluminium coated aluminium alloy is widely used in the aerospace industry and, as the shear strengths of adhesives are also critically dependent on the nature of the substrate, it is evident that tests should also be conducted using this material. The remaining tests to be described were therefore carried out using aluminium substrate.

The adhesive shear strengths of modified DGEBA and pure DGEBA were again determined as with mild steel, but only TETA and anhydride were used as hardeners. The results obtained (average of four replicates) are summarized in *Table 4*. Again, superior strengths were obtained with the modified resin, and similar enhancement was achieved with the anhydride cured material as when mild steel test pieces were used. The percentage improvement with the amine cure was lower than formerly, although this was due principally to a large increase in the shear strength obtained with the pure DGEBA.

Lap shear measurements at elevated temperature

The modification of a material by introducing a component which is flexible and hence has a low T_g, is expected to have a deleterious effect on its strength at elevated temperatures. It is therefore important to assess this effect and so lap joints were prepared with various hardeners and tested at 70°C. The results, which are the average of six replicates, are given in *Table 5*.

Table 5 Comparison of the lap shear strengths of modified and unmodified DGEBA at ambient and 70°C

Curing system	Resin	Average lap shear strength (MN/m²)		Change (%)
		Ambient	70°C	
Aliphatic amine	Unmodified	17.3	17.1	−1.2
	Modified	27.0	14.7	−45.6
Aromatic amine	Unmodified	27.2	28.2	+3.7
	Modified	30.8	21.7	−29.5
Polyamide	Unmodified	27.7	10.0	−63.9
	Modified	26.1	14.4	−44.8
Anhydride	Unmodified	19.0	21.3	+12.1
	Modified	31.8	23.3	−26.7

The results indicate clearly the adverse effect of the aliphatic polymeric moieties on the elevated temperature performance of the cured adhesive. In all cases the modified resin shows a marked drop in shear strength, ranging from 27% for the anhydride to 45% with TETA and polyamide when compared with those recorded at ambient. This contrasts with the much smaller fall in values obtained with pure DGEBA so that the shear strengths of the two materials are more comparable at 70°C than at ambient temperature.

Environmental testing

The test at 96% relative humidity for 1000 h at 43°C was repeated using aluminium substrate and anhydride cured modified material. The average value from six replicates showed a 16% loss compared with the shear strength obtained from laboratory stored specimens. This relatively small loss is acceptable for an aeronautical adhesive.

Exposure to de-icing fluid for 1000 h at 43°C

Six replicates of anhydride cured modified resin were used and the average loss in shear strength was 15%. Again this is a satisfactory result for an aeronautical adhesive.

Phosphonitrilic chloride: 27. Synthesis and properties of cyclophosphazene polymers

Meisetsu Kajiwara and Hajime Saito

Department of Applied Chemistry, Faculty of Engineering, Nayoya University, Nagoya, Japan
(Received 9 December 1974)

The products of the reaction between dichlorocyclotriphosphazene, $(NPCl_2)_3$, and 3,3'-diamino-benzidine, $(H_2N)_2C_6H_3C_6H_3(NH_2)_2$, in pyridine were shown to be amorphous, black coloured solids and slightly soluble in polar organic solvents, but insoluble in non-polar organic solvents. Measurement of the degree of swelling showed that the products were not crosslinked structures. The products were decomposed by heating at relatively low temperatures and by dilute acids and alkalis.

INTRODUCTION

Cyclolinear- and cyclomatrix-phosphazene or crosslinked polymers prepared by the polycondensation reaction between dichlorocyclotriphosphazene and 3,3'-diamino-benzidine were usually rigid, with high melting points, of resinous composition, and had good stability at high temperature. The polycondensation reactions (1) or (2) are assumed to occur if the reaction is carried out in pyridine.

Cyclolinear structure

(1)

Crosslinked structure

(2)
The properties of the products are described in this paper.

EXPERIMENTAL

Dichlorocyclotriphosphazene, $(NPCl_2)_3$, was prepared by the modified method of Saito and Kajiwara[1]. The pure trimer (m.p. 112°C) was obtained by repeated fractional crystallization from light petroleum ether.

Dichlorocyclotriphosphazene (10^{-2} mol) and 3,3'-diaminobenzidine (3×10^{-2}, 2×10^{-2} and 1×10^{-2} mol) in pyridine (200 ml) were heated under reflux for 24 h. The insoluble products removed by filtration were washed with 150 ml of dry chloroform, distilled water and were dried over P_2O_5 for 24 h.

Analytical data

The infra-red spectra were recorded on a Shimazu Model-450 type spectrometer in the region 4000 to 200 cm^{-1} using the pressed KBr disc technique.

The thermal analyses were recorded on a Shimazu Model-20B and the thermal decomposition products formed by heating were determined by a Hitachi RMS-4 mass spectrometer. The properties of the products were measured by the methods described in previous papers[2,3]. The volume fraction (*VF*) and the degree of volume swelling (*DVS*) of the products formed by the polycondensation reaction were calculated by the following equation:

$$VF = \frac{1}{1 + (\rho_2/\rho_1)(W_a/W_b) - \rho_2/\rho_1}$$

where W_b is weight of the product, W_a is weight of the product reached at steady state in benzene solution, ρ_1 is specific gravity of benzene and ρ_2 is specific gravity of the product in benzene.

RESULTS AND DISCUSSION

The properties and yield of the products are summarized in *Table 1*. All of the products are amorphous, black coloured

Table 1 Yield, molecular weight, volume fraction and degree of swelling of the products obtained by polycondensation reaction between dichlorocyclotriphosphazene and 3,3'-diaminobenzine

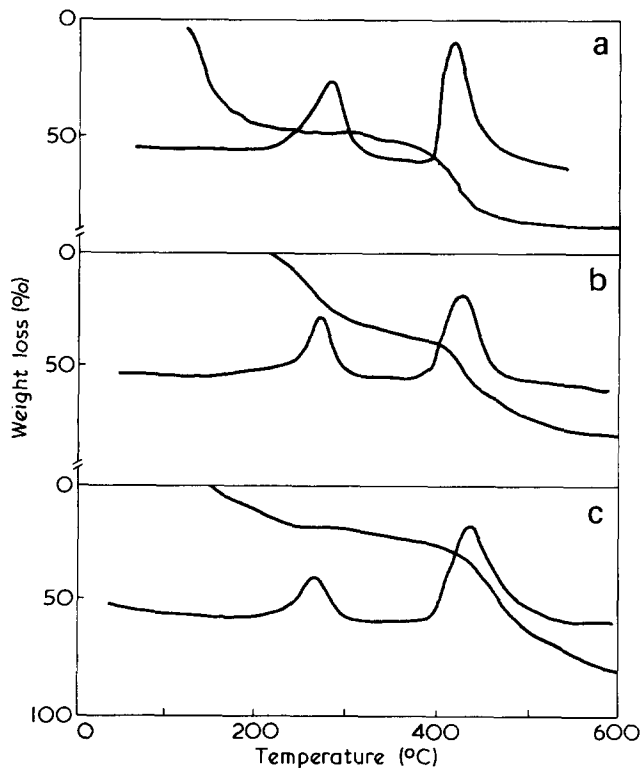
Mole ratio $(NPCl_2)_3/$ diamine	Yield (g)	Molecular weight	Volume fraction	Degree of swelling
1:1	9.78	17 500	1.03	0.97
1:2	6.92	5 800	0.96	1.04
1:3	5.32	4 300	0.93	1.07


Figure 1 Thermal gravimetric and differential thermal analysis of the products formed by polycondensation reaction between dichlorocyclotriphosphazene and 3,3'-diaminobenzidine in air at heating rate of 5°C/min. (NPCl₂)₃/diamine: (a) 1:1; (b) 1:2; (c) 1:3

solids, slightly soluble in polar organic solvents. However, the solubility was adequate for molecular weight measurement using vapour pressure or other methods.

The i.r. spectra of the products showed a characteristic band in the region 1300 to 1100 cm^{-1} attributable to the presence of P=N in P$_3$N$_3$ ring. On the other hand, P–NH–R formed by the polycondensation reaction between PCl$_2$ group and –NH$_2$ group, appears in the region 1000 to 900 cm^{-1} [4].

The low value of the degree of swelling (*Table 1*) supports the view that polycondensation occurred by reaction (1).

The softening points of the products appear to be over 300°C. Thermal decomposition temperatures as measured by differential thermal analysis and thermogravimetric analysis are shown in *Figure 1*. For all the products, the exothermic reaction peaks appear at 430°C and 270°C, respectively. Other properties of the products are specific gravity (25°C) 1.56 and water absorption (25°C) 22.0%.

The product is decomposed by 10% aqueous sulphuric acid, 5% and 10% aqueous sodium hydroxide and 5% and 10% aqueous nitric acid.

Crystallization of polyamides under elevated pressure:
2. Pressure-induced crystallization of nylon-6 (polycapramide) from the melt

S. Gogolewski* and A. J. Pennings

Laboratory of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands
(Received 30 December 1974)

A study has been made on the crystallization of nylon-6 from the melt under elevated pressures. Crystallization induced by pressures of up to 8 kbar at temperatures between 270° and 310°C did not lead to a significant increase of the melting temperature for nylon-6 containing 8% caprolactam. However, the melting peak temperature, as determined by differential scanning calorimetry was found to increase from 220° to 250°C for nylon-6 without caprolactam and crystallized under pressures exceeding 5 kbar for 50 h. The heat of melting of the nylon specimen crystallized under these conditions increased from 14 to 37 cal/g. Thermal decomposition of the polymer could be diminished by heating under pressure and extruding the nylon under vacuum prior to the high pressure crystallization experiments. The specific volume diminished gradually during isothermal crystallization and the melting temperature was found to increase with crystallization time. These observations point to a one stage process for the development of extended-chain crystals of nylon-6. The highest melting peak temperature of 256°C was recorded on nylon-6 which was crystallized at 315°C and 8 kbar for a period of 320 h.

INTRODUCTION

Pressure may have a pronounced effect on the solidification of polymers such as linear polyethylene. Extended chain crystals of polyethylene are formed if the crystallization is induced at an appropriate temperature by pressures exceeding 3 kbar as was shown by Wunderlich and Arakawa[1]. It was found by Rees and Bassett[2] that the molecules may not be fully extended after crystallization under elevated pressure but the fold length or lamellar thickness may increase with time. Additionally, Rees and Bassett provided evidence that extended chain crystals could also be produced by annealing polyethylene folded chain crystals near the melting temperature. Furthermore from differential thermal analysis as well as from dilatometry under pressure Bassett and Turner[3] concluded that above 3 kbar a new high-pressure phase[27] is formed in polyethylene and that the melting and crystallization process under these conditions occur in two stages. The effect of pressure on the crystallization of thin films of natural rubber was studied by Phillips and Andrews[4]. Edwards and Phillips[5] further developed the intensified argon high pressure system by which they were able to determine the increase of the lamellar growth rates with pressure and to observe concurrently the growth of single crystals, spherulites and oblate spheroids at different pressures applied to thin films of *cis*-polyisoprene.

So far little attention has been devoted to the effect of pressure on the crystallization of polyamides. Katayama and Yoneda[6] measured the crystallization kinetics and the increase in melting temperature of nylon-6 with pressure up to 2.5 kbar but they did not report any effect of pressure on the crystallinity, the structure and morphology of nylon-6. In general melt crystallized nylon-6 has a rather

low crystallinity in the order of 35% but a highly crystalline specimen may be prepared by zone-polymerization of ε-caprolactam as described by Liberti and Wunderlich[7]. The step heights in the fracture surfaces of this sample ranged up to 6700 Å which corresponds roughly to the extended chain length.

The main objective of the present investigation was to explore the possibilities of growing extended chain crystals of nylon-6 by subjecting the melt to elevated pressures. In the case of the high pressure crystallization of nylon-6 one may expect some complication resulting from the thermal degradation which is likely to occur when the polymer is heated to high crystallization temperatures above the ceiling temperature of roughly 250°C. This thermal decomposition, which is affected by catalyst residues and water present in the polymer, may be suppressed to some extent by high pressures if the thermodynamic stability of nylon-6 is similar to that of other polymers for which it was established that the ceiling temperature increased with pressure[8]. That the rate of formation of monomer and possibly oligomers may form a major problem in the high pressure crystallization of nylon-6 is strongly suggested by our finding[9] that application of this technique only led to an increase of crystallinity and melting temperature when previously the free caprolactam was removed from the polymer. This finding is well in line with the observation by Wunderlich[10] that pressure did not have a significant effect on the lamellar thickness of folded chain crystals of polyethylene grown from dilute xylene solutions. In their recent publication Treiber *et al.*[11] reported that about 8% of xylene in polyethylene suffice to inhibit the formation of extended chain crystals under pressure.

The present paper describes in detail the effect of pressure, temperature, time, thermal treatment, and sample purification on the crystallization behaviour of nylon-6. Changes in the solid state of the polymer as a result of vary-

ing the crystallization conditions were assessed by using differential scanning calorimetry.

EXPERIMENTAL

High pressure technique

The crystallization experiments were carried out using a simple piston—cylinder apparatus[12]. The thick-walled cylinder was equipped with a heating mantle of 500 W which was connected to a temperature regulator. This was monitored by a thermocouple inserted in the lower piston. The upper one was connected to a high-pressure ball-bearing so that the piston could be rotated during the crystallization experiments. By this set-up the stick-slip effect of the upper piston could be overcome[13]. The sealing of the cell was achieved by using small triangular shaped Teflon rings in conjunction with small anti-extrusion rings of graphitized bronze. The pressure was generated by a hydraulic press which was fitted with a Bordon gauge, a pressure regulator and a valve by which the pressure could be varied more accurately. Volume changes could be determined by measuring the displacement of the upper piston using a dial indicator that could be read to 0.001 mm. The inside diameter of the cylinder was 14 mm ± 0.001 and the polymer samples examined were approximately 1 cm in height. We did not employ a liquid as a pressure transmitting medium in these experiments.

The calibration of the Bordon gauge was performed with the aid of a Philips unbonded strain gauge. Pressure losses were assessed by measuring the pressure at which the solid—solid phase transition occurs in ammonium fluoride[14] (analytical reagent containing 5% H_2O). This I—II transition, accompanied by a volume decrease of 24%, takes place at a pressure of 3606 bars at a temperature of 25°C. The piston displacement *versus* pressure cycles were measured up to 10 kbars and were found to be reproducible if readings of the piston height were taken after some vibration of the piston by quickly opening and closing the release valve. Nevertheless the compression and decompression curves displayed a hysteresis which may in part be due to the internal friction of the medium. In the compression stroke the I—II transition was observed at 3800 bars. The phase change was completed in 6 min. It could be interrupted by a slight variation of the pressure. The II—I transition on decompression occurred at 3440 bars and was finished in 42 min. In general pressure losses for increasing and decreasing pressure in the case of non-hydrostatic systems may not be equal. This casts some doubt on the validity of averaging the two values of the transition pressure[15]. Nevertheless, the difference between the two pressures is relatively small and averaging gives the correct value so that further correction for the applied pressures were omitted. This seems certainly justified in view of the fact that the volume—pressure and volume—temperature curves for the solid and the melt did not exhibit any hysteresis if volume readings were made after moving the piston three times over a small distance and the time interval between successive volume changes was not less than 10 min. This period of time might be needed for dissipation of the heat of compression or decompression and for relaxation of stress and pressure gradients[23].

Thermal analysis

For the thermal analysis of the samples a Perkin Elmer differential scanning calorimeter 1B was used which was

calibrated with benzoic acid and indium according to standard procedures. Thermograms were measured at a scan speed of 8°C/min if not stated otherwise.

Materials

In the course of this study four nylon-6 samples were used which will be referred to as samples A, B, C, and D.

Sample A was unfractionated nylon-6 (received from Akzo) obtained by catalytic polymerization of caprolactam. The polymer did not contain titanium dioxide. The viscosity-average molecular weight was 85×10^3. The viscosity measurements were carried out on 98% sulphuric acid solutions at 25°C and the viscosity-average molecular weights were calculated from the Matthes equation[16]. The amount of free caprolactam in the nylon-6 was 8% by wt.

Sample B was prepared by dissolving sample A in concentrated formic acid to a 5% solution. Subsequently the polymer was precipitated by pouring the solution into an excess of a 50% by wt mixture of acetone and water. The precipitate was washed with water and methanol and finally with acetone before drying to a constant weight in a vacuum desiccator at room temperature. The polymer, purified by this technique, had a viscosity-average molecular weight of 90×10^3 and did not contain caprolactam according to the infra-red analysis. Absorption bands at 11.2 and 11.5 μm ascribed to caprolactam were absent[17].

Sample C was obtained by the following treatment of the original nylon-6. Pellets were first extracted with hot water and acetone to remove the caprolactam. After drying the polymer was extruded under vacuum according to the technique developed by Gogolewski[18]. By this method residual caprolactam is removed effectively. After purification the polymer had a viscosity-average molecular weight of 95×10^3.

Sample D was prepared by polycondensation of caprolactam in the presence of water. This fibre-forming quality was free from TiO_2 and caprolactam. It was extracted with water in a Soxhlet, washed with alcohol and acetone and dried in a vacuum desiccator over P_2O_5 for 24 h (Toyo Rayon Company Ltd). The viscosity-average molecular weight was 29.8×10^3 and $M_w/M_n = 1.48$[19].

RESULTS

Characterization

The effect of pressure on the crystallization of nylon-6 may be evaluated by using several techniques such as scanning and transmission electron microscopy on fracture surfaces, i.r. reflection spectroscopy, wide and small-angle X-ray diffraction and differential scanning calorimetry (d.s.c.). Although it is recognized that the application of all these methods is needed to gain a better understanding of the phase transition under pressure, in our search for the optimum conditions for producing extended chain crystals of nylon-6 it was found appropriate to rely primarily on the calorimetric technique for characterization of the samples crystallized under high pressures.

Thermograms for various nylon-6 samples crystallized under widely different conditions of pressure and temperature are shown in *Figure 1*. The melting peak temperatures of these endotherms vary from 175° to 250°C and furthermore the heat of fusion is seen to differ considerably. Thermograms were also taken at temperatures in the neighbourhood of the glass transition temperature which may appear at about 50°C if the nylon is conditioned properly[20].
Figure 1 Melting thermograms for various nylon-6 samples. 1, endotherm for the original sample (A); – – –, sample without caprolactam, both crystallized at ambient pressure. Crystallized at 295°C and 6.5 kbars for 50 h: 2, original sample (A); 3, sample B free from caprolactam; 4, sample C extruded under vacuum
Figure 2 Effect of the scan speed on the melting peak temperature for various nylon-6 samples. ○, Original sample (A); ×, sample B free from caprolactam; ●, sample C extruded under vacuum; □, sample B crystallized at 295°C and 6.5 kbars for 50 h; △, sample C crystallized at 295°C and 6.5 kbars for 50 h

The d.s.c. scans for the nylon-6 crystallized under high pressure did not exhibit any endothermic peak or change in the specific heat between room temperature and the melting range. The high pressure crystallized samples could be distinguished from those crystallized under ambient pressure in a marked difference in superheatability. *Figure 2* illustrates the effect of the scan speed on the melting peak temperature. Samples crystallized at atmospheric pressure exhibit only a slight superheating whereas the melting peak temperature for the high pressure crystallized nylon-6 increases from 250°C at a scan speed of 8°C/min to 274°C at a scan speed of 64°C/min.

Effect of pressure on the melting temperature

In order to be able to select the appropriate crystallization conditions it was necessary to dispose of information

about the dependence of the melting temperature on pressure. For this reason the specific volume was determined as a function of temperature at various pressures. At first the nylon specimen of 2 g was compressed under a pressure of 10 kbars for 2 h. After adjustment of the pressure to the proper value, the temperature was raised in steps of 5°C. When temperature equilibrium was attained the piston was moved three times in order to reduce the pressure loss by friction and the height of the piston was measured. Each temperature step was carried out in about 25 min. A typical volume–temperature curve for sample B measured at a pressure of 5 kbars is shown in *Figure 3*. In general such curves did not display an abrupt beginning of the melting process but the end of melting could be determined rather accurately from the sudden change in thermal expansion (T_3). Also the beginning of crystallization upon reversing the temperature programme could be detected (T_2). It should be noted that the curves for the change in volume on increasing and decreasing the temperature for the polymer melt coincide. This indicates that the pressure losses due to internal stresses and interfacial friction appear to be within experimental error for the applied method. The effectiveness of the crystallization under pressure is indicated by the final volume contraction at the end of the temperature–volume cycle.

The effect of pressure on the final melting temperature (T_3) for two melt-crystallized nylon-6 samples is illustrated in *Figure 4*. The increase in melting temperature with
Figure 3 Dependence of the specific volume on temperature for nylon-6 (free from caprolactam) under a pressure of 5 kbars. The end of melting and the beginning and end of crystallization are indicated by T_3, T_2, and T_1 respectively. ○, Heating run; ●, cooling run
Figure 4 Dependence of the end melting temperature on the applied pressure for nylon-6. ○, Sample C ($\overline{M}_v = 85 \times 10^3$); ●, sample D ($\overline{M}_v = 29.8 \times 10^3$)
Figure 5 Dependence of the atmospheric melting peak temperature on the crystallization temperature and pressure for various nylon-6 samples. The crystallization time amounted to 50 hours. Sample B: ✕, 3.2; ■, 3.9; ○, 4.5; △, 4.9; ●, 6.5; ▽, 8 kbars. Sample C: □, 4.5; ▲, 4.9; +, 6.5; ▼, 8 kbars

pressure amounts to $16°C/kbar$ and appears to be the same for the high molecular weight nylon-6 (sample B) ($M_\nu = 90 \times 10^3$) and the fibre forming quality with $M_\nu = 29.8 \times 10^3$ (sample D).

Pressure induced crystallization of sample A

The first high pressure crystallization experiments were carried out on the original nylon-6 containing 8% by wt caprolactam. Crystallization was induced by heating the polymer to temperatures in the range of 225°C to 260°C and applying pressures ranging from 0.65 to 4.5 kbars. After 60 h the high pressure dilatometer was cooled down to room temperature and subsequently the pressure was reduced to 1 atmosphere. The d.s.c. thermograms of these samples displayed a melting peak at 225°C and a tail at lower temperatures. These thermograms should be compared with that of the original nylon-6 which only had a melting peak at 220°C (*Figure 1*).

Attempts were made to improve the crystalline structure of the nylon-6 by heating sample A to temperatures between 270° and 310°C and inducing crystallization by pressures between 4.9 and 8 kbars. Samples crystallized for 60 h under these conditions were found to be rather sticky, smelled of ammonia and the d.s.c. traces showed a melting peak at 215°C and a long low temperature tail originating from crosslinking and from the low molecular weight polymer that was formed by thermal degradation[21].

Pressure induced crystallization of sample B

Thermal stability of the nylon-6 may be improved by removal of the catalyst residues[21] and for this reason the polymer was dissolved in formic acid and recovered by pouring the solution into an excess of acetone water mixture. By this method of purification also the caprolactam is removed and thermal stability may have improved additionally as a result of blocking the amine end-groups by reaction with formic acid. This nylon, referred to as sample B, was first compressed at room temperature by applying 8 kbars for 30 min. After releasing the pressure to 1 bar the sample was heated up to 290°C and crystallization was initiated by applying 6.5 kbars. It should be mentioned that for melting of the nylon at 290°C, a period of 15 min was required to obtain samples that appeared to be homo-

geneous. If heating at this temperature was carried out for a shorter period the core of the specimen remained powderlike. Crystallization under these conditions for 48 h resulted in a marked shift in the melting peak temperature from 220° to 235°C. This increase in melting temperature seems to be caused by the isothermal crystallization at 290°C since a variation in the cooling rate between 10°C/h and 100°C/h did not affect the melting behaviour.

In this exploratory stage of this investigation several treatments of the nylon-6 were tried out for improving the crystalline order during high pressure crystallization. For instance, nylon-6 specimens were annealed in order to bring about complete conversion from the γ- to the more stable α-crystalline modification[20]. If sample B was aged at 100°C and 8 kbars for 15 h, prior to the high pressure crystallization according to the method described above, a d.s.c. melting peak temperature of 240°C was found. Thus the annealing step resulted in an additional increase of 5°C in melting temperature. Infra-red analysis of this sample revealed that a small amount of caprolactam was formed in the course of this crystallization experiment. Since the removal of caprolactam from nylon-6 had such a pronounced effect on the crystallization under pressure it was considered to be pertinent to avoid all experimental conditions that may favour the formation of monomer and other compounds. Therefore the nylon-6 was heated to the crystallization temperature of 290°C under a pressure of 6.5 kbars. Subsequently the pressure was reduced to 100 bars for 15 min to melt the polymer and crystallization was set in by enhancing the pressure to 6.5 kbars. Applying this alternative method to sample B gave rise to a melting temperature at ambient pressure of 246°C another gain of 6°C due to heating under pressure.

It seems justified to conclude from these experiments that it is of basic importance for the high pressure crystallization of nylon-6 to avoid any thermal depolymerization and degradation. It was found that the thermal decomposition was negligible if the samples were melted for 15 min at temperatures up to 315°C (under pressure).

The next step in this research was to find the optimum crystallization conditions as regards pressure and temperature. At first the crystallization temperature was varied while the other steps of the procedure remained unchanged. As is illustrated in *Figure 5* the melting peak temperature measured at atmospheric pressure increased with the crystallization temperature. For a pressure of 6.5 kbars and crystallization temperatures of 273°C and 290°C melting temperatures were found of 240°C and 246°C respectively. Such experiments were also carried out at different pressures. This allows crystallizing the polymer in different temperature ranges under similar degrees of supercooling. At low pressures up to 3.9 kbars an increase in crystallization temperature range of 20°C appears to have only little effect on the crystallization process as judged from the d.s.c. thermograms. The same holds for crystallization temperatures of about 280° and 310°C and pressures of 6.5 and 8 kbars, respectively, although the level of the melting peak temperatures of these nylon-6 crystals is substantially higher than that of samples crystallized at lower pressures.

Sample C

Similar experiments were performed on sample C which was obtained by extruding the original nylon-6 under vacuum. Characteristic of this sample was that it did not contain caprolactam and since it was extruded in a glass pipe
Figure 6 Dependence of the atmospheric melting peak temperature on the applied crystallization pressure for various nylon samples. The crystallization temperature was 40°C below the end melting temperature for all specimens. Crystallization time was 50 h. ▲, Sample A containing 8% caprolactam; ○, sample B free from caprolactam; ●, sample C free from caprolactam and extruded under vacuum; ×, sample C with additional ageing at 100°C for 15 h prior to crystallization

with an inside diameter equal to that of the high pressure dilatometer, sample C contained considerably less voids and trapped air at the beginning of the high pressure experiments than samples A and B. Some of the data for sample C are compiled in *Figure 5* which illustrates that by applying the same crystallization procedure the atmospheric melting peak temperature is about 5°C higher than that for sample B crystallized under corresponding conditions.

A comparison of the effect of pressure on the melting temperature of the three nylon-6 samples A, B, and C is made in *Figure 6*. All data points in this graph were obtained by crystallizing the samples for 50 h and at the same degree of supercooling of 40°C, viz., the crystallization temperature was 40°C below the end melting temperature of the folded chain crystals under the corresponding pressure. *Figure 6* clearly illustrates that the pressure induced crystallization had little effect on sample A and raised the melting temperature of sample C and B about 25°C. The difference in melting temperature of 5°C between sample C and B was already found for crystallization from the melt at ambient pressure. At 8 kbars the difference amounts to 8°C. A further distinction between these two nylon-6 specimens is that annealing of the extruded sample at 100°C under 8 kbars for 15 h had no measurable effect on the high pressure crystallization. The data points for the annealed and unannealed sample C lie on the same curve demonstrating the reproducibility of the measurements. The most conspicuous observation is that up to 2 kbars there is hardly any effect of pressure noticeable but the most pronounced influence of pressure occurs between 3 and 5 kbars. Especially for sample C a strong increase in melting peak temperatures is observed for crystallization pressures close to 5 kbars. For pressures exceeding 5 kbars there is a decrease in melting temperatures for sample A whereas for samples B and C there is still a slight increase. It was verified whether thermal degradation had occurred during the crystallization at these pressures beyond 5 kbars

but i.r. analysis and viscosity measurement could not detect any change in molecular structure. In conclusion, 5 kbars seems to be the most effective pressure to induce crystallization in nylon-6 for crystallization times of ~50 h.

Another thermal quantity that reflects the degree of order of the nylon-6 samples is the heat of fusion. The curve in *Figure 7* represents the dependence of the heat of fusion as measured in d.s.c. on the crystallization pressure, and a comparison is made between sample C and B for the 50 h crystallization experiments. Again sample C has the highest values for the heat of fusion which varies from 15 to 37 cal/g for crystallization under 8 kbars. A marked increase in this heat of melting occurs around 5 kbars.

Crystallization time

The preceding sections have been concerned with experiments in which the isothermal crystallization was extended over periods of 48 or 50 h. These crystallization times were rather arbitrary and it was considered pertinent to investigate the influence of time on the solidification process under pressure. *Figure 8* shows that there is a rather strong dependence of the crystallization time on the crystalline state as reflected by the d.s.c. melting peak temperature. The rise in the melting temperature is most pronounced up to a crystallization time of 80 h and appears to depend on pressure and crystallization temperature. There is a trend that at lower pressures the melting temperature continues to increase over a longer period than at higher crystallization pressures. These data suggest again that the crystallization process proceeds more rapidly at the higher temperatures and pressures. For instance at a crystallization temperature of 295°C and a pressure of 6.5 kbar the
Figure 7 Dependence of the heat of melting on the crystallization pressure. The crystallization time was 50 h and the temperature 40°C below the end melting temperature. ○, Sample C; ●, sample B
Figure 8 Dependence of the atmospheric melting peak temperature on the crystallization time. Sample B: X, 245°C and 3.2 kbars; O, 260°C and 3.9 kbars; ●, 265°C and 4.5 kbars; □, 270°C and 4.9 kbars; ■, 295°C and 6.5 kbars. Sample C: ▲, 270°C and 4.9 kbars; △, 295°C and 6.5 kbars

maximum melting temperature of 246°C for sample B was reached after 50 h but at 245°C and 3.2 kbars the melting temperature still increased after 200 h. It should be mentioned that although the melting temperature appeared to be constant after a certain period the crystallization process seemed to continue for considerably longer times as disclosed by the piston displacement that was recorded during crystallization (*Figure 9*). In separate experiments at this temperature of 295°C and 6.5 kbars the crystallization was interrupted at various crystallization times and the nylon-6 samples were analysed by differential scanning calorimetry. These thermograms are inserted in *Figure 9* at the corresponding crystallization time. They show a considerable narrowing of the melting peak as the crystallization proceeds and there seems to be no two peak melting processes as might be expected if folded chain crystals would transfer abruptly into extended chain crystals.

The results described above clearly indicate that also the crystallization time is an important variable and extension to longer times may lead to a more perfect crystalline state. The ultimate conditions for pressure induced crystallization were tried out at 315°C and 8 kbars for a period of 320 h. The ultimate melting temperature of sample B, crystallized under these circumstances, turned out to be 246°C which is the same value as was obtained by crystallization under less extreme circumstances. According to the i.r. analysis some caprolactam was formed. However, sample C appeared to be able to withstand these severe conditions better and no decomposition could be detected after such a crystallization experiment. The melting peak temperature of this nylon-6 specimen was 256°C.

DISCUSSION

The experimental observations described above clearly demonstrate that pressure has a marked effect on the crystallization process of nylon-6 if the polymer has been purified prior to the crystallization experiment. Removal of the free caprolactam either by dissolving the polymer or by the extrusion under vacuum does not lead to the same increase of the melting temperature and the heat of fusion of the high pressure crystallized nylon-6. The difference in crystallization behaviour between the nylons purified by these two methods is to be attributed to a difference in

void content. Compression of the nylon powder, obtained by the precipitation method, even at 10 kbars and 100°C did not yield a material with homogeneous appearance when examined under the microscope. The presence of voids, remaining as a result of internal friction, and possibly of trapped air, apparently enhanced the rate of thermal degradation. The nylon, that was extruded under vacuum, turned out to be more resistant to be exposed for longer times to high temperatures which resulted in a more perfect solid state. It seems to be the amount of the caprolactam rather than for instance a variation in the water content that interferes with the development of a highly crystalline nylon. The effect of the water content has not been investigated systematically but variation in exposure time to the humidity in the laboratory and keeping specimen in a vacuum desiccator over P_2O_5 did not give rise to any discernable difference in high pressure crystallization behaviour[24].

The basic question that may be raised is therefore why caprolactam inhibits the chain extension during the high pressure crystallization. This may essentially be the same phenomenon as the suppression of chain extension in polyethylene by the presence of xylene. In the case of polyethylene the formation of extended chain crystals occurs through the intermediate phase as concluded by Bassett *et al.*[25]. For nylon-6 we did not notice any plateau in the volume–temperature curve and the gradual decrease in volume upon isothermal crystallization also did not show any interruption indicative of a two-stage process. The crystallization mechanism of polyethylene may differ substantially from that of nylon in which the breakage and formation of hydrogen bonds plays such a prevailing role. Hydrogen bond formation was also the rate determining step in the formation of folds during annealing of oriented nylon-6. If indeed the lower melting temperatures and heat of fusions need be ascribed to the presence of folds then one may say that the caprolactam molecules stabilize the folds and that thereby the effect of pressure on the crystallization has been diminished. Another difference between polyethylene and nylon-6 is that a pressure of 5 kbars seems to be most effect for the latter while for the former polymer chain extension occurs already at 3 kbars.

Finally, some remark should be made about the melting temperature. The value of 256°C, found for the extruded
Figure 9 Change of piston height *versus* the crystallization time for sample B at 295°C and 6.5 kbars as well as thermograms and melting peak temperatures of the nylon-6 at various crystallization times. A, $T_m = 220°$, $\Delta H_m = 12.3$; B, $T_m = 223°$, $\Delta H_m = 22.1$; C, $T_m = 230°$, $\Delta H_m = 26.7$; D, $T_m = 246°$C, $\Delta H_m = 36.5$ cal/g

nylon crystallized at 315°C and 8 kbars, exceeds substantially the melting point of an equilibrium crystal which is reported[7] to be 232°C. On the other hand, Arakawa and Nagastoshi[26] estimated that the melting point of nylon-6 might be at least 270°C or even 306°C. It is our impression that values higher than 256°C may be achievable if extreme measures are taken to remove caprolactam and conditions for improvement of the solid state are adopted that avoid any formation of the monomer.

Effect of molecular weight on crystallization isotherms of high molecular weight poly(ethylene oxide) fractions

J. Q. G. Maclaine and C. Booth

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 8 January 1975)

Dilatometric crystallization isotherms have been determined for a set of poly(ethylene oxide) fractions ranging in molecular weight from 2×10^4 to 1.6×10^6. For a given fraction the isotherms obtained for different crystallization temperatures can be superimposed over most of the crystallization. For a given crystallization temperature the degree of crystallinity obtained in the primary stage of the crystallization varies greatly with molecular weight, and superimposition of the isotherms is not possible. Secondary crystallization processes are pronounced when the molecular weight $(\overline{M}_v)$ exceeds 10^5.

INTRODUCTION

In a recent paper[1] we have reported the molecular weight dependence of spherulite growth rate for a set of poly(ethylene oxide) fractions with molecular weights in the range 10^4 to 10^6 (g/mol). The molecular weight dependence of other features of the crystallization process are of interest. The bulk crystallization rate and the final extent of crystallinity are accessible, in principle at least, via dilatometric determination of the crystallization isotherm[2,3]. Most work, in this area, on poly(ethylene oxide) fractions has been with molecular weights less than 20 000[4-8] or with one or two high molecular weight fractions only[6,8,9]. In this paper we present dilatometric data for seven poly(ethylene oxide) fractions covering the molecular weight range $(\overline{M}_v)$ 23 000 to 1 600 000.

EXPERIMENTAL

Preparation and characterization of fractions

The preparation and characterization of fractions has been described earlier[1]. The fractions used in the dilatometric work are listed in *Table 1*, together with their intrinsic viscosities (benzene at $25°C$), viscosity-average molecular weights[10], and molecular weight ratios $(\overline{M}_w/\overline{M}_n$, g.p.c.). [Shear corrections were not applied to the intrinsic viscosity of fraction N1600000, so the molecular weight of this fraction will be too low by a few per cent.] The prefixes used in denoting the fractions refer to their sources: H to Hoechst Chemicals; R to our own preparation; W to Polyox

WSR-35 and N to Polyox N-750, both supplied by Union Carbide Ltd.

Dilatometry

The dilatometers were constructed of glass, being L-shaped with a horizontal tube (4–6 mm i.d., volume 1 to 2 cm³) part-filled with polymer and with a vertical capillary (0.5 mm i.d. Veridia tubing). A known weight of polymer (100–200 mg) was moulded in high vacuum, sealed into the dilatometer, outgassed and confined with mercury. In a crystallization experiment the dilatometer was usually placed in boiling water for 10 min and then transferred to a stirred oil bath held (to ±0.05K) at the required crystallization temperature, T_c. The temperature of the dilatometer fell almost to T_c within 0.5 min and reached T_c within 2 min. The height of mercury in the capillary was followed by means of a cathetometer (to ±0.004 cm). The total contraction owing to crystallization was usually in the range 3 to 8 cm. The time of transfer was taken as the starting time for the crystallization, and the height of mercury in the capillary 2 min from transfer was taken as the starting height. Our technique was suitable for determination of crystallization isotherms with half-lives as low as 10 min.

In order to assess the possible loss of polymer during its incorporation into the dilatometer, certain dilatometers were opened after measurements were completed and the polymer was recovered. These experiments show that the weight of polymer is known to within 2%. The largest error in determining the crystallization isotherms is in determining the initial height of the mercury in the capillary. We estimate an overall precision of ±3% for our estimates of the extent of crystallinity.

RESULTS AND DISCUSSION

Observations with the polarizing microscope of thin films of these fractions have been reported earlier[1]. Results pertinent to this work are as follows: (i) spherulites were initiated sporadically with time over the initial part of the crystallization; (ii) for given crystallization conditions the spherulite number density, ν, varied from fraction to fraction. Fraction W84000 had an abnormally low value of

Table 1 Characteristics of poly(ethylene oxide) fractions

Fraction	$[\eta]$ in benzene at 25°C (cm³/g)	$\overline{M}_v$	$\overline{M}_w/\overline{M}_n$ (g.p.c.)
H23000	37	23 000	1.20
R42000	59	42 000	1.30
W84000	95	84 000	1.21
N130000	125	126 000	1.35
W240000	194	244 000	1.22
W540000	339	538 000	1.53
N1600000	707	1 570 000	1.85

v; (iii) spherulite radii increased linearly with time up to the point of impingement. Impinged spherulites eventually filled the field of view; (iv) the spherulites had a close-textured appearance which did not differ from fraction to fraction.

We have also used low-angle X-ray scattering (the method has been described earlier[11]) to check that the essential structure of the crystalline state, i.e. a stacked crystalline lamella system, was unchanged across the range of molecular weights studied. Lamella spacings (T_c = 55.7°C) ranged from 23 nm (H23000) to about 30 nm (N1600000).

Volume contractions were usually measured for fractions melted at 100°C for 10 min. Certain crystallizations were studied after melting at 80°C for 10 min. The crystallizations were faster under these conditions, in keeping with the higher spherulite number densities observed[1,6] at lower melting temperatures. Otherwise the crystallization isotherms were identical with those obtained normally. The results given below all pertain to melting at 100°C for 10 min.

Crystallization isotherms, $X_v(t)$

The weight fraction of polymer in the crystalline state at crystallization temperature T_c and at time t can be defined by:

$$X_v(t) = \frac{V(t) - V_l^0}{V_c^0 - V_l^0} \tag{1}$$
Figure 1 Superimposed crystallization isotherms of poly(ethylene oxide) fraction H23000 for crystallization temperatures of: ○, 54.7°; ●, 55.6°; □, 57.0°; ■, 58.1°C
Figure 2 Superimposed crystallization isotherms of poly(ethylene oxide) fraction N130000 for crystallization temperatures of: ○, 57.0°; ●, 58.1°; □, 59.4°C

Figure 4 Superimposed crystallization isotherms at crystallization temperature 57.0°C for poly(ethylene oxide) fractions: ○, H23000; ●, N130000; □, W540000; ■, N1600000

where V_l^0 and V_c^0 represent the specific volumes of liquid and crystalline polymer at temperature T_c, and $V(t)$ represents the specific volume of the system at temperature T_c and time t. Values for V_l^0 and V_c^0 can be determined, for a given T_c, from known values of the specific volumes of molten polymer (from pyknometric measurements) and crystalline polymer (via unit cell dimensions from wide-angle X-ray measurements) together with appropriate coefficients of expansion (α_l^0, α_c^0: from dilatometric measurements). For poly(ethylene oxide) we use the following data:

Liquid: $V_l^0(25°C, cm^3/g) = 0.891^{12}$, $\alpha_l^0(cm^3\ g^{-1}\ K^{-1}) =$

$0.00069^{12,13}$

Crystal: $V_c^0(25°C, cm^3/g) = 0.813^{14}$, $\alpha_c^0(cm^3\ g^{-1}\ K^{-1}) =$

0.00015^{12}

Evaluated in this way the crystallization isotherm $X_v(t)$ represents the absolute degree of crystallinity of the polymer (as assessed by dilatometry).

Crystallization isotherms (semilogarithmic plots of X_v against t) are illustrated in *Figures 1* to *5*. These isotherms are all superimposed at the point $X_v(t) = 0.1$: crystallization times to $X_v(t) = 0.1$ ($t_{0.1}$) are listed in *Table 2*. For a given fraction the isotherms obtained for different crystallization temperatures can be superimposed over most of the crystallization. This is illustrated in *Figures 1* to *3* for fractions H23000, N130000 and N1600000. Over the range of

fractions we have studied the superimposition of isotherms improves as the molecular weight increases (compare *Figures 1* and *3*). This is because the degree of crystallinity achieved in the primary stage of crystallization is less influenced by T_c when the molecular weight of the fraction is high.

For a given crystallization temperature the isotherms $X_v(t)$ obtained for different fractions cannot be superimposed (*Figures 4* and *5*) except for the two fractions of lowest molecular weight (*Figure 6*). It is possible that the nature of the spherulite initiation process varies somewhat within the range of molecular weights we have investigated[6]. Most obviously, however, it is clear that the degree of crystallinity achieved in the primary stage of the crystallization varies markedly with $\bar{M}_v$ when $\bar{M}_v > 50\,000$ (see *Table 3*). It is also apparent that the isotherms of the higher molecular weight fractions are affected by a slow secondary process.

We know, from observations with the polarizing microscope, that the termination of the space filling process (i.e. the point at which the spherulites completely fill space) is at or about the end of the fast part of the crystallization process (as judged by the crystallization isotherm). For the lower molecular weight fractions (H23000, R42000) this is at or about the end of the crystallization process. For the higher molecular weight fractions ($\bar{M}_v \geqslant 84\,000$) X_v increases slowly with time long after the space filling process is complete. Such a slow volume contraction is usually[3] called a secondary crystallization process, to distinguish it from the primary (space filling) process. Further observations on the secondary process in the crystallization of our highest molecular weight fraction (N1600000) are reported in the Appendix to this paper.

In view of the secondary process, and the limited time scale of our experiments, it is not possible to identify the ultimate degree of crystallinity for most of the fractions. Here we compare $X_v(t)$ evaluated at a comparable stage of each crystallization by taking as the point of comparison a time $t' = 100t_{0.1}$. Values of $X_v(t')$, obtained by extrapolation or interpolation of the isotherms, are listed in *Table 3*. Only for fractions H23000 and H42000 do the values of $X_v(t')$ coincide with the ultimate extents of crystallinity[15]: for the highest fractions the ultimate crystallinity may greatly exceed the values we quote (see *Figure 4* and Appendix). For a given fraction $X_v(t')$ is increased slightly as T_c is increased. For a given T_c, $X_v(t')$ is decreased markedly as $\bar{M}_v$ is increased beyond 50 000. The variation of $X_v(t')$ at 57°C with $\bar{M}_v$ is illustrated in *Figure 7*. Other data[12] for a fraction of $\bar{M}_v \sim 11\,000$ are included in *Figure 7*. Fractions with $\bar{M}_v$ in the range 6000–4000, when crystallized at 57°C, form extended chain crystals[11,16] and have low crystallinities (at 57°C) due to fractionation.

Crystallization rates

The time ($t_{0.1}$) to attain a degree of crystallinity $X_v = 0.1$ is a measure of the overall crystallization rate which can be sensibly compared for different fractions because the isotherms $X_v(t)$ are roughly superimposable before $t_{0.1}$ (*Figures 4* and *5*). Reciprocal tenth-lives, taken from *Table 2*, are plotted against $\bar{M}_v$ (double logarithmic plot) in *Figure 8*. Data for fraction W84000 are omitted from this plot in view of the anomalously low spherulite number density observed for this sample. The overall crystallization rate ($1/t_{0.1}$) measured at constant T_c is increased

as $\overline{M}_v$ is increased, and perhaps attains a maximum near $\overline{M}_v = 8 \times 10^5$. Bearing in mind that the spherulite number density in the fractions is observed[1] to increase as $\overline{M}_v$ is increased, these results are consistent with the molecular weight dependence of the spherulite growth rates, G_s presented elsewhere[1], i.e. a maximum in G_s *versus* $\overline{M}_v$ at or about $\overline{M}_v = 2 \times 10^5$.

The temperature dependence of $t_{0.1}$ leads, via the usual assumptions[1], to values of end interfacial free energy σ_e for the higher molecular weight fractions ($\overline{M}_v > 10^5$) of 5 to 6 kJ/mol of chains emerging. This is in good agreement with the value of σ_e obtained[1] from the temperature dependence of the spherulite growth rates of the higher molecular weight fractions, i.e. $\sigma_e \sim 5.5$ kJ/mol. This correspondence between the temperature dependence of spherulite growth rate and of overall crystallization rate (provided that elementary precautions are taken with regard to melting and crystallization procedures) has been noted earlier[17]

Crystallization isotherms, $\chi_v(t)$

The weight fractions of polymer incorporated into the crystalline (spherulitic) phase at the crystallization temperature and at time t can be defined by:

$$\chi_v(t) = \frac{V(t) - V_l^0}{V_c(t) - V_l^0} \tag{2}$$

where $V_c(t)$ represents the specific volume of the crystalline phase at temperature T_c as it actually exists within the spherulite at time t. (The other symbols have been defined earlier.) This specific volume, $V_c(t)$, cannot be determined except in the simple case that the crystallization is by a single process, occurring at the spherulite boundary, and that the (impinged) spherulites eventually fill space. For this case V_c is independent of t and equal to the specific volume of the system when crystallization is complete, and:

$$\chi_v(t) = \frac{V(t) - V(0)}{V(\infty) - V(0)} \tag{3}$$

where the specific volumes relate to zero time $[V(0) = V_l^0]$ and infinite time $[V(\infty) = V_c]$.

For a given phase morphology and phase initiation process, a simple crystallization process as described above leads to a crystallization isotherm $\chi_v(t)$ which can be described by an Avrami equation[2,3]:

$$1 - \chi_v(t) = \exp(-zt^n) \tag{4}$$

The phase morphology is spherulitic which, together with the observation that not all spherulites are initiated instantaneously, means that the exponent n should have a value somewhat greater than 3. The rate constant z depends upon the spherulite growth rate and the spherulite number density (which is a function of time) and can be related directly to $t_{0.1}$ only if the crystallization isotherms fit equation (4)[2,3].

Fractions with molecular weights exceeding 50 000 cannot be analysed in this simple way because of the prominent secondary process. Crystallization isotherms (semilogarithmic plots of χ_v against t) for fractions H23000 and R42000 are illustrated in *Figure 9*. The isotherms are superimposed

at the point $\chi_v(t) = 0.1$. The curve drawn through the data is the Avrami isotherm with $n = 3$. The best value of n to fit equation (4) to the data of *Figure 9* is about 3.5. In view of the complexity of the crystallization process the agreement between the prediction (from the observations with the microscope) and the experimental result is satisfactory.

Comparison with polyethylene

Crystallization isotherms for a set of fractions of linear polyethylene with molecular weights in the range 4000 to 8 000 000 have been reported by Ergoz *et al.*[18]. In most respects our results for poly(ethylene oxide) parallel the results for polyethylene. For example our data can be superimposed to a similar extent; the variation of the extent of crystallinity $[X_v(t')]$ with molecular weight is similar, as is the range of $X_v(t')$ observed; and the variation of crystallization rate with molecular weight is also similar. We have considered fitting the crystallization isotherms X_v with an Avrami equation (as advocated by Ergoz *et al.*) but we do not find integral values of the exponent n.

APPENDIX

We have investigated the secondary process in the crystallization of fraction N1600000 in some detail. A sample was crystallized at 57.0°C for 100 min (to $X_v = 0.38$), by which time the primary crystallization was complete (see *Figure 3*). The dilatometer was then transferred to an oil bath usually held at a higher temperature T_a. After 15 to 30 min the dilatometer was returned briefly to the primary crystallization bath in order to determine whether partial melting had occurred at T_a; in the event partial melting only occurred to an appreciable extent at $T_a = 66.4°C$ when the value of X_v dropped by 0.015. The changes in X_v, from the values 2 min after transfer to the bath at T_a, are plotted against time in *Figure A1*. In the range $55 < T_a < 60°C$ the secondary process is practically temperature independent. In the range $60 < T_a < 67°C$ the secondary process varies with temperature, though not in a systematic way. Melting temperatures for samples held at T_a, measured as described earlier[11,19], are listed in *Table A1*. The increase in T_m during the secondary process may be taken to indicate that some process of crystal perfecting occurs.

Taken together these data give no indication that the secondary process in the crystallization of this high molecular weight fraction of poly(ethylene oxide) can be reduced to a simple mechanism, be it lamella crystal thickening[20] or volume relaxation[9].

Dynamic transition of grafted polybutadiene in ABS resins

T. Riccò, A. Pavan and F. Danusso
Industrial Chemistry Department, Macromolecular Chemistry and Materials Section, Polytechnic Institute, 20133 Milan, Italy
(Received 31 December 1974)

Dynamic mechanical properties of a series of ABS (acrylonitrile—butadiene—styrene) resins, having a constant rubber basis grafted to different extents, were studied in the temperature range $-120°$ to $20°C$. The observed viscoelastic transition of the rubbery phase shows two main effects: the amplitude of the transition and the transition temperature decrease as the degree of grafting increases. The grafted component had been prepared by graft copolymerization of butadiene rubber in emulsion with different comonomers/rubber ratios. Both the dynamic effects observed on ABS are discussed in terms of structure variations induced by the change of the grafting condition.

INTRODUCTION

Toughening of a normally brittle glassy polymer by incorporation of dispersed particles of rubber is well established. The mechanism of this reinforcement remains to be fully understood, but it is now generally accepted that a two phase structure is necessary and a good adhesion between phases is requisite to the dispersed phase toughening action[1-3].

Good interfacial adhesion is usually achieved by grafting the glassy polymer to the rubber particles. To what extent and way these have to be grafted in order to obtain the maximum toughening efficiency seems to be still one of the points for clarification.

To this aim we have undertaken experimental work on ABS samples with rubber particles grafted to different degrees and in this paper report some first results of a dynamic mechanical characterization.

EXPERIMENTAL

Materials

A series of grafted rubber latexes was prepared by graft copolymerization of a nearly azeotropic mixture of styrene and acrylonitrile onto a prevailingly *cis*-tactic polybutadiene latex. The grafting process was carried out by adding the glassy resin-forming comonomers to the rubber latex in the presence of a water-soluble free-radical initiator. To obtain samples grafted to different extent, the comonomers: rubber ratio w_{mo}/w_r was varied from sample to sample as reported in *Table 1*, all other conditions having been kept constant. Practically, the reaction was carried out to complete conversion, so that w_{mo}/w_r also represents the whole resin/rubber ratio in the graft product.

The samples for the dynamic mechanical examination (i.e. samples 1, 2, 4, 6, 10, 13 and 16) were then brought to the same resin/rubber ratio 2.08 (that of sample 16) by mixing each graft latex with the appropriate amount of a stock latex of nearly azeotropic styrene–acrylonitrile copolymer (SAN resin) and the final ABS samples were recovered from these latexes by coagulation. As the final ABS samples have the same basic rubber content (32.5 wt % polybutadiene), the correlation of the mechanical properties with the degree of grafting may be regarded as of actual meaning*.

Determination of degree of grafting

The degree of grafting (*GD*) defined as the mass ratio of grafted glassy polymer to rubber, will be in general less than w_{mo}/w_r, i.e. the total glassy polymer/rubber ratio in the graft product, owing to a limited 'grafting efficiency' of the copolymerization. The degree of grafting of each sample was measured by extracting the ungrafted (or 'free') SAN resin by methyl ethyl ketone, according to a separation technique described elsewhere[4].

---

*   The SAN resin added and that formed in the course of the grafting process could be structurally different. However, the reaction conditions used in this work yield molecular weights high enough not to substantially affect the mechanical properties studied here, and monomeric units disposition is likely to be similar to that of the added resin.

Test specimens

The specimens needed for dynamic mechanical measurements are strip bars of about 2.5 x 1.0 cm, 0.10–0.15 cm thick. All specimens were compression moulded at 180°C, annealed at 105°C for 2 h and then slowly cooled to room temperature (cooling rate 0.2°C/min).

Dynamic mechanical measurements

The measurements were performed by an INUA tester[5], at different temperatures, from −120°C to room temperature. The apparatus used allows measurement, for a given material at a given temperature, of the resonance frequency ν_r of transversal vibrations of a slab-shaped sample of known dimensions, and the width of the resonance band as the difference $\Delta\nu$ between the frequencies at which the amplitude of the vibrations is $1/\sqrt{2}$ of its maximum value. From these data the real part of the elastic modulus, E', and the loss angle tangent, $\tan\delta$, can be calculated by the following equations[6]:

$$E' = \rho K_1 \, \frac{L^4}{d^2}\left[\nu_r^2 + \frac{(\Delta\nu)^2}{2}\right] \tag{1}$$

$$\tan\delta = \frac{\Delta\nu}{\nu_r}\left[1 - 1/2\left(\frac{\Delta\nu}{\nu_r}\right)^2\right] \tag{2}$$

where ρ is the density of the examined material, L and d are the specimen length and thickness respectively, and K_1 is a dimensionless constant which is related to the particular observed vibrational mode.

As may be seen from equation (1), the determination of E' can be strongly affected by small errors in the measurement of the dimensions of the specimen, so that only a qualitative meaning can be attributed to the curves $E'(T)$ obtained. We shall therefore discuss only $\tan\delta$ vs. temperature curves. Each specimen was stepwise cooled from room temperature at intervals of 5 to 7°C, and conditioned at the desired temperature for 10 to 15 min before each measurement. The resonance frequencies of each specimen varied by about 200 Hz when the temperature was lowered from room temperature to −120°C.

RESULTS

Experimental degrees of grafting are listed in *Table 1* and plotted in *Figure 1* against comonomers/rubber ratio. Also

shown in *Figure 1* is the 'ideal' degree of grafting that would have resulted if all of the resin-forming comonomers fed would have been grafted on the pre-formed rubber, equal to w_{mo}/w_r (broken line).

According to Rosen[3] an upper limit to the extent of grafting arises from thermodynamical incompatibility between rubber and glassy phase formed in the course of the copolymerization process. Regardless of the chemical nature of the grafting process itself, a simple model has been developed which provides a quantitative estimate of that upper limit as a function of the conversion, and monomer/rubber ratio in the feed. At total conversion, the maximum possible degree of grafting, GD_{max}, should be:

$$GD_{max} = \ln\left(1 + \frac{w_{mo}}{w_r}\right) \tag{3}$$

corresponding to the solid line also reported in *Figure 1*.

The observed agreement can seem striking, considering the very simplifying assumptions on which the Rosen's model is based.

In *Figure 2* the experimental values of $\tan\delta$ are reported as a function of the temperature, for each sample. Each curve shows a peak indicating a dynamic transition of the material or part of it. This transition is to be associated with the glass transition of the microphase of differently grafted polybutadiene embodied by each ABS sample.

The amplitude $(\tan\delta)_{max}$ and the location T_d of each peak maximum are plotted against the degree of grafting in *Figure 3*. As the degree of grafting increases T_d shifts to lower temperatures and $(\tan\delta)_{max}$ decreases, except for the ungrafted sample 1.

In *Table 2* the temperatures T_d are reported together with the frequencies at which the peak maxima occur. It is noticeable that, although these frequencies are not equal, they do not differ greatly and the relationship between T_d and GD should not be substantially inferred by such a variation. Anyway, to remove this doubt we have tentatively reduced the T_d values to the same mean frequency ($\nu = 565$ Hz) through the empirical correlations between T_d and ν found by Lewis for various polymers[7]. According to
Figure 2   Loss factor $\tan\delta$ *versus* temperature T, for the series of ABS samples examined: X, sample 1; ●, sample 2; ○, sample 4; +, sample 6; ■, sample 10; ▲, sample 13; △, sample 16
Figure 3 Loss factor maxima $(\tan \delta)_{max}$ (a) and dynamic transition temperatures T_d (b) as functions of degree of grafting (GD)

Lewis, plots of $\log \nu$ *versus* $1/T_d$ for polymeric materials are straight lines passing, with an approximation, through a common point, which is different for two characteristic classes of polymers: (a) with a rigid chain and/or bulky lateral groups (sterically restricted polymers), and (b) with a more flexible chain, without bulky lateral groups (sterically non-restricted polymers). Since we do not possess enough elements to assign the polybutadiene with different degrees of grafting of our samples to either of these classes, we have taken into account both possibilities. From the known coordinates of the common point and our experimental values of ν and T_d, the relationship between $\log \nu$ and $1/T_d$ has been determined for each sample. From these relationships we have interpolated the values of T_d corresponding to the mean frequency of 565 Hz. These values do not differ substantially from the experimental ones (see *Table 2*).

Lewis also proposed an empirical correlation between the 'static' glass transition temperature, T_g, and the dynamic transition temperature T_d at $\log \nu = -1.5$:

$$T_d (\log \nu = -1.5) = aT_g + b \qquad (4)$$

where a and b are two constants different for the two classes of polymers, the sterically restricted and the sterically non-restricted polymers. From this equation we have calculated the values of T_g for our samples: the results are reported in *Table 2* and plotted against the degree of grafting in *Figure 4*. As may be expected, the glass transition temperatures T_g are lower than the dynamic transition temperatures, T_d; however, the dependence of T_g on the degree of grafting is quite similar to that of T_d.

The value $T_g = -115.8°C$ obtained for the ungrafted polybutadiene (sample 1) in the hypothesis of sterically non-restricted polymer, compares fairly well with literature values of $-112°C$[8] and $-108°C$[9–11] of free (and pure) *cis*-tactic polybutadiene.

DISCUSSION

The two main results, i.e. the decrease of $(\tan \delta)_{max}$ and of T_g as the degree of grafting increases, although related to each other, can be discussed separately.

As for the first result, Illers and Jenckel[12] and McCrum[13–16] have found that the amplitude of the dynamic transition of a component of a composite material is directly related to the relative quantity of the component itself. The same result has been obtained by Dickie[17] from a theoretical calculation based on a simple mechanical model of composite material.

The observed decrease of $(\tan \delta)_{max}$ may then appear as a reduction of the relative quantity of a rubber 'active' in the dynamic transition. Since the weight fraction of polybutadiene in the examined ABS samples was kept constant, such a reduction may be interpreted as due to a progressive immobilization of the rubber particles at least on their outer shells when they are increasingly grafted.

Table 2 Effect of frequency on transition temperature

Figure 4 Glass transition temperatures T_g calculated according to equation (4), as function of degree of grafting (GD): ●, hypothesis of sterically non-restricted polymers; ○, hypothesis of sterically restricted polymers
Figure 5 Evidence of coalescence of rubber particles in lightly grafted ABS samples. (a) Phase contrast electron photomicrograph of sample 2 and (b) pattern showing coalescence points

Photomicrographs obtained by electron microscopy* of sections of the specimens (see, e.g., the pictures taken from samples 2 and 16 shown in *Figures 5a* and *6a* respectively), support this hypothesis. As one may see from *Figure 5a*, for the scarcely grafted sample, sample 2, the incompatibility of the polybutadiene particles with the matrix induces them to coalesce (see examples indicated in *Figure 5b*); in the case of sample 16 a sort of barrier seems to prevent them from coalescing (see examples indicated in *Figure 6b*), which may be evidence of the existence of an outer shell formed by the glassy copolymer grafted on the rubber particles.

The behaviour of sample 1 remains, however, unexplained under the described hypothesis.

From the series of photomicrographs obtained for the different samples, one can observe an increasing amount of glassy polymer subinclusions distributed in the rubber particles as the *GD* increases. From the aforesaid considerations it may be inferred that these subinclusions too can immobilize part of the rubber, further reducing $(\tan \delta)_{max}$. On the other hand, they increase the overall volume fraction of the dispersed phase, which is known to raise $(\tan \delta)_{max}$[17-19]

The experimental results must then be interpreted by assuming that the immobilization of the rubber shells at the boundaries with the glassy polymer is the prevailing effect.

---

* These photomicrographs have been supplied by courtesy of the ANIC SpA, S. Donato Milanese (Italy).

As for the second result, i.e. the decrease of the transition temperature T_d, or T_g, it can be ascribed to the presence of thermal stresses built up by cooling the samples, as a consequence of the different thermal expansion coefficients of rubber phase and glassy matrix[20-22]. Because of the greater thermal contraction of rubber with respect to glassy matrix, a state of triaxial tension is to be expected in each rubber particle. As a consequence the free volume of rubber increases, and results in a decrease of the glass transition temperature[21,23].

Of course, such an effect presupposes a sufficient adhesion between the two phases, generally believed to be secured by the usual grafting operation. However, the *progressive* shift of the transition to lower temperatures observed as the degree of grafting increases can be explained only by assuming that the degree of adhesion varies together with the degree of grafting.

As for other possible factors, the increasing amount of glassy subinclusions in the rubber particles should give an opposite effect, both because it increases the overall fraction of dispersed phase[17] and reduces the level of thermal stresses in rubber[24]. Other minor effects, such as copolymerization effects and crosslinking, would also play a role in the same direction.

We must conclude that the first effect prevails, and a substantial degree of grafting has to be reached for a high degree of adhesion between rubber particles and glassy
Figure 6 Evidence of hindrance to coalescence of rubber particles in highly grafted ABS samples. (a) Phase contrast electron photomicrograph of sample 16 and (b) pattern showing points of hindrance to coalescence by shells of grafted glassy polymer. Subinclusions of glassy polymer in the rubber particles are also evident in (a)

matrix, even if rather low degrees of grafting are usually satisfactory in the production of high impact composite materials.

Notes to the Editor

Synthesis and characterization of styrene–butadiene graft copolymers

D. C. Evans, M. H. George and J. A. Barrie
Department of Chemistry, Imperial College of Science and Technology, London, SW7 2AY, UK
(Received 31 July 1974; revised 23 April 1975)

INTRODUCTION

Synthesis of graft copolymers by anionic polymerization techniques have been widely reported. There are two principal methods[1]. In the first of these, living polymer is deactivated by a backbone polymer molecule containing a suitable functional group. In the second, anionic polymerization of the grafted polymer is initiated by a backbone polymer molecule which has been converted into a multi-functional initiator. It is generally considered that the former method gives products that can be more fully characterized[1] and its use in the synthesis of well characterized branched polystyrenes[2] and polystyrene-g-polyisoprene copolymers[3] has been reported recently. This report describes attempts to prepare styrene–butadiene graft copolymers of approximately predetermined structure using the second method. This method is of importance since the grafted side chains remain active after polymerization is complete, and so the grafts can be terminated with functional groups. For example, controlled crosslinking of graft copolymers with grafts terminated with a carboxyl group should lead to network polymers of controlled structure.

When polystyrene is metalated by n-butyl lithium (n-BuLi) in the presence of N,N,N',N'-tetramethylethylenediamine (TMEDA), metalation occurs at the *meta* and *para* positions on the aromatic ring[4,5]. The metalated polymer behaves as a multifunctional anionic initiator and addition of butadiene results in graft polymerization of butadiene onto polystyrene. The synthesis of such a copolymer by this technique has been reported earlier[6], but few details were given.

The graft copolymers were isolated, purified and characterized with respect to molecular weight, composition and chain microstructure. Solution and bulk properties of one copolymer were investigated and the results are presented below and compared to those for similar systems.

EXPERIMENTAL AND RESULTS

Synthesis and characterization of graft copolymers

Polystyrene, prepared anionically and of molecular wieght above 110 000, was metalated by n-BuLi/TMEDA in cyclohexane at 55°C under dry argon as described previously[4]. At a known time of reaction, the mixture was cooled in ice and butadiene in cyclohexane was added under a pressure of argon. The reaction mixture was stirred continuously and allowed to warm to room temperature during the polymerization of the butadiene. The molecular weight of the polybutadiene grafts was designed to be less than approximately 15 000. The reaction was terminated by degassed methanol. After dilution, the polymer was precipitated into methanol containing a trace of antioxidant (2,6-di-t-butyl-p-cresol).

Difficulties were encountered in the purification of the graft copolymer, owing to the presence of homopolybutadiene, produced by the polymerization of butadiene initiated by the n-BuLi that did not take part in the metalation reaction. Product separation was achieved by fractional precipitation. A 1:1 v/v toluene/n-heptane mixture, containing approximately 0.05% w/v antioxidant was used as solvent and methanol as precipitant. The composition of the fractions obtained was followed by gel permeation chromatography (g.p.c.). Full details of these experimental procedures have been given elsewhere[7].

Yields of graft copolymer were low; the weight of graft copolymer finally obtained was generally only slightly higher than the starting weight of polystyrene. This is probably a result of polystyrene molecules with a small number of branches remaining in solution after the remainder of the graft copolymer had been extracted during fractional precipitation.

The graft copolymers and samples of homopolybutadiene which were isolated from the initial reaction product were characterized as described below.

Number-average molecular weights $(\overline{M}_n)$ of all samples were determined by membrane or vapour phase osmometry.

Weight-average molecular weights $(\overline{M}_w)$ of graft copolymers were measured by light scattering from toluene solutions at room temperature and values of $\overline{M}_w$ were obtained from Zimm plots.

Ultra-violet spectroscopy was used to determine overall compositions of graft copolymers by estimation of the polystyrene content[8].

Infra-red spectra of all samples were recorded. Spectra of graft copolymers were equivalent to the sum of those of polystyrene and ungrafted polybutadiene. By comparison with published spectra[9] grafted polybutadiene was shown to have a predominantly 1,2-microstructure.

Proton n.m.r. spectra of ungrafted polybutadiene were analysed[10] and corresponded to a microstructure of approximately: 1,2-, 84% and 1,4-, 16%. It has been reported elsewhere[11] that polybutadiene, initiated by n-BuLi/TMEDA in hydrocarbon solvent has a high 1,2-content.

Properties of graft copolymers

Limiting viscosity numbers of the graft copolymers were measured as a function of temperature and of solvent composition in mixed solvent systems. In all solvent mixtures, changes in the limiting viscosity number $[\eta]$ of the copolymer were virtually the same as those in that of the polystyrene backbone. An example is shown in *Figure 1* in which toluene–cyclohexane solvent mixtures were used.

For a variety of graft copolymers it has been reported[14,15] that $[\eta]$ increases in mixed solvent systems as the solvent becomes more selective for one of the components of the
Figure 1 Dependence of limiting viscosity number of styrene—butadiene graft copolymer (O), polystyrene backbone (X) and polybutadiene samples (●) on solvent composition in toluene—cyclohexane solvent mixtures at 25°C
Figure 2 Dependence of limiting viscosity number of styrene—butadiene graft copolymer sample on temperature in toluene (O) and dioxane (X)

graft copolymer. The increase in $[\eta]$ is maintained until one of the components collapses and 'monomolecular micelles' are produced[16], resulting in a sharp fall in $[\eta]$. This behaviour was not observed with the styrene—butadiene graft copolymers described in this study.

Limiting viscosity numbers of the styrene—butadiene graft polymers in toluene and in dioxane were almost independent of temperature within the temperature range studied (*Figure 2*), as were those of the homopolymers. These results differ from those reported for other graft copolymers in good solvents for both components[17,18]. In these cases, a transitory increase in $[\eta]$ of the copolymer was observed, generally at or just below room temperature.

These results suggest that in the sample of styrene—butadiene graft copolymer, repulsive interactions between

unlike polymer chains are weak. Such interactions result from a positive heat of mixing of unlike polymers and are responsible for the phase separation that is generally observed in solutions of two homopolymers[19] and for the microphase separation of block copolymers in the solid state[20]. The weakness of these interactions in the graft copolymers of this study is probably a result of the low molecular weight of the polybutadiene branches since polystyrene and polybutadiene are inherently incompatible as demonstrated by the complete microphase separation obtained with styrene—butadiene block copolymers[20]. Molecular weight results and some related data for one sample of graft copolymer are given in *Table 1*. Also included are data for the polystyrene, used as the backbone polymer, and for the homopolybutadiene prepared during the grafting reaction. Since $\bar{M}_w$ for the graft copolymer was determined from measurements in a single solvent, its value will be an apparent one only and will be higher than the true $\bar{M}_w$[12]. However, the high value of $\bar{M}_w/\bar{M}_n$ (2.1) is chiefly a result of oxidative crosslinking during fractionation of the polymer. The use of antioxidant reduced, but did not completely eliminate, crosslinking. In *Table 1*, the branching frequency is defined as the average number of polybutadiene branches per backbone molecule. It is emphasized that this is an average value since it has been shown[13] that there is a distribution of metalated sites among polystyrene molecules.

The results of differential thermal analysis are given in *Table 2*; for comparison, the experimentally measured glass transition temperatures (T_g) of the sample of homopolybutadiene prepared with the graft copolymer and a literature value for the T_g of polystyrene[21] are included.

With block and graft copolymers, if microphase separation is not complete, the T_g of each block moves towards that of a random copolymer of similar overall composition[22]. On this the results in *Table 2* indicate that microphase separation of unlike blocks in the graft copolymer is not complete.

That microphase separation does occur, is demonstrated by transmission electron microscopy. Thin films of polymer were prepared from benzene solution directly onto copper grids by flash evaporation of the solvent, and were stained with osmium tetroxide[23]. Micrographs, such as shown in *Figure 3*, were obtained with a VEM—7 electron microscope operated at 100 kV. In *Figure 3*, the dark

Effect of annealing on thermomechanical properties of poly(ethylene oxide)

E. Alfthan and A. de Ruvo
Department of Physics, Swedish Forest Products Research Laboratory, Box 5604, S-114 86, Stockholm, Sweden
(Received 24 March 1975; revised 23 April 1975)

INTRODUCTION

The purpose of this note is to demonstrate how the thermal prehistory of poly(ethylene oxides) influences their dynamic mechanical properties, especially with regard to the second order transition. Samples with different molecular weights have been used in this investigation, which confirmed the results obtained by previous authors on the relationship between first and second order transition and molecular weight.

Many previous papers have dealt with similar studies of poly(ethylene oxides), and the first and second transitions have been determined by means of mechanical spectroscopy[1,2], dielectric measurements[3], n.m.r.[4] and e.s.r.[5]. It is noteworthy that the theoretically predicted inverse relationship[6] between the glass transition temperature and molecular weight is not obtained. Instead, the glass transition temperature reaches a maximum at intermediate molecular weights (4000—10 000). This anomalous behaviour has been attributed to the presence of the crystalline phase, which restrains the chain mobility in the amorphous regions. In terms of the concept of free volume, this implies a corresponding reduction in the free volume of the amorphous phase[7]. This may be achieved either by compressional restraints or by the interaction or adhesion between the crystalline surfaces and the amorphous chain segments.

EXPERIMENTAL

The samples used in this investigation were kindly provided by J. Törmala and J. Lindberg and used in their investigation of the relaxations of poly(ethylene oxides) (PEO) at temperatures above T_g[5]. This investigation employed e.s.r. studies of the rotational relaxation of nitroxyl radicals used as probes or labels in the polymer.

The PEO samples were of commercial origin (Fluka AG and E. Merck AG) and were labelled according to the technique described by Lindberg. All samples had a fairly narrow distribution of molecular weight. The data obtained by Törmala and Lindberg are reproduced in *Table 1* together with the transition temperatures measured in this study.

Thermal prehistories

In the first series the samples were dried at 105°C in a nitrogen atmosphere for 1 h after which the temperature was lowered at the rate of 40°C/h to 20°C. The sample was conditioned for 1 h before testing. These samples were

Effect of annealing on thermomechanical properties of poly(ethylene oxide)

E. Alfthan and A. de Ruvo
Department of Physics, Swedish Forest Products Research Laboratory, Box 5604, S-114 86, Stockholm, Sweden
(Received 24 March 1975; revised 23 April 1975)

INTRODUCTION

The purpose of this note is to demonstrate how the thermal prehistory of poly(ethylene oxides) influences their dynamic mechanical properties, especially with regard to the second order transition. Samples with different molecular weights have been used in this investigation, which confirmed the results obtained by previous authors on the relationship between first and second order transition and molecular weight.

Many previous papers have dealt with similar studies of poly(ethylene oxides), and the first and second transitions have been determined by means of mechanical spectroscopy[1,2], dielectric measurements[3], n.m.r.[4] and e.s.r.[5]. It is noteworthy that the theoretically predicted inverse relationship[6] between the glass transition temperature and molecular weight is not obtained. Instead, the glass transition temperature reaches a maximum at intermediate molecular weights (4000—10 000). This anomalous behaviour has been attributed to the presence of the crystalline phase, which restrains the chain mobility in the amorphous regions. In terms of the concept of free volume, this implies a corresponding reduction in the free volume of the amorphous phase[7]. This may be achieved either by compressional restraints or by the interaction or adhesion between the crystalline surfaces and the amorphous chain segments.

EXPERIMENTAL

The samples used in this investigation were kindly provided by J. Törmala and J. Lindberg and used in their investigation of the relaxations of poly(ethylene oxides) (PEO) at temperatures above T_g[5]. This investigation employed e.s.r. studies of the rotational relaxation of nitroxyl radicals used as probes or labels in the polymer.

The PEO samples were of commercial origin (Fluka AG and E. Merck AG) and were labelled according to the technique described by Lindberg. All samples had a fairly narrow distribution of molecular weight. The data obtained by Törmala and Lindberg are reproduced in *Table 1* together with the transition temperatures measured in this study.

Thermal prehistories

In the first series the samples were dried at 105°C in a nitrogen atmosphere for 1 h after which the temperature was lowered at the rate of 40°C/h to 20°C. The sample was conditioned for 1 h before testing. These samples were

used for determining T_m. In a second series the temperature of the samples was lowered from $105°$ to $-60°C$ in 30 min (rapid cooling). In the third series the samples were cooled to a temperature of $10°C$. After a certain time, the sample was cooled to $-60°C$ in 5 min after which its glass transition temperature and melting temperature were measured. Samples kept for more than three days were considered to be annealed. Finally, the samples were quenched from $105°C$ to $-60°C$.

Thermomechanical testing

All measurements were performed in a commercial torsional pendulum, TBA (Chemical Instruments Corp.). The basic principle of this instrument has been described previously[8]. All samples were impregnated on a glass braid and the resonance frequency and damping of the composite sample were recorded. All changes in these parameters were assumed to be caused by thermally induced changes in the polymer. The polymers were impregnated on the braid from an aqueous solution of 10% concentration. Total deposition on the braid was 20–40 wt %.

Thermomechanical spectra were recorded at a scanning rate of $1°C/min$ and the damping and resonance frequency were measured automatically by a computer at every second degree. This ensured that the evaluation of the damping was performed in an objective and reproducible manner, which is especially necessary at high damping numbers.

RESULTS

It can be seen from *Figure 1* that damping rises sharply to a maximum in the region of melting. The temperature of maximum damping corresponds to the T_m as measured with d.s.c.[9]. Previous work[10] on similar samples using the TBA technique has not shown that damping reaches a maximum at the temperature of melting. This may to some extent be ascribed to the difficulty of evaluating high damping numbers in an objective manner. Furthermore, previous work on homogeneous samples also indicates the existence of a maximum level of damping at the melting temperature[11].

A linear relationship is obtained between $1/T_m$ and $1/M$. However, the application of the Flory theory to evaluate the heat of fusion is questionable primarily as it can only be applied to polymers having a most probable molecular weight distribution[14]. Previous authors have accordingly noted a significant discrepancy between a calculated heat of fusion and that experimentally determined by means of calorimetry[13].
Table 1 Molecular characteristics and transition temperatures of PEO samples

		T_g (°C)			T_m (°C)	
M_n	M_w/M_n	Quench-ed	Rapid cool-ed	Anneal-ed	TBA	D.s.c.*
2050 ± 150	1.28	−45	−39	−36	50.3	48.5
4000 ± 500	1.28	−39	−38	−35	56.7	55.5
6700 ± 700	1.23	−	−38	−	58.7	55.5
9500 ± 500	1.10	−	−39	−	60.4	57.5
15000 ± 2000	1.09	−	−45	−	61.8	60.5
22000	1.08	−57	−47	−46	63.0	62.0

* D.s.c. values reproduced from the work of Törmala and Lindberg
Figure 2 Glass transition temperature as a function of annealing time for PEO of various molecular weights, M: ○, 2000; △, 4000; ●, 22000

From *Table 1* it is evident that T_g reaches its maximum value at intermediate molecular weights, in accordance with previously reported results[1-5]. In this case the maximum values are somewhat lower than those obtained by Read. It seems likely that these differences are the result of annealing effects. Thus, as can be seen in *Table 1* and *Figure 2*, longer annealing times result in an increase in T_g values. The dependence of T_g on the length of the annealing process can presumably be explained by the kinetics of crystallization. It is worth noting that the extent of the change in T_g depends on the molecular weight. This should mean that each sample will differ in its rate of crystallization. Moreover, the effect of the time of annealing on T_g is most pronounced at the lowest (2000) and highest (22000) molecular weights. At M = 4000 the change in T_g for different times of annealing is noticeably lower than is the case with the other samples.

It is significant that a transition from chain-extended to chain-folded structures takes place in the crystallites at the intermediate molecular weight[12-14]. Moreover, the fact that chain-folded structures are formed at a faster rate tends to

Figure 1 Thermomechanical spectrum of PEO (M = 4000). ○, Damping; ●, rigidity

favour their presence when crystallization occurs at low temperatures[14]. Thus the low sensitivity of T_g to the annealing time at $M = 4000$ may be attributed to the rapid completion of crystallization and the resultant preferential forming of chain-folded structures.

At the lowest molecular weight, therefore, the pronounced dependence of T_g on the time of annealing can be ascribed to a slow and therefore incomplete crystallization. This corresponds to the previously mentioned forming of chain-extended structures at low molecular weights.

Finally, the extent to which T_g changes in response to the length of annealing time is greater at high molecular weights. This is probably caused by the retarding effect of the increased melt viscosity.

CONCLUSIONS

Wide variations exist in the literature for the T_g of PEO and for the maximum T_g obtained at a given molecular weight. These inconsistencies probably stem from the rather complicated crystallization mechanism of the polymer, in which both crystallization temperature and molecular weight govern the rate of crystallization and the preferred type of crystalline structure[12]. Consequently, these parameters and the time of annealing essentially control the resulting crystallinity and morphology, and thus also determine the location of T_g. It is apparent that both T_g and crystallinity reach a maximum in the region of molecular weight where the transition from chain-extended to chain-folded structure takes place. Thus it can be expected that the absolute value and the intensity of the maxima will be greatly influenced by the thermal prehistory of the sample. It is this which differs significantly in many previous investigations.

Letter

Spectroscopic evidence for ion-pair equilibria involving polyvinylbiphenyl carbanions

Introduction

The absorption spectra of solutions of the ions of several aromatic hydrocarbons exhibit a sensitivity to temperature, counterion and solvent which provides direct evidence for the existence of tight and loose ion-pairs, in addition to free ions[1]. The simultaneous participation of some, or all, of these species in the propagation of the anionic polymerization of monomers such as styrene was proposed by Szwarc and coworkers on the basis of kinetic evidence[2]. The present report presents preliminary spectroscopic data for the ion-pairs of the polymer anions derived from vinyl biphenyl and isopropenyl biphenyl.

Experimental

The monomers were purified by recrystallization from ethanol, followed by vacuum sublimation. Polymerization was initiated by butyl lithium or by brief contact with a mirror of sodium metal, using standard high vacuum techniques. The solutions so obtained were stable for several days. Spectroscopic measurements were conducted using quartz cells (0.1 cm pathlength) immersed in ethanol contained in an unsilvered Dewar vessel. The temperature was lowered by the controlled passage of liquid nitrogen through a copper coil submerged in the alcohol.

Results

At ambient temperatures the visible absorption spectrum of poly(vinylbiphenyl lithium) in 2-methyltetrahydrofuran
Figure 1 Absorption spectrum of poly(vinylbiphenyl lithium) in 2-methyltetrahydrofuran. ———, +25°; · · · ·, −10°; − − −, −45°C

Table 1 Changes in entropy $(J\ mol^{-1}\ K^{-1})$ and in enthalpy (kJ/mol) for the conversion of tight to loose ion-pairs

Monomer	Cation	Solvent	$-\Delta H^{\circ}$	$-\Delta S^{\circ}$
VB	Li	MTHF	27	97
VB	Li	Oxepane	13	46
VB	Na	THF	23	85
IB	Li	MTHF	35	123

VB = 4-vinylbiphenyl; IB = 4-isopropenylbiphenyl; MTHF = 2-methyltetrahydrofuran; oxepane = oxacycloheptane

consisted of a single absorption band whose maximum lay at 452 nm (*Figure 1*). As expected, the spectra of samples prepared using lithium metal and butyl lithium were identical. When the temperature was lowered, the absorbance decreased and a new band was formed at 512 nm. The spectra recorded at a series of temperatures passed through an isosbestic point at 476 nm and the changes in the spectrum were completely reversible. Such behaviour is in accordance with the conversion of a tight ion-pair (λ_{max} 452 nm) to a loose ion-pair (λ_{max} 512 nm). The absence of electrical conductivity and the independence of the spectra of the concentration of the solution supported this conclusion and eliminated the possibilities of dissociation or aggregation.

Analysis of the absorption spectrum, making the necessary adjustment for overlap, enables the determination of the equilibrium constant K = [loose ion pair] / [tight ion pair]. The van't Hoff plot of $\ln K$ vs. $1/T$ was linear and corresponded to $\Delta H^{\circ} = -27\ kJ/mol$ and $\Delta S^{\circ} = -97\ J\ mol^{-1}\ K^{-1}$ for the conversion of tight to loose pairs. Similar spectral sensitivity to temperature was exhibited by several other systems based on vinyl and isopropenyl biphenyl and the results of detailed analysis are summarized in *Table 1*.

The potassium, rubidium and caesium based polymers were prepared in methyltetrahydrofuran but the extent of the conversion of these to the loose ion-pairs even at the glass temperatures of the solvent was insufficient to permit the determination of the thermodynamic parameters.

These results offer a clear opportunity of testing the correlation of ion-pair equilibria with the kinetics of polymerization. Work on the latter is presently in progress.

Book Reviews

Fire resistant and flame retardant polymers
M. W. Ranney
Noyes Data Corporation, Park Ridge, NJ, 1974, 395 pp. $36.00

This book is one of the well known Noyes Chemical Technology Reviews and provides detailed descriptive information on fire resistant and flame retardant polymers based on US patent literature. In all 273 patents are cited (ranging from USP 2 590 211 to USP 3 784 509 dated January 8, 1974). Each patent is summarized in readable technical language, free from legal jargon and phraseology. The claims and essential technical details of manufacture and use are given. The book is organized in a systematic and easy-to-follow manner and deals with: polyurethanes; polyesters, epoxides, silicones; polypropylene and polyethylene; polystyrene and ABS; polyamides, acrylics and other thermoplastics, and finally with patents on general utility additives. The individual chemical approaches are systematically listed in a contents and subject index at the beginning of the book.

The text is easy to read but the size of the print may prompt some of the older readers to feel the need of a magnifying glass. This is particularly true for tables which have been reproduced from patents, some of which have 16 lines to the inch.

It is felt that this book will be invaluable to chemists working in the field, even taking into account that they will probably have access to the original patents.

It is well bound and printed. The author and publishers are to be congratulated in producing it so quickly and including such recent patent literature.

Thermal analysis of polymers
Advances in Polymer Science, Volume 13
W. Wrasidlo
Springer Verlag, Berlin, 1974. 99 pp. DM 46

Any experiment in which quantitative account is taken of a temperature change or a heat flow falls within the scheme of thermal analysis. The author, recognizing the breadth of his title, chooses to review two important areas: (a) glass formation and the glassy state; and (b) crystallization, melting and the crystalline state. My feeling is that he has attempted too much, for a proper consideration of either of these subjects might occupy the space available.

The review of the glass transition emphasizes the rationalization of experimental results by use of free volume or kinetic theories.

It includes a useful summary of thermal (T_g, α, C_p) and viscometric data for more than 60 polymers and copolymers. This section is concise and informative.

Not so the review of crystallization and melting, which is something of a *pot-pourri* of effects and examples. In this case there is no accepted framework of theory within which to present the experimental observations. Nevertheless an opportunity has been missed to emphasize those experiments and ideas which lead to useful (if oversimplified) models of the crystallization process and the crystalline state.

The editing is noticeably lax: several references are incomplete; several names are misspelt; several entries in the tables are incomprehensible. There is no evidence that the review was rushed into print, since the references terminate in mid-1972.

Altogether, at a cost of more than £8.00, this is a disappointing volume.

C. Booth

Macromolecular syntheses, Volume 5
Edited by Emerson L. Wittbecker
John Wiley, London & New York, 1974. £5.40

To those familiar with this series it suffices to say that the new volume extends the range of reactions documented in its four predecessors. For others the essential information is that the book contains detailed practical instructions for the preparation of twenty-three different polymers by methods which have been carefully checked by independent assessors. In passing, one notes that one of the preparations was checked by a team in the same laboratory as the originators of the procedure, a fact which detracts somewhat from the value of the monitoring process.

Although, as might be expected, emphasis falls on the addition and condensation routes, there are examples of cyclo-addition and ring-opening reactions as well as of polymer transformations by means of chemical reagents and mechanical forces. Some of the polymers are esoteric but any collection which includes as diverse a range of materials as thiocarbonyl fluoride, cyanoethyl cellulose, squaric acid and isotactic polypropylene can scarcely be condemned for lack of variety or originality.

This book will surely be a welcome addition to all polymer chemistry libraries.

Conference Announcement

VII International Congress on Rheology
Gothenburg, Sweden, 23–27 August 1976

The VIIth International Congress on Rheology will take place at Chalmers University of Technology, Gothenburg, Sweden from 23 to 27 August, 1976. All aspects of rheology will be discussed and contributions that aim at a reduction of the diversity of the theoretical and empirical framework by introducing new unifying concepts will be especially welcome. Prospective contributors should send their title and 300 word summary by *1 October 1975* to the Chairman of the Organizing Committee, Professor Josef Kubát, Department of Polymeric Materials, Chalmers University of Technology, Fack, S-402 20 Gothenburg 5, Sweden, from whom Circular 2 will also be available.

Segregation and conformational transitions in triblock copolymers in dilute solution: 3. Viscometric investigations in solvent mixtures

Anastasios Dondos
Laboratory of Physical Chemistry, University of Athens, 144 Athens, Greece

and Paul Rempp and Henri Benoit
Centre de Recherches sur les Macromolécules, CNRS, 6 rue Boussingault, 67083 Strasbourg, France
(Received 12 February 1975; revised 7 April 1975)

Viscometric measurements were carried out on a triblock copolymer PMMA/PS/PMMA at two temperatures in two binary solvent mixtures, in order to establish to what extent segregation between the two kinds of blocks is maintained as the composition of the solvent mixture i.e. its preferential affinity to one of the blocks, changes. From the variation of the limiting viscosity number of the polymer *versus* composition of the solvent mixture, taking into account the corresponding plots for the two homopolymers, it was established: that at relatively low temperature the molecular dimensions of the block copolymer are very close to those calculated neglecting the heterocontact interactions, i.e. assuming segregation, and that at higher temperatures the dimensions observed for the block copolymer are higher than the values calculated by assuming segregation, thus showing that the heterocontacts exert some influence, inducing the chain to expand. A comparison with a PS/PMMA random copolymer of the same composition showed, however, that in the same solvent mixtures the number of heterocontacts was far lower in the case of the block copolymer than in the case of the random copolymer, even at elevated temperatures.

INTRODUCTION

For more than ten years now, block copolymers of various kinds have been investigated thoroughly, using many different techniques, in dilute solution as well as in bulk. There are, however, still large discrepancies between the proposed structures of block copolymers in dilute solution. Some authors[1-3] claim that, owing to the strong repulsions between chemically unlike sequences of the same molecule, the block copolymer adopts 'segregated' conformations, i.e. conformations in which the A part and the B part of the molecule are located in different domains of space, involving consequently very few A—B contacts. Other authors[4,5] do not agree with segregation and they claim that the conformations of a block copolymer chain obey Gaussian statistics, with some extra expansion originating from A—B type interactions, as in the case of random copolymers[6].

In previous investigations along this line[6-8] we have shown that the viscosity of a block copolymer can be calculated from those of the corresponding homopolymers applying some additivity rule[8], and taking no account of AB interactions. The good fit between the calculated values and the corresponding experimental limiting viscosity numbers is a strong argument in favour of segregation.

In a subsequent step we carried out viscosity and light scattering experiments on BAB triblock copolymers at various temperatures. We were thus able to detect some 'transition' phenomena which can be attributed to a conformational change[8,9]: on raising the temperature above T_c, the probability of AB heterocontacts increases. These 'transitions' are readily observable for triblock copolymers, as they introduce discontinuities in the variation of $[\eta]$

and of the second virial coefficient A_2 as a function of temperature. Similar transitions were observed by other authors, especially on polystyrene/polyisoprene/polystyrene triblock copolymers[10]. In the case of two block copolymers, however, no such transition has been observed. If there is segregation it is independant of temperature. In one case only a similar change was observed for a two-block copolymer of styrene and α-methylstyrene[11].

In the present communication, the behaviour of triblock copolymers in dilute solution in solvent mixtures is discussed with reference to the problem of segregation of unlike sequences and of possible conformational transitions.

Let us first recall that the morphology of a homopolymer in a binary solvent mixture is influenced by two factors: (i) the segment—segment interaction parameter χ; it does not vary linearly with the solvent composition, since it also depends upon the interactions between solvent 1 and solvent 2[12]; and (ii) preferential solvation[13,14], which is a consequence of the thermodynamic interactions existing in the system, leads to experimentally detectable differences of the solvent mixture composition within the polymer coils.

In the case of a block copolymer, if segregation is established one can expect each part of the molecule to exhibit on its own preferential solvation and not necessarily by the same constituent of the solvent mixture. Furthermore, the AB heterocontact interaction parameter, usually referred to as χ_{AB}, which should exert an influence at higher temperatures, when segregation decreases, can be expected to noticeably depend upon solvent composition.

For the present investigation we used the same BAB triblock copolymer of styrene (A) and methyl methacry-

late (B)[8,9], and we measured the limiting viscosity number of that copolymer in two solvent mixtures: benzene—chloroform and benzene—tetrahydrofuran, as a function of solvent composition.

It should be recalled that poly(methyl methacrylate) (PMMA) homopolymer exhibits a conformational transition in benzene at around 30°C[15], whereas no discontinuity is observed in the $[\eta]$ *versus* temperature plots in THF or in CHCl$_3$. It was shown recently, however, that in both solvent mixtures used here, PMMA exhibits, at a given content of polar solvent (THF or CHCl$_3$) a slightly temperature dependent[16] transition of the same type. This transition is thus a characteristic feature of the individual PMMA chain, and this may be helpful in the interpretation of the observed behaviour of the triblock copolymer.

In spite of the complexity of these systems and of the numerous parameters to be considered an investigation of the limiting viscosity number of triblock copolymers in binary solvent mixtures is of great interest, if it is carried out in close comparison with the corresponding homopolymers. An attempt had already been made along the same line[17], using a two-block copolymer of styrene and methyl methacrylate, in three different solvent mixtures. But in this early work the conformational transition of PMMA in these solvent mixtures had been overseen, and furthermore segregation was totally achieved throughout the systems of solvents investigated.

EXPERIMENTAL

The triblock copolymer BAB with a centre block of polystyrene (PS) surrounded by two B blocks of poly(methylmethacrylate) was made anionically, according to a well known procedure[8]. α-Methylstyrene 'tetramer' was used as initiator and THF as solvent. After completion of the styrene polymerization a few drops of diphenylethylene were added to prevent side reactions involving the ester functions of the methyl methacrylate from occurring. Then this latter monomer was added.

Characterization of the obtained polymer involved gel permeation chromatography and light scattering measurements. Satisfactory homogeneity of the sample was attained, and the presence of two-block copolymer, arising from deactivation of one out of two living ends of the precursor polystyrene, was not detectable.

The weight-average molecular weight of the block copolymer amounted to 425 000, and its styrene content was 53% by weight.

The two homopolymers (PS and PMMA) which were used in this investigation were also prepared anionically, and their polydispersities as estimated from the ratios of their weight- and number-average molecular weights were of the order of 1.1 for PS and 1.2 for PMMA. Their molecular weights were: M_{PS} = 400 000 and M_{PMMA} = 435 000.

All the viscosity measurements were carried out using a capillary viscometer of the modified Ubbelohde type, requiring no corrections for flow kinetics or hydrostatic pressure. The temperature control of the thermostat was better than ±0.1°C.

When working on solvent mixtures, we always dissolved the polymer in a mixture of the solvents of adequate composition. We never adjusted the composition of a polymer solution by addition of a single constituent.

The calculation of the theoretical values of $[\eta]_{cal}$ are based upon the following considerations[8]. It is well known

that under the assumption of segregation the limiting viscosity number in a θ-solvent (for both parts of the copolymer) is given by:

$$|\eta|_\theta = \left\{ x[\eta]_{\theta,A}^{2/3} + (1-x)[\eta]_{\theta,B}^{2/3} \right\}^{3/2} \qquad (1)$$

since $K_\theta = xK_{\theta,A} + (1-x)K_{\theta,B}$ where x is the A content of the block copolymer, and K_θ is the well known parameter characterizing the unperturbed dimensions, and defined by: $K_\theta = [\eta]_\theta / M^{1/2}$. As we are working here in thermodynamically good solvents we have to evaluate the viscometric expansion coefficient α_η^3 which, assuming segregation, can be put in the very simple form:

$$\alpha_\eta^3 = x\alpha_{\eta A}^3 + (1-x)\alpha_{\eta B}^3$$

and it follows:

$$\alpha_\eta^3 = x\left(\frac{[\eta]_A M^{-1/2}}{K_{\theta,A}} \right) + (1-x)\left(\frac{[\eta]_B M^{-1/2}}{K_{\theta,B}} \right) \qquad (2)$$

Since α_η is molecular weight dependent the calculated value of the expansion was evaluated from data on homopolymers A and B exhibiting the same molecular weight as the whole copolymer (and not as its A part respectively, its B part alone).

It is therefore possible to calculate the limiting viscosity number of the copolymer:

$$[\eta]_{cal} = \alpha_\eta^3 \cdot [\eta]_\theta \qquad (3)$$

using equations (1) and (2).

RESULTS AND DISCUSSION

Measurements in benzene—chloroform mixtures

The excess free enthalpy of mixing of benzene and chloroform has been found to be negative[18]. This means that the interaction energy between unlike molecules is higher than the average energy between pairs of molecules of the same species; for any polymer dissolved in this solvent mixture the variation of $[\eta]$ with solvent composition should exhibit a negative deviation from linearity[12]. This is what is observed, at any temperature, for polystyrene (*Figure 1*). In the case of poly(methyl methacrylate) the variation of $[\eta]$ with solvent composition has two characteristic features: first, the slope is much higher, showing that chloroform is a better solvent for PMMA than benzene; secondly, the conformational transition of PMMA is shown in the curve around 35% of chloroform by a sharp variation. This discontinuity is more pronounced at 55°C than at 25°C (*Figure 1*).

From these curves it is possible to calculate the anticipated viscosity behaviour of the block copolymer as a function of solvent composition, under the assumption of segregation, using equation (3). These calculated curves are shown in *Figures 2* and *3*, together with the actual experimental curves.

At 25°C (*Figure 2*) a temperature at which a very high degree of segregation can be expected[8,9], no discontinuity is visible on the experimental curve, and for all compositions the measured values of $[\eta]$ are below the calculated ones, except for pure chloroform and for pure benzene.

At 55°C, (*Figure 3*) previous results have shown that the heterocontacts are no longer negligible. This can explain

that even for pure benzene and for pure chloroform there is no good agreement between the measured values of $[\eta]$ and the values calculated under the assumption of segregation. It should be noted that the PMMA transition appears here very distinctly around 40% of chloroform, and that the two parts of the $[\eta]$ *versus* composition curve exhibit sharp negative deviations from linearity.

Since, at the lower temperature, we assume no interactions between PS and PMMA, the copolymer should show the transition of PMMA. It is possible that this abnormal behaviour is due to the difference in solubility of both types of blocks: the outside of the molecule will be made mainly of PS hiding the transition of PMMA.

Furthermore, the very marked negative deviations from linearity observed in the $[\eta]$ vs. composition plot may be due to the fact that incompatibility between the homopolymer sequences in mixtures of these solvents is less than would be expected from the χ_{AB} values in the pure solvents.

Figure 2 Variation of measured limiting viscosity number of the triblock copolymer (PMMA/PS/PMMA) as a function of $CHCl_3$ content of the solvent mixture (benzene—chloroform) at 25°C. ----, Calculated values under the assumption of segregation

Figure 1 Variation of the limiting viscosity number of polystyrene (----) and of poly(methyl methacrylate) (——) *versus* the $CHCl_3$ content of the benzene—chloroform solvent mixture. O, 25°C; △, 55°C
Figure 3 Same as *Figure 2*, except temperature = 55°C

All these conclusions are very qualitative since it is impossible to write equations for such a four-component system.

Measurements in benzene—THF mixtures

This solvent mixture is also characterized by a negative deviation from linearity observed in the $[\eta]$ vs. composition curve for pure polystyrene (*Figure 4*). For PMMA a discontinuity is observed in the $[\eta]$ vs. composition plot, and both parts of the curve exhibit upward curvatures (i.e. negative deviations from linearity). As the temperature rises the magnitude of the discontinuity increases, and its position in the composition diagram moves slightly to higher THF contents. An interpretation of this behaviour was proposed recently[16].

It was also of interest to investigate how the incompatibility of the two homopolymers changes with solvent composition. It is known that the critical demixtion concentration c_D of the two homopolymers in a given solvent is a measure of the χ_{AB} interaction parameter. *Figure 5* shows a plot of c_D versus solvent composition; this plot was obtained using equal amounts of a PS sample of molecular weight $M_w = 700\,000$ and of a PMMA sample of $M_w = 438\,000$ at room temperature. The plot obtained shows a positive deviation from linearity, which indicates that the two polymers are less incompatible in benzene—THF mixtures than would be expected from the critical demixtion concentrations measured (for the same polymers and at the same temperature) in pure benzene and in pure THF.

A further proof of this fact is given by the variation of the limiting viscosity number of a PS/PMMA random copo-

lymer ($M_w = 210\,000$, 52% styrene) over the whole composition range of the solvent mixture. The sharp negative deviation from linearity of this plot (*Figure 6*) cannot be explained without assuming that χ_{AB} is smaller in these mixtures with respect to its values in the two pure solvents. In the same Figure we have plotted the viscosity of the completely segregated block copolymer of the same molecular weight and composition, as a function of the composition of the solvent mixture, using equation (3). This
Figure 5 Critical demixtion concentration c_D of a polystyrene ($M = 700\,000$)/PMMA ($M = 435\,000$) mixture in benzene—THF mixed solvents *versus* THF content of the solvent (c_D is expressed in g PS + PMMA/100 cm³ of the solvent mixture)

Figure 4 Variation of the limiting viscosity number of polystyrene (----) and of PMMA (——) *versus* THF content of the solvent mixture (benzene—THF). O, 17°C; △, 55°C
Figure 6 Variation of the limiting viscosity number for a given random copolymer of styrene and MMA as function of the THF content of the benzene—THF solvent mixture. Measurements carried out at 25°C; ----, values calculated neglecting heterocontacts

curve is always below the curve corresponding to the statistical copolymer showing that χ_{AB} is positive, increasing when the mixture becomes rich in THF.

Figure 7 shows the experimental viscosities of the triblock copolymer at 17°C as a function of composition of solvent mixture. As in the preceding case, we have calculated a theoretical curve using equation (3).

The agreement is excellent showing that no contribution of the χ_{AB} term on the viscosity number can be detected, and thus bringing new arguments in favour of a completely segregated model. In this case, as in the preceding benzene—CHCl$_3$ mixture at 25°C the transition of PMMA is not detected. The same type of experimental and calculated results have been plotted in *Figure 8*, in this case at 55°C.

There is now no agreement: the experimental points are higher than the calculated curve. The difference between experimental and calculated curves varies with composition similarly[1] to that observed for statistical copolymers (*Figure 6*), but to a much lesser extent suggesting that the behaviour of this copolymer is somewhere between the completely segregated and the statistical copolymer.

CONCLUSION

The present investigation was mainly aimed to study segregation effects in triblock copolymers as a function of solvent composition and at different temperatures.

The samples used were interesting since they contained two PMMA blocks which exhibit a conformational transition in non-polar solvents. This transition is also observed in solvent mixtures, for a given content of polar solvent. The solvent mixtures used were chosen such as to cover a wide range of polarity and to vary the solvation of the individual sequences as much as possible within the composition range of the mixtures.

In both solvent mixtures investigated the behaviour of the triblock copolymer of styrene and MMA is not the same at 15—25°C as at temperatures of the order of 50°C.

In the lower temperature range segregation apparently prevents AB heterocontacts from occurring and the fit is good (especially in benzene—THF mixtures) between the experimental [η] values and those calculated on the basis of segregation. It is interesting to note that under these con-
Figure 8 Same as *Figure 7* except temperature = 55°C

ditions the conformational transition of the PMMA disappears almost entirely. Whether this is due to the fact that PMMA is hidden by the more soluble PS block or that the contribution of PMMA to viscosity is too small to be detected, is questionable.

At elevated temperature the behaviour of the triblock copolymer in the chosen solvent mixtures cannot be accounted for on the basis of complete segregation.

One can state that it is intermediate between segregated and statistical copolymers. This shows that if segregation does exist there is no abrupt transition between the completely segregated and unsegregated status but that one goes progressively for a segregated to a less segregated conformation, as temperature increases.

Finally, it should be noted that equation (3) which was used to evaluate the dimensions in the segregated conformation does not take into account the fact that we have a triblock copolymer.

Crystallization of isotactic polystyrene induced by organic vapours

N. Overbergh, H. Berghmans and G. Smets
Laboratory of Macromolecular and Organic Chemistry, University of Leuven, 3030 Heverlee, Belgium
(Received 3 January 1975; revised 24 March 1975)

The crystallization of isotactic polystyrene induced by dichloromethane and acetone was studied. From equilibrium absorption data, the critical concentration for crystallization was deduced. The crystallization kinetics were followed and diffusion coefficients were calculated. It was found that the crystallization was diffusion controlled. The increase in the rate of crystallization is explained by the high rate of diffusion and nucleation in the presence of the organic solvents. Evidence for the high nucleation probability was found in morphological observations (SAXS and electron microscope observations). The melting behaviour of the solvent crystallized samples suggests formation of a very unstable crystalline structure which re-organizes rapidly on heating.

INTRODUCTION

The crystallization of polymers is facilitated by the presence of organic vapours[1-6]. These low molecular weight plasticizers greatly increase the rate of crystallization owing to an increase of nucleation probability and/or a higher rate of chain segment diffusion. Both factors influence the onset of the crystallization as well as the growth of the crystalline phase.

In order to gain some insight into the mechanism of this crystallization, we have studied the crystallization of isotactic polystyrene (IPS) induced by dichloromethane and acetone. The morphology and the melting behaviour of the structures formed were also studied.

EXPERIMENTAL

Polymers

The synthesis of isotactic polystyrene (IPS) was reported elsewhere[7]. Atactic polystyrene (APS) was prepared by thermal polymerization in benzene at 125°C[8].

Absorption measurements

The apparatus used for the absorption measurements is shown in *Figure 1*. The organic solvent was introduced under high vacuum into flask A which was then attached to the apparatus (B). The polymer sample of about 50 mg was suspended on a calibrated quartz spring with an average extension of 1.8 mm/mg. When the high vacuum in B is obtained, solvent vapour is allowed to flow from A to B by breaking the breakseal which separates the two compartments. The vapour pressure of the solvent was determined by a thermostatic bath (T_1). The water jacket (T_2) surrounding the sample determines the crystallization temperature; this corresponds to the temperature of the air chamber around the apparatus. The extension of the quartz spring measures the degree of vapour absorption and is followed with a cathetometer.

For determining the kinetics of absorption, the spring extension is followed as a function of time under different vapour pressures. Equilibrium absorption measurements as a function of the vapour pressure were carried out with one sample, beginning with the lowest vapour pressure. Before

measurement the sample was kept under constant vapour pressure for at least 24 h.

Density measurements

Densities were measured using a density gradient column, filled with an aqueous solution of potassium chloride, thermostated at 23°C. The densities at the top and the bottom of the column were respectively 1.040 and 1.099. For the calculation of the degree of crystallinity values of 1.057 and 1.125 [9] were taken for the densities of the amorphous phase and the crystal lattice respectively.

Annealing

About 20 mg of the crystallized samples were annealed under vacuum under various conditions of temperature and time.
Figure 1 Absorption apparatus

Calorimetric observations

Calorimetric measurements were made with a Perkin-Elmer DSC-1B, after drying the samples for two weeks at room temperature followed by 60–70°C for one week.

The glass transition temperature of polymer–solvent mixtures was measured at a heating rate of 32°C/min. In order to prevent evaporation of the solvent, liquid sample pans were used[10].

Microscopy

Optical observations on microtome sections (~5 μm) were carried out with a polarizing microscope (Leitz-Dialux-Pol). The spherulitic morphology was examined on ultramicrotome sections of about 500 Å (LKB Ultratome III) with a Jeol 100U electron microscope.

X-ray analysis

Small angle X-ray scattering (SAXS) experiments were performed with a Kratky camera with counting equipment. Monochromatic Cu-radiation was obtained by using a NiKβ-filter and detected by a proportional counter and pulse height discrimination. Appropriate slit height collimation corrections were applied using a computer program described by Vonk[11]. Wide angle X-ray diffraction patterns were recorded with a vertical diffractometer in the transmission mode. A Cu-target tube was used and the diffracted radiation was passed through a curved crystal focalizer.

RESULTS AND DISCUSSION

Equilibrium absorptions

Equilibrium absorption data for polystyrene–dichloromethane and polystyrene–acetone systems are represented in *Figure 2*, where the degree of absorption is plotted
Figure 3 (a) Integral dichloromethane absorption kinetics of IPS (————) and APS (- - - -) at 25°C and different partial vapour pressures (sample thickness 0.25 mm). p/p_0: ●, 0.85; x 0.76; △, 0.69; ○, 0.63; □, 0.61; ◇, 0.575; +, 0.532. (b) Integral acetone absorption kinetics of IPS at 30°C (sample thickness 0.25 mm). p/p_0: ○, 0.81; △, 0.91

against the reduced vapour pressure p/p_0, p being the actual vapour pressure and p_0 the equilibrium vapour pressure at the temperature of the experiment.

At low degrees of absorption, the curves for IPS and APS coincide. From dichloromethane and acetone contents of 22% and 11% respectively (p/p_0 0.50 and 0.73 respectively) onwards, the equilibrium absorption of IPS falls below that of APS. This is ascribed to the onset of crystallization; indeed, during this process solvent is rejected from the crystallizing region, lowering the overall degree of absorption. Increasing the vapour pressure still further causes a marked difference in the behaviour of both polystyrenes. This is the consequence of a gradual increase of the crystallinity with increasing vapour pressure. At p/p_0 = 0.62 for dichloromethane and 0.92 for acetone, the degrees of crystallinity determined by d.s.c. are respectively 0.23 and 0.27. At higher vapour pressure, the degree of crystallinity remains constant and further solvent absorption occurs parallel to the absorption in APS.

From these data we conclude that the minimum solvent content required for crystallization is 22% for dichloromethane and 11% for acetone. The glass transition temperature at these critical concentrations of both solvents is −5°C (d.s.c.) This is about 30°C below the crystallization temperature.

Figure 2 Equilibrium absorption isotherms for IPS (dichloromethane, ▲; acetone, ●) and for APS (dichloromethane, △; acetone, ○)

Kinetics of absorption and crystallization

The absorption isotherms for dichloromethane and acetone are represented in *Figures 3a* and *3b*. In agreement with Fick's equation[12] the uptake of solvent is plotted against $(t)^{1/2}/d$ where t is the absorption time and d the half thickness of the sample. After a small induction period the curves are linear up to an absorption of 80% and 70% (for dichloromethane and acetone respectively) of the maximum amount that can be absorbed. The curves of APS and IPS are coincident. Above this content a deviation of the IPS curves occurs, owing to a decrease of the absorption rate, followed by an important desorption. This behaviour is ascribed to the onset of crystallization; the samples become opaque.

The rates of absorption and desorption as well as the degree of desorption increase by increasing the reduced vapour pressures. At low p/p_0 values (0.532 and 0.575 for dichloromethane) no desorption occurs, although the samples crystallize (x_v is respectively 0.12 and 0.18).

From the linear part of the reduced absorption curves of IPS, diffusion coefficients were calculated, using the equation of Fick[12]:

$$M_t/M_\infty = \frac{2}{d}\left[\frac{\bar{D}t}{\pi}\right]^{1/2} \qquad (1)$$

where M_t is the quantity of solvent absorbed at time t, M_∞ the equilibrium value and $\bar{D}$ the integral diffusion coefficient. This integral diffusion coefficient is temperature and concentration dependent.

The concentration dependence is given by:

$$\bar{D} = D_{c\to0}\exp(kc) \qquad (2)$$

where $D_{c\to0}$ is the diffusion coefficient at zero concentration, c is the concentration and k a positive parameter characteristic of a polymer system at a given temperature[13]. The numerical results for the absorption of dichloromethane are given in *Table 1*; the $D_{c\to0}$ values are by given combination of equations (1) and (2).

The kinetics of absorption depend not only on the reduced vapour pressure but also on the temperature and film thickness.

Figure 4 Integral dichloromethane absorption kinetics of IPS at 30°C and different thicknesses (○, 2 mm; △, 0.25 mm) The absorption kinetics of APS are also represented (●, 2 mm)

The critical concentration for crystallization decreases with increasing temperature. In the presence of 23% dichloromethane, IPS crystallizes readily at 40°C, but very slowly at 25°C. At 35°C, 13% of acetone is sufficient while at 25°C no crystallization occurs at that concentration.

The influence of film thickness on the absorption kinetics is illustrated in *Figure 4.*

With a thin sample (*Figure 4,* 0.25 mm,) an important desorption is observed, while no desorption occurs with a thicker sample (*Figure 4,* 2 mm). This is explained by a diffusion controlled crystallization. In the thin sample, the critical concentration is obtained practically over the whole sample before the onset of crystallization. As a consequence, solvent is rejected from the sample during the crystallization as evidenced by this desorption. In thicker samples, a solvent gradient is built up in the sample and the critical concentration for crystallization is attained initially at the surface of the sample. As a consequence crystallization begins at the surface. As the absorption proceeds, a front with this critical concentration moves into the sample followed by a crystalline front. During this crystallization, part of the rejected solvent is absorbed into the centre of the sample. Therefore no desorption is observed while the rate of absorption is strongly reduced. This absorption rate is also lower than in the case of atactic polystyrene of the same thickness (*Figure 4*).

This diffusion controlled crystallization is illustrated in *Figure 5* on microtomed sections of samples of different thickness, made during the initial stages of crystallization; a crystalline border can be observed (crossed polarizers) while the interior of the sample is still amorphous. In *Figure 5a,* the arrow indicates the centre of the sample. The crystalline phase is composed of small spherulites as revealed by electron microscope observations on ultramicrotomed sections (*Figure 6*). The spherulites have an average diameter of 6 μm. The arrow indicates the diffusion direction.

Because of this diffusion controlled crystallization, it is impossible to follow the crystallization kinetics in order to derive Avrami parameters[4,14-16]. The crystallinity measured by conventional methods is only an average value. Difficulties also arise from the continuation of the crystallization during the elimination of the solvent under vacuum. Because of the presence of the crystalline layer, evaporation is retarded and it is impossible to bring the sample quickly below the critical concentration for crystallization.

In the presence of organic vapours the rate of crystallization is greatly enhanced. A sample with a thickness of 0.25 mm, crystallized in dichloromethane vapour (p/p_0 =

0.75 and T_c = 25°C), is completely crystalline in 25 min. The crystallization of a sample without solvent, prepared under the same conditions, takes many hours even at the temperature of maximum crystallization rate. Crystallization kinetics depend upon ability of diffusion and nucleation. They are determined by the difference between the crystallization temperature, T_c, and the glass transition temperature ($T_c - T_g$) and the equilibrium melting point ($T_m^o - T_c = \Delta T$) respectively[17,18]. We have taken T_m^o = 240°C and T_g = 95°C.

The dependence of T_g on solvent concentration was investigated and is shown in *Figure 7*. At high solvent concentrations the onset of crystallization cannot be prevented. This introduces an error of the order of a few degrees in this domain.

A T_g of 25°C was obtained with a concentration of 15% by wt for dichloromethane and 7% by wt for acetone. A T_g of 23.5°C was found by Jenckel[19] for APS containing 16.8% of dichloromethane.

Owing to the volatility of the solvents, it is impossible to determine experimentally the dependence of T_m on solvent concentration. As a consequence, the degree of undercooling (ΔT) at different concentrations cannot be calculated.

This degree was estimated from the SAXS measurements. The SAXS maximum of samples crystallized by swelling with a solvent are broad and low in intensity (*Figure 8*). In the presence of 40% dichloromethane or 24% acetone these maxima appear at greater diffraction angles than for samples crystallized in the absence of any solvent at T_c = 135°C (ΔT = 105°C). The long periods are reported in the Figure. It is known from crystallization theories that L is related to the reciprocal of the degree of undercooling, ΔT. The crystals with the smallest long period are grown at the largest degree of undercooling. Consequently during crystallization in the presence of 40% dichloromethane or 24% acetone, ΔT is larger than during the thermal crystallization at 135°C, i.e. ΔT > 105°C. This also implies that in the presence of a solvent, the nucleation probability is higher. But under these conditions, the diffusion of the chains to the growing crystal surface is also enhanced. In the presence of 40% of dichloromethane, T_g = −40°C and at 25°C $T_c - T_g$ = 65°C. At T_c = 135°C without solvent $T_c - T_g$ is only 40°C.

The high crystallization rate in the presence of a solvent can therefore be ascribed to an increased nucleation probability and a lower diffusion activation energy.

Further confirmation of the high degree of undercooling

in the presence of solvent is found in the high nucleation density, reflected in the large number of small spherulites formed (*Figure 6*). A much smaller number of spherulites is formed in samples, prepared under the same conditions as the samples used in this work and crystallized in absence of solvent at the highest possible degree of undercooling.

Because of the small crystallite thickness (*Figure 8*) a low melting point is expected for these structures. However, under different rates of heating the solvent crystallized (dried) samples show only one melting endotherm with a final melting point depending only on the heating rate. A melting point dependent on heating rate is an indication for a re-organization of an unstable crystalline structure, which was clearly illustrated for thermally crystallized IPS[7]. The final melting points of solvent crystallized samples are the same as those obtained with thermally crystallized samples which re-organize during heating at the same rate. This demonstrates that the crystallites must be very unstable so they re-organize easily on heating.

Annealing experiments clearly illustrate this fast re-organization (*Table 2*). During heating above the crystallization temperature, the crystallinity of the samples increases. Above 200°C partial melting followed by recrystallization is observed. At lower temperatures, no initial drop of the crystallinity can be detected, although the annealing temperature is in the melting region of the originally formed crystallites. This suggests that during the annealing the crystallites re-organize directly to a more stable phase. This is reflected in the SAXS patterns.

After annealing below 200°C the maxima shift to smaller scattering angles, the width increases and the intensity increases (*Figure 8*). In the WAXS, a sharpening of the (211) reflections is observed. These changes in the SAXS and WAXS indicate an increase in crystallite thickness and improvement of the perfection of the crystals.

We can conclude that during this very rapid crystallization an unstable crystalline structure is formed, which re-organizes very quickly by heating.

(Received 28 January 1975)

The time-averaged ^{1}H n.m.r. spectra of ethylene–propylene–dicyclopentadiene, ethylene–propylene–ethylidene norbornene and isobutylene–isoprene copolymers were measured. Assignments of the olefinic resonances were carried out by comparing the spectra with those of each homopolymer and starting monomers. The concentration of the olefinic unit in copolymer was determined by measuring the intensity ratio between the olefinic proton signal and the signal of trichloroethylene which was added as an internal standard of intensity measurements. The concentrations of unsaturation in copolymers determined by using the iodine–mercuric acetate method were proportional to those determined by the n.m.r. method. The accuracy and precision of the n.m.r. measurements were shown to be better than 10% for a mixture of polyisobutylene and polyisoprene containing 1.24 mol % of unsaturation as a model compound of isobutylene–isoprene copolymer.

INTRODUCTION

In the polymerization of isobutylene or copolymerization of ethylene and propylene a small amount of unsaturation is introduced into the chain to facilitate the sulphur vulcanization of the polymers. Several different types of diene monomer are employed in commercially produced rubber, i.e., dicyclopentadiene, ethylidene norbornene, methylidene norbornene, or 1,4-hexadiene for ethylene–propylene terpolymer (EPDM) and isoprene for butyl rubber (IIR). Identification and quantitative analysis of those diolefinic units in copolymers have been technically rather difficult owing to the low concentration of the units and also to the fact that these diene units polymerize to give several types of the isomeric structure.

Chemical and infra-red (i.r.) spectroscopic analyses have been widely used to determine the unsaturation in copolymers. The iodine number methods utilize the addition reaction of halogen using reagents such as iodine monochloride[1], iodine–mercuric acetate[2] or pyridinium bromide perbromide[3] were investigated in detail. However, this is still somewhat unsatisfactory because of the presence of side reactions and of incomplete addition reaction of these reagents. On the other hand, the infra-red method is of limited application, e.g., the content of isoprene units in butyl rubber cannot be determined by this method owing to the absence of characteristic infra-red bands as well as small absorptivity of the units. Recently, time-averaged ^{1}H n.m.r. spectroscopy has been used for the determination of small amounts of copolymer components[4–6] and the isomeric structure of polyisoprene[7,8]. A low signal-to-noise ratio of the spectrum can be improved by the use of this technique. However, direct measurements of the relative intensity of the olefinic proton signals are practically

impossible in EPDM and IIR, because the intensity of these signals is usually very small in comparison with that of the other aliphatic proton signals. Different settings of output signal attenuations in the instrument were used in the spectra of the olefinic signals and aliphatic signals of EPDM[6], but there still remains uncertainty for calibrating the attenuation differences.

The present investigation was undertaken to develop a new method for determining a small amount of unsaturation in EPDM and IIR by the time-averaged ^{1}H n.m.r. measurement. In addition, the accuracy and precision of the analysis were checked in detail. The concentration of unsaturation in commercially produced EPDM and IIR sample was determined by the n.m.r. method. The results were compared with those obtained by the iodine–mercury acetate method[2].

EXPERIMENTAL

Materials

The commercially produced ethylene–propylene–dicyclopentadiene (EPDM-D), ethylene–propylene–ethylidene norbornene (EPDM-N), and isobutylene–isoprene (IIR) rubbers were purified by repeated reprecipitations from cyclohexane solution with methanol. The viscosity of the polymer solution was reduced by irradiating the ultrasonic wave at 25 kHz under nitrogen atmosphere.

^{1}H n.m.r. measurements

The ^{1}H n.m.r. spectra were measured at 24°C in a 5 mm o.d. or 10 mm o.d. sample tube on a JEOL-4H-100 spectrometer. A JNM-SB-2 S/N booster equipped with spectral

δ (ppm)
Figure 1 N.m.r. spectra of (a) EPDM and (b) IIR

data points of 1024 bits was used for the time-averaging work. The signal-to-noise ratio of the spectrum was enhanced by the multiple scan average technique. The olefinic proton resonances were time-averaged with a sweep time of 85 sec for 8 to 4 ppm (δ) sweep width. The samples were dissolved in carbon tetrachloride to give a concentration of 20% w/v for the measurement of olefinic proton resonances and 5% for aliphatic proton resonances. Trichloroethylene was used as an internal standard of intensity measurements. The relative intensities between the trichloroethylene signal and the olefinic proton signal were measured by cutting and weighing each peak area of a Xerox copy of the spectrum. The time-averaged spectra were taken with the accumulation of 32 to 128 scans using a 10 mm o.d. sample tube and 64 to 256 scans using a 5 mm o.d. sample tube for the determination of unsaturation in IIR and EPDM, respectively. The settings of a radiofrequency field were decided in such a way that trichloroethylene exhibited a well resolved signal in the time-averaged spectrum.

Iodine number method

The degree of unsaturation in the copolymers was determined using the iodine–mercury acetate–trichloroacetic acid method[2] according to the procedure developed by McNall and Eby[9]. A solution of copolymer in carbon tetrachloride was reacted for 30 min with iodine in the presence of mercuric acetate and trichloroacetic acid. Afterwards, the excess iodine was titrated with sodium sulphate.

RESULTS AND DISCUSSION

Assignments of the signals

The unsaturation units in EPDM or IIR cannot be detected with the usual n.m.r. measurements, since the signals from the olefinic protons are of such low intensity that they cannot be distinguished from the background noise as shown in *Figure 1*. On the other hand, the olefinic

resonances of isoprene, dicyclopentadiene and ethylidene norbornene units in the copolymers were clearly observed by means of the time-averaged measurements as shown in *Figure 2*. The signal at 5.02 ppm in the spectrum of IIR (*Figure 2a*) is assigned to the methine protons of *cis*-1,4- and/or *trans*-1,4-isoprene units on the basis of the assignments in the spectrum of polyisoprene[10–13]. It is noteworthy that the olefinic resonances due to the isoprene units in 3,4- and 1,2-addition are not detected in the spectrum of IIR. This fact gives support to the early findings obtained in the degradation of IIR by ozone that all of the isoprene units are present in 1,4-addition along the polymer chain[14].

The olefinic resonances of ethylidene norbornene units in EPDM-N appeared as two doublets centred at 5.20 and 4.95 ppm (*Figure 2b*). Similar resonance was observed in the spectrum of ethylidene norbornene monomer. In view of the fact that the starting ethylidene norbornene monomer is a mixture of two steric isomers (I and III), the signals at 4.95 and 5.20 ppm are attributed to the substituted methine protons in the configuration of II and IV, respectively[15–17]. No signals from the olefinic 5,6-methine protons were observed in the spectrum.
This indicates that the ethylidene norbornene units are incorporated into the copolymer in a structure polymerized through norbornene double bond. Therefore, the concentration of unsaturation can be determined from the relative intensity of the peak around 5.0–5.2 ppm.

It was found by i.r. analysis that dicyclopentadiene is incorporated in EPDM by addition at 9,10-double bond[18]. The olefinic resonance of the dicyclopentadiene units in EPDM appeared as a doublet centred at 5.48 ppm (*Figure 2c*), which is assigned to two methine protons of 1,2-position (VI).

The time-averaged spectra of the samples irradiated with ultrasonic wave at 25 kHz were compared with those of the starting copolymer samples. No significant difference was observed between them for IIR and EPDM samples except for the improvement in resolution of the spectra by irradiation. This indicates the usefulness of the ultrasonic treatment to obtain a well resolved spectrum in the time-averaged measurement. Ultrasonic irradiation results in chain scission of polymer[19] and lowering of solution viscosity as well as homogenizing of polymer solution. These effects might bring great advantages for measuring the n.m.r. spectrum of high molecular weight polymer. An improve-
Figure 2 Time-averaged n.m.r. spectra of (a) IIR, (b) EPDM (ethylidene nor-bornene) and (c) EPDM (dicyclopentadiene) containing C_2HCl_3 as an internal standard of intensity measurement. The spectra were obtained with accumulations of 128 scans

ment of resolution by the ultrasonic treatment was observed also in the ^{13}C n.m.r. measurement of polybutadiene[20].

Quantitative determination of copolymer composition

The signals from olefinic protons in IIR and EPDM are of such low intensity that the direct measurement of the relative intensity against the aliphatic proton signals is practically impossible even if the time-averaging technique is adapted. As a method for measuring intensity ratios, the settings of the output signal attenuation in the n.m.r. instrument were calibrated for each of the olefinic and aliphatic resonances[6]. However, it is very difficult to maintain the same conditions as calibrated beforehand for a long time. In our method an internal standard for intensity measurement was adapted as shown in *Figure 2*. For this purpose known quantities of trichloroethylene were added into the sample as a solution in carbon tetrachloride.

The concentration of the isoprene, ethylidene norbornene or dicyclopentadiene units (mol/g copolymer) were determined according to the following equations:

$$[IP] \text{ or } [ENB] = C \cdot W_s/W_c \cdot I(=CH)/I(C_2HCl_3) \quad (1)$$

$$[DCP] = C \cdot W_s/W_c \cdot I(=CH)/2I(C_2HCl_3) \quad (2)$$

where C is the concentration of C_2HCl_3 in CCl_4 (mol/g), W_s and W_c are weights of the C_2HCl_3 solution and copolymer incorporated into the n.m.r. tube, respectively, and $I(\ )$ represents the relative integrated intensity of the signal due to the proton indicated in parenthesis.

The concentration of the isobutylene unit in IIR is determined from the concentration of the isoprene unit:

$$68.11[IP] + 56.10[IB] = 1 \quad (3)$$

The concentration of the ethylene and propylene units in EPDM is determined from the intensity ratio between the methyl proton signal around 0.85 ppm and the other aliphatic proton signals centred at 1.3 ppm (*Figure 1b*) by considering overlap of the signals from termonomer units.

$$\begin{cases} 3[P]/(3[P] + 4[E] + 11[ENB]) = \\ \qquad\qquad I(-CH_3)/I(>CH_2, >CH-) \quad (4) \\ 28.05[E] + 42.08[P] + 120.19[ENB] = 1 \end{cases}$$

$$\begin{cases} 3[P]/(3[P] + 4[E] + 10[DCP]) = \\ \qquad\qquad I(-CH_3)/I(>CH_2, >CH-) \quad (5) \\ 28.05[E] + 42.08[P] + 130.20[DCP] = 1 \end{cases}$$

In *Tables 1* and *2* are shown the compositions of commercially obtained IIR and EPDM samples determined by the n.m.r. measurements together with those determined by the iodine number method using the following equation[9]:

$$\text{Unsaturation (mol/g)} = \frac{\text{Iodine No.}}{126.91F} \times 10^{-2} \quad (6)$$

Here, F is a stoichiometric factor depending on the reaction condition. The concentration of unsaturation in IIR and

Figure 3 Comparison of the n.m.r. measurements with the iodine number measurements. ○, EPDM (ENB); ✕, EPDM (DCP); ●, IIR

EPDM was calculated by the use of an F value of 2.61 which was decided by McNall and Eby[9] for IIR using the radio-isotope tracer analysis as a standard. The correlation of these two determinations gave a good straight line as shown in *Figure 3*. The apparent deviation from the expected correspondence, which is illustrated by the broken line in the Figure, may arise from the F value employed in equation (6). The F value expected for these ethylidene norbornene and dicyclopentadiene units is assumed to be 2.38 on the basis of the n.m.r. measurements.

Accuracy and precision of n.m.r. analysis

The accuracy and precision of intensity measurements, i.e. the deviation from theoretical values and the scatter of the measurements, respectively, were evaluated for a mixture of polyisobutylene and polyisoprene (1.24 mol%) as a model of IIR. The concentration of the isoprene units in the mixture was determined according to the procedure mentioned above using the accumulation of 64 scans. The composition of the mixture was found to be 1.33, 1.13, 1.31, 1.27, and 1.10 mol% (mean value 1.23 mol%). These observed values are in close agreement with the theoretical value of 1.24 mol %. The accuracy and the precision of these five measurements were calculated as percentages as follows:

$$\text{Accuracy} = 100 \cdot (\bar{x} - x_t)/x_t$$

$$\text{Precision} = 100 \cdot t_\phi(\alpha)(S/n^{1/2})/\bar{x}$$

where $\alpha = 0.05, n = 5, \phi = 4$. Here, x_i, x_t and $\bar{x}$ represent the observed, theoretical, and mean values, respectively, S, n and $t_\phi(\alpha)$ denote the root mean square $\{\Sigma(x_i - \bar{x})^2/(n - 1)\}^{1/2}$, number of measurements and critical value of the Student t distribution for confidence coefficient of 95%, respectively. The accuracy and the precision of these measurements are 0.8 and 10.3%, respectively.

The actual reproducibility of the time-averaged n.m.r. measurements was evaluated with statistical treatments of five measurements using accumulations of 32, 64, 128,

and 256 scans for an EPDM sample (No.12 in *Table 2*). The results are given in *Table 3*. The precision of the measurements was calculated to be 4.14%. The result of the analysis was practically independent of the number of scans employed. In the case of commercially obtained IIR and EPDM samples the most satisfactory results were obtained by the accumulation of 32 to 256 scans. The measurement of integrated intensity was almost impossible in the spectrum obtained with the accumulation less than 32 scans, even when a 10 mm o.d. sample tube was used. The scatter of intensity measurements might decrease with increasing the accumulation. However, the overall precision of measurement is affected rather by the stabilization of the n.m.r. instrument, i.e. the stability of magnetic field against slow drift and of the detection phase. In the time-averaged measurement the detection phase is adjusted to a pure absorption mode at the beginning for the aliphatic proton signals. Consequently, a slight change in the phase during the accumulation results in a significant deformation of the time-averaged signals.

The accuracy and precision of the usual n.m.r. measurement were evaluated for squalene as a model compound of ethylene—propylene copolymer. The intensity ratio between the methyl-proton peak (0.85 ppm) and the other aliphatic proton peak (1.2 ppm) was measured for the spectrum of squalane. The mean value of five measurements was 0.633 (theoretical value 0.6316). The accuracy and the precision of the intensity measurement are 0.25 and 1.96%, respectively. This indicates that highly accurate results can be obtained by this n.m.r. method.

It was reported that the accuracy of the n.m.r. analysis was improved by the use of an internal standard of the intensity measurement[21]. The main advantage of the internal standard method is that it is possible to measure the relative intensity using the peaks of similar intensities. In the case of the time-averaged measurement, it is difficult to decide the optimum value of radiofrequency field because of the uncertainty of knowing whether saturation is occurring in the spectrum. Therefore, the settings of output signal attenuations in the instrument are decided so as to get a well resolved signal of the internal standard. Under these conditions the errors arising from saturation will be less than the amount of saturation itself[21]. Trichloroethylene was chosen as an internal standard in our experiments, because the chemical shift of it is close to that of the olefinic proton signals under examination. It is preferable to use an internal standard having a similar half-width of peak as that of the olefinic proton signal in copolymer.

The radio-isotope labelling method has been employed to determine the unsaturation in IIR or EPDM using copolymer containing ^{14}C-labelled diolefin monomers. The tracer analysis has been reputed to be the most reliable method and was employed as a standard method for the

Table 3 Reproducibility of the measurement of ethylidene norbornene unit in ethylene—propylene terpolymer

No. of scans	ENB content	
	$\times 10^4$ mol/g copolymer	mol %
32	6.57	2.35
64	6.84	2.45

256	6.85	2.45
256	7.21	2.59

determination of a stoichiometric factor in the iodine number method[9] or for the determination of extinction coefficients in i.r. methods[18,23]. However, it should be considered that the content of unsaturation in copolymer is not always compatible with that of the ^{14}C-labelled monomer unit. In the case of methylidene norbornene, it was reported that some of the monomer unit polymerized to give a saturated structure through a transannular reaction by the use of cationic catalysts[24,25]. Occurrence of a similar polymerization process is expected for ethylidene norbornene:
since the aliphatic resonance corresponding to methyl proton is observed in the spectrum of ethylidene norbornene homopolymer prepared with VOCl$_3$/AlEt$_2$Cl catalyst. The loss of some unsaturation has been suggested also in the case of dicyclopentadiene through side reactions such as branching or oxidation in the course of copolymerization[18] In practice, it is necessary to determine the content of unsaturation in EPDM and IIR in order to evaluate the facility of vulcanization. In this sense the n.m.r. method is well suited for the analysis of unsaturation in copolymer.

The i.r. spectroscopy and refractive index measurements are widely used for the determination of unsaturation in copolymer, which provide facilities for routine analyses of a series of samples in a short time. These analyses are carried out by the use of extinction coefficients or calibration curves determined on the basis of the chemical analysis of unsaturation. Another advantage of the n.m.r. method against the chemical or radio-isotope procedure is that it takes only one or two hours to obtain the time-averaged spectrum. Taking account of these facts, this n.m.r. method is available for determining a calibration curve for physical procedures of unsaturation analysis.

Structural effects in the sub-millimetre wave spectrum of isotactic polypropylene

J. Haigh, A. S. M. Ali and G. J. Davies

Post Office Telecommunications Headquarters Research Department, Dollis Hill, London NW2 7DT, UK
(Received 17 February 1975; revised 28 April 1975)

A partial resolution of the polypropylene submillimetre crystal lattice band has been observed at low temperatures. At room temperature, the band profile varies, at constant crystallinity, with the free energy of fusion of the crystallites. Amorphous polypropylene shows no peak, indicating that there is no pseudo-lattice mode.

INTRODUCTION

Recent developments in telecommunications systems[1] suggest that a material of low dielectric loss at millimetric wavelengths (30–300 GHz, 1–10 cm^{-1}) may soon be required. Isotactic polypropylene (IPP) is an attractive candidate for such a material. Chantry and coworkers[2,3], Goldstein *et al.*[4] and Ayers *et al.*[5] have shown that the dielectric loss spectrum has a weak broad peak near 1000 GHz (33 cm^{-1}) which tails into the millimetric region. (The corresponding peak in the absorption spectrum lies near 1500 GHz (50 cm^{-1}).) Goldstein *et al.* have shown qualitatively that the sharpness and peak height increase with X-ray crystallinity, and that its frequency shifts upwards by about 250 GHz on lowering the temperature to 100 K. This indicates that a part of the absorption at least is due to crystal lattice modes. They predict that five infra-red active lattice modes should be distinguishable. Alternatively Chantry[2] has pointed out that the absorption profile resembles those found in liquids and attributed to dipolar fluctuations caused by collisions. He has postulated that a collisional fluctuation mechanism in the amorphous regions (a 'pseudolattice' mode) may contribute to the peak. Because of the technological importance a detailed analysis of the mechanism is needed. The present work attempts to define the effects of making small changes in crystallization parameters such as might be feasible in component production.

EXPERIMENTAL

Sample preparation

Polypropylene powder free of additives and of high tacticity was supplied by ICI Ltd (Plastics Division). They also supplied atactic polypropylene gum. These materials were cast into solid blocks by the vacuum-melt-extraction and casting technique (VMEC), which is described elsewhere[5,6]. Samples of varied crystal growth rate were produced by cooling in vacuum through the temperature band 450–410 K, at various rates. Crystallization was complete at 415 K, so that no β- (hexagonal) crystal modification was formed[7,8]. Practical considerations of the rate of heat removal, the response of the control equipment, and the need to avoid oxidative degradation, limited the cooling rate range.

Because of the very low submillimetre absorption thick samples (>1.0 cm) had to be made, using a falling-tempera-ture solidification method. To avoid cracks and voids between contracting spherulites it was necessary to cool the polymer melt in such a way as to maintain flat isothermal surfaces in it, and hence a flat solid/melt interface. This was done by imposing a linear temperature gradient from top to bottom of the sample, hotter at the top. Although isothermal crystallization is impossible with this technique, by imposing a linear temperature–time profile all parts of the sample can be given the same thermal history, so that an average crystal growth rate calculated for the whole sample has meaning. Using this method (suggested by Mr K. A. Buckingham, of ICI Plastics Division) void-free cylinders 5 cm in diameter and up to 5 cm thick can be made.

Sub-millimetre wave spectra

Two Grubb Parsons/NPL cube interferometric spectrometers were modified to cover the spectral ranges 60–930 GHz and 600–12 000 GHz. Collimating optics were incorporated to remove beam convergence effects[9]. Over the range 600–3000 GHz quartz and diamond-windowed Golay detectors were used, the resolution was 120 GHz, and reproducibility between consecutive runs was 1%. Over the range 60–930 GHz a Rollin InSb liquid helium-cooled detector[10] was used with a 4 mm black polyethylene filter; resolution was 60 GHz and reproducibility about 0.2%. The method used to compute the sample absorption spectrum removed errors due to radiation reflected from sample surfaces[11]. The 4 K spectrum was obtained with a liquid helium cooled sample cell. It was not corrected for surface reflection effects, and the sample cell design prevented observations above 60 cm^{-1}. Assuming a frequency-independent refractive index of 1.5, the loss tangent spectrum against frequency is

$$\tan(\delta(\nu)) \approx \frac{\alpha(\nu) \cdot c}{3\pi\nu}$$

where c is the speed of light.

Density measurements

Density measurements were made using a Davenport density gradient column at 23°C with a resolution of 0.001 g/cm^3. X-ray diffraction scans were obtained using a Philips PQ 1010 diffractometer with CuK$_\alpha$ radiation and pulse height discrimination, working in transmission. Finally,
Figure 1 Wide-angle X-ray diffraction patterns of isotactic polypropylene samples cooled from the melt at (a) 50 and (b) 25 K/h

differential scanning calorimetry (d.s.c.) traces of the melting endotherms were obtained with a Perkin-Elmer thermal analysis system, the d.s.c. module being calibrated with indium. Heating rates of 8, 4 and 2 K/min gave the same pattern of results, but those at 4 K/min were most reproducible.

RESULTS

Crystal structure of the isotactic samples

The X-ray diffraction patterns (*Figure 1*) relate to samples cooled at 25 and 50 K/h. Crystalline/amorphous ratios were defined, dividing the scans into areas A and C corresponding to amorphous scatter and crystalline diffraction, as $C/(C + yA)$ where y is a correction factor of 0.94. The values were 62 and 63%. The densities were 0.9094 and 0.9100 g/cm^3. The d.s.c. endotherms showed a single peak in each case, due to the melting of the crystalline regions. This lay at 430 K (50 K/h cooling), 431 (25 K/h) and 433 K (10 K/h).

Sub-millimetre wave spectra

Dielectric loss tangent spectra are shown in *Figures 2* and *3* on a logarithmic frequency scale. Small voids in the sample used for curve D (*Figure 2*) distort the spectrum by scattering below 1000 GHz, so this section is omitted.

Reducing the crystal growth rate sharpens the absorption band and shifts it up in frequency (Goldstein *et al.* showed that a similar sharpening, but not the frequency shift, occurred when X-ray crystallinity was increased). The atactic material, which was almost completely amorphous, shows only a trace of a lattice band on top of a large background absorption which is featureless up to at least 6000 GHz (200 cm^{-1}).

Figure 3 shows that partial resolution of the lattice mode components in the isotactic material occurs at 4 K, and that the separation of resolvable lattice mode frequencies at this temperature is 300 GHz.

DISCUSSION

Technologically significant changes in the submillimetre loss spectrum can be brought about by small changes in polymer structure. Their explanation requires hypotheses

relating structure to molecular motions in the 10–3000 GHz range. We would expect, on a simple view, that slowing crystal growth from the melt would (a) increase the crystalline/amorphous ratio, and (b) increase the size of individual crystallites while suppressing disorder-producing features such as surface loop distortion[12]. X-ray crystallinity data show that over the range considered here there is no significant change in the crystalline/amorphous ratio. The small upward shift in melting endotherm temperature confirms that the crystal free energy is lowered[13] as growth rate is reduced: this could be due to increased crystal size, reduced defect concentration or decreased surface fold distortion. The latter factor, as Bank and Krimm showed[14] in polyethylene, would also account for the upward shift in lattice vibration frequency.

The almost featureless continuum observed in the amorphous atactic polymer indicates that we should expect no
Figure 2 300 K submillimetre wave loss tangent spectra of atactic polypropylene (A) and isotactic polypropylene cooled from the melt at: B, 50; C, 25; D, 10 K/h
Figure 3 4 K submillimetre wave loss tangent spectrum of isotactic polypropylene sample cooled from the melt at 25 K/h

pseudo-lattice band structure in the amorphous regions of the isotactic polymer. Indeed if the absorptions of the two types of chain, in random conformation, are comparable, then the truly amorphous fraction in the isotactic polymer must be much less than the figure from X-ray data, since the total dielectric loss of the isotactic polymer away from the lattice band centre is much less than 38% of that of the atactic polymer (*Figure 2*). This is to be expected since the amorphous domains contain chainfolds, cilia etc. which are attached to crystallites and therefore constrained in their motions.

More extensive studies are clearly needed, but it appears that the submillimetre absorption band is a true lattice absorption broadened by imperfections such as surface loop distortion: the amorphous regions appear to contribute only a featureless continuum.

Stereoregular polymerization of vinyl chloride with the redox system ferrous sulphate/hydrogen peroxide/oxalic acid: 2. Process kinetics

L. Slavtcheva and K. Dimov

Higher Institute of Chemical Technology, Sofia 56, Bulgaria
(Received 27 January 1975; revised 2 April 1975)

Kinetics relationships of the polymerization of vinyl chloride with the redox system ferrous sulphate/ hydrogen peroxide/oxalic acid in the presence of emulsifier have been determined. The investigations have been made at constant monomer, initiator and emulsifier concentrations in the temperature range −30°C to +15°C. The influence of the polymerization temperature on the rate and the activation energy of the process has been clarified. The process is discussed from the point of view of simultaneous polymerization in solution, emulsion and solid phase and the order of the total reaction with respect to monomer concentration has been determined.

INTRODUCTION

Emulsion polymerization has found wide application in the production of poly(vinyl chloride) (PVC). The theory of Smith and Ewart[1] is the basis of its quantitative kinetic description. However, during the polymerization of vinyl chloride (VC), owing to the insolubility of the polymer in the monomer and to the solubility of VC in water (0.25% by wt at 0°C), the process deviates from the Smith and Ewart theory and can be best described by the theory of Medvedev and Sheinker[2].

In the initial stage of emulsion polymerization and before the stationary condition determined by the constant concentration of N particles, is reached, it is possible that the process takes place in the solution and thus it can be formally described by the relationships of radical homogeneous polymerization.

The increase of conversion during polymerization leads to lowering of the stability of the polymer particles and results in their consolidation and coagulation. However, the process can continue in the solid phase of the polymer by diffusion of the monomer molecules. Therefore, in its last stages the process is similar to a bulk heterogeneous polymerization and can be described by the equation of Bengough and Norrish[3].

This investigation aims at the elucidation of some problems of the formal kinetics of emulsion polymerization using the redox initiation system ferrous sulphate/hydrogen peroxide/oxalic acid in water−methanol over the temperature range −30°C to +15°C.

EXPERIMENTAL

The polymerization of VC was carried out by a method previously described[4]. The rate was experimentally determined by gas chromatographic analysis. The initial components of the mixture in the reactor are given in *Table 1*. The operating conditions were constant reagent concentrations, as calculated with respect to the total volume of the reac-

tion medium and different polymerization temperatures, T_p. The monomer concentration in the reaction medium was determined by use of an inner standard − in our case n-pentane added in the reactor before the beginning of the process.

RESULTS AND DISCUSSION

Emulsion polymerization of VC in water−methanol with the redox system ferrous sulphate/hydrogen peroxide/ oxalic acid is a heterogeneous process. The presence of methanol in the reaction medium increases the monomer solubility. The initiation system is soluble in water− methanol and the process can be considered as a homogeneous one; its velocity is formally described by the equation of the homogeneous radical polymerization. The newly formed polymer in the presence of methanol forms a sludge that carries away part of the emulsifier of the system thus reducing its concentration [E] in the solution and therefore reducing the number of the particles, N, and thus their contribution to the polymerization.

The polymerization in the micelles obeys the kinetics of the Medvedev−Sheinker theory and the spectral analysis shows the presence of linear polymer[5]. This supports the view that the polymerization takes place on the surface of

Table 1 Initial mixture in the reactor

Substance	Concentration (mol/l)
water	24.5200
methanol	5.5200
n-pentane	0.2330
vinyl chloride	4.4000
ferrous sulphate (hydrated)	0.0040
hydrogen peroxide	0.0377
oxalic acid	0.0029
sodium salt of mepasin sulphonic acid	0.0638
Figure 1 Polymerization of VC with the redox system ferrous sulphate/hydrogen peroxide/oxalic acid in water—methanol and in the presence of emulsifier. □, 15°; ●, 0°; ×, −14°; ○, −25°C
Figure 2 Order of reaction towards the monomer concentration at different polymerization temperatures. □, 15°; ●, 0°; ×, −14°; ○, −25°C

the particles. Otherwise, the chain growth would occur within the polymer because of its high concentration and the result would be branch-chained PVC.

The presence of methanol in the reaction medium leads to precipitation of the PVC (or the macroradical) and the polymerization recurs by the monomer diffusion. This process is similar to a bulk polymerization and can be described by the equation of Bengough and Norrish.

The monomer distribution in the reaction medium at any time would be as follows:

[M]   total monomer concentration,
[m_1] monomer concentration in the water—methanol phase (dissolved monomer): [m_1] = α[M],
[m_2] monomer concentration in the micelles: [m_2] = β[M] = γ[m_1],
[m_3] monomer concentration in the solid phase (absorbed monomer): [m_3] = δ[M] = ϵ[m_1],
[m_4] monomer concentration in the drops (dispersed monomer): [m_4] = τ[M] .

$\alpha, \beta, \gamma, \delta, \epsilon$ and τ are constants depending on the polymerization conditions. Since we operated at constant reagent concentrations and only the polymerization temperature, T_p varied, it was to be expected that these coefficients would depend on T_p.

The experimentally determined monomer concentration can be considered as the sum total of [m_1], [m_2] and [m_4]. We accept that [m_3] has a very small value since the monomer diffuses from the solution into the solid phase which is much denser. Since the monomer concentration is determined by quantitative analysis by means of an independent standard, soluble in the monomer, the error made in all analyses will be of the same order and the equation [M] = $f(t)$ will give the kinetic curve of the process (*Figure 1*).

The order of the total reaction towards the monomer is approximately first order. This can be seen from the integral curves (*Figure 2*) that show the plot ln [M] /[M_0] = $f(t)$. The conditions of the polymerization using the redox system in water—methanol in the presence of emulsifier may occur by three separate processes that take place according to different mechanisms:

1. Polymerization in solution — polymer separates from the reaction medium. Its rate of formation can be formally described by the equation of the homogeneous radical polymerization:

$$R_{p1} = k_{p1} [m_1] \left(\frac{R_i}{2k_{01}} \right)^{1/2}$$

where k_{p1} is the rate constant for propagation of the chain; R_i is initiation rate. In our case $R_i = k_r$[H_2O_2] [$FeSO_4 \cdot 7H_2O$], where k_r is the initiation rate constant and k_{01} is rate constant for termination.

2. Emulsion polymerization that takes place on the surface of the particles and its rate will be determined according to the Medvedev—Sheinker theory:

$$R_{p2} \propto N^{1/5}, [E]^{1/2}, [I]^{1/2}$$

where [I] is the initiator concentration.

3. Polymerization in the solid phase — according to the equation of Bengough and Norrish:

$$R_{p3} = k_{p3} [I]^{1/2} [m_3] \left\{ 1 + \frac{k'[P]^{2/3}}{[m_3]} \right\}$$

where k_{p3} is the propagation rate constant; [P] is concentration of the polymer formed; and k' is a constant.

The auto-acceleration, noticed in the course of our investigations, is due to the high degree of the conversion
Figure 3 Monomer conversion at different temperatures. □, 15°; ●, 0°; ×, −14°; ○, −25°C
Figure 4 Temperature dependence of the polymerization rate

and to the gel effect (or the so-called Trommsdorff effect) and is favoured by the third process. This can be proved by the S shape of the conversion—time curve (*Figure 3*).

The overall rate will be a sum total of the rates of the three kinds of polymerization:

$$R_p = R_{p1} + R_{p2} + R_{p3}$$

The value of R_p depends on the reaction conditions which in our case were constant values of $[M_0]$, $[I_0]$, $[E_0]$, constant composition of the medium and continuous agitation. Therefore, R_p depends only on T_p and on the degree of conversion. This dependence can be expressed by means of the activation energy E_R which will be the sum total of the activation energies of the three separate polymerizations:

$$E_R = E_{R1} + E_{R2} + E_{R3}$$

E_{R1} can be considered as the activation energy of the polymerization in solution. With increasing T_p, $[m_1]$ and R_i increase. This results in an increase of R_{p1} and a decrease of E_{R1}.

The experimentally determined E_R has a negative absolute value -7.63 kcal/mol (31.8×10^3 J/mol). E_R was calculated from the slope of the line expressing the dependence $\log\theta = f(1/T)$. The values of θ are calculated by transformation of the curves $[M] = f(t)$ [6] ($\theta = t_{st}/t$, determined under conditions of constant conversion, *Figure 4*). The value of E_R is considerably lower than most of the values of the activation energies of polymerization processes, initiated by the thermal decomposition of the initiator (~ 20 kcal/mol; 83.6×10^3 J/mol).

Stiffness of aqueous sodium carboxymethyl cellulose from electric birefringence data

Alan R. Foweraker and Barry R. Jennings
Department of Physics, Brunel University, Uxbridge, Middlesex UB8 3PH, UK
(Received 24 March 1975)

Electric birefringence studies have been made on some five samples of sodium carboxymethyl cellulose of different molecular weights (*M*) in water. The orientational relaxation times were evaluated from the decay rates of pulsed field experiments. These were analysed in terms of theories for rigid rods, weakly bending rods and worm-like chains. At *M* less than 5×10^3, the rod model appeared to be representative of the molecular conformation. The optical anisotropy factor $(g_3 - g_1)$ and the electrical polarizability anisotropy $(\alpha_3 - \alpha_1)$ were also evaluated at each molecular weight and in terms of the rod model. It appears that, the electrical polarizability anisotropy when reduced to unit length is a sensitive parameter which is constant in the rod-like region but deviates rapidly with the onset of flexibility. It is suggested that this parameter may be of value (a) to indicate the molecular weight at which the flexibility is significant, and (b) as an indicator of the relative flexibility of different members of the polysaccharide family.

INTRODUCTION

The experimental investigation of flexibility in solutions of linear polymers has long been of interest. Apart from the characterization of this property, flexibility has proved something of a *bête noir* in that theories are generally developed for the completely rigid or completely randomly coiled molecule. The intermediate situation has been described often only through comparisons with either extreme model. Whereas hydrodynamic methods such as viscosity and flow birefringence have been used traditionally, recent electro-optic techniques have been shown to lead to useful qualitative data[1-3].

In this study five differing molecular weight samples of sodium carboxymethyl cellulose (SCMC) were studied in aqueous solution in which they exhibit polyelectrolytic behaviour.

In an effort to study both the molecular properties and the flexibility of SCMC the electric birefringence technique was employed[4,5].

Measurements were made on each sample as a function of the applied field strength and the data were interpreted in terms of molecular hydrodynamical, optical and electrical parameters.

THEORY

In a dilute solution, each macromolecule can be considered as isolated and in some random orientation relative to any arbitrary direction. Thus the overall effect of these optically anisotropic molecules is to present a bulk isotropic solution. However, on application of a pulsed electric field, the individual molecules experience an orienting torque owing to the interaction of the applied pulsed field and their inherent or induced electrical dipoles. These torques lead to an ordering of the molecular array and the bulk solution begins to manifest the optical anisotropy of the individual molecules.

The conventional method of measuring the birefringence is thus to measure the light transmitted through a system consisting of polarizer, cell containing the solution under test, and analyser. The field is applied to the solution at an azimuth of 45° to the polarizer transmission axis. In this work, the analyser was not crossed with the polarizer but was offset by a small angle σ. The birefringence accompanying particle orientation was indicated as a change in the transmitted intensity, recorded by means of a photodetector. If I^* and a^* are the intensity and the amplitude respectively of the linearly polarized beam incident on the cell, and K is a constant which accounts for the light loss due to absorption and reflection losses in the optical components, then, with *no* electric field applied to the cell, the transmitted intensity is given by the law of Malus, namely:

$$I_{E=0} = KI^* \sin^2 \sigma \tag{1}$$

Upon application of the field, the solution becomes birefringent. The incident beam can be visualized as two equivalent linear oscillations of equal amplitude, one parallel to and the other perpendicular to the field direction. After leaving the cell, these components would have amplitudes given by the equations:

$$a^{\parallel} = \frac{a^*}{\sqrt{2}} \sin(\omega t - \delta)$$

$$a^{\perp} = \frac{a^*}{\sqrt{2}} \sin \omega t \tag{2}$$

where the superscripts indicate the parallel and perpendicular components. The phase lag δ, arising from the birefringence or refractive index difference Δn for these two directions at a wavelength λ and for a cell length l is given
Figure 1 Tracing of a typical transient obtained using a SCMC sample of molecular weight 30 000 at an applied field of E = 8.4 kV/cm and 145 μs duration. Time scale is from left to right

by:

$$\delta = \frac{2\pi l \Delta n}{\lambda} \qquad (3)$$

The result of these two components passing through the analyser is a beam of intensity:

$$I_E = \frac{KI^*}{2}(1 - \cos 2\sigma \cos \delta) \qquad (4)$$

Hence, the relative intensity change of the light beam reaching the photomultiplier on application of the electric field is given by:

$$\frac{\Delta I}{I_{E=0}} = \frac{I_E - I_{E=0}}{I_{E=0}} = \frac{\sin^2(\delta/2) \cos 2\sigma}{\sin^2 \sigma} \qquad (5)$$

Hence, one can determine δ, and from equation (3), Δn.

For a solution of concentration c g/ml, and $\bar{v}$ partial specific volume, Peterlin and Stuart[6] have shown that:

$$\Delta n = \frac{2\pi c \bar{v}(g_3 - g_1)}{n} \Phi \qquad (6)$$

where n is the refractive index and $(g_3 - g_1)$ the optical anisotropy factor for the solute molecules, which are distributed and oriented as controlled by the orientation function, Φ. For rigid particles and low degrees of orientation[4], as at low field strengths (E),

$$\Phi = \frac{1}{15}(\beta^2 + 2\gamma) \qquad (7)$$

where $\beta = \mu_3 E/kT$ and $\gamma = (\alpha_3 - \alpha_1)E^2/2kT$ for molecules with a permanent moment μ and polarizability components α. Subscripts 3 and 1 indicate the major and a minor

(transverse) axis respectively. At high applied fields, such that the condition of full molecular orientation is attained, $\Phi = 1$.

Experimentally one applies a square wave pulsed electric field. This induces an optical response which is recorded by the photomultiplier as a transient signal (*Figure 1*). For easier analysis, we consider this as consisting of three distinct regions:

1. This is an initial rise region which is characterized by a compound interaction of the electrical, optical and geometrical properties of the molecules. It is rather more difficult to handle theoretically than the following.

2. This is a saturation region in time where the electrical orientating forces are equally balanced by the Brownian randomizing factors. In this region, measurements of the induced birefringence (Δn) as a function of the applied field strength (E) are made. The data are then plotted in the form of Δn vs. E^2 which leads to a characteristic plot for the molecules under study (*Figure 2*). The initial linear slope at low applied field strengths is described by the combination of equations (6) and (7) and leads directly to the electrical properties of the molecules. The saturation value of the plot as E approaches infinity leads to the optical anisotropy factor ($g_3 - g_1$).

3. The third region is a field free relaxation region which is, to a first approximation, dependent solely on the hydrodynamical properties of the molecules. If the molecular motion be characterized through a molecular rotary relaxation time τ, then the latter stage is a first order diffusion process, which for a monodisperse system is described by the equation[5]:

$$(\Delta n)_t = (\Delta n)_0 \exp(-t/\tau) \qquad (8)$$

where $(\Delta n)_t$ is the birefringence at any time t after the start of the decay and $(\Delta n)_0$ is the measured birefringence at time $t = 0$. Analysis of the transient decays in terms of a log-linear plot of normalized amplitude *versus* time (*Figure 3*) gives a value for τ, which in turn leads to molecular dimensions on consideration of specific molecular models.

EXPERIMENTAL

The samples were kindly supplied by Dr I. Robb of Unilever Research Limited, Port Sunlight, Cheshire, the molecular weights of which were obtained from viscosity measurements. Each sample was dissolved in water by

250	2.13	64.9	715.5	0.2	0.3

Subscripts r, WBR, WLC refer to the true equivalent rod, the 'weakly bending rod' and 'worm-like chain' models respectively

continuous stirring to form a stock solution of known concentration. This was subsequently diluted as required with de-ionized water. Measurements were made on all samples at a molecular concentration of 5×10^{-4} g/cm^3 and at a wavelength of 546 nm.

The apparatus used was similar to that described elsewhere[3] for electric dichroism measurements. An additional polarizer was incorporated as the analyser in the detecting system. Measurements were made in the linear birefringence[7] mode in which the analyser was offset by an angle σ. This allowed the sign of the birefringence to be measured and also enabled fluctuations in the lamp output to be monitored. A typical transient response, taken from the oscilloscope, is shown in *Figure 1* in which the photomultiplier load resistance was 1 kΩ. Such a load reduced the detection system time constant to the order of

0.1 μs, which was well below that of the molecular relaxation time. Pulses of 40 to 100 μs duration and of 0 to 7 kV amplitude were applied to the solutions.

RESULTS AND DISCUSSION

The relaxation data were analysed by means of normalized semi-logarithmic plots (*Figure 3*). In each case the initial slope of the decay was measured as being the most characteristic average for the sample[8]. The relaxation times obtained for each sample are shown in *Table 1*.

Interpretation of the rotary relaxation times in terms of molecular sizes depends upon the assumed molecular model and in this case three such models were considered namely:

(a) the rigid rod model[9] whence

$$\tau = \frac{\pi \eta_0 l_r^3}{18kT[\ln(2p) - 0.8]} \tag{9}$$

(b) the weakly bending rod model[10] whence

$$\tau = \frac{\pi \eta_0 M^3}{6kT\rho^3} \left\{ 3\ln\left(\frac{M}{2\rho b}\right) - 4.92 + 4\left(\frac{b}{a}\right) + \frac{M}{4\rho q}\left[4.5\ln\left(\frac{M}{2\rho b}\right) - 10.2 + 4\left(\frac{b}{a}\right)\right]\right\}^{-1} \tag{10}$$

and (c) the worm-like chain model[10] whence

$$\tau = \frac{\eta_0 q M^2}{6kT\rho^2}\left[0.126\left(\frac{M}{q\rho}\right)^{1/2} + 0.159\ln\left(\frac{2q}{b}\right) - 0.37 + 0.16\left(\frac{b}{a}\right)\right]^{-1} \tag{11}$$

where η_0 is the viscosity of the solvent, l_r is designated the equivalent rigid rod length, p is the axial ratio, ρ is the mass per unit length, q is the persistence length[11] and the parameters a and b are frictional parameters. In this, as in earlier[12] work, they are assumed to be equal to the rod diameter.

The relaxation data were analysed in terms of each of the above models and the results are presented in *Table 1* along with the estimated hydrodynamical length L calculated assuming each monomer unit to be of lengths 0.69 nm. This length was estimated from an unfolded amylose helix[13]. Hence, for a degree of polymerization Z, $L = 0.69Z$ nm. *Figure 4* compares the equivalent rigid rod

250	11.5	4.78	7.37	0.67

data (l_r) and the calculated extended length (L) as a function of molecular weight. If the molecules were rigid rods these curves would remain coincident and linear with increasing molecular weight. It is seen that there is almost immediate deviation from the rigid rod model at molecular weights exceeding 5×10^3.

Figure 5 shows the persistence lengths q, evaluated from equations (10) and (11), for both the weakly bending rod and the worm-like chain models plotted as a function of molecular weight. The similarity between the values obtained for either model does not enable us to differentiate between them.

The approach through the use of equations for rigid rod-like molecules does indicate the rigid behaviour of the SCMC molecule at low molecular weights and the degree of departure from this model at $M > 5 \times 10^3$. No such sensitivity is offered through the evaluation of q.

In order to analyse the electrical parameters, one needs to know the relative contributions of the permanent and induced dipoles to the factor Φ. In principle, one of two methods could be used. The first is to use pulses or bursts of alternating current in order to obtain a frequency dispersion plot[14]. We had no suitable apparatus at our disposal which could give fields of high enough amplitude and frequency and which could be switched with fast relays. The second method is to apply a reversing pair of d.c. pulses in juxtaposition. We were unable to generate such a pair at the voltages required. Because of the poly-electrolytic nature of this polymer in water, it is realistic to assume that counter-ion polarization processes must play an important role and that induced dipole moments predominate. Should all of the observed birefringence be attributed to permanent dipoles (for a rod molecule applied to the appropriate low molecular weight data), then dipole moments of some 10^2 D (3.34×10^{-28} C m) per monomer unit would be obtained. This is clearly unrealistic by more than an order of magnitude.

A typical plot of the dependence of the observed birefringence on field strength is shown in *Figure 2*. At high E, the effect becomes field independent, $\Phi \rightarrow 1$ and $(g_3 - g_1)$ can be evaluated (*Table 2*). The high molecular weight material has the biggest dipole moment in a field E and is thus more readily saturated. As $(g_3 - g_1)$ is evaluated from the high field (saturation) data, we accept the high M average of $(g_3 - g_1) = 12.2 \times 10^{-3}$ as the most reliable estimation of this parameter.

We are not aware of other determinations of this optical factor for SCMC but note the order of magnitude similarity with the following water-borne macromolecules: 6 to 9×10^{-3} for tobacco mosaic virus[15], 7 or 34×10^{-3} for DNA, depending on the experimental method used[16] and 8×10^{-3} for sodium polyethylene sulphonate[17].

From the low field dependence of Δn on E^2, the electrical anisotropy values listed in *Table 2* were obtained. The molecular origin of this anisotropy may be ascribed to a volume effect[6] or a surface polarizability[18] or a combination of the two. Whichever is the case, one would expect the polarizability to be dependent on the molecular length for a rod-like model. This appears to be the case at low molecular weights where the rod behaviour is closely indicated in *Figures 4* and *6*. By this argument one would expect, for a rigid molecular system, that the parameter $(\alpha_3 - \alpha_1)$ *per unit length* would be independent of molecular weight. In *Figure 7* the parameters $(\alpha_3 - \alpha_1)/l_r$ and
Figure 6 Excess molecular polarizability difference as a function of molecular weight. — — —, Semi-theoretically predicted rigid rod-like behaviour based on the excess polarizability per unit length parameter at the low molecular weight limit of *Figure 7*
Figure 7 Excess polarizability per unit length as a function of molecular weight using hydrodynamical contour lengths L (X) and effective rod lengths l_r (O)

$(\alpha_3 - \alpha_1)/L$ are plotted as a function of M. The graph exhibits a number of important features. First, the parameters plotted are *not* constant throughout the molecular weight range studied. This indicates that the molecules are not rigid, at least at the higher molecular weights, but do flex. Secondly, as M is reduced towards zero the molecules indicate increasing conformity to the rigid rod-like behaviour. In the low M limit, the parameter $(\alpha_3 - \alpha_1)$ per unit length is constant whether l_r or L are used for the equivalent length. This can only indicate that l_r becomes identical with the length L at low M. Thirdly, the intercept suggests the value of $3.7 \ (\pm 0.3) \times 10^{-24}$ Fm as the truly characteristic value for the excess polarizability per unit length for the SCMC molecular system. At this low M, the theory used herein becomes fully appropriate.

Finally, there are two further points which are worthy of comment. (a) We note the similarity between the value of the excess polarizability per unit length obtained here for SCMC and that obtained $(3.5 \pm 0.2 \times 10^{-24}$ Fm) for amylose[3] in complexed aqueous dispersion even though different electro-optic methods were used in the two studies. It has not escaped our notice that this parameter might be a useful characteristic of the polysaccharide family. (b) Although the persistence length values determined herein for SCMC are similar to those found for amylose, we note differences in the curves of $(\alpha_3 - \alpha_1)$ per unit length *versus* M for these two systems. Not only is the degree of polymerization at which the curves of $(\alpha_3 - \alpha_1)$ per unit length depart from linearity different, (25 for SCMC and 350 for amylose), but also the *rate* of divergence is different. It seems to us that the reduced electrical polarizability anisotropy per unit length is a potentially useful parameter which is very sensitive to the departure from rigid rod behaviour and hence the increasing flexibility, of stiff but flexible polymers as their molecular weight increases. It would appear to be much more indicative of flexibility than q.

Molecular motion in polystyrene–plasticizer systems as studied by dielectric relaxation*

Philip J. Hains and Graham Williams
Edward Davies Chemical Laboratories, University College of Wales, Aberystwyth SY23 1NE, UK
(Received 7 February 1975; revised 20 March 1975)

The dielectric relaxation behaviour of mixtures of polystyrene with the glass-forming liquids di-n-butyl phthalate, tri-tolyl phosphate and di-octyl phthalate, has been studied over a wide range of compositions. Three distinct dipole relaxation processes are observed, the α process being due to the re-orientation of solvent molecules as modified by the polymer molecules in the environment, the α'' process is due to the motion of solvent molecules in cooperation with, and largely determined by, the motion of the polymer molecules, and the α' process is due to the partial re-orientation of solvent molecules. A comparison is made between the behaviour of these systems and of pure solid dipolar polymers and of supercooled molecular liquids.

INTRODUCTION

It is now well known that both amorphous solid polymers[1-3] and supercooled non-associated molecular liquids[4-8] exhibit quite similar dielectric relaxation behaviour. The α process, which is due to large-scale Brownian motions, has a contour in the plot ϵ'' against $\log$ (frequency) which is quite similar for many polymers and molecular liquids[4,9]. In addition, the observation of a temperature dependent apparent activation energy in both systems is suggestive of a common mechanism[4,5,9]. The β process, which is thought to be due to local motions of dipole units, gives rather broad loss curves and low apparent activation energies. No simple mechanism can be proposed for the β process[1,3,8]. In view of the apparent similarity between the dielectric behaviour of amorphous solid polymers and supercooled molecular liquids, it seemed desirable to study their mixtures. In order that the dielectric loss processes could be assigned to the motions of only one component, we studied the polar solutes, di-n-butyl phthalate (DBP), tri-tolyl phosphate (TTP) and di-n-octyl phthalate (DOP), in (essentially non-dipolar) atactic polystyrene. DBP and TTP form glasses without the complication of crystallization, with glass transitions near 193 K and 217 K respectively, and with T_g (polystyrene) being near 363 K, the variation in relaxation frequency with composition was expected to be very large. We note that Davies and Edwards[10] and Davies and Swain[11] studied the low frequency dielectric relaxation of several small molecules in polystyrene, while Thurn and Würstlin[12] and Hartmann[13] studied poly(vinyl chloride)/plasticizer systems.

EXPERIMENTAL

Di-n-butyl phthalate (BDH) was distilled before use, tri-tolyl phosphate (BDH, Chromatography Grade) and di-n-octyl phthalate (BDH) were used as received. Polystyrene (BDH No.29790, M_w 2.5 x 10^5 g/mol) gave negligible dielectric loss, so was used as received. Dielectric measurements were made using two and three terminal cells together with a General Radio 1620-A Assembly (10^2-10^5 Hz) and a Scheiber Bridge (10^{-1} to 10^2 Hz). Mixtures were prepared by dissolving the components in *trans*-1,2-dichloroethylene followed by vacuum removal of this solvent on a water bath. For high polystyrene concentrations (>80% w/w) the materials were glassy solids at room temperature, and discs were made by compression moulding at temperatures exceeding the softening temperature.

RESULTS

Di-n-butyl phthalate–polystyrene

Dielectric measurements were made on the following mixtures: 9.6, 20.5, 28.4, 35.4, 41.1, 58.7, 73 and 100% DBP/polystyrene (wt %). The detailed results are deposited with the British Library Lending Division, SUP 90013. *Figures 1–4* show[†] representative loss data at three frequencies, while these and other data are summarized in *Table 1*. The overall behaviour is as follows. Pure DPB exhibits one process, the α process, which is due to the large-scale Brownian motions of the molecules. As the polystyrene content is raised, the α process broadens very considerably and moves to higher temperatures at a given frequency. At approximately 40% polystyrene, the single broad α process separates into two broad processes; the lower temperature process (α' process) appears to be a continuation of the α process; the higher temperature process (α'' process) appears to be associated with the plasticization of polystyrene. These variations are conveniently illustrated in *Figure 5*. We note that the α, α' and α'' processes are

† The Figures in the SUP are numbered *Figures 1–21* and should not be confused with *Figures 1–6* of the present paper.
Figure 1 ϵ'' against temperature for 9.63% DBP in polystyrene at 120 Hz (■), 1 kHz (♦) and 10 kHz (●)
Figure 2 ϵ'' against temperature for 20.5% DBP in polystyrene at 120 Hz (■), 1 kHz (♦) and 10 kHz (●)

all due to the motions of the (dipolar) DBP molecules, but are an indirect measure of the motions of the (non-dipolar) polystyrene. *Table 1* shows that the apparent activation energy, Q, for the α' process decreases with increasing polystyrene content, whereas Q for the α'' process remains approximately constant. Q(DBP) is given as 98 kJ/mol by Shears and Williams[7]. $Q_{\alpha''} > Q_{\alpha'}$ in all cases, and $Q_{\alpha''}$ is similar to that commonly found for the glass-transition (α) process in amorphous solid polymers and for polystyrene in particular[1]. The half-width of the plot ϵ'' *versus* log (frequency) for the α process increases from 1.8 to 3.5 decades on going from $0 \to 40\%$ polystyrene; then the α' process, being a continuation of the α process, has a half-width ranging from 3.5 decades at 40% polystyrene to 5 decades at 80% polystyrene. It was not possible to obtain a half-width for the α'' process with any degree of certainty, but it is in excess of five decades of frequency. Thus the α and α'' processes are extremely broad in comparison with the α process observed in most amorphous solid polymers[1], and in supercooled liquids[4-9]. The suggestions that there is a common mechanism[4-8] for the α process in both

systems may well be true, but it appears that other factors are involved in their mixtures, leading to the observed complex behaviour.

Figures 1—4 show that the maximum loss factor ϵ_m'' for the α'' process exceeds that of the α' process for the 9.6% DBP system, but the reverse is the case for DBP greater than 14%. Now $(\epsilon_{m\alpha'}''/\epsilon_{m\alpha''}'') = (\Delta_{\alpha'}\bar{\beta}_{\alpha'})/(\Delta_{\alpha''}\bar{\beta}_{\alpha'})$ where Δ and $\bar{\beta}$ are the dispersion magnitude and the distribution parameter for a given process. we find that $\bar{\beta}_{\alpha'} \simeq \bar{\beta}_{\alpha''}$ for $C_{DBP} < 14\%$, and hence deduce that the relative variation of $\epsilon_{m\alpha'}''$ and $\epsilon_{m\alpha''}''$ with increasing DBP concentration corresponds to the relative variations in the dispersion magnitudes. Both $\Delta_{\alpha'}$ and $\Delta_{\alpha''}$ increase with increasing DBP, but

$\Delta_{\alpha'}$ increases more rapidly than $\Delta_{\alpha''}$ leading to a reversal in their relative magnitudes for $C_{DBP} > 14\%$.

One explanation for the mechanism of α' and α'' processes would be that at low DBP concentrations, certain DBP molecules are 'free' to re-orientate, uninfluenced by the polymer matrix, leading to the α' process, while others are 'bound' in the immediate vicinity of polymer chains. These 'bound' molecules may only move in cooperation with the motions of the polymer chains, leading to the α'' process, which corresponds then to the α relaxation of the plasticized polymer. This cannot be the complete explanation however, since both the α' and α'' processes are very broad in the frequency domain, indicating a variety of mechanisms for both processes. Also the location of the α' process differs from that of the α process, indicating that the motions are hindered by the presence of polymer chains. A more satisfactory rationalization for the mechanism of α, α' and α'' processes is as follows. For very small DBP concentration, the DBP molecules are isolated from each other in the polymer matrix. These molecules find themselves in a variety of environments, so that some are fairly free to re-orientate their dipole moment in the fixed local potential field of the polymer chains. The re-orientation of these molecules leads to the α' relaxation

and is partial relaxation of their dipole moments. The unrelaxed moment can only be relaxed by the Brownian motions of the environment[8,14], i.e. the motions of the polymer chains, leading to a contribution to the α'' relaxation. Some DBP molecules will be completely constrained from local motion (α' process) by the environment, thus all of their mean square moment will be relaxed only by the Brownian motions of the environment, again making a contribution to the α'' process. The DBP molecules will be distributed over a whole range of local environments, thus leading to the α' process, being partial relaxation in an environment which does not change its configuration within the timescale of the process, and the α'' process, being the cooperative, large scale, Brownian motions of the polymer matrix and DBP molecules. In terms of this general approach, both α' and α'' processes are expected to, and do, have broad loss curves in the frequency domain. At low DBP concentration the observation $\Delta_{\alpha'} < \Delta_{\alpha''}$ indicates that the polymer environment suppresses the local relaxation of DBP molecules. As the DBP concentration is increased there is a corresponding increased probability that DBP molecules are adjacent in the medium, and their cooperation in re-orientational motions leads to an increase in the magnitude of the α' process at the expense of the magnitude of the α'' process, in accord with experiment since $\Delta_{\alpha'} > \Delta_{\alpha''}$ for $C_{DBP} > 14\%$. The α' process, being the partial relaxation of DBP molecules in the polymer environment tends to the character of the α process as the DBP concentration is further increased, and for $C_{DBP} > 60\%$ the polymer chains have only a modifying influence on the DBP motions, leading to the α process (*Figure 5*) which contains within it all the available relaxation strength. When the partial relaxation (α') becomes the α relaxation all of the relaxation strength will be contained in the α relaxation thus only one process can be observed*. The α relaxation, observed in the range 60–100% DBP, becomes faster (see *Figure 5*) and narrows as the DBP concentration is raised. The half-width of the

* The α'' curve in *Figure 5* cannot cross the α–α' line to give an observable α'' process at higher DBP concentrations. A similar condition applies to the α, β, ($\alpha\beta$) relaxations in solid polymers[15,16].

plot ϵ_α'' *versus* log (frequency) at 73% DBP is near 3 decades of frequency, which should be compared with 1.8 decades for pure DBP. Thus although the polymer chains do not limit the equilibrium orientation distribution of the DBP molecules in this concentration range, the DBP molecules clearly move in a cooperative manner with the polymer chains, and broad loss curves result.

Tri-tolyl phosphate–polystyrene, di-octyl phthalate–polystyrene and related mixtures

Dielectric measurements were made on 14.3, 27.9 and 50% TTP/polystyrene (wt %) and 15.5, 34.7 and 50% DOP/polystyrene (wt %). The data are given in SUP 90013. The behaviour of these systems was analogous to that observed for DBP/polystyrene; α, α' and α'' relaxations being observed, and the α'' relaxation being larger in magnitude than the α relaxation at low solute concentrations, the converse being true at higher solute concentrations. *Figure 6* and *Table 2* summarize a portion of the results for TTP/polystyrene, and the general behaviour is seen to be quite analogous to that for DBP/polystyrene. For $C_{TTP} = 14.3\%$ the magnitude of the α'' relaxation exceeds that of the α' relaxation, while the converse is true for $C_{TTP} = 27.9\%$. For $C_{DOP} = 15.5\%$ the magnitudes of the α' and α'' processes are comparable, and for $C_{DOP} = 34.7\%$ the α' relaxation is dominant. Some measurements were made on the α'' relaxation in the systems anthrone/polystyrene/*o*-terphenyl, anthrone/polystyrene and phthalic anhydride/polystyrene, all at low (<10%) dipolar solute concentration. The process was found to be extremely broad and reflected the cooperative Brownian motions of solute and polymer matrix, i.e. is a measure of the relaxation of plasticized polystyrene.

Figure 6 Temperature of maximum loss at 1 kHz as a function of composition for TTP/polystyrene

DISCUSSION

The occurrence of α, α' and α'' relaxations was unexpected, especially since these relaxations arise only from the dipolar solute. Similar studies on dipolar solutes in supercooled non-polar solvents[4-8] give an α relaxation, and a lower temperature β relaxation. There the α relaxation corresponds to the cooperative Brownian motions of solute and solvent, and the β relaxation is thought[8] to be due to partial re-orientation of the solute molecules. It is significant in *Table 1* that the apparent activation energy for the α'' relaxation is approximately a constant and large, being comparable with the α relaxation in both solid amorphous polymers and in supercooled molecular liquids. The apparent activation energy for the α' relaxation decreases with decreasing DBP. It appears that the apparent activation energy for the α' relaxation is a little high to be regarded as analogous to that for the β relaxation in polymers[1] ($Q_\beta \simeq 40$ kJ/mol) or in supercooled molecular liquids[4,5] ($Q_\beta \simeq 20$ kJ/mol). The α' relaxation appears to be due to partial re-orientation of solute in a (predominantly) polymer environment, and the α'' and α relaxations appear to be due to the cooperative Brownian motions of solute and polymer as discussed above.

Obviously one interpretation of the occurrence of α' and α'' processes would be that our systems were two-phase in nature. All specimens were optically transparent suggesting that if certain compositions were two-phase that this was not at a macroscopic level. We note that Jenckel and Heusch[17] observed only one T_g in their study of plasticized polystyrene, a study which included the TTP/polystyrene system, again suggesting a one-phase system. Also Wasser and Kurath[22] studied the viscoelastic relaxation of TTP/polystyrene systems over the range 5 to 67% by wt of polystyrene and the observed behaviour is consistent with a one-phase system for this range of composition. The present data show systematic variations with composition, suggestive of a one-phase system at all compositions, and we did not observe discontinuities seen in poly(vinyl chloride)/plasticizer systems by Thurn and Würstlin[12] (their Fig.2) and by Hartmann[13] (his Fig.2). Thus we consider it likely that our systems are essentially one-phase systems at all compositions but we should not ignore the possibility that there may be a tendency towards a separation at the microscopic level for systems containing a small proportion of the plasticizer (TTP or DBP).

Much of the earlier work on polymers containing small molecules relates to poly(vinyl chloride) as the polymer. The simplest such system appears to be that of PVC/di-

phenyl, which in polarity is the reverse of the systems studied here. Fuoss[18] showed that the dielectric α relaxation moved uniformly to lower temperatures, without any appreciable change in shape as the diphenyl concentration was raised from 0 to 20%. In this case the dielectric measurements correspond to the *direct* observation of the motion of the (dipolar) polymer chains, in contrast with the α'' relaxation of the present work in which the motions of the DBP, TTP or DOP molecules are in cooperation with the motions of the polymer chains, but the correlation is not exact. This would explain our observation that the α'' process is rather broad in comparison with the α relaxation of a pure amorphous polymer. Other work on PVC systems has involved plasticizing the dipolar polymer with dipolar plasticizers[12,13,19,20]. For example, Würstlin[19] found one dielectric process at each extreme of composition, and two processes at intermediate compositions, being assigned to polymer and plasticizer contributions.

At lower concentrations of plasticizer the loss peak is largely due to the polymer chain motions as modified by the plasticizer molecules. The plasticizer exhibits a separate peak when the polymer molecules are fully solvated[19] (see also ref 1, p 433), and it has been suggested[13] that there will be ~4 to 6 repeat units of the chain per 'bound' plasticizer molecule. Later works by Luther and Weisel[20] and by Thurn and Wurstlin[12] have suggested that the PVC/plasticizer results are consistent with the superposition of individual processes. The interpretation of multiple loss peaks in two component mixtures in which both components are dipolar is perhaps more difficult than in the present case where the intensity of the multiple loss peaks is due only to the plasticizer molecule.

It is of interest to consider the α, α' and α'' processes in terms of cooperative relaxation as envisaged by Simmons and Macedo[21] for inorganic oxide glasses and by Shears and Williams[7] for organic molecular liquids in their supercooled state. Simmons and Macedo have suggested that cooperative relaxation may be considered in terms of Λ, the 'range' of concentration fluctuations and r_0, the finite range for interactions which lead to relaxation. For the low frequency relaxation region, $\Lambda \geqslant r_0$, relaxing species are well embedded within the range of fluctuations, and the width of the loss curves is predicted to be broad, being a superposition of individual curves each arising from a different environment. A similar model has been suggested by Shears and Williams[7], and was introduced to rationalize the unusual variation, with composition, of the width of dielectric loss curves for DBP/*o*-terphenyl mixtures. For the polystyrene/plasticizer systems studied here we suggest the following model for relaxation. The natural Brownian motions of the system, involving the re-orientational and translational motions of chain segments and plasticizer molecules, lead to gross fluctuations (in time)

of the local composition of the medium. The reorientational motions of molecules, giving rise to α, α' and α'' relaxations will occur on a much shorter time scale than that for fluctuations in composition, thus the dipoles reorientate in an environment of apparently fixed composition. The wide range of local environments then leads to very broad α, α' and α'' relaxations. The partial relaxation (α') and total relaxation (α'') processes are themselves allowed to occur by local density fluctuations, and are a measure of these fluctuations; similarly for the α process, except now the local fluctuations succeed in re-orientating the small molecules completely, and no α'' process can be observed in the concentration range where the α process occurs.

E.p.r. study of radicals produced mechanically in PGMA and their interaction with oxygen

J. Pilař and K. Ulbert

Institute of Macromolecular Chemistry, Czechoslovak Academy of Sciences, 162 06 Prague 6, Czechoslovakia

The vibrational grinding of poly(ethyleneglycol methacrylate) (PGMA) *in vacuo* at the liquid nitrogen temperature gives rise to polymer radicals in high concentrations. Changes in the radical concentration as a function of temperature in the presence and absence of oxygen were followed by means of electron paramagnetic resonance. It was found that polymer radicals reacted at very low temperatures with oxygen with simultaneous formation of polymer peroxy radicals and of a non-paramagnetic polymer tetroxide. This polymer tetroxide, which has been proved indirectly, can decompose to yield polymer peroxy radicals and non-paramagnetic products; the observed anomalies on the curve of the thermal decomposition of radicals may be thus elucidated. The relative participation of polymer tetroxide depends on the oxygen concentration, on the temperature of the sample in contact with oxygen and on the concentration of polymer radicals arising by grinding predominantly on the surface of polymer particles.

INTRODUCTION

The formation of polymer radicals during the mechanical degradation of a polymer by vibrational grinding was first observed by Bresler[1] and Butyagin et al.[2]. Later, Butyagin[3,4] studied in detail processes taking place during the grinding of the polymer. Bresler et al. investigated, in the temperature range of 40–100°C, the decay of polymer radicals prepared by the vibrational grinding of poly(methyl methacrylate) (PMMA) *in vacuo* at the liquid nitrogen temperature[5], the interaction of the radicals with oxygen accompanied by the formation of polymer peroxy radicals[6] at temperatures ranging from −20° to −80°C and the decay of polymer peroxy radicals[5] at temperatures from 5 to 37°C. Butyagin et al.[7] studied transformations of the polymer peroxy radicals *in vacuo* and in an oxygen atmosphere at temperatures above −30°C. In this paper we report some results obtained in the study of polymer radicals prepared by the vibrational grinding of PGMA and of their transformations due to an interaction with oxygen at lower temperatures, ranging from −150 to −60°C.

EXPERIMENTAL

Material

The starting polymer material was poly(ethyleneglycol methacrylate) (PGMA) crosslinked to 40% with ethyleneglycol dimethacrylate prepared[8,9] in the form of porous globules (Spheron 300®). The size of the globules varied from 100 to 200 μm.

Sample preparation and grinding

400 mg of PGMA globules were evacuated at room temperature for 2–3 h in a glass grinding vessel (*Figure 1*) at 10^{-3} mmHg. After sealing off, the glass grinding vessel containing the polymer and glass beads was fixed in a quickchange chuck of a driving grinding unit. The latter consisted of an adapted vibratory stirrer (100 W) with an

adjustable vibration amplitude at a frequency of 100 Hz. The vibration amplitude was adjusted within a range of 2-4 mm. During the grinding, which proceeded for 15–60
Figure 1 Glass grinding vessel used for evacuation, vibrational grinding and measuring e.p.r. spectra of the polymer: 1, milling part with glass beads; 2, measuring tube; 3, break-type glass valve; 4, final seal; 5, evacuation port

min, the holder and the vessel were immersed in liquid nitrogen. After completion of grinding the holder was quickly disconnected, turned by 180° and fixed to the driving unit by its other end. The ground polymer sticking to the inner walls of the vessel and to the glass beads was (while still in liquid nitrogen) shaken off by short-time vibrations (1–2 min) into a measuring tube with an outer diameter of 5 mm, forming part of the grinding vessel. The measuring tube was filled up to such a level which equals the length of the cavity of the spectrometer to eliminate the 'filling factor' effect. A break-type glass valve was also part of the vessel, allowing oxygen or other gases to be admitted into it. It was found that the radical concentration in the ground polymer strongly depended on the vibration amplitude; the dependence on the time of grinding had the same character as the dependence established by Butyagin[3].

E.p.r. spectra measurements

Electron paramagnetic resonance (e.p.r.) spectra were recorded with a JES-3B JEOLCO Tokyo spectrometer, the measuring cavity of which can be thermostated within a temperature of −150° to +200°C with an accuracy of ±1°C. Mn^{2+} in MgO was used as the internal standard. The first derivative and first and second integral of the spectrum were recorded simultaneously. An analogue electronic integrator and a digital electro-optical integrator[10], respectively, were used for integration.

Determination of relative and absolute radical concentrations

When comparing radical concentrations measured in the sample under various conditions (before and after introduction of oxygen, at different temperatures etc.), we expected changes in the quality of the cavity (from change in the amplitude of the signal of the internal standard) and changes in the occupation of the energy levels of the unpaired electron in the magnetic field due to temperature (from the Boltzmann distribution law[11]). All measurements were performed at the same amplitude of the high-frequency magnetic modulation and at the same power input to the measuring cavity of the spectrometer (~1 mW) in virtually identical measuring specimen tubes. The experimental error of determination of relative radical concentrations was estimated to be about 15%. The absolute radical concentrations in the samples were determined by a comparison with a standard sample — benzene solution of diphenylpicrylhydrazyl (DPPH). The radical concentration in this solution was determined from electron spectra in the visible region[12] (λ_{max} = 520 nm, ϵ = 11 500 l mol⁻¹ cm⁻¹). For e.p.r. spectra measurements the benzene solution of DPPH was filled into the same measuring tubes and measured at room temperature under otherwise the same conditions as for polymer samples. The absolute concentrations of polymer radicals in the samples measured immediately after grinding at −150°C ($[R^{\cdot}]_0^{-150}$) varied between 1 and 3 × 10¹⁸ g⁻¹ depending on the conditions of grinding. In those cases when two different radicals appeared in the sample simultaneously, a WANG 600 14 computer was used for computing the first derivatives of simulated superimposed spectra, and for computing the second integrals of both components forming the superimposed spectrum, by twofold numerical integration.

RESULTS

Polymer radicals R·

Szöcs and Ulbert[13] have found that the spectrum of polymer radicals formed in an X-irradiated PGMA coincides with the characteristic spectrum referred to in the literature as the '5 + 4 line' spectrum and most frequently attributed to the radical of type Ia. A spectrum of the same shape was also obtained in the study of PGMA irradiated by a high-frequency discharge in rarefied nitrogen gas. The spectrum of polymer radicals obtained by vibrational grinding of PGMA *in vacuo* at the liquid nitrogen temperature recorded at −150°C (*Figure 2b*) differs from the former spectrum by the width and ratio of intensities of the individual components of the hyperfine structure (third and seventh lines of the spectrum exhibit a stronger intensity than the central fifth line). An increase in the sample temperature has as a consequence a narrowing of the spectral lines accompanied by gradual transformation of the spectrum into the '5 + 4 line' shape and a decrease in the radical concentration of the sample (*Table 1*). The spectrum of a sample left for several minutes at room temperature (*Figure 2a*) has also the form '5 + 4 line'. If the sample temperature is kept constant within a range of −150° to −60°C, the radical concentration changes do not exceed the experimental error. The observed changes in the shape of the spectrum and in the radical concentration with temperature are not reversible.

Interaction of polymer radicals with oxygen

After the introduction of oxygen at atmospheric pressure and a temperature T_r = −150°C a very fast decrease in the radical concentration takes place in the sample, and the observed spectrum (*Figure 2c*) is a superposition of the spectrum of polymer radicals R· (*Figure 2b*) and of that of polymer peroxy radicals ROO· (*Figure 2d*). If the sample is left at −150°C for several tens of minutes the further decrease in the concentration of radicals R· is very small. The concentration of ROO· remains virtually unchanged. An increase in the sample temperature (by 20°C up to −60°C) leads to a fast decrease in the concentration of R· to zero, and to an increase in the concentration of ROO· attaining at −60°C a maximum value which is higher than the total radical concentration measured in the sample immediately after the introduction of oxygen at −150°C ($[R^{\cdot}]^{-150}$ + $[ROO^{\cdot}]^{-150}$). At temperatures −60°C and higher the concentration of ROO· rapidly decreases with time and temperature. The measured relative radical concentrations are given in the first line of *Table 1*. Further lines contain the results of experiments in which oxygen was introduced into the sample at higher T_r, the result of an experiment in which air was introduced into the sample, and also of an experiment in which the sample after grinding was left at room temperature for some 30 min. Changes in the radical concentration with temperature are very fast as mentioned above. All measurements were carried out on samples in an almost stationary state when on the contrary changes in the shape of the spectra and in the radical concentrations are very small and slow. *Table 1* summarizes mean values of measurements carried out during a time between 10 and 60 min after the change in temperature or the introduction of oxygen. In order to rule out the possibility that the decrease in the radical concentration in the sample is due to a heating of the sample cooled to −150°C owing to the introduction of uncooled gas (the gas introduced was always at room temperature), we carried out an

a $[R']_0^{-150}$ is concentration of radicals R' measured in the sample immediately after grinding at $-150°C$. $[R']_0^{T_r}$ is concentration of radicals R' measured in the sample at $T_r°C$ closely before introduction of oxygen. $[R']^{-150}$ and $[ROO']^{-150}$ respectively are concentrations of radicals R' and ROO' measured in the sample after introduction of oxygen at $-150°C$ ($-120°C$, $-100°C$, $-80°C$, $-60°C$). The numbers are mean values determined from several measurements. The experimental error of radical concentration in relative units does not exceed 15%
b T_r is sample temperature at the time of introduction of oxygen
c Air introduced into the sample
d The sample after grinding left at room temperature about 30 min

experiment in which nitrogen was introduced into the sample. However, both the shape of the spectrum and the radical concentration remained unchanged after nitrogen had been introduced into the sample at $-150°C$.

DISCUSSION

The primary process taking place after the introduction of oxygen into the sample is clearly the formation of polymer peroxy radicals:

$$R' + O_2 \rightarrow ROO' \qquad (1)$$

Ingold and Thomas[14,15] assume that at a low temperature low molecular tertiary peroxy radicals can form non-paramagnetic tetroxide via a fast mutual exothermal reaction:

$$ROO' + ROO' \rightleftharpoons ROO-OOR \qquad (2)$$

By using the e.p.r. method, Barlett and Guaraldi[16] have found that with increasing temperature the equilibrium in reaction (2) is shifted towards the peroxy radicals; changes in the concentration of the peroxy radicals are completely reversible within a temperature range of -150 to $-70°C$.

On consuming some activation energy the low molecular tertiary tetroxides can decompose via possible formation of trioxide and alkoxy radicals as intermediates to give peroxides ROOR, oxygen and further products[14,15]

The observed changes in the radical concentrations in polymer samples (*Table 1*) may be elucidated by assuming the possible formation of a polymer tetroxide with similar properties. The introduction of oxygen into the sample at $T_r = -150°C$ has as a consequence the transformation of some 75% of polymer radicals $R^•$ via reactions (1) and (2) into non-paramagnetic polymer tetroxide. With an increase in the sample temperature from -150 to $-60°C$ the remaining polymer radicals react with oxygen while giving rise to polymer peroxy radicals and partly also to polymer tetroxide. The latter decomposes to a greater extent directly into stable non-paramagnetic products, and to a lesser extent back into polymer peroxy radicals. At temperatures $-60°C$ and higher reactions transforming peroxy radicals directly into final products seem to predominate. In contrast with low molecular peroxy radicals[16] the concentration changes of polymer peroxy radicals with temperature are not completely reversible, which may be due, on the one hand, to their lower mobility, and on the other to a partial decomposition of polymer tetroxide into non-paramagnetic products already at very low temperatures. It may also be deduced from what has been said above that the method applied by Bresler *et al.*[6] in their study of the interaction of polymer radicals prepared by the vibrational grinding of PMMA with oxygen at atmospheric pressure and temperatures ranging from -80 to $-20°C$, which is based only on measurements of the concentrations of forming polymer peroxy radicals, does not adequately describe an important region of behaviour of the mechanically degraded polymer. We believe that the formation and gradual decomposition of polymer tetroxide is also the cause of the so far unexplained increase in the total concentration of polymer radicals and polymer peroxy radicals after heating of samples prepared by the mechanical degradation of polymers by filing as observed by Kawashima *et al.*[17] in their investigation of polypropylene and other polymers.

The conditions of formation of polymer tetroxide become worse with increasing temperature T_r at which oxygen is introduced into the sample. This is due to an increase in temperature at which polymer radicals react with oxygen, and particularly to the decrease in the concentration of polymer radicals on the surface of particles of the ground polymer which during the rise in the sample temperature under vacuum from $-150°C$ to T_r disappear by recombination. At the same time the portion of polymer radicals from $[R^•]_0^{T_r}$ transformed into non-paramagnetic products by the decomposition of the polymer teroxide is decreasing, while the relative concentration of polymer peroxy radicals in the sample is rising (*Table 1*). We assumed that the polymer radicals were prevailingly localized on the surface of microscopic polymer particles produced by grinding. This is supported by the high rate of their reaction with oxygen even at very low temperatures. The observed recombination of polymer radicals is probably related to a steep decrease in the surface area of the ground polymer observed by Butyagin[4] in his study of PMMA in the temperature region around $-140°C$ and attributed by him to the sintering of the polymer.

If air is introduced into the sample instead of oxygen at $T_r = -150°C$, only some 50% of polymer radicals are transformed into the non-paramagnetic tetroxide form, which is evidence that the transformation is a function of the partial concentration of oxygen. The overall radical concentration remains practically unchanged during heating of the sample: either the remaining polymer radicals are only oxidized to polymer peroxy radicals, or the formation of polymer tetroxide (if any) is in a dynamic equilibrium with its decomposition back to polymer peroxy radicals. The introduction of oxygen at $T_r = -150°C$ into the sample left after grinding at room temperature for some 30 min has as a consequence the transformation of only about 20% of the remaining polymer radicals into the non-paramagnetic form. We suppose that on exposure of the sample to room temperature surface radicals predominantly recombine, thus raising the relative participation of radicals existing at various depths below the surface of microscopic polymer particles. These subsurface radicals do not any more react readily with oxygen, and the formation of polymer tetroxide by reactions (1) and (2) accompanied by a decrease in the overall radical concentration proceeds to a great extent also at increasing sample temperature from $-150°$ to $-100°C$. During the further increase in temperature the decomposition of polymer tetroxide probably prevails, and the concentration of polymer peroxy radicals increases.

In the discussion of the results one cannot avoid an analysis of the shape of the spectrum, and consequently of the structure of polymer radicals formed by the vibrational grinding of PGMA. In particular, one has to analyse the difference in the shapes of the spectra of polymer radicals obtained by X-irradiation[13] and vibrational grinding. The first explanation that comes to mind is that the spectrum in *Figure 2b* is a superposition of the '5 + 4 line' spectrum (*Figure 2a*) attributed to radical Ib and of the spectrum of another radical or several radicals which with increasing temperature of the sample recombine faster than radicals Ib. Butyagin *et al.* in their study of radicals formed by the vibrational grinding of PMMA[18,19] observed similar departures from the shape of the '5 + 4 line' spectrum deepening with the time of vibrational grinding of the polymer to such an extent that after 28 h of grinding the spectrum of polymer radicals was only a broad doublet. They assigned the doublet to radical IIa and found that its decay *in vacuo* at constant temperature in the interval between $-36°$ and $-0°C$ was controlled by second order kinetics[19]. A doublet observed on heating of the X-irradiated PGMA[13] at $65°C$ in vacuum for 6 h is assumingly due to the radical IIb the superposition of which on the '5 + 4 line' spectrum is reflected in an increase in the intensities of the fourth and sixth lines of the spectrum. However, some difficulties are met when one is trying to explain the formation of radicals II during the mechanical destruction of polymers. In the vibrational grinding of PMMA, radicals IIIa should be formed simultaneously with radicals Ia as primary radicals owing to the breaking of the polymer chain. In the crosslinked PGMA, radicals IV should perhaps arise in addition to radicals Ib and IIIb owing to breaking of the connecting chains. Radicals III and IV could not be recorded so far,

(I)

(II)

$$CH_3$$
$$\sim CH_2-\overset{\cdot}{\underset{\underset{COOR}{|}}{C}}-\overset{\cdot}{C}H_2$$

$$CH_3$$
$$\sim CH_2-\underset{\underset{\underset{\underset{\overset{|}{C}H_2}{|}}{COO}}{|}}{C}-CH_2\sim$$

(III)   (IV)

(a) R = CH$_3$

(b) R = CH$_2$CH$_2$OH

$$R = CH_2\underset{\underset{\underset{\overset{|}{\underset{\underset{CH_3}{|}}{\sim CH_2-C-CH_2\sim}}}{COO}}{|}}{CH_2}$$
probably because of their high reactivity. Radicals II may be formed as secondary radicals in the mechanical degradation of the polymer owing to the tearing off of the hydrogen atom of the methylene group in the polymer chain by reactive radicals III or IV rather than as primary radicals by direct breaking of the C–H bond of the methylene group, as has been suggested by Butyagin *et al.*[18]. Besides the fact that the observed shape of the spectrum can be due to the superposition of some of radicals IIb, IIIb, and IV, or of all of them simultaneously on the spectrum of radical Ib, the possibility should also be borne in mind that the observed departures from the shape of the '5 + 4 line' spectrum may be caused by intermolecular interactions alone between radicals Ib at a high concentration of the latter on the surface of the polymer particles. The changes in the shape of the spectrum could also be a result of the formation and decay of radical pairs similarly to irradiated polyethylene[20,21], but so far no spectra corresponding to the $\Delta M_s = 2$ transition have been recorded. The results of an attempt to simulate numerically the shape of the spectrum in *Figure 2b* and also the results of measurement of the differential spectrum of a sample kept after grinding at $-150°C$ and a sample left at room temperature have only led to a conclusion that the spectrum given in *Figure 2b* can be produced by the superposition of a very broad unresolved singlet on the '5 + 4 line' spectrum. This singlet can be the spectrum of any of radicals IIb, IIIb and IV. Moreover, the superposition of such singlet does not rule out the possibility that both spectra differ only owing to the above mentioned intermolecular interaction of radicals Ib.

If the ground PGMA contains also some of radicals IIb, IIIb, and IV, one may expect that after the introduction of oxygen into the sample the above radicals would react similarly to radicals Ib. It can be expected of course that the properties of the respective polymer tetroxide would be different from those of the tetroxide of radical Ib. In such case the observed fact that with increasing T_r the relative concentration of polymer peroxy radicals $[ROO^\cdot]^{-60}/[R^\cdot]_0^{T_r}$ increases, but their relative concentration $[ROO^\cdot]^{-60}/[R^\cdot]_0^{-150}$ remains practically the same could be explained by the finding that at low temperatures the decomposition of the tetroxide proceeds prevailingly

by a mechanism leading directly to non-paramagnetic products. Owing to the observed shapes of the spectra, radicals IIb, IIIb and IV should recombine faster on heating of the sample than radicals Ib, and their participation in the polymer radical concentration $[R^\cdot]_0^{T_r}$ should decrease with increasing T_r.

It is clear that the suggested mechanism of interaction of polymer radicals with oxygen at low temperatures requires a further experimental investigation. Attempts are needed to obtain more insight into the problem by analysing reaction products using chemical and physicochemical methods, which along with a further examination of the transformations of polymer radicals and shapes of their spectra are the object of a further study.

Experiments have been carried out with the aim of revealing the role played by an antioxidant in the reaction of polymer radicals with oxygen under the described conditions. The first results obtained with samples prepared by grinding the polymer with 1% of added antioxidant show that a pronounced interaction of polymer peroxy radicals with the antioxidant occurs at temperatures $-60°C$ and higher.

A route to anionic hydrophilic films of copolymers of L-leucine, L-aspartic acid and L-aspartic acid esters

W. L. Sederel, A. Bantjes and J. Feijen

Polymer Division, Department of Chemical Technology, Twente University of Technology, Enschede, The Netherlands
(Received 11 November 1974; revised 24 March 1975)

A series of copolymers of L-leucine and β-benzyl-L-aspartate [Leu/Asp(OBz)] covering the range 30—70 mol % of L-leucine, was synthesized by the *N*-carboxyanhydride (NCA) method. The copolymers were characterized by elemental analysis, infra-red spectroscopy and viscometry. For all compositions high molecular weight copolymers were prepared with excellent film-forming properties. Tercopolymers of L-leucine, β-benzyl-L-aspartate and β-methyl-L-aspartate [Leu/Asp(OBz)/Asp(OMe)] were obtained after an ester interchange reaction (conversion 85—95%) with the original copolymer systems. These tercopolymers were characterized by elemental analysis and i.r. spectroscopy. Films of the tercopolymers, cast from organic solvents, could be converted into hydrophilic films by saponification of the methyl ester groups using alkaline water/organic solvent media. The hydrophilic films, which will be further investigated for their use as haemodialysis membranes were characterized by potentiometric titration and i.r. spectroscopy.

INTRODUCTION

During the last decade, there has been an intensified search for biomaterials. Synthetic polypeptides, well known as model compounds for the elucidation of natural processes, show great potential as biomaterials. These materials have already been studied for the utilization as biodegradable sutures[1], artificial skin[2,3], tissue implants[4] or as membranes in haemodialysers[5—8] and blood oxygenators[9].

In haemodialysis membrane applications, where the materials are exposed to blood, it is necessary to get an understanding of the phenomena, which take place at the blood—material interface. In this respect negatively charged materials are of special interest, since it is thought that negatively charged surfaces repel platelets, erythrocytes and other blood elements, which are also negatively charged. Therefore, we are interested in the synthesis of a series of well characterized, negatively charged, water insoluble films, which can be made from synthetic polypeptides in a reproducible way.

Two approaches can be followed: (a) incorporation of L-glutamic acid or L-aspartic acid in hydrophobic polypeptides, such as poly (L-leucine); (b) crosslinking of polyacids such as poly (L-glutamic acid) or poly (L-aspartic acid). One disadvantage of many chemically crosslinked polymers is that the crosslinking (and sometimes the polymerization) is accomplished at the same time the membrane is being formed. As a result, it is often difficult to obtain reproducible pinhole free membranes. Therefore we decided to follow approach (a).

In principle copolymers of L-leucine and L-aspartic acid [Leu/Asp(OH)] can be made by hydrogen bromide treatment of the corresponding β-benzyl-ester derivatives [Leu/Asp(OBz)] (I). The copolymers of L-leucine and γ-benzyl-L-glutamate [Leu/Glu(OBz)] were treated in this way by Klein *et al.*[6]. The resultant polymers [Leu/Glu(OH)] were generally poorly soluble in common solvents. Membrane formation from mixtures of solvents yielded weak membranes.

On the basis of the results with the glutamic acid series an alternative pathway was chosen to reach our goal. This report describes the synthesis and characterization of hydrophilic films of high molecular weight copolypeptides of L-leucine, β-benzyl-L-aspartate, β-methyl-L-aspartate and L-aspartic acid [Leu/Asp(OBz)/Asp(OMe)/Asp(OH)] (III). The films were obtained: (a) directly from films made of copolymers of L-leucine, β-benzyl-L-aspartate and β-methyl-L-aspartate [Leu/Asp(OBz)/Asp(OMe)] (II) by treatment with alkaline aqueous/organic solvent mixtures; and (b) by dissolving polymers (III) in pyridine and casting films from these solutions. The copolypeptides (II) were obtained from L-leucine and β-benzyl-L-aspartate [Leu/Asp(OBz)] (I) copolymers via an ester interchange reaction.

EXPERIMENTAL

Materials

β-Benzyl-L-aspartate was synthesized by the method described by Benoiton[10], (m.p. 220°C). The monomers β-benzyl-L-aspartate-NCA (m.p. 125—126°C) and L-leucine-NCA (m.p. 76°C) were prepared by methods described in the literature[11,12].

Typical polymerization procedure for 50:50 Leu/Asp(OBz) (I)

L-Asp(OBz)-NCA (9.96 g, 40 mmol) was dissolved in a mixture of dry dioxane (70 ml) and of dry benzene (130 ml); L-leucine-NCA (6.28 g, 40 mmol) was dissolved in dry benzene (150 ml). The two solutions were filtered and introduced in the polymerization flask. Triethylamine (TEA) was used as an initiator at anhydride: initiator ratios (A/I) of 200 and 500. Polymerization reactions were allowed to proceed for 5 days at room temperature. A part of the clear viscous solution (35 ml) was slowly poured into methanol (500 ml) and the fibrous polymer was isolated and dried *in vacuo* at 50°C.

Elemental analyses (I) (%) Leu$_x$/Asp(OBz)$_{1-x}$

Leu/Asp(OBz)/Asp(OMe) (II)

The polymer solution of (I) (315 ml) was diluted with benzene (300 ml) and the solution was heated to 65°C and treated with methanol (150 ml) containing concentrated sulphuric acid (6 ml) for 60 h.

On cooling the polymer precipitated and the mixture was concentrated by evaporation. The resulting gel was dissolved in tetrahydrofuran (THF) and the solution was poured into water (1.8 1). The polymer was isolated and washed with water until neutral and then dried *in vacuo* at 50°C. The composition of copolymers (II) was determined by elemental analyses.

Elemental analyses (II) (%) Leu$_x$/Asp(OBz)$_{1-x-y}$/Asp(OMe)$_y$

	O	25.64	25.40

Leu/Asp(OBz)/Asp(OMe)/Asp(OH) (III)

II (2 g) was dissolved in THF (50 ml) at 45°C. The viscous solution was poured onto a glass plate and films were cast by use of a Dokter's knife. A second glass plate placed over the first one at a distance of about 1–2 cm was used to control the evaporation rate. The films (20 x 35 cm, 20–40 μm thick) were placed in a mixture of acetone (500 ml) and 0.1 N sodium hydroxide (500 ml) for various times (0–4 h). The films were then placed in 0.2 N hydrogen chloride (200 ml). After washing with distilled water the films were dried and stored.

Measurements

Viscosity measurements of Leu/Asp(OBz) copolymers were carried out in Ubbelohde type capillary viscometers at 25°C. Elemental analyses were carried out in the section of Chemical Analyses of our Department (Mr W. Potman).

The mol % of ionic groups in the end-products were determined by potentiometric titration in the same division (Dr M. Bos). Infra-red absorption spectra of solid films were measured with a Beckmann IR-33 spectrophotometer in the region 600–4000 cm^{-1}.

RESULTS AND DISCUSSION

Hydrophilic copolymers of L-leucine, L-aspartic acid and L-aspartic acid esters can be obtained by saponification of β-alkyl aspartate residues.

The β-alkyl ester groups can be introduced following two approaches: (a) copolymerization of L-leucine and β-alkyl-L-aspartates; and (b) copolymerization of L-leucine with β-benzyl-L-aspartate, followed by an ester interchange reaction to convert the β-benzyl ester groups into β-alkyl ester groups[13]. Until now poly(β-alkyl-L-aspartates) can only be prepared with low molecular weights, whereas β-benzyl-L-aspartate-NCA can be polymerized with molecular weights over 100 000[13]. Therefore we started with the synthesis of the as yet unknown high molecular weight random copolymers Leu/Asp(OBz) (I). In 1972 the synthesis of the low molecular weight sequential poly[Leu-Leu-Asp(OBz)] was reported[14].

High molecular weight Leu/Asp(OBz) (I) polymers are prepared by polymerization of the corresponding α-amino acid N-carboxyanhydrides (NCAs). Optimum polymerization results are dependent on the choice of solvent(s) and molar ratios of the α-amino acid-NCAs for a particular polymerization reaction.

Polymers (I), containing more than 50 mol % of L-leucine can be polymerized best in benzene/dioxane (4:1 up to 6:1 v/v) mixtures. When the content of L-leucine in I is less than 50 mol %, the use of benzene/dioxane leads to lower yields and the polymerization solution becomes turbid. The polymerization of β-benzyl-L-aspartate-NCA in mixtures of dioxane and chloroform, using triethylamine as an initiator yields irreproducible products[15]. Notwithstanding the partial insolubility of β-benzyl-L-aspartate-NCA in chloroform, better results are obtained by using this solvent[15]. Therefore the 30:70 mixture of NCAs was polymerized in chloroform resulting in a polymer with a comparable composition.

Table 1 Reaction conditions and characterization of Leu/Asp(OBz) (I) copolymers[a]

Molar ratios of Leu-NCA and Asp/(OBz)-NCA	A/I	Polymer composition[b] (mol % Leu)	η_{sp}/c (c = 0.2, DCA, 25°C) (dl/g)	$[\eta]$ 25°C CHCl$_3$ (dl/g)
70:30	200	68	0.92	1.7[c]
67:33	200	67	0.96	2.8
60:40	200	57	0.79	—
60:40	500		1.23	3.4
50:50	200	47	0.56	1.7
50:50	500		1.52	5.3
40:60	200	49	0.56	—
40:60	500		0.76	—
30:70	200	26	0.53	1.1

[a] The total NCA concentration is 5% by weight; triethylamine was used as an initiator. All the reactions were performed in benzene/dioxane (4:1 up to: 6:1 v/v) mixtures except the 30:70 copolymer where chloroform was used
[b] Based on hydrogen and nitrogen elemental analysis (*Figure 2*)
[c] In CHCl$_3$–DCA (90:10 v/v)
Figure 1 Infra-red spectra of (a) Leu/Asp(OBz) (70:30) and (b) Leu/Asp(OBz) (30:70). Films: 70:30 cast from benzene/dioxane; 30:70 from chloroform

The compositions of polymers (I) based on molar ratios of NCAs used can be verified by elemental analyses (hydrogen and nitrogen). The results are given in *Table 1*. In general, good agreement was observed.

The polymers described in *Table 1* are soluble in chloroform, except Leu/Asp(OBz), (70:30). All the polymers are soluble in dichloroacetic acid. Polymers containing from 50 to 80 mol % L-leucine are soluble in benzene/dioxane (4:1 v/v) mixtures. Non-solvents for all the polymers are alcohols, dimethylformamide (DMF), dimethylsulphoxide, acetonitrile and water.

Viscosity measurements on polymers (I) have been carried out at $25°C$ in dichloroacetic acid (DCA) solutions (η_{sp}/c, $c = 0.2$ g/dl,) as well as in chloroform solutions ([η] ; $c = 0.05-0.25$ g/dl). It is clear that by using higher NCA–initiator (A/I) ratios the viscosity values are increasing for the same polymer compositions. Preliminary o.r.d. measurements on Leu/Asp(OBz) (50:50) dissolved in DCA indicate that this polymer was not completely in the random coil conformation. Therefore it is not possible to determine the molecular weight of these polymers using the equation of Doty *et al.*[16] for poly (γ-benzyl-L-glutamate). The viscosity values in chloroform indicate a rod-like structure and/or strong association of the polymer chains.

Figure 1 shows the i.r. spectra of films of Leu/Asp(OBz) (70:30 and 30:70). The absorption at 1745 cm^{-1} reveals the change in the amount of benzyl ester groups in the copolymers. The occurrence of the amide I band at about 1650 cm^{-1} and the amide II band at 1548 cm^{-1} in combination with a weak absorption at 1516 cm^{-1} indicates that in the films the polymer chains are predominantly in the α-helical conformation.

The copolymers (I) are converted to II using the method of Bradbury *et al.*[13]. Viscous solutions of I (±4% w/v in benzene/dioxane) are diluted with one volume of benzene. After the addition of an excess of methanol containing catalytic amounts of sulphuric acid reactions are performed at $65°C$ for 60 h. The copolymers are isolated and purified by standard methods. Films having thicknesses from 20 to 40 μm can be cast from 1, 1, 2, 2-tetrachloroethane (II, 70 mol % L-leucine) or from THF (II, 60, 50 and 40 mol %

L-leucine). The ester interchange reaction can be followed by i.r. spectroscopy (*Figure 2a*).

When we compare the spectrum of II (50 mol % L-leucine) (*Figure 2a*) with the spectra of I (70 and 30 mol % L-leucine) (*Figure 1*), the peaks at 3080, 745–735 and 690 cm^{-1} (benzyl absorbance) disappear, whereas the peak at 1435 cm^{-1} (methyl) becomes stronger. These data in combination with elemental analyses of the methylated products indicate that the ester interchange occurs with 85–95% conversion.

Films of II originally based on 50, 60 and 70 mol % of L-leucine are saponified at room temperature by treatment for up to 4 h in 0.1 N sodium hydroxide/acetone (1:1 v/v) mixtures. Wet films of Leu/Asp(OBz)/Asp(OMe)/Asp(ONa) are strongly swollen and are mechanically weak and difficult to handle. Upon treatment with acetone the films shrink
Figure 2 (a) Infra-red spectrum of Leu/Asp(OBz)/Asp(OMe), 50 mol % of L-leucine. Film cast from tetrahydrofuran. (b) Infrared spectrum of partially hydrolysed Leu/Asp(OBz)/Asp(OMe)/Asp(ONa) with 50 mol % of L-leucine
Figure 3 Ion capacity of hydrolysed film of Leu/Asp(OBz)/Asp(OMe) (47:3:50) 50 mol % of L-leucine (40 μm thickness) as a function of hydrolysis time
Figure 4 Potentiometric titration curve for Leu/Asp(OBz)/
Asp(OMe)/Asp(OH) and Leu/Asp(OBz)/Asp(OMe)/Asp(ONa). ○,
52.10 mg 'Leu/Asp(OH)' in 8 ml 0.1 M NaClO₄ titrated with
1.003 N NaOH; △, 31.52 mg 'Leu/Asp(ONa)' treated with 0.15 ml
1.056 N HClO₄ in 10 ml 0.1 M NaClO₄ and titrated with 1.013 N
NaOH

markedly and can be better handled. After the reaction,
alkali is removed by using an excess of 0.2 N hydrogen
chloride. Wet films of Leu/Asp(OBz)/Asp(OMe)/Asp(OH)
are much stronger than wet films of the sodium salt deriva-
tives. Probably because acetone is a non-solvent for Leu/
Asp(OBz)/Asp(OMe)/Asp(ONa) saponification levels off
after a certain time. For Leu/Asp(OBz)/Asp(OMe) (47:3:50)
we found this to occur after 2 h (*Figure 3*), at 2.7 mequiv./g
or 34 mol % of COOH groups. When higher ionic contents are
required treatment with 0.1 N sodium hydroxide in acetone
for 2 h and then treatment with 0.1 N sodium hydroxide is
an appropriate procedure. The copolymers (III) are soluble
in pyridine (1.5–2.7 mequiv./g) or tetrahydrofuran. There-
fore it is also possible to cast films from these solutions. The
composition of these films will be more homogeneous than
the films obtained directly after the saponification treatment.

The saponification can be followed by i.r. spectroscopy
(*Figure 2b*). The mol % of ionic groups in the polymer (III)
is dependent on saponification times and film thicknesses.

The determination of the amount of ionic groups can be
carried out by potentiometric titration in the presence of
0.1 N NaClO₄ by two ways: (a) titration of the acid form
with sodium hydroxide; (b) titration of the sodium salt
form by adding excess HClO₄ and after equilibrium has
been established, titration with sodium hydroxide (*Figure 4*).
A pK_a value of 5.0 for Leu/Asp(OBz)/Asp(OMe)/Asp(OH)
(60% Leu) is found graphically from *Figure 4* using method
(a). The method of least squares to obtain the best theoreti-
cal curve yields a value of pK_a = 5.18.

CONCLUSION

A series of well characterized negatively charged films of
random copolymers of L-leucine, β-benzyl-L-aspartate, β-
methyl-L-aspartate and L-aspartic acid [Leu/Asp(OBz)/
Asp(OMe)/Asp(OH)] (III) was obtained after saponification
of hydrophobic films of random copolymers of L-leucine,
β-benzyl-L-aspartate and β-methyl-L-aspartate [Leu/Asp(OBz)/
Asp(OMe)] (II) in alkaline water/organic solvent media.
Polymers (II) were obtained after an ester interchange
reaction with random copolymers of L-leucine and β-benzyl-
L-aspartate, [Leu/Asp(OBz)] (I).

The series of copolymers (I) covering the range 30–
70 mol % of L-leucine was synthesized by the *N*-carboxy-
anhydride (NCA) method.

Structure and molecular relaxation of alternating copolymers of styrene and N-substituted maleimides

H. Block, P. W. Lord and S. M. Walker

Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

The dielectric relaxations of twelve differing styrene/N-substituted maleimide alternating copolymers are reported. Five processes common to most member copolymers have been observed, and their molecular origins are discussed. Supplementary evidence based on measured X-ray structural factors and differential scanning calorimetry, together with comparative literature data on N-substituted polymaleimides and a styrene—maleic anhydride copolymer is presented as further evidence supporting the suggested origins for loss peaks in these structurally related polymers.

INTRODUCTION

Mechanical, dielectric and nuclear magnetic resonance (n.m.r.) techniques are of increasing importance in the study of molecular motion in polymeric materials in the solid state. However, the assignment of particular molecular re-arrangements to an observed relaxation presents problems whose solution often necessitates the study of a series of polymeric materials with only rather minor structural variations.

One such series of polymers is the homologous group based on N-substituted polymaleimides whose relaxation behaviour has formed the basis of a previous report[1]. Another allied macromolecular system is the alternating copolymer of styrene with maleic anhydride[2]. Below we report on the relaxation behaviour of alternating copolymers of twelve N-substituted maleimides with styrene. These were readily obtained from a styrene—maleic anhydride copolymer precursor. In their dielectric and n.m.r. relaxation behaviour these materials show five processes (α to ϵ), two assignable to main chain motions, two to maleimide ring deformations and a further process which is probably a ring deformation but whose assignment is less well substantiated. Thus, the copolymer system presents the same general relaxation behaviour as that of the homopolymers[1] but with significant and informative differences of detail, discussed below. Also presented is evidence based on X-ray investigation as to the structure and morphology of the styrene/N-substituted maleimide copolymers, and this evidence is discussed in relation to the molecular motions which occur.

The investigation described below covers a frequency range of 10^{-5} to 10^6 Hz over a temperature range from 90 to 500 K.

EXPERIMENTAL

Materials

Styrene—maleic anhydride copolymer was prepared by free radical initiation (0.15% azobisisobutyronitrile) of equimolar proportions of monomers in acetone as diluent (~75%). Polymerization was carried out under vacuum ($<10^{-3}$ mmHg) at 50°C for several hours[3]. The resulting polymer was isolated by precipitation into light petroleum ether and vacuum dried. Alternating N-substituted maleimide copolymers were synthesized from the anhydride copolymer by reacting a 6% solution with an excess of the appropriate amine in refluxing glacial acetic acid for 4 h[4]. After complete precipitation into light petroleum ether the copolymers were reprecipitated from chloroform and vacuum dried. All materials showed strong imide absorption bands at 1690 cm^{-1} and an absence of the 1850 cm^{-1} anhydride band, present in the precursor copolymer. Elemental analysis and other characterizing data are shown in *Table 1*.

Differential scanning calorimetry

Thermograms were obtained using a Perkin-Elmer DSC 1B differential scanning calorimeter operating at a scan rate of 16°C/min and using small compressed pellets (~0.5 mm thickness) of polymer. The T_g values obtained are shown in *Table 2*.

X-ray structural studies

X-ray diffraction photographs were obtained from small disc samples (~1 mm thickness) made by pressing the powdered polymer. These were mounted in a flat-plate camera and irradiated with vanadium-filtered CrKα radiation (wavelength 0.22896 nm) for small angle scattering and nickel-filtered CuKα radiation (wavelength 0.15405 nm) for large angle scattering. The calculated spacings for the amorphous halos were corrected by Ehrenfest's relation[5] $[d = 1.25d_{Bragg}]$ Derived spacings are shown in *Table 2*.

Molecular weights

For polymers soluble in tetrahydrofuran, weight- and number-average molecular weights were estimated from gel permeation chromatograms performed at the Rubber and Plastics Research Association. Data so obtained are given in *Table 1*.

Dielectric studies

Discs of polymer (51 mm in diameter x ~1 mm thick) were prepared by pressing powdered material (which had

previously been vacuum dried for ≥24 h) in a stainless-steel die using an Apex hydraulic press. The press had facility for working at thermostatically controlled elevated temperatures. Discs prepared at ambient temperatures were pressed for ~1 h at 1.6 x 10^7 N/m² whilst those prepared at 20–30°C above their T_g were pressed at 3.2 x 10^6 N/m² for ~1/2 h. Certain sample discs were treated by heating at 30°C above their T_g for several hours and then quenching in liquid nitrogen to provide a more disordered morphology. For measurements performed in two terminal dielectric cells the discs were provided with tin foil electrodes (25 μm thickness) using a thin layer of petroleum jelly (refined by passage down an alumina column at 90°C) as bonding agent.

Capacitance/conductance measurements in the range 105–20 x 10^3 Hz were made with a B221 Wayne–Kerr

transformer ratio-arm bridge energized externally with a TSA 635/2 Venner Electronics wide range oscillator fitted with a RSC TA6 amplifier and matching transformer. Null detection was achieved with a Brookdeal Electronics model 464 high gain tuned amplifier. For the frequency range 10^5–10^6 Hz a Wayne–Kerr radiofrequency B601 bridge was used with a SR268 combined source–detector unit.

Dielectric relaxation measurements in the range 10^{-5}–10^{-1} Hz were obtained by the dielectric step-response technique in which the charge/discharge currents of a capacitor are monitored as a function of time. After subtracting the steady state current in the charging mode from the time dependent charge current, charge and discharge current curves were practically identical; their mean values were Fourier transformed. A stable, continuously variable high voltage d.c. source (E. M. Wareham Ltd, Model SO7) acted as charging source (in the range 0–40 V) and a Keithley 602 electrometer (input resistance > 10^{14} Ω) was employed as a picoammeter. Data were automatically logged using a Solartron LM1620 digital voltmeter gated at fixed preset intervals using digital timing circuitry. These data were recorded, either manually or onto paper tape with a Solartron punch drive unit and Addo punch head acting as a decimal-binary converter. The capacitor cell and electrometer were shielded by enclosing them in a ground box and all electrical connections were made with the minimum lengths of low-loss coaxial cable screened to earth. These precautions were essential to obtain a low random noise level of ±10^{-14} A which was uninfluenced by variations in temperature.

Measurements were made using three alternative dielectric cells. A General Radio type 1690A two-terminal micrometer electrode assembly mounted in a Perspex box through which was passed heated or cooled nitrogen, served for the temperature range –80° to +90°C. Temperature control (±0.5°C) was achieved by adjustment of gas flow rate which was preheated or cooled (liquid nitrogen). A copper–constantan thermocouple embedded in the lower electrode enabled the continuous monitoring of temperature. In order to achieve a wider temperature range (–196° to +220°C) the cell shown in *Figure 1* was constructed. This
was a three terminal cell enclosed in a brass housing sealed by a silicone 'O' ring and the entire assembly had facility for total immersion in a cooling bath, or for the introduction of precooled or heated nitrogen through the 20 cm long chimneys. These also served as inlet ports for the electrode and thermocouple connections. A wide versatility in temperature was achieved with this construction. A similar cell provided with an externally wound heater, but without facility for gas streaming, was used in the step-response measurements, which were all made at temperatures above ambient.

The Fourier transformation of current/time data was processed using the University of Liverpool KDF 9 computer and the procedure suitable for dielectric data, previously described[6]. This method of transforming the charge/decay curves makes no assumptions such as that of the Hamon approximation[7], as to the nature of current decay functions.

RESULTS AND DISCUSSION

X-ray diffraction

The X-ray photographs of all the copolymers studied exhibited only one or two diffuse halos, indicating that they all had an essentially amorphous morphology. An identical lack of crystallinity has been reported for those poly(N-substituted maleimides) investigated[8]. Calculated spacings based on the positions of maximum intensity of the halos are shown in *Table 2*. Of the two observable spacings only the larger one, derived from the more dominant inner halo, is significantly influenced by the nature of the substituent on the maleimide nitrogen. Thus we attribute this spacing to the average interchain separation. Such a view is supported by the variation of this spacing with substituent chain length in the alkyl series [*Table 2* which also includes data reported by Cubbon[4] and corrected by the Ehrenfest relation[5] for the amorphous chain environment].

There is a linear increase in spacing with methylene group content from the amyl to the dodecyl members whilst up to and including C_5 the spacing remains approximately constant at ~1.5 nm. Finally, the octadecyl copolymer appears anomalous. The increase in spacing above C_5 is consistent with increasing side chain bulk; the near constancy of the spacing below C_5 we attribute to the dominance of the phenyl group in determining the interchain separation in these cases. The intermolecular spacing for the octadecyl polymer is of similar magnitude to that of the dodecyl polymer and these observations suggests that above C_{12} inter-side chain stacking of the methylene

groups may terminate the trend of separation with increasing side chain size, although further studies including more members above C_{12} are necessary before such a hypothesis can be confirmed. The magnitude of 1.5 nm for the average chain separation of the lower members (one to five carbon atoms) is consistent with a local 3_1 helical chain conformation (cross-section 1.52 nm) depicted in *Figure 2*. The pitch of this helix is ~0.45 nm and we believe that the smaller spacing calculated for favourable cases from the position of the weaker halo (*Table 2*) reflects this regularity. Two polymers, those with dodecyl and phenyl substuents on the nitrogen, appear to have a larger helical pitch than the remainder. The pitch in these cases may indicate a change of dominant conformer to a 4_1 helix (depicted in *Figure 2*). Such a duality of helix type has been reported to occur in substituted maleimide homopolymers both from X-ray[8] and dielectric studies[1]. In the present study, dielectric observations (next section) lend support to the view that two local structures are also present in the copolymer systems. The estimated cross-section of the 4_1 helix from measurements on space-filling models is 2.17 nm. Either 3_1 or 4_1 helices result from a *trans* addition to the double bonds to give a *three* di-isotactic local order.

Relaxation studies

α- and β-*processes*. The least facile of all the dielectric relaxation processes (the α-processes) are displayed in *Figure 3* in the temperature plane at a fixed frequency of 10^{-3} Hz. These loss peaks are all temperature-dependent, and frequency maxima (f_m)-temperature dependencies are shown in *Figure 4* in the form of Arrhenius plots. With the heptyl-, nonyl- and dodecyl-maleimide copolymers two linear portions of differing slope were observed. In these cases we believe that the results obtained at the higher frequency and temperatures are influenced by the β-process, whose resolution from α-process has not been
Figure 2 The proposed 3_1 and 4_1 helical forms of styrene/N-substituted maleimide copolymers
Figure 3 Temperature dependence of dielectric loss at 10^{-3} Hz for the α-process for styrene/N-substituted maleimide copolymers. ———, $k = 1$; ———, $k = 5$; ·····, $k = 10$
Figure 4 Arrhenius plots for the α-process in styrene/N-substituted maleimide copolymers

adequately achieved in these ranges. For this reason the true α-process parameters have been taken from the linear low temperature portions of the curves. The α-process in this region for all polymers investigated tends to extrapolate at very low frequencies towards the T_g observed on the d.s.c. traces and enumerated in *Table 2*. Although the slopes of the Arrhenius plots are very steep and therefore subject to substantial errors they do provide estimates for an apparent activation energy (*Table 2*) which are of considerable magnitude. The position and slope of the temperature dependence of maximum frequency strongly support the presumption that the α-process in all these copolymers correspond to micro-Brownian motion accompanying the glass-rubber transition. This is so even though the data do not obey the WLF equation[9], a discrepancy known to occur with other polymer systems[10]. The trends in magnitude of the apparent activation energies as a function of hydrocarbon chain lengths mirrors the interchain separation obtained from X-ray data. Thus, chain separation due to side chains, which commences to have significance at C_5 to C_7, results in an easier glass-rubber process because of the extra free volume available. Alternatively, self-plasticization commences at about C_5 to C_7. Increasing the side chain bulk still further has little effect on the

apparent activation energy of the α-process until C_{16} is reached whereupon the apparent activation energy again rises. Although the information for these higher alkyl members is restricted, it may be that at and above C_{16} the glass-rubber transition becomes less free, because of the start of some inter-side chain stacking.

The presence of a phenyl or substituted phenyl ring on the maleimide nitrogen appears to provide enough free volume to make the chain movement equivalent to hydrocarbon chains between C_6 and C_{14}.

The distribution of relaxation times making up the α-peaks is generally narrow and results in slightly asymmetric Cole–Cole diagrams. A typical example is shown in *Figure 5* which depicts the results for the amyl derivative: the Cole–Cole distribution parameter α for this system is 0.8 and other members of the series show similar values for α, as do the maleimide homopolymers[1]. The skewed arc behaviour is attributable to the presence of the β-relaxation close to the α-peak. This β-relaxation is manifest by a small loss peak or shoulder close to the α-peak on the low frequency/high temperature side of most of the copolymers studied (the exception being STDM and SHDM). In the main the β-relaxation could not be completely resolved from the large neighbouring α-process, but its partial resolution in the temperature plane could be optimized by the judicious choice of frequency. Values of ϵ'', T and optimum frequency for the peak maxima are shown in *Table 3* and examples of the peak for SNM and SDDM are depicted in *Figure 6*.

Because of the difficulties in resolving the β- and α-peaks, and because of the small magnitude of the former with respect to the latter, quantitative evaluation of the activation energy for the β-processes was not possible. In qualitative terms the activation energies for the β-process in any copolymer were less, sometimes considerably less, than those for the α-process. Trends in the facility of both processes with side chain length can best be illustrated (*Figure 7*) by changes in the temperature at relaxation
Figure 5 Plot to determine the Cole–Cole distribution parameters for the α-process in SAM at a temperature of 422K

Figure 7 Interdependence of the α- (O) and β- (●) processes as illustrated by the temperature for loss maximum at 10^{-3} Hz for the series of styrene/N-n-alkyl substituted maleimide copolymers

maximum measured at a fixed frequency of 10^{-3} Hz. As can be seen, the β-process becomes more difficult with increasing chain length up to C_{12}, which is the inverse of the behaviour of the α-process. For ODM this trend has

been reversed. The apparent inverse correlation supports the view that main chain motion is involved in the β-process also, probably as some form of local mode. The behaviour shown in *Figure 7* then reflects, that up to C_{12}, increasing chain length eases the micro-Brownian movement of the α-process, because of increased free volume, but decreases the ease of localized motion because as the chain length increases, steric factors make side chain rotation about the main chain more difficult. With the SODM copolymer these trends may have changed because of the possibility of the side-chain/side-chain interaction already referred to.

γ- and δ-relaxations. A selection fo the copolymers were studied in the frequency range 10^2 to 10^6 Hz. In this region relaxations were observed to occur at temperatures below that characteristic for the β-process. In most cases two distinct maxima were observed by a suitable choice of measuring frequency; the SDDM copolymer was an exception in that it was found impossible to satisfactorily resolve its low temperature/high frequency processes. The loss peaks in these regions are designated γ and δ and are shown in *Figure 8*. The intensities of the γ and δ loss peaks and their relative magnitudes were markedly affected by the thermal history of the sample. Quenching of the sample from above the T_g to liquid nitrogen temperature caused a reduction in loss peak magnitudes which was most marked for the high temperature γ peak (*Figure 8*). Typical activation energies for the γ and δ processes are tabulated in *Table 4*; estimates for the γ process, which exhibits the smaller loss peak are subject to the larger error because of overlap of peaks. It is evident that although both processes have different activation energies, with most copolymers only minor variations in activation energy result from change of substituent. Also, quenching has, with the exception of STM no significant effect on the activation energy. The γ and δ processes occurring in STM show anomaly in activation energy from the lower chain length members of the series.

The magnitude of the activation energies for the γ and δ processes suggest that a localized dipole relaxation in the

side chain is responsible for the dielectric loss. Very similar relaxations have been observed in the maleimide homopolymers, both dielectrically[1] and by pulsed and broadline proton n.m.r.[11]. The copolymer of styrene and maleic anhydride also exhibits similar dielectric relaxations[2] but in this case the process is not observed in pulsed proton n.m.r.[11]. For the maleimide co- and homo-polymers we suggest that inversion of the non-planar succinimide ring is the mode responsible for both the γ and δ processes. Support for non-planarity of the succinimide ring is already to hand[12]. With the styrene—maleic anhydride system a similar process implies a non-planar ring system, and is consistent with its appearance in the dielectric experiments (presence of a dipole change) and its absence in the proton n.m.r. experiments (absence of protons in the inverting part of the ring system).

That the loss magnitudes of the γ and δ processes are decreased by quenching, suggests that both processes occur in regions of structural order. The X-ray evidence already discussed indicates that any such structure is of limited extent and does not represent the presence of fully crystalline regions. There is also some minimum evidence that more than one structure (3_1 and 4_1 helices) may be present, and similar variants in conformation are known for the maleimide homopolymers[8]. It is possible that the γ and δ doublet which occurs in this system, and also in some polymaleimides[1] and the styrene—maleic anhydride copolymer[2], reflects heterocyclic ring deformations in two such essentially different conformational environments. The lower appearance temperature for γ and δ loss peaks in the maleimide—styrene copolymers *vis-à-vis* the homopolymers, when measured at a common frequency, indicates that the deformations are easier in the copolymer systems. This is consistent with the likely increase in

free volume for such a process, when styrene residues separate the heterocyclic rings.

ε-relaxation. At low temperatures and high frequencies, SCPM, SDDM and the homopolymer poly(*N*-n-amylmaleimide) exhibit a small relaxation peak. Similar relaxations have been observed for poly(*N*-n-amylmaleimide) by n.m.r.[11] for SDDM by pulsed n.m.r. studies (ϵ''_{max} = 1.56 x 10^{-2} at 1 MHz and $-120°C$). In the dielectric mode adequate resolution from the γ − δ losses for activation energy determination has only been achieved for the homopolymer, providing an estimate of 15 kJ/mol for this system. The close correspondence of these relaxations in SDDM, SCPM and poly(*N*-n-amylmaleimide) suggests that a common molecular origin is responsible for the ε process. Since the process occurs in the homopolymer, the presence of styrene residues is not causative; the low activation energy essentially precludes a form of main chain motion and the presence of the relaxation in SCPM suggests that relaxation of alkyl side chain is not the mode involved. In view of the assignment of the γ and δ relaxations to ring deformation in a defined conformational environment, it is possible that the ε relaxation has a similar origin but in regions of gross chain disorder where steric hindrances are at a minimum. This would be consistent with the low activation energy observed. The small magnitude of the loss suggests that if ring deformation is involved, then the number of dipoles in such a free, disordered environment is small. A final assignment of ε relaxations to molecular processes does, however, require further study.

Thermoluminescence and induced phosphorescence in irradiated doped PMMA

D. J. Morantz and C. S. Bilen

London College of Printing, London SE1 6SB, UK
(Received 5 December 1974; revised 20 February 1975)

Thermoluminescence (t.l.) is reported for doped poly(methyl methacrylate) (PMMA), irradiated by X-rays and u.v. light. The results are correlated with those we previously reported for induced phosphorescence in the same system. These luminescence results are accounted for in terms of transient species which have been reported for irradiated PMMA and which were detected by e.s.r. and optical absorption techniques. The transient species responsible for t.l., and induced phosphorescence, appears to be the same, namely a radical derived from PMMA. A brief outline is given of the production of such transients and their subsequent reactions in the post-irradiation period. The energy transfer processes involved are discussed in terms of an energy level diagram.

INTRODUCTION

Phosphorescence[1,2] of organic substances is well known and has been extensively studied in glassy solutions at low temperatures. Thermoluminescence of irradiated inorganic materials[3-5] above room temperature is also well known as is the thermoluminescence of irradiated organic glasses[6-8] at low (77 K) temperatures. The correlation of these two luminescence effects has, however, been attempted by few authors[9].

Recently, we have found and reported[10] the existence of strong *room temperature* phosphorescences in certain doped irradiated polymeric glasses. The ability to phosphoresce may be induced in a doped matrix by irradiation using X-rays, u.v. light, or electron bombardment; prolonged heating of the matrix at 200°C will also produce this result. The term 'induced phosphorescence' has been proposed by us for this effect[10]. The induced phosphorescence was found to be associated with species which were created by irradiation of the polymeric glass and which could be destroyed, i.e., 'bleached', by heating the doped matrix above its glass transition. We now report that during such bleaching of the induced phosphorescence, thermoluminescence takes place. This report outlines the features of the thermoluminescence and a model to account for the phenomenon. Previous studies of thermoluminescence in organic materials generally depend on the creation of charged species at *reduced* temperatures. We now find that there is a direct correlation between induced phosphorescence and thermoluminescence in that their kinetics, during and after irradiation, are similar. Indeed, there is strong evidence that the same species are responsible for both of these effects. Our thermoluminescence results provide an indication of the nature of these active species and these would appear to be radical species.

EXPERIMENTAL

The induced phosphorescence investigations used a laboratory built spectrophotometer with a HBO 200 W mercury lamp as the source of excitation light, focused through a quartz lens and filtered to remove infra-red through 15 cm of a 3% nickel sulphate solution. The excitation band was selected by means of a Hilger and Watts grating monochromator (M/65/7) in conjunction with an OX7 filter to cut off any stray visible light. The sample box had a locating device for a matching sample holder so that the emission from the same area of the sample was analysed using a high resolution grating monochromator (Hilger and Watts D 330/1 Mark II). The spectrum was plotted by means of a motor drive scan of 25 nm/min. The detection system for the emission was a photomultiplier (EMI 5824 B) connected to a d.c. amplifier and chart recorder.

Sample preparation and irradiation procedures have been described elsewhere[10].

The thermoluminescence apparatus is shown schematically in *Figures 1a* and *1b*. The doped samples were irradiated in the X-ray apparatus or by an unfiltered HBO 200 W u.v. lamp for 10–60 min. The irradiated samples were inspected under a u.v. inspection lamp (CAMAG Meetlenz Schivanz 220 V/50 Hz) for fluorescence and phosphorescence. The non-irradiated part showed normal fluorescence, whereas the irradiated part showed both fluorescence and phosphorescence. The sample was then placed in the thermoluminescence apparatus sample chamber and its glow curve was recorded.

During some experiments, the irradiated samples were first placed in the emission spectrophotometer, their emission spectra (including fluorescence and phosphorescence bands) were recorded, and then the same samples were examined in the thermoluminescence apparatus to obtain the thermoluminescence curves. This allowed direct comparison of the two effects. A sample which was to be used for a variety of irradiation periods was annealed, after each experiment, in an electric oven at 160°C for 20 min and then kept in the dark for 30 min to cool to room temperature. Otherwise each irradiation experiment was undertaken using a fresh sample.

RESULTS

A typical emission spectrum for dibenzothiophene (DBT) doped PMMA showing the presence of induced phosphorescence bands, after X-ray irradiation for 1 h is shown in

Figure 2a. The thermoluminescence of a similar sample after X-ray irradiation is shown in *Figure 2b*. The thermoluminescence peak was found to be at 340 K i.e., approximately at the glass transition temperature of the matrix when the induced species are created by X-ray irradiation. However, in the case of u.v. irradiation of doped polymer samples, the situation is more complex. In the earlier stages of the u.v. irradiation the peak position corresponded, as for X-ray irradiation, to the glass transition temperature. As irradiation with u.v. proceeded, the peak appeared to shift to higher temperatures and new higher temperature peaks appeared. The intensity of the 340 K peak was down by an order of magnitude (see *Figure 3a*).

Figure 3b shows the emissions of a DBT doped PMMA sample at various stages of u.v. irradiation. The solid curve shows the DBT emission (fluorescence only) of an un-irradiated sample. The curve showing the emission of a sample after optimum u.v. irradiation includes fluorescence as well as phosphorescence bands. The effect of further u.v. irradiation, producing an induced fluorescence peak at 380 nm is shown in the broken curve. For X-ray excitation, the induced phosphorescence peak intensity rises to a maximum with increasing irradiation period as shown in *Figure 4* (solid curve); the broken curve in *Figure 4* shows the corresponding curve of thermoluminescence peak intensity against X-ray irradiation periods. The u.v. irradiation behaviour follows a different pattern as shown in *Figure 5*. The thermoluminescence curve of triphenylene (TP) doped PMMA after excessive irradiation is shown in *Figure 6a* and the corresponding u.v. induced phosphorescence is shown in *Figure 6b*. The induced fluorescence at 390 nm is much more pronounced for TP (*Figure 6b*) than for DBT (*Figure 3b*).

DISCUSSION

These thermoluminescence results and our previously reported induced phosphorescence[10] results, as well as the reported e.s.r. and optical studies, may all be explained in terms of common transient species produced by irradiation

in the matrix. Previous studies using e.s.r.[11,12] and t.l. (thermoluminescence)[13] with X-ray and γ-irradiated PMMA samples, demonstrated that a variety of charged as well as uncharged species are present under various experimental conditions. David *et al.*[13] found that most of the charged species produced by γ-irradiation in PMMA samples doped with acridine will recombine to give a t.l. peak at 160 K. However, the absorption spectrum, due to uncharged radicals, continued to exist until the glass transition point (360 K) of the matrix. There was also a correlation between the t.l. decay curve and the decay curve for the disappearance of the radical anion absorption band due to the dopant. After the t.l. and anion decay most of the anions were converted to uncharged radicals.

Recently, Geuskens and David[11] studied the evolution of the e.s.r. spectrum of PMMA after γ-irradiation, between 110 K and 320 K, and suggested that up to six different types of radicals may be found depending on the temperature range. At room temperature, the radical, R, predominated and was of the form:

$$\begin{array}{c} CH_3 \\ | \\ -CH_2-C^\bullet \\ | \\ COOCH_3 \end{array}$$
This was identified by a strong 9 line e.s.r. spectrum.

Szocs and Lazar[12] found that at or above room temperature the radical responsible for the nine line spectrum decayed rapidly at 340 K while some other radical species, giving doublet and singlet e.s.r. peaks, persisted and decayed at about 373 K and higher. The nine line spectrum did not appear in irradiated PMMA samples even at room temperature when these were carefully freed from monomer before irradiation. However, doublet and singlet peaks, occurring in such samples, changed very rapidly to a strong nine line signal when monomer vapour was allowed to diffuse into the irradiated sample.

The induced phosphorescence effect in our X-ray irradiated doped PMMA samples also decays rapidly at 340 K and furthermore these samples show a strong t.l. peak at about the same temperature during the glow experiment, suggesting therefore that the species responsible for the induced phosphorescence and t.l. effects may be the same radical, R. Such species have also been observed by e.s.r., for u.v. irradiated PMMA[14].

We confirm that, during the initial u.v. irradiation periods (up to 20 min) of our doped PMMA samples, such transient species were produced, and we note the similarity of the emission curves of X-ray and u.v. irradiated samples (see *Figures 2a* and *3b*); *in both cases* the induced phosphorescence peaks appear to be due to the presence of radiation induced radical species. These species are affected by oxygen in a similar manner to that reported for the species observed using e.s.r.[11,12]. The t.l. peaks for X-ray and u.v. irradiated samples (*Figures 2a* and *3b*) are both approximately at the same temperature (340 K). The curve in *Figure 4* which describes the increase in the induced phosphorescence during X-ray irradiation shows similar features to the corresponding curve for the t.l. effect. Again the behaviour of the two luminescence effects in the case of u.v. irradiation (*Figure 5*) shows strikingly similar kinetic behaviour, owing to the presence of the same species. Such species may, moreover, be responsible for the current peak under a thermal gradient observed at 340 K, when

X-ray and γ-irradiated samples were heated[15]. However, during our studies in some cases (where long u.v. irradiations were carried out in air), t.l. peaks were observed at temperatures higher than 340 K. Such peaks are shown in *Figure 3b*, and also in *Figure 6a*. Samples showing these later t.l. peaks did not show much induced phosphorescence but exhibited new induced fluorescence peaks (see *Figure 3a* and *Figure 6a*). In these cases, the species responsible for induced phosphorescence and the t.l. peak at 340 K appear to have undergone further reaction with oxygen (in the presence of u.v. light) so as to give new species responsible for induced fluorescence and high temperature t.l. peaks. It is also seen that with excessive u.v. irradiation not only does the intensity of the 340 K peak decrease, but also the peak maximum appears to shift towards higher temperatures (*Figure 3b*). This indicates that those species (SP 1) which are at shallow trapping depths are more readily converted to the other species (SP 2) responsible for the higher temperature t.l. peaks. Those species, of kind SP 1, at deeper trapping depths, are left behind and are not converted to SP 2. We propose the following scheme for production, and subsequent reactions of these species. During irradiation and the primary reactions, chain scissions of the polymer matrix occur. The species produced may be any one of those suggested by David *et al.*[13], dependent upon temperature and other experimental conditions. At room temperature where X-ray irradiation is carried out in our samples in the presence of oxygen, uncharged radicals, R, will predominate. These radicals, by virtue of the energy levels they possess, will take part in energy transfer processes resulting in induced phosphorescence[10] until and unless they are consumed by various secondary reactions. The latter reactions comprise radical–radical recombinations and radical reactions with oxygen in the presence or absence of u.v. light. In the case of X-ray irradiation, charged species and radical fragments of both main and side chains are produced. There is also a small probability of the production of monomer radical and dissociation of the dopant molecule. During u.v. irradiation of the system both types of radical fragmentation as well as excitation of the dopant occur. There is little probability of the production of charged species. The other distinction between the effects of these two types of

irradiation is the bulk (for X-ray) and surface (for u.v.) nature of the reactions. In the post-irradiation period the predominant reaction is recombination of the transient radical species (SP 1). In the presence of oxygen and u.v. light combination these transient species may be converted to stable species (SP 2) by secondary reactions. Whenever the products of any of these reactions are formed in their excited states, these undergo normal deactivation processes leading to fluorescence, phosphorescence and non-radiative thermal degradation.

We conclude that the species responsible (SP 1) for the 340 K t.l. peak is radical R and that this radical is also involved in the transfer of energy to the triplet level of the dopant molecule and hence the induced phosphorescence. The energy transfer processes involved, between the energy levels of the species (SP 1), the normal matrix and the dopant molecules are shown schematically in *Figure 7*. The species responsible for the higher temperature t.l. peaks and the induced fluorescence peaks, in the case of excessive u.v. irradiated samples, are thought to be radical peroxides as the products (SP 2) of radical reactions. The energy levels corresponding to species SP 2 are shown in *Figure 7*, which demonstrates, as well, the difference in the nature of SP 1 and SP 2. The latter is emissive and SP 1 is non-emissive. We recall as well that the SP 1 species are transient and are converted, in secondary reactions to stable, SP 2 species. We recall, moreover, that e.s.r. studies[13] show that the signals corresponding to SP 2 were absent when irradiation was carried out in the absence of oxygen. These considerations support the view that SP 2 are oxidized products of SP 1.

Kinetics of the thermal oxidation of isotactic poly(1-pentene)*

S. M. Gabbay, S. S. Stivala and L. Reich
Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030, USA
(Received 7 April 1975)

The kinetics of the thermal oxidation of isotactic poly(1-pentene) was studied in the bulk phase. The experimental data were obtained from the quantitative estimation of carbonyl groups formed in the non-volatile oxidation products using infra-red spectroscopy. Reaction temperature varied from 100° to 115° and oxygen concentrations from 10% to 100% by volume. A general kinetic scheme and mathematical expressions previously reported for the thermal autoxidation of polyolefins satisfactorily explained the experimental results. Activation energies of this polymer for various steps in the kinetic scheme were compared with polypropylene and poly(1-butene).

INTRODUCTION

Among the thermal oxidation studies of polymers, the polyolefins, e.g., polyethylene, polypropylene, and poly(1-butene), have received considerable attention[1,2]. Stivala and Reich have previously presented a general kinetic scheme for the thermal oxidation of polyolefins[1]. Mathematical expressions derived from the scheme were satisfactorily applied to the thermal oxidation of isotactic polypropylene (IPP)[3], atactic polypropylene (APP)[4-9], isotactic poly(1-butene) (IPB)[10], and atactic poly(1-butene) (APB)[11] in the bulk phase under various experimental conditions (temperatures, oxygen concentrations, and metal catalyst concentrations). Bawn and Chaudri[12,13] successfully used this kinetic scheme to both metal catalysed and uncatalysed autoxidation of APP in solution in explaining various kinetic dependencies. The purpose of this paper is to examine the kinetics of the thermal oxidation of isotactic poly(1-pentene) (IPP-1) in the bulk phase using infra-red (i.r.) spectroscopy. The rates of formation of the non-volatile products, at various temperatures and oxygen concentrations, were assessed from the i.r. bands of the carbonyl groups. The volatile products evolved during the thermal oxidation of IPP-1 were identified by thermal and mass chromatography[14]; this method was also used in studying the volatile products evolved from the thermal oxidation of poly(4-methyl-1-pentene)[15].

EXPERIMENTAL

Starting material

The IPP-1 sample used in this study was unstabilized pure polymer obtained through the courtesy of Dr Gianotti from Montedison Company, Italy. Its intrinsic viscosity in tetralin at 135°C was 4.7 g/dl. Upon ignition, the sample gave an ash content of 0.01% by weight. A crystal-

line melting point of 78°C was determined by a Perkin–Elmer Differential Scanning Calorimeter (DSC) using a programmed heating rate of 10°C/min. IPP-1 studied in this work was modification 1.

Apparatus

A Perkin-Elmer recording spectrophotometer, Model 21, was used. Attached to this instrument was an oxidation cell which was essentially similar to that previously described[4]. The temperature controller, a Fisher Proportional Temperature Control, had a temperature range up to 250°C, with a nominal temperature variation of ±0.02°C. The cell chamber temperature was measured with an iron–constantan thermocouple connected to a millivolt potentiometer (Leeds and Northup). The thermonitor temperature reading was calibrated against the potentiometer.

Procedure

Clear and uniform films of approximately 2 to 2.5 mil thickness of modification 2 were prepared when IPP-1 sample was compression moulded in vacuum at 140°C and cooled to room temperature over a 20 min period. These films were converted to modification 1 by refluxing them in absolute ethanol overnight and subsequently dried in a vacuum oven at 50°C for 12 h (thickness not appreciably affected). These films were then placed on sodium chloride discs which were assembled in the oxidation cell mounted onto the infra-red spectrophotometer. By means of i.r. spectra, as shown in *Figure 1*, it was ascertained that no pre-oxidation of the sample occurred, during film preparation or when the sample was heated to the desired reaction temperature under a blanket of nitrogen.

Known mixtures of pure dry oxygen and nitrogen were passed into the oxidation cell at a constant rate of 30 cm³/min after the desired reaction temperature was reached. The ratios of oxygen to nitrogen mixtures used were (by volume): 10 : 90, 25 : 75, 50 : 50, 75 : 25, and 100 : 0. Reaction temperatures were 100°, 105°, 110° and 115°C. I.r. spectra of the carbonyl (5.50–6.00 μm)
Figure 1 I.r. spectra of IPP-1 (modification 1). (a) Before oxidation; (b) after oxidation at 115°C
Figure 2 Plots of carbonyl absorbance area *versus* time for IPP-1 at 100°C under various oxygen concentrations: □, 10; ○, 25; ×, 50; △, 75; ●, 100%

region were recorded at various temperatures and oxygen concentrations, as a function of exposure time. The carbonyl areas for a given film were computed in terms of the total absorbance area (cm²) of the carbonyl band using a Fortran IV program[16]. This program converts the carbonyl transmittance band to absorbance, and then replots the area computed by the trapezoid method while maintaining the same baseline as previously reported[4]. The computed absorbance area is normalized to unit film thickness from an *a priori* calibration of maximum absorbance at 7.30 μm (due to —CH₂CH₃) *versus* known film thicknesses[16]. Thus, the computed carbonyl area of a given film thickness was divided by the value of the maximum absorbance of the corresponding film thickness from the linear calibration curve at a given oxygen concentration and temperature[16]. The weight loss of modification 1 was 1% at 115°C under 100% oxygen for 75 min. Diffusion control was found to be absent for the mil thickness of the films used in this study, pursuant to procedure described earlier[1,4].

RESULTS

As in the cases of IPP[3], APP[4], IPB[10], and APB[11], it was observed that at all oxygen concentrations employed, the reaction rate increased while the induction period decreased with increasing reaction temperature. Further, as the

oxygen concentration was increased, the rate of formation of total carbonyl increased while the induction time decreased, at any one given temperature (*Figure 2*). Maximum rates of formation of total carbonyl (ρ_m) were determined from plots of carbonyl absorbance area *versus* time (cf. *Figure 2*) for various temperatures and oxygen concentrations. These values are listed in *Table 1*. *Figure 3* has been constructed from the data in *Table 1*.

DISCUSSION

Modification 2 was found to resist oxidation at 65°C in pure oxygen for 4 h. Higher temperatures of oxidation would approach the melting point of this form (78°C), thus rendering thermal oxidative studies in the bulk phase impractical. On the other hand, modification 1, by virtue of its higher melting point (128°C), was more amenable for examining its thermal oxidative properties. At 65°C modification 2 would have required, for less than 100%

K_1, K_2, K_3 defined in equations (10a), (10b) and (10c)

oxygen, very long exposure time to detect carbonyl formation. (Diffusion rate is low at lower temperatures thus requiring long exposure times at lower oxygen concentrations.)

The kinetic scheme and assumptions presented previously by Stivala et al.[3] for the thermal oxidation of polypropylene were used in this study. For convenience, the scheme is reproduced below:

$$RH + O_2 \xrightarrow{k_i, \phi_i} R\cdot + HO_2\cdot \tag{1}$$

$$R\cdot + O_2 \xrightarrow{k_2} RO_2\cdot \tag{2}$$

$$RO_2\cdot + RH \xrightarrow{k_3} RO_2R + H\cdot \tag{3}$$
$$\text{(one R may be H)}$$

$$RO_2\cdot + RH \xrightarrow{k_4} \text{inactive products} \tag{4}$$

$$RO_2R \xrightarrow{k_5} 2RO\cdot \tag{5}$$

$$RO_2R \xrightarrow{k_6} \text{inactive non-volatile products} \tag{6}$$

$$RO\cdot \xrightarrow{k_7} R\cdot' + \text{volatile products} \tag{7}$$

$$R\cdot' + RH \xrightarrow{k_8} R\cdot + R'H \tag{8}$$

$$R\cdot' + O_2 \xrightarrow{k_9} \text{less reactive products} \tag{9}$$
where RH represents the polyolefin. The pertinent expressions which were derived are summarized in equations (10)–(13).

The maximum rate of formation of non-volatile carbonyl products, ρ_m, at a given temperature and oxygen concentration is expressed as:

$$\rho_m = \frac{K_1[O_2]}{1 - K_2/(K_3 + [O_2])} \tag{10}$$

where

$$K_1 = \frac{Ck_i k_3 k_6 [RH]}{(k_3 + k_4)(k_5 + k_6)} \tag{10a}$$

and $C = (1 - e^{-At_m}) \approx$ constant, since At_m (where t_m equals the time to reach maximum reaction rate) is approximately constant under the experimental conditions used over the range of temperatures and oxygen concentrations employed.

$$K_2 = \frac{2k_3 k_5 k_8 [RH]}{k_9(k_3 + k_4)(k_5 + k_6)} \tag{10b}$$

$$K_3 = \frac{k_8}{k_9} [RH] \tag{10c}$$

$$K_5 = \frac{(k_3 + k_4)k'K_2}{2k_3 K_3} \tag{11}$$

$$A' = 1 - \frac{K_2}{K_3 + [O_2]} \tag{12}$$

where

$$A' = \frac{A}{k'} = \frac{A}{k_5 + k_6} \tag{12a}$$

and

$$-\ln(\rho_m - \rho)/\rho_m = At \tag{13}$$

when $\rho \ll \rho_m$. For relatively high values of $[O_2]$, equation (10) becomes:

$$\rho_m = K_1 K_3 + K_1 [O_2] \tag{10d}$$

From equation (10d), it can be seen that a plot of ρ_m versus $[O_2]$ should give a linear curve of slope K_1 and intercept $K_1 K_3$. By rewritting equation (10) in the form:

$$\{K_3 + [O_2]\}\{\rho_m - K_1[O_2]\} = K_2 \cdot \rho_m \tag{10e}$$

and plotting the left hand side of equation (10e) versus ρ_m, a linear curve of slope K_2 can be obtained. Hence, values for K_1, K_2, and K_3 may be estimated. Values for these constants are given in Table 1 for various temperatures (from 100° to 115°C) and oxygen concentrations (from 10 to 100%). From these values, various values of ρ_m were calculated and found to agree satisfactorily with observed values (cf. Table 1). From equation (13) values of A were determined at various temperatures and oxygen concentrations (Table 2). Corresponding values of A' were calculated from equation (12). The values of k', at a given temperature and for various oxygen concentrations, were about constant. Arrhenius plots of $\log K_3$ and $\log [K_2/(K_1 K_3)]$ were constructed as shown in Figure 4. From the slopes of the linear relationships obtained and from equations (10a) to (10c), the following values were obtained: $E_8 - E_9 \approx 13$ kcal/mol and $E_i + E_6 - E_5 \approx 20$ kcal/mol. From equation (11), it can also be seen that if k_4/k_3 is constant over the temperature range used [this was previously indicated to be true[17]], then an Arrhenius plot of $-\log[k'K_2/K_3]$ should afford a value of E_5. In

Table 3 Comparison of activation energies of IPP-1 at various oxidation stages to other polyolefins

	Activation energies (kcal/mol)			
Polyolefins	$(E_8 - E_9)$	$(E_i + E_6 - E_5)$	$(E_i + E_6)$	(E_5)
IPP (3)	6	18	51	33
APP (4)	9	17	48	31
IPB (10)	14	13	38	25
APB (11)	10	14	43	29
IPP-1 (this work)	13	20	46	26

this manner, $E_5 \approx 26$ kcal/mol (cf. *Figure 5*). This value was checked by means of a plot of $-\log \rho_m A/[O_2]$ *versus* reciprocal temperature [cf. *Figure 5* and equations (10), (10a), and (12a)] to yield a value of $E_i + E_6 \approx 46$ kcal/ mol from which a value of $E_5 \approx 26$ kcal/mol was calculated.

Values of the activation energies for the various stages obtained in this work for IPP-1 are compared with corresponding values for other polyolefins, previously reported from this laboratory in *Table 3*. From this Table, it appears that various autoxidation process may be occurring less rapidly for IPP-1 than for IPB but more so than in IPP, under similar experimental conditions.

Derivation of accurate glass transition temperatures by differential scanning calorimetry

M. J. Richardson and N. G. Savill

Division of Materials Applications, National Physical Laboratory, Teddington, Middlesex TW11 0LW, UK
(Received 3 March 1975)

Glass transition temperatures, T_g, cannot be directly determined from differential scanning calorimetry (d.s.c.) curves because of kinetic effects which are especially serious for well annealed samples. Using an anionic polystyrene as an example it is shown how d.s.c. data can be transformed to enthalpy curves which give T_g with an accuracy of ± 1K. As the rate of cooling through the glassy region is lowered T_g is found to decrease by 2.2 K per decade decrease in cooling rate. Quantitative data are given for the specific heat increment at T_g.

INTRODUCTION

The specific heat, c_p, of a polymer changes abruptly at the glass transition temperature, T_g, and, since the signal from a differential scanning calorimeter (d.s.c.) is proportional to c_p, this form of calorimetry has found a ready application in the characterization of T_g. Unfortunately a d.s.c. is a dynamic instrument and because the glass transition is a strongly rate dependent phenomenon, kinetic effects make the interpretation of experimental d.s.c. curves difficult, if not impossible. Consistent, but arbitrary, treatment allows the definition of a dynamic glass temperature, T_{gd}, but such a quantity has little value other than for showing differences between samples. In particular, it cannot be related to values obtained by other techniques.

This paper describes how a simple treatment of d.s.c. data gives 'equilibrium' values of T_g, which are independent of the heating rate. By contrast, the rate of cooling (annealing) through the transition region has a well defined effect on the glass temperature and quantitative data are given for this and also for the specific heat increment at T_g.

EXPERIMENTAL

The polymer was an anionic polystyrene of $M_n = 36\,000$ (Pressure Chemical Co., Batch No.7b). Before any measurements were made, samples were heated in the d.s.c. to about 450 K with the dual purpose of removing any residual low molecular weight impurities and giving a stable sample geometry for subsequent experiments (polystyrene of this molecular weight slowly flows above T_g and without this pretreatment the calorimeter output may be perturbed). Polymer was transformed to the glassy state by cooling through T_g at various rates in the calorimeter itself, the only exception being for the slowest rate (2.5 K/day) where the stabilized sample was cooled, in an atmosphere of nitrogen, in an oil bath.

Experiments were carried out with a Perkin-Elmer DSC-2 using alumina as the enthalpy calibrant. Full details have been given earlier[1-3] but we emphasize the important points here. The calorimeter temperature was raised from one steady value, T_1, to another, T_2, where $T_1 < T_g < T_2$, in the sequence: (i) empty, (ii) calibrant, (iii) sample. The results of (i) and (ii) gave the area-to-enthalpy conversion factor and reference data for specific heats which, in conjunction with (i) and (iii), led to the total enthalpy change in the polymer $H_l(T_2) - H_g(T_1)$, where g and l refer to the glassy and liquid states, respectively, as well as specific heats in the interval T_1 to T_2.

RESULTS

Results for a variety of thermal treatments are summarized in *Table 1*. The computer programme transformed the d.s.c. output into the overall enthalpy change, column 4, and a table of specific heats at intervals of about a Kelvin, the actual figure depending on the heating rate and the frequency of sampling for the tape output. Specific heat data for the glassy and liquid states were then fitted to separate polynomials in temperature, care being taken to exclude data from the transition region itself. Simple linear relationships were found to adequately represent the c_p/temperature behaviour of both the glassy and the liquid state in the range $T_g \pm 70$ K and columns 5-8 show values calculated from these least squares fits at rounded temperatures. They give a good idea of the reproducibility of the experimental data, a figure of $\pm 1\%$ encompasses all results from 20 separate experiments. *Table 1* cannot reveal rate effects in the transition region itself and these are shown in *Figures 1* and *2*. Specific heat curves should be coincident, at least in the liquidus (the glassy state is discussed below), and the observed deviations in *Figures 1* and *2* reflect the experimental errors discussed above. We should emphasize that our computer procedure[3] is based on the isothermal temperature calibration plus a correction for thermal lag, owing to the finite heating rate, which is derived from the sample curve itself. This correction was 0.7 (5), 1.6 (10) 3.1 (20) and 6.3 K (40 K/min) for the heating rates noted in parentheses and it is clear that the lag varies, as expected, in direct proportion to the heating rate. We therefore believe sample temperatures are properly corrected and features of *Figures*

1 and *2* may be ascribed to material, rather than instrumental, effects. An exception is the anomalous peak height for the 40 K/min heating rate (*Figure 1*). This is low because the true peak was missed owing to the slow sampling rate (one point per 1.3 K) used.

DISCUSSION

Calculation of T_g

T_g is defined by the point of intersection of enthalpy curves for the glassy and liquid states. The glassy state is generally not well defined thermodynamically but under particular circumstances pseudo-equilibrium conditions can be assumed and thermodynamic arguments employed. The specific assumption of this paper is that a given cooling rate yields a reproducible configuration so that the overall enthalpy change $H_l(T_2) - H_g(T_1)$ is a meaningful thermo-

dynamic quantity. T_1 was always arranged to be some 70 or 80 K below T_g so that any 'glassy annealing' effects would require a time-scale orders of magnitude larger than that of the experiments.

Schematic enthalpy and specific heat curves for both quenched and well annealed samples are shown in *Figure 3*. The well known tendency of annealed material to superheat is apparent in *Figure 3*, and calculation of the dynamic T_{gd} from the c_p discontinuity yields a value which is higher than that for quenched materials, the opposite of the true situation.

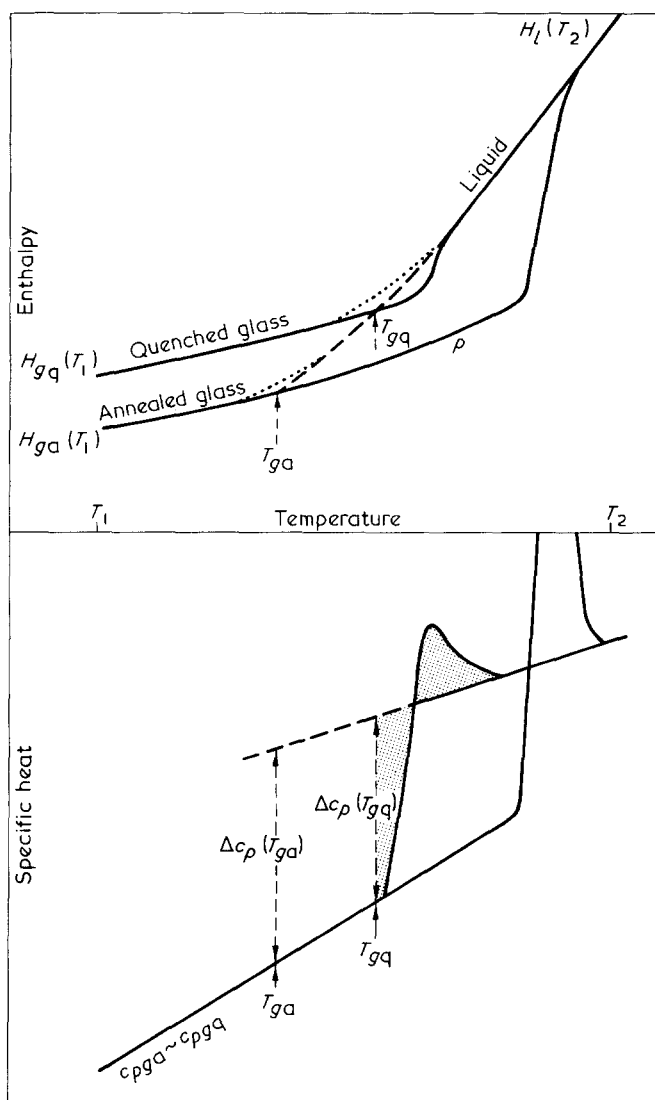
Our approach has been to construct enthalpy curves for the glass and solid which are linked by the overall enthalpy change but which ignore all details of transition region itself. In effect, enthalpy curves from well defined regions are extrapolated to the glass temperature which is defined by $H_g(T_g) = H_l(T_g)$. Integration of the specific heat equations $c_{pg} = a + bT$ and $c_{pl} = A + BT$ gives:


Figure 3 Schematic enthalpy and corresponding specific heat curves. Full lines show typical experimental paths; broken lines, which represent ideal conditions in the absence of rate effects, show how T_g is defined

$$H_g(T) = aT + \tfrac{1}{2}cT^2 + P$$

$$H_l(T) = AT + \tfrac{1}{2}BT^2 + Q$$

and, since $H_l(T_2)-H_g(T_1)$ is an experimental quantity, the integration constant $Q-P$ is readily obtained. It is then a trivial matter to solve the quadratic equation for T_g as defined by the point of intersection of the two enthalpy curves and the glass temperatures shown in *Table 1* and *Figure 4* have been calculated in this way.

Effects of heating rate

Figure 1 shows small but systematic displacement of both the point of maximum slope and the peak position with respect to heating rate, R. These are to be expected since the superheating effect (*Figure 3*) is rate dependent but they give the misleading impression that T_g is also a function of R whereas it should, if it is to have any thermodynamic significance, be independent of such an experimental parameter. *Table 1* shows that this is indeed true when enthalpy curves are used to calculate T_g. These calculated values have been inserted on *Figure 1* and it is clear that there is no simple

construction (such as the point of deviation from the low temperature baseline, or the point of intersection of this baseline with a tangent to the point of maximum slope) whereby the 'dynamic' quantity T_{gd} can be transformed to the equilibrium or 'enthalpy' value T_{gH}. In one sense it is fortunate that for this rapidly cooled polymer, which simulates the conditions under which most components are fabricated, there are only a few Kelvins difference between T_{gd}, however defined, and T_{gH}. However, the following results obtained on more carefully annealed samples show that the confidence thereby generated in the T_g values is in fact misplaced.

Effects of annealing

Anomalies in the definition of T_g from c_p curves alone are clearly illustrated in *Figure 2* in which curves 1 and 3 are quantitative examples of, respectively, the schematic quenched and annealed samples of *Figure 3*. Again, T_{gH} values have been inserted and the most striking feature is the total lack of structure in curve 3 until more than 10 K above T_{gH}. It is not the purpose of this paper to comment on the kinetic implications of these results, we restrict ourselves to the 'equilibrium' characteristics of the glassy region. However, it must be emphasized that, since relaxation times around T_g are of the order of normal experimental time scales, anomalies are not peculiar to d.s.c. but are the general rule. For example, in dilatometry a glass brought to a point on the volume–temperature curve corresponding to P (*Figure 3*) shows a steady increase in volume for a time that can extend to many hours.

When T_{gH} is plotted against log (cooling rate) there is an excellent linear correlation (*Figure 4*), a result which is completely hidden in the specific heat curves and is in fact not easily attainable by any other technique. Transformation of specific heat data as described in this paper shows that T_g decreases by 2.2 K per decade decrease in cooling rate, a figure which is constant over the molecular weight range 2×10^3 to 2×10^6 [4].

Dilatometry[4] gives 363.6 K for the glass temperature of this polymer after cooling at 2.5 K/day, a figure which agrees well with the value shown in *Table 1* and which confirms the validity of our procedure.

It is appropriate to mention here that the overall enthalpy change is affected by the annealing treatment in two ways. Not only does T_g change, as in *Figure 4*, but also c_{pg}, which should strictly be written $c_{pg\alpha}$ where α represents a particular configuration corresponding to a given thermal treatment, for example, the 'annealed' or 'quenched' samples of *Figure 3*. Thus:
Figure 4 Glass temperatures as a function of the rate of cooling through T_g. Heating rates: X, 5; ○, 10; +, 20; □, 40 K/min

$$H_l(T_2) - H_g(T_1) = \int_{T_1}^{T_{g\alpha}} c_{pg\alpha} dT + \int_{T_{g\alpha}}^{T_2} c_{pl} dT$$

Table 1 clearly shows that c_{pg} does not change markedly with differing annealing processes but we have preliminary evidence, from very accurate measurements where the bulk of the signal is backed off against a reference material[5], that c_{pg} decreases by 0.1–0.2% as the cooling rate is decreased from 20 to 0.625 K/min.

Cooling curves

A d.s.c. gives quantitative results on cooling, as well as heating, and *Figure 5* shows c_p curves for a sample cooled at 20 K/min and subsequently reheated at the same rate. Calculated values of T_{gH} are nearly equal (*Table 1*), as indeed they should be since the same glass is considered in both cases but although the two curves are remarkably similar, values of T_{gd}, however derived, are different. A *rough* correlation between T_{gd} and T_{gH} is again found and it is clear that this simply reflects the low degree of 'superheating' in this relatively quenched sample.

It would be wrong to suggest that, lacking rate effects, T_g is defined by a sharp intersection of two enthalpy curves. Rather, there is curvature indicated by the dotted lines of *Figure 3* and by the fact that the cooling curve of *Figure 5* enters the transition region some 10 K above T_{gH}. A wide range of relaxation times is needed to explain experimental observations[6] and the particular temperature chosen has to reflect an average value.

Accuracy

At T_g the specific heat difference between the two states $\Delta c_p = c_{pl} - c_{pg}$ is about 0.3 J/g/degree (column 9, *Table 1*) so that an error of ±0.3 J/g would, at first sight, imply an error of ±1 K in T_g. Since the overall enthalpy change may be 200–300 J/g this would seem to call for unprecedented
Figure 5 Specific heat curves on cooling.(A) and subsequent reheating (B) through T_g; all 20 K/min

calorimetric accuracy. Fortunately this is not so since, although we are indeed looking for enthalpy differences of this order, we use results which are internally calibrated in the sense that $H_l(T_2) - H_g(T_1)$ is related to c_{pg} and c_{pl} so that if the last are in error by a certain amount, so is the overall enthalpy change and the net result is a cancellation of errors. For example, in the first four rows of *Table 1* $H_l(T_2) - H_g(T_1)$ should be the same; as it is, observed values are well within our anticipated ±1% accuracy and the highest enthalpy change is simply associated with the highest c_p values.

Reproducibility of T_{gH} is excellent. Eleven determinations on different samples cooled at 20 K/min, using a variety of heating rates, gave an average T_{gH} of 371.7 K with a standard deviation of ±0.8 K. The overall accuracy of T_{gH} is less easy to assess. It has been seen that results are internally consistent with respect to the influence of annealing and, more significantly in the present context, agree to within one Kelvin with a dilatometric value and we feel that this uncertainty, ±1 K, is a realistic estimate of the accuracy of the technique.

General remarks

Karasz *et al.*[7] have shown that for the very low heating rates of about 0.1 K/min which are used in adiabatic calorimetry, T_{gH} is essentially the same as T_{gd}, defined as the point of inflection of the sigmoid T_g transition. This is clear evidence of the diffuse nature of the glass transition and should suggest that, if an attempt is made to extract T_g from specific heat curves, the 'onset' temperature should *not* feature in the suggested method. This point was made by Strella and Erhardt[8] who recommend the extrapolation of points of inflection to zero heating rates. However, even if this is a valid procedure, there are ambiguities in the definition of the point of inflection and, of course, it is inconvenient to sacrifice the practical benefits of high heating rates in the d.s.c. A technique based on enthalpy curves has been devised by Guttman and reported by Flynn[9] and this should be used where the full analysis reported here is not possible. However, since the present technique is so simple, and the additional information regarding the glass transition so valuable, we feel that it should always be used when any form of data treatment, and this is increasingly common, is available.

Specific heats at T_g

There has recently been considerable interest in numerical values of Δc_p at T_g and various generalizations have been suggested either for Δc_p or the product $\Delta c_p T_g$[10,11] Since our technique gives all these quantities we comment briefly on results for this particular polymer. Specific heats at T_g were extrapolated from the linear equations used to describe the glass and liquid and Δc_p and $\Delta c_p T_g$ are given in *Table 1*. There are fairly large uncertainties in Δc_p because there is only a 20% difference between c_{pl} and c_{pg}, although, even here, errors partly compensate — only partly since extrapolated values are used. The fluctuations in Δc_p conceal real differences which, if $c_{pga} \sim c_{pgq}$ (section on annealing above) where a and q refer to different annealing processes, originate in the change of T_g with annealing. For example, when T_g decreases by 10 K, Δc_p would be expected to increase by about 3%, a figure which is almost exactly compensated by the drop in T_g, so that the product

$\Delta c_p T_g$ should be constant. It is encouraging that adiabatic calorimetry[7] gives $\Delta c_p = 0.296$ J/g/degree and $\Delta c_p T_g = 107$ J/g. The suggested value of 0.33 J/g/degree[10] is based on an unusually high figure for c_{pl} which subsequent work has shown to be incorrect[12].

CONCLUSIONS

Transformation of d.s.c. data to enthalpy curves gives accurate values of T_g when the curves for the glass and liquid which lie outisde the transition region are extrapolated to meet. The point of intersection is T_g and this is independent of the d.s.c. heating rate unlike the directly recorded curves. Quantitative data are now readily available for the effects of annealing and the technique should allow the influence of other important parameters such as pressure and drawing, to be studied directly rather than by inference.

On the ^{13}C n.m.r. spectrum of alternating copolymers from α-methylstyrene and methacrylonitrile

N.m.r. spectra of random copolymers from α-methylstyrene (A) and methacrylonitrile (N) consist of several groups of resonance signals with complicated substructure concerning configurational and compositional sequences of monomeric units. Thus, for understanding the complexity of the spectra it should be reasonable to study the spectra of alternating copolymers first. Alternating copolymers from α-methylstyrene and methacrylonitrile composed in a head-to-tail arrangement are prepared easily by a method described by Gaylord[1,2].

(I)

(II)

(III)
Formulae (I), (II) and (III) represent segments of the polymer chain. Each monomeric unit contains an asymmetric carbon atom leading to a ditactic arrangement according to Natta's ditacticity designation[3]. If a polymer is isotactic with respect to the substituents of the monomeric units A and N, two structures are possible: erythro-diisotactic (I) and threo-diisotactic (II). The relative configurational enchainment of A and N in (I) is m (meso), whereas the relative enchainment in (II) is r (racemic). Hence, the configurational sequence of I and II are $A_m N_m A_m N_m A$ and $A_r N_r A_r N_r A$, respectively. As shown by III a disyndiotactic polymer consists of equal amounts of erythro- and threo-diisotactic placements. The relative configurational enchainment of segment III is $A_r N_m A_r N_m A$. However, since ^{13}C n.m.r. spectroscopy cannot observationally distinguish between a sequence and its reverse form, e.g. $A_r N_m A$ and $A_m N_r A$, the sum of both sequences, $A_m N_r A + A_r N_m A$, is marked by $A_r N_m A^+$ in the following. Numbered carbon atoms in formula I refer to spectra in Figures 1 and 2. For

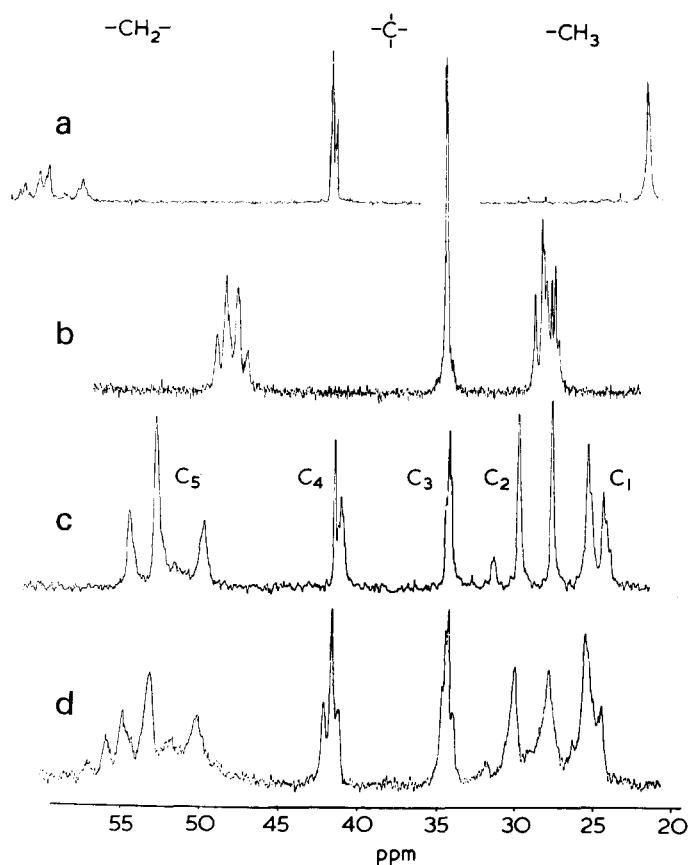
assignment it is important to compare the spectra of the homopolymers with the spectrum of the alternating copolymer. As shown in Figure 2 the shape of the resonances of carbon C_1, C_2, C_3, C_4 and C_5 of the alternating copolymer appears similar to the shape of the resonances of the two corresponding homopolymers. Especially the resonances of the non-protonated carbon in poly(α-methylstyrene) and methacrylonitrile correspond to the resonance spectrum of the alternating copolymer. Whereas large chemical shifts of a particular carbon nucleus depend on its bonding and chemical environment the substructure of these resonances stems from pronounced sensitivity of the ^{13}C chemical shift to configuration. Since both homopolymers of A and N, the spectra of which are shown in Figures 1 and 2, are dominantly syndiotactic[4–6], the alternating copolymer too has to be considered dominantly
Figure 1 ^{13}C n.m.r. spectra of poly(α-methylstyrene), methacrylonitrile and their copolymers. Resonance region of the aromatic carbons and the nitrile group. Spectra are continued in Figure 2. (a) Poly(α-methylstyrene), for assignment see refs 5 and 6; (b) polymethacrylonitrile, for assignment see ref.7; (c) alternating copolymer from α-methylstyrene and methacrylonitrile; (d) random copolymer from α-methylstyrene and methacrylonitrile; fraction of monomeric unit corresponding to α-methylstyrene in copolymer, $m_A = 0.47$


Figure 2 ^{13}C n.m.r. spectra of poly(α-methylstyrene), methacrylonitrile and their copolymers. Spectra continued from *Figure 1*. Resonance region of the aliphatic carbons. (a) Poly(α-methylstyrene); (b) polymethacrylonitrile; (c) alternating copolymer; (d) random copolymer
Figure 3 ^{13}C n.m.r. spectrum of an alternating copolymer from α-methylstyrene and methacrylonitrile. Enlarged spectrum according to *Figure 2c*. Resonance region of the CH$_3$ groups. (a) Monomeric unit corresponding to methacrylonitrile; (b) monomeric unit corresponding to α-methylstyrene

syndiotactic in contrast to results obtained by ^{1}H n.m.r. spectroscopy[1].

The assignment of the resonance signals of both CH$_3$ groups can be performed as shown in *Figure 3*. The splitting of the resonance signals of the CH$_3$ group of the monomeric unit due to N (see *Figure 2c*, carbon C$_2$) appears in the same succession as in the homopolymer but with larger chemical shifts as given in *Table 1* and without pentad splitting. On the other hand, the triad splitting of the CH$_3$ group of the monomeric unit due to A (see *Figure 2c*, carbon C$_1$) is smaller but with outlined pentad splitting. It is remarkable that the CH$_3$ resonance signal provides information on configuration, since in homopolymer spectra as shown in *Figure 1a* no splitting has yet been observed.

The enlarged resonance spectrum of the carbon C'_2, C'_3, C'_4 and C_6 is shown in *Figure 4*. Triad assignment in analogy to α-methylstyrene–acrylonitrile copolymers[7] and peak intensities of the aromatic carbons are given in *Table 2*. Triad fractions have been determined by curve fitting techniques. Within experimental error observed and calculated values are in good agreement.

The assignment of the resonances of the carbon atoms C$_1$, C$_2$, C'_2, C'_3 and C'_4, given in *Tables 1* and *2*, respectively, rests on the dominantly syndiotactic enchainment of the monomeric units in poly(α-methylstyrene) and polymethacrylonitrile and validity of Bernoullian statistics. The assumption of Bernoullian statistics is valid for the alternating copolymer, too, if $\rho = 2 \cdot m \cdot r/mr = 1$. A value of $\rho = 1.00 \pm 0.1$ has been calculated from triad fractions of the corresponding carbons C$_1$, C$_2$, C'_2, C'_3 and C'_4, respectively.

Resonance signals of the aromatic carbon C'_1 occur in the downfield part of the ^{13}C n.m.r. spectrum. The expanded resonance region is shown in *Figure 5*. The well resolved lines are assigned to configurational pentads, since there are more lines than expected for triad splitting. Chemical shift data and line intensities determined by curve fitting are presented in *Table 3*. Within experimental error observed peak intensities and intensities calculated from Bernoullian statistics are in good agreement.

The alternating copolymer under study is thus of random configuration with dominantly syndiotactic enchainment of the monomeric units. The resonance spectra of carbon C$_3$, C$_4$, C$_5$ as well as C$_6$ will be discussed in a later paper concerning the ^{13}C n.m.r. spectra of random copolymers from α-methylstyrene and methacrylonitrile. Attention should be directed to a resonance signal at 123.1 ppm shown in *Figure 4*. This signal is unambiguously assigned to the triad NNA$^+$ or its corresponding pentads. This means that there is slight deviation from exact alternating copolymerization.

Experimental

The alternating copolymer was prepared as described by Gaylord *et al.*[1]. The polymerization was started by adding methacrylonitrile to the n-hexane solution of ethyl aluminium sesquichloride at −78°C. After adding α-methylstyrene at −10°C the polymerization was carried out at this temperature.

The proton decoupled ^{13}C n.mr. spectra of the polymer samples were obtained in CDCl$_3$ at 40°C using a Bruker-Spectrospin HX 270 operating at 67.88 MHz. Spectro-meter settings were: sweep width, 12 kHz; pulse width, 35 μsec; transients, 8 K; data points of spectrum, 8 K. Internal standard was octamethyltetrasiloxane (OMTS) = 0 ppm.

Spectra simulations have been performed by a DuPont 310 curve resolver adjusted to Lorentzian line shape.

On the ^{13}C n.m.r. spectrum of alternating copolymers from butadiene and methacrylonitrile

^{13}C n.m.r. spectroscopy has been used frequently for studying the structure of polybutadienes. Especially, the resonance spectrum of the carbon double bond[1] is very sensitive to differences in the sequence distribution of monomeric units forming the polymer backbone chain. Thus, an extension of ^{13}C n.m.r. spectroscopy on copolymers from butadiene should be quite promising. This letter deals with the assignment of the ^{13}C n.m.r. spectrum of the alternating copolymer as a first attempt to study the complicated spectra of random copolymers from butadiene and methacrylonitrile.

The formula represents a chain segment of the alternating copolymer. Numbered carbons refer to spectra in *Figures 2* and *3*. This sequence of six monomeric units is designated by T–NT–NT–N. In this abbreviation T stands for *trans*-1,4-butadiene and –N for methacrylonitrile with respect to the relative position of the methylene carbon C_5. As a consequence, carbon nuclei C_1 and C_2 are expected to have different chemical shifts owing to their different distances to the nitrilic group.

Alternating copolymers from butadiene and methacrylonitrile can be prepared according to the method decribed by Furukawa[2,3], originally developed for alternating copolymers from butadiene and acrylonitrile. As expected[4], methacrylonitrile and butadiene undergo alternating copolymerization by the same catalyst system. The polymerization is assumed to generate a head-

to-tail arrangement of the monomeric units. Crystallinity, observed in the Debye–Scherrer diagram is a proof of predominantly *trans*-1,4-enchainment of butadiene.

Figure 1a represents the proton-decoupled ^{13}C spectrum of the alternating copolymer. With respect to their different bonding, individual carbon nuclei are identified from the non-decoupled spectrum as shown in *Figure 1b*. Consequently, C_3, C_6 and C_8 are assigned to corresponding resonance signals at 122.96, 35.94 and 22.99 ppm, respectively. Exact peak positions and assignment are given in *Table 1*.

For comparison spectra of homopolymers, alternating and random copolymers are shown in *Figures 2* and *3*. Resonance signals of both homopolymers cannot be observed in the resonance spectrum of the alternating copolymer. On the other hand, owing to compositional sequences, the spectrum of the random copolymer is of increased complexity as compared to the alternating copolymer. In low molecular weight compounds such as alkanes[5], alkenes[6] and nitriles[7] the study of substituent effects has given rise to empirical additivity correlations. Additionally, the nitrile triple bond has been found to

exhibit a very much reduced α- and β-deshielding effect[7]. Thus, the above mentioned additivity correlations should be applicable to some degree to nitrile substituted alkanes as well. In this way chemical shifts for C_4, C_5 and C_7, respectively, have been predicted in analogy to alkanes. Results are given in *Table 1*. The agreement is good even for C_6 and C_8, which have been assigned independently from the non-decoupled spectrum in *Figure 1b*. With respect to the increased γ-shielding effect[7] the tendency of chemical shift of the carbon atoms C_1 and C_2 of the carbon double bond can be predicted by analogy to alkenes.

Thus, the assignment can be performed as shown in *Figures 4* and *5*. With respect to a particular carbon atom all signals of high intensity (C_1 to C_8) are assigned to pentads, T–NT–NT and –NT–NT–N, respectively. Signals of low intensity in *Figures 4* and *5* indicate deviation from exact alternation and, therefore, have to be

assigned to TT–N and –N–NT, respectively. The amount of deviation can be diminished by using only aluminium sesquichloride as catalyst. As a result, intensities of TT–N, –N–NT, and hence their corresponding pentads

$$-\underset{T}{\overset{N}{\mathrm{T}}}\mathrm{TT}-\mathrm{N}-\underset{T}{\overset{N}{\mathrm{}}} \quad \text{and} \quad -\underset{T}{\overset{N}{\mathrm{}}}-\mathrm{N}-\mathrm{NT}-\underset{T}{\overset{N}{\mathrm{}}},$$
respectively, tend to zero. Pentad assignment will be discusssed in a later paper[8] concerned with random copolymers from butadiene and methacrylonitrile.

Experimental

The alternating copolymer under study was prepared as described by Furukawa[2,3]. The copolymerization was carried out at $0°C$ in n-hexane using ethyl aluminium dichloride and $VOCl_3$ as a catalyst. Additionally, an alternating copolymer was prepared using only aluminium sequichloride as a catalyst. This copolymerization was carried out at $-10°C$. The yield was 10 and 3%, respectively.

Detection of tacticity in polypropylenimine by ^{13}C n.m.r.

Linear isotactic polypropylenimine, prepared by Saegusa's method[1] starting from L-alanine and using dimethyl sulphate at 120°C to polymerize the intermediate L-4-methyloxazoline, was found to have the expected three lines in its ^{13}C{^{1}H} n.m.r. spectrum. With D$_2$O at 60°C as solvent these occur at 55.11 (CH), 53.75 (CH$_2$) and 20.08 ppm (CH$_3$) relative to TSP. The corresponding polymer made from DL-alanine has an almost identical spectrum (*Figure 1a*) but with the methine peak broadened and shifted very slightly upfield to 54.92 ppm. On adding sufficient concentrated hydrochloric acid to react with all the imine groups, the spectrum shown in *Figure 1b* is obtained. The methine resonance moves downfield by 0.77 ppm and splits into two equal peaks separated by 0.14 ppm; the methylene resonance moves upfield by 4.11 ppm and splits into three peaks covering a range of 0.37 ppm and in intensity ratio 1:2:1; and the methyl resonance also moves upfield (by 2.83 ppm) and splits into two approximately equal peaks separated by 0.28 ppm. Addition of some of the isotactic polymer to this solution causes the peaks labelled *m* or *mm* to increase in intensity. The polymer made from the racemic monomer

Detection of tacticity in polypropylenimine by ^{13}C n.m.r.

Linear isotactic polypropylenimine, prepared by Saegusa's method[1] starting from L-alanine and using dimethyl sulphate at 120°C to polymerize the intermediate L-4-methyloxazoline, was found to have the expected three lines in its ^{13}C$\{^{1}$H$\}$ n.m.r. spectrum. With D$_2$O at 60°C as solvent these occur at 55.11 (CH), 53.75 (CH$_2$) and 20.08 ppm (CH$_3$) relative to TSP. The corresponding polymer made from DL-alanine has an almost identical spectrum (*Figure 1a*) but with the methine peak broadened and shifted very slightly upfield to 54.92 ppm. On adding sufficient concentrated hydrochloric acid to react with all the imine groups, the spectrum shown in *Figure 1b* is obtained. The methine resonance moves downfield by 0.77 ppm and splits into two equal peaks separated by 0.14 ppm; the methylene resonance moves upfield by 4.11 ppm and splits into three peaks covering a range of 0.37 ppm and in intensity ratio 1:2:1; and the methyl resonance also moves upfield (by 2.83 ppm) and splits into two approximately equal peaks separated by 0.28 ppm. Addition of some of the isotactic polymer to this solution causes the peaks labelled *m* or *mm* to increase in intensity. The polymer made from the racemic monomer

Figure 1 $^{13}C\{^1H\}$ n.m.r. spectra (22.63 MHz) of (a) atactic poly-propylenimine in D_2O at 60°C, and (b) with added concentrated hydrochloric acid. 28 000 scans in each case. Sweep width 2000 Hz. Reference signal, TSP (sodium trimethylsilyl-1-propane sulphonate). The assignment for (a) was made by an off-resonance experiment. The line order CH > CH_2 > CH_3 is the same for (b)

Table 1 Titration shifts[3] δ (ppm upfield) for RNH_2 → RNH_3^+ compared with the observed shifts for [$CH_2CH(CH_3)NH$] $_n$

Polymer		Model compound	δ	Sum	Observed
CH	α-NH	$(CH_3)_2CHNH_2$	−2.36	2.46	−0.77
	β-NH	$CH_3CH_2CH_2NH_2$	4.82		
CH_2	α-NH	$CH_3CH_2CH_2NH_2$	1.44	5.90	4.11
	β-NH	$(CH_3)_2CHNH_2$	4.46		
CH_3	β-NH	$(CH_3)_2CHNH_2$	4.46	5.02	2.83
	γ-NH	$CH_3CH_2CH_2NH_2$	0.56		

is thus atactic, with equal proportions of the four possible triads, which may be labelled *mm* (isotactic), *mr, rm* (heterotactic), *rr* (syndiotactic), where *m* denotes that adjacent methyl groups in the Fischer projection structure are written on the same side of the chain, and *r* denotes that they are written on the opposite side of the chain. (The terms meso and racemic are not strictly applicable to such a chain although the letters *m* and *r* can be retained with the above meaning.)

It should be noted that the two heterotactic structures *mr* and *rm* are not identical
One cannot say, without use of model compounds, to which *m* and *r* dyad peaks the centre methine and methyl carbons contribute in each case. A similar situation exists for poly(propylene sulphide)[2]. The line order for the two downfield methylene peaks, *rr, (rm, mr)*, is assumed by analogy with many other polymers. The line order for the CH *r* and *m* shifts is evidently reversed by the addition of HCl.

The shifts caused by the addition of acid, known as titration shifts[3], are to be interpreted in terms of electric field effects and conformational changes. In primary amines the shifts are usually upfield, partly as a result of the greater polarizability of C–H bonds compared with C–C bonds[3]. Each carbon atom in the polymer will be subject to electric field effects from two adjacent NH_2^+ groups as well as from more distant parts of the chain. The net effect of nearest

neighbours is less than the sum of the individual effects in the primary amines (see *Table 1*), as might be expected, but the relative order of magnitude of the shifts ($CH < CH_3 < CH_2$) is the same. In the polymer it appears that the shift caused by the $β-NH_2^+$ group is only about half that in the corresponding primary amine.

A further effect may result from electrostatic repulsion of adjacent NH_2^+ groups in the polymer, which will lead to a change in the proportion of *gauche* interactions suffered by the different carbon atoms. Thus if we write the isotactic chain in its fully extended form:
we see that the gamma-interactions to left and right of each carbon atom are as follows: methine (t; t); methylene (t, g; t); methyl (g; g). Hence stiffening of the chains will cause: (a) an increase in *gauche* interactions for methyl carbons, which may be expected to result in an additional upfield shift; and (b) a decrease in *gauche* interactions for the methine carbons, resulting in an additional downfield shift. The fine structure for each carbon resonance presumably results from subtle variations of this conformational effect with the tacticity.

Solvent effect on the unperturbed dimensions of poly(aryl isocyanates)

Introduction

The conformation and the rigidity of poly (n-alkyl isocyanate) molecules in solution have been investigated by various physical methods[1-5]. Although there are some significant qualitative differences among the data reported, all these studies are in agreement concerning the high degree of rigidity of these chains. However, the precise origin of this high rigidity is still uncertain.

Considerably less attention has been given to the study of poly (aryl isocyanates); some dynamo-optical and electro-optical data reports by Tsetkov[6] on an unfractionated sample of poly(4-methylphenyl isocyanate) leads us to believe that the conformation of this polymer is quite different from that of the polymers with aliphatic side chains.

In order to shed some light on the problem of the conformation of the polyisocyanates, we are actually carrying out a systematic investigation on the hydrodynamic properties of both types of polymers. The present communication concerns essentially the study of the hydrodynamic properties of poly (4-methoxyphenyl isocyanate) (PMIC) and poly (4-methylphenyl isocyanate) (PTIC) in several solvents. The results clearly show that: (i) the replacement of the aliphatic side chain by an aromatic one induces an important decrease in the rigidity of the main chain; and (ii) the two-parameter theory does not strictly apply to the aromatic polymers i.e., the unperturbed dimensions of the chains strongly depend on the nature of the solvents.

Experimental

Polymers were synthesized by the method of Shashoua[7] with DMF as solvent and NaCN as catalyst at the initial temperature of $-58°C$. They were fractionated by the precipitation technique using CH_2Cl_2 as solvent and heptane as non-solvent. The fractions were analysed by gel permeation chromatography. They exhibit a polydispersity of 1.2--1.4.

Viscosity measurements were carried out at $25°C$ in Desreux--Bischoff suspended level dilution viscometers and as a function of temperature with a new type of sealed capillary viscometer[8].

Light scattering measurements were performed at $25°C$ in $CHCl_3$ and C_6H_5Cl with a standard Sofica diffusometer using vertically polarized light ($\lambda = 5460$ Å).

Sedimentation coefficients of some fractions of both polymers were determined in C_6H_5Cl at $25°C$ using a Spinco Model E ultra-centrifuge.

Results

The temperature dependence of limiting viscosity numbers of solutions of PMIC in $CHCl_2CHCl_2$ ($10-80°C$), $CHCl_3$ ($10-55°C$) and C_6H_5Cl ($10-80°C$) does not show any anomaly as is the case for polymers with aliphatic side groups[9].

The relationships between the intrinsic viscosity and the molecular weight were obtained over a wide range of molecular weight (80 000 to 1 500 000 for PMIC and 150 000 to 1 100 000 for PTIC). The K and a values for the Mark--Houwink relations are given in *Table 1* and are quite different from those reported for poly (alkyl isocyanates)[1,2,4]; they are characteristic of flexible polymers.

The Flory constants K_θ were evaluated by plotting the data at $25°C$ according to the treatments of Kurata--Stockmayer--Roig, Burchard--Stockmayer--Fixman (BSF), Inagaki--Suzuki--Kurata and Cowie. As an example the BSF plot for PMIC is shown in *Figure 1*; this relation fits satisfactorily our data for each solvent. The four extrapolation methods lead almost to the same K_θ value for each solvent considered separately, but the values are different from one solvent to another.

The K_θ values and the corresponding characteristic ratios A or $(<\overline{r}_0^2>/M)^{1/2}$ obtained from the well-known Flory relation are given in *Table 1*. A few characteristic ratios obtained by light scattering and sedimentation, using the Baumann[11] (*Figure 2*) and Cowie--Bywater[12] treatments are also given in this Table. In the calculation of the ratios, the theoretical limiting value of the Flory universal parameter Φ was chosen and appropriate heterogeneity corrections were made[10,13]. The characteristic ratios obtained by these different methods are in good agreement with each other and their magnitude is of the expected order for polymers with flexible chain.

Discussion

In conflict with the two-parameter theory for polymer solutions, the influence of the solvent on the unperturbed dimensions has already been reported several times[10,14].

Analysing the literature data for polyvinyl chains, Dondos and Benoit[15] have recently shown that small variations of K_θ with the nature of solvent are found for this type of

flexible polymer when polar side groups interact with solvent molecules. In this connection, it is important to point out that the experimental data are not always very precise and their comparison is often rather hazardous, except when they have been obtained under identical conditions (temperature, sample preparation, experimental procedure ...).

In 1961, Ivin et al.[16] in a study of the solution properties of poly (hexene-1-sulphone) expressed the hypothesis that the solvent effect on the unperturbed dimensions might be particularly important in the case of polymers with polar groups in their main chains; important variations of K_θ have been reported for such polymers: poly (propylene

sulphide)[17], poly (ethylene oxide)[18], polytetrahydrofuran[19] amylose derivatives[20].

The solvent effect in the case of the poly (aryl isocyanates) is also fairly great since the ratios of the extreme K_θ values equal two; from this point of view, the behaviour of these polymers is quite different from that of common flexible polymers such as polymethacrylates.

This influence of the solvent on the K_θ values of poly-(aryl isocyanates) is very likely due to interactions between the solvent molecules on the one hand, the aromatic side chains and especially the carbonyl groups of the backbone on the other hand. A correlation between the K_θ values and some physical properties of solvents is rather difficult to find; several parameters have been considered, such as internal cohesive density, dielectric constant, but without success when solvents of different chemical nature are considered. Yet, the K_θ values for PMIC and PTIC dissolved in alphatic chlorinated solvents increase regularly with the molar volume or the molar refraction of these solvents (*Figure 3*); the increase in the unperturbed dimensions is probably due to the steric hindrance of the backbone motions resulting from the solvatation of the carbonyl groups.

The infra-red spectra bring complementary data; contrary to what is observed in the case of the poly(n-alkyl isocyanates), we have found that the carbonyl absorption band of the poly(aryl isocyanates) can be resolved into several components, the relative intensities of which depend on the particular solvent considered. Moreover, the complexity of this band decreases in solvents where high K_θ values are obtained, namely $CHCl_3$ and $CHCl_2CHCl_2$. Recently, Volchek and Nikitin[21] reported a difference between the i.r. spectra of poly(n-butyl-) and poly(n-methylphenyl isocyanates) in $CHCl_3$ as in solid state. They attributed the complexity of the carbonyl vibration band in the case of PTIC to the existence of rotational isomers associated with the possibility of rotation about the C—N bond. In this hypothesis, a change in the degree of the main chain flexibility should involve a redistribution of the intensities of the band components. This is supported by our results for PMIC and PTIC in several solvents.

Lastly, from the study of the dielectric properties of PMIC and PTIC solutions[22], we may discard the hypothesis that the increased rigidity of these polymers in some solvents might be due to short rigid sequences [as in poly(n-alkyl isocyanates)] statistically distributed in a more flexible backbone.
Figure 3 K_θ dependence on the electronic polarizability of the solvent; —, PTIC; ----, PMIC; I, $CHCl_2CHCl_2$; II, $CHCl_3$; III, CH_2Cl_2; IV, CH_2ClCH_2Cl

Conclusion

In conclusion, if the aromatic polyisocyanates may be considered as flexible polymers, their hydrodynamic behaviour is nevertheless quite different, the solvent effect being important; the presence in the main chain of polar groups reacting with the solvent molecules is very probably an important factor of the K_θ variations; the series of chlorinated aliphatic solvents still containing one or more hydrogen atoms (CCl_4 and $Cl_2C=CCl_2$ are nonsolvent) is particularly interesting, the corresponding solutions of the aromatic polyisocyanates being characterized by practically the same exponent a of the Mark—Houwink relation. These observations raise once more the question of the exact meaning of the K_θ values for polymers strongly interacting with the solvent molecules and of the corresponding unperturbed dimensions.

Investigations on low molecular weight samples would probably clarify these problems as well as the determination of the K_θ values in pure θ solvents.

Book Reviews

Adhesive bonding
J. Shields
Oxford University Press, London (for Design
Council of BSI and CEI). 1974, 24 pp. £1.00

This book is one of a series intended for 'engineering designers'
and is particularly intended to introduce them to the scope and
application of adhesive materials and processes.

It certainly gives a very wide and informative review of adhe-
sive types but the balance, considering the intended audience, is
surprising. The various adhesives for the manufacture of plywood
and their durability are discussed fully. The range of thermosetting
adhesives, which are those of major importance for structural engi-
neering, is somewhat limited and the account of their properties
does less than justice to their significance. One is particularly struck
by the paucity of detail on the various types of adhesive involving
epoxides.

The review of the geometry on the various types of adhesive
involving epoxide joints, their features, and consequent strengths
is very good and clear. It should leave a designer in no doubt about
some of the less immediately obvious stress patterns and their
consequences.

The bibliography is one of the weaker features. It contains only
20 references up to fourteen years old and omitting direct reference
to some of the most useful general monographs although including
several rather elementary and superficial tests.

The style and presentation is very satisfactory but because of
the amount which is included within small compass it necessarily
demands careful reading.

At contemporary prices it is very reasonable value and in spite
of its shortcomings represents a useful contribution to the review
literature in this area.

K. W. Allen

Molecular behaviour and the development of poly-
meric materials
Edited by A. Ledwith and A. M. North
Chapman and Hall, London. 1975. £12.00

This book has been prepared in commemoration of the work of
Professor C. E. H. Bawn (an Editor of *Polymer* since its inception in
1960 and formerly of the University of Liverpool), who retired in
1973, and indeed the eminence of the contributors and the effort
which has been put into its production is a remarkable tribute to
one to whom the world of polymers owes so much.

The opening chapters deal more specifically with the chemistry
of polymerization processes, the roles of Ionic intermediates and
of Radical intermediates being treated respectively by M. Szwarc
and C. M. Bamford, while the subject of Transition metal catalysts
for olefin polymerization is examined by D. G. H. Ballard. This
leads on to two chapters dealing with elastomers, the first by
E. W. Duck, which is concerned primarily with butadiene-based
polymers, and the next by W. Cooper, of more general scope. Each
of these considers industrial developments in a historical setting
and examines the progress made in achieving desirable physical
characteristics. The production and properties of polyolefins are
systematically examined in a chapter by P. A. Small, the emphasis
here being more on the relation between physical properties and
morphology, while the class of materials known as polyurethanes,
which are in many respects more versatile than other types of poly-
mers, is comprehensively surveyed from both chemical, physical,
and industrial standpoints by C. Hepburn and R. J. W. Reynolds in
the following chapter.

Further primarily chemical topics included are Chemical reac-
tions on polymeric fibre surfaces (H. N. Friedlander and V.
Menikheim) which has important practical applications, particularly
in connection with bond formation, and Catalytic applications of
synthetic polymers (A. Ledwith and D. C. Sherrington).

Later chapters contain valuable reviews of structure and mor-

phology as well as of associated techniques of investigation. Appli-
cations of X-ray diffraction are surveyed broadly by C. W. Bunn,
while A. M. North, in a penetrating article, discusses the funda-
mentals of molecular motion in polymers as revealed by mechani-
cal and dielectric relaxation phenomena. This is followed by a
critical discussion of the glassy state, including the controversial
question of the physical interpretation of the glass transition, by
R. N. Haward. Closely related to this is the chapter on the Micro-
structure and properties of polymers, as revealed by ingenious
experimental techniques, by D. Hull. The concluding chapter by
H. Block grapples with the difficult but potentially important
question of the reduction of turbulent drag by polymers.

This brief summary of its contents is necessarily inadequate,
and fails to do justice to this stimulating work, which is marked
throughout by careful selection of material and lively presentation.
It is reliable, informative, and a pleasure to read.

L. R. G. Treloar

The role of additives in plastics
L. Mascia
Arnold, London, 1974. 172 pp. £4.00

A report on a recent meeting of the Polymer Properties Group
of the Plastics Institute (*Plastics and Polymers* 1975, 43, 6) reads
'. . . the full effect of making additions of materials such as plasti-
cizers, process aids and fillers to polymers was only partly under-
stood and in only a few cases had it been studied to any depth.
Little recent work appeared to have been published'. With this
statement in mind the present book was received with considerable
interest for it was felt that the author had wisely selected an area
which well merited attention. The book is written so as to deal
with a wide range of additives in plastics compositions and to this
extent he does much to meet this. It is devoted to theory rather
than practice, presenting a background of the principles involved.

After a general introduction dealing with types of additives
employed in service, compatibility, mixing, hazards, and electrical
properties, five chapters deal respectively with: processing aids;
plasticizers, fillers and reinforcing materials; additives to modify
surface colour, and optical properties; and resistance to ageing.
The final chapter relates to the use of blowing agents and fire
retardants. Over a third of the book (chapter 3) discusses in some
detail the mechanical properties of polymers and their modification
by plasticizers and the use of fibrous or particulate additions, con-
siderable attention being given to the rheological and materials
engineering principles involved. Elsewhere the treatment is less
uniform or detailed; sometimes (e.g. on test methods) it is perhaps
barely adequate, although one appreciates the limitations imposed
by space in a book of only some 170 pages.

References to relevant literature are given at the end of each
chapter and in this respect the reader has guidance to a number
of useful publications. Unfortunately the text is not always easy
to follow and a serious criticism is the inexcusable number of
vagaries or errors in the print. These are far too numerous to detail
here but, for example, we read on p 5, 'i.e. ΔF^M must be negative
or ΔF^M positive'; Table 2.1 omits the butyl groups in the chemical
formula for Santowhite, and gives a grouping as 'di-tibutyl'; Table
2.1 (p 25) should read Table 2.3; oxirane is given as 'oxyrane' (p 30);
some errors occur in the references for Chapter 3: R. A. Horsely
should read R. A. Horsley, F. R. Einrich should be F. R. Eirich
and the relevant page number in Gordon's book is 114, not 14. In
the index (which is comprehensive and useful) one is surprised to
read 'Arrhenious plot' and an incorrect page number given (on p 22
the spelling is Arrhanius). Many of the errors are of a minor nature
but serve to undermine confidence in the reliability of other parts
of the text.

However, despite these faults the book is a brave attempt to deal
with a diverse and often difficult subject in a uniform manner and
it can be a useful introduction to some aspects of polymer science
and technology which are often regarded as empirical.

Copolymerization behaviour of N,N' — divinylureas

G. C. Corfield and H. H. Monks

Department of Chemistry and Biology, Sheffield Polytechnic, Sheffield S1 1WB, UK

and L. P. Ellinger

The British Petroleum Company Limited, Research and Development Department, Epsom, Surrey, UK

Copolymerizations of 1,3-divinylimidazolid-2-one (DVI), 1,3-divinylhexahydropyrimid-2-one (DVHHP) and 1-ethyl-3-vinylimidazolid-2-one (EVI) with ethyl acrylate (EA) have been carried out and reactivity ratios determined. For DVI–EA, $r_1 = 0.090$, $r_2 = 0.388$; DVHHP–EA, $r_1 = 0.137$, $r_2 = 0.549$; EVI–EA, $r_1 = 0.094$, $r_2 = 0.530$. The Q and e values for these N-vinylureas have been calculated. 1,3-Diphenyl-1,3-divinylurea inhibits or retards the polymerization of other monomers. The results support the proposal that the N,N'-divinylureas are highly conjugated molecules.

INTRODUCTION

The homopolymerization of a number of N,N'-divinylureas has been reported in earlier papers[1,2]. 1,3-Divinylimidazolid-2-one (DVI) and 1,3-divinylhexahydropyrimid-2-one (DVHHP) gave insoluble crosslinked polymers not cyclopolymers and 1,3-diphenyl-1,3-divinylurea (DPDVU) could not be polymerized under a variety of conditions. These results were attributed to the continuous overlap of π orbitals of the vinyl and carbonyl groups with p_z orbitals on the nitrogen atoms.

As a means of gaining further information on the nature and reactivity of N,N'-divinylureas and the radicals produced from them, a number of copolymerization studies have been carried out.

COPOLYMERIZATION OF N-VINYLUREAS WITH ETHYL ACRYLATE

The copolymer composition equation is used to determine the reactivity ratios and Q and e parameters for the copolymerization of DVI, DVHHP and 1-ethyl-3-vinylimidazolid-2-one (EVI) with ethyl acrylate.

Mixtures of the N-vinylureas and ethyl acrylate in benzene were copolymerized to low conversions using azobisisobutyronitrile as initiator. After precipitation

and purification, the copolymers were analysed for nitrogen content from which the N-vinylurea residues in the copolymer were calculated. Results are summarized in *Table 1*.

Beynon[3,4] investigated the copolymerization of difunctional monomers (diallyl phosphonates and diallylureas) with monofunctional comonomers using the normal form of the copolymerization equation (equation 1). He decided that this equation could be used if the two groups in the difunctional monomer were equivalent, whether or not both functional groups are involved in the polymerization. Thus, for the copolymerization of the N-vinylureas with ethyl acrylate equation (1) (and its derivatives) has been used for the determination of reactivity ratios:

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]}{[M_2]} \cdot \frac{r_1[M_1] + [M_2]}{r_2[M_2] + [M_1]} \tag{1}$$

The reactivity ratios were calculated by computer[5] using the method of Fineman and Ross[6] and are given in *Table 2*.

The Q and e values[7] obtained for the N-vinylureas, using values of $Q = 0.52$, $e = 0.22$ for ethyl acrylate, are given in *Table 3*. The values obtained for some other N-vinyl monomers are included for comparison.

The reactivity ratios r_1 and r_2 for the copolymerization of all the N-vinyl monomers studied and ethyl acrylate were both less than one. In such cases there is a strong tendency to form alternating copolymers. The values of r_2 are the reactivity ratios for ethyl acrylate relative to the N-vinyl-

ethyl acrylate/1-ethyl-3-vinylimidazolid-2-one $(R_2=r_2)$,
$R_2 = 0.530$

Thus, the N-vinyl groups in 1,3-divinylimidazolid-2-one and 1,3-divinylhexahydropyrimid-2-one are less reactive than the N-vinyl group in 1-ethyl-3-vinylimidazolid-2-one. This seems to support the proposal of Crawshaw and Jones[1] that a conjugated (resonance stabilized) structure would explain their inability to cyclopolymerize.

The values in *Table 3* show that the e values for the new N-vinyl compounds are consistent with other N-vinyl monomers. Since the N-vinyl group will dominate the copolymerization behaviour, and the influence of the various N-substituents will be very similar, it is understandable that the parameter, e, which denotes the polar properties of the monomers and their radicals, will be similar for this series of compounds.

The Q values for the new monomers are much higher than those for the other monomers. However, since the Q–e scheme is an empirical method of analysis, the parameters of which are susceptible only to a quasi-theoretical interpretation, it would be extending the significance of the scheme to attach fundamental importance to these high results.

ATTEMPTED COPOLYMERIZATIONS OF 1,3-DIPHENYL-1,3-DIVINYLUREA

It has already been noted that 1,3-diphenyl-1,3-divinylurea (DPDVU) could not be polymerized by free radical initiators under various conditions, and this was attributed to resonance stabilization of the free radical derived from this monomer[2].

To characterize the polymerization behaviour of DPDVU further, copolymerizations were attempted with certain comonomers. 50% w/w mixtures of DPDVU with vinyl

acetate, ethyl acrylate, methyl acrylate or acrylic anhydride were heated in the presence of 2–3% of initiator (azobisisobutyronitrile) under conditions under which the comonomer alone was shown to be polymerized to high conversion; from none of these mixtures could any (co)polymer be isolated. When styrene was examined as comonomer its polymerization in benzene solution, initiated by azobisisobutyronitrile, was found to be retarded by DPDVU; the product appears to be a copolymer. The rate of copolymerization declines and the DPDVU content of the copolymer increases as the proportion of DPDVU in the comonomer mixture is increased (*Table 4*). This retardation by DPDVU was observed also in a dilatometric study of the thermally initiated polymerization of styrene alone and with DPDVU (5%) in benzene solution.

DPDVU (50% w/w) was also found to inhibit the polymerization of DVI or DVHHP using 1–5 mol % di-t-butyl peroxide as initiator at 150°C for periods up to 10 h. With 101 mol % initiator (based on DPDVU), during 4.5 h at 150°C glassy polymers were obtained with both comonomers. The infra-red spectra of the latter (after extraction with ethanol) were found to be almost identical to those of poly(1,3-divinylimidazolid-2-one) or poly(1,3-divinylhexahydropyrimid-2-one) respectively.

The results of these copolymerization studies are consistent with the radical derived from DPDVU being rather unreactive; this may be ascribable to resonance stabilization.

EXPERIMENTAL

Purification of monomers and solvents for copolymerization

1,3-Divinylimidazolid-2-one and 1,3-divinylhexahydropyrimid-2-one were crystallized twice from light petroleum ether (b.p. 40–60°C) (analytical reagent) dried at reduced pressure and stored at −5°C.

1-Ethyl-3-vinylimidazolid-2-one was distilled through a Nester–Faust spinning band distillation column equipped with an 18 in stainless-steel band and partial take off head, b.p. 110°C at 1.0 mmHg and stored at −5°C. Ethyl acrylate (mid.cut) was redistilled through a 30 cm column packed with glass helices equipped with a partial take off head (reflux ratio 3:1) b.p. 98.8–99.0°C and stored at −5°C.

Benzene (analytical reagent) was redistilled, b.p. 80.5°C.

Azobisisobutyronitrile was crystallized twice from methanol (analytical reagent) dried over phosphorus pentoxide under reduced pressure and stored at −5°C.

Table 4 Attempted copolymerization of 1,3-diphenyl-1,3-divinyl-urea with styrene[a]

Feed		Copolymer		
DPDVU (%)	Styrene (%)	Conversion[b]	DPDVU[c] in polymer (wt %)	Reduced[d] viscosity
0.0	100.00	22	0.0	0.256
5.0	95.0	20	1.5	0.228
10.0	90.0	18	2.3	0.166
20.0	80.0	16	2.7	0.124
30.0	70.0	14	3.5	0.109

[a] Polymerized at 50% w/w monomer concentration in benzene with 0.5% w/w azobisisobutyronitrile as initiator for 5 h at 70°C
[b] Estimated gravimetrically by precipitation in methanol
[c] Calculated from nitrogen analysis
[d] Determined in toluene

Copolymerization of 1,3-divinylimidazolid-2-one, 1,3-divinylhexahydropyrimid-2-one or 1-ethyl-3-vinylimidazolid-2-one with ethyl acrylate

Vinylurea monomer and ethyl acrylate (total weight 2.000 g) were weighed into stoppered bottles and transferred using two aliquots of benzene (5 ml each) to polymer tubes containing azobisisobutyronitrile (0.13 mol %). The contents of each polymer tube were made up to 20.0 g with benzene, purged with dry nitrogen and sealed with a rubber serum cap. The tubes were vigorously agitated and placed in a thermostated water bath at $60° \pm 0.1°C$. When the reaction was judged to have proceeded to a few per cent conversion the contents of the tube were slowly poured into vigorously stirred light petroleum ether (b.p. $40-60°C$) (200 ml). The precipitate was collected by filtration, washed repeatedly with light petroleum ether and dried at $55°C$ and 0.1 mmHg for 6 h. The polymers were ground to a fine powder, washed repeatedly with light petroleum ether and dried at $55°C$ and 0.1 mmHg for 24 h. The nitrogen content of the copolymer gave the percentage of vinylurea in the copolymer.

Light scattering Rayleigh linewidth measurements upon solutions of globular proteins containing high molecular weight impurities

D. B. Sellen

Astbury Department of Biophysics, University of Leeds, Leeds LS2 9JT, UK
(Received 24 February 1975)

A theory is presented showing that the effect of a very small amount of high molecular weight impurity on a globular protein solution is to decrease the measured diffusion constant and increase the weight average molecular weight in equal proportions. This applies when the diffusion constant is determined by a light scattering Rayleigh linewidth measurement using the autocorrelation method. Experimental verification of this is provided by the results of measurements upon a solution of bovine plasma albumin containing a high molecular weight impurity. The effects of different amounts of impurity were simulated by making measurements at different angles of scatter. The limitations of the theory are discussed.

INTRODUCTION

Investigation of the spectra of light scattered from macromolecular solutions is now an established technique for the determination of translational diffusion constants[1-7]. The most convenient method of making these measurements is by means of the optical homodyne technique in which the power spectrum of a photoelectric signal is investigated. In recent years it has been found advantageous to do this by obtaining the autocorrelation function by use of a suitable computer[4,5,7]. The present paper discusses the effect which a small amount of high molecular weight impurity or a small number of large aggregates (henceforward called agglomerates), has upon the measured diffusion constant of a globular protein, when the autocorrelation method is used.

THEORY

As the diffusion constant of a globular molecule of given shape and density is inversely proportional to the cube root of its molecular weight, it might at first appear that the presence of a small number of large agglomerates in a solution of globular protein would have little effect upon the measured diffusion constant. However, it will be shown that, owing to the types of average involved, this is not the case.

Where spectral broadening is due to translational diffusion alone, the autocorrelation function of the photoelectric signal resulting from light scattered from a polydisperse solution of macromolecules is given by[7]:

$$\phi(\tau) = \frac{c^2\gamma^2}{2} \left[\Sigma_n I_n \exp\left(-K^2 D_n \tau\right)\right]^2 \tag{1}$$

c is the overall photosensitivity of the detecting system and

γ a coherence factor depending upon the geometry of the optics[6]. τ is the autocorrelation delay time, I_n the scattered intensity from that component having diffusion constant D_n and:

$$K = \frac{4\pi}{\lambda} \sin\theta/2 \tag{2}$$

where λ is the wavelength *in the solution* and θ is the angle of scatter. If $\ln\phi(\tau)$ is plotted against τ the slope of the graph at $\tau = 0$ is $-2K^2 D_z$ where D_z is the Z-average diffusion constant[7]. Unless the degree of polydispersity is very high however, $\phi(\tau)$ will not differ significantly from a single exponential, in which case a logarithmic plot will be a straight line of slope $-2K^2 D_z$ [7].

Light scattering measurements therefore yield weight average molecular weights and Z-average diffusion constants. A mixture of a globular protein and a small number of agglomerates has a weight average molecular weight given by:

$$M_w = M_G(1 + I_A/I_G) \tag{3}$$

where $C_A/C_G \ll 1$, M, I and C refer to the molecular weight, scattered intensity and concentration, and the subscripts G and A refer to the protein and agglomerates respectively. The Z-average diffusion constant is given by:

$$D_z = \frac{D_G(1 + D_A I_A/D_G I_G)}{1 + I_A/I_G} \tag{4}$$

D_G here is the diffusion constant of the protein and D_A the Z-average diffusion constant of the agglomerates. D_A will always be less than D_G and if:

$$D_A I_A/D_G I_G \ll 1 \tag{5}$$

then:

$$D_z = \frac{D_G}{1 + I_A/I_G} \qquad (6)$$

Thus the proportionate decrease in diffusion constant due to the presence of a small number of agglomerates is equal to the proportionate increase in weight average molecular weight, i.e.

$$D_z M_w = D_G M_G \qquad (7)$$

It must be emphasized that no assumptions have been made here about the nature of the agglomerates or their range of sizes. I_A refers to their total scattered intensity. The only assumption is that the Z-average diffusion constant of the agglomerates is much less than that of the protein.

EXPERIMENTAL VERIFICATION

When a solution of bovine plasma albumin is left to stand for some time it acquires a dissymmetry of scatter. This is due to the formation of very high molecular weight aggregates which make a greater contribution at lower angles. From the point of view of the light scattering technique therefore, the protein may be regarded as being in a different state of 'agglomeration' for different angles of scatter, and each angle will have a corresponding weight average molecular weight associated with it. Thus by making conventional light scattering measurements and light scattering Rayleigh linewidth measurements at various angles, it should be possible to verify the above theory.

A stock solution of bovine plasma albumin [fraction $\overline{V}$ from bovine plasma (Armour Pharmaceutical Co.)] was made up at a concentration of approximately 2% with a 0.1 M aqueous solution of NaCl plus 0.01 M phosphate buffer (pH = 7) as solvent. This was centrifuged at 20 000 x g for 1 h and then made to pass through a 1.2 μm Millipore filter directly into the light scattering cell. No dissymmetry of scatter was observed and the molecular weight was determined in the usual way using the Aminco (American Instrument Co. Inc., Silver Spring, Maryland, USA) apparatus. The cell was transferred to the light scattering Rayleigh linewidth apparatus and the diffusion constant was determined in the manner previously described[7]. The stock solution was then allowed to stand at room temperature for 2 days and refiltered into the light scattering cell. A rise in scatter of some 16% at $\theta = 25°$ was observed with light of wavelength 546 nm. It is necessary, however, to find effective molecular weights at various angles for light of wavelength 633 nm (the wavelength of the He–Ne laser). To do this, plots were made of KC/R_θ against $(\sin^2 \theta/2)/\lambda^2$ (where the symbols have their usual meaning) for the wavelengths 546 and 436 nm. The Debye theory[8] predicts that these should form a single plot and this was found to be the case. Effective molecular weights for 633 nm were found by interpolation. The fact that the plots at the two wavelengths could be superimposed to yield a single plot indicated that the dissymmetry of scatter was due to agglomerated material and not to large dust particles. In the latter case KC/R_θ would be much lower at 546 than 436 nm for the lower values of $(\sin^2 \theta/2)/\lambda^2$. The absence of dust particles is important as they are mostly
Figure 1 Diffusion constant of bovine plasma albumin containing various amounts of high molecular weight impurity (see text) as a function of weight average molecular weight: ○, measurements taken on first making up the solution; ●, after standing at room temperature for 2 days

comparable in size to the illuminated volume from which scattered light is received in the Rayleigh linewidth apparatus, $\sim$(0.1 mm)^3, and lead to spasmodic vertical movements of the recorded autocorrelation function[7], whereas in the conventional light scattering apparatus they simply increase the overall scatter. Effective diffusion constants were determined for $\theta = 30°, 35°, 40°, 50°, 70°, 90°$ and a plot made (*Figure 1*) of $1/D$ against the molecular weight determined at the same angle. According to equation (7) the data should lie within experimental error on a straight line through the origin and this is seen to be the case. The straight line through the origin which best fits the data has a slope $1/D_G M_G$ and in this case $D_G M_G$ is found to be 4.00×10^{-3} kg mm^2 s^{-1} mol^{-1}. In practice the accuracy of this figure is limited by the accuracy of calibration of the conventional light scattering apparatus ($\sim$±5%).

DISCUSSION AND CONCLUSION

It must be emphasized that the above results are presented merely in order to illustrate the theory. It is *not* recommended that such a procedure be followed in place of normal clarification procedures such as differential centrifugation which in most cases are sufficient to remove any dissymmetry of scatter. The theory, however, applies in many cases where there is no detectable dissymmetry of scatter and the exact conditions under which it applies will now be discussed. The inequality (5) may be written:

$$\frac{D_A}{D_G} < p \, \frac{I_G}{I_A} \qquad (8)$$

where p is the precision required expressed as a fraction. In fact this is the *only* condition necessary as the further condition to validate equation (3), i.e. $C_A/C_G < p$ is automatically fulfilled as equation (8) may be written $C_A/G_G < p(M_G/M_A)(D_G/D_A)$ where M indicates weight average molecular weight. $(M_G/M_A)(D_G/D_A)$ is always less than unity although its actual value depends very much on the polydispersity of the agglomerates (M_A is a weight average and D_A a Z-average). If the arbitrary but typical values $p \sim 0.02$ and $I_G/I_A \sim 5$ are taken then equation (8) yields $D_A/D_G < \sim 10$. The *larger* agglomerates (D_A is a Z-average) should therefore be typically greater than about 50 nm in diameter for the theory to be applicable (or proportionately smaller if a lower precision is acceptable or

if the agglomerates make a lower contribution to the total scatter). The presence of particles of this size which account for 20% of the scattered intensity would result in a dissymmetry of scatter, $D_{45/135}$, of only 1.04. Thus although these large agglomerates may be removed by high speed centrifugation there is no way of knowing when complete clarification has been achieved. In fact it is the presence of very small but variable amounts of material of this sort which is likely to lead to variable weight average molecular weights as determined by light scattering, and it is the purpose of this paper to point out that this will lead to the same proportionate variability in the measured diffusion constants. The latter is far more serious than the former in assessing the size of the protein. If, however, both conventional light scattering measurements and light scattering Rayleigh linewidth measurements are made on the same solutions it might be possible to correct the measured diffusion constant using equation (7) if the molecular weight of the globular protein is known by other means, e.g. osmotic pressure measurements. The procedure would be self-justifying if the appropriate correlation could be obtained between molecular weight and diffusion constant for different attempts at clarification.

So far the only case considered is where the increase in scattered intensity is due to very small amounts of high molecular weight material. This does not mean that low molecular weight aggregates (i.e. dimers, trimers, etc.) cannot be present provided that inequality (8) is satisfied. The maximum proportion of the material (by weight) which may in any circumstance contain anything but the pure monomer is p. The theory does not apply in cases where the increase in scatter arises from a very much higher proportion of low molecular weight aggregates. However, if

the distribution is such that the low molecular weight aggregates and the high molecular weight agglomerates may be regarded as distinct from each other then the theory may be re-interpreted so that D_G, M_G, I_G, C_G now refer to the Z-average diffusion constant of the monomer plus low molecular weight aggregates and the corresponding weight average molecular weight, scattered intensity and concentration respectively. If it is possible to find the weight average molecular weight in the absence of the agglomerates, M_G, possibly by the use of a sedimentation equilibrium method, then equation (7) yields the Z-average diffusion constant of the monomer plus low molecular weight aggregates.

In conclusion it must once again be emphasized that the results of light scattering Rayleigh linewidth measurements are likely to be much more useful if conventional light scattering measurements are made at the same time on identical solutions.

Study of the conformational rigidity of polyelectrolytes by elastic neutron scattering: 1. Carboxymethylcelluloses in the intermediate momentum range

Michel Moan and Claude Wolff

Laboratoire d'Hydrodynamique Moléculaire, Université de Bretagne Occidentale, 29283 Brest Cedex, France
(Received 28 April 1975)

Small angle elastic neutron scattered intensity $I(q)$ by dilute solutions of a high molecular weight and low charge density carboxymethylcellulose (CMC) in D_2O, without added-salt has been measured. The variation of $I(q)$ is proportional to q^{-2} (q = momentum transfer) for $q < q^*$, and to q^{-1} for $q > q^*$. The dependence on q^{-2} shows that the distribution of the statistical units is Gaussian whereas the existence of q^* provides the possibility of calculating the length of such a unit; according to the dependence on q^{-1}, we conclude that these units are rigid. The length increases with dilution and charge density, which agrees with our previous results obtained by viscosity.

INTRODUCTION

Many workers[1,2] have shown that the root mean square end-to-end distance of polyelectrolytes in aqueous solutions decreases as the concentration or the ionic strength increases; but to explain such phenomena as the non-Newtonian viscosity, besides the expansion of the polyion, it is necessary to take a certain rigidity into account. The quantitative study of this last parameter is very difficult: we thought that neutron small-angle scattering, previously applied to the study of non-ionic polymers in dilute or concentrated solutions and in the solid state[3,4], could be very fruitful for conformational studies of polyelectrolytes in dilute solutions, as was recently showed by preliminary measurements[5].

After a brief theoretical outline, neutron diffraction will be used to study the mechanism of the conformational changes of polyelectrolytes with the concentration, the ionic strength and the charge density along the chain, and compared to viscometric results. The first part of this work deals only with carboxymethylcelluloses (CMC), the second part with poly(methacrylic acid) (PMA).

SCATTERING THEORY

In elastic neutron scattering on polymer solutions, the dependence of scattered intensity on scattering vector q, defined by:

$$\mathbf{q} = \mathbf{k} - \mathbf{k}'$$

and

$$q = |\mathbf{q}| = \frac{4\pi}{\lambda} \sin \theta/2 \simeq \frac{2\pi\theta}{\lambda} \text{ (for small } \theta)$$

where $\mathbf{k}'$ and $\mathbf{k}$ are the wave vectors of the incident and scattered beams, θ the scattering angle and λ the wavelength of the neutron, can be written in the following form, assuming that the interactions between macromolecules are negligible:

$$I(q) = kN^2 S(q) \tag{1}$$

N is the number of independent sub-units in the polymer chain, k the contrast factor between polymer and solvent and $S(q)$ a function of intrachain correlation for which several expressions have been proposed according to the statistical configuration of the chains and the range of the q values. For an ideal Gaussian chain, the Debye approximation[6] is:

$$S(q) = \frac{2}{x^2} [e^{-x} - 1 + x] \tag{2}$$

with $x = q^2 R_g^2$ and R_g the radius of gyration of the chain. When the chain dimensions are such as $qR_g \ll 1$ (Guinier's approximation[7]) relation (2) gives:

$$S(q) = (1 - q^2 R_g^2/3) \tag{3}$$

In the intermediate momentum-transfer range, $qR_g > 1$, $S(q)$ can be formulated in first approximation as follows:

$$S(q) = \frac{2}{q^2 R_g^2} \tag{4}$$

This last result holds for q smaller than the inverse of the persistence length b of the chain; for $qb > 1$, the scattered intensity should reveal an asymptotic q^{-1} law[8]. Moreover, different factors such as the concentration[9] or the polydispersity have an effect on the scattering law.
Figure 1 Variation of $I \times q^2$ with q, for $C = 2 \times 10^{-2}$ g/cm^3. O, Curve uncorrected for the hydrogen background; X and □, corrected curves and q respectively calculated with $\bar{\lambda} = 7.60$ Å and $\langle \lambda^2 \rangle^{1/2} = 8.02$ Å. In all the plots, the scattered intensity is given in arbitrary units

EXPERIMENTAL

Neutron diffraction

The experiments were performed on the EL-3 reactor of the Commissariat à l'Energie Atomique. The instrument[10] used in this work allows a precise angular resolution of the neutron beam while keeping a suitable intensity by a broad wavelength distribution. The characteristics of the wavelength spectrum are the following: mean value of the wavelength distribution,

$$\bar{\lambda} = \int_0^\infty \lambda f(\lambda) d\lambda = 7.60 \text{ Å}$$

wavelength of the maximum of the distribution density, $\lambda_M = 5.12$ Å. The distance between the sample and the detector is 2.60 m, and the momentum-transfer q (calculated with $\bar{\lambda}$) ranges from 10^{-2} to 10^{-1} Å^{-1}. The cell containing the solution has a 15 mm diameter and is 5 mm thick.

Two corrections must be brought to the scattered intensity. For polymer solutions in D$_2$O, the first correction comes from the very high incoherent scattering cross-section of the hydrogen atoms of the solute molecules; this background, which is independent of the scattering vector, has been measured with a D$_2$O solution containing the same amount of protons as the polymer solution. In practice, the scattered intensity I (θ) recorded for an angle depends on the wavelength distribution and the discussion of the experimental results must be made using the statistical mean of each quantity. For example, in the small

momentum range, using equation (3), I (θ) is given by:

$$I(\theta) = \int_0^\infty f(\lambda) S(q) d\lambda$$

$$= \int_0^\infty f(\lambda) \left[1 - 1/3 \left(\frac{2\pi\theta}{\lambda} \right)^2 R_g^2 \right] d\lambda$$

$$I(\theta) = 1 - \frac{4\pi^2\theta^2}{3} R_g^2 \int_0^\infty [f(\lambda)/\lambda^2] d\lambda$$

and the momentum transfer q will be computed with a wavelength defined by:

$$\langle 1/\lambda^2 \rangle^{-1/2} = \int_0^\infty [f(\lambda)/\lambda^2] d\lambda$$

in the same way for a q^{-1} scattering law, the mean value $\bar{\lambda}$ will be used.

The respective effects of these two corrections, which have been made systematically, are shown in *Figure 1* in a typical plot of the results $I(q) \times q^2 = f(q)$; the abscissa value of the intersection of the two parts of the curve is independent of the average wavelength.

Viscosity

The viscosity measurements have been performed at $25 \pm 0.005°C$, using a capillary viscometer with automatic measurement of efflux times[11]. For the measurements at fixed shear rate, we used an Ostwald viscometer with a capillary diameter 0.4 mm, giving for water an efflux time of 120 s and a shear rate of 1400 s^{-1} at the wall.

Polyelectrolyte

The carboxymethylcelluloses (CMC) are polyelectrolytes prepared from Linters powder[12]. The mean degree of substitution $\overline{DS}$, i.e. the number of carboxymethyl groups by monomeric unit was 0.68; the molecular weight determined by viscosity[13] was $M_v = 300\,000$, i.e., a mean degree of polymerization, $\overline{DP} = 1400$. The electrical charges of the chain are due to the dissociation of carboxylic groups obtained by the progressive neutralization of the acid form H-CMC (stoichiometric degree of neutralization $\alpha_s = 0$) by sodium hydroxide to the fully neutralized form Na-CMC ($\alpha_s = 1$). To improve the contrast between solute and solvent, the solutions were prepared with D$_2$O (contrast ratio D$_2$O/H$_2$O $\simeq$ 2 for CMC).

The domain of polyelectrolyte concentrations was 2.57×10^{-2} to 10^{-3} g/cm^3; it corresponds, at least for the highest concentrations, to a state in which the chains can overlap. This 'semi-dilute' regime holds for C higher than a critical concentration defined for Gaussian coils by $C^* = M/NR_g^3$ (M = molecular weight and N = Avogadro number). Using the R_g values of *Table 1*, we obtain $C^* = 10^{-2}$ g/cm^3 for $R_g = 368$ Å and $C^* = 4.5 \times 10^{-3}$ for $R_g = 481$ Å; this result could mean that the regime is semi-dilute for the highest concentrations and dilute for the lowest.
Figure 2 Variation of the inverse of the scattered intensity with q^2, for C = 2.57 x 10^{-2} g/cm^3

RESULTS AND DISCUSSION

Scattering curve of the carboxymethylcelluloses

As a consequence of the high molecular weight, the measurements of neutron scattering have been made in the intermediate momentum transfer range q, that is for $qR_g > 1$, to study the effect of the polyelectrolyte concentration and the charge density on the conformation of the polyion. In practice, the scattering curves have been studied, as shown in *Figure 1*, plotting $I(q)$ x q^2 vs. q since the product $I(q)$ x q^2 must be constant when the scattering law is described by the Debye approximation.

The plots of *Figures 3, 6* and *7*, show two different scattering branches on both sides of a critical value q^* of the scattering vector: for $q < q^*$, the horizontal line indicates a q^{-2} scattering law; this result is confirmed by the plot of $I^{-1}(q)$ vs. q^2 shown in *Figure 2*; for $q > q^*$, the oblique line corresponds to a q^{-1} dependence of the scattered intensity.

The q^* value, which corresponds to the intersection of the two lines of the $I(q)$ x $q^2 = f(q)$ plots, can be determined with an accuracy of 0.2 x 10^{-2}Å^{-1}. On the basis of the persistence length model, Kratky and Porod[14] have shown that the persistence length b of the chain and the length a of a statistical unit in the Kuhn model[15], can be deduced from the transition point of the scattering curve by:

$$a = 2b = 2/q^* \tag{5}$$

As we have observed a q^{-2} behaviour in our range of concentrations, we can conclude that the chain of the polyion is a Gaussian distribution of rigid segments, whose length is approximately a. However, this result cannot be generalized to all CMC, because our sample has two particular characteristics which can explain a Gaussian conformation, in spite of our experimental conditions (zero external ionic strength and low enough concentration): the length of the chain which is relatively large and the low charge density, i.e., an average minimum distance of about 8 Å between charges, if all carboxylic groups are ionized.

Polyelectrolyte concentration dependence of q*

The effect of the concentration on the conformation of the polyion was first studied by successive dilutions of the Na-CMC (α_s = 0.6) in pure D$_2$O without simple electrolyte added.

The $I(q)$ x $q^2 = f(q)$ plots of *Figure 3* show very clearly the effect of the concentration on q^*; q^* decreases with the polyelectrolyte concentration. The different q^* values obtained and the corresponding characteristic lengths b (equation 5) are summarized in *Table 1*. This q^* value permits an approximate determination of the characteristic lengths b of the chain; the increase of b when the concentration decreases confirms the results obtained by viscosity, i.e. the rigidity of the polyion increases with dilution, which increases the electrostatic repulsions between the charged sites along the chain. *Figure 4* shows a linear variation of q^* with $C^{1/2}$, which is the same as the
Figure 3 Variation of I x q^2 with q for different concentrations: ■, 2.57 x 10^{-2}; □, 10^{-2}; ○, 8 x 10^{-3}; ●, 2.5 x 10^{-3}; x, 10^{-3} g/cm^3

10^{-3}	2.05	47.6	481
Figure 4 Variation of the critical value q^* with the square-root of the concentration

variation of the reciprocal of the reduced viscosity of polyelectrolyte solutions according to the Fuoss relation[16], typical of electrostatic interactions.

The extrapolation of the b values to zero concentration is $b = 61$ Å, but it seems unreasonable to give a particular meaning to this value, because very dilute solutions could not be studied here and the existence, in that range of concentrations, of cooperative phenomena[17] which leads to a variation of the viscosity no longer proportional to $C^{-1/2}$.

The distance of effectiveness of these electrostatic interactions can be evaluated by calculating the radius χ^{-1} of the ionic atmosphere around fixed charges on the polyion; if we assume that all the charged sites of the chain are not ionized, but only a fraction corresponding to the osmotic coefficient Φ (Φ is the fraction of free counterions) which has been determined by Rinaudo and Milas[18] for CMC, we obtain χ^{-1} by the following relation[19]:

$$\chi^{-1} = \left[\frac{v.\epsilon_0 kT}{n.4\pi e^2} \right]^{1/2} \tag{6}$$

where v is the volume occupied by a polyion, n the number of effective charges of the chain, e the charge of the electron, k the Boltzmann constant, T the absolute temperature, and ϵ_0 the dielectric constant of the medium. *Figure 5* shows a linear variation of b with χ^{-1} and this clearly indicates again that the b values are directly connected to the interactions between charged sites along a chain.

If the polyion is represented by a distribution of quite-rigid segments of length $a = 2b$ freely joined by the bond between two glucose units (bond angle $\alpha = \pi - \theta \simeq 110°$), then the radius of gyration R_g is given by:

$$R_g^2 = \frac{Na^2}{6} [(1 + \cos\theta)/(1 - \cos\theta)] \tag{7}$$

where $N = L/a$, L being the length of the fully extended chain; the calculated values of R_g are shown in *Table 1*.

We have demonstrated by viscosity measurements[20] that the conformation of the polyion does not change if the dilutions are made by the procedure of 'isoionic dilution' which keeps the *total* ionic strength of the polyelectrolyte solution constant. The decrease of ionic strength with dilution is prevented by the addition of a simple

electrolyte, such as NaCl. These 'isoionic dilution' procedures have been used at the departure from the most concentrated polyelectrolyte solution, $C = 2 \times 10^{-3}$ g/cm^3, which corresponds to an ionic strength $I = 3 \times 10^{-2}$ mol/l. The $I(q) \times q^2$ plots of *Figure 6* do not show, contrary to the plots of *Figure 3*, a variation of q^* with the polyelectrolyte concentration. Thus, the neutron scattering also confirms in this case the deductions made from the viscosity results. Under the same experimental conditions, the intrinsic viscosity, extrapolated to zero shear-rate is $[\eta] = 561$ cm^3/g; from this result, the radius of gyration can be calculated by the Fox–Flory[21] equation for a statistical coil:

$$R_g^3 = \frac{M[\eta]}{6^{3/2}.\Phi}$$

where $\Phi = 2.5 \times 10^{23}$; the value obtained $R_g = 357$ Å, is in unexpected agreement with the value $R_g = 387$ Å, deduced from q^* by equations (5) and (7).

Effect of the charge density on q*

As pointed out[20], viscosity studies show that the expansion of the polyion increases progressively with the charge density along the chain; such a variation of the charge density is obtained by changing α_s from 0.2 to 1. The

0.4	3.65	27.4	366
0.6	2.75	36.4	421
1	—	—	—
Figure 8 Effect of the charge density on the b length; --- and ——, variation of b with α_S and $i.\overline{DS}$, respectively

$I(q) \times q^2 = f(q)$ plots of *Figure 7*, for a polyelectrolyte concentration $C = 8 \times 10^{-3}$ g/cm³ show the influence of α_S on q^* values, and on the corresponding R_g values; the data are reported in *Table 2*. *Figure 8* shows that the greatest stretching of the polyion occurs at $\alpha_S = 0.6$; a similar conclusion has been drawn from earlier viscosity measurements[20]. Since all the sites are not ionized, the most interesting parameter is not α_S, but $i.\overline{DS}$, the effective charge per monomeric unit; *Figure 8* also shows that the variation of b, which is equivalent to the rigid segment length, is linear with $i.\overline{DS}$.

CONCLUSION

The law of the small-angle scattered intensity $I(q)$ of a high molecular weight and low charge density CMC is different on the two sides of a critical value q^* of the scattering vector: for $q < q^*$, the law is proportional to q^{-2} and for $q > q^*$, $I(q) \sim q^{-1}$.

According to this behaviour, it is concluded that, under our experimental conditions, these CMC macromolecules behave as a Gaussian distribution of rigid segments, whose $a = 2/q^*$ length increases with dilution and charge density. These results agree fairly well with previous results obtained by viscometric methods; but, because of the sample characteristics (high molecular weight and low charge density) and the impossibility to perform neutron scattering experiments on higher dilute solutions, we have not succeeded, on this sample, in showing that the extension of the polyion may become anisotropic, as suggested by our previous viscosity results.

Study of the conformational rigidity of polyelectrolytes by elastic neutron scattering: 2. Molecular dimensions and conformation of poly(methacrylic acid)

Michel Moan and Claude Wolff

Laboratoire d'Hydrodynamique Moléculaire, Université de Bretagne Occidentale, 29283 Brest Cedex, France

and Raymond Ober

Laboratoire de la Matière condensée, Collège de France, 75231 Paris-Cedex 05, France
(Received 14 May 1975)

Elastic neutron scattering at small angles allows the radius of gyration of a PMA sample of molecular weight $M_v \sim 13\,000$ to be measured in highly dilute solution; the variation of this parameter with concentration and charge density to be followed, and the viscometric results to be confirmed. The scattered intensity is proportional to q^{-2} (q = momentum transfer) for the highest concentrations studied, which correspond to a Gaussian distribution function of the sub units of the chain, and to q^{-1} at the lowest concentrations, of which it is concluded that the polyion is then a zig-zag with only a few subunits.

INTRODUCTION

In Part 1[1], small angle neutron scattering was used for the study of the conformation of polyelectrolytes, when the values of the scattering vector are such that $qR_g > 1$ (R_g = radius of gyration). Under the same experimental conditions ($10^{-2} < q < 10^{-1}$ Å^{-1}), the investigation of Guinier's range, where $qR_g < 1$, requires a macromolecule whose radius of gyration lies between 10 to 100 Å. For this purpose, we used a sample of poly(methacrylic acid) (PMA) with a very low degree of polymerization ($DP = 150$) and thus a radius of gyration of about 100 Å if we assume that the chain is fully extended.

EXPERIMENTAL

The experimental conditions of measurement of neutron scattering and viscosity are the same as in Part 1. The molecular weight of the poly(methacrylic acid) (PMA-A)

Table 1 Variation of R_g with the polyelectrolyte concentration C

1	88	248	3.2×10^{-2}

determined from the viscometric law of Katchalsky *et al.*[2] was $M_v = 13\,000$. The domain of polyelectrolyte concentrations was 3.2×10^{-2} to 5×10^{-4} g/cm^3; it corresponds for all the solutions to a state in which the chains cannot overlap; indeed, the values of the critical concentration C^* reported in *Tables 1* and *2*, clearly show that the conditions $C < C^*$ is always satisfied. As in Part 1, the scattered intensity has been systematically corrected to take into account the broad wavelength distribution and the incoherent scattering of the hydrogen atoms of PMA.

RESULTS AND DISCUSSION

In the elastic scattering, the study of Guinier's range allows us to obtain directly the radius of gyration of the molecule, without assumptions on its geometrical form. When it was possible, the measurements were carried on beyond this range to obtain information on the conformation of the polyion[1].
Figure 1 Guinier's plots for solutions of PMA (α_s = 0.27) in D_2O. ○, 3.2×10^{-2}; △, 2×10^{-2}; □, 10^{-2}; X, 8.2×10^{-3}; ●, 3.2×10^{-3}; ▽, 10^{-3}; ■, 5×10^{-4} g/cm^3

Study of the gyration radius

Effect of the polyelectrolyte concentration. This study was made on sodium salt (PMA-Na) whose stoichiometric degree of neutralization by sodium hydroxide was $\alpha_s = 0.27$; the solutions were prepared with pure water (respectively D_2O and H_2O in neutron scattering and viscosity) without simple electrolyte added.

Qualitatively, the effect of the polyelectrolyte concentration on the dimensions of the polyion can be shown by the increase of reduced viscosity $\eta_{sp}/C(\eta_{sp} = (\eta - \eta_0)/\eta_0$, with η, η_0 absolute viscosities of solution and solvent, C polyelectrolyte concentration) when the concentration decreases; for this sample in pure water solution without external salt, the 'polyelectrolyte' behaviour clearly appears only at concentrations lower than 10^{-2} g/cm^3. This concentration is much lower than the critical concentration $C^* = 5.7 \times 10^{-1}$ g/cm^3 calculated for $R_g = 33.7$ Å.

In neutron scattering experiments, the intensity scattered by these solutions is sufficient (after the various corrections) to carry on the study down to dilutions of about 5×10^{-4} g/cm^3. *Figure 1* shows Guinier's plots $\log (I^{-1} (q)) = f(q^2)$, for various PMA-Na concentrations; the slope of these straight lines gives the apparent polyion gyration radius, if the interparticular effects are negligible (see relations (2) and (3) of Part 1[1]). The values obtained at various concentrations, are summarized in *Table 1* and *Figure 2*. The radius of gyration remains almost constant at the highest concentrations, then increases from $C = 8 \times 10^{-3}$ g/cm^3; this result is in agreement with the variation of reduced viscosity. The second part of *Figure 2* also shows that, in the concentration range where the sample has a 'polyelectrolyte' behaviour, the radius of gyration has a linear variation with $C^{-1/2}$; this fact is characteristic of the expansion of the polyion as a consequence of the electrostatic repulsions which increase with the dilution.

The $R_g = 49$ Å value obtained for the lowest concentration ($C = 5 \times 10^{-4}$ g/cm^3) is still far from the radius of gyration of the fully stretched polyion (about 100Å). It

can be accounted for by the low degree of neutralization $\alpha_s = 0.27$. There is less than one electrical charge for three monomeric units, so the electrostatic repulsions are much lower than the forces of hydrogen bonding between the non-ionized carboxylic groups which keep the structure of the polyion compact.

Effect of the charge density. As in Part 1[1], the variation of the charge density along the chain is obtained by progressive neutralization of the acid form PMA-A; the effect of the charge density, which is a function of the stoichiometric degree of neutralization α_s, was studied at a constant concentration $C = 10^{-2}$ g/cm^3 for various α_s. Several workers[3] have shown that the increase of the reduced viscosity with the increase of α_s was then very important, except at low charge density, as indicated by the data of *Figure 3*.

The neutron scattering allows us to obtain directly the variation of the radius of gyration under the same conditions; the R_g values obtained by this method are shown in *Table 2* and the variation of R_g with α_s is also given in *Figure 3*. From this important increase of the polyion dimensions it follows that the condition $qRg < 1$ is no longer satisfied except in a more and more restricted range of the q values, and an accurate determination of R_g is then more difficult.

The highest value obtained $R_g = 88$ Å differs little from the radius of gyration of the fully stretched chain and it suggests that the polyion has then a rod-like conformation.

Interactions between polyions

The previous results only consider the apparent radii of gyration, i.e., measured at finite polyelectrolyte concentra-
Figure 2 Variation of gyration radius R_g, respectively with C and $C^{-1/2}$
Figure 3 Variation of reduced viscosity η_{sp}/C (——) and gyration radius (- - - -) with the degree of neutralization α_s, at constant concentration

tion. The Zimm method[4], used in light scattering, allows us to obtain by extrapolation to both zero concentration and zero angle the radius of gyration at zero concentration and the second virial coefficient A_2. However, it is unrealistic to use the Zimm method when there are important conformational changes due to intra- and inter-molecular interactions. So, the Zimm plot of *Figure 4* was drawn only for the four highest concentrations (at $\alpha_s = 0.27$) when the radius of gyration is almost constant. The relation[4]:

$$\frac{KC}{I(q)} = \frac{1}{M}(1 + q^2 R_g^2/3) + 2A_2 C \qquad (1)$$

yields $A_2 = 7 \times 10^{-5}$ g^{-2} cm^3.

For non-ionic polymers, A_2 is related to the effect of excluded volume arising from the interactions between the solvent and the polymer; thus, the low value A_2 can be explained by the hydrophobic character of methyl groups of PMA.

According to relation (1), the intensity extrapolated to zero angle at each concentration can be written in the form:

$$\frac{KC}{I(0)} = \frac{1}{M} + 2A_2 C \qquad (2)$$

Figure 5 shows the variation of $C/I(0)$ with C, in the whole range of concentrations studies: $C/I(0)$ decreases sharply at the lowest concentrations and does not follow relation (2). If we only consider the range of concentrations down to 4×10^{-3} g/cm^3, an approximate value $A_2 = 3.5 \times 10^{-3}$ g^{-2} cm^3 can be obtained. It is much higher than the preceding value; this anomalous decrease of $C/I(0)$ can be explained by the important increase of the polyion interactions, as the concentration is reduced, caus-

ing further expansion of the ionic atmosphere of each polyion[5].

Intermediate momentum-transfer range

When $qRg > 1$, the scattering law gives information on the conformation and the rigidity of the polyion[1]. This study has been made on this sample in the whole preceding range of concentrations, but only for a degree of neutralization $\alpha_s = 0.27$. *Figure 6* shows the variation of the product $I(q) \times q^2$ with q, for the most concentrated PMA solution ($C = 3.2 \times 10^{-2}$ g/cm^3) and the most diluted one ($C = 5 \times 10^{-4}$ g/cm^3); the plots obtained in these two cases are very different. For $C = 3.2 \times 10^{-2}$ g/cm^3 after Guinier's range, the $I(q) \times q^2$ term is constant and, then the scattered intensity is proportional to q^{-2}; this result, which is valid for $C \geqslant 3 \times 10^{-3}$ g/cm^3, indicates that the polyion has a Gaussian conformation[6]. A careful statistical analysis shows that a law $I(q) \sim q^{-5/3}$ as predicted theoretically by Des Cloizeuax[8] and De Gennes[9] for Gaussian coil with excluded volume is more probable in this case than the $I(q) \sim q^{-2}$ law. With respect to Part 1[1], it can be noted that in the investigated momentum-range, a critical value q^* is not observed; however, that study which has not been carried on beyond $q = 10^{-1}$Å^{-1}, does not allow the existence of such a q^* value to be denied.

In the case of very dilute solutions $C \leqslant 10^{-3}$ the scattered intensity varies as q^{-1} and not as q^{-2}; for example, the data of *Figure 7* plotted for $C = 5 \times 10^{-4}$ g/cm^3 show this
Figure 4 Zimm plot for the four highest concentrations of *Figure 1*
Figure 5 Variation of $C/I(0)$ with concentration, for the same solutions as in *Figure 1*
Figure 6 Variation of $I \times q^2$ with q for (a) $C = 3.2 \times 10^{-4}$ and (b) $C = 5 \times 10^{-4}$ g/cm^3. The intensity I is given in arbitrary units

Figure 7 Variation of the inverse scattered intensity with q, for $C = 5 \times 10^{-4}$ g/cm^3

behaviour; from this curve, we can draw two conclusions: (1) the q^* value, if q^* exists, is lower than $q_m = 2.5 \times 10^{-2}$ Å^{-1} which corresponds to a rigid segment length higher than $a_m = 2/q_m = 80$ Å; (2), although the q^{-1} behaviour is predicted by the calculation of Porod and Kratky[7] in the case of rod-like particles, we can reasonably suppose that the polyion conformation is closer to a chain of a few rigid segments rather than to a long rod, if we consider the respective values of the gyration radius R_g, of the fully extended length and of a_m.

In such a case (low molecular weight polyelectrolyte in a low ionic strength solvent), it is possible to calculate from the values of R_g and a_m the few configurations which are possible; this will be discussed later.

ACKNOWLEDGEMENTS

We are grateful to Dr Zana (CNRS, Strasbourg) for the

supply of the PMA sample and to the C.E.N. Saclay for allowing us to use the E. L 3 Reactor.

Potentiometric study of poly(L-glutamic acid) in water—dioxane mixtures

Michel Morcellet and Claude Loucheux

Laboratoire de Chimie Macromoléculaire, Université des Sciences et Techniques de Lille, BP 36, 59650 Villeneuve d'Ascq, France

The potentiometric behaviour of poly(L-glutamic acid) (PLGA) has been studied in several water—dioxane mixtures and 0.2 M NaCl/dioxane mixtures. The intrinsic ionization constant pK_0 was found to increase with dioxane content and decreasing temperature. This variation of pK_0 with dioxane content can be explained by the variation of the dielectric constant, ϵ of the solvent. The free energy change ΔF° associated with the helix—coil transition for the uncharged conformers has been determined. At 25°C, the absolute value of ΔF° increases when decreasing the dielectric constant (i.e. when increasing the dioxane content) but the comparison with the experimental results of other authors show that a change in ϵ is not sufficient to explain the variations of ΔF° in all solvent mixtures. The temperature dependence of ΔF° in different 0.2 M NaCl/dioxane mixtures was determined between 3° and 55°C. The experimental results show that the stabilization of the α helix by dioxane has an entropic origin as it was already found for a 0.1 M KCl/ethanol/PLGA system. In the absence of salt, a sharp change in the variation of ΔF° is observed for the solvent composition at which a solvent induced conformational transition occurs, along with a change in the absolute adsorption of dioxane on the PLGA molecule. The free energy change involved in the adsorption of a molecule of dioxane on a PLGA residue has been evaluated.

INTRODUCTION

The potentiometric behaviour of poly(L-glutamic acid) (PLGA) has been extensively studied especially in aqueous solutions because the experimental data allows the standard free energy change ΔF° for the transition between the uncharged α helix and the (hypothetical) uncharged random coil to be determined. The effect of the ionic strength[1-3], of the nature of the counterion[4-7], and of the temperature[3,8,9] have also been studied.

The addition of an organic solvent to aqueous solutions of PLGA increases the absolute value of ΔF° and thus increases the stabilization of the α helix. Such an effect has been shown for ethanol[10,11] and other aliphatic alcohols[12]. Dioxane is known to have a stabilizing effect on the α helical conformation of PLGA which is qualitatively similar to that of ethanol (for example the pH of the transition which is 4.9 in 0.2 M NaCl becomes 6.00 in the presence of 33% dioxane[13,14] and 5.8 in the presence of 20% ethanol at 25°C[10]). Nevertheless only few potentiometric measurements have been carried out in water—dioxane mixtures in the presence of salt[3,14].

The purpose of this work has been to study more completely the potentiometric behaviour of PLGA in water—dioxane mixtures in the presence or in the absence of salt, at different temperatures. Moreover, PLGA is known to undergo, at constant pH, a solvent induced transition which has been shown to be correlated to a sharp increase in the absolute adsorption of the organic solvent on the polymer[13]. Therefore it was interesting to seek a possible further correlation between this preferential adsorption and the value of ΔF° when varying the composition of the water—dioxane mixtures.

EXPERIMENTAL

The PLGA sample (in the acid form) was prepared in the laboratory by debenzylation of a poly(γ-benzyl-L-glutamate) sample according to the method of Idelson and Blout[15]. The intrinsic viscosity, measured under the standard conditions of Wada[1], i.e. 25°C, pH 7.3 in 0.2 M NaCl, is 29.0 ml/g, corresponding to a weight-average molecular weight M_w = 12 200. In some cases measurements were also carried out on another sample (M_w = 33 000). The results obtained for both samples were always self consistent within experimental errors. pH measurements were made with a Radiometer pH M 26 pHmeter with the use of a G 202 C glass electrode in conjunction with a K.101 calomel electrode. The pHmeter was standardized with aqueous buffers (pH 8.00 and 4.45). No corrections were made for the actual hydrogen ion activity in water—dioxane mixtures. Thus apparent pH values were used throughout this paper. The temperature in the titration vessel was maintained at the desired value within ±0.1°C.

The solutions were prepared by dissolving a weighted amount of PLGA in the solvent of the required composition, containing a slight excess of NaOH.

The titrations were carried out on fresh solutions containing about 40 mg in 20 ml of solution. Appropriate blank titrations of the solvent were also performed.

Dielectric constant

The dielectric constant of pure water was taken as ϵ_w = 78.3 at 25°C. For salt solutions the relation $\epsilon = \epsilon_w + 2\delta c$ was used, where c is the salt concentration in mol/l and δ is a constant depending on the nature of the salt[16]. For
Figure 1 Modified titrations curves for PLGA in (a) 0.2 M NaCl and (b) 0.2 M NaCl/dioxane mixture (70:30 v/v) at 25°C

NaCl and KCl, $\bar{\delta}$ = —5.51/mol and —5.01/mol respectively. Thus ϵ is 76.1 for 0.2 M NaCl and 77.3 for 0.1 M KCl. In the case of mixtures with dioxane (ϵ = 2.2) or ethanol (ϵ = 24.3) the dielectric constant was assumed to be linearly dependent on the composition.

RESULTS AND DISCUSSION

pH induced transition

Values of $p K_0$. Some of the modified titration curves where the apparent pK, $pK_{app} = pH - \log \alpha/(1 - \alpha)$[17] are plotted as a function of the degree of ionization α, are shown in *Figure 1*. At 25°C, in the presence of salt (0.2 M NaCl) (*Figure 1a*) the parts of the curve corresponding to the pure helix ($\alpha < 0.38$) and to the pure coil ($\alpha > 0.70$) are straight lines. A linear extrapolation at α = 0 for the helix and for the coil gives the same value for the intrinsic ionization constant pK_0 of the polyacid. The values of pK_0 obtained as a function of the dioxane content at different temperatures are given in *Table 1*.

It can be seen that pK_0 increases when increasing the dioxane content and/or decreasing temperature. The value of pK_0 = 4.40 obtained at 25°C in 0.2 M NaCl is in good agreement with those of other authors: 4.45[2], 4.37[14]. In 0.2 M NaCl/dioxane mixtures the enthalpy of ionization of PLGA can be deduced from the temperature dependence of pK_0. This value was found to be ΔH = 3100, 3000 and 2900 cal/mol for 10, 20 and 30% of dioxane respectively. Thus, an increase of ΔH is observed by adding dioxane as in the case of ethanol[10] (the value of ΔH is only 550 cal/ mol in the absence of any organic solvent[10]).

At 25°C, in the lower pH range, a deviation from a pure helix titration curve is observed below α = 0.18, which is known as the 'aggregation peak'. The extrapolation of this part of the titration curve leads to a value of pK_0 which is the same as the value obtained when extrapolating either the 'coil part' or the 'helix part' of the titration curve. When adding dioxane, the aggregation disappears and the preceding peak vanishes (see in *Figure 1* the curve corresponding to a 30% dioxane mixture). In the absence of salt curvilinear extrapolations[2,14] were used in order to determine the value of pK_0 at α = 0 assuming also that pK_0 must be the same for the helix and for the coil. The values obtained are also given in *Table 1*. It can be seen that pK_0 increases in the same manner in the presence or in the

absence of salt being, however, slightly smaller in the first case.

The increase in the values of pK_0 when adding dioxane, accounts for the changes observed in the values of pH 1/2, the pH at the midpoint of the helix—coil transition of PLGA. For instance, the helix—coil transition was monitored by circular dichroism in several solvent mixtures. The values of pH 1/2 and pK_0 are collected in *Table 2*. It can be concluded that pH 1/2 and pK_0 increase simultaneously.

Conio and Patrone[10] have suggested that the variations of pK_0 with the solvent composition should be qualitatively explained by a variation of the dielectric constant ϵ, as it is the case for model aliphatic monofunctional carboxylic acids.

In *Figure 2* the values of pK_0 measured in different solvent mixtures are plotted as a function of ϵ. Some literature data are also given in this Figure along with data relative to acetic acid in water—dioxane mixtures[18]. The small difference of 0.1 pK unit observed between the two curves corresponding to water—dioxane mixtures and 0.2 M NaCl/dioxane mixtures can be assigned to the variation of the ionic strength[3,19]. In all cases the variation of the dielectric constant accounts for the variation of pK_0, in water—dioxane mixtures and in ethanol—water mixtures where the variations of pK_0 with organic solvent composition are much smaller. This effect can be quantitatively described by the Born's relation[20]:

$$- \log \frac{{}_sK_A}{{}_wK_A} = \frac{e^2}{rkT\ln 10} \left[\frac{1}{\epsilon} - \frac{1}{\epsilon_w} \right]$$

where ${}_sK_A$ and ${}_wK_A$ are the ionization constants in the solvent mixture and in water, e is the charge of the proton, k the Boltzmann's constant, T the absolute temperature, ϵ

Table 1 Values of pK_0 for 0.2 M NaCl/dioxane and water—dioxane solutions of PLGA at different temperatures

	5.35	4.45
0.2 M NaCl/dioxane (2:1)	6.00	5.50
H_2O/dioxane (2:1)	6.95	5.95
Figure 2 Variation of pK_0 *versus* the dielectric constant ϵ at 25°C: +, PLGA in 0.2 M NaCl/dioxane mixtures ●, PLGA in water—dioxane mixtures ○, PLGA in 0.1 M KCl/ethanol mixtures[10]; ▲, PLGA in 0.1 M KCl/ethanol mixtures[11]; △, acetic acid in water—dioxane mixtures[18]

and ϵ_w the dielectric constant of the solvent mixture and of water respectively. The use of this equation constant gives for the water—dioxane—PLGA system:

$$- \log \frac{{}_sK_A}{{}_wK_A} = -1.79 + \frac{140}{\epsilon}$$

which can be compared with:

$$- \log \frac{{}_sK_A}{{}_wK_A} = -1.77 + \frac{140}{\epsilon}$$

obtained for the propionic acid in the same solvent mixture[21].

Thus, the effect of the solvent on the ionization constant of PLGA is quite similar to that observed for the low molecular weight models. This result is not surprising if one considers that the pK_0 values are obtained by an extrapolation at $\alpha = 0$, in order to eliminate the effect of the interactions between neighbouring carboxylic groups.

Values of α at the midpoint of the transition. The values $\alpha_{1/2}$ of α at the midpoint of the transition are plotted in *Figure 3* as a function of the temperature for the different solvent mixtures. It can be seen that $\alpha_{1/2}$ decreases when increasing the temperature in each solvent mixture. This decrease of $\alpha_{1/2}$ is accompanied by a decrease of the pH at the midpoint of the transition. This result was easily foreseeable, for it is well known that an increase of the temperature decreases the stability of the α helix.

Free energy of the helix—coil transition. The free energy ΔF° of the transition between the uncharged conformers can be determined from the preceding modified titration curves. According to Zimm and Rice[17] the area

A between the actual curve and the extrapolated curves for the helix and the coil is related to the free energy of transition: $-\Delta F^\circ = A\,RT \ln 10$. The experimental values of ΔF° have been determined at 25°C for several water—dioxane and 0.2 M NaCl/dioxane mixtures. These data are plotted in *Figure 4* as ΔF° *versus* the dioxane content (% v/v) along with data of Conio and Patrone[10] relative to 0.1 M KCl/ethanol mixtures. At 0% dioxane in 0.2 M NaCl, $\Delta F^\circ = -106$ cal/mol is in very good agreement with the values of other authors[22]. In the absence of salt, the values of ΔF° are somewhat less accurate owing to the use of curvilinear extrapolation necessary to obtain the same pK_0 value for helix and coil. In the absence of salt and dioxane, the value of ΔF° is -175 ± 10 cal/mol, in rather good agreement with the value of -192 cal/mol reported by Olander and Holtzer[3] for PLGA in 0.01 M NaCl.

The effect of dioxane is to increase the absolute value of ΔF° i.e. to stabilize the α helix as observed for ethanol[10]. In both cases (i.e. in the presence or in the absence of salt) the variation of ΔF° with the solvent composition is linear until about 25% dioxane. In the presence of salt the variation of ΔF° with the composition of the solvent is much greater in the case of ethanol. The question arises whether that difference is due or not to a difference in the ionic strength or in the nature of the salt.

In the case of KCl or KSCN, it has been shown that a variation of the ionic strength from 0.1 to 1.2 was of little effect on the value of ΔF° [22]. Moreover, the counterions K^+ and Na^+ have the same effect on the variation of ΔF° [7]. Thus the change from 0.1 M KCl to 0.2 M NaCl has probably a negligible effect on the variation of ΔF°. As confirmation we determined the value of ΔF° in a mixture of 0.2 M NaCl/ethanol (81:19 v/v). It was found to be -190 cal/mol, in good agreement with the results of Conio and Patrone[10] for 0.1 M KCl/ethanol mixtures.

Figure 4 Variation of ΔF° at 25°C *versus* the dioxane content. X, PLGA in 0.2 M NaCl/dioxane mixtures; ●, PLGA in water—dioxane mixtures; ○, PLGA in 0.1 M KCl/ethanol mixtures[10]

In 0.2 M NaCl, the value of ΔF° obtained for 33% dioxane is very different from the linear behaviour exhibited for lower dioxane contents. Beyond this solvent composition, further addition of dioxane causes the polymer to precipitate[23]. Pederson *et al.*[24] have determined the free energy involved by the transfer on the peptidic backbone of poly(L-lysine) from pure water to 10% ethanol mixture. They found $\Delta F^\circ = 41$ cal/mol, a value which is close to the free energy of transfer of a peptidic group from water to 10% ethanol (60 cal/mol)[25] for model low molecular weight amides or amino acids.

In the case of PLGA the transfer from water to 10% ethanol mixture gives $\Delta F^\circ = 41$ cal/mol[10] while the transfer from water to 10% dioxane gives 16 cal/mol in our experiments. Thus dioxane has a much less stabilizing effect on the PLGA helix than ethanol.

Rather than in terms of organic solvent composition, the experimental results may be treated as a function of the methylene molarity according to Von Hippel and Wong[26]. On this ground, Conio *et al.*[12] found that the increment of the free energy per methylene molarity $[\Delta(\Delta F^\circ)/\text{mmol}]$ was constant for PLGA or poly(L-ornithine) in mixtures of water with methanol, ethanol, propanol, and butanol on the entire range of solvent composition. This value is $\Delta(\Delta F^\circ)/\text{mmol} = -13$ cal/mmol. Such a calculation, applied to the PLGA/water/dioxane system gives an increment of the free energy per methylene molarity equal to -3 cal/mmol. This result supports the

conclusion that dioxane has a much less stabilizing effect than ethanol. In a more recent paper, Dubin[27] proposed an alternative way to account for experimental results in the domain. Using the data of Conio *et al.*[12], he showed that a plot of ΔF° *versus* the dielectric constant ϵ was a unique curve regardless of the nature of the alcohol. This is in good agreement with the fact that ΔF° depends only on methylene molarity, at least in water/alcohol mixtures. Nevertheless, Dubin suggests that parameters other than the dielectric constant must have an influence on ΔF°. Our experimental results obtained in 0.2 M NaCl/dioxane mixtures support this suggestion. *Figure 5* shows that in this case a linear variation of ΔF° with ϵ is obtained, but the curve is very different from the corresponding curve for alcohols. Thus it seems that the nature of the organic solvent plays an important role in the stabilization of the α helix.

Further investigation must be carried out in other water/organic solvent systems to cast some light on this problem.

Temperature dependence of the free energy of transition

The temperature dependence of ΔF° in 0.2 M NaCl/dioxane mixtures was previously studied by Bychkova and Coll[14] for 25% and 33% dioxane mixtures. They found that a common straight line can be drawn through the values corresponding to these two mixtures, giving $\Delta H^\circ = -1700$ cal/mol and $\Delta S^\circ = -4.86$ for the enthalpy and the entropy of transition.

Nevertheless, the results of *Figure 4* show that, at 25°C, the values of ΔF° beyond 25% of dioxane are disturbed by the vicinity of the limit of precipitation. Thus we re-investigated the temperature dependence of ΔF° in mixtures with 10, 20 and 30% of dioxane. The results obtained are shown in *Figure 6*. The corresponding values of ΔH° and ΔS° are given in *Table 3*. These results are similar to those previously reported for PLGA in 0.1 M KCl/ethanol mixtures[10] leading to the conclusion that the stabilization of the α helix by dioxane is essentially an entropic effect. Conio *et al.* have suggested that, in the case of ethanol, the solvation of the peptide amide group in the randomly coiled conformation may be responsible for the observed increase in ΔS°. In the case of dioxane, we have shown[13] that a strong preferential adsorption of dioxane occurs on the ionized coil PLGA molecule. This supports the assumption that the solvation of the random coil takes an important part in the changes of ΔS°.

Solvent-induced transition

In the absence of salt, the solubility limit is reached beyond 50% of dioxane. Between 30 and 50% of dioxane,
Figure 5 Variation of ΔF° at 25°C *versus* the dielectric constant ϵ. ○, PLGA in 0.2 M NaCl/dioxane mixtures; +, data of Conio and Patrone[10] for PLGA in 0.1 M KCl/ethanol mixtures

ΔS°	−3.3	0	−0.3	0

[a] Data of Ciferri *et al.*[22]

a sharp variation of ΔF° is observed (*Figure 4*). This sharp variation occurs at a solvent composition for which, at constant pH, a solvent induced helix—coil transition takes place. This transition has been monitored by circular dichroism by plotting the ellipticity at 222 nm, $[\theta]_{222}$ as a function of the solvent composition[13]. *Figure 7* shows that the variation of ΔF° parallels exactly the transition followed by circular dichroism.

Moreover, light scattering and differential refractometry studies on some proteins[24–27] and on PLGA[13] in solvent mixtures have shown that the preferential and absolute adsorption of the organic solvent on the polymer can be related to the conformational transition induced by the change of the solvent composition. Especially it has been pointed out that the absolute adsorption of organic solvent increases with the helix content.

In *Figure 7*, is also plotted the variation of the absolute adsorption A_3 of dioxane on PLGA[13]. The change of the absolute adsorption between 30 and 50% of dioxane (i.e. between the beginning and the end of the transition) is about half a molecule of dioxane per residue of PLGA. (There is about half a molecule of dioxane adsorbed at 30% of dioxane and about one molecule at 50% when extrapolating the experimental curve to 100% helicity.) Taking

into account the value of about 50 cal/mol for the change in ΔF°, the free energy change involved by the adsorption of a dioxane molecule on a PLGA residue can be estimated to be 80–100 cal/mol. This value must be considered only as an estimation for two reasons: first the unreliability on the values of ΔF° measured in the absence of salt; secondly, the unreliability on the number of dioxane molecule bound to a PLGA residue, partly due to the fact that PLGA begins to precipitate before the transition is completely achieved. Moreover, the observed change in ΔF° is the sum of at least two contributions: (i) the change in ΔF° due to the adsorption of dioxane on the molecule which has been shown to increase strongly beyond 30% of dioxane; (ii) the change in ΔF° involved by the solvent induced transition which is not achieved when the solubility limit is reached. At the present time, the splitting between the different contributions is difficult.

CONCLUSION

The experimental results show that the variation of the pK_0 of PLGA in solvent mixtures depends on the variation of the dielectric constant ϵ as it is in the case for model carboxylic acids. The free energy of the helix coil transition is also dependent on ϵ but other parameters are probably involved in the stabilization of the α helix. In the absence of salt, a sharp variation of ΔF° is observed which is related to the solvent induced helix—coil transition and to the absolute adsorption of the organic solvent on the polymer, showing that the free energy of the helix—coil transition is strongly dependent on the state of solvation of the polymer.

Electro-optical properties of poly(ε-carbobenzoxy-L-lysine) in organic solvents

Masaharu Nishioka, Kazuo Kikuchi and Koshiro Yoshioka

Department of Chemistry, College of General Education, University of Tokyo, Meguroku, Tokyo, Japan
(Received 17 February 1975; revised 25 March 1975)

The electric birefringence of poly(ε-carbobenzoxy-L-lysine) (PCBL) in various helicogenic organic solvents and solvent mixtures has been measured over a wide range of field strengths by application of rectangular pulses. The apparent permanent dipole moment and the optical anisotropy factor were separately determined from the field strength dependence of the steady-state birefringence. The apparent dipole moment per residue for a PCBL sample with molecular weight close to 1×10^5 fell in the range of 4.7 to 5.9 D in spite of the large variation of the solvent dielectric constant. The optical anisotropy factor was appreciably small and changed its sign depending upon the solvent. The intrinsic birefringence of PCBL was found to be negative in sign on the basis of the Peterlin–Stuart theory. This was interpreted in terms of the orientation of the side chains with respect to the helical backbone. The apparent dipole moment per residue for high molecular weight PCBL samples was much smaller, indicating a considerable flexibility of the helix.

INTRODUCTION

Poly(ε-carbobenzoxy-L-lysine) (PCBL) is a precursor of poly(L-lysine) in the ordinary synthetic procedure. The optical rotatory dispersion and circular dichroism spectra indicate that this un-ionized polypeptide exists in a helical conformation in a variety of organic solvents[1–4]. Helix–coil transitions of PCBL in solution, induced by changing the solvent composition or the temperature, have been investigated by polarimetric, calorimetric and viscometric measurements[4,5–9]. The stability of the helix of PCBL was shown to be weaker than that of poly(γ-benzyl-L-glutamate) (PBLG), a closely analogous polypeptide[5]. The transition in PCBL systems was found to be considerably more cooperative, compared with PBLG or poly(β-benzyl-L-aspartate)[4,6].

Light scattering and hydrodynamic studies (including viscosity, diffusion, sedimentation and flow birefringence) on PCBL samples of widely different molecular weights have revealed that the PCBL helix is distinctly more flexible than the PBLG helix[1,2,4,10,11]. This was attributed to the existence of more frequent breaks in the PCBL helix. The nature of the side chain might play an important role in determining both the stability and the flexibility of polypeptide helices[2,10].

Recently, two dielectric studies on PCBL solutions have been reported. Frolov et al.[12] have measured the dielectric dispersion of dilute chloroform solutions of various PCBL samples, determining the specific static dielectric increment and the critical frequency as functions of the molecular weight. From the results the persistence length and the permanent dipole moment per amino acid residue were calculated to be 26 nm and 4 D, respectively. Omura et al.[13] have measured the dielectric dispersion of PCBL preparations with relatively low molecular weights (rang-

ing from 2.3×10^4 to 8.7×10^4) in *m*-cresol at various temperatures. As found by Matsuoka et al.[4], PCBL in *m*-cresol undergoes a sharp, thermally induced helix–coil transition of inverse type near the room temperature. From the temperature dependence of the dielectric dispersion and the optical rotation, the square average of the dipole moment and the dielectric relaxation time were obtained as functions of the helical content.

Only one electro-optical study on PCBL has ever been published, as far as we are aware. Tsvetkov et al.[14] have measured the electric birefringence of one sample of PCBL in dimethylformamide (DMF) and dichloroacetic acid. The specific Kerr constant of the helical conformation of PCBL in DMF was found to be much smaller than that of PBLG with nearly the same molecular weight in the same solvent.

In the present work we have studied the electro-optical properties of a number of PCBL samples in various helicogenic organic solvents and their mixtures. From the field strength dependence of the electric birefringence the permanent dipole moment and the optical anisotropy factor were separately determined according to the usual procedure. The results indicate that the optical anisotropy factor of PCBL is appreciably smaller than that of PBLG and changes its sign depending upon the solvent.

EXPERIMENTAL

The PCBL samples were prepared by the polymerization of ε,N-carbobenzoxy-L-lysine N-carboxyanhydride in dioxane using sodium methoxide as an initiator according to the method of Fasman et al.[5]. The resulting polymers were precipitated with ethanol, dissolved in chloroform and reprecipitated with n-hexane. Finally they were lyophilized from dioxane and stored in a refrigerator at low tempera-

Table 1 Intrinsic viscosity in DMF and molecular weight data for PCBL samples

Sample	Intrinsic viscosity (dl/g)	Molecular weight x 10^{-4}
I	0.549	9.9
II	0.633	12
III	5.77	62
IV	8.92	88

tures. Measurement of the intrinsic viscosity in DMF at 25°C enabled the molecular weight of these samples to be determined using the relationship obtained by Matsuoka et al.[4]. Intrinsic viscosity and molecular weight data for the PCBL samples used are quoted in *Table 1*.

The solvents used were dichloroethane, chloroform, tetrabromoethane, dioxane, tetrahydrofuran, DMF, hexa-methylphosphoramide (HMPA) and m-cresol. Most of these solvents were purified by the standard procedure. The tetrabromoethane was of reagent grade and used without further purification. Mixed solvents were made up on a volume basis.

The electric birefringence measurements were carried out in the apparatus previously described[15–17]. The electric field was applied to the solution in a Kerr cell in the form of single rectangular pulses of up to 6 kV amplitude. The Kerr cell contained two platinum electrodes spaced 0.205 cm apart.

The optical retardation δ of the solution due to the electric field was obtained following the procedure described in a previous paper[17]. The electric birefringence, Δn, is related to δ by:

$$\Delta n/\lambda = \delta/2\pi l \qquad (1)$$

where l is the path length of light through the birefringent medium and λ is the wavelength of light *in vacuo*. In this experiment, l = 0.979 cm and λ = 546 nm. We define the Kerr constant B by:

$$B = (\delta/2\pi l E^2)_{E\to 0} = (\Delta n/\lambda E^2)_{E\to 0} \qquad (2)$$

where E is the applied field strength.

In the case of determining the sign of the electric birefringence of the solution, a Babinet–Soleil compensator was interposed between the Kerr cell and the analyser crossed with the polarizer[18]. Its optic axis was parallel to the electric field. For this optical system the change in light intensity at the photomultiplier produced by the field, ΔI, is given by:

$$\Delta I = I_0 \sin(\delta/2) \sin(\delta/2 + \delta_c) \qquad (3)$$

where I_0 is the change in light intensity upon rotating the analyser from the crossed to the parallel position in the absence of optical retardation and δ_c is the retardation of the compensator. For large δ_c and small δ, equation (3) is approximated by:

$$\Delta I = I_0(\delta/2) \sin \delta_c \qquad (4)$$

Thus the light signal increases if δ is positive and decreases if δ is negative. This permits us to determine the sign of the birefringence.

The contribution of the solvent to the birefringence

was subtracted from the experimental values for solutions, whenever it was not negligible. This solvent correction is especially large in the case of DMF, HMPA and m-cresol, since these solvents have large Kerr constants. For solutions we employ the specific Kerr constant defined by B/c, where c is the polymer concentration in g/cm³. Strictly speaking, it is defined by $(B_{solution} - B_{solvent})/c$.

RESULTS

The steady-state electric birefringence of the PCBL samples in various organic solvents was measured as a function of field strength. *Figure 1* shows the $\Delta n/\lambda c$ versus E^2 plots for sample I in dichloroethane, chloroform, dioxane, tetrahydrofuran, DMF, HMPA and m-cresol. All these solvents are helicogenic solvents for PCBL. The measuring temperature was 25°C except for m-cresol solution. Measurement of the latter was made at 35°C; PCBL is partly helical in this condition[4]. The concentration dependence of $\Delta n/\lambda c$ was small in the range of 0.5 x 10^{-3} to 3.5 x 10^{-3} g/cm³. PCBL molecules are to some extent associated in dioxane, as judged from the relaxation time of the rise and decay process of the birefringence. The sign of the birefringence was negative in HMPA and m-cresol and positive in other solvents.

The plots in *Figure 1* are linear at low fields, i.e., Kerr's law holds. The initial slope gives the specific Kerr constant. However, large deviations from Kerr's law are observed at higher fields. These plots can be fitted to a theoretical equation of the electric birefringence for the
Figure 1 Plots of $\Delta n/\lambda c$ versus E^2 for sample I (M = 9.9 x 10^4) in organic solvents: ○, DMF (c = 1.3 x 10^{-3} g/cm³); □, dichloroethane (c = 1.6 x 10^{-3} g/cm³); △, tetrahydrofuran (c = 2.7 x 10^{-3} g/cm³); ▽, dioxane (c = 1.6 x 10^{-3} g/cm³); ●, chloroform (c = 3.2 x 10^{-3} g/cm³); ■, m-cresol (c = 2.0 x 10^{-3} g/cm³); ▲, HMPA (c = 1.5 x 10^{-3} g/cm³). The solid curves are calculated by means of equation (5) selecting appropriate values of μ' and $g_1 - g_2$

Table 2 Specific Kerr constant, dipole moment, dipole moment per residue and optical anisotropy factor of sample I in organic solvents

Solvent	Temp. (°C)	B/c x 10³	μ' (D)	μ'/res. (D)	$(g_1 - g_2)$ x 10⁴	n_D	ε

Dioxane	25	6.4	1880	5.0	7.0	1.420	2.21
Tetrahydrofuran	25	10.0	2060	5.5	8.7	1.405	7.58
DMF	25	11.5	1780	4.7	11	1.428	36.7
HMPA	25	−5.3	1960	5.6	−4.7	1.457	30
m-Cresol	35	−2.0	1100	2.9	−7.0	1.540	11.8

case of pure permanent dipole moment orientation. The electric birefringence of a dilute solution of rigid, axially symmetric macromolecules with a permanent dipole moment along the symmetry axis is given by:

$$\Delta n = \frac{2\pi \bar{v} c}{n}(g_1 - g_2)\left[1 - \frac{3(\coth \beta - 1/\beta)}{\beta} \right] \quad (5)$$

with

$$\beta = \mu' E/kT \quad (6)$$

where n is the refractive index of the solution, $\bar{v}$ is the partial specific volume of the solute, $g_1 - g_2$ is the optical anisotropy factor (i.e., the difference between the excess optical polarizability per unit volume of the macromolecule along the symmetry axis and that along the transverse axis), μ' is the apparent permanent dipole moment, k is the Boltzmann constant and T is the absolute temperature[19]. The solid curves in *Figure 1* are the theoretical curves obtained by assigning appropriate values to the two parameters, μ' and $g_1 - g_2$, in equation (5). The partial specific volume of PCBL is taken as 0.803 cm³/g[4]. The agreement between the calculated and experimental values is fairly good in spite of the polydispersity of the sample. Thus the apparent permanent dipole moment and the optical anisotropy factor can be separately determined. The data for the specific Kerr constant, the apparent dipole moment, the apparent dipole moment per residue and the optical anisotropy factor are summarized in *Table 2*. In this Table are also included literature values of the refractive index and the dielectric constant of the solvents. The specific Kerr constant is given in statvolt⁻² cm⁴ g⁻¹ (1 statvolt⁻² cm⁴ g⁻¹ = 1.113 x 10⁻¹⁰ V⁻² m⁴ kg⁻¹) and the dipole moment in Debye unit (1 D = 3.336 x 10⁻³⁰ C m).

As can be seen from *Table 2*, the apparent dipole moment per residue is of the same order of magnitude as that of PBLG and does not depend very much upon the solvent. The exceptionally small value of μ' in m-cresol may be ascribed to the incomplete helix in this condition. On the other hand, the optical anisotropy factor is considerably small and changes its sign depending upon the solvent. It is to be noted that the sign of the optical anisotropy factor is negative in HMPA and m-cresol which have large refractive indices.

The $\Delta n/\lambda c$ versus E^2 plots for PCBL samples of different molecular weights in DMF and HMPA are presented in *Figures 2* and *3*, respectively. The solid curves in these Figures are those calculated according to equation (5). Contrary to expectation, the agreement between the calculated and experimental values is fairly good even for high molecular weight samples (samples III and IV). Thus it is possible to assign pertinent values to μ' and $g_1 - g_2$

IV	25	53.2	4340	1.3	11

for these samples. However, these values must be regarded as tentative, since the high molecular weight PCBL helices behave as flexible rods[2,10]. The data for B/c, μ' and $g_1 - g_2$ of PCBL samples in DMF and HMPA are listed in *Tables 3* and *4*, respectively. The small values of the apparent dipole

moment per residue for high molecular weight samples reflect a considerable flexibility of the helix.

Furthermore, the electric birefringence of sample I was studied in mixed organic solvents. *Figure 4* shows the field strength dependence of the birefringence in chloroform—HMPA mixtures. The solid curves in this Figure represent the theoretical ones based on equation (5). The specific Kerr constant and the optical anisotropy factor obtained in the same manner as above are plotted against the solvent composition in *Figure 5*. A reversal in the sign of the specific Kerr constant and the optical anisotropy factor is observed in the vicinity of 70 vol % HMPA. Another example of the sign reversal is encountered in the case of PCBL in chloroform—tetrabromoethane mixtures, as shown in *Figure 6*. Incidentally we note that PCBL is not soluble in pure tetrabromoethane. We also noticed that the negative sign of the electric birefringence of helical PCBL in *m*-cresol turned positive with the addition of methanol. In *Figure 6*, the electric birefringence of PCBL in a *m*-cresol—methanol mixture (75:25 by vol) is also presented.

DISCUSSION

The following discussion is mainly concerned with the electro-optical properties of sample I, since the low molecular weight PCBL helices (with molecular weight below 1 x 10^5) show the characteristic behaviour of rigid rods according to the study of Daniel and Katchalski[10].

As can be seen from *Table 2*, the apparent dipole moment per residue lies in the range of 4.7 to 5.9 D in spite of the large variation of the dielectric constant of the solvents used. This indicates that the internal field correction factor is rather small for such elongated, thin macromole-

cules. The values quoted are somewhat larger than those for PBLG in the corresponding solvents.

The reversal of the sign of the optical anisotropy factor accompanied by the variation of the solvent can be explained on the basis of the theory of Peterlin and Stuart[20] for rigid ellipsoids of revolution. In their theory the particle is assumed to be a continuous dielectric and immersed in a continuous medium (solvent). The dimensions of the particle are assumed to be small compared to the wavelength of light. Resting on these assumptions, the optical anisotropy factor is given by:
Figure 5 Specific Kerr constant (●) and optical anisotropy factor (O) of sample I plotted against the solvent composition of chloroform—HMPA mixtures
Figure 6 Plots of $\Delta n/\lambda c$ versus E^2 for sample I in chloroform—tetrabromoethane mixtures at 25°C and in a *m*-cresol—methanol mixture at 35°C: O, chloroform; △, 16.7% tetrabromoethane; ∇, 50% tetrabromoethane; ●, *m*-cresol—methanol mixture (75:25 by vol)

Tetrahydrofuran	1.405	0.87	4.5	−3.6	−1.6

$$g_1 - g_2 = \frac{1}{4\pi} \frac{(n_1^2 - n_2^2) + e(n_1^2 - n_0^2)(n_2^2 - n_0^2)/n_0^2}{\left[\frac{n_1^2 + 2n_0^2}{3n_0^2} - \frac{2e}{3} \cdot \frac{n_1^2 - n_0^2}{n_0^2} \right]\left[\frac{n_2^2 + 2n_0^2}{3n_0^2} + \frac{e}{3} \cdot \frac{n_2^2 - n_0^2}{n_0^2} \right]} \tag{7}$$

where n_1 and n_2 are the refractive indices of the particle along the symmetry and transverse axes, n_0 is the refractive index of the solvent and e is a form factor which depends only on the axial ratio.

In the case of a prolate ellipsoid the value of e approaches its asymptotic value of 0.5 when the axial ratio is very large. Then, equation (7) reduces to:

$$g_1 - g_2 = \frac{2n_0^2(n_1^2 - n_2^2)}{4\pi(\bar{n}^2 + n_0^2)} + \frac{(\bar{n}^2 - n_0^2)^2}{4\pi(\bar{n}^2 + n_0^2)} \tag{8}$$

where $\bar{n}$ is the mean refractive index of the particle. The first term in the right side of equation (8) arises from the intrinsic anisotropy of the particle itself and the second from the form anisotropy, which depends on the difference in the refractive indices of the particle and the solvent. Let the former be represented by $(g_1 - g_2)_{intrinsic}$ and the latter by $(g_1 - g_2)_{form}$. While $(g_1 - g_2)_{form}$ is always positive except for the special case of $n_0 = \bar{n}$, $(g_1 - g_2)_{intrinsic}$ is positive, zero or negative according as $n_1 > n_2$, $n_1 = n_2$ or $n_1 < n_2$. If $n_1 > n_2$, $g_1 - g_2$ is positive for all values of the refractive index of the solvent. On the other hand, the sign of $g_1 - g_2$ can be changed by suitable variation of n_0, if $n_1 < n_2$.

The mean refractive index of the solute particle can be obtained from the specific refractive index increment of the solution, dn/dc, using the simple equation[21]:

$$dn/dc = \bar{v}(\bar{n} - n_0) \tag{9}$$

For PCBL, $dn/dc = 0.117$ cm^3/g (in DMF, at 546 nm)[4]. Thus $\bar{n} = 1.574$. Using this value, $(g_1 - g_2)_{form}$ was calculated for each PCBL–solvent system. Then, $(g_1 - g_2)_{intrinsic}$ was obtained by subtracting $(g_1 - g_2)_{form}$ from the experimental value of $g_1 - g_2$. Finally, the intrinsic birefringence, $n_1 - n_2$, was calculated from $(g_1 - g_2)_{intrinsic}$. These data are quoted in *Table 5*.

The intrinsic birefringence should be constant in different solvents. However, it varies to some extent with the solvent according to *Table 5*. This might be due to the experimental inaccuracy and the inadequacy of the Peterlin–Stuart theory. Cassim and Taylor[22] examined the sources of error in the Peterlin–Stuart theory and showed that this theory overestimated the form contribution to the optical anisotropy factor. The error produced will become larger as the refractive index of the solvent departs from that of the solute particle. Subsequently their conclusions were supported by Oriel and Schellman[23].

Notwithstanding these uncertainties, we can conclude

that the intrinsic birefringence of PCBL is negative in sign. The sign reversal and the small absolute value of the optical anisotropy factor are explained on this basis. On the other hand, the intrinsic birefringence of PBLG has been found to be positive in sign[22]. Correspondingly the optical anisotropy factor of PBLG is fairly large; for example, $g_1 - g_2 = 4 \times 10^{-3}$ in dichloroethane[19,24].

Recently, particular attention has been paid to the orientation of the side chains of polypeptide molecules with respect to the helical backbone[25]. Charney et al.[26] measured the electric dichroism of PBLG in dichloroethane at 258 nm and inferred that the electronic transition moment lying in the plane of the phenyl group makes an angle of 53.5° with the helix axis. Since the side chain of PCBL [−(CH$_2$)$_4$NHCOOCH$_2$C$_6$H$_5$] is longer than that of PBLG [−(CH$_2$)$_2$COOCH$_2$C$_6$H$_5$] and contains an amide group with planar character, the former will assume a transverse conformation rather than a longitudinal one[27]. If the terminal phenyl ring is so oriented as to protrude relative to the helical backbone, it will contribute greatly to the optical polarizability along the transverse axis. This will give rise to the negative intrinsic birefringence of PCBL.

Evidently the sign reversal of the optical anisotropy factor of PCBL in chloroform–HMPA mixtures is not due to a conformational change of the helical backbone, since the values of the Moffitt parameter b_0 are nearly the same in chloroform and in HMPA[4]. However, the possibility of the change of side-chain conformations cannot be entirely excluded.

Acoustic studies of chain flexibility in copolymers of *N*-vinylcarbazole

P. N. Shankar Iyer, Alastair M. North, Richard A. Pethrick and Daniel B. Steinhauer
Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow G1 1XL, UK
(Received 30 January 1975; revised 25 February 1975)

Acoustic relaxation studies of a series of copolymers of *N*-vinylcarbazole with methyl acrylate and with styrene have shown that the incorporation of up to 20% of the sterically less hindered comonomer promotes very little flexibility in the stiff poly(*N*-vinylcarbazole) chain.

INTRODUCTION

Interest in the molecular physics of poly(*N*-vinylcarbazole) has led to studies of segmental rotation by both dielectric relaxation[1,2] and luminescence[3,4] techniques. These have shown that the chain is relatively 'stiff', with a room temperature segmental rotation frequency between 1 MHz (dielectric relaxation) and 3 MHz (fluorescence depolarization) in dilute solution. Furthermore, observations of electronic energy transfer down poly(*N*-vinylcarbazole) chains containing methyl acrylate comonomer units have suggested[4] that the comonomer has surprisingly little effect on the ease of energy migration, and so presumably on the separation of neighbouring carbazole units. Since relatively unhindered comonomers such as methyl acrylate are often added to increase the 'flexibility' of 'stiff' polymer chains, it becomes a matter of interest as to whether such a comonomer exerts its normal 'flexibilizing' action on the very hindered poly(*N*-vinylcarbazole) chain. In this context it is the resistance to segmental motion caused by intramolecular energy barriers that is of interest and not the factors arising from the strong inter-chain interactions of the carbazole groups in solid polymer. For this reason we refer to the speed of segmental rotation of the dissolved (isolated) chain as the 'intrinsic flexibility'.

Consideration of the reactivity ratios for copolymerization of *N*-vinylcarbazole with methyl acrylate[5] and styrene[6] suggests that while the former comonomer exhibits a strong tendency to alternation ($r_1, r_2 < 1, r_1, r_2 \ll 1$) there is a tendency for sequences of more than one styrene unit to occur in the appropriate copolymer ($r_2 > 1$). Consequently an added point of investigation concerns the effect of sequence distribution of any 'flexibilizing' action.

EXPERIMENTAL

A series of copolymers of *N*-vinylcarbazole with methyl acrylate and with styrene were prepared by conventional

free radical polymerization of the mixed monomers at 353 K using di-t-butyl peroxide as initiator. The polymer compositions as determined by elemental analysis are recorded in *Table 1*. Molecular weights were determined by light scattering from dilute solutions in benzene. The refractive index increment in each case was measured in a Brice-Phoenix differential refractometer and ranged from +0.13 to +0.16 for the styrene copolymers and +0.16 to +0.175 for the methyl acrylate series. The determinations had a precision of 10%, but in view of the difficulty of interpretation of light scattering data from copolymers we do not place a significance greater than 30% on the calculated values. They are reported, however, to confirm that the chains studied were sufficiently long to make acoustic effects due to end-groups insignificant.

Acoustic measurements were carried out using pulse and resonator techniques as described previously[7].

RESULTS

As an example, the acoustic absorption observed in a 2.5% w/v solution of the copolymer, methyl acrylate 4, in toluene at 318 K, is illustrated in *Figure 1*. The normal mode contribution[7] to the absorption was calculated from the solution viscosity using the model of Yu and Stockmayer[8] for stiff chains. The remaining absorption was analysed[7] to give the internal relaxation amplitude, frequency and Cole—Cole distribution parameter.

Table 1 Characteristics of copolymers of *N*-vinylcarbazole

Comonomer	$M_w \times 10^{-4}$	Mole ratio carbazole/ comonomer
styrene: 1	63	6
2	25	5
3	59	4
methyl acrylate: 4	5.1	13
5	6.4	6
6	3.0	4
Figure 1 Acoustic absorption in the *N*-vinylcarbazole/methyl acrylate copolymer designated methyl acrylate 4, in toluene at 318 K. ●, Observed absorption; ○, normal mode contribution

Table 2 Relaxation parameters of copolymers

Copolymer	Temp. (K)	Relaxation amplitude $\times 10^{15}$ $(m^{-1}s^{-2})$	Relaxation frequency (MHz)	Cole–Davidson distribution parameter
styrene: 1	308	114	1.4 ± 0.6	0.6
2	308	128	1.4 ± 0.4	0.6
	328	111	1.3 ± 0.4	0.6
3	308	133	1.2 ± 0.4	0.6
	328	116	1.2 ± 0.4	0.6
methyl acrylate: 4	308	124	1.3 ± 0.3	0.7
	328	126	1.3 ± 0.4	0.7
5	308	193	1.4 ± 0.6	0.6
	328	169	1.3 ± 0.7	0.6
6	308	81	1.4 ± 0.5	0.7
	328	69	1.6 ± 0.4	0.6

Because the complete relaxation extended in frequency below the accessible instrument range, the error in the calculated acoustic parameters is larger (see below) than that reported[7] for polystyrene and similar systems. The absorption curves for the other copolymers are very similar to the example illustrated. When the data are portrayed on the same graph the individual curves cannot be distinguished over most of the frequency range. The derived relaxation data are presented in Table 2.

DISCUSSION

For all the polymers studied the relaxation frequencies are indistinguishable (within experimental error) from that reported for poly(N-vinylcarbazole). The rather surprising conclusion is that incorporation of up to 20% comonomer promotes a negligible increase in the intrinsic rate of segmental motion in the hindered poly(N-vinylcarbazole) chain. This is true although the copolymer containing 20% styrene units has an observable probability of containing sequences of two or more styrene units.

The reason for the lack of comonomer effect must lie in the fact that the barriers to segmental rotation have

their origin in long range dipole–dipole interactions between carbazole groups as well as in the strong short range 'steric' effects. Thus the acoustic results confirm the conclusions of the dielectric studies[2] that the rotating unit contains several monomer residues and so is little affected by a 'chemical defect'.

For all of the styrene copolymers and the methyl acrylate copolymer of lowest comonomer content the relaxation amplitudes are the same within 10% spread. There is no consistent trend in the relaxation amplitudes of the two polymers of higher methyl acrylate comonomer content, and it may be that the discrepancy arises in the difficulty of estimating the absorption at frequencies well below the experimental measurements by curve fitting to the upper half of the relaxation. These relaxation amplitudes (though not the relaxation frequencies) are particularly sensitive to errors in the lowest frequency points obtained by the resonator technique.

Saturated hydrocarbon prepolymers by ozonolysis*

R. A. Rhein and J. D. Ingham

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, Ca 91103, USA
(Received 13 March 1975; revised 1 July 1975)

The preparation and isocyanate cure of hydroxyl-containing, saturated hydrocarbon prepolymers is described, with emphasis on ethylene—propylene copolymers. The preparation consists of ozonolysis and subsequent reduction, with alkylaluminium hydride materials, of precursors derived from commercially available polymers. The methods for obtaining the precursors are: (a) no prior treatment; (b) bromination followed by dehydrobromination, so as to create sites of main-chain unsaturation; or (c) thermal degradation of the parent polymer to a viscous, unsaturated oligomer. Liquid ethylene—propylene (copolymer) prepolymers, approximately difunctional in hydroxyl, were prepared and cured with di-isocyanates; analogous prepolymers of polyisobutylene and amorphous polypropylene were also prepared.

INTRODUCTION

The objective of this work is the preparation of saturated hydrocarbon prepolymers with terminal hydroxyl groups for use in solid propellant binders.

Relatively low molecular weight polymers containing reactive terminal or pendant functional groups are useful as precursors or components of castable polymer systems, and as additives in formulations of inherently hard or brittle polymers such as epoxy resins, to increase toughness or decrease hardness. The work described in this paper is part of a long-term investigation to prepare and evaluate saturated hydrocarbon prepolymers that are not generally available. Besides allowing increased versatility in formulating castable polymeric systems, such prepolymers are expected to have enhanced thermal and oxidative stability compared with available polybutadiene and polyether prepolymers. Although hydroxyl[1] and carboxyl[2] terminated polyisobutylene can be prepared by ozonolysis and subsequent conversion of ozonolysis and subsequent conversion of ozonized butyl rubber to the desired product, this process is generally limited to isobutylene polymers because other high molecular hydrocarbon polymers containing occasional sites of main-chain unsaturation are not readily obtained.

This paper describes the preparation, and isocyanate curing, of saturated hydrocarbon prepolymers containing hydroxyl functionality of the following types: ethylene—propylene copolymer, amorphous polypropylene, and polyisobutylene; it is an extension of a published[3] preliminary study on the preparation of ethylene—propylene (copolymer) prepolymers. Following the preparation of hydroxy-terminated polyisobutylenes by ozonization of butyl rubber, we attempted the preparation of the ethylene—propylene analogues by bromination followed by dehydrobromination so as to create occasional main-chain unsaturation, followed by ozonolysis and reduction, and obtained hydroxyl-containing ethylene—propylene prepolymers in this manner.

It was found, also, that hydroxyl prepolymers could be prepared by ozonolysis of a solution of ethylene—propylene copolymer, amorphous polypropylene, or polyisobutylene followed by reduction. A more convenient method of prepolymer preparation was subsequently developed in which ethylene—propylene copolymer or amorphous polypropylene was partly thermally degraded at elevated temperatures and then ozonized and reduced.

EXPERIMENTAL AND RESULTS

Solution viscosities were measured using a Ubbelohde viscometer held at 30.00 ± 0.02°C by a Hallikainen Thermotrol Viscometer Bath. Intrinsic viscosities were estimated from the equation[15]:

$$\eta_{sp}/C = [\eta] + 0.4[\eta]^2 C$$

where η_{sp} is the specific viscosity, C the concentration (g/dl) and $[\eta]$ the intrinsic viscosity (dl/g).

Ozone was produced from oxygen by a Welsbach T-816 Ozonator at a concentration of 0.055 kg/m³. The flow rate of oxygen—ozone mixture was generally held at 1.0 l/min.

Di-isobutyl aluminium hydride (DIBAL-H)[4,5], sodium aluminium diethyl dihydride (OMH-1), and sodium dihydrobis(2-methoxyethoxy)aluminate (Red-Al)[7,8] were found to be effective in reducing the ozonized polymer terminal groups to hydroxyl. The temperatures, reaction times, solvents, and mole ratios of hydride-ozonized terminal group for DIBAL-H were 100°C, 2 h, heptane, and mole ratio 3.2; for OMH-1, 25°C, 30 min, benzene, and mole ratio 2.0; for Red-Al, 80°C, 2 h, benzene, mole ratio 2.42. These reagents replace the more costly LiAlH₄ suggested in the literature[7].

Number-average molecular weights were determined by vapour pressure osmometry (v.p.o.) (in benzene at 30°C); number- and weight-average molecular weights were determined from gel permeation chromatography, calibrated from the v.p.o. measurements.

We prepared samples of hydroxy-terminated polyisobutylene by ozonolysis and reduction of butyl rubber by

the method of Jones and Marvel[1] except that DIBAL-H was used as the reducing agent. The results are presented in *Table 1*.

This work was extended in an attempt to prepare hydroxy-terminated ethylene—propylene copolymer by ozonolysis of an ethylene—propylene copolymer containing occasional main-chain unsaturation sites, prepared in turn by bromination and dehydrobromination. The parent polymer used was Exxon Vistalon 404, an ethylene—propylene copolymer containing 43% ethylene. This copolymer was first subjected to bromination and dehydro-bromination for polymers designated in *Table 2* as EPR 6281A and EPR 2102. A 5 wt % solution in carbon tetrachloride was treated with 1.0 mol Br₂/kg of copolymer; bromination was complete in about 1 hour upon exposure of the solution to sunlight. This brominated polymer was then precipitated in acetone and solvent removed by vacuum evaporation. For dehydrobromination, the polymer, EPR 6281A (*Table 2*) was treated with potassium t-butoxide in tetrahydrofuran (24 equiv./kg polymer) (from a suggestion by Dr F. P. Baldwin, Exxon Corp.), for 1.75 h, at 66°C; polymer EPR 2102 (*Table 2*) was treated with N-ethylpiperidine (50 equiv./kg polymer) in decalin, for 1.75 h, at 131°C. The polymers were then dissolved in heptane (5 wt %), ozonized and reduced to yield products with properties given in *Table 2*.

This study of the ozonolysis of saturated polymers was extended to amorphous polypropylene (Eastman M-5L), polyisobutylene (Exxon Vistanex 80), and poly(1-butene) (Cellomer Associates). *Figure 1* shows the decrease in intrinsic viscosity with ozonization for these polymers. The polypropylene samples were ozonized in CCl_4, the solvent removed, the ozonized product re-dissolved in heptane and reduced with DIBAL-H. The hydroxyl content and molecular weight of the resulting prepolymers are presented in *Table 1*.

The observation (M. F. Humphrey, personal communication) that ethylene—propylene rubber degraded to a viscous liquid upon heating to elevated temperatures prompted an investigation of thermal degradation as a means of preparing precursors of liquid oligomers. The polymers subjected to thermal degradation were the commercially available EPR and EPDM parent polymers, listed in *Table 3*. The apparatus used for thermal degradation consists of a Vycor tube, 0.0254 m diameter and 0.5 m long, with 24/40 male joint at each end, suspended vertically, the bottom joint fitting in the cover of a 500 ml resin kettle. A constriction 0.09 m from the bottom of the tube held in place a small, very loose-fitting Pyrex disc. Borosilicate Raschig rings added to the tube filled a space 0.127 m above the disc. The tube was fitted in a tube furnace (Hoskins FH 303A) so that the bottom of the tube furnace (length 0.33 m) lined up with the constriction/disc. A gas inlet tube was attached to the resin kettle cover. At the top of the reaction tube was attached a condenser and a 500 ml flask for collecting the volatile degradation products.

In the experiments, the furnace temperature was controlled to a preset level, and in most cases nitrogen was passed into the resin kettle, hence upwards through the reaction tube, at 100 ml/min. Small pieces of polymer were added periodically from above into the reaction tube. *Table 3* gives the results for the various polymers and degradation temperatures. It was observed that during the course of thermal degradation the polymer, initially resting at the top of the Raschig rings, would liquefy and flow downwards between the rings while the countercurrent nitrogen flow swept gaseous and volatile liquid products upwards and out through the condenser.

Although nitrogen was generally selected as the carrier

gas, in the preparation of sample EPR430—air (*Table 3*) air was used in place of N_2, resulting in a somewhat lower yield of liquid polymer. We found that at furnace temperatures above about 500°C, the use of air as carrier gas resulted in combustion within the furnace. Two-step processing of EPR was used in the preparation of samples EPR540—350A and —B. The first step, at 540°C occurred in the presence of N_2, but without countercurrent flow. The rather fluid product from the first step was added dropwise to the apparatus held at 350°C with countercurrent N_2 flow to remove the volatiles. Experiment EPR600, conducted at 600°C, gave no liquid polymer in the resin kettle.

Higher temperatures were required to degrade amorphous polypropylene; the products resulting from temperatures of 500° to 700°C, i.e., samples PP500, —600, —700A, and —700B are shown in *Table 3*. Only volatile products resulted at a degradation temperature of 800°C. The polypropylene samples were also degraded in the presence of nitrogen, but only sample PP500 was subjected to countercurrent N_2 flow.

The degradation products from EPR, EPDM, and polypropylene were found to contain olefinic unsaturation, identified from the infra-red spectrum by absorption peaks at 6.0—6.1 and then quantitatively determined by the mercuric acetate method, and shown in *Table 3*.

Several of these precursors were ozonized and then reduced with OMH-1 (benzene solvent, 30 min, ambient temperature) (*Tables 1* and *2*).

Curing studies on a number of prepolymers prepared in this effort were conducted. Generally, the curing experiments consisted of degassing 0.005—0.01 kg of prepolymer in a vacuum, mixing in the isocyanate — generally tolylene-2,4-diisocyanate (TDI) or the di-isocyanate derivative of dimer acid (General Mills Corp.; isocyanate equivalent wt. 300) (DDI) in the amounts recorded in *Tables 4* and *5*, and pouring the mixture into an aluminium dish 2½ in. in diameter, pretreated with MS122 fluorocarbon Release Agent (Milles-Stephenson Chemical Co.). If ferric acetylacetonate was used it was dissolved in the isocyanate to give a concentration of 4.95 x 10^{-3} kg/l (TDI) or 1.09 x 10^{-3} kg/l (DDI) os isocyanate (i.e., mole ratio FeAA/isocyanate = 10^{-3}) before adding the isocyanate to the prepolymer. The mixture was heated at 70°C in an oven

for either 3 or 10 days. If the mixture cured, the Shore A hardness was measured, and 9 x 10^{-6} m diameter samples (~2 x 10^{-4} kg) were immersed in 100 ml of toluene for determination of gel fraction and gel swelling. The curing results are shown in *Tables 4* and *5*.

DISCUSSION

This effort was initiated by the need for saturated hydro-carbon prepolymers with reactive functional groups for solid propellant binders.

The successful preparation of hydroxy-terminated polyisobutylene by ozonolysis of butyl rubber in solution, followed by reduction with LiAlH$_4$, by the method of Jones and Marvel[1] prompted the investigation of other, less expensive and more convenient, reducing agents. We found that commercially available reducing agents capable of reducing the carbonyl (resulting from ozonolytic scission

of main-chain unsaturation) to hydroxyl, besides LiAlH$_4$, were di-isobutyl aluminium hydride[4,5] (DIBAL-H), sodium bis(2-methoxyethoxy) aluminium hydride[7,8] (Red-Al), and sodium aluminium diethyl dihydride[6] (OMH-1). Since economics favour DIBAL-H and OMH-1, they were used extensively in this effort for the reduction of ozonized groups of saturated prepolymers.

The successful preparation of hydroxyl-terminated polyisobutylene prompted investigation of the preparation of prepolymers of ethylene–propylene copolymer by the method of bromination, dehydrobromination to produce main-chain unsaturation, and ozonolysis followed by reduc-tion. Bromination was expected to take place at tertiary carbon sites[9], and bromination of ethylene–propylene copolymer in CCl$_4$ solution has been reported[10,11]. We found here that bromination of the ethylene–propylene copolymers in CCl$_4$ solution occurred readily under ordi-nary laboratory fluorescent lighting in either Pyrex or quartz vessels.

For dehydrobromination, we found potassium t-butoxide in tetrahydrofuran and N-ethylpiperidine in heptane to be satisfactory, but have used a substantial excess of dehydrobromination agent; further research may show that appreciably less is required.

The process of bromination, dehydrobromination, ozonolysis, and reduction successfully produced viscous, liquid hydroxyl-containing curable prepolymers from ethylene—propylene rubber. We found that a sample of ethylene—propylene copolymer, Exxon Vistalon 404, brominated to the extent of 1.0 equiv. Br_2/kg polymer, when not subjected to dehydrohalogenation also was degraded by ozonolysis; this observation prompted the investigation of ozonolysis of saturated hydrocarbon polymers as a means of prepolymer preparation.

Although there is substantial literature on the reaction between olefins and ozone and the reactions involved have been clearly defined[12], there have been relatively few investigations of the effects of ozone on saturated compounds. However, Geiseler and coworkers found that ozone reacts with n-octadecane to form carboxyl and carbonyl species, and have investigated the reaction mechanism[13]. Subsequently they examined the degradation of polyolefins by ozone in oxygen[14]. The saturated hydrocarbon polymers investigated included high and low density polyethylene, and polypropylene as suspensions in carbon tetrachloride and polyisobutylene dissolved in carbon tetrachloride. They observed substantial reductions of intrinsic viscosities for these polymer systems, as well as infra-red evidence for the formation of carboxyl and other species containing oxygen.

In this work it has been found that solutions of ethylene—propylene rubber (EPR), amorphous polypropylene and poly(1-butene) can be ozonized to give low molecular weight products that can subsequently be reduced to prepolymers containing hydroxyl groups. The prepolymers can then be reacted with di-isocyanates to obtain crosslinked polyurethane hydrocarbon elastomers.

Figure 1 shows the observed relationships of polymer intrinsic viscosities and ozone consumption for the three types of polymers. Since the values for ozone required represent the total amount bubbled into the reaction mixtures, and concentrations were variable, no rigorous conclusions about the kinetics of ozonization are possible. However, the slopes generally appear to be slightly larger for ethylene—propylene rubber than the other polymers. Following ozonization, the products were treated with di-isobutylaluminium hydride (DIBAL-H, Texas Alkyls) 25 wt % in heptane and reduced, using the same procedure as for lithium aluminium hydride[1]. Ozonization conditions, approximate intrinsic viscosities, hydroxyl concentration and functionalities are shown in *Table 1*. Functionality is the number of hydroxyl groups/mol of prepolymer. Since these products often have functionalities exceeding two, some hydroxyl groups must be present along the chains as well as at the ends. Preliminary experiments have shown that crosslinked polymers are obtained when these prepolymers are cured with approximately equivalent amounts of di-isocyanates. Since the cured polymers usually contained about 10% sol or less, it can be concluded that relatively few monofunctional species were formed during ozonolysis and reduction.

Although the reaction times and amounts of ozone required for ozonization of saturated hydrocarbon polymers are greater than for ozonolysis of butyl rubber[1,2] the process described here allows preparation of hydrocarbon

prepolymers of different chemical structure and with high functionality that can be used in the formulation of a variety of castable hydrocarbon polymer systems.

We observed in each experiment that EPR and EPDM underwent thermal degradation to viscous oligomers, suggesting chain scission rather than unzipping, as in the case of polyisobutylene[16]. The molecular weight of the residue, as non-volatile oligomer, decreased with increasing degradation temperature. The EPDM materials were apparently more subject to thermal degradation that was EPR (*Table 3*) as indicated by lower molecular weight product.

The relatively high unsaturation functionality (~2) of the EPR degraded products is difficult to explain, since chain scission alone would be expected to give monofunctional unsaturated materials[17], one possible explanation is the reaction:

$$\text{wwwCH—CH}_2\text{www} \xrightarrow{\Delta} \text{CH}_4 + \text{wwwCH=CHwww}$$
occurring in addition to chain scission for the EPR products. This reaction is indicated by the fact that ozonolysis results in further reduction in molecular weight. (Ozonolysis of isobutylene—diene copolymer containing mainchain unsaturation results in substantial molecular weight reduction due to olefin cleavage[1].)

The viscous oligomers that were ozonized to the extent of 6.0 equiv./kg, were substantially over-ozonized since the unsaturation levels in the oligomers were ~2 equiv./kg (*Table 2*). Consequently, not only were ozone—olefin. reactions[12] occurring, but also ozone degradation of saturated EPR was taking place.

After reduction of these ozonized oligomers, essentially complete conversion of all oxygen species to hydroxyl was observed from the infra-red spectra.

The preliminary curing experiments of the hydroxy-terminated polyisobutylene samples prepared from butyl rubber (*Table 4*) indicate that since crosslinking took place only upon the addition of triols to the polymer that the polyisobutylene samples were mixtures of diol with species less than difunctional in hydroxyl. The polyisobutylene sample PIBLM, prepared from butyl containing 4.2% unsaturation, warrants further investigation. Its molecular weight is lower than that prepared from butyl of only 2% unsaturation, resulting in a lower bulk viscosity [2460 P (Dr S. Kalfayan, Jet Propulsion Laboratory) at $23°C$ vs. 8000 P at $21°C$ for an analogous polyisobutylene[2] of M_n 1800].

The ethylene—propylene prepolymer cured readily with TDI and DDI (*Table 5*); with TDI the cured products were rather hard materials. With DDI the cured products were flexible and had a high gel fraction.

The polypropylene prepolymers also cured with isocyanates, as shown in *Table 4*, producing rather soft polymer.

CONCLUSIONS

Ozonolysis of polymers (with or without main-chain unsaturation) in solution, followed by reduction, leads to curable, viscous liquid prepolymers containing hydroxyl groups. Ethylene—propylene copolymers with main-chain

unsaturation are much more readily cleaved by ozonolysis than are fully saturated polymers.

Main-chain unsaturation can be produced in a saturated hydrocarbon by bromination followed by dehydrobromination.

Bromination occurs readily in CCl_4 solution; potassium t-butoxide and *N*-ethylpiperidine have been found to be effective in dehydrobromination.

The thermal degradation at temperatures ranging from 350–550°C of one type of EPR and several types of EPDM, and at temperatures from 500 to 700°C for amorphous polypropylene resulted in viscous liquid oligomers which were mono- to di-functional in unsaturation. The molecular weight of the oligomers is inversely related to the degradation temperature. Ozonolysis followed by reduction of these oligomers produced prepolymers approximately di-functional in hydroxyl.

Reduction of ozonized, degraded polymer to produce hydroxyl groups can be effected with lithium aluminium hydride, di-isobutyl aluminium hydride, sodium bis(2-methoxyethoxy) aluminium hydride, and sodium aluminium diethyl dihydride.

Saturated ethylene–propylene prepolymers with hydroxyl groups can be cured with difunctional isocyanates under a variety of conditions.

An infra-red investigation of cardo polymer solutions

(Received 2 February 1975)

Intermolecular interaction of certain cardo polyarylates, polyamides, polyimides with solvents such as chloroform, *sym.*-tetrachloroethane, *m*-cresol, has been investigated. Integrated intensities for the carbonyl stretching bands point to the formation of hydrogen bonds with solvent molecules. The lactone carbonyl is most capable of forming such a bond. The formation of hydrogen bond in polyamides is weakened by the polymer interchain interaction. The proportion of the solvated lactone carbonyls decreases when passing to polymers with more rigid chains.

INTRODUCTION

In recent years soluble cardo polymers[1,2] with increased heat resistance have aroused considerable interest. The solubility of such polymers is dependent on their chemical structure[3]. Because of this, determination of the mechanism of dissolution of these polymers seems to be a topical problem from the scientific and practical viewpoints.

Since the interaction of individual groups of the macromolecule with the molecules of the solvent plays a significant part in dissolution, the need for studying intermolecular interactions in the polymer—solvent system becomes obvious. Infra-red analysis is one of the most direct methods; it was, therefore, of interest to use it for studying solutions of the cardo polymers.

EXPERIMENTAL

In this study aromatic polyesters (polyarylates), polyamides, and polyimides have been investigated.

The polyarylates were synthesized by high temperature polycondensation of bisphenols (phenolphthalein, phenolfluorene, and phenolanthrone) and dicarboxylic acid dichlorides (sebacic, terephthalic, 4,4'-diphenyl dicarboxylic, and 4,4'-diphenyloxide dicarboxylic acids)[1-3].

The polyamides were prepared by low temperature solution polycondensation of anilinephthalein, anilinefluorene, anilineanthrone with isophthaloyl and terephthaloyl chlorides[1-3]. The polyimides were prepared by high temperature one-step polycondensation of anilinephthalein and anilinefluorene and pyromellitic, 3,3', 4,4'-diphenyloxide tetracarboxylic, and 3,3',4,4'-diphenyl tetracarboxylic dianhydrides[1-3]. All polymers were dried under vacuum at 100—120°C. Water content (by Karl—Fischer reagent) does not exceed 0.2—0.3%. Model compounds were prepared by known methods; melting points and solvents for crystallization were as follows: phthalide,

71°C (water); 3,3-diphenylphthalide, 117—118°C (ethanol); anthrone, 161—162°C (benzene/petroleum ether); 9,9-diphenylanthrone, 194—195°C (ethanol).

Polymethylenephthalide selected as a model polymer was synthesized by polymerization in dimethylformamide (DMF) in the presence of benzoyl peroxide initiator[1,2].

Chloroform, *sym.*-tetrachloroethane (TCE) dimethyl sulphoxide (DMSO), and *m*-cresol dissolve the polymers and do not absorb selectively in the investigated region of the spectrum. The water content did not exceed 0.01%.

The i.r. spectra were recorded on a UR-20 double-beam spectrophotometer.

The spectra of films of polymers were taken in the 700—1800 cm⁻¹ region with a NaCl prism. The polymer solutions (0.035 mol/l) were investigated in the carbonyl absorption region of 1600—1800 cm⁻¹. The compensation method was applied to polymer solution investigation, using two similar demountable cells (sample cell and compensation cell), the thickness of which was checked interferrometrically before each run.

The films of polyarylates and all polyimides were obtained from solutions in TCE and those of the polyamides from solutions of the polymers in DMF.

The 800 cm⁻¹ band was used to control the drying of polymer films obtained from DMF. Integrated intensities of the absorption bands were determined by the Ramsay method[4]. In the case of the overlapped bands, the integrated intensity was determined by direct area measurements with correction for wings. Such bands were preliminarily separated graphically.

SPECTRA OF POLYMER SOLUTIONS

Polyarylates

Figure 1a gives the spectra of solutions of polyarylates I—III in TCE. It can be seen (*Table 1*) that there is a band
Figure 1 I.r. spectra of 0.035 mol solutions of polyarylates I—III in (a) TCE and (b) *m*-cresol

in the spectrum that is slightly shifted to low frequency as compared to that of the film.

Similar spectra were obtained with solutions of polyarylates II and III in chloroform. The half-band widths of the $\nu_{C=O}$ band in this solvent is 25 cm^{-1} as in the spectrum of the film, and the integrated absorption coefficient $A_{C=O}$ for carbonyl groups is 3.1×10^4 1 cm^{-2} mol^{-1}.

The integrated absorption coefficients $A_{C=O}$ of the ester group for solutions of polyesters in TCE are given in *Table 1*.

The spectrum of the polyarylate V solution in TCE is given in *Figure 2a*. There is double band with maxima at 1741 and 1766 cm^{-1} which are shifted to the low frequencies as compared to the spectra of films. The spectra of solutions of polyarylate V in chloroform are similar. It is interesting that in both cases, that the carbonyl stretching band of the lactone is shifted most in going from film to solution.

The integral absorption coefficient $A_{C=O}$ of the lactone in TCE solution (*Table 1*) was determined from the value calculated for the polymethylenephthalide.

The shift towards low frequencies, when passing from film to solutions in chloroform and TCE, is also observed for polyarylate VI (*Figure 2a*). But, unlike polyarylate V, both bands in the spectrum of the solution reveal practically the same shift under the influence of solvent.

The integrated coefficient for the carbonyl band of anthrone in TCE solutions calculated after graphical separation from the integrated coefficient of the carbonyl band of the ester bond of polymers I—III is given in *Table 1*. The shift of the carbonyl bands in solutions of the polyesters in TCE and chloroform towards low frequencies is indicative

of the formation of hydrogen bonds between the solvent molecules and the carbonyl groups of polymer molecules. This is also confirmed by the increase of the integrated absorption coefficient of the carbonyl band in solutions as compared to its value for carbonyl groups unperturbed by hydrogen bonds.

More substantial changes in spectral parameters of the carbonyl band take place in the spectra of solutions of the polyarylates-in *m*-cresol.

Figure 1 shows the spectrum of polyarylate I in *m*-cresol. The complex band with a maximum at 1723 cm^{-1} is markedly shifted towards low frequencies as compared to its position in the film, and this again points to the formation of a hydrogen bond between the carbonyl groups of the polymer with the OH groups of solvent molecules. The presence of a shoulder in the high frequency region indicates that not all carbonyl groups participate in hydrogen bond formation. H-bond formation is also confirmed by an increased half-band width as well as by an increased integral absorption coefficient for the ester groups.

The integral absorption coefficient of the solvated carbonyl group was calculated after determination of the number of unassociated carbonyl groups from the known coefficient of the unperturbed band in the spectrum of the film (*Table 1*). The content of the free carbonyl groups in the solution was 0.5.

The same changes in spectral parameters, when passing from film to *m*-cresol solution, occur also for polyarylates II, III (*Figure 1b*) but the content of unbonded carbonyl groups is less than in the polyarylate I and is equal to 0.2. This can be connected with decreasing steric hindrance in the interaction of the carbonyl with solvent molecules, when passing from polyarylate I to polyarylates II—III. Indeed, the linear dimensions of diphenyl and diphenyl-oxide dicarboxylic acids are more than twice the distance between the carbonyl groups of terephthalic acid (polyarylate I), the dimensions of which are commensurable with those of the solvent.
It is known that molecules containing two adjacent polar groups can have two conformations (rotational isomers):

In the latter case the steric effect will probably be particularly significant.

It should be noted that the possibility of rotational isomerism does not exclude the fact that the splitting of the carbonyl band in *m*-cresol solutions could be associated with the field effect due to proximity of the carbonyl groups[5—7].

Figure 2b shows the spectrum of the solution of polyarylate V in *m*-cresol. It is seen that the carbonyl of both the lactone and the ester group are shifted to low frequencies. It should be noted that if both carbonyl groups interact with

* For comparison
† In DMSO

the solvent, changes in the position of the ester carbonyl groups was slightly less than in the spectra of solutions of polyarylates I–III in m-cresol. Simultaneously with the shift of the band in the polyarylate V spectrum a redistribution of the intensities of two carbonyl bands in favour of the high intensity lactone carbonyl band has occurred.

The integral absorption coefficient of the lactone of polyarylate V was calculated from that of carbonyl absorption of the ester groups associated with m-cresol in the solution of polyarylate I. The value of integral coefficient $A_{C=O}$ of the acetone carbonyl groups of polyarylate V was 8.5 x 10^4 1 cm^{-2} mol^{-1}, the same as for solutions of polymethylenephthalide and 3,3-diphenylphthalide in m-cresol.

Hydrogen bonds are formed in solutions of polyarylate VI in m-cresol but, unlike sample V, the magnitude of the shift and the integral coefficients $A_{C=O}$ of the C=O absorption of the anthrone and ester bond are close to each other (*Table 1, Figures 1, 2a* and *2b*).

Thus, the spectrum parameters (the shift of carbonyl band is 20–30 cm^{-1}) undergo more significant changes in m-cresol solutions as a consequence of the greater proton-donating ability.

An analysis of the spectrum parameters of absorption bands of different carbonyl groups in solutions of polyarylates in TCE and m-cresol indicates that all groups participate in H bonding. But the considerable shifts and the high value of $A_{C=O}$ for the lactone point to the greater ability of this group to form H bonds. This can be explained both by higher basicity of the lactone carbonyl as compared to the carbonyl groups of ester and ketones[8] and by steric factors.

Polyamides

Table 2 shows the results obtained by investigations of the polyamide films and solutions. The spectra of the solutions of polyamides VII, VIII and X in *m*-cresol reveal one absorption band slightly shifted to low frequencies as compared to the film spectra.

The spectrum of the solution of polyamide IX has two bands shifted to low frequencies, the higher frequency band corresponding to the lactone carbonyl group as in the case of polyarylate V.

However, it is interesting that the magnitude of the shift of the carbonyl band in polyamides is considerably less than that of ester groups in the spectra of solutions of similarly composed polyarylates in the same solvent.

This can probably be explained by the fact that the polyamide carbonyl groups participate in the formation of H bonds –NH . . . O=C< in the polymer.

Polyimides

The spectra of the solutions of polyimides XII and XIII in TCE and *m*-cresol contain two absorption bands and the shift to low frequencies compared to the films of these polyimides points to the formation of hydrogen bonds with

the solvents (*Table 3*). It should be emphasized that the absorption band corresponding to the antisymmetric C=O vibration of the cyclic imide is shifted to a greater extent than that corresponding to the symmetric vibration.

In the spectra of *m*-cresol solutions of the polyimides XIV–XV (*Figure 3*) there are three bands in the carbonyl absorption region as opposed to two bands in the spectra of their films and TCE solutions. The appearance of a band at 1750 cm^{-1} probably characteristic of C=O stretching of the lactone (as in solutions of polyarylate V and polyamide IX) can be explained by the fact that this band in the presence of the solvent shifted to a greater extent than the band which overlaps the former in the film spectrum and this is assigned to the symmetric C=O vibration of the imide. The shift value of the carbonyl band of the lactone is 30 cm^{-1}.

The proportion of the lactone carbonyl groups of polyimide participating in the H bond formation with the solvent molecules was calculated from the known $A_{C=O}$ value for the lactone in *m*-cresol.

The proportion of the bonded carbonyl groups of the lactone in polyimide XV was 0.09 and almost half that of polyimide XIV (0.17). An increased proportion of the lactone carbonyl groups participating in the H bond formation for polyimide XIV as compared to polyimide XV can

apparently be explained by better flexibility of the polymeric chain of polyimide XIV, which facilitates the interaction of the carbonyl groups of the polymer with the molecules of the solvent. It should be noted that the proportion of the solvated lactone carbonyl groups increases still further (~0.43) in solutions of polymers with less rigid chains, e.g. polyarylates.

Thus the comparative investigations of solution of regularly changing cardo polyarylates, polyamides, polyimides, and polymethylenephthalide has shown that, besides the polar groups of the polymer backbone, the polar groups of the cardo group, in particular the carbonyl group of the anthrone and especially phthalide rings, make a considerable contribution to intermolecular interaction of the macromolecule with the molecules of the solvent.

Transport of water in synthetic *cis*-1,4-polyisoprenes and natural rubber

J. A. Barrie, D. Machin* and A. Nunn†

Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK
(Received 25 April 1975; revised 11 July 1975)

The sorption, permeation and diffusion of water in two synthetic *cis*-1,4-polyisoprenes and natural rubber and of methanol in natural rubber have been measured in the range 25 to 60°C. At the higher relative pressures the diffusion coefficient in all systems decreases with concentration and activation energies for diffusion increase with concentration. The results are consistent with increased clustering of the sorbed penetrant at higher relative pressures which renders an increasing fraction of the penetrant relatively immobile. The effect of polar impurities on the sorption and diffusion process is discussed to account for differences in behaviour of the various samples at lower relative pressures.

INTRODUCTION

For a number of water–polymer systems, the diffusion coefficient D decreases as the total concentration C of water sorbed is increased[1–4]; the effect is more pronounced with elastomers containing amounts of water-soluble salts such as sodium chloride[2]. It is generally accepted that clustering of the sorbed water through hydrogen-bond formation is responsible and that the molecules in clusters are virtually immobilized relative to the unassociated water, the fraction of which decreases as C increases.

Of the elastomers, the silicone and polyurethane rubbers have been studied in some detail[2,5–8]. The results of earlier work on the water–natural rubber system indicate that D should decrease with C for this elastomer[9,10]. In the present investigation water transport in high purity synthetic *cis*-1,4-polyisoprenes and natural rubber is investigated in some detail. Some measurements have also been made with methanol as it was observed that in the silicone rubber systems D for this penetrant again decreased with C[2]. The effect of sodium chloride 'filler' on the transport process is examined briefly in the region of relative pressure, $p/p_0 < 0.75$; the region of higher water activity has been the subject of another investigation[11].

EXPERIMENTAL

Rubber samples in the form of thin sheets, 0.5 to 1 mm in thickness were supplied by the Malaysian Rubber Producers Research Association (UK). The samples comprised: a natural rubber in the form of deproteinized pale crepe (NR); two synthetic polyisoprenes, Natsyn 2200 (Goodyear Chemical Co.) and Cariflex IR 305 (Shell Chemicals UK) with a high *cis*-1,4-content, >92%; a Cariflex IR 305 sample containing 0.5 parts of crushed sodium chloride per 100 parts of rubber.

All of the sheets were cured with 3% dicumyl peroxide for 35 min at 140°C, refluxed with acetone for two days under an atmosphere of nitrogen in a darkened Soxhlet

apparatus and stored under vacuum in darkened containers. To investigate the effect of a 'limited' degree of ageing on the solubility of water in natural rubber, a few measurements were made with a sample which had been stored for ~3 years in the dark and under vacuum with occasional exposures to air and light. Sorption isotherms for water were obtained using an electronic microbalance (Sartorius 4102) and for methanol using a calibrated silica spiral as described earlier[2]. Steady-state permeation rates were determined as a function of the pressure on the ingoing face of the membrane by sorbing the outgoing vapour in a dehydrated aluminosilicate suspended from a calibrated silica spiral[12]. Alternatively, the pressure at the outgoing face of the membrane was monitored using an electronic micromanometer (M.K.S. Instruments Inc.) with a receiving volume of not less than 6 litres so as to minimize effects arising from the sorption of water on glass surfaces[13].

RESULTS

Typical sorption isotherms are shown in *Figures 1–3*. The water isotherms for the synthetic polyisoprenes are of the same type as observed with the silicone rubbers and have a
Figure 1 Sorption of water in Cariflex IR305. A, 36.6°; B, 42.2°; C, 50.3°; D, 61.3°C
Figure 2 Water sorption at ~50°C. A, Cariflex IR305; B, Cariflex IR305. +, NaCl; △, Natsyn 2200; ●, natural rubber; ○, 'aged' natural rubber
Figure 3 Sorption of methanol in natural rubber. ○, 26°; ●, 35.1°; ×, 50°; △, 60°C

linear region at low relative pressures from which values of $\sigma_{C=O}$, the Henry's law solubility constant, were obtained and are given in *Table 1*. For the natural rubber samples, particularly at the lower temperatures, there was an indication of a Langmuir-type sorption at lower relative pressures. This feature of the natural rubber isotherms is more evident for the 'aged' specimen as shown in *Figure 2*. Since the shape of the isotherm at the lower relative pressures was not established with sufficient accuracy, values of $\sigma_{C=O}$ are not estimated for the natural rubber samples.

The tendency for penetrant to cluster in the polymer was examined using the clustering functions G_{AA}/V_A and $[1 + \phi_A(G_{AA}/V_A)]$ of the Zimm/Lundberg theory where G_{AA} is a cluster integral for the penetrant and V_A and ϕ_A are the partial molecular volume and volume fraction of the penetrant, respectively[14,15]. Values of $G_{AA}/V_A > -1$ and < -1 denote, respectively, clustering and segregation of the penetrant molecules, and the function $[1 + \phi_A(G_{AA}/V_A)]$ is a measure of the mean cluster size. The clustering functions for the synthetic polyisoprene—water and natural rubber—methanol systems are given as a function of concentration in *Table 2*. Some heats $\Delta \bar{H}_A$ and entropies $\Delta \bar{S}_A$ of dilution were obtained as a function of concentration and are given in *Table 3*.

Steady-state permeation measurements were made for all samples with the exception of the 'aged' natural rubber and, in all cases, the permeation rate J varied linearly with the ingoing relative pressure in the range 0 to 0.9. Typical plots of the normalized flux Jl against relative pressure are shown in *Figure 4*; for water these are linear but for methanol in natural rubber there is curvature at the higher

relative pressures. Steady state diffusion coefficients were obtained from the relation $D = dJl/dc$ by graphical differentiation of plots of Jl against the concentration of penetrant in the ingoing face of the membrane. The concentration dependence of D is illustrated in *Figures 5* and *6* and values of $D_{C=0}$, the diffusion coefficient in the limit of zero concentration, and of $\overline{P}_{C=0}$ are given in *Table 4*.
The temperature dependences of D and of $\overline{P}$ were described

respectively by the expressions $D = D_0 \exp(-E_D/RT)$ and $\overline{P} = \overline{P}_0 \exp(-E_{\overline{P}}/RT)$ and values of E_D and $E_{\overline{P}}$ are given as a function of penetrant concentration in *Table 5*.

DISCUSSION

The results indicate that the solubility of water in the Cariflex sample is comparable with that in polydimethylsiloxane but for the Natsyn sample it is significantly greater and

even more so for the natural rubber and 'aged' natural rubber. The results for the synthetic polyisoprenes suggest that impurities of a polar nature are present to a greater extent in the Natsyn sample. The more exothermic heat of sorption $\Delta \bar{H}_s$ for Natsyn at low coverages and the somewhat greater tendency for water to cluster in the Cariflex sample supports this view. Further support comes from typical ash contents of the two materials, namely 0.35 and 0.05% for the Natsyn and Cariflex samples respectively. The most likely sources of impurities are metallic salts which may not extract readily on refluxing or polar groups arising from partial oxidation of the polymer.

It was previously established for silicone rubbers that the introduction of water-soluble metallic salts, by milling prior to crosslinking, had little effect on water sorption at relative pressures below that of the saturated salt solution[2]. The results of *Table 1* and of *Figure 2* show that the addition of crushed sodium chloride to the Cariflex rubber has no marked effect on the water sorption at lower relative pressures. It is unlikely therefore that metallic salt impurities can account for the differences between the Natsyn and Cariflex samples and it appears that partial oxidation of the former sample has occurred. It has been established that water sorption in natural rubber increases appreciably on oxidative degradation[16] and it is probable that this factor partly accounts for the higher water sorptions of the natural rubber and 'aged' natural rubber samples. In addition the presence of residual protein groups in natural rubber will also lead to an enhanced water sorption. The effect of impurities on the equilibrium sorption of water by natural rubber has already been reviewed[17]. In general the results of the present investigation are consistent with those of earlier studies.

The clustering functions indicate a strong tendency for water to cluster in all samples at higher relative pressures. The tendency for $\Delta \bar{H}_A$ and $\Delta \bar{S}_A$ to decrease with C is also consistent with clustering of the penetrant molecules. The linear variation of the water flux with relative pressure and the decrease of D with increasing C for the synthetic polyisoprenes and natural rubber can be interpreted in terms of a relative immobilization of penetrant molecules in clusters[2]. The $D-C$ curves for the synthetic polyisoprenes are similar in shape to those for water diffusing in silicone rubber and show an initial region of constant D. The tendency for E_D to increase with C subscribes further to the view that clustering of penetrant occurs. As indicated there was some indication of curvature in the water isotherms for natural rubber at low relative pressures suggesting that the $D-C$ curve in this region would pass through a maximum. Since the sorption measurements were not of sufficient accuracy to determine precisely the isotherm shape it is not possible to analyse the $D-C$ dependence accurately in this region. Unfortunately permeation measurements were not made on the 'aged' natural rubber sample, for which the isotherm at low relative pressures shows more marked curvature and one anticipates a stronger maximum in this region for this sample.

Although the Natsyn sorbs more water than the Cariflex sample, the latter has the greater permeability; this reflects the higher D for the Cariflex and is again consistent with a greater fraction of the penetrant being immobilized in the Natsyn sample by some form of specific-site sorption. Similarly the permeability of natural rubber is comparable to that of Natsyn and since $\sigma_{C=O}$ will be higher for the natural rubber then one anticipates a considerably smaller $D_{C=O}$ for this polymer consistent with a higher degree of localized sorption.

Finally, the sorption and permeation results for methanol in natural rubber indicate that a significant degree of clustering with immobilization also occurs with this penetrant. There is no indication of a Langmuir-type sorption at low relative pressures and methanol sorption for natural rubber is in fact somewhat smaller than for silicone rubber. The increase in the permeability at higher relative pressures can be attributed to some degree of plasticization compatible with the relatively high uptake of penetrant in this region.

Cationic copolymerization of vinyl ethers with styrene derivatives and their model reactions: selectivity of a growing carbocation

Kenji Yamamoto and Toshinobu Higashimura
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606, Japan
(Received 11 March 1975; revised 9 June 1975)

In order to assess the possibility of cross propagation in cationic copolymerization, vinyl ethers were copolymerized with styrene derivatives using $BF_3O(C_2H_5)_2$ catalyst in toluene and methylene chloride at $-78°C$, and the monomer reactivity ratios were determined. The experimental results were compared with the relative reactivity of these olefins in the electrophilic addition of diethyl acetal and of Ph_3CSnCl_5. The addition of diethyl acetal could be a model for the reaction of vinyl ether-type propagating species, and that of Ph_3CSnCl_5 for styrene-type propagating species. Either in the copolymerizations or in the model reactions a carbocation preferred to react with one having a similar structure to the two olefinic compounds, provided that a steric interruption between the carbocation and the olefins is not significant.

INTRODUCTION

In most cationic copolymerizations it has been observed that the product of monomer reactivity ratios, $r_1 \times r_2$, is close to unity. This indicates that the relative reactivity of a monomer depends only on the kind of the monomer and is independent of the type of growing carbocation[1]. However, in cationic copolymerizations of a pair of monomers having different structures such as vinyl ethers/styrene derivatives[2] or styrene/isobutene[3] pair, both r_1 and r_2 tend to become larger than unity. This means that a propagating carbocation prefers to react with a monomer having a structure more similar to the carbocation. For example, in the copolymerization of vinyl ethers with styrene derivatives, a carbocation produced from a vinyl ether reacts preferentially with a vinyl ether and a carbocation produced from a styrene derivative with a styrene derivative. The present authors define this sort of phenomenon as 'selectivity of carbocation', and use this term throughout this paper. The selectivity leads to a difficulty of cross propagation and a formation of block-like copolymers in cationic copolymerizations.

As propagation in cationic polymerization is an electrophilic addition of a propagating carbocation to an olefinic compound, it is very unlikely that a block copolymer is produced through the cationic copolymerization. This study was undertaken to assess the possibility of cross propagation in the cationic copolymerization of vinyl ethers with styrene derivatives. Moreover, the selectivity was also tested with other electrophilic additions. Ethoxyethyl cation produced from diethyl acetal and triphenylmethyl cation produced from triphenylmethyl pentachlorostannate were chosen as the models for a vinyl ether-type and a styrene-type propagating carbocation, respectively. The addition of acetal to vinyl ethers[4,5] and styrene derivatives[6,7] in the presence of acid and that of triphenylmethyl cation to vinyl ethers[8] and styrene derivatives[9,10] have been reported. However, no insight into the experimental results from a standpoint of the selectivity has been given.

In the present study, non-vinyl type olefins such as α-methylstyrene and cis-phenyl propenyl ether were also used to investigate the steric effect of α- or β-methyl group on the selectivity of the monomers.

EXPERIMENTAL

Materials

α-Methylstyrene (α-MS), p-methylstyrene (p-MS), phenyl vinyl ether (PhVE), and 2-chlorethyl vinyl ether (CEVE) were commercially available. These olefinic compounds were purified by usual methods and distilled from calcium hydride before use. p-Methoxystyrene (p-MOS) was synthesized from p-methoxyacetophenone through reduction and dehydration[11]. The synthesis of cis-phenyl propenyl ether (cis-PhPE) has been reported previously[12]. The purity of these olefins was more than 99.5% by gas chromatography.

Toluene, methylene chloride and ethylene dichloride were purified by usual methods and distilled from calcium hydride before use. $BF_3O(C_2H_5)_2$ was purified by distillation. Tetralin and bromobenzene, which were used as internal standards for gas chromatography, were purified by distillation. Diethyl acetal was distilled twice or more from calcium hydride before use. The purity was more than 99.9% by gas chromatography. Triphenylmethyl pentachlorostannate (Ph_3CSnCl_5) was synthesized from Ph_3CCl and $SnCl_4$ according to the method reported[13] and recrystallized twice from toluene.

Figure 1 First-order plot of the monomer consumption in the competitive addition of diethyl acetal to PhVE and p-MOS in CH₂Cl₂ at 0°C: △, PhVE; ○, p-MOS, $BF_3O(C_2H_5)_2$, 3.0 mmol/l

Methods

Copolymerization was carried out in a closed vessel equipped with a stopcock under dry nitrogen. The concentration of inevitable water was in the order of 10^{-4} mol/l in all the runs. Details of the copolymerization have been described elsewhere[12]. Copolymer compositions were calculated on the basis of the amounts of unreacted monomers measured by gas chromatography. Monomer reactivity ratios were calculated by the curve-fitting method and the improved Finemann-Ross method[14].

The relative reactivity of two olefinic compounds in the addition of diethyl acetal was determined by a competitive method. Solvent, 2% v/v of olefins (1% v/v for each olefin), 10% v/v of diethyl acetal and 1% v/v of the internal standard for gas chromatography were introduced by a syringe into the vessel under dry nitrogen and the mixture was kept at 0°C. Tetralin was chosen as an internal standard. Only for the CEVE/p-MOS system was a mixture of tetralin and bomobenzene used. The reaction was started by introducing a catalyst solution to the mixture by a syringe under dry nitrogen. At specified time intervals small portions of the reaction mixture were withdrawn by a syringe, and mixed with ammonia—methanol to stop the reaction. The consumption of the two olefinic compounds was determined by measuring the amount of unreacted compounds by gas chromatography to give the relative reactivity.

The relative reactivity of two olefinic compounds in the addition of Ph₃CSnCl₅ was determined by following the consumption of Ph₃CSnCl₅. The reaction was started by

adding the specific amount of Ph₃CSnCl₅ solution to an ethylene dichloride solution containing an olefinic compound at 30°C. The rate of the consumption of Ph₃CSnCl₅ was followed by measuring the optical density at 430 nm due to triphenylmethyl cation with Shimadzu UV-210 double-beam spectrophotometer. Two sets of experiments with different olefins gave the relative reactivity.

RESULTS

Copolymerization of vinyl ethers with styrene derivatives

PhVE was copolymerized with p-MOS or p-MS in toluene and methylene chloride at $-78°C$ by $BF_3O(C_2H_5)_2$ as catalyst. cis-PhPE and α-MS were also used in order to examine the steric effect of α- or β-methyl substituent. The monomer reactivity ratios are summarized in *Table 1*. White methanol-insoluble copolymers were produced in all the copolymerizations. The formation of a true copolymer of the vinyl ethers and the styrene derivatives was verified by the same method as described in a previous paper[2].

As *Table 1* shows, a polarity of a solvent strongly affected the monomer reactivity ratio in copolymerization of a polar monomer with a non-polar one (PhVE/p-MS, PhVE/α-MS and cis-PhPE/α-MS). The solvent effect on the monomer reactivity ratios could be explained in terms of the selective solvation of a growing carbocation by the polar monomer in the non-polar solvent.

The selectivity of growing carbocation in the copolymerization will be discussed later.

Diethyl acetal additions to vinyl ethers and styrene derivatives

In order to compare the relative reactivity of vinyl ethers against styrene derivatives towards a vinyl ether-type carbocation, the addition of diethyl acetal to these olefins was investigated in toluene and methylene chloride at 0°C. In this series of experiments, CEVE was also investigated for comparison. *Figure 1* shows the first-order plot of the concentrations of PhVE and p-MOS consumed competitively by a carbocation produced from diethyl acetal. This reaction was performed in methylene chloride at 0°C with BF_3O-$(C_2H_5)_2$ as a catalyst. The first-order plot with respect to each olefin was so linear that the reaction of each olefin was not interferred with by the other olefin. The relative reactivity was estimated by comparing the slopes of the straight lines. The relative reactivities of vinyl ethers against styrene derivatives towards an ethoxyethyl cation are listed in *Table 2*. It shows, with some exceptions,

Table 2 Relative reactivities of vinyl ethers against styrene derivatives in diethyl acetal addition catalysed by $BF_3O(C_2H_5)_2$ at 0°C

Monomer pair	Relative reactivity of vinyl ethers against styrene derivatives	
	in C₆H₅CH₃	in CH₂Cl₂

Solvent = $(CH_2Cl)_2$; temp. = 30°C

cation, the addition of Ph_3CSnCl_5 to these olefinic compounds was studied. As Ph_3CSnCl_5 is not soluble in non-polar solvents such as toluene, all the reactions were carried out in ethylene dichloride at 30°C. Details of the procedure have been described elsewhere[9]. The concentration dependence of the rate was determined by varying the initial concentration of an olefin or Ph_3CSnCl_5. In the present study, the apparent molar extinction coefficient at 430 nm was found to be 1.71×10^4 l/mol cm (lit.[9] 1.69×10^4 l/mol cm). For all the compounds used in this experiment the following relationship held over the whole range of conversion:

$$-d[C]/dt = k [C] [M] \qquad (1)$$

$[C]$ and $[M]$ being the concentration of Ph_3CSnCl_5 and an olefin, respectively. *Figures 2a* and *2b* show the typical first-order plot for the consumption of vinyl ethers and styrene derivatives, respectively. *Table 3* summarizes the rate constant, k, in the Ph_3CSnCl_5 addition defined by equation (1). The reactivity of olefinic compound towards the triphenylmethyl cation decreased, as is clear from *Table 3*, in the following order: p-MOS $\geqslant$ CEVE $>$ PhVE $>$ p-MS $>$ α-MS $\geqslant$ cis-PhPE. The k values for α-MS and p-MOS obtained in the present study are comparable with those previously reported under similar conditions[9,15].

DISCUSSION

Table 4 summarizes the relative reactivities of vinyl ethers against styrene derivatives towards various carbocations in a polar solvent. The results of the copolymerization of CEVE with p-MOS and with p-MS[2] are also shown in this Table.

Table 4 shows that a carbocation prefers to attack a monomer which has a structure similar to that of the carbocation, i.e. the selectivity of carbocation is observable in most cases. For example, in the copolymerization of PhVE(M_1) with p-MOS(M_2), r_1 is larger than $1/r_2$ so that the selective addition of a propagating carbocation is observed. The selective addition is also concluded on the basis of the relative reactivity of PhVE against p-MOS in diethyl acetal addition (c_1) and Ph_3CSnCl_5 addition ($1/c_2$). The former, c_1, corresponds to r_1 and the latter, $1/c_2$, to

[a] Reaction temp. = $-78°$C; solvent = CH_2Cl_2

[b] Reaction temp. = $0°$C; solvent = CH_2Cl_2

[c] Reaction temp. = $30°$C; solvent = $(CH_2Cl)_2$

$1/r_2$ in the copolymerization of these olefins, and c_1 is larger than $1/c_2$. Thus, the selectivity of carbocation does exist either in copolymerization or in addition reaction with the pair PhVE/p-MOS.

As the conditions in copolymerization are somewhat different from those in addition reactions, the comparison of these reactions cannot be made on a completely quantitative level. However, there is no trouble from the viewpoint of a qualitative investigation about the selectivity of carbocation.

In the first place, the copolymerization and the addition reaction of vinylic olefins (CH_2=CHR) will be discussed, where the steric interruption between substituents is not very important (A–D in *Table 4*). The selective addition occurs with the olefin pair, PhVE/p-MOS, as was described above. Similarly, the selective addition is observed for all other olefin pairs, vinyl ether (M_1)-ring substituted styrene (M_2). This conclusion is based on the fact that $r_1 > 1/r_2$ and $c_1 > 1/c_2$. For the olefin pair, PhVE(M_1)/p-MS(M_2), the selectivity in the copolymerization was not high in methylene chloride ($r_1 \sim 1/r_2$), but it was large in toluene ($r_1 = 8.96$, $1/r_2 = 1.64$). However, the selectivity in the electrophilic addition is clearly observable with this olefin pair.

On the other hand, when α-MS or propenyl ether (M_2) is used as a pair for PhVE or CEVE (E $\sim$ H in *Table 4*), the selectivity was not clearly observed. This could be explained in terms of a steric interruption between a bulky triphenylmethyl cation or propagating carbocation formed from M_2 and an α- or β-methyl groups in M_2.

In conclusion, we can safely say that a carbocation adds to a monomer having a similar structure to the carbocation when vinyl ethers and styrene derivatives are involved, pro-

vided that steric interactions between the substituents of the carbocation and the olefin is not significant. However, the reason for the selective addition in these monomer pairs is not clear at present. It is necessary to know the precise nature of the propagating species in these systems (i.e. free ions, ion pairs) in order to know the reason and further study of this problem is in progress.

Reactivity and mechanism in the cationic polymerization of p-methoxystyrene initiated by cycloheptatrienyl hexachloroantimonate

A. M. Goka* and D. C. Sherrington

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow G1 1XL, UK
(Received 16 December 1974; revised 4 February 1975)

The cationic polymerization of p-methoxystyrene initiated by cycloheptatrienyl hexachloroantimonate in dichloromethane solution has been studied in some detail. Reactions proved to be highly exothermic, and rates of monomer consumption were measured using an adiabatic calorimetric technique. Termination was deduced to be insignificant during kinetic lifetimes, and $\bar{M}_n$ values in the range 10 000—50 000 showed chain breaking to occur by transfer mechanisms. Appropriate analysis of conversion/time curves allowed computation of enthalpies of polymerization and rate coefficients for propagation, k_p (obs), under various conditions. Data for k_p (obs) were found to vary with the initial concentrations of initiator and monomer employed, and these dependences are discussed in terms of current theories regarding ion pair/free ion equilibria in non-aqueous solvents. In particular values of 3.6×10^3 $M^{-1}s^{-1}$ and 4.8×10^3 $M^{-1}s^{-1}$ at $0°$ and $+10°C$ respectively for the rate constant for propagation by free poly(p-methoxystyryl) cation have been deduced, and a tentative value of 450 $M^{-1}s^{-1}$ at $0°C$ has been estimated for the rate constant for propagation by the corresponding hexachloroantimonate ion pairs. These data and the related activation parameters are compared with independent results in the literature. Polymerizations carried out in the presence of excess common ion salt, dimethyl benzyl phenyl ammonium hexachloroantimonate, showed rate depressions far in excess of those predicted by a simple mass law effect, arising possibly as a result of a more dramatic ionic association than simple ion pairing.

INTRODUCTION

Of all the substituted styrene monomers, p-methoxystyrene is one of the most useful since it is readily polymerized with high reactivity by free radical[1], anionic[2] and cationic[3] means. In principle therefore it should be possible to assess quantitatively the difference in reactivity which arises with these mechanisms.

Molecular iodine has been most widely investigated[3–5] as as initiator of cationic polymerization of p-methoxystyrene. Okamura and his coworkers[3] have reported rate constants for the propagation reaction, k_p, in solvents of varying polarity. The interpretation of these results in terms of current theories of ionic equilibria is difficult, and the overall low order of magnitude of k_p (~10–0.1 $M^{-1}s^{-1}$) would seem to indicate that the data may be seriously affected by a kinetic term from the initiation processes. The same system has been investigated by Ise and his group[4]. They were particularly interested in the effect of an applied electric field, and have shown that the overall rate of polymerization increases under such conditions. The increase was attributed to a field-facilitated dissociation of propagating ion pairs into free ions, the latter, it was assumed, being the more reactive. Unfortunately the complexity of the system precluded evaluation of the various contributing rate constants.

More recently, Sigwalt and his collaborators[6] have studied in detail the kinetics of the polymerization of this monomer initiated by triphenylmethyl hexachloroantimonate. They have also recognized the possibility of contributions from various types of ionic intermediate, though they do not report any quantitative estimation of individual reactivities.

The present work represents a continuation of our studies of absolute reactivity in cationic polymerizations[7–9] and extends those monomers investigated to include p-methoxystyrene. Polymerizations were carried out homogeneously in dichloromethane solutions under high vacuum conditions employing preformed cycloheptatrienyl hexachloroantimonate ($C_7H_7^+SbCl_6^-$) as the initiator. Reaction rates were measured by an adiabatic calorimetric technique as before[7], employing initiator concentrations covering a wider range ($\sim10^{-4}$ to 10^{-6} M) than previously for a single monomer. This was possible because of the clean and highly reproducible polymerizations exhibited by this monomer, which was readily converted to 100% polymer with rates measurable by our technique, over this wide range of catalyst concentrations. Rather conveniently data for ion pair dissociation constants (K_d) for a variety of organic hexachloroantimonate salts[10] fall within this range, and the results of the present kinetic experiments are discussed later with this in mind.
Figure 1 Monomer storage and metering vessel

EXPERIMENTAL

Materials

Dichloromethane was dried and purified as previously reported[7]. Its method of storage and metering under vacuum has also been described elsewhere[8]. Cycloheptatrienyl hexachloroantimonate, used for the kinetic experiments, was prepared as before[7]; however, on this occasion the salt was recrystallized from dry dichloromethane, without addition of carbon tetrachloride. It was stored *in vacuo* in the absence of light. Both melting point and micro-analysis were consistent with previous reports. The corresponding tetrafluoroborate salt was used in a 1:1 molar reaction with p-methoxystyrene in methanol, in order to characterize the initiation mechanism. It was prepared according to the method reported by Conrow[11] and was recrystallized from acetonitrile before use. Benzyldimethylphenyl ammonium hexachloroantimonate was also prepared, purified and characterized as described previously[12].

p-Methoxystyrene (10 ml) (Koch-Light Laboratories) was diluted with petroleum ether (20 ml, b.p. 30–40°C). The solution was shaken with 1% aqueous sodium hydroxide (3 × 50 ml) to remove the stabilizer, t-butyl catechol, and finally with distilled water (4 × 50 ml) until the pH of the washings remained constant. After drying over anhydrous calcium chloride for 2 h the solution was decanted onto freshly crushed calcium hydride, where it was left overnight. The following day the solution was transferred to a fresh sample of calcium hydride, refluxed for 40 min, and then fractionated under vacuum ($\sim 10^{-3}$ mmHg). After removal of the petroleum ether, a middle fraction of the monomer (b.p. $\sim 60°C$ at $\sim 10^{-3}$ mmHg) was collected, and then pipetted into limb A of a previously prepared storage/metering vessel (*Figure 1*). Freshly crushed calcium hydride was added via side arm B, which was then sealed in the usual manner. The monomer was then degassed several

times at 10^{-5} mmHg and allowed to stand on the drying agent overnight, well protected from light by a black polyethylene sleeve. After further degassing the next day, the vessel was sealed from the vacuum line at constriction C, and the monomer was filtered from the drying agent by tipping through sinter D (pore size 3). Finally the monomer was chilled in limb E, and the unwanted limb A was sealed off at constriction F. The storage vessel with its vacuum burette arrangement for metering of the monomer was then stored in the dark in a deep freeze.

Calibration technique

The adiabatic calorimeter used in these experiments was similar to one described before[8], and employed a resistance thermometer as the temperature sensor. The temperature coefficient of the latter was determined using the freezing points of pure solvents as definitive temperatures. The heat capacity of the calorimeter and its contents (100 ml of solvent) was determined at 0°C by polymerizing isobutyl vinyl ether under the same conditions as those used in the kinetic experiments. The known heat of polymerization of this monomer[7] allowed computation of the required heat capacity. Data at other temperatures were then calculated assuming the same temperature dependence of the heat capacity as previously determined[7].

Kinetic technique

The operation of the calorimeter has already been adequately described[7] and the only significant variation in the procedure was the method of introduction of the monomer. Because of the high boiling point of p-methoxystyrene, direct quantitative distillation into the calorimeter was found to be impossible. Instead glass phials of monomer were prepared under vacuum in a similar manner to the phials of initiator solution, using the vacuum burette described earlier (*Figure 1*). For a normal kinetic run a phial of monomer was placed in the upper position in the phial holder, and a catalyst phial in the lower (see diagram p122, ref 7). After sealing the calorimeter and distilling in solvent, the upper phial was crushed first, and the monomer was allowed to mix thoroughly with the solvent. The temperature of the solution was then adjusted to the steady value required using a Dewar of chilled methanol, and then the initiator phial was crushed. The temperature rise was recorded on a Bryans 27 000 chart recorder, and after polymerization the polymer yield was established gravimetrically as in the polymerization of N-vinylcarbazole[8]. Molecular weights of polymer samples were determined by gel permeation chromatography using a Waters Anaprep machine fitted with polystyrene gel columns. The latter were calibrated using narrow molecular weight polystyrene standards, and the data generated for the samples therefore refer to equivalent polystyrene molecular weights. In the analysis of chromatograms no attempt was made to correct for dispersion effects and so distributions will tend to appear larger than they really are.

In one experiment involving successive additions of two monomer samples a slightly modified procedure was adopted. The required weight of initiator was weighed directly into the calorimeter base and two monomer phials (each containing 1 ml of monomer and 1 ml of solvent to prevent freezing at 0°C) were placed in the phial holder. Crushing of the first phial initiated polymerization, and

when this was complete the second phial was crushed and polymerization resumed.

A number of experiments involving a common ion salt were also performed. In these the common ion salt, benzyldimethylphenyl ammonium hexachloroantimonate, was weighed directly into the calorimeter base, and then the normal procedure followed.

Measurements of dielectric constants

The dielectric constants of dichloromethane and dichloromethane/p-methoxystyrene mixtures were measured at 0° and +10°C using an automatic liquid dielectric bridge (Calvert Designs).

RESULTS

Calibration of the calorimeter

Kinetic experiments were carried out at −25°, 0° and +10°C. The calorimeter calibration parameters required at these temperatures are shown in *Table 1*.

Kinetic data

Without exception the normal kinetic runs produced S-shaped conversion curves similar to those reported in the polymerizations of vinyl ethers[7,9] and some solutions became pale red in colour. Unlike vinyl ether reactions, however, even at very low initiator concentrations ($\sim 10^{-6}$ M) a steady polymerization to 100% conversion was obtained. Only when attempts were made to extend the range even further, did termination appear to become significant during kinetic lifetimes. Indeed absence of any appreciable termination was dramatically demonstrated by

addition of a second monomer sample to a completed polymerization, whereupon reaction was resumed and 100% polymer was obtained. Recorder traces were analysed by a technique reported earlier (see appendix to ref 7), based on a simple two stage mechanism involving only initiation and propagation reactions. This analysis produced the data for rate coefficients for propagation, k_p (obs), shown in *Tables 2–4*. The calorimetric technique also readily allows the evaluation of corresponding enthalpies of polymerization, ΔH_p, and these are also shown in the Tables, together with appropriate molecular weight data.

Common ion experiments

The results of experiments involving addition of a common ion salt are shown in *Table 5*. No attempt was made to analyse the recorder traces obtained, since polymer yields were always less than quantitative during the time of observation.

Dielectric constant measurements

The influence of p-methoxystyrene on the dielectric constant of dichloromethane in the concentration range used in polymerizations is shown in *Table 6*. As might be expected a steady fall is observed as the volume fraction of monomer increases.

Yield A was calculated from the maximum temperature rise recorded on the trace. Yield B was obtained a short time later, after the reaction was killed with methanol, by gravimetric analysis

Reaction of p-methoxystyrene with cycloheptatrienyl tetrafluoroborate in methanol

The tetrafluoroborate salt (5.0 g) was dissolved in dry acetonitrile (100 ml) in a three-necked flask, fitted with a dropping funnel containing a solution of p-methoxystyrene (4.0 g) in dry methanol (50 ml). This solution was added slowly to the initiator solution over a period of 7 min, with constant stirring at room temperature. The orange red colour that developed after the initial addition grew progressively more intense as the remainder of the solution was added. After allowing the reaction mixture to stand for a further 8 min it was shaken with a 1% aqueous solution of caustic soda (200 ml), the resulting mixture being slightly alkaline. The organic products were then extracted into dichloromethane, and after separation this solution was washed with water and dried over anhydrous calcium chloride. Finally, the solvent was removed on a rotary evaporator, and the product, a yellow oil, dried in a vacuum oven at $30°C$ (yield 6.5 g).

A high resolution mass spectrum of the impure product showed a parent ion $C_{17}H_{20}O_2^+$, mass = 256.15, and a fragmentation pattern totally consistent with this as the major species. Thin-layer chromatography (t.l.c.) analysis using a silica solid phase and a liquid phase, 90% petroleum ether (b.p.30–40°C): 10% diethyl ether, confirmed the presence of one major product accompanied by five other species in much smaller proportions. Only one of these was developed faster than the major product.

Two grammes of the product were purified by column chromatography using 100 g of silica gel (MFC) and the same solvent mixture as that used in the t.l.c. analysis. The first detectable sample from the column was shown to be unreacted monomer by infra-red analysis. The second and major sample, a pale yellow oil, was shown by high resolution proton n.m.r. spectroscopy to have the following structure:
τ	Protons
2 → 3.3	8a, 8b
~ 3.4	4
~ 3.8	3
~ 4.8	2
~ 5.8	6
~ 6.2	9
~ 6.9	7
~ 7.7–8.4	1, 5

DISCUSSION

All polymerizations of p-methoxystyrene were complete within 4 min under the conditions described, and invariably produced quantitative yields of polymer. Reactions were highly exothermic and the average values of the heats of polymerization determined are summarized in Table 7.

The S-shaped conversion curves obtained provide strong evidence for a relatively slow initiation process followed by a faster propagation reaction. Significant termination was shown to be absent in the experiment in which successive additions of monomer were made. Molecular weight data for the polymers isolated at the end of polymerizations showed little correlation with initiator concentrations, and indicated that chain breaking occurs as a result of transfer processes. Detailed mechanistic features of the initiation and propagation reactions will be discussed in detail.

Initiation

The pale red coloration formed on breaking initiator phials (particularly the ones of higher concentration) persisted during polymerizations, but disappeared on addition of methanol, used to kill reactions. Attempts to record a visible spectrum of this failed. Cycloheptatrienyl cation is known to form coloured charge transfer complexes with various substituted aromatic residues[13], and the initial coloration may indeed be due to this. However, Olah and his coworkers have recorded the ultra-violet/visible spectra of a number of benzylic cations including a p-methoxy-substituted derivative [14]. Although very different conditions were employed to those in the present work, their results are not inconsistent with the view that the pale red colour

persisting during our polymerizations may be due to the poly-(*p*-methoxystyryl) cation. On the other hand, as with the colours observed in related polymerizations of vinyl ethers[7,9] and indene[15,16] those remaining after complete reaction may arise as a result of post-polymerization interactions with the polymer backbone.

In a separate experiment in which a catalyst phial was broken into a monomer solution below ~−50°C a stable pale red colour formed*. No polymer was precipitated on addition of excess methanol, providing the solution was not allowed to warm up before the addition took place. It does seem likely therefore that initiation is preceded by formation of a charge transfer complex, which under favourable conditions collapses to yield a propagating cation. Overwhelming evidence that this collapse involves addition of the cycloheptatrienyl cation to the double bond of the monomer-producing species (I), is provided by the isolation and characterization of derivative (II), from the 1:1 molar reaction in methanol.
Closely related addition reactions of cycloheptatrienyl cation have been reported previously[17−19].

In contrast to this mechanism triphenylmethyl cation is known to abstract hydride ion from suitable substrates under many reaction conditions, rather than undergo addition[20,21]. It is generally accepted that this carbocation has a relatively hindered electrophilic centre, with an overall propeller symmetry. Whereas approach of a nucleophile to a planar cycloheptatrienyl cation can take place without steric hindrance, close approach to the central carbon atom of triphenylemthyl cation is difficult, particularly for vinyl monomer molecules. In fact steric hindrance can force reaction to take place preferentially in the *para* position of one of the phenyl groups[21,22], via one of the resonant structures believed to contribute to the delocalization of this cation. This inherent difference between cycloheptatrienyl and triphenylmethyl cation may well give rise to different initiation mechanisms, with correspondingly different efficiencies. This point will be raised again in the discussion of the propagation data obtained in this study.

---

* Concentrations similar to those used in kinetic experiments.

Propagation

The derived rate coefficients for propagation, k_p (obs), in *Tables 2–4* were obtained assuming a simple two stage mechanism as below

Initiation: $C^+ + M \underset{\text{fast}}{\rightleftharpoons}$ [complex] $\xrightarrow{k_i}$ CM^+

Propagation: $CM^+ + M \xrightarrow{k_p(\text{obs})}$ polymer
(counterion omitted for simplicity)

The data at 0° and 10°C are most complete and show k_p (obs) to be a function of both the initial catalyst, $[C]_0$, and monomer concentrations, $[M]_0$. These dependences are shown graphically in *Figures 2* and *3*.
Figure 2 Plot of k_p (obs) *versus* $[C]_0$. ○, +10°; □, 0°C
Figure 3 Plot of k_p (obs) *versus* $[M]_0$. ○, +10°; □, 0°C

Close examination of previous results[9] shows a similar though less well defined variation of k_p(obs) with $[C]_0$. The range of $[C]_0$ used in the present work was in fact much larger, and therefore more likely to identify such a trend.

Variation of k_p *(obs) with* $[C]_0$

The decrease in k_p(obs) with $[C]_0$ can be explained reasonably in three ways: (a) inefficient conversion of initiating cations into propagating active centres; (b) contributions to propagation from free cations in equilibrium with ion pair species; (c) a combination of these effects. The first two possibilities will be examined separately in more detail.

The method of kinetic analysis assumes that during the earlier part of polymerizations (say below ~15% conversion) all cycloheptatrienyl cations are converted to growing active centres, (i.e. $[C]_0 \rightarrow [P_n^+]_t$, the concentration of active centres at time t), the concentration of which thereafter remains constant, i.e.

$$\frac{-d\ln[M]_t}{dt} = k_p(\text{obs}) [P_n^+]_t$$

Sigwalt and his coworkers[6] have shown that in the case of triphenylmethyl cation as initiator only about 10% of the catalyst is consumed in the initiation process. If such a situation prevailed in the present system then clearly the estimation of $[P_n^+]_t$ would be in error. Furthermore as $[C]_0$ is increased it might be argued that the proportion of cations successfully initiating polymer chain growth would fall. Hence the error in the value of $[P_n^+]_t$ employed in the calculation would rise, and the deviation of k_p(obs) from a constant value would also increase. In fact inspection shows that k_p(obs) would be expected to fall in value as $[C]_0$ rises, precisely the trend observed in practice.

Contrary to this argument, however, are a number of observations. First, cycloheptatrienyl cation is likely to react more efficiently with monomer than triphenylmethyl cation for the reasons already advanced. Also if there is non-quantitative use of initiator then no steady state can be achieved during these polymerizations. Hence in the experiment in which a second addition of monomer was carried out, a continuing generation of active centres would be expected, and should be reflected in the data for k_p(obs). However, analysis of the two conversion envelopes occurring within this experiment, yields values of k_p(obs) which differ only within the known experimental error (see *Table 3*).

Attempts to settle this question unequivocally by observing directly the consumption of initiator were unfortunately only partly successful. Cycloheptatrienyl cation has a characteristic singlet proton n.m.r. peak at $\tau = 0.63$. Using Fourier transform n.m.r. spectroscopy this signal was successfully detected in solutions of concentration as low as $\sim 10^{-4}$ M in CD_2Cl_2 i.e. the upper end of the concentration range employed in the polymerization reactions, and within the region where inefficient use of catalyst is most likely to be detectable. Addition of p-methoxystyrene in the same concentration as that used in the polymerizations destroyed the cycloheptatrienyl resonance. However, because of computer limitations, this second spectrum had to be accumulated over a period of ~ 10 min after the addition

of monomer. Since polymerization is complete within ~ 3 min under these conditions, the disappearance of cycloheptatrienyl cation (at $\sim 10^{-4}$ M) cannot be unambiguously attributed to the initiation reaction alone. Excess unused initiator may be consumed for example in post-polymerization processes such as aromatic alkylation. Nevertheless the new ability of Fourier transform proton n.m.r. to detect low concentrations, typical of those of active centres in ionic polymerizations is extremely important, and considerable scope remains for further investigations in this area.

The second and perhaps more attractive explanation for the variation of k_p(obs) with $[C]_0$ has proved equally difficult to substantiate. It is generally accepted that where an equilibrium exists between free ions and ion pair species, the latter are generally the less reactive. Thus with the present results, if the kinetic analysis is assumed to be correct, it can be argued that the variations in k_p(obs) merely reflects the contributions from free ion and ion pair growth according to the general expression:

$$k_p(\text{obs}) = \alpha k_p^+ + (1 - \alpha) k_p^\pm$$

where, k_p^+ is the rate constant for propagation by free ions and $k_p^\pm$ that by ion pairs, α being the fraction of free ions present.

Under conditions when propagating ions are either largely associated ($\alpha \rightarrow 0$) or substantially dissociated ($\alpha \rightarrow 1$) then it can be shown that:

for $\alpha \rightarrow 0$

$$k_p(\text{obs}) = k_p^\pm + K_d^{1/2} k_p^+ [P_n^+]_t^{-1/2} \tag{1}$$

for $\alpha \rightarrow 1$

$$k_p(\text{obs}) = k_p^+ - k_p^+ K_d^{-1} [P_n^+]_t \tag{2}$$

where K_d is the ion pair dissociation constant of the growing ion pair. These approximations are most accurate under the condition $k_p^+ \gg k_p^\pm$, which, by analogy with the results from anionic polymerizations[23], is the situation often assumed to prevail in cationic systems. The latter very often employ more polar solvents, however, and this assumption may well require modification in the future. If for example the major ion pair species is a solvent separated one, then reactivity may be comparable with the free ion. This appears to be the case in ring opening polymerizations by cationic mechanisms[24,25].

In spite of this, however, if the present results do simply reflect some ionic equilibria as above, then addition of a suitable common ion salt should be able to disturb this equilibrium, and change k_p(obs) at least within the range of values obtained experimentally. The results of such experiments are summarized in *Table 5*. Polymerizations were found to be retarded much more dramatically than would be predicted from a simple common ion effect, and kinetic analysis of the recorder traces was not attempted. The increase in polymer yields detected between stopping the calorimeter (calculated from recorder trace) and killing the reaction (gravimetric analysis) showed that in all cases the polymerization process was continuing, although very slowly. It is possible therefore that the concentrations of added salts were such that agglomerates of propagating cations and counterions much larger than ion pairs are
Figure 4 Plot of k_p (obs) *versus* $[C]_0^{-1/2}$ at $0°C$

formed, and that these give rise to much slower polymerizations. The detailed nature of solutions of high ionic strength in which one ion possesses a long 'polymeric tail' still requires investigation, and work in this direction has been embarked upon recently.

Significance of kinetic data

If it is assumed that K_d for the propagating species is of the same order of magnitude as that for simple hexachloroantimonate salts under similar conditions (i.e. 10^{-4} to 10^{-5}M) [10] then the data for k_p (obs) at the higher concentrations of $[C]_0$ may be analysed according to equation (1) above. Indeed a plot of k_p (obs) *versus* $[C]_0^{-1/2}$ (i.e. $[P_n^+]_t^{-1/2}$) for data at $0°C$ does produce a straight line in this region as shown in *Figure 4*, allowing a tentative estimation of the rate constant for ion pair propagation, $k_p^{\pm}$, of 450 M^{-1}s^{-1} at $0°C$. A much poorer fit is obtained at $+10$ and $-25°C$.

It is rather fortuitous, that irrespective of which explanation for the variation of k_p (obs) is the correct one, the same prediction can be made concerning the significance of the extrapolated value of k_p (obs) at the lower extremes of $[C]_0$. Under such conditions, i.e. $[C]_0 < 10^{-6}$M, initiation is most likely to be quantitative and therefore the kinetic analysis most likely to be valid. Furthermore in this limit the vast majority of ions will be free (assuming the same magnitude for K_d as before). The extrapolated value of k_p (obs) will therefore represent a measure of the reactivity in propagation of free poly(p-methoxystyryl) cation i.e. k_p^+. Even if the second explanation for the variation of k_p (obs) were the correct one, this also predicts the data to approach k_p^+ linearly as the concentration of active centres is reduced substantially below K_d (i.e. equation 2). Such an extrapolation yields estimated data for k_p^+ at $0°C$ of 3.6×10^3 and 4.8×10^3M^{-1}s^{-1} respectively. The corresponding Arrhenius activation energy is ~ 20 kJ/mol and the pre-exponential factor $\sim 1.3 \times 10^7$. The latter value is consistent with a free ionic mechanism since it compares favourably with similar data from free radical propagations where entropy factors would be expected to be similar. It is also anticipated that pre-exponential factors for ion pair growth will be some orders of magnitude less than this[26].

Rather interestingly the rate constant for propagation via ion pairs appears to be only one order of magnitude less

than that for propagation via free ions. Such a result has been reported previously[24,25] and may well indicate that the major ion pair species present in dichloromethane is a loose or solvent separated entity. Such comparable reactivity has already been unambiguously demonstrated in anionic systems[23].

Sigwalt and his coworkers[6] have reported a value of 2.8×10^4 M^{-1}s^{-1} for the overall rate constant for propagation in cationic polymerization of p-methoxystyrene in dichloromethane at $10°C$. Though these authors made no attempt to place quantitative significance on these data in terms of the possible ionic species present, at least superficially some measure of agreement seems to emerge. Ise and his collaborators[2] have determined a value of 4×10^4 M^{-1}s^{-1} for the rate constant for propagation by free poly(p-methoxystyryl) anion, i.e. k_p^-, in tetrahydrofuran (dielectric constant ~ 7) at $25°C$. The present data would predict a value for k_p^+ at $25°C$ in dichloromethane (dielectric constant ~ 9) of $\sim 7 \times 10^3$ M^{-1}s^{-1}. Media of increasingly higher solvation power are known to reduce the rates of elementary reactions involving charge dispersal in going from initial to transition states e.g. propagation. Hence taking the dielectric constants as indicative of solvating abilities, values of k_p^- and k_p^+ would be expected to be very similar in a common solvent. It is usually anticipated that under similar conditions k_p^- should be less than k_p^+, since the attack of a nucleophile on a vinyl double bond requires the use of high antibonding orbitals on the monomer, whereas attack of an electrophile can proceed via overlap of the π-electron cloud of the monomer with vacant orbitals (of relatively lower energy) on the electron deficient centre. The latter process should therefore be less activated. This argument, however, neglects to account for the relative stabilities of the nucleophilic and electrophilic species. In the case of p-methoxystyrene, the free cationic derivative would be expected to be more stabilized by the *para* substituent than the corresponding free anionic species. It is not unreasonable, therefore, to argue that these opposing factors may well balance each other, making k_p^+ and k_p^- of comparable numerical size.

The increased stability of the propagating free cation in the polymerization of p-methoxystyrene, relative to that in styrene polymerizations, would also explain the increased activation energy (~ 20 kJ/mol) relative to that for propagation by free polystyryl cation[27] (~ 0 kJ/mol).

Variation of k_p (obs) with $[M]_0$

The other major observations made from the data in *Tables 2-4* and shown graphically in *Figure 3* is that k_p (obs) varies almost linearly with the initial concentration of monomer used in polymerizatons. It could be argued therefore that this merely reflects a second order rate dependence on monomer. However, a second order plot over the whole conversion range in a single polymerization showed poor linearity hence excluding this possibility, and showing the relationship to be fortuitous. It seems most likely therefore that the effect has its origins in the differing solvation ability of monomer and solvent. Indeed *Table 6* shows clearly that the dielectric constant of a reaction solution falls progressively, as the percentage of monomer added rises through the range of values used in the polymerizations. If it is assumed that the solvation effects of a methoxy phenyl residue are the same in the monomer as in the polymer, then at least in a given polymerization the overall dielectric constant can be taken as fixed.

In any reaction involving a number of different ionic species in equilibrium, the solvent can influence the absolute reactivity of each of the species, and simultaneously disturb the equilibrium between them. In ionic propagation reactions whether the active centre is a free ion or an ion pair, decreasing the solvation ability of the medium increases data for individual rate constants. This may explain the observed increase in k_p (obs) with increase in $[M]_0$ (i.e. decrease in dielectric constant). The overall change in the dielectric constant is, however, small and it seems unlikely that such changes in k_p (obs) could be attributed to the above effect alone. It is more likely that a disturbance of the equilibrium between free ions and ion pairs takes place. Unfortunately little is known about the effects of monomer type molecules on the ion pair dissociation constants of organic salts. Dryvers and Goethals[25] have reported that excess sulphide functions (in the cationic polymerization of cyclic sulphides) do not influence the ion pair dissociation constant of the initiator salt used in their studies. However, Jones and Plesch[28] have observed an increase by a factor of ~2 in the dissociation constant of triphenylmethyl hexafluorophosphate in dichloromethane, on addition of traces of diethyl ether, despite the latter being a less polar solvent. These authors interpreted the results in terms of specific solvation of the cation by ether molecules.

In the case of p-methoxystyrene both n- and π-donor sites are present, and it is possible that specific solvation of active centres may occur, increasing the proportion of free ions as $[M]_0$ is increased. Since free ions are likely to be more reactive than ion pairs, k_p (obs), which probably includes contributions from both, would be expected to increase also. In order to enable a deeper understanding of this and related polymerizations, a systematic study of the effect of additives on the dissociation constants of some model salts is being carried out at the present moment.

Synthesis and solution properties of comb polystyrenes*

J. E. L. Roovers

Division of Chemistry, National Research Council of Canada, Ottawa K1A OR9, Canada
(Received 14 April 1975)

A new method for the synthesis of comb shaped polystyrenes of predetermined structure is described. Silicon–chlorine bonds are introduced into the backbone polystyrene by reaction of $SiMe_2Cl_2$ with hydrolysed styrene/vinyl acetate copolymers and coupled with polystyryl-lithium in benzene. From a common backbone polymer a series of comb polymers are prepared that have a constant number of branches but vary in branch length. The M_w/M_n of the whole comb polymers is about 1.3. The comb polymers with high branch density show $\theta(A_2)$ temperatures lower than that for linear polystyrene. The radius of gyration at $\theta(A_2)$ [$\langle S^2 \rangle_{\theta (A_2)}$] is always larger than calculated from random flight statistics. For comb polymers with 20–30 branches $\langle S^2 \rangle_{\theta (A_2)}/\langle S^2 \rangle_{0,bb}$ increases with $\lambda^{-0.46}$ where λ is the fraction of polymer in the backbone. The intrinsic viscosities of the comb polystyrenes at $\theta(A_2)$ are equal to that of the parent backbone polymer when $\lambda > 0.25$ and increase only little when λ becomes equal to 0.1. Similar behaviour is found in toluene. Intrinsic viscosities in cyclohexane at 35°C show a complex pattern because of the θ-temperature variation.

INTRODUCTION

The coupling reactions with living anionic polymers to produce polymers of a predetermined branched structure have been studied extensively, because such polymers would allow the correlation of solution and bulk properties of polymers with their branch structure.

The multiple reaction of living anionic polymers with aromatic chloromethyl groups, which was pioneered at the Mellon Institute[1], has been most frequently used. When the chloromethyl groups are attached to one benzene ring, star polymers are formed on reaction with living polymer. Three[2,4], four[1,3,5] and six[1,5] branched star polystyrenes were prepared in this way. When the chloromethyl groups are incorporated in polystyrene, comb polymers are produced on coupling with living polymer[1,6–8]. The preparation of a poly(styrene-g-isoprene) by this method is also reported[9]. The coupling reaction is known to be accompanied by a lithium chlorine exchange reaction which may lead to products of higher molecular weight and to gelation[1,5–9]. This side reaction can be reduced by the use of tetrahydrofuran as the solvent[1,4,5] and/or by the replacement of lithium by potassium as the polystyryl counter-ion[3,4,7,8] but it cannot be completely suppressed[6]. There is evidence that the substitution is not always complete[6,8,9]. As a result, researchers are forced to carefully fractionate the branched polymer in order to obtain narrow molecular weight distribution fractions. Such fractionations are not completely satisfactory since the solution properties of branched polymers depend not only on their molecular weight but also on the number of branches per molecule.

The use of silicon–chloride bonds to couple polystyryl-lithium[10,11] and polyisoprenyllithium[12] resulted in the quantitative formation of four- and six-branched star polymers. We have now investigated the introduction of silicon–chloride groups into polystyrene and the coupling of such polymers with polystyryllithium. Some solution properties of the resulting branched polymers have been studied.

EXPERIMENTAL

The synthesis of the comb polystyrenes is given schematically:

Preparation of styrene–vinyl acetate copolymer

The starting styrene–vinyl acetate random copolymers were prepared from distilled and degassed monomers with 2,2'-azobisisobutyronitrile as the initiator at 60°C. A number of trial polymerizations to low conversion (<5% of the styrene) were run. The reactivity ratio for the monomer pair was found to be r_1 = 84 ± 10 (styrene) and r_2 = 0.03 ± 0.02. This is somewhat different from an older determination: r_1 = 55 ± 10, r_2 = 0.01 obtained at higher conversion[13], but in good agreement with values published during the course of this work: r_1 = 70 ± 20 and r_2 = 0.025 ± 0.02[14].

Table 1 Molecular weight data of the backbone copolymers

	Sample 3	Sample 6
vinyl acetate in feed (mol %)	60.0	23.4
vinyl acetate in copolymer (mol %)	1.93[a]	0.38[b]
% conversion (styrene)	8.9	8.6
$M_n \times 10^{-5}$	1.03	4.2
$M_w \times 10^{-5}$	1.58	6.6_5

	Sample 3 fraction c	Sample 6 fraction bc
total copolymer (wt %)	31	30
$M_n \times 10^{-5}$	1.43	6.2
$M_w \times 10^{-5}$	1.58	6.9
after hydrolysis: $M_n \times 10^{-5}$	–	6.2
$M_w \times 10^{-5}$	–	7.0
after chlorosilylation: $M_n \times 10^{-5}$	1.33	–
$M_w \times 10^{-5}$	–	6.7
theoretical no. of branch sites per molecule	26.5	22.7

[a] Vinyl acetate content determined by i.r. analysis of the C=O bond at 1730 cm^{-1} in chloroform measured against a polystyrene solution and calculated using poly(vinyl acetate) standards
[b] Calculated from the experimental reactivity ratios

The characteristics of two large polymer samples are collected in *Table 1*. These polymers were fractionally precipitated from a benzene–methanol mixture. A middle fraction of sample 3 was retained. The middle fraction of sample 6 was subjected to one further fractionation. The data of the resulting polymers retained for further modification and, as such the parent backbone polymers, are given in *Table 1*.

Chemical modification of the backbone copolymer

The vinyl acetate groups of the copolymer were hydrolysed with KOH at room temperature. The completeness of the reaction was checked by the absence of C=O absorption in the i.r. spectrum of the polymer. The polymer was precipitated three times from filtered benzene solutions into methanol, freeze-dried from benzene and further dried at 50°C at 10^{-5} mmHg for 24 h. All subsequent manipulations were performed using high vacuum techniques. To a 2 to 3% polymer solution in benzene–pyridine (90:10 v/v) was added distilled and degassed Si(CH$_3$)$_2$Cl$_2$ in 100-fold excess over hydroxyl groups. The mixture was stirred for 18 h at room temperature. The benzene, pyridine and excess Si(CH$_3$)$_2$Cl$_2$ were removed by freeze-drying. The polymer was redissolved in benzene (distilled from n-butyllithium), the solution was filtered and freeze-dried. Finally, a 5 to 10% solution of the polymer in benzene was subdivided into ampoules with break-seals. Molecular weight data of the copolymers after the modification are given in *Table 1*. A sample of copolymer 3c was treated with n-butyllithium. N.m.r. analysis of the Si(CH$_3$)$_2$CH$_2$ protons indicated a 66% yield. When Si(CH$_3$)$_2$Cl$_2$ was replaced by Si(CH$_3$)$_3$Cl an 80% conversion was obtained. In order to obtain comb polymers with the same number of branches from one backbone polymer the chlorosilylation reaction was performed in one batch.

Preparation of the comb polymers

The living polystyrene, which was to be used as the branch material, was prepared with s-butyllithium in benzene[15]. A sample was removed for molecular weight characterization. The chlorosilylated polystyrene was slowly added through a filter to a two-fold excess of living

polystyryllithium over a period of 2 to 3 h under vigorous stirring. The reaction mixture was left for 18 h at room temperature. The polystyryllithium concentration changed very little during this time. Excess living polymer was terminated with t-butanol. The polymer was fractionally precipitated. The comb polymer was recovered almost entirely in the first fraction which contained less than 1% of the unreacted branch material as indicated by g.p.c. and ultracentrifugation sedimentation.

Measurements of physical properties

Osmotic molecular weights were determined in toluene at 35°C with a Mechrolab 503 osmometer. Molecular weights lower than 10 000 were determined with a Perkin–Hitachi vapour pressure osmometer in toluene at 37°C. Light scattering measurements were performed in cyclohexane at 35°C unless otherwise specified with either a Sofica photogoniometer or with a Fica 50 instrument. Technical details of the measurements and required constants are given in previous reports[10,11]. Ultracentrifugation (u.c.) sedimentations were run on a Beckmann model E instrument at 59 780 rev/min. Cyclohexane at 35°C was the solvent. Gel permeation chromatograms (Waters 301) were obtained in toluene at 35°C. Three foot columns of $3 \times 10^6, 5 \times 10^5, 6.5 \times 10^4, 2.5 \times 10^4, 8.5 \times 10^3, 2.5 \times 10^3$, 500 and 100 Å were used. Viscosity measurements were performed in a Cannon–Ubbelohde viscometer, with negligible kinetic energy correction.

RESULTS AND DISCUSSION

Preparation and characterization of comb polystyrenes

A comparison of the properties of comb polymers with theory demands the correct determination of the molecular weight and molecular weight distribution of the samples obtained. The latter has seldom been done previously and is quite difficult in practice. Estimation of the degree of branching depends on the sample polydispersity. In the present case modification of the backbone polymer involves three reactions. The first, hydrolysis of the acetate groups has been shown to go to completion and no change in the molecular weight and molecular weight distribution of the sample could be detected. The second step, dimethylchlorosilylation is a variant of the trimethylsilylation reaction used extensively in analytical derivation. This reaction normally goes to completion in less than 10 min with isopropanol. With the polymeric hydroxyl compound, however, only 70–80% yields are observed as determined by n.m.r. analysis on the butyldimethylsilyl or trimethylsilyl model substitutions. This may be due to the low concentration of the hydrolysable groups which poses analytical problems but the possibility cannot be excluded that some hydroxyl groups are not readily available for derivation[16]. Intra- and inter-molecular crosslinking between a pendant silicon chloride group and a residual hydroxyl group has been minimized by rapidly adding an excess of dichlorodimethylsilane. In any case the data in *Table 1* show no evidence for an increased molecular weight of the backbone after the chlorosilylation reaction. The efficiency of the coupling reaction can only be assessed by examining the ratio between the calculated and observed molecular weight of the comb polymers. The experience gained in the synthesis of star polymers suggests it should be quantitative[10-12].
Figure 1 Gel permeation chromatograms of comb polystyrenes: A, C051; B, C031; C, C041A; D, C061; E, bb3c; F, narrow molecular weight distribution polystyrene PS100f2 [10]

Examination of the final g.p.c. (*Figure 1*) and u.c. data shows that the comb polymers have a fairly narrow molecular weight distribution, little wider than the original backbone polymer. It should nevertheless be noted that if different degrees of branching are present in the samples g.p.c. analysis will underestimate the broadness of the molecular weight distribution. The data from number-average and weight-average molecular weight determinations (*Table 2*) suggest a broader distribution. The M_n values from stoichiometry (*Table 2*, column 4) are subject to error in the quantity of starting backbone polymer admitted to react and also relies on quantitative recovery of the comb polymer in the fractionation process. The osmotically determined M_n values, available for two comb polymers, can be seriously affected by small amounts of branch material. Therefore, from the latter values one derives $M_w/M_n \leqslant$ 1.35 in poor agreement with g.p.c. results but consistent with a 70–80% yield in the chlorosilylation reaction.

Some broadening of the molecular weight distribution over that of the backbone is expected for the complete coupling of near monodisperse branches to a randomly substituted backbone according to[17]:

$$\left(\frac{M_w}{M_n}\right)_{comb} = \left(\frac{M_w}{M_n}\right)_{bb} + \frac{\bar{p}_n y^2 (\bar{x}_n - \bar{p}_n)}{\bar{x}_n (\bar{x}_n + \bar{p}_n y)^2} \qquad (1)$$

in which $\bar{x}_n$ and $\bar{x}_w$ are number- and weight-average degrees of polymerization of the backbone and y is the degree of polymerization of the branch. But this broadening is small in the present experiments and would lead to an increase in the M_w/M_n ratio of less than 0.04 in all cases. A final M_w/M_n ratio of 1.35 for the combs is therefore not entirely consistent with the M_w/M_n ratio of 1.11 for the original backbone polymer, or the value of 1.15 derived from the g.p.c. curve of the backbone polymer after correction for axial dispersion.

Because the molecular weight distribution is known with uncertainty and because no M_n values for the high molecular weight combs are available, p was determined from:

$$p = \frac{M_{w,comb} - M_{w,bb}}{M_{n,br}} \qquad (2)$$

This is essentially equivalent to using M_w's throughout as the branch material is not likely to have $M_w/M_n > 1.1$ and usually much less than that. The error in using $M_{w,comb}$ is reduced by simultaneously using $M_{w,bb}$. Equation (2) will, however, overestimate the number of branches.

Physical measurements

Light scattering measurements on dilute polymer solutions furnish, beside the weight-average molecular weight, the second virial coefficient, A_2, and through its temperature dependence $\theta(A_2)$ the temperature at which $A_2 = 0$. The $\theta(A_2)$ temperature for each comb polymer in cyclohexane is given in *Table 3*. Decreases of the $\theta(A_2)$ temperature for branched polymers are now well documented[6,8,11,12,18,19]. In each series of comb polymers with a common backbone the θ temperature decreases more from that of linear polystyrene (34.5°C) as the branch length decreases. A comparison of the two series of combs show that the one with the smaller backbone has the largest $\theta(A_2)$ temperature depression. The $\theta(A_2)$ temperature decreases observed here are similar to those for comparable comb polystyrenes 1B and 2A of Candau[8]. On the basis of these results polymers A53:2 and A68.4 of Berry[20] would not have a sufficiently high branch density to exhibit a $\theta(A_2)$ temperature lowering, as was indeed observed.

The decrease in the $\theta(A_2)$ temperature has been related to increased segment density and hence number of triple contacts in branched polymers[21]. From this hypothesis an expression for $\theta(A_2)$ was derived:

$$\frac{\theta}{\theta(A_2)} - 1 = \frac{3^{3/2}}{2^4} \frac{C'_M}{C_M} \frac{(1/3 - \chi_2)}{\psi} \frac{H(K')}{M^{1/2} g_{exp}^{3/2}} \qquad (3)$$

a Using p = 29 for combs C031–C061 and p = 25 for combs C101–C141 in equation (4)

b In cyclohexane, linear polystyrene at 34.5°C
Figure 2 Log—log plot of the ratio of the mean square radius of gyration of a comb to that of its backbone against the ratio of their molecular weights. Experimental points: $\bigcirc$, this work; $\square$, ref 20; $\triangle$, ref 21. — — —, represents linear polystyrene. Curves: equation (5) with $p = 25$ (upper) and $p = 29$ (lower)

in which C'_M and C_M contain polymer and solvent constants, $(1/3 - \chi_2)$ is the triple contact term and $H(K')$ is a function that depends on α. A plot of $\alpha^8 - \alpha^6$ versus $\alpha^3 [1 - (\theta/T)]$ allows the evaluation of $(1/3 - \chi_2)$ and ψ for each comb polymer[22]. However, no consistent set of these parameters could be obtained by this analysis, as was also observed previously[21]. Using values of $(1/3 - \chi_2) = 0.045$ and $\psi = 0.321$, obtained for four- and six-branched star polystyrenes[11], equation (3) predicts $\theta(A_2)$ temperatures that vary much less with branch length than observed experimentally.

The angular dependence of light scattering after extrapolation to zero concentration gives the radius of gyration of the polymer in solution. Branched polymers have a smaller radius of gyration than linear polymers of the same molecular weight. Random flight statistics allow the calculation of the theoretical ratio, g, between the radius of gyration of a randomly branched comb and that of its linear homologue[22]:

$$g = \frac{\langle S^2 \rangle_{0,\text{comb}}}{\langle S^2 \rangle_{0,\text{lin}}} = \lambda + \frac{3}{p}(1 - \lambda)^2 + \frac{(1 - \lambda)^3}{p^2} \qquad (4)$$

where λ is the fraction of polymer in the backbone. Since $\lambda \cdot \langle S^2 \rangle_{0,\text{lin}} = \langle S^2 \rangle_{0,\text{bb}}$, a more useful relation between the radius of gyration of a comb and its backbone can be derived from equation (4)[20]:

$$\frac{\langle S^2 \rangle_{0,\text{comb}}}{\langle S^2 \rangle_{0,\text{bb}}} \approx 1 + \frac{3}{p \cdot \lambda}(1 - \lambda)^2 \qquad (5)$$

Any effect of polydispersity on $\langle S^2 \rangle_{0,\text{comb}}$ is cancelled largely by comparing it with the experimentally measured $\langle S^2 \rangle_{0,\text{bb}}$. The initial slope was obtained using the $P(\theta)$ function for linear polymers as outlined previously[11]. The variable $\mu = 16\pi^2(\langle S^2 \rangle/\lambda'^2) \sin^2 \theta/2$ is always smaller than 2, and the $P(\theta)$ function of combs and linear polymers having the same radius of gyration differ very little[22]. *Table 3* lists the calculated (equation 4) and experimentally determined g values for the comb polymers. The latter are derived with $\langle S^2 \rangle_{0,\text{lin}}/M_w = 8.4 \times 10^{-12}$ cm^2 g mol as obtained on the slightly polydisperse backbone polymer 6bc. At $\theta(A_2)$, where on the average polymer—polymer and polymer—solvent interactions cancel, all experimental g values are larger than the theoretical ones (equation 4). The

increase of $\langle S^2 \rangle_{\theta(A_2),\text{comb}}$ over that of $\langle S^2 \rangle_{0,\text{bb}}$ on grafting a constant number of progressively larger branches is shown in *Figure 2*. In contrast to the theoretical prediction, short branches increase the radius of gyration significantly. *Figure 2* also indicates that, to a first approximation and for combs with 20—30 branches:

$$\frac{\langle S^2 \rangle_{\theta(A_2),\text{comb}}}{\langle S^2 \rangle_{0,\text{bb}}} = \left(\frac{1}{\lambda}\right)^{0.46} \qquad (6)$$

independent of the molecular weight of the backbone. In the case of linear polymers the exponent is, of course, equal to one. Comb polymers with a near star structure deviate from this line, however[6].

Intrinsic viscosity measurements on the comb polymers were performed in cyclohexane at $\theta(A_2)$, in cyclohexane and in toluene at 35°C. When the intrinsic viscosities of the comb polymers are measured at their individual $\theta(A_2)$ temperature, where, on the average polymer—polymer and polymer—solvent interactions cancel and the excluded volume becomes zero, the data for the two series of comb polymers fall on a single line and are equal to that of the parent backbone polymer whenever $M_{w,\text{comb}}/M_{w,\text{bb}} < 4$. Above this ratio there is a small increase in the intrinsic viscosities which reaches 15% when $M_{w,\text{comb}} \approx 10 \cdot M_{w,\text{bb}}$ as shown in *Figure 3*.

The curves obtained for the dependence of the intrinsic viscosity on $1/\lambda$ in cyclohexane at 35°C are caused by the varying thermodynamic conditions in which the combs exist in that solvent. The larger the θ-temperature depression of the comb, the more expanded is the polymer at 35°C and the more the intrinsic viscosity is increased from that at $\theta(A_2)$. Clearly, this effect is most pronounced for combs with small branches and/or a high branch density. Similar curves were observed previously, the highly branched combs showing the largest increase in the intrinsic viscosity from that of their backbone[7].

In toluene at 35°C the thermodynamic conditions of the combs are probably not very different. The intrinsic

^{a} $g' = $ [η]$_{comb}$/[η]$_{lin}$ with [η]$_{lin}$ = 8.3 x 10^{-4} $M_w^{0.5}$ in cyclohexane at 35°C and [η]$_{lin}$ = 1.02 x 10^{-4} $M_w^{0.73}$ in toluene [10]

viscosities show a behaviour similar to that found under $\theta(A_2)$ conditions. However, the increase of the intrinsic viscosity above that of the backbone as the molecular weight increases occurs at lower molecular weight and is somewhat greater. Nevertheless, the increase is much smaller than observed on increasing the molecular weight in linear polymers.

The results in *Table 4* reveal that all intrinsic viscosities at $\theta(A_2)$ and in toluene are lower than predicted by the Zimm—Kilb relation[23]:

$$g' = \frac{[\eta]_{comb}}{[\eta]_{lin}} = g_{th}^{1/2} \tag{7}$$

A similar although smaller effect was observed in regular star polymers[10-12]. As with the star polymers, the experimental g' values are lower in the good solvent than under θ-conditions. A search for a correlation between g'_{exp} and g_{th} of the form:

$$g' = g_{th}^{m} \tag{8}$$

failed to yield a constant exponent[20]. It is more likely that progress in deciphering the factors determining the intrinsic viscosities of comb polymers will be made by comparison with the intrinsic viscosity of the parent backbone as shown in *Figure 3*. While the effect of the backbone length was investigated, the effect of the number of branches requires further study; so do the factors influencing the upswing of the intrinsic viscosities and the effect of the polydispersity.

The comb polymers, that have intrinsic viscosities that do not differ from that of the backbone, have nevertheless increased hydrodynamic volumes (V_e) through the increase in M_w.

$$[\eta] \cdot M_w = \text{constant} \times V_e = \phi \langle S^2 \rangle^{3/2} \tag{9}$$

For the comb polymers with $1/\lambda < 10$ [η]$_{\theta(A_2)} \cdot M_w \approx$ $1/\lambda$. It follows from equation (6) that $\langle S^2 \rangle_{\theta(A_2),comb}^{3/2}$ varies according to $(1/\lambda)^{0.69}$. Therefore:

$$\phi_{\theta(A_2),comb} \approx \phi_{0,lin} \cdot \left(\frac{1}{\lambda}\right)^{\sim 1/3} \tag{10}$$

This approximation seems to hold for combs with 20—30 branches with backbone polymers between 1.5 x 10⁵ and 1.3 x 10⁶ [20]. When $1/\lambda > 10$ the comb polymers become

star-like polymers and $\phi_{\theta,comb}$ will increase faster than indicated by equation (10). There is some evidence that in a good solvent $\phi_{comb} \approx \phi_{lin}$ [20]. Since the polydispersity of the polymer sample has an important effect on the exact value of ϕ, these variations of ϕ with polymer branching have to be considered exploratory.

CONCLUSIONS

It is shown that Si—Cl bonds can be introduced into polystyrene and can be used to react with living anionic polymer. The number-average number of branches in the resulting comb polymer is somewhat less than calculated from the original reaction sites in the backbone polymer, probably because of incomplete chlorodimethylsilylation or loss of Si—Cl bonds in the work-up of the polymer. A series of combs with a constant number of branches are obtained. Their exact molecular weight distribution is difficult to determine and leaves some uncertainty as to the exact meaning of the physical properties of the comb polymers. The effect of the unreacted groups in the polymers, especially polar groups, is not known and forms another limitation on the results. These are areas for future improvement.

The $\theta(A_2)$ temperatures of the combs are lower than for linear polystyrene. At $\theta(A_2)$ the radii of gyration of the combs are larger than can be calculated from random flight statistics. The intrinsic viscosities at $\theta(A_2)$ and also in a good solvent are lower than predicted by the Zimm—Kilb relation. The ratio of the radii of gyration of the combs and their backbone varies with the ratio of the molecular weight of the combs and their backbone. Similar variation is found for the intrinsic viscosities of the combs. Both these variations do not seem very sensitive to the exact number of branches between 20—30 branches per chain and are independent of the molecular weight of the backbone polymer between 1.5 x 10⁵ and 1.5 x 10⁶.

Use of organotin compounds in the thermal stabilization of PVC: 6. A radiochemical study of the effect of variations in molecular weight on the reaction between PVC and di(butylthiolato)dibutyltin

F. Alavi-Moghadam, G. Ayrey and R. C. Poller

Department of Chemistry, Queen Elizabeth College, Campden Hill Road, London W8 7AH, UK
(Received 2 May 1975)

Reactions between PVC samples of differing molecular weight and di(butyl[35S] thiolato)dibutyltin have been examined. There is an inverse relationship between the amount of radioactivity taken up by the polymer and its molecular weight.

INTRODUCTION

In a previous paper[1] we showed that when a specimen of PVC ($\bar{M}_n$ 28 000) in chlorobenzene was heated with di-(butyl[35S] thiolato)dibutyltin at 180°C *in vacuo* there was only limited uptake of radioactivity during an induction period. This was ascribed to exchange between allylic chlorine atoms in the polymer with 35S groups. At the end of the induction period incorporation of radioactivity occurred more rapidly due to addition of liberated [35S] butane thiol to double bonds in the degrading polymer. In the present paper we report the results obtained when a series of PVC samples of differing molecular weight reacted with the labelled stabilizer.

EXPERIMENTAL

The suspension polymerized PVC used in this work was a gift from Mr R. Khana of ICI Ltd (Plastics Division). The samples were purified by precipitation from tetrahydrofuran solution using methanol and dried to constant weight in a vacuum oven at 45°C. The molecular weights were determined by gel permeation chromatography and by osmometry. Tetrahydrofuran was allowed to stand over sodium and then refluxed with lithium aluminium hydride. Immediately before use it was fractionally distilled through a 40 cm × 2.6 cm column packed with Fenske helices and the pure material shown to be free from peroxides. Chlorobenzene was similarly fractionally distilled immediately before use. Methanol was Analar grade without further purification.

Details of the preparation of di(butyl[35S] thiolato)-dibutyltin and of the radiochemical assays are given in our previous paper[1].

Interaction between PVC and Bu₂Sn(³⁵SBu)₂

A solution of PVC in chlorobenzene (10–40 cm³ depending upon concentration) containing 0.200 g of polymer and $Bu_2Sn(^{35}SBu)_2$ in chlorobenzene (0.20% w/v, 5 cm³) was degassed, sealed at $<10^{-4}$ mmHg pressure and heated at 180°C. The polymer was precipitated with methanol, washed and dried. Standard cycles of dissolution in tetrahydrofuran, followed by precipitation with methanol were then carried out (6–8 times) until the radioactivity reached a constant value.

RESULTS AND DISCUSSION

In our previous study[1] of the reaction between PVC and di(butyl[35S] thiolato)dibutyltin, reaction periods of up to 8 h were used and there was no indication of any decrease in the rate of uptake of 35S. The present work arose when this phenomenon was further investigated using PVC of higher molecular weight. The specimen of PVC used was identical with that used earlier except that it had $\bar{M}_n$ 79 800. The amounts of radioactivity incorporated into the polymer are shown in *Table 1*, from which it can be seen that the uptake of radioactivity continues steadily for 45 h at which point the polymer is highly degraded. When these results are compared with those obtained earlier[1] it is seen that the retained radioactivity after a reaction period of 8 h is 72.4×10^3 for PVC with $\bar{M}_n$ 79 800 compared with 364 × 10^3 disintegrations $min^{-1}g^{-1}$ PVC for polymer having $\bar{M}_n$ 28 000 (the same specimen of labelled stabilizer being used). It seemed possible that the lower molecular weight

* Figures in parenthesis are repeat experiments

material has a higher concentration of allylic chlorine atoms leading to more rapid degradation and consequently an enhanced rate of addition of $Bu^{35}SH$ to the formed polyene. It was of interest to examine more closely the relationship between molecular weight and uptake of radioactivity.

The six samples of PVC having molecular weights shown in *Table 2* were each treated, in solution, with Bu_2Sn-$(^{35}SBu)_2$, at 180°C *in vacuo* for 5 h. The polymer samples were then purified, as before, by repeated dissolution in tetrahydrofuran followed by precipitation with methanol until essentially constant values for radioactivity were obtained (at least 6 cycles in each case). The results are shown in *Table 3* from which it can be seen that uptake of radioactivity depends inversely on the molecular weight of the polymer. Although the values for samples 3 and 4 are not in the expected order, repeated experiments showed that the radioactivity values could be reproduced to within 5% or better. The apparent discrepancy is undoubtedly due to the fact that the error in the molecular weight determinations is unlikely to be better than ±10%. This method of purification underestimates the dependance of uptake of radioactivity on molecular weight since the lower molecular weight components in each sample are preferentially removed. This is clearly seen in columns 4 and 5 of *Table 3* where after 6 or 8 cycles of dissolution and precipitation, significantly smaller amounts of the original 0.200 g of sample are left in the case of the lower molecular weight polymers.

Although previous workers have shown that there is an inverse relationship between the rate of dehydrochlorination and the molecular weight of PVC^{2-4} this is the first demonstration that the rate of incorporation of X groups from a stabilizer R_2SnX_2 shows a similar relationship. This confirms the view proposed earlier[1] that, after the induction period, the stabilizer $Bu_2Sn(^{35}SBu)_2$ absorbs hydrogen chloride to give Bu_2SnCl_2 and $Bu^{35}SH$, the latter then adds to the double bonds in the degrading polymer. Thus the organotin stabilizer functions not only by prolonging the induction period before the onset of dehydrochlorination but exerts a continuing favourable influence by inhibiting hydrogen chloride catalysis and also by reducing the lengths of the conjugated polyene systems.

Dielectric and dynamic mechanical relaxation studies of styrene—acrylonitrile copolymers*

M. Cook and G. Williams
Edward Davies Chemical Laboratories, University College of Wales, Aberystwyth SY23 1NE, UK

and T. Tyssul Jones
Research Department, Monsanto Chemicals Ltd, Corporation Road, Newport, NPT OXF, UK
(Received 27 May 1975)

Dynamic mechanical measurements ($\sim$1 Hz) and dielectric measurements (10^{-4} to 10^5 Hz) are presented for styrene—acrylonitrile copolymers containing 25 and 32.5% acrylonitrile. Two dielectric (α, β) and one mechanical (α) processes were observed and their mechanisms are discussed. It is shown that the Montrose—Litovitz fluctuation theory and Phillips—Barlow—Lamb defect-diffusion theory give reasonable representations of the dielectric α relaxation process.

INTRODUCTION

Styrene—acrylonitrile (S—AN) copolymers are commercial thermoplastic materials whose importance arises from the fact that they are relatively inexpensive and possess an excellent balance of physical and chemical properties. They are strong, rigid and transparent, have excellent dimensional stability and high craze resistance and are relatively easy to fabricate. S—AN copolymers are superior to unmodified polystyrene in their greatly improved resistance to chemical attack and their somewhat greater tensile strength and elongation. In this investigation the dielectric and mechanical relaxation of two S—AN copolymers, containing 25 and 32.5% acrylonitrile, have been studied over a large temperature range. The investigation was carried out for two reasons. First, we wished to see how the magnitude, location and shape of the multiple relaxations varied with acrylonitrile content, and secondly, we wished to obtain information about the relaxation behaviour as a necessary basis for the more complicated, but related, acrylonitrile—butadiene—styrene (ABS) materials.

EXPERIMENTAL

The dynamic mechanical measurements were made using a torsion pendulum of a design similar to that described by Heijboer *et al.*[1]. Using a combination of liquid nitrogen and heating elements, the temperature range 90 to 473 K could be covered. Values of the real (G') and imaginary (G'') parts of the complex shear modulus ($G*$),

the quantity $G = (G'^2 + G''^2)^{1/2}$, the logarithmic decrement Δ, the loss tangent $\tan \delta_G$ and the measurement frequency were evaluated at each temperature. The dielectric measurements were made using: (i) a General Radio 1620-A Bridge (10^2 to 10^5 Hz); (ii) a Scheiber Bridge (10^{-2} to 10^2 Hz); and (iii) a d.c. transient current method (10^{-4} to 10^{-2} Hz). The latter technique gave information on the α relaxation in the time domain which was transformed into the frequency-dependent loss factor $\epsilon''(f)$ using the Hamon approximation[2,3] together with correction factors given by Williams *et al.*[4,5] for the special case of a Williams—Watts distribution with $\bar{\beta} = 0.5$ which is appropriate for these copolymers. The two S—AN copolymers (I and II) were suspension polymerized materials with molecular weight near 6×10^4 g/mol. S—AN I and S—AN II contained 25 and 32.5% (w/w) acrylonitrile, respectively. Samples were compression moulded at 433 K, and for mechanical measurements rectangular specimens 7 cm x 0.6 cm x (4×10^{-2} cm) were used, and for electrical measurements disc samples 3.5 cm diameter and 0.1 to 0.3 cm in thickness were used.

RESULTS

Only representative data are presented in this paper, the full experimental data are given in the SUP. *Figure 1* shows† G and $\tan \delta_G$ against temperature for S—AN I (i.e. 25% acrylonitrile copolymer). Only one mechanical relaxation region is observed in the range 173 to 403 K, and is associated with the glass transition of the copolymer ($T_g = 368$ K). *Figure 2* shows the dielectric loss factor ϵ'' as a function of temperature for S—AN I at a fixed frequency of 1 kHz. Two relaxation regions are observed, the large high temperature process (α process) correlates in its location with the mechanical process, and is due to the large scale Brownian motions of the dipoles. The lower temperature process (β process) is due to limited
Figure 1 G and tan δ_G against absolute temperature for S–AN I. The frequency of measurement for $T < 320$ K is 2.3 Hz and falls to 1.04 Hz at the peak of tan δ_G
Figure 2 ϵ'' against absolute temperature for S–AN I at 1 kHz

motions of dipoles in the glassy state of the copolymer. Figures 3 and 4 show plots of ϵ' and ϵ'' against log (frequency) for the α and β processes in S–AN I. The results for S–AN II were similar to those shown in Figures 1–4 for S–AN I, and are given in the supplementary publication. Dielectric experiments contain information on:
(a) the magnitude of the dipole relaxation processes;
(b) their frequency–temperature locations; and (c) the form of the dipole-correlation function as given by the shape of the ϵ'' vs. log (frequency) plots.

Magnitude

The values of ϵ_0 and ϵ_∞ (ϵ_0 and ϵ_∞ are the limiting low and high frequency permittivities for a given relaxation process) for the α process in S–AN I and S–AN II are given in the supplementary publication. The magnitude of the relaxation could be obtained by the difference $(\epsilon_{0\alpha} - \epsilon_{\infty\alpha})$ where these are the experimental permittivities, or more approximately, but conveniently, using the relation[5]:

$$(\epsilon_{0\alpha} - \epsilon_{\infty\alpha}) = K(\bar{\beta}) \epsilon''_m \Delta \log f \qquad (1)$$

where $\Delta \log f$ is the half width of the loss curve for the α

process, ϵ''_m is the maximum loss factor and $K(\bar{\beta})$ is a function of the distribution parameter $\bar{\beta}$. For the curves of Figure 3, $\bar{\beta} = 0.5$ thus $K(\bar{\beta}) = 1.66$. The ratio of the magnitude of the α relaxation in S–AN II to that in S–AN I was found to be[‡]:

$$\frac{(\epsilon_{0\alpha} - \epsilon_{\infty\alpha})_{\text{S-AN II}}}{(\epsilon_{0\alpha} - \epsilon_{\infty\alpha})_{\text{S-AN I}}} = 1.26 \pm 0.02 \qquad (2)$$

Similarly for the β relaxation:

$$\frac{(\epsilon_{0\beta} - \epsilon_{\infty\beta})_{\text{S-AN II}}}{(\epsilon_{0\beta} - \epsilon_{\infty\beta})_{\text{S-AN I}}} = 1.36 \pm 0.04 \qquad (3)$$

‡ Further details are given in the SUP, *Table 1*.

Figure 4 ϵ' and ϵ'' against log (frequency) for the low temperature process in S–AN I. ○, 233; ×, 223; □, 213.5; △, 203.5; ●, 194.5 K
Figure 5 Log f against $1/T$ for the α process in S—AN I and S—AN II. ● and ○, dielectrio data; ■ and □, mechanical (tan δ) data for S—AN I and S—AN II, respectively. The dielectric data relate to frequency of maximum ϵ'' at a given T; the mechanical data relate to temperature of maximum tan δ from *Figure 1* and Fig.9 of SUP
Figure 6 Log f_{max} against $1/T$ for the dielectric β process in S—AN I (●) and S—AN II (○)

These are to be compared with the known ratio of acrylonitrile contents in the two copolymers, being $32.5/25 = 1.30$. The good agreement suggests that the dielectric technique provides a convenient method for determining the acrylonitrile content in these copolymers, and also confirms that both the α and β dielectric relaxations are associated with the motions of acrylonitrile groups in the copolymer.

Location

Figures 5 and *6* show the plots of log f_{max} against $1/T(K)$ for the α and β relaxations in S—AN I and S—AN II. First, the location of the α process is quite similar for both polymers and the correlation between the dielectric data and mechanical data for the α process is good, confirming that the same motional process is being observed by the two techniques, and that the dynamic T_g is nearly independent of composition for the range studied here. The α process (*Figure 5*) shows WLF type behaviour while the β process (*Figure 6*) exhibits a constant apparent activation energy Q. Typical values are 300 kJ/mol at 413 K for the α process in both copolymers, and 39 kJ/mol at 233 K for the β process in both copolymers.

Shape

The shape of the plots of ϵ_α'' against log f remains approximately constant as temperature is changed from 369 K to 413 K for both copolymers. *Figures 7* and *8* show the normalized plots for both the dispersion and absorption in S—AN I and S—AN II. The excellence of the superposition should be noted. The complex dielectric permittivity in normalized form may be related to frequency according to[2,6]:

$$\frac{\epsilon'(\omega) - \epsilon_\infty}{\epsilon_0 - \epsilon_\infty} = \int_0^\infty \frac{\phi(\tau)d\tau}{1 + \omega^2\tau^2} \tag{4a}$$

$$\frac{\epsilon''(\omega)}{\epsilon_0 - \epsilon_\infty} = \int_0^\infty \frac{\phi(\tau)\omega\tau d\tau}{1 + \omega^2\tau^2} \tag{4b}$$

and the curves of *Figures 7* and *8* could be fitted by choice of a suitable distribution function. However, such a procedure implies that the relaxation is to be regarded as a weighted sum of single relaxation time functions, which may not be the physical situation[6]. An alternative approach is to deduce the form of the transient step-response function $\phi_\alpha(t)$ from the data of *Figures 7* and *8* via the relation[2,5,7]:

$$\left[\frac{\epsilon_0 - \epsilon'(\omega)}{\epsilon_0 - \epsilon_\infty}\right]_\alpha = \omega \int_0^\infty \phi_\alpha(t) \sin \omega t \, dt \tag{5a}$$
Figure 7 (a) $(\epsilon' - \epsilon_\infty)/(\epsilon_0 - \epsilon_\infty)$ and (b) $(\epsilon''/\epsilon_{max}'')$ against log f/f_{max} for the α dielectric relaxation in S—AN I. ■, 373; ●, 377; +, 381; ×, 385.5; ▽, 390; △, 397; □, 403; ○, 413 K
Figure 8 (a) $(\epsilon' - \epsilon_\infty)/(\epsilon_0 - \epsilon_\infty)$ and (b) $(\epsilon''/\epsilon''_{max})$ against log f/f_{max} for the α dielectric relaxation in S—AN II. ■, 375; ●, 379; +, 383.5; ×, 388.5; ▽, 393; △, 398; □, 403; ○, 413 K

$$\left[\frac{\epsilon''(\omega)}{\epsilon_0 - \epsilon_\infty}\right]_\alpha = \omega \int_0^\infty \phi_\alpha(t)\cos\omega t\, dt \qquad (5b)$$

$\phi_\alpha(t)$ may be obtained by Fourier inversion of equation (5) or by fitting $\epsilon'(\omega)$ and $\epsilon''(\omega)$ to an empirical form of $\phi_\alpha(t)$. We have found that the data of *Figures 7* and *8* are fairly well represented by the function $\phi_\alpha(t) = \exp - (t/\tau_0)^\beta$ where $\bar\beta = 0.5$ and the solid lines in *Figures 7* and *8* were calculated using this function. The inadequacy of this representation is only apparent at $\log(f/f_m) > 2$, and means, of course, that the short-time behaviour of the empirical function is inconsistent with the experimental data for the α relaxation, as was found for poly(vinyl acetate) and poly(vinyl octanoate)[5]. Inspection of *Figures 5* and *6* shows that the α relaxation has an appreciable overlap with the higher frequency portion of the β relaxation so the observation in *Figures 7* and *8* that the observed loss exceeded the calculated loss may be associated with the β process.

DISCUSSION

Both S—AN I and S—AN II show only one mechanical relaxation process and in both materials this occurs in the temperature range 343 to 393 K. The sudden fall in modulus and the accompanying maximum in mechanical damping is typical of amorphous polymers when they pass through a range of temperature where a group on the chain or segments of the chain pass from a state of im-

mobility, a frozen-in state, to one of comparative freedom or mobility with respect to the frequency of measurement. In the mobile state groups and chain segments will execute continual Brownian motion. The mechanical α relaxation is related to motion at the molecular level by a rather complicated time-correlation function[8]. The dielectric α and β relaxations are related to the time correlation function $\langle \vec{M}(0) \cdot \vec{M}(t)\rangle$ where $\vec{M}(t)$ is the macroscopic dipole moment of a suitably chosen assembly of dipoles[6,7]. In the absence of orientational correlations *between* polymer chains, which would be the case if the polymer molecules do not interpenetrate (see ref 9, pp 549–551), then this time correlation function may be expanded[7] in terms of autocorrelations $\langle \vec{\mu}_i(0) \cdot \vec{\mu}_i(t)\rangle$ and cross-correlations $\langle \vec{\mu}_i(0) \cdot \vec{\mu}_j(t)\rangle$ within a given polymer chain. The work of Leffingwell and Beuche[10] indicates that the time dependence of the auto- and cross-correlation functions are quite similar for styrene/p-chlorostyrene copolymers, and the fact that the curves of *Figures 7* and *8* are essentially identical suggests that here too the auto- and cross-correlation functions have similar time dependencies. Williams *et al.*[11] have emphasized the similarity between the shapes of the α relaxations in several polymers and copolymers and in certain supercooled liquids as was noted earlier by Johari and Smyth[12,13] and Johari and Goldstein[14,15], and this has been reviewed recently[16]. Thus the present data for the α relaxation (*Figures 7* and *8*) for styrene—acrylonitrile gives direct information on the dipole correlation function $\langle \vec{\mu}_i(0) \cdot \vec{\mu}_i(t)\rangle$ for a reference dipole in the copolymer chain. Ignoring the internal field factors[6,7] which are involved in relating $\langle \vec{\mu}_i(0) \cdot \vec{\mu}_i(t)\rangle$ to the complex permittivity, we have $\langle \vec{\mu}_i(0) \cdot \vec{\mu}_i(t)\rangle \simeq \mu^2 \exp - (t/\tau_0)^{0.50}$. The question now arises as to how one can interpret such behaviour in terms of a molecular model for the re-orientational process. The observation that the α relaxation has similar characteristics in a wide range of materials[2,10–16] means that the detailed molecular structure, whilst it determines the magnitude of the relaxation process through $\langle \mu^2\rangle$ and the frequency of maximum loss at a given temperature, is not the dominant factor determining the form of dipole correlation function (i.e. the shape of the ϵ'' vs. $\log f$ plot). We therefore look for mechanisms which are of quite general applicability to include S—AN and other systems.

One approach is to consider that the dipole in S—AN may only move if it is allowed to do so by the immediate environment. One mechanism would be that via the diffusion of a defect to the reference dipole from the environment. The defect-diffusion model of Glarum[17] as modified by Phillips *et al.*[18] leads to a correlation function:

$$\phi_a(t') = \phi_0(t')[(1 - 2t')\phi_0(t') + 2(t'/\pi)^{1/2}] \qquad (6)$$

where $t' = t/\tau_\alpha$, τ_α is the defect-diffusion time, and $\phi_0(t') = \exp(t')\,\mathrm{erfc}\,(t')^{1/2}$. This correlation function, which is deduced for one dimensional diffusion of defects and takes into account nearest and second nearest neighbour defects, is numerically fitted[19] by the empirical decay function with $\bar\beta = 0.514$. Then we might say that the gross motions of the acrylonitrile portions of the chain, which give rise to the α relaxation, occur via the diffusion of 'defects' through the polymer medium. However, the model is one of one dimensional diffusion, and its generalization to the three-dimensional case gives results quite different[20] from equation (6).

DiMarzio and Bishop[21] have generalized the Debye theory for the re-orientation of a sphere to include a viscoelastic medium rather than a viscous medium. Their result differs from the Debye theory in that the relaxation time τ is now replaced by $\tau(\omega) = 3V\eta(\omega)/kT$, where V is the volume of the (spherical) molecule and $\eta(\omega) = G(\omega)/i\omega$, where η and G are the viscosity and shear modulus respectively. DiMarzio and Bishop found that $\tau(\omega)$, using published $G(\omega)$ data for several polymers, generated broad asymmetric loss curves similar to the experimental dielectric data for those polymers and, indeed, very similar to the present data (*Figures 7* and *8*). Whilst one might employ their approach to the S—AN systems, i.e. the characteristic broad shape arises since dipoles turn in a viscoelastic environment, the approach is a macroscopic one involving a sphere turning in a continuum, and its interpretation in molecular terms seems difficult.

There is little doubt that the relaxation behaviour observed here is best thought of in terms of the natural fluctuations in these amorphous systems. The equilibrium theory of fluctuations in volume, temperature, pressure and entropy for a subsystem of a macroscopic body is well established[22] and we have, for example, that the mean square temperature deviation $\langle \Delta T^2 \rangle$ and mean square volume deviation $\langle \Delta V^2 \rangle$ for N particles are given by:

$$\langle \Delta T^2 \rangle = \frac{kT^2}{C_v} \tag{7a}$$

$$\langle \Delta V^2 \rangle = -kT \left(\frac{\partial V}{\partial T} \right)_P \tag{7b}$$

These fluctuations provide a means whereby the segments of the polymer chains relax from a given initial orientation, but equation (7), being time-averaged quantities (i.e. equilibrium quantities) do not give any indication of the rate of the fluctuations or their evolution in time. Montrose and Litovitz[23] have considered structural relaxation in glass-forming molecular liquids using a model for fluctuations in local order which involve the diffusion of holes and a time constant τ'_0 (for the average time between molecular jumps). Their resultant relaxation function in time yields, on Fourier transformation, Argand diagrams for the frequency-dependent complex compliance which vary from a semi-circular arc (single relaxation time) for $\sigma^2/(D\tau'_0) \to \infty$ (σ and D are a correlation length and the diffusion coefficient for the order respectively[23]), through a Cole—Davidson-like function with $\beta = 0.5$ for $\sigma^2/(D\tau'_0) = 4$ to a very depressed arc for $\sigma^2/(D\tau'_0) \to 0$. Since σ^2/D characterizes the interval required for diffusion to effect an equilibration of the structure over the range σ then $\sigma^2/(D\tau'_0)$ is the ratio of this interval to the 'intrinsic' jump time τ'_0. Our data* of *Figures 7* and *8* may be fitted approximately by the function of Montrose and Litovitz[23] for $\sigma^2/(D\tau'_0) \to 0$. Physically this corresponds to the situation where the relaxation is determined by the diffusion of the fluctuations. Clearly there are similarities between the result of this model and that for the diffusion of defects given in equation (6) above.

---

* Note that these data which are fitted quite accurately by our empirical function $\bar{\beta} = 0.50$ may be approximately fitted to the Davidson—Cole function[24,25] with $\beta = 0.30$.

Thus the general features of the α process in the S—AN copolymers and other amorphous polymers may be consistent with a model of fluctuations or of defect-diffusion in which the dipolar chain segments relax not by their own intrinsic relaxation rate in a fixed environment, but as a cooperative motion between the segments and the environment in which the motions of the environment plays a dominant role. This is in accord with the observations of the dielectric α relaxation in viscous molecular liquids[16]. With regard to the β process in the S—AN copolymers, whilst it arises due to the local motion of the dipolar groups, the large breadth of the process (*Figure 4*) precludes its interpretation in terms of any simple mechanism.

Migration of PVC plasticizers into alcohols

Emmanuel M. Kampouris, F. Regas, S. Rokotas, S. Polychronakis and M. Pantazoglou
Laboratory of Special Chemical Technology, National Technical University of Athens, Athens 147, Greece
(Received 14 April 1975; revised 4 July 1975)

The use of labelled plasticizers and radioactivity measurements in conjunction with weight loss, can give quantitative information on the amount of migrated plasticizer, and on the amount of the liquid medium that diffuses into the polymer during the migration process. In the case of PVC plasticized with dibutyl phthalate and dioctyl phthalate and immersed in alcohols, the specimens soon become heterogeneous due to loss in compatibility between the polymer and the mixtures of plasticizer—alcohol high in alcohol. These mixtures are formed in the polymer as a result of continuous migration and diffusion processes. The following factors affecting the migration process were examined: nature of alcohol, nature of phthalate plasticizer, amount of plasticizer, molecular weight of polymer, thickness of specimens, presence of epoxy plasticizers, plasticization process, presence of stabilizers, temperature, and time.

INTRODUCTION

The problem of plasticizer migration is of special interest in the case of polymers modified with considerable amounts of plasticizers. Of the common polymers PVC is the one used in the largest volume as flexible or plasticized PVC. Therefore any study on the plasticization and migration processes may be of practical importance for the PVC industry.

In all applications a plasticized polymer is in contact with some kind of surrounding medium. Under these conditions the plasticizer must stay in place during the useful life of the formed plastic item, otherwise it migrates with the result that (a) the polymer, because of loss of plasticizer, stiffens and becomes less desirable, and (b) the surrounding medium is contaminated by the plasticizer.

Thus there arises the need for a thorough study of factors affecting the migration process, and for a simple and accurate method of measuring amounts of plasticizer which may be present in a given medium.

The possible factors which can affect the migration process can be classified in relation to: (a) the polymer, i.e. nature, molecular weight, crystallinity; (b) the plasticizer, i.e. nature, amount, possible interactions (especially in the case of mixed plasticization systems); (c) the other components usually present in the plasticized polymer, i.e. stabilizers, lubricants, fillers; (d) the plasticization process and conditions, and therefore the homogeneity of the system; (e) the surrounding medium, i.e. nature, compatibility with the plasticizer, effect on polymer; (f) the conditions of the test, i.e. time, temperature, type of contact.

The plasticizer that migrates can be estimated as: the amount leaving the polymer, or the amount entering into the liquid. In the first case the amount can be measured by weight[1] or radioactivity[2] loss. In the second case the amount of plasticizer can be measured by chromatography[3,4], spectrometry[5], impulse-polarography[6], and radioactivity[7,8].

This paper presents the results, obtained by radiometric and weight loss methods, of a study of the effect of the following factors upon the migration of phthalate plasticizers from plasticized PVC into alcohols: nature of alcohol, molecular weight of the polymer, nature of plasticizer, amount of plasticizer, presence of epoxy plasticizers, presence of stabilizers, plasticization process, thickness of specimens, temperature, and time. ·

EXPERIMENTAL

Synthesis of labelled dibutyl phthalate (DBP)

5 mg of labelled n-butanol (1-^{14}C; 0.25 mCi) were diluted with n-butanol(28 ml) and added to a four-necked flask containing powdered phthalic anhydride (49 g). The flask was equipped with stirrer, thermometer, N_2 inlet tube, and a side condenser. The mixture was heated at 100°C for 1 h, then n-butanol (95 ml) and concentrated sulphuric acid (0.4 ml) were added, and the mixture was heated at 130°C for 3 h. During this period a slow stream of N_2 was passed and n-butanol was periodically added to make up for that distilling. After cooling, the reaction product was diluted with ether (500 ml) and the ethereal solution was washed with 10% aqueous sodium carbonate solution, then with water, and finally evaporated to remove ether and unreacted n-butanol. The diester was purified by vacuum distillation (yield 82 g of labelled DBP of radioactivity 4.8 x 10^3 counts/mg/min). Products with lower radioactivities were obtained by dilution with pure unlabelled DBP.

Synthesis of labelled dioctyl phthalate (DOP)

The product was synthesized according to the literature method[8] from labelled phthalic anhydride (7-^{14}C) and 2-ethylhexanol.

Preparation of specimens

Suspension polymerized PVC was blended at 80°C with the calculated amounts of plasticizers and stabilizers. No

lubricant was used. For stabilization Ba—Cd (1.5 phr) and alkyl aryl phosphite (0.5 phr) type stabilizers were used. The dry blend was then plasticized by hot working for 7 min in the mixing head of a Brabender Plasticorder at 160°C and 30 rev/min. The plasticized mass was then formed by hot rolling to a sheet from which specimens of 20 x 50 mm were cut.

Immersion

Each of the specimens was immersed in 250 ml of the liquid medium contained in a 300 ml glass-stoppered Erlenmeyer flask. The following alcohols were used as liquids: methanol, ethanol, 96% ethyl alcohol, n-propanol, isopropanol, n-butanol, isobutanol, and 2-ethylhexanol. All tests were made in duplicate, the flasks were kept at temperatures maintained to ±2°C, and the specimens were selected with weight differences not exceeding 100 mg.

Measurement

The radioactivity of the liquid medium, at a given time after immersion, was measured by transferring 0.5 ml of the content of the flasks to a glass measuring vial containing 10 ml of the scintillation solution, shaking to ensure complete solution, and measuring the radioactivity by means of a Packard Tri-Carb 3385 liquid scintillation spectrometer over a period of 10 min. The scintillation solution was made by dissolving 5 g of 2,5-diphenyloxazole (PPO) and 300 mg of 2,2'-*p*-phenylenebis(4-methyl-5-phenyl-oxazole)(Dimethyl-POPOP) in one litre of toluene. From each flask, two samples were taken thus each quoted result represents the average of four measurements. Corrections were made for background and quenching.

The radioactivity loss was calculated from radioactivity measurements of the specimens before and after immersion. In both cases about 10 mg of the specimens were dissolved in 1 ml of tetrahydrofuran, 10 ml of the scintillation solution were added, and the radioactivity was measured in the usual way. Efforts were made to obtain representative samples; all measurements were made in fivefold and the average obtained.

RESULTS AND DISCUSSION

Effect of the nature of alcohols

This effect was examined at 25°C using *k* 65 PVC plasticized with 50 phr DBP or DOP. The results obtained are given in *Tables 1* and *2*. As the data in *Table 1* indicate, the amount of migrated DBP is high in the case of n-alcohols

Table 2 Effect of the nature of alcohol upon the migration (mg) of DBP and DOP from plasticized PVC: comparison of the results after 30 days of immersion

I = Migrated plasticizer, by radioactivity loss; II = migrated plasticizer by radioactivity of the alcohol; III = weight loss; IV = difference II — III (diffused alcohol)

and much lower with iso-alcohols. In both cases the greater the molecular weight of the alcohol, the lower is the amount of plasticizer. In the case of DOP the greater migration rates also occur with n-alcohols, but the effect of the molecular weight of is different. Now the greater the molecular weight n- or iso-alcohols, the greater is the amount of migrated plasticizer.

As the data in *Table 2* indicate, the radioactivity loss method can give results approximately the same as obtained by measurements of the radioactivity of the liquid medium. Comparison between the results obtained by the weight loss method and that of the radioactivity of the liquid, for both DBP and DOP, indicates that in no case can the weight loss method be used for the measurement of the amount of migrated plasticizer. Correlation of the results of the two methods, supposing no other matter except plasticizer is migrated, can give quantitative information on the amount of the alcohol diffused into the polymer, during the migration process. In no case can the amount of diffused alcohol be related with the molecular weight. The only clear observation is that n-alcohols diffused in greater amounts than iso-alcohols both in the case of DBP and DOP. It also holds true that the lower alcohols diffused faster in PVC plasticized with DBP, while the higher alcohols diffused faster in PVC plasticized with DOP.

In most cases the specimens gradually lose their transparency and become opaque to white, during the migration process. This can be explained by the fact that the plasticizer—alcohol mixture, which plasticizes the polymer, becomes gradually a non-solvent for the polymer and
Figure 1 Formation of a long hole, a number of small ones, and lines of differentiation in the mass of PVC plasticized with 50 phr DBP and immersed in ethanol (X35)

separates as a second phase in the mass. This is shown in the microphoto of *Figure 1*.

Effect of the nature of phthalate plasticizer

This effect was examined for both DBP and DOP, two common plasticizers with differences in molecular weight, viscosity and volatility. It is often stated, in examining the tendency of plasticizers to migrate, that the greater the molecular weight, the greater the viscosity, or the lower the volatility, the lower is the migration rate[8-10]. The data in *Table 1* indicate that there is no firm relationship between molecular weight, viscosity, or volatility of plasticizer and the rate of the migration process. Generally only in the case of contact with methanol does DBP migrate faster than DOP, while the opposite is true in the other cases.

The nature of plasticizer affects the diffusion of alco-

hols exhibiting a selective action. As the data in *Table 2* indicate, the lower alcohols diffuse faster in PVC plasticized with DBP, while the higher alcohols do so in PVC plasticized with DOP.

Effect of the amount of plasticizer

This effect was examined in the case of k 65 PVC plasticized with 20, 40 and 60 phr of DBP. The temperature of the test was 30°C, the duration 80 days, and the liquid medium ethanol. The results obtained are given in *Table 3*. As the data indicate the amount of plasticizer strongly affects the migration process and the greater the amount of plasticizer, the greater is the amount lost by migration. During the course of the process the migration rate was faster for the specimens plasticized with the greater amounts of plasticizer. The result was a reversal of the order and after a certain time the specimen with the greater amount of plasticizer ends up with the lowest amount. This behaviour can be explained only in cases of high diffusion rates. In the case examined it is evident that the greater the amount of plasticizer, the greater is the amount of diffused ethanol. At the end of the test the specimen plasticized with 20 phr DBP becomes plasticized with about 16 phr of a mixture containing 4% ethanol, the specimen plasticized with 40 phr becomes plasticized with about 26 phr of a mixture containing 65% ethanol, and finally the specimen plasticized with 60 phr DBP becomes plasticized with about 30 phr of a mixture containing 80% ethanol.

Effect of the molecular weight of the polymer

For this test four samples of PVC (k values 55, 65, 70, and 73 respectively) were plasticized with 50 phr DBP and immersed in ethanol at 30°C for 60 days. The results obtained are given in *Table 4*. As the data indicate the molecular weight of the polymer affects migration and the greater the molecular weight, the lower is the amount of migrated plasticizer.

Effect of the thickness of specimens

In some cases[10,11] short-time tests led to the conclusion that the thickness of specimens has little or no effect on the migration of plasticizers. In this test specimens of k

65 PVC plasticized with 50 phr DBP were used immersed in ethanol at 30°C. For higher accuracy the weight of 20 x 50 mm specimens was used as an indication of thickness. The results in *Table 5* indicate that the greater the thickness of the specimens, the greater is the amount of migrated plasticizer. At the end of the test the major part of the plasticizer had migrated and the amount remaining was greater for the thicker specimens.

Effect of the epoxy plasticizer

In examining the effect of epoxy plasticizers upon the migration of the main (phthalate) plasticizer, specimens were made from *k* 65 PVC plasticized with 50 phr DBP or DOP and 6 phr of epoxy plasticizer (a commercial epoxidized soyabean oil). The specimens were immersed in ethanol for 30 days at 25°C. The results obtained are given in *Table 6*. As the data indicate, the epoxy plasticizer affects migration, promoting that of the main plasticizer. This behaviour seems to be selective; DOP migrates to a greater extent than does DBP.

Effect of the plasticization process

This effect was studied for *k* 65 PVC plasticized with 50 phr DBP and immersed in ethanol at 30°C for 60 days. The plasticization process generally used in this work was followed with variations in the time of hot working which

ranged from 2.5 to 15 min. As the data in *Table 7* indicate, differences in the plasticization process (due to variations in plasticization time) affect migration and the greater the working time, the lower is the amount of migrated plasticizer.

Effect of stabilization

This effect was examined for *k* 65 PVC plasticized with 60 phr DBP or DOP and immersed in 96% ethanol for 30 days at 25°C. In the case of non-stabilized PVC, plasticized with 60 phr DOP, two series of samples were prepared with different plasticization times, i.e. 7 and 15 min. The results in *Table 8* indicate that stabilization affects strongly the migration process, and the greater amounts are migrating from the stabilized specimens. In the case of unstabilized specimens the effect of the plasticization time is greater than in the case of stabilized ones.

Effect of temperature

The effect of temperature was studied in the case of *k* 65 PVC plasticized with 50 phr DBP and immersed in ethanol

at temperatures ranging from 10° to 60°C. The results in *Table 9* indicate that the temperature affects strongly the migration of plasticizer; any rise in temperature increases drastically the amount of migrated plasticizer. Thus 30 days of immersion at 10°C gave the same amount of migrated plasticizer, as 2 days at 30°C. Schematic presentation of the results leads to the conclusion that the relation temperature/amount of migrated plasticizer is not a linear one.

Effect of time

Examining the effect of time, in all the above cases, we can conclude that there is no linear relation between the amount of migrated plasticizer and time, or the square root of time. Contradictory results in the literature may

be explained by the small intervals of time. Generally the greatest migration rates occur in the first stages of the process. They become then lower and tend to minimize. For long enough periods the total amount of plasticizer can migrate, leaving the polymer plasticized, or swelled, by a mixture containing low amounts of plasticizer.

Notes to the Editor

Effect of temperature and molecular weight on the crystallization of a *cis*-1,4-butadiene/isoprene copolymer

Aurelio De Chirico

Laboratori Ricerche Polimeri, Snamprogetti-Diris, S. Donato Milanese, Milan, Italy
(Received 19 March 1975, revised 19 May 1975)

INTRODUCTION

The crystallization rates of polymers depend on their degree of structural regularity, crystallization temperature, T_c, and according to recent research[1–7] on molecular weight (MW) and molecular weight distribution (MWD).

There is a substantial dependence of the half-crystallization time, $t_{1/2}$, with MW, as has been found for high density polyethylene[1], for *cis*-1,4-polyisoprene[5,6], and *cis*-1,4-polybutadiene[7].

As a contribution towards a better understanding of the role of MW on $t_{1/2}$, in polymers, the results obtained with a *cis*-1,4-butadiene/isoprene copolymer (7 mol % of isoprene) are now reported.

EXPERIMENTAL

Dilatometry

The sample ($\sim$ 1 g) was placed in the cup of a dilatometer and was degassed at 10^{-2} mmHg for about 2 h before the introduction of the mercury. The dilatometer assembly was kept at $80°C$ for 1 h and then placed in a cryostat at the predetermined T_c. During crystallization and fusion, the mercury level in the capillary was followed with a cathetometer. A heating rate of $0.25°C/min$ was maintained throughout the fusion.

Polymer sample

A *cis*-1,4-butadiene/isoprene copolymer with 7 mol % isoprene, was prepared using a catalyst based on π-allyl uranium derivatives[8]. The sample had the following characteristics: $[\eta] = 3.85$ (dl/g) in toluene at $30°C$; $\overline{M}_{osm} = 110\,000$; 1,4-trans(%) = 1.1; 1,2-vinyl(%) = 0.8; 1,4-cis(%) = 98.1.

N.m.r. spectra analysis

The isoprene content was determined from n.m.r. data using CCl_4 as solvent.

RESULTS AND DISCUSSION

The crystallization kinetics of the (*cis*-1,4-butadiene/ isoprene) copolymer are highly accelerated by lowering

the T_c in the same way as has been reported for polybutadienes[7] with different 1,4-*cis* content.

The half-time of crystallization, the melting temperature, T_m^*, and the crystallinity, reported as ΔV_{sp}, as a function of T_c are plotted in *Figure 1*. The $t_{1/2}$ increases exponentially and ΔV_{sp} decreases as T_c increases (i.e. faster kinetics and a higher degrees of crystallinity at lower T_c were obtained).

Whole copolymer		3.85	7.2	130	4.0	−5.8
Figure 2 Integral *MWD* for cis-1,4-butadiene/isoprene copolymer (●), isoprene content (+), and melting point of the fractions (X) as a function of intrinsic viscosity

As noted for cis-1,4-polybutadiene[7], T_m^* cannot be easily extrapolated against T_c in order to obtain the equilibrium melting temperature, T_m^o, (*Figure 1*). The slow rate of the isothermal crystallization kinetics at higher T_c does not allow other T_m^* values to be experimentally obtained which approach T_m^o more closely. This value can be obtained by trial and error by introducing the $t_{1/2}$ and the corresponding T_c into the equation recently reported by Giuliani[9]. In this way it has been possible to obtain a T_m^o of 22°C for the cis-1,4-butadiene/isoprene copolymer used in this paper and a T_m^o of 30°C for cis-1,4-polybutadiene (99% cis-) on the basis of data previously published by us[7].

In order to elucidate the relationship between bulk isothermal crystallization kinetics and *MW* we have fractionated this copolymer by the fractional precipitation technique. All fractions obtained were characterized by different techniques and the results are collected in *Table 1*. The isoprene content is essentially constant at around 7 mol %, and there is a large *MWD* (*Figure 2*).

Half-crystallization times of the fractions, measured at −25°C, plotted against their intrinsic viscosities, [η], show a parabolic shaped curve (*Figure 3*).

The effect of *MWD* on $t_{1/2}$ is shown by the position of the point referred to the initial unfractionated sample in
Figure 3 Half-crystallization time (+) at −25°C, and Avrami index (●) for fractions and for unfractionated (△,▽) cis-1,4-butadiene/isoprene copolymer *versus* intrinsic viscosity

the same Figure. The polydispersity accelerates $t_{1/2}$ in some synthetic elastomers[5−7] and in natural rubber[5] at equal viscosity-average molecular weight. It appears that $t_{1/2}$ of the polydispersed sample is determined by the fractions with highest crystallization rates. The melting temperature is essentially constant except for the last low *MW* fractions (*Figure 2*).

The Avrami index, n, shows a broad minimum for the fractions with the highest value of $t_{1/2}$ (*Figure 3*). The same dependence of n with MW is shown more distinctly by *cis*-1,4-polybutadiene (99% cis)[7]. These results and others[2–5,7] previously reported confirm that the dependence of $t_{1/2}$ on MW is also affected by a different nucleation mechanism.

ACKNOWLEDGEMENT

The author thanks Dr M. Bruzzone for useful discussions.

Temperature dependence of the unperturbed dimensions of poly(*p*-biphenyl methacrylate)

N. Hadjichristidis

Department of Industrial Chemistry, University of Athens, 13A Navarinou Street, Athens 144, Greece
(Received 9 June 1975; revised 24 June 1975)

INTRODUCTION

The temperature coefficient of the unperturbed dimensions, $d\ln\langle r_0^2\rangle/dT$, has a fundamental importance in the analysis of chain configuration of macromolecules[1-5]. This coefficient may be positive[6-8], zero[9,10] or negative[11-13] depending on the polymer and on the solvent[14]. In order to correlate this thermal coefficient with the chemical structure of the side groups of some polymethacrylate esters, we present here the results for poly(*p*-biphenyl methacrylate).

EXPERIMENTAL

The synthesis of the monomer, the preparation and the fractionation of poly(*p*-biphenyl methacrylate) have been published elsewhere[15]. Five fractions, F1 to F5, were selected for the work reported here. The fractions were analysed by gel permeation chromatography at 25°C in tetrahydrofuran (THF) with a Waters GPC 200 instrument. The polydispersity was 1.3 to 1.4.

Viscosities in benzene at various temperatures, 12.5°C to 60°C, were measured in a new type of sealed capillary viscometer[16] designed to have negligible kinetic energy correction. Solutions were prepared by weight and the concentration was corrected for the change of density with temperature.

Light scattering measurements were carried out at 25°C in benzene with a Sofica apparatus at 5460 Å. Dust free solutions and solvent were obtained by filtration through a flotronic membrane. The refractive index increment, dn/dc, under the same conditions, measured with a differential refractometer was 0.113 + 0.001 cm³/g.

RESULTS AND DISCUSSION

The weight-average molecular weight, $\overline{M}_w$ and the intrinsic viscosities, (η), in benzene at different temperatures are given in *Table 1*. The experimental values of the constants for the Mark–Houwink equation:

$$(\eta) = K_a \overline{M}_w^a$$

have been established at different temperatures by plotting

data of (η) against $\overline{M}_w$ on log–log coordinates. The results are given in *Table 2*.

By plotting the values of a vs. T (*Figure 1*) and extrapolating at $a = 0.5$ we obtain the θ-temperature of poly(*p*-biphenyl methacrylate) in benzene (11°C).

The value of K_θ leading to the unperturbed dimension $\langle r_0^2\rangle$:

$$K_\theta = \Phi(\langle r_0^2\rangle/M)^{3/2} \tag{1}$$

has been calculated by the well known and simple Stockmayer–Fixman relation[17]:

$$(\eta)M^{-1/2} = K_\theta + 0.51B\Phi M^{1/2}$$

The plots of $(\eta)\overline{M}_w^{-1/2}$ vs. $\overline{M}_w^{1/2}$ are linear in the entire molecular weight range.

Variation of K_θ with temperature is given in *Figure 2*. As shown in *Figure 2*, K_θ increases with increasing temperature but more rapidly in the range from 12.5° to 40°C($d\ln K_\theta/dT = 3.5 \times 10^{-3}$) than in the range from 40° to 60°C ($d\ln K_\theta/dT = 1.8 \times 10^{-3}$).

Table 2 Constants of the Mark—Houwink relation in benzene at different temperatures

T (°C)	$K_a \times 10^4$ (dl/g)	a
12.5	4.00	0.51
15	3.26	0.53
20	2.85	0.54₅
25	2.20	0.57
30	2.06	0.58
35	1.87	0.59
40	1.70	0.60
45	1.54	0.61
50	1.48	0.61₅
55	1.41	0.62
60	1.35	0.62₅

From equation (1), temperature coefficient of $\langle r_0^2 \rangle$ is obtained by:

$$d\ln\langle r_0^2 \rangle / dT = (2/3)d\ln K_\theta / dT$$

Consequently the value of the thermal coefficient of $\langle r_0^2 \rangle$ is 2.3×10^{-3} (from $12.5°$ to $40°C$) and 1.2×10^{-3} (from $40°$ to $60°C$). This dependence of $d\ln\langle r_0^2 \rangle / dT$ from the temperature has been reported elsewhere[18,19].

The β transition and frequency sensitivity in fatigue crack propagation of polymers

During the past decade, it has become clear that a number of mechanical phenomena in polymers are closely related to the location (in terms of temperature and frequency) and other characteristics of the β transition. As discussed by Oberst[1], Heijboer[2,3], Boyer[4], and Vincent[5], impact strength often undergoes a transition in the region of the β relaxation. Retting[6] and Bauwens[7] have shown that the yield stress of PVC is related to the relative position and intensity of the test conditions with respect to the β transition. Broutman and Kobayashi[8] observed that the fracture energy of PMMA was directly related to both the α (glass) and β (secondary) transitions. Johnson and Radon[9,10], have also shown that the time to failure in static tests with PMMA and PVC (at the ductile—brittle transition temperature) is approximately equal to the relaxation time of the β process at the same temperature. In this communication we wish to report an apparent correlation between the frequency dependence of fatigue crack propagation (FCP) in polymers and the frequency of the β transition at the test temperature concerned.

As part of a continuing study on FCP, an examination of the role of frequency, wave-form, and time under load was begun[11]. It was noted that the sensitivity of FCP to frequency varied widely from polymer to polymer. Thus, the crack growth rates of polycarbonate (PC) and nylon-6,6 were little affected by changing the frequency from 0.3 Hz to 10 Hz, while 2-fold to 3-fold effects (lower crack growth rates the higher the frequency) were observed for several other polymers such as PMMA and polystyrene(PS).

On examination of the data, it was then found that the behaviour appeared to be correlated with the estimated frequency of motion of the segments concerned with the β process at room temperature (~300 K). Values of this frequency were estimated by extrapolating or interpolating existing data gathered as follows: for PMMA, PC, PS, PVC, poly(vinylidene fluoride) (PVDF), and nylon-6,6 by McCrum et al.[12]; for poly(propylene oxide) (PPO) by de Petris et al.[13], Stoelting et al.[14] and Eisenberg and Cayrol[15]; and for polysulphone (PSF) by Butta et al.[16]. To characterize frequency response, a frequency sensitivity factor (FSF) was defined as the multiple by which the FCP rate changes per decade change in frequency. Values of FSF were determined at low mean stress levels ($R \leqslant 0.1$, where $R = K_{min}/K_{max}$, K being the stress intensity factor) in the range of intermediate crack velocities (around 10^{-5} cm/cycle). Figure 1 shows the relationship between the FSF and the frequency of the β process at the test temperature, and also indicates the range of frequencies used in the fatigue tests.

From the data presented, it certainly seems likely that the greatest sensitivity of FCP frequency occurs when the test frequency is close to the frequency of the β process. In all of the insensitive materials, the β frequency is far above the test range, while with the more sensitive materials the β frequency tends to be close to or within the test range. While a precise mechanistic explanation of the behaviour is not yet available, it seems likely that the
Figure 1 Relationship between FCP frequency sensitivity and the room temperature jump frequency for several polymers

behaviour reflects indirectly the tendency of a given polymer to undergo a crazing type of response, at least under the conditions used in these tests[17]. Thus all the polymers exhibiting high values of the FSF tend to fail through crazes under the test conditions used, while the other polymers do not. With the more sensitive polymers, a higher frequency may well inhibit the craze-related failure mechanism.

Estimation of the correlation length in polymer melts from nuclear magnetic relaxation dispersion

In this communication we use nuclear magnetic relaxation dispersion measurements for the estimation of the medium length of unidirectional chain orientation in poly(ethylene oxide) melts. This length is considered to be a characteristic size of the short-range order. Thus, a contribution to the discussion of the microstructure in polymer melts can be expected by this kind of investigation.

Molecular motion of molten polymers is anisotropic. We expect a rapid segment re-orientation fluctuation around the chain axis: this type of motion is connected with the diffusion of defects (e.g. kinks and torsions[1]) and will not completely destroy the autocorrelation of the dipolar interaction[2]. Considering for the moment only this anisotropic segment fluctuation process, we can express the unnormalized time autocorrelation function as the sum of a time dependent function $G_s(\tau)$, decreasing to zero at infinite times τ, and a constant term $|\overline{R}|^2$, characterizing the anisotropy of the motion. ($|\overline{R}|^2$ would be zero for isotropic motions.)

The remaining correlation $|\overline{R}|^2$ will be finally reduced to zero by any further process which completely destroys the memory to the initial chain orientation at a reference segment. We now define a correlation function $R(0)R^*(\tau)$ concerning this superimposed process. Assuming this type of motion to be slow compared with segment fluctuation, we may write for the total correlation function:

$$G(\tau) \approx G_s(\tau) + \overline{R(0)R^*(\tau)} = G_s(\tau) + |\overline{R}|^2\widetilde{G}_c(\tau) \qquad (1)$$

where we have introduced $\widetilde{G}_c(\tau)$ as the normalized auto-correlation function for the second process. [$G_s(\tau)$ is the time dependent contribution of segment re-orientation to the total correlation function.]

The dominant type of motion responsible for the final disorientation of the reference chain part is expected to be the longitudinal chain diffusion or 'reptation' defined by de Gennes[3]. The reference segment diffuses via defect diffusion on a curvilinear path along the chain's spatial configuration. After a certain diffusion path, the correlation to the initial segment orientation will be lost. Therefore, the time correlation function $G_c(\tau)$ consists of a configurational and a motional part.

We write:

$$\widetilde{G}_c(\tau) = \int_{-\infty}^{\infty} C(X)\eta(X, \tau)\,dX \qquad (2)$$

where $C(X)$ is the normalized orientation correlation function (with respect to the spatial coordinate dependent function R), and $\eta(X, \tau)$ is the probability that the reference segment diffuses a distance X during a period τ. Thus, the time correlation function $\widetilde{G}_c(\tau)$ is connected with a configurational correlation function.

The simplest, i.e. exponential, correlation function results if the stochastic problem is Poisson like. We therefore assume:

$$C(X) = \exp\left(-|X|/l\right) \qquad (3)$$

where l is the orientation correlation length. The solution of the one-dimensional diffusion equation yields:

$$\eta(X, \tau) = \frac{1}{2(\pi D_1 |\tau|)^{1/2}} \exp\left(-X^2/4D_1|\tau|\right) \qquad (4)$$

D_1 is the one-dimensional (i.e. curvilinear) diffusion coefficient of segments).

We find from equations (2) to (4):

$$\widetilde{G}_c(\tau) = \exp\left(D_1|\tau|/l^2\right)\left\{1 - \mathrm{erf}\left[(D_1|\tau|)^{1/2}/l\right]\right\} \qquad (5)$$

in agreement with the function found by Hunt and Powles[4] for a similar problem.

In the frequency range, slow compared with segment fluctuation rates, we obtain for the intensity function by Fourier transforming equation (1):

$$I(\omega_L) = I_s(o) + |\overline{R}|^2 \frac{\tau_l^{1/2}}{\omega_L^{1/2}(1 + 2\omega_L^{1/2}\tau_l + 2\omega_L\tau_l)} \qquad (6)$$

with $\tau_l = l^2/2D_1$. The constant term $I_s(o)$ arises from segment fluctuation.

For the longitudinal relaxation rate it holds then[5]:

$$\frac{1}{T_1} = |\overline{R}|^2 \left[k + \frac{\tau_l^{1/2}}{\omega_L^{1/2}(1 + 2\omega_L^{1/2}\tau_l^{1/2} + 2\omega_L\tau_l)} + \frac{4\tau_l^{1/2}}{(2\omega_L)^{1/2}[1 + 2(2\omega_L\tau_l)^{1/2} + 4\omega_L\tau_l]}\right] \qquad (7)$$

The constant k contains the contribution of segment re-orientation in the extreme narrowing condition (divided by $|\overline{R}|^2$). In this equation we have three parameters: τ_l, k and $|\overline{R}|^2$. The latter merely influences the absolute value of the relaxation rate and can therefore easily be fitted to experimental values.

In *Figure 1* the experimental T_1-dispersion of poly(ethylene oxide) melts is plotted in the range $\omega_L = 5 \times 10^4 \ldots 5 \times 10^6$ Hz. The data are taken from ref.6 and were obtained by the aid of a field modulation technique[7].

Typical orders of magnitude for segment re-orientation rates for this kind of polymers were found to be in the range $10^{10} \ldots 10^{12}$ Hz [8,9]. Thus, even if this re-orientation process is 'broadened' by environmental fluctuations[2], we may assume the extreme narrowing case for the segmental contribution, and equation (7) can be used for the interpretation of the measurements.

Good agreement between the theoretical and the experimental slope of the dispersion curves was found for $\tau_l \leqslant 2.6 \times 10^{-8}$ sec. In order to derive the curvilinear dif-

Estimation of the correlation length in polymer melts from nuclear magnetic relaxation dispersion

In this communication we use nuclear magnetic relaxation dispersion measurements for the estimation of the medium length of unidirectional chain orientation in poly(ethylene oxide) melts. This length is considered to be a characteristic size of the short-range order. Thus, a contribution to the discussion of the microstructure in polymer melts can be expected by this kind of investigation.

Molecular motion of molten polymers is anisotropic. We expect a rapid segment re-orientation fluctuation around the chain axis: this type of motion is connected with the diffusion of defects (e.g. kinks and torsions[1]) and will not completely destroy the autocorrelation of the dipolar interaction[2]. Considering for the moment only this anisotropic segment fluctuation process, we can express the unnormalized time autocorrelation function as the sum of a time dependent function $G_s(\tau)$, decreasing to zero at infinite times τ, and a constant term $|\bar{R}|^2$, characterizing the anisotropy of the motion. ($|\bar{R}|^2$ would be zero for isotropic motions.)

The remaining correlation $|\bar{R}|^2$ will be finally reduced to zero by any further process which completely destroys the memory to the initial chain orientation at a reference segment. We now define a correlation function $R(0)R^*(\tau)$ concerning this superimposed process. Assuming this type of motion to be slow compared with segment fluctuation, we may write for the total correlation function:

$$G(\tau) \approx G_s(\tau) + \overline{R(0)R^*(\tau)} = G_s(\tau) + |\bar{R}|^2 \tilde{G}_c(\tau) \qquad (1)$$

where we have introduced $\tilde{G}_c(\tau)$ as the normalized autocorrelation function for the second process. [$G_s(\tau)$ is the time dependent contribution of segment re-orientation to the total correlation function.]

The dominant type of motion responsible for the final disorientation of the reference chain part is expected to be the longitudinal chain diffusion or 'reptation' defined by de Gennes[3]. The reference segment diffuses via defect diffusion on a curvilinear path along the chain's spatial configuration. After a certain diffusion path, the correlation to the initial segment orientation will be lost. Therefore, the time correlation function $G_c(\tau)$ consists of a configurational and a motional part.

We write:

$$\tilde{G}_c(\tau) = \int\limits_{-\infty}^{\infty} C(X)\eta(X, \tau)\,dX \qquad (2)$$

where $C(X)$ is the normalized orientation correlation function (with respect to the spatial coordinate dependent function R), and $\eta(X, \tau)$ is the probability that the reference segment diffuses a distance X during a period τ. Thus, the time correlation function $\tilde{G}_c(\tau)$ is connected with a configurational correlation function.

The simplest, i.e. exponential, correlation function results if the stochastic problem is Poisson like. We therefore assume:

$$C(X) = \exp(-|X|/l) \qquad (3)$$

where l is the orientation correlation length. The solution of the one-dimensional diffusion equation yields:

$$\eta(X, \tau) = \frac{1}{2(\pi D_1|\tau|)^{1/2}} \exp(-X^2/4D_1|\tau|) \qquad (4)$$

D_1 is the one-dimensional (i.e. curvilinear) diffusion coefficient of segments).

We find from equations (2) to (4):

$$\tilde{G}_c(\tau) = \exp(D_1|\tau|/l^2)\left\{1 - \mathrm{erf}[(D_1|\tau|)^{1/2}/l]\right\} \qquad (5)$$

in agreement with the function found by Hunt and Powles[4] for a similar problem.

In the frequency range, slow compared with segment fluctuation rates, we obtain for the intensity function by Fourier transforming equation (1):

$$I(\omega_L) = I_s(o) + |\bar{R}|^2 \frac{\tau_l^{1/2}}{\omega_L^{1/2}(1 + 2\omega_L^{1/2}\tau_l + 2\omega_L\tau_l)} \qquad (6)$$

with $\tau_l = l^2/2D_1$. The constant term $I_s(o)$ arises from segment fluctuation.

For the longitudinal relaxation rate it holds then[5]:

$$\frac{1}{T_1} = |\bar{R}|^2 \left[k + \frac{\tau_l^{1/2}}{\omega_L^{1/2}(1 + 2\omega_L^{1/2}\tau_l^{1/2} + 2\omega_L\tau_l)} + \frac{4\tau_l^{1/2}}{(2\omega_L)^{1/2}[1 + 2(2\omega_L\tau_l)^{1/2} + 4\omega_L\tau_l]} \right] \qquad (7)$$

The constant k contains the contribution of segment re-orientation in the extreme narrowing condition (divided by $|\bar{R}|^2$). In this equation we have three parameters: τ_l, k and $|\bar{R}|^2$. The latter merely influences the absolute value of the relaxation rate and can therefore easily be fitted to experimental values.

In *Figure 1* the experimental T_1-dispersion of poly(ethylene oxide) melts is plotted in the range $\omega_L = 5 \times 10^4 \ldots 5 \times 10^6$ Hz. The data are taken from ref.6 and were obtained by the aid of a field modulation technique[7].

Typical orders of magnitude for segment re-orientation rates for this kind of polymers were found to be in the range $10^{10} \ldots 10^{12}$ Hz [8,9]. Thus, even if this re-orientation process is 'broadened' by environmental fluctuations[2], we may assume the extreme narrowing case for the segmental contribution, and equation (7) can be used for the interpretation of the measurements.

Good agreement between the theoretical and the experimental slope of the dispersion curves was found for $\tau_l \leqslant 2.6 \times 10^{-8}$ sec. In order to derive the curvilinear dif-

Figure 1 Theoretical curves of the T_1^{-1} dispersion according to equation (7) for diverse values of k (constant term of equation 7). The experimental data[6] concern a poly(ethylene oxide) melt at 344K (M = 27 000). They are compatible with the theoretical curves in a certain range of k, leading to a range τ_l = 1 x 10^{-9} . . . 3 x 10^{-8} sec. The ω_L-scale and the plotted theoretical curves correspond to τ_l = 2.6 x 10^{-8} sec and $|R|^2$ = 8.3 x 10^4 sec^{-2}. ——, k = 0; A, k = 2.7 x 10^{-8}; B, k = 2.7 x 10^{-7}; C, k = 2.7 x 10^{-6}; D, k = 8.1 x 10^{-6}; E, k = 2.7 x 10^{-5}; F, k = 5.4 x 10^{-5}; G, k = 8.1 x 10^{-5}; H, k = 2.7 x 10^{-4} sec

fusion coefficient from the value found from three-dimensional measurements, we have to take into consideration the configuration of the chain. Limiting cases are fully stretched chains and randomly coiled chains.

Estimating the curvilinear diffusion coefficient from field gradient data[10], we thus find the range: 2 x 10^{-8} cm^2/sec $< D_1 < 2$ x 10^{-6} cm^2/sec. The correlation length l should therefore be essentially shorter than 30 Å.

The basic assumptions of the suggested interpretation are the dominance of the 'reptation' diffusion process and the validity of the one-dimensional diffusion equation for this process. The complete discussion would exceed the scope of this Letter and will be the subject of a subsequent paper.

A formula for the β-relaxation in polymers

The β-loss peak in polymers is asymmetric in shape in the temperature domain, being steeper on the high temperature side (it can be the opposite in a few cases). In polymers such as poly(vinyl fluoride) (PVF), where it is well resolved from the α peak, the β peak may be extrapolated on the steeper side to meet the temperature axis at a point, such as T_c, in *Figure 1*. T_c may be taken approximately as the temperature at which the β process would tend to vanish, as the α process becomes more favoured. 'Cut-off' procedures of this kind are known to yield good approximations to the actual situations and to simplify mathematical treatments, e.g. the Debye treatment of specific heat.

A recently published formula due to Jonscher[1] described dielectric loss in polymers as a function of frequency. No formula as yet exists in the literature, which gives loss as a function of temperature. We report here the loss formula:

$$\tan \delta = A(\omega) \left[\frac{1}{B(T_c - T)} \right]^2 \text{sech}^2 \left[\frac{1}{B(T_c - T)} \right] \quad (1)$$

which has been found to agree very well with the dielectric β-relaxation data for a number of amorphous and partly crystalline polymers that have been investigated by the author. In equation (1), T_c is the β cut-off temperature, as introduced above; and T is any temperature within the relaxation region at which dielectric loss is being measured. B is a constant, which was found to be 1.427 x 10^{-2} K^{-1}, for all the polymers investigated. $A(\omega)$ is a frequency-dependent amplitude. Equation (1) is a peaked function, for which the temperature of maximum loss, T_m, is related to T_c via:

$$B|T_c - T_m| = 1.2 \quad (2)$$

$A(\omega)$ is also related to the maximum loss, $(\tan \delta)_{\text{max}}$, by:

$$A(\omega) = (\tan \delta)_{\text{max}}/0.44 \quad (3)$$

which is the normalization condition.

To fit experimental data to equation (1), all that has to be done is to match the maximum of equation (1) to that of the experimental curve, using the experimental value of T_m and the normalization condition (3), and then determining the value of T_c which gives the best fit. Clearly T_c is an adjustable parameter.

A typical agreement between equation (1) and experimental data is as shown in *Figure 2* for PVF. Other poly-

Figure 1 A typical β peak and the high temperature cut-off procedure

Figure 1 Theoretical curves of the T_1^{-1} dispersion according to equation (7) for diverse values of k (constant term of equation 7). The experimental data[6] concern a poly(ethylene oxide) melt at 344K ($\overline{M}$ = 27 000). They are compatible with the theoretical curves in a certain range of k, leading to a range τ_l = 1 x 10^{-9} ... 3 x 10^{-8} sec. The ω_L-scale and the plotted theoretical curves correspond to τ_l = 2.6 x 10^{-8} sec and $|R|^2$ = 8.3 x 10^4 sec^{-2}. ——, k = 0; A, k = 2.7 x 10^{-8}; B, k = 2.7 x 10^{-7}; C, k = 2.7 x 10^{-6}; D, k = 8.1 x 10^{-6}; E, k = 2.7 x 10^{-5}; F, k = 5.4 x 10^{-5}; G, k = 8.1 x 10^{-5}; H, k = 2.7 x 10^{-4} sec

fusion coefficient from the value found from three-dimensional measurements, we have to take into consideration the configuration of the chain. Limiting cases are fully stretched chains and randomly coiled chains.

Estimating the curvilinear diffusion coefficient from field gradient data[10], we thus find the range: 2 x 10^{-8} cm^2/ sec $< D_1 < 2$ x 10^{-6} cm^2/sec. The correlation length l should therefore be essentially shorter than 30 Å.

The basic assumptions of the suggested interpretation are the dominance of the 'reptation' diffusion process and the validity of the one-dimensional diffusion equation for this process. The complete discussion would exceed the scope of this Letter and will be the subject of a subsequent paper.

A formula for the β-relaxation in polymers

The β-loss peak in polymers is asymmetric in shape in the temperature domain, being steeper on the high temperature side (it can be the opposite in a few cases). In polymers such as poly(vinyl fluoride) (PVF), where it is well resolved from the α peak, the β peak may be extrapolated on the steeper side to meet the temperature axis at a point, such as T_c, in *Figure 1*. T_c may be taken approximately as the temperature at which the β process would tend to vanish, as the α process becomes more favoured. 'Cut-off' procedures of this kind are known to yield good approximations to the actual situations and to simplify mathematical treatments, e.g. the Debye treatment of specific heat.

A recently published formula due to Jonscher[1] described dielectric loss in polymers as a function of frequency. No formula as yet exists in the literature, which gives loss as a function of temperature. We report here the loss formula:

$$\tan \delta = A(\omega) \left[\frac{1}{B(T_c - T)} \right]^2 \text{sech}^2 \left[\frac{1}{B(T_c - T)} \right] \quad (1)$$

which has been found to agree very well with the dielectric β-relaxation data for a number of amorphous and partly crystalline polymers that have been investigated by the author. In equation (1), T_c is the β cut-off temperature, as introduced above; and T is any temperature within the relaxation region at which dielectric loss is being measured. B is a constant, which was found to be 1.427 x 10^{-2} K^{-1}, for all the polymers investigated. $A(\omega)$ is a frequency-dependent amplitude. Equation (1) is a peaked function, for which the temperature of maximum loss, T_m, is related to T_c via:

$$B|T_c - T_m| = 1.2 \quad (2)$$

$A(\omega)$ is also related to the maximum loss, $(\tan \delta)_{max}$, by:

$$A(\omega) = (\tan \delta)_{max}/0.44 \quad (3)$$

which is the normalization condition.

To fit experimental data to equation (1), all that has to be done is to match the maximum of equation (1) to that of the experimental curve, using the experimental value of T_m and the normalization condition (3), and then determining the value of T_c which gives the best fit. Clearly T_c is an adjustable parameter.

A typical agreement between equation (1) and experimental data is as shown in *Figure 2* for PVF. Other poly-

Figure 1 A typical β peak and the high temperature cut-off procedure

Figure 2 A comparison between equation (1) and experimental data for PVF at 1 kHz

mers which were studied and found to show similar agreement are phenoxy resin; poly(ether sulphone), poly(ethylene terephthalate) and a poly(vinyl chloride)— poly(vinylidene chloride) copolymer, at frequencies from 100 Hz to 100 kHz. Polysulphone showed fairfly good agreement above 1 kHz. Equation (1) was applied to the glass—rubber relaxation in poly(vinylidene fluoride), and agreement was fairly good.

Book Reviews

Plastics materials
J. A. Brydson
Newnes—Butterworths, London, 1975. 3rd Edn. 731 pp. £13.75

This book aims at providing an account of the preparation and properties of all the important plastic materials in a single large volume. It is, of course, based on previous editions of the same work though these have been updated, e.g. by adding information on two phase polymers and by including a useful chapter on additives in plastics.

The book consists essentially of two parts, the first part in which the general properties of plastics are outlined and the second, and larger part, where the various plastics materials are described in turn. The latter includes chapters on virtually all the commercially significant plastics in use today.

A book of this type makes very formidable demands on the author concerned, more particularly as it is often difficult to locate authoritative descriptions of the different processes used for manufacturing plastics. Generally the book maintains a satisfactory standard, but inevitably, a reviewer looks at certain parts from the standpoint of his own particular expertise, and such an examination reveals some limitations.

For example the level of low strain modulus in rigid plastics (D_{OE} in Tucket's original classification) is now generally explained in terms of intermolecular forces and not due to bond bending, which has been shown by Sakurada and Treloar to lead to much higher modulus figures. Again in the suspension polymerization of styrene, it is not true that 70% of the kettle is taken up by water. Generally more than 50% by volume of monomer is used along with a stabilizer which is often a special calcium phosphate [but not poly(vinyl alcohol)]. This, of course, makes the process more viable compared with the bulk process than would otherwise be the case.

The reviewer understands that the complete elimination of errors of this type in a comprehensive work is not at all easy.

Generally the information given is satisfactory but the reader should be wary of taking the process details given as authoritative. With this reservation the book may be recommended as a useful starting point for the understanding and comparison of different plastic materials.

Selected papers on rheology
Markus Reiner
Elsevier, Amsterdam, 1975. 463 pp. Dfl. 110

Rheology, the study of deformation and flow, is generally accepted to have been born, as a separate science, about fifty years ago. This book is a record of and tribute to one man's contribution during the first fifty years.

Professor Reiner has played a stimulating central role in the development of this subject: his best known work 'Deformation and Flow' is still one of the most readable general texts available. The most appealing aspect of this work is the broad range of materials and concepts which it embraces. From the volumetric creep of concrete to considerations of the rigidity of gases the author is at his best in the description and discussion of phenomena. Professor Reiner is also a pioneer and adept of 'spring and dashpot' imagery — a powerful tool though now largely neglected. The theoretical aspect of the 'Selected Papers' makes a less satisfying pattern and the reader is left with a suspicion that this collection represents a defence of the author's views as well as a statement thereof. It is true that some of Professor Reiner's views are unfashionable today but they need no defence. In a young science where everything flows views are bound to change as new evidence becomes available and in the last fifteen years the abundance of experimental and theoretical work on polymers, an area in which Professor Reiner has done little work himself, has shifted the balance within rheology. Times will change again.

Figure 2 A comparison between equation (1) and experimental data for PVF at 1 kHz

mers which were studied and found to show similar agreement are phenoxy resin; poly(ether sulphone), poly(ethylene terephthalate) and a poly(vinyl chloride)– poly(vinylidene chloride) copolymer, at frequencies from 100 Hz to 100 kHz. Polysulphone showed fairfly good agreement above 1 kHz. Equation (1) was applied to the glass–rubber relaxation in poly(vinylidene fluoride), and agreement was fairly good.

R. N. Haward

Selected papers on rheology
Markus Reiner
Elsevier, Amsterdam, 1975. 463 pp. Dfl. 110

Rheology, the study of deformation and flow, is generally accepted to have been born, as a separate science, about fifty years ago. This book is a record of and tribute to one man's contribution during the first fifty years.

Professor Reiner has played a stimulating central role in the development of this subject: his best known work 'Deformation and Flow' is still one of the most readable general texts available. The most appealing aspect of this work is the broad range of materials and concepts which it embraces. From the volumetric creep of concrete to considerations of the rigidity of gases the author is at his best in the description and discussion of phenomena. Professor Reiner is also a pioneer and adept of 'spring and dashpot' imagery – a powerful tool though now largely neglected. The theoretical aspect of the 'Selected Papers' makes a less satisfying pattern and the reader is left with a suspicion that this collection represents a defence of the author's views as well as a statement thereof. It is true that some of Professor Reiner's views are unfashionable today but they need no defence. In a young science where everything flows views are bound to change as new evidence becomes available and in the last fifteen years the abundance of experimental and theoretical work on polymers, an area in which Professor Reiner has done little work himself, has shifted the balance within rheology. Times will change again.

For the man interested in the flow of polymers this book is a firm reminder that there are other materials. In indicating the broader horizon this collection of papers will be found both stimulating and challenging.

F. N. Cogswell

Kinetics and mechanisms of polymerisation reactions
P. E. M. Allen and C. R. Patrick
Ellis Horwood, Chichester, 1974. 596 pp. £18.00

This book carries a main sub-title — Applications of physico-chemical principles — and the authors have really kept to this objective as indicated by the seven chapter headings: Basic physical chemistry of polymerization reactions, diffusion-controlled reactions, Chain reactions in polymerizations, Thermodynamics of polymerization processes, Polyesterification and polyamidation, Reactivity of radicals and ions and the susceptibility of unsaturated and cyclic compounds to their attack, Kinetics of addition polymerization.

Overall the book is extremely well written and well researched. It contains many lists of rate coefficients for the various propagation processes in chain reaction polymerization and will be very useful to active workers in the field. As might be expected, from the research interests of the authors, the chapters on diffusion effects and chain reactions are particularly informative and well presented.

Whilst the objective of integrating reactivity of active intermediates in both polymerization and small molecule processes is to be commended, there must be some reservation as to the method chosen in this particular book. Thus chapter 6 entitled Reactivity of radicals and ions etc. comprises 140 pages of text and really is a somewhat arbitary compilation of electrophilic, nucleophilic and radical reactions. There are many existing textbooks in physical organic chemistry which provide better discussions of these topics. Similarly the final, and very important, chapter dealing with kinetics of addition polymerization, treats the subject as a whole without any major separation into radical, cationic, anionic etc. processes. Whilst this approach is both novel and readily comprehended by those expert in the field it will be much less valuable to readers drawn from other areas of polymer science or physical organic chemistry.

In summary the book is extremely well presented and is strongly recommended to those concerned with kinetics of polymerization processes. It is remarkably free from typographical errors but, at the price, it is not likely to be acquired for personal use by the general body of polymer scientists.

A. Ledwith

Immobilized enzymes: preparation and engineering techniques
S. J. Gutcho
Noyes Data Corporation, Park Ridge, NJ, 1974. 198 pp. $36.00

This book consists almost entirely of a series of abstracts of relevant United States patents. Each abstract contains detailed technical information which will be valuable to researchers wishing to design their own immobilization procedures and enzyme derivatives described because the author often leaves this aspect to emerge solely from the factual abstracts. In general, the author's personal contribution by way of informed discussion and criticism is minimal.

The text includes a forward and list of points expressing the importance of information gathered from the US patent literature. Doubtless most of the arguments presented are valid but the book as a whole leaves one with the feeling that a much more balanced and informative account would have resulted if the author had drawn also on the learned journals for his material. The claim is made that innovations derived from research are frequently first disclosed in the patent literature. However, in many instances, this is not the case. It is recognized that many research workers file provisional patents immediately prior to publication in the periodical literature. The latter may be in print before a complete patent specification is on file, let alone examined and published. Furthermore, a number of important and far reaching discoveries in immobilized enzyme technology have not been the subject of patent application.

Just over 170 pages of the text are devoted to patents dealing with the synthesis and properties of enzyme conjugates. Much of the experimental information has not been abstracted in such detail elsewhere and, as such, is of value. The reviewer found a number of passages repetitive and, consequently, boring. For example, the basic advantages of immobilized enzymes, including ease of recovery, re-use potential and improved stability to heat denaturation and storage, are restated several times. Too often a given abstract reviews irrelevant or very elementary material such as the state of the art at the date of filing, the general methods available for enzyme immobilization or the relatively few current commercial applications.

A mere 20 pages are devoted specifically to enzyme reactors and detailed applications. It is an inevitable consequence of the method of selecting material that the section on engineering techniques leaves much to be desired. There is a lack of information on enzyme reactors employing magnetic separators and fluidized beds.

Another deficiency is the lack of an alphabetical subject index. The device of presenting a combined table of contents and subject index is inadequate. For example, it is no easy task to find all the references in the text to a particular enzyme. On the other hand, the inclusion of separate company, inventor and patent indexes is useful.

Newcomers to the subject will find it difficult to gain an understanding in depth of such essential problems in enzyme immobilization as matrix and conjugate micro-architecture, compatability considerations and mechanisms of enzyme stabilization. However, the book will be of value to those with established interests in the field or with extensive knowledge of practical enzymology. It is sturdily bound and would be a useful laboratory handbook.

R. Epton

Structural polymers — testing methods, Volumes I and II
P. M. Ogibalov, N. I. Malinin, V. P. Netreko and B. P. Kishkin (translated from the Russian)
John Wiley, London & New York, 1974. 600 pp. £22.10

This 600 page work is not, as the title suggests a handbook of standard test methods. It comprises a collection of treatises on a variety of topics related to the physical properties of polymers. Subjects covered include various types of mechanical tests, viscoelastic theory, environmental effects and stress optical behaviour with shorter sections on processing stresses, adhesion and data analysis. With the exception of some useful details of Russian testing instruments the general emphasis is on the theoretical considerations underlying various test methods and hence the book will appeal more to the postgraduate student concerned with theoretical aspects of polymer behaviour than the industrial polymer technologist. As a concise summary, well translated by present standards, of current Russian literature the book is undoubtedly a success and it contains much information which is not otherwise readily available. Composite materials and in particular GRP are treated in particular detail but here, as in other areas, the general usefulness of the text would have been greatly increased by the inclusion of more examples describing the applications of the theories discussed to real situations. A more minor comment also cocerns the extensive use of Russian designations for materials, tests and instruments which without further details renders some of the text difficult to follow. For these reasons coupled with the relatively high cost it is doubtful if the book will enjoy a wide readership but it is certainly a useful addition to the reference library and with the exception of the photographic plates the presentation and reproduction is of a high standard.

Developments with thermosetting plastics
Edited by A. Whelan and J. A. Brydson
Applied Science, London. 1975. 198 pp. £7.00

Thermosetting plastics account for 25–30% of the total plastics consumed in Britain and this timely review contains eleven papers written by practising industrial specialists in the thermosetting plastics field originally presented at a symposium at the National College of Rubber Technology, London. Authoritative accounts are given of materials currently developed or in which there is present industrial interest and most of the contributions are well to the fore in achieving their objectives with special attention to economic trends of up and coming grades, crosslinking reagents and applications to 1972–73.

The first chapter is concerned with trends, prospects, and tonnages of materials used followed by five chapters covering separately amino resins, polyesters, Friedel–Crafts resins, furane resins, and polyurethanes. These are followed by another five chapters reviewing a selected number of processing technology aspects specific to powder coating, polyurethane foam processing, fire reinforced plastics, and injection moulding of thermosets.

Emphasis is on practice, only the minimum of theory necessary to understand the text being given and resulting in a lucid easily read text of interest to the general technical reader rather than a specialist in the field. Nevertheless all who are professionally active in this field should find it a considerable convenience to have this state of the art review in a single slim volume.

Editing has been to a good standard and no errors noted though meticulous transcription of all units to apparent SI nomenclature has produced its share of strange bedfellows. A reasonable index is provided; paper, printing quality, and binding is acceptable and the price, while high for a book of moderate length and simple line diagrams, probably necessary when a limited specialist circulation is envisaged. In brief this is a useful addition to topical literature in the thermosetting plastics field.

C. Hepburn

The mathematics of diffusion
J. Crank
Clarendon Press, Oxford, 1975. 2nd Edn. 414 pp. £12.50

Since the first edition appeared in 1956 this book has become one of the most important reference texts for those interested in diffusion problems. This is shown by referring to *Science Citation Index* which has listed almost 200 references every year to this book. Relatively few of these citations have been in polymer journals and in view of the increasing importance of polymers in diffusion technology it is particularly interesting that this new edition includes two extra chapters that are of special relevance to the polymer scientist. The first of these deals with the so-called non-Fickian diffusion and gives a very valuable summary of the mathematics of the time dependent diffusion effects that occur in glassy polymers. The second new chapter on heterogeneous media includes a synoptic examination of past mathematical solutions relating to diffusion in layer structures and to the geometrical effects of fillers and crystallites on diffusion. This chapter also includes the author's most recent work in this field.

The other thirteen chapters in this second edition are expanded versions of those in the first edition and include many of the recent mathematical developments of the last 20 years. Chapter 8, however, on numerical methods has been practically completely redone to tie in with the modern use of high speed digital computers. It enables a novice to work out the answers for himself in simple diffusion situations and to understand what is involved in more complicated problems. The clear and unambiguous style of writing of the new edition, like that of the first edition, will make it extremely useful to those who are interested in diffusion but are not mathematical specialists.

The book is nicely produced and is good value at a cost of about 3p per page. Every polymer scientist with an interest in diffusion will find it necessary to have access to this book.

Announcing a new international journal from IPC Science and Technology Press

APPLIED MATHEMATICAL MODELLING

ADVANCES IN NUMERICAL SIMULATION APPLICABLE TO ENVIRONMENTAL, SOCIAL & ENGINEERING PROBLEMS

Editor Dr. C. A. Brebbia Southampton University Southampton SO9 5NH, UK

Associate Editor Professor J. J. Connor Massachusetts Institute of Technology, Cambridge, Mass. 02139, USA

The journal will aim to coordinate the recent rapid advances in mathematical modelling as applied to multidisciplinary problems. Special emphasis will be given to the practical applicability, the reliability of the models, and the adequacy of the mathematical formulae and the numerical techniques used. Associated computer techniques will also fall within the scope of the journal.

APPLIED MATHEMATICAL MODEL-LING will feature mainly short communications (approx. 3000 equivalent words), which will be published in less than six months. Longer papers and review papers covering specific fields of application will also appear.

To minimize delays in publication, the Editors will ensure rapid refereeing of all contributions. Manuscripts should be sent in triplicate to the Editor.

The cost of a one year subscription (four issues) to APPLIED MATHEMATICAL MODELLING will be £25.00 ($65.00) but you can order your first year's copies NOW at the special pre publication offer price of £18.00 ($46.80) if ordered before 31st March 1976.

To be published quarterly in 1976 commencing with June issue

Heat capacity of copolymers of chlorotrifluoroethylene and vinylidene fluoride

K. C. Wong, F. C. Chen and C. L. Choy

Department of Physics, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong
(Received 19 May 1975; revised 16 June 1975)

The heat capacities of two copolymers of chlorotrifluoroethylene and vinylidene fluoride, one 30:70 mol % and the other 44:56 mol % in composition, were measured in an adiabatic calorimeter from 80 to 340 K. The glass-transition points T_g observed at 256 and 269 K for the 30:70 and 44:56 samples, respectively, closely agree with the prediction of the theory of Flory and Fox; the accompanying jump of heat capacities at these points was found to be 2.2 cal/K 'per bead' for both samples, in fair agreement with the 'constant ΔC_p rule'. A small peak was observed immediately above T_g, and interpreted as a time-dependent effect arising from the lack of equilibrium in the region. The data of the heat capacities were analysed in detail in the framework of the Tarasov model and the principle of additivity, and were found to agree well ($\lesssim$ 1–3%) with theory up to the respective glass-transition points in all cases, thus giving support to the validity of the previously published segmental values of heat capacity and of characteristic temperature θ_1.

INTRODUCTION

In a previous paper[1] we reported measurements of the heat capacity of a copolymer of ethylene and tetrafluoroethylene (TFE), and showed that the results could well be understood in the framework of the Tarasov model[2] and the principle of additivity[3]. We also extracted the heat capacities of the four segments CH_2, CF_2, CHF and CFCl from an analysis of the available heat capacities of TFE, polyethylene (PE) and four other fluoropolymers, and showed that the characteristic temperature θ_1 in the Tarasov model roughly obeys additivity, too.

Similar measurements in the temperature range 80 to 340 K have now been completed on two copolymers of chlorotrifluoroethylene and vinylidene fluoride (CTFE/VF_2), one 30:70 mol % and the other 44:56 mol % in composition. The results give further support to the above-mentioned framework, and confirm the validity of the segmental values of the heat capacities and of θ_1 obtained in the previous work[1]. In addition, we have observed the glass-transition in both copolymers, and discussed the behaviour of the heat capacity around the transition regions.

EXPERIMENTAL

The two CTFE/VF_2 samples used in this experiment were obtained from the Minnesota Mining and Manufacturing Company and bear the trade names Kel-F 3700 and Kel-F 5500, respectively. Kel-F 3700 is known to contain 30 mol % of CTFE, but there is some slight uncertainty as to the exact molar composition of Kel-F 5500[4,5]. The data have therefore been analysed on the assumption of various compositions ranging from 44 to 56 mol % content of CTFE, but all were found to yield nearly exactly the same results and features. In the rest of this paper we shall follow Wall and Florin[4,5] and simply take the CTFE content of Kel-F 5500 to be 44 mol %.

The sample stocks in the form of a white rubbery foam were cut into small pieces, and approximately 70 g were used for each measurement of heat capacity at constant pressure C_p from 80 to 340 K in an adiabatic calorimeter. Details of the measurement have already been reported previously[6] and will not be repeated here.

RESULTS AND DISCUSSION

The smoothed data on C_p obtained from 2 to 3 runs on each of the two samples are shown in *Figures 1* and *2*. A repeat unit of the copolymer is defined to consist of two chain atoms, so that the effective molecular weights of the 30:70 and 44:56 mol % samples are 79.7657 and 87.1066, respectively.

Transitions

The heat capacity curves show a jump and then a change of slope at 256 and 269 K for the 30:70 and 44:56 mol % samples, respectively. These can readily be identified with the glass-transition points T_g of the copolymers. If we apply the phenomenological theory of Fox and Flory[7] and assume that the inverse of the glass-transition temperatures of the constituent homopolymers (T_g = 228 K for PVF_2[8] and = 325 K for $PCTFE$[9]) combine linearly by their respective weight fractions then the two resultant T_g values for the copolymers come out respectively to be 262 and 277 K, which are within 3% of the above experimental values.

The jump ΔC_p in heat capacity at T_g is 18 J/K mol for both samples, or 2.2 cal/K 'per bead' which is on the low side but still in fair agreement with the 'constant ΔC_p rule', i.e. ΔC_p = 2.7 ± 0.5 cal/K bead[3].

We also observe a small peak in the C_p curve immediately above T_g (*Figure 3*). The measurement was then scanned three times through the transition region in 0.8–2.5 K steps on the 44:56 mol % sample. Since all the points obtained in
Figure 1 Heat capacity of 30:70 mol % CTFE/VF$_2$. I, Acoustical contribution calculated from the Tarasov model; II, optical contribution; III, total heat capacity, C_V; ●, observed values of C_p; — — —, linear combinations of segmental values; ......, linear combinations of experimental values of C_p for PCTFE and PVF$_2$
these latter runs lie consistently on the same smooth curve, the peak seems to be quite genuine. The same phenomenon in many other polymers has been studied systematically by differential thermal analysis[10], and it is believed to be a time-dependent effect arising from the lack of equilibrium in the glass-transition region through relatively fast heating. In this respect we note that in each run of our experiment the sample was cooled down very slowly through the transition region at a rate of 2–5 K/h and under high vacuum, while the equilibrium time allowed for each measured point at 0.8 to 2.5 K intervals was about 2–5 min, amounting to an effective heating rate of about 0.2–0.5 K/min, considerably lower than the heating rates reported earlier[10].

The Tarasov model

The Tarasov model[2] approximates the acoustical vibrations of a polymer by those of a one-dimensional continuum superimposed on a three-dimensional continuum, with respective cut-off temperatures θ_1 and θ_3; the optical vibrations are calculated from the spectroscopic data, with the assumption that each mode gives rise to a sharp line. The heat capacity of a polymer is then calculated from the resultant vibrational spectrum. The analysis of the experimental results in this model is practically identical to our previous work[1,6]: the optical contribution to C_v (heat capacity at constant volume) of the copolymer is obtained by a linear combination of the optical contributions to C_v of the constituent homopolymers deduced from their respective spectral lines[8,11], in proportion to their respective molecular fractions; 4 acoustical modes with identical characteristic temperatures θ_1 and θ_3 are assigned to each repeat unit; θ_3 (which does not affect C_v appreciably in our temperature

Figure 2 Heat capacity of 44:56 mol % CTFE/VF$_2$. The legends are as given in the caption to *Figure 1*
Figure 3 Details of the peak at the glass-transition region of 44:56 mol % CTFE/VF$_2$: △, ▽ and □ are experimental points of three separate scans at 0.8 to 2.5 K intervals; X and ○ are points obtained at 4 to 5 K intervals, and hence not reliable in the vicinity of the peak. The solid line is drawn freely through the more reliable experimental points △, ▽ and □

Table 1 Additivity of θ_1

Sample (mol %)	Observed[a] values	Calculated values	
		1[b]	2[c]
30:70	320	320 (0%)	334 (4%)
44:56	290	303 (5%)	314 (8%)

[a] Obtained by a direct fit of the Tarasov model to experimental data

[b] Calculated from the appropriate linear combination of the observed values for PCTFE and PVF$_2$, as given by refs 6 and 10

[c] Calculated from the appropriate linear combination of the segmental values given by ref. 1

range) is set quite arbitrarily to 70 K, midway between the values for PVF$_2$ and PCTFE, and θ_1 is adjusted for the best fit to data up to 200 K. The results are θ_1 = 320 K for the 30:70 mol % CTFE-VF$_2$ sample and θ_1 = 290 K for the 44:56 mol % sample. At these values of θ_1 the Tarasov model gives reasonably good fit to the data (within 3%) from 80 to 200 K (curves I, II, and III of *Figures 1* and *2*).

As usual, the fit falls considerably below the data above 200 K because of the difference between C_p and C_v. Since no data exist for the expansivity and compressibility of the copolymer, it is not possible to make correction for this discrepancy as in previous work[1,8].

Principle of additivity

The principle of additivity[3] can be studied in three slightly different and yet closely related aspects. One can compare C_p of the copolymer to the appropriate linear combination of C_p of the constituent homopolymers. With the exception of one point at 80 K, the agreement is excellent ($\lesssim$ 1%) for both samples up to their respective glass-transition temperatures (*Figures 1* and *2*). One can also directly 'calculate' C_p of the copolymer from the segmental heat capacities of CH$_2$, CF$_2$ and CFCl tabulated in our previous work[1]. This affords an opportunity to verify the validity of the CFCl segmental values, which, unlike the other segmental values, were not obtained from least-squares fits to several different experimental values. As shown in the Figures,

the results of the calculation are also in good agreement ($\lesssim$ 3%) with the data for both samples up to the glass-transition region.

We have previously advanced an argument that the characteristic temperature θ_1 is approximately additive in the same way as C_p, and extracted θ_1 values for the four fluoropolymer segments[1]. It is thus straightforward to make a test of this statement on the two CTFE/VF$_2$ samples. As seen from *Table 1*, the agreement is reasonably good ($\lesssim$ 8%) for both samples, especially in view of the considerable uncertainty usually connected with the determination of θ_1.

In summary, it is seen that both the Tarasov model and the principle of additivity in its various aspects can be relied on to give reasonably good (i.e. within 3%) prediction of the heat capacities of copolymers, even though the additivity of θ_1 generally holds to no better than 10% and should only be used with caution.

Phosphonitrilic chloride: 30. Synthesis of chelating polymers from cyclophosphazene derivatives and studies of their electrical conductivity and thermal properties

M. Kajiwara, M. Hashimoto and H. Saito

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan
(Received 24 February 1975)

Chelating polymers containing copper, nickel and cobalt have been formed by reaction of the cyclophosphazene derivatives $P_3N_3(NCSNHC_6H_5)_6$ or $P_3N_3(NCSNHNHC_6H_5)_6$ and the corresponding metal ions. The polymers prepared are amorphous solids and insoluble in most organic solvents. The electrical conductivity of the products range from 8.8×10^9 to 1.8×10^{14} Ω-cm. The products are more stable than the corresponding ligand compounds.

INTRODUCTION

The electrical conductivity of chelating polymers prepared from cyclophosphazene thiocarbamate and metals has been described previously[1]. In this work, some cyclotriphosphazene derivatives are synthesized from hexathiocyancyclotriphosphazene, $N_3P_3(SCN)_6$, and the electrical conductivity of the chelated products containing copper, nickel and cobalt is described.

EXPERIMENTAL

Hexachlorocyclophosphazene trimer, $(NPCl_2)_3$, was prepared by the modified method of Saito and Kajiwara[2]. The pure trimer (m.p.112°C) was obtained by repeated fractional crystallization from light petroleum ether. Hexathiocyancyclophosphazene trimer, $N_3P_3(SCN)_6$ (PTT) and hexaphenylthiouredocyclophosphazene trimer N_3P_3-$(NHCSNHC_6H_5)_6$ [PNP(I)] were prepared by the methods described by Audrith[3,4] and Shvetsov[5]. Hexaphenylthiosemicarbamatecyclophosphazene trimer, $N_3P_3(NHCSNHNH-C_6H_5)_6$ (PNPS) (mp.165°C) was prepared from PTT and phenylhydrazine.

Chelated polymers were formed from PNP and copper, nickel or cobalt as follows. 1.04 g (0.001 M) were dissolved in 20 ml of methanol, and 10 ml of pyridine were added. 0.006 M aqueous acetate or nitrate salt solutions of metal ions in 50 ml water and 10 ml pyridine, were added dropwise to the PNP solution with vigorous stirring. The mixture was then warmed for 20 min, the precipitate was filtered, washed with water, ethanol and ether, and then dried over P_2O_5 or under vacuum at 1.5 mmHg for 24 h. The products formed from copper, nickel and cobalt are designated as (II), (III) and (IV).

Chelated polymers were formed from PNPS and copper, nickel or cobalt as follows. 1.13 g (0.001 M) PNPS were dissolved in 20 ml of methanol, and then 5 ml of pyridine were added. 0.006 M aqueous acetate or

nitrate salt solutions of the metal ions in 60 ml water and 5 ml pyridine, were added dropwise to the PNPS solution with vigorous stirring at room temperature. The reaction mixture was refluxed for 3 h, the precipitate was filtered, and washed or dried as described above. The products are designated as (V), (VI) and (VII).

Infra-red (i.r.) spectra of the products were obtained using the pressed KBr disc technique with a Shimazu Co. IRG-2 type spectrometer. The variation of resistivity with temperature for the chelated polymers were measured by the method described by Kajiwara[1].

RESULTS AND DISCUSSION

Spectro-analysis of the products

I.r. spectra of the chelated products formed are shown in *Figure 1*. The $-NH_2$ frequency of the products II, III, IV, V, VI and VII observed in the region of 3360 cm^{-1} is shifted to long wavelengths compared with PNP or PNPS. The $-NCS$ frequency of the products II, III, IV, V, VI and VII observed in the region of 1450 cm^{-1} is slightly weaker than PNP or PNPS. These observations suggest that metal ions are attached to $-NH_2$ or $-NCS$ groups. Although the structure of the products have not been elucidated, it is assumed that they have a similar structure to that previously described[1] viz:

PNP : $R = C_6H_5$
PNPS : $R = NHC_6H_5$
M = Cu, Ni, Co
Py = C_6H_5N
Figure 1 Infra-red absorption of chelating polymers in the region of 4000 to 2800 cm^{-1}. I, PNP; II, PNP/Co/Py; III, PNP/Ni/Py; IV, PNP/Cu/Py; V, PNPS/Co/Py; VI, PNPS/Ni/Py; VII, PNPS/Cu/Py
Figure 2 Resistivity vs. time at 25°C for product III

The products are amorphous solids, and insoluble in most organic solvents.

Electrical conductivity of the products

The relationship between the resistivity and time is shown in *Figure 2*. The resistivity of product II attains a constant value only after considerable time and this suggests that the electrical conductivity contributes to an ionic mechanism. Products IV, VI and VII show similar behaviour. On the other hand, products II and V immediately approach the con-

stant value. The variation of resistivity with temperature is shown in *Figures 3* and *4*, and the energy gaps of the products calculated from the general relation for semi-conductors are summarized in *Table 1*.

The value of ΔE of the products in PNP system and all of the same order, but in PNPS system the value of ΔE tend to decrease in the order: V < VII < VI. It can therefore be

Chelated products	ρ (25°C) (Ω-cm)	ΔE (eV)
(I) PNP	1.2×10^{14}	0.94
(II) Cu	2.3×10^{13}	1.29
(III) Ni	3.0×10^{13}	1.27
(IV) Co	1.8×10^{14}	1.28
PNPS	—	—
(V) Cu	8.8×10^{9}	0.59
(VI) Ni	1.4×10^{14}	0.98
(VII) Co	2.8×10^{12}	0.93
Figure 5 Thermal decomposition of the products formed from PNP and metal salts in air at 5°C/min

Figure 6 Thermal decomposition of the products formed from PNPS and metal salts in air at 5°C/min

The thermal decomposition of PNP(I) occurred at 150°C; however, products II, III and IV are more stable than PNP(I) itself. On other hand, PNPS decomposes dramatically owing to the presence of hydrazine groups. It seems that the thermal stability of products V, VI and VII is similar to the products formed from PNP system.

presumed that the lowest value observed with (V) arises from the influence of spin interaction of copper atoms.

Thermal stability of the products

The thermal stability of the products investigated using a thermal balance, are shown in *Figures 5* and *6*.

Effect of intra-chain double bonds on the crystallization of polyethylene from the melt

L. Amelino and E. Martuscelli

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, 80072 Arco Felice (Napoli), Italy
(Received 27 May 1975; revised 30 July 1975)

Crystallization rates, from the melts of linear polyethylene and ethylene—butadiene copolymers, have been measured by differential thermal analysis. The effect of the intra-chain double bonds on the crystallization is discussed. The results are analysed in terms of the Avrami equation. Analysis of the dependence of the rate of crystallization on the undercooling shows that the growth of the spherulites is controlled by a process of surface secondary coherent nucleation. The free energy of formation of a nucleus of critical dimensions depend upon the number of *trans* double bonds in the polymer chain.

INTRODUCTION

The investigation reported in the present paper was undertaken with the objective of studying the effect of intra-chain *trans* double bonds on the rate of crystallization, from the melt, of samples of ethylene—butadiene copolymers. This work is part of a more general research leading to the knowledge of the properties of polymers with chemical defects or structural irregularities statistically distributed along the chain[1]. The final goal is the improvement of some technological and mechanical properties of polymeric materials by insertion of a known amount of constitutional or configurational irregularities in the macromolecular chain.

EXPERIMENTAL

Materials

The polymers used were unfractionated samples of random ethylene—butadiene copolymers (1,4-enchainment) and of high density polyethylene (Vestolen 6013). The polymers were kindly provided by Dr Bruzzoni (ENI-Snam Progetti, Milano, Italy). The copolymers were synthesized using vanadium-based catalysts.

The composition of the samples, determined by i.r. and n.m.r., and some melt rheological properties related to molecular weight values and to their distribution are reported in *Table 1*. The polymers have a rather sharp distribution

Table 1 Chemical composition and values of the melt flow index (*MFI*) of samples of ethylene—butadiene (EB) copolymers and of linear polyethylene

Sample	Butadiene composition (mol %)	MFI [2.16(g/10')]	$\frac{MFI[21.6}{(g/10')]}{MFI[2.16}{(g/10')]}$	Viscosity average molecular weight[a]

[a] In decalin at 135°C

of molecular weight; the samples are comparable in both distribution and average molecular weight (see *Table 1*). The presence in the copolymer samples of butadiene units in the *cis* configuration is excluded by i.r. analysis.

Calorimetry

Crystallization isotherms were obtained using a Perkin—Elmer differential scanning calorimeter DSC-1B. The calorimeter had been previously calibrated with standard low molecular weight substances. The general procedure used for obtaining the crystallization exotherm of the polymer samples was as follows: the polymer was placed in the calorimetric cell and first melted by raising the temperature 10°C above the melting point with a scan rate of 16°C/min. After maintaining the samples at this temperature for about 15 min, to remove any traces of crystallinity, the temperature indicator dial was manually adjusted to the desired crystallization temperature. Zero time of crystallization was taken as the time when the control light came on indicating thermal equilibrium. The crystallization exotherm is registered by running the chart at a suitable rate. A typical curve of crystallization, recorded by using a scanning calorimeter, is shown in *Figure 1*. The weight fraction X_t of crystallized material at time t is determined by means of the relation:

$$X_t = \frac{Q_t}{Q_\infty}$$

where Q_∞, the total heat generated from the sample at the end of the crystallization, is proportional to the overall area of the exotherm. Q_t, the heat generated at time t, is proportional to the shaded area of *Figure 1*. The melting temperature of each sample was determined, after isothermal crystallization, from the maximum of d.s.c. endotherm of fusion.

RESULTS AND DISCUSSION

Typical crystallization isotherms of samples of linear polyethylene and of ethylene—butadiene copolymers are shown in *Figures 2a* and *2b*. From such plots the half time $t_{1/2}$ of
Figure 1 Typical curve of crystallization obtained by use of a differential scar ng calorimeter. t_0 is the zero time of crystallization (see text)
Figure 2 Crystallization isotherm for (a) linear polyethylene and (b) ethylene—butadiene copolymer (4). T_c: □, 392.5; △, 394; ○, 396; ×, 398; ■, 383.3; ▽, 387.5; ▲, 389.3; +, 391.8 K

the polymers was determined for various crystallization temperatures. The values are reported in *Table 2*. The crystallization exotherm of the polymers can be analysed by means of the Avrami equation[2]:

$$(1 - X_t) = \exp\left[-K_n t^n\right] \qquad (1)$$

where X_t is the weight fraction of crystallizable polymer crystallized at time t, K_n is a kinetic rate constant and n the Avrami exponent.

In a more useful form equation (1) can be written as:

$$\log[-\log(1 - X_t)] = n \log t + \log \frac{K_n}{2.3} \qquad (2)$$

By plotting the quantity $\log[-\log(1 - K_t)]$ against $\log t$ it is possible from the slope of the curve, providing that the trend is linear, to determine the values of the Avrami exponent n.

Plots of $\log[-\log(1 - K_t)]$ as a function of $\log t$ are reported in *Figure 3* for samples of linear polyethylene and ethylene—butadiene copolymers. In all cases examined a linear trend was observed.

The values of n determined from the slopes of such curves are reported in *Table 2*. An average value of 2.6 was calculated.

The rate constant K_n was calculated from half-life times $t_{1/2}$ using the following relation:

$$K_n = \frac{\ln 2}{t_{1/2}^n} \qquad (3)$$

The melting temperature of the polymers increases with the crystallization temperature with a linear trend according to[3]:

$$T_m = T_m^0 \left(\frac{\gamma - 1}{\gamma}\right) + \frac{T_c}{\gamma} \qquad (4)$$

where γ is a parameter that is constant with temperature. The intersection of the T_m versus T_c line with the line $T_c = T_m$ yields the value of the equilibrium melting temperature T_m^0. Examples of the method used for the determination

It is well known that the crystallization of linear polymers, from the melt, leads to the formation of lamellar spherulites. The linear growth rate G of the spherulites can be expressed as:

$$G = G_0 \exp \left\{ - \frac{\Delta F^*}{RT_c} \right\} \exp \left\{ - \frac{\Delta \Phi^*}{KT_c} \right\} \quad (5)$$

In this equation G_0 is a parameter usually considered constant, ΔF^* represents the activation energy characteristic of transport across the liquid—crystal interface, $\Delta \Phi^*$ is the work required to form a nucleus of critical size, T_c is the crystallization temperature and K is the Boltzmann constant.

When a coherent two-dimensional surface secondary nucleation process controls the radial growth of lamellar spherulites, then the following expression holds for $\Delta \Phi^*$ [4]:

$$\Delta \Phi^* = \frac{4b_0 \sigma \cdot \sigma_e \cdot T_m^0}{\Delta H_F \cdot \Delta T} \quad (6)$$

where b_0 is the thickness of the surface layer, σ and σ_e are interfacial free energies per unit area parallel and perpendicular respectively to the molecular chain direction, ΔH_F is the heat of fusion, T_m^0 the equilibrium melting temperature and $\Delta T = T_m^0 - T_c$ is the undercooling. By using equations (5) and (6) the rate of overall crystallization may be expressed by the equations[4,5]:

$$\frac{1}{3} \log K_n = A_0 - \frac{\Delta F^*}{2.3RT_c} - \frac{4b_0 \sigma \sigma_e T_m^0}{2.3K \Delta H_F \cdot T_c \Delta T} \quad (7)$$

or

$$\frac{n}{3} \log (1/t_{1/2}) = A_0 - \frac{\Delta F^*}{2.3RT_c} - \frac{1}{3} \log \ln 2 -$$

$$\frac{4b_0 \sigma \sigma_e T_m^0}{2.3K \Delta H_F \cdot T_c \Delta T} \quad (8)$$

of T_m^0 are illustrated in *Figures 4a* and *4b*. No significant influence of the number of intra-chain double bonds on the value of T_m^0 had been observed at least for our range of composition. For linear polyethylene and for ethylene—butadiene copolymers we found, in fact, almost the same value of 412 K for T_m^0.

The dependence of $\log(1/t_{1/2})$ on the percentage of butadiene in the polymer chain is shown in *Figure 5* for values of the undercooling between 25 and 17°C. The trend of the curves shows that for lower values of the undercooling the rate of crystallization decreases with increasing the number of double bonds in the macromolecule. The extent of this effect becomes negligible at higher values of the undercooling.

Table 3 Values of $4b_0\sigma\sigma_e/K\Delta H_F$ calculated from the slopes of the curves of *Figures 6* and *7* and the corresponding average

| | $\dfrac{4b_0\sigma\sigma_e}{K\Delta H_F}$ (K) | | |
| | From slopes of curves of | From slopes of curves of | |
Polymer	Figure 6	Figure 7	Average
Vestolen	108.0	106.9	107.5
EB (1)	155.0	134.5	144.7
EB (2)	194.0	198.9	196.4
EB (3)	208.0	211.6	209.8
EB (4)	200.0	184	192.0

The variation of the quantity $\log(1/t_{1/2})$ as a function of $T_m^0/T_c\Delta T$ in the case of samples of polyethylene and ethylene—butadiene copolymers is reported in *Figure 6*.

A linear trend is observed indicating that the transport term $\Delta F^*/2.3RT_c$ in equation (8) almost maintains a constant value when the polymers are isothermally crystallized at a relatively low value of undercooling. From the slopes of the curves of *Figure 6* the quantity $4b_0\sigma\sigma_e/K\Delta H_F$ was calculated. The values are reported in *Table 3*.

In this calculation, we assumed for the exponent of the Avrami equation n, an integral value of 3 for all polymers.

The transport term in equations (7) and (8) may be equated to the activation energy for viscous flow which has a temperature dependence, derived from WLF equations[5,6]:

$$\Delta F^* = \Delta F_{WLF} = \frac{C_1 T_c}{C_2 + T_c - T_g} \quad (9)$$

where C_1 and C_2 are constants generally made equal to 4.12 kcal/mol and 51.5 K respectively and T_g is the glass transition temperature of the polymer.

In *Figure 7* the quantity $1/3 \log K_n + (\Delta F_{WLF}/2.3RT_c)$ is plotted against $T_m^0/2.3T_c\Delta T$ in the case of polyethylene and ethylene—butadiene copolymers. In all cases the trend is linear. In the calculation of ΔF_{WLF}, by means of equation (9), we assumed for the T_g of the ethylene—butadiene copolymers a value of 148 K, i.e. the glass transition temperature of linear polyethylene[7]. The value of the quantity $4b_0\sigma\sigma_e/K\Delta H_F$ calculated from the slopes of the curves of *Figure 7* agree fairly well with that calculated from the slopes of the curves $\log(1/t_{1/2})$ against $T_m^0/T_c\Delta T$ (see *Table 3*). As shown in *Figure 8* the quantity $4b_0\sigma\sigma_e/K\Delta H_F$ depends upon the number of *trans* double bonds in the chain. In fact, for linear polyethylene we found an average value of 107.5 K while the same quantity assumes in the case of ethylene—butadiene[4] copolymer a value of 192.0 K.

From the data of *Table 3* and by using equation (6) the value of the free energy of formation of a nucleus of critical size $\Delta\Phi^*$ may be calculated for each sample. The variation of $\Delta\Phi^*$ with the percentage of butadiene is shown in *Figure 9*. The comparison is made for the same value of ΔT. For lower value of the undercooling, $\Delta\Phi^*$ drastically increases with the amount of double bonds in the chain.

CONCLUSIONS

fit the Avrami equation for the description of the primary crystallization kinetics. From the analysis of the results, it can be concluded that the random insertion of some *trans* double bonds along the chain of polyethylene decreases the rate of crystallization, from the melt, of the polymer. This effect is more prominent in the vicinity of the melting point.

Analysis of the temperature dependence of crystallization kinetics for linear polyethylene and ethylene—butadiene copolymers, carried out in terms of the kinetic crystallization theory proposed by Hoffman *et al.*[3-5], agrees with a growth process of spherulites controlled by a surface two-dimensional coherent nucleation. The observed decrease of the rate of crystallization of ethylene—butadiene copolymers, with increasing the percentage of butadiene, is to be ascribed mainly to the fact that *trans* double bonds, when inserted along the chain of polyethylene, cause a rather drastic increase in the value of the free energy of formation $\Delta\Phi^*$ of a nucleus of critical dimensions. On the contrary, the free energy of activation ΔF^*, related to the phenomenon of mass transport at the liquid—crystal interface seems to be almost constant, at least under our crystallization conditions.

Dynamic mechanical spectra of poly-(itaconic acid esters) containing phenyl and cyclohexyl rings

J. M. G. Cowie and I. J. McEwen

Department of Chemistry, University of Stirling, Stirling FK9 4LA, UK

and J. Veličković

Faculty of Technology and Metallurgy, Belgrade, Yugoslavia
(Received 2 June 1975)

The dynamic mechanical response of a series of poly(itaconic acid esters), in which the ester group, $-COOR$, has $R = (CH_2)_n \phi$ with n = 0, 1, 2 and ϕ is either a phenyl or cyclohexyl ring, was studied over the temperature range 90 to 425K. In each case the glass transition temperature T_g, of the cyclohexyl derivative is higher than the corresponding phenyl derivative, and T_g also decreases as n increases. A β-transition, located in both the phenyl and cyclohexyl series, is attributed to motion of the ester groups. In addition the cyclohexyl polymers exhibit a prominant γ-transition caused by cyclohexyl ring movement and there is also a δ-transition in this series which is believed to be a precursor of the γ-transition.

INTRODUCTION

Polymers based on the esters of itaconic acid have received very little attention in the past. Some work has been reported[1-4] on the solution behaviour of polymers prepared from the dialkyl ester derivatives and their copolymers with styrene, but to date nothing has been published on the mechanical behaviour of either these or related poly(itaconic esters). This area merits study, first because the fundamental monomer, itaconic acid, is not an oil-based product, but is obtained commercially by a fermentation process, and secondly, the esters are similar in structure to the poly(alkyl methacrylates). One can regard poly(itaconic acid di-esters) as poly(alkyl methacrylates) in which one hydrogen of the α-methyl group is replaced by a second ester group. It is of interest then to explore this area further and to make comparisons with these established polymers.

This is the first in a series of papers in which the physical behaviour of poly(itaconic esters) will be examined. The polymers studied here have the general repeat unit:
Comparison of these two main series also allows one to evaluate the influence of the ring type on the mechanical response.

EXPERIMENTAL

Preparation of itaconic acid esters

The synthesis of cycloaliphatic and aromatic esters of itaconic acid was first described by Veličković *et al.*[5]. Dicyclohexyl, dimethyl cyclohexyl, diethyl cyclohexyl,

dibenzyl, diethyl phenyl and dipropyl phenyl itaconate monomers were all prepared by reacting itaconic acid (1 mol) with the appropriate alcohol (3 mol) in toluene, in the presence of sulphuric acid/p-toluene sulphonic acid catalyst. The system was refluxed for several hours then the mixture was neutralized with aqueous sodium carbonate. The toluene layer was separated, dried, and filtered, and the toluene was removed by distillation. The monomer was isolated from the residue by vacuum distillation. Diphenyl itaconate was prepared in a different manner. Itaconic acid was dissolved by refluxing a suspension in benzene. A slight stoichiometric excess of phenol was added to the solution and refluxing was continued for 2 h. At this point a slight excess of phosphorus pentoxide was added and the reaction allowed to continue for a further 4 h. The mixture was cooled, washed repeatedly with water and saturated sodium bicarbonate, before separating the organic layer. Benzene was removed from the mixture and the residue was dissolved in diethyl ether. Washing was repeated, followed by drying with sodium sulphate. The ether was removed and the residue dissolved in hot petroleum ether from which the monomer separated on cooling as white crystals (m.p. = 340K).

Polymerization

The monomers were polymerized in bulk, under vacuum, at temperatures between 333 and 343K; the initiator was α, α'-azobisisobutyronitrile. Polymerizations, carried out over a period of 24 to 48 h, produced highly viscous or solid products which were dissolved in benzene. The polymer was isolated by precipitation using methanol and purified by repeated dissolution and precipitation. The polymers were characterized and a summary of the data is presented in *Table 1*.

Dynamic mechanical measurements

The dynamic thermomechanical response of each sample was measured over the temperature range 90 to 425K and at five frequencies using two techniques.

Table 1 Data characterizing poly(itaconic acid esters) and poly-(methyl methacrylate)

Polymer	Code	$[\eta]$ † (cm^3/g)	$M_v \times 10^{-4}$

† Measured in toluene at 298K

Torsional braid analysis (t.b.a.). A torsional braid analyser (t.b.a.), model 100-B1 Chemical Instruments Corporation, was used to obtain thermomechanical spectra at frequencies of less than 1 Hz. Glass braids were impregnated with polymer by immersion in a concentrated solution (10% w/v) of the sample under investigation. The braid was then suspended, under a small load, in a drying cell and the solvent was removed under vacuum. The sample braid was transferred to the measuring chamber of the t.b.a., which was flushed continually by a stream of dry nitrogen, then cooled to liquid nitrogen temperature and equilibrated there for 30 min. The sample chamber and sample were then allowed to warm slowly at a rate of about 1.0 to 1.5 K/min, and the dynamic mechanical response of the sample was recorded at 2 to 4K intervals. The number of oscillations, *n*, was counted for each decay pattern between two fixed but arbitrary boundary amplitudes. The characteristic mechanical damping index $1/n$, which is related to the logarithmic decrement of the free resonance vibrations, can then be obtained as a function of temperature. Data are plotted as $-\log n$ against temperature.

Rheovibron linear viscoelastometer (r.v.). Measurements of the dynamic mechanical behaviour at frequencies of 3.5, 11.0, 35 and 110 Hz were made using a Rheovibron viscoelastometer model DDV-II-C. The instrument is most useful when the sample is mechanically strong and is sufficiently crystalline to maintain the sample shape as the polymer passes through the glass transition. In order to extend the measurements to the polyitaconates, which form very brittle films and are mechanically weak above their glass transition temperature, T_g, samples were supported on glass fibre filter paper which was inert over the temperature range of interest.

Strips of GF/C glass fibre filter paper (2.5 cm × 0.5 cm) were impregnated with polymer solution and allowed to dry. The solvent was removed from the composite as far as possible by further drying under vacuum at room temperature. The instrument measures the damping in the system (tan δ) directly and spectra were constructed from plots of tan δ against temperature. These were similar in shape to those obtained using the t.b.a. Values of tan δ maxima were also extrapolated to a frequency of 1 Hz, in some cases, for comparison with other data.

Differential thermal analysis

Thermograms were obtained using a Du Pont 900—DSC module. Glass transition temperatures were estimated by locating the intersection of the base line with the extrapolated slope of the curve formed during a base line shift.

The instrument was calibrated regularly using gallium and indium as standards.

RESULTS AND DISCUSSION

Mechanical damping index curves obtained from t.b.a. measurements are shown as a function of temperature in *Figure 1* for each cyclohexyl and phenyl pair. Four damping peaks can be located in the spectra of the cyclohexyl derivatives but only two are prominent in the spectra of the phenyl derivatives.

α-Transitions. Well defined α-transitions exist for both series of polymers which are identified as the glass transition. Estimates of the temperatures at which the α-maxima occur are shown in *Table 2* for t.b.a. and for r.v. measurements at 1 Hz, where they can be compared with the values of T_g obtained from d.s.c. measurements. The T_g (d.s.c.) values are consistently lower than those obtained from
Figure 1 T.b.a. mechanical damping index curves for (a) PDFI (———) and PDCHI (—————); (b) PDBzI (———) and PDMCHI (—————); (c) PDEFI (———) and PDECHI (—————)

Table 2 Glass transition temperatures from d.s.c. and dynamic mechanical measurements

Polymer	T_g(K)			T_β/T_g
	d.s.c.	t.b.a.	r.v. (1 Hz)	
PDFI	405	414	430	0.58
PDCHI	417	435	446	0.64
PDBzI	328	335	–	0.75
PDMCHI	356	361	379	0.66
PDEFI	308	317	–	–
PDECHI	321	327	322	–

PDMI	371	375	395	–
PMMA	396	–	419	–

mechanical measurements although the agreement improves as the ester group lengthens. Heijboer[6] also reported that the damping maxima at 1 Hz (tan δ), associated with the glass transition or 'softening zone', were often 10 to 30K higher than static T_g values.

In each case T_g for the cyclohexyl derivative is higher than the corresponding phenyl derivative, implying that the steric hindrance to rotation in the backbone chain, imposed by the cyclohexyl ring is greater than the phenyl. This was not observed in the analogous poly(phenyl methacrylates) and poly(cyclohexyl methacrylates), both of which exhibited damping curves with α-transition maxima at 403K[6,7]. Furthermore one can assess the influence of the second ester side chain in poly(itaconic esters) by comparing the T_g values for poly(methyl methacrylate) (PMMA) and poly(dimethyl itaconate) (PDMI) with the present series using r.v. data extrapolated to 1 Hz. If PDMI is considered to be PMMA with one hydrogen of the α-methyl group replaced by a —COOCH$_3$ group, then it can be seen from the data in *Table 2* that this substitution leads to a lowering of T_g presumably owing to the plasticizing effect of the additional flexible ester group. Replacement of both methyl groups in PDMI by either cyclohexyl or phenyl rings results in a substantial increase in T_g of between 35 and 50K caused by the increased steric restrictions to rotation arising from the larger molar volume of the rings. Insertion of methylene units to lengthen the ester side chains increases their flexibility and leads to internal plasticization of the polymer. This results in a progressive decrease in T_g as the side chains lengthen.

β-Transition. The β-transition is much more difficult to locate accurately as it appears as a shoulder in the damping curve rather than a pronounced peak. In the PDCHI and PDMCHI samples it occurs in the region of 250K but it is apparently suppressed in the PDECHI polymer. In PDFI and PDBzI the β-shoulder appears in the lower temperature range 200 to 250K and again is less evident in the higher esters PDEFI and PDPFI. The ratio T_β/T_g lies between 0.6 and 0.75 which is similar to that reported for other polymers[8].

The mechanism underlying the β-damping in poly(alkyl methacrylates) has been discussed at some length by Heijboer[6] who attributes its existence to rotation of the pendant group —COOR. Other workers[8] stress that the β-relaxation is a precursor to cooperative chain motion leading to the glass transition and that backbone motion is involved. The two viewpoints are not totally incompatible and we attribute the β-relaxation to rotation of both ester groups which will ultimately aid and reinforce the extensive main chain motion required for the glass transition.

γ-Transition. The presence of a damping maximum at about 180K is observed only for the esters containing a cyclohexyl ring. This peak is absent in the phenyl derivatives and leads to the conclusion that the damping is caused exclusively by cyclohexyl ring movement. Heijboer[7,9] detected a comparable transition at 193K for poly(cyclohexyl methacrylate) which was ascribed to a chair—chair transition in the cyclohexyl ring with an apparent activation energy ΔH‡ of 48.1 kJ/mol. The frequency dependence of the tan δ maximum for each cyclohexyl derivative examined here is shown in *Figure 2*. From a least squares analysis of the data ΔH‡ can be estimated to be 65.5 kJ/mol for PDCHI, while PDMCHI and PDECHI have slightly lower values of 52.3 and 50.4 kJ/mol respectively. The motion appears to be less impeded when the ring is moved further away from the main chain by the methylene units and in all cases ΔH‡ is greater than Heijboer's value for poly(cyclohexyl methacrylate). This may indicate a greater degree of steric hindrance in the itaconic ester polymers. While the transition can be ascribed to cyclohexyl ring motion, we are inclined to favour the idea that it is caused by a chair to skewboat transition. This avoids having the chain, attaching the cyclohexyl ring to the backbone, in an unfavourable axial conformation which it would be forced to adopt for one of the chain positions in Heijboer's mechanism.

δ-Transition. A small loss peak can be observed in the region of 100K which is more difficult to resolve because it occurs near the lower limit of our attainable temperature range. This δ-transition is most obvious in the cyclohexyl derivatives and there is only a very slight suggestion of its presence in PDFI and PDBzI. Molecular motion in this region has been attributed to a variety of mechanisms: methyl group rotation, crankshaft motion, and pendant group reorientation. Because of the doubt concerning the presence of a δ-peak in the phenyl derivatives, it would appear most
Figure 2 Plots of log$_{10}$ (frequency) against reciprocal temperature of the γ-transition tan δ maxima for PDCHI (△), PDMCHI (□), and PDECHI (○)

likely that the damping is caused by group motion which is a precursor to the more pronounced movement of the cyclohexyl ring at higher temperatures. This could either be a simple migration of the cyclohexyl ring into a vacant hole or a torsional motion within the ring.

CONCLUSIONS

The use of glass fibre supports to prepare composites of brittle or mechanically weak polymers for study in the Rheovibron appears to be satisfactory. As with t.b.a., the sample size cannot be defined, consequently the results are not absolute and often yield T_g values higher than those obtained using static techniques, even after extrapolation to low frequencies. The data can, however, be compared on a relative basis and both glass and subglass transitions are easily located.

The substitution of a ring system in the ester group leads to an increase in T_g relative to PMMA, and this increase is greater for the cyclohexyl derivatives than for the phenyl derivatives. Observations made on the influence of ring substitution in these samples compared with PMMA, must of course be tempered by the knowledge that the T_g of PMMA is a function of sample stereostructure. The PMMA sample used here is an atactic sample with ~75% syndiotactic diad placements in the chain; it is assumed that as the polyitaconates were obtained by free radical polymerization the

stereostructure would be roughly the same, namely atactic. Any microstructural differences would only affect conclusions based on the relative magnitudes of T_g, and should not alter the general trends, detected here, to any marked extent.

Elastic behaviour of ideal polystyrene networks

F. Rietsch and D. Froelich

University of Lille, BP 36, 59650 Villeneuve d'Ascq, France
(Received 23 December 1974; revised 28 May 1975)

Polystyrene gels were prepared by anionic copolymerization of styrene and divinylbenzene in dilute solution (7.5%), the molecular weight between crosslinks ranging from 10 000 to 75 000. A study of the photoelasticity of these networks swollen to equilibrium in benzene and cyclohexane allowed some molecular parameters such as the memory term, the number of elastic chains, the functionality of the crosslinks, and the optical anisotropy of the random links to be calculated. The Mooney–Rivlin representation shows that both in elongation and compression, the C_2 term is nul, the C_1 term becoming identified with the theoretical modulus from the Flory, Wall and Hermans theory.

INTRODUCTION

Up to now networks have been prepared by radical polymerization in which the chain order of the different monomers results from statistical probability, the parameters being concentrations (initiator and monomer) and ratios of radical reactivity[1,2]. The result is a large distribution of linear sequences between crosslinks and an unknown and varied functionality of the crosslinkage points. Such a method of preparation leads to networks whose structure is not well defined and which, according to certain authors[3,4] can present an inhomogeneous structure.

To ensure a better control of these networks we made use of an anionic polymerization method developed by Rempp and coworkers[5–7]. It is well known that the polymerization of styrene initiated by a bifunctional organometallic initiator, such as naphthalene(sodium salt) or the disodium tetramer of α-methylstyrene, can by a nucleophile attack of the double bounds, result in a polystyrene with reactive organo-sodium sites at both ends. The dicarbanion obtained in this way is linear and is of low polydispersity. If a difunctional monomer is added, such as divinylbenzene (DVB) which is likely to be initiated by the styryl carbanions, we obtain a three-dimensional network.

This technique offers the following advantages: (1) polystyrene chains are linear and monodisperse; the molecular weights of these chains can be made to vary in large proportions and be measured experimentally before crosslinking; (2) concentration in segments in the gel is equal to the one that already existed in the solution before the DVB was added. Here, the gel point corresponds to multiple linkages between the polymeric chain ends; (3) the total concentration of polymer in its solvent can undergo large variations which makes it possible to avoid syneresis[8].

On the other hand, those networks very closely related to the ideal model, present the following defects: (1) a certain number of polystyrene chains can become deactivated during preparation. A formation of 'free' chains is observed if deactivation occurs at both chain-ends, whereas pendant chains will appear if deactivation takes place at one chain-end only; (2) physical knots or entanglements can form in the crosslinking process. These can behave like physical crosslinks while the network is being deformed; (3) cyclizations can occur, but this probability is low and experimental results have shown that the phenomenon is

negligible; (4) the functionality of the branching points is not clearly defined.

THEORETICAL

Elasticity and swelling of a three-dimensional Gaussian network

Over the last few years, the molecular theory of rubberlike elasticity has caused great controversy about two established theories, that of Flory, Wall and Hermans[9–13] on the one hand and of James and Guth[14–17] on the other.

Dusek and Prins[18] have in a recent review, summarized this controversy with emphasis on the variation of free energy in elastic deformation:

$$\Delta F_{network} = \frac{A\nu_e kT}{2}(\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3) -$$

$$B\nu_e kT \log \lambda_x \lambda_y \lambda_z \qquad (1)$$

where ν_e stands for the number of elastic chains, λ_x, λ_y, λ_z, the deformation ratios projected on three reference axes, k, the Boltzmann constant, and T, the Kelvin temperature.

According to Flory, Wall and Hermans $A = 1$, $B = 2/f$ in which f represents the functionality of the crosslinks. According to James and Guth $A = 1/2$ and $B = 0$.

When the network is swollen at equilibrium, the chemical potential of the solvent is:

$$\Delta \mu_1 = A\nu_e RT\overline{V}_1 q_0^{-2/3} q_i^{-1/3} - BRT\nu_e \overline{V}_1 q_i^{-1} +$$

$$RT[\log(1 - q_i^{-1}) + q_i^{-1} + \chi q_i^{-2}] = 0 \qquad (2)$$

where $\overline{V}_1$ = partial molar volume of the diluent

$$q_0^{2/3} = \frac{\langle r_{OS}^2 \rangle}{\langle r_D^2 \rangle} = \frac{\langle r_{OS}^2 \rangle}{\langle r_c^2 \rangle} q_c^{2/3}$$

q_c^{-1} = volume fraction of polymer at crosslinking stage
q_i = swelling ratio of the network
χ = the Flory–Huggins interaction parameter

$\langle r^2_{OD} \rangle$ and $\langle r^2_{OS} \rangle$ = mean square end-to-end distance of network chains in the dry and swollen reference states respectively

$\langle r^2_D \rangle$ = mean square end-to-end distance of network chains in the dry state

$\langle r^2_c \rangle$ = mean square end-to-end distance of network chains after crosslinking

q_0 = the swelling of the gel in the swollen reference state

It is called the 'memory term' as it is linked to q_c^{-1}, the volume fraction for the polymer at the crosslinking stage.

When the swollen gel undergoes a unidirectional stress σ (force per unit swollen and strained cross-section) its degree of swelling will change from q_i to q. The relation (2) yields:

$$\sigma = A q_0^{-2/3} q_i^{-1/3} \nu_e^* RT \left[\Lambda_x^2 - \frac{q}{q_i} \Lambda_x^{-1} \right] \quad (3)$$

where ν_e^* = concentration of network chains (per unit dry volume)

$\Lambda_x = L/L_i$ where L_i = the initial length of the sample swollen at equilibrium and L = the stressed length of swollen sample

Stress birefringence

Studies of the photoelastic properties of rubberlike polymers have been interpreted in terms of the Kuhn and Grün theory[19] in which the molecule can be described as a chain of randomly jointed optically anisotropic links.

If $\bar{n}_0$ is the mean refractive index of the network and $\Delta\alpha_c$ the optical anisotropy of the random link, the optical coefficient is defined as:

$$c = \frac{\Delta n}{\sigma} = \frac{2\pi}{45kT} \frac{(\bar{n}_0^2 + 2)^2}{\bar{n}_0} \Delta\alpha_c \quad (4)$$

where Δn is the stress birefringence.

The knowledge of the optical anisotropy of a monomer unit makes it possible to measure the length of the random link and verify the validity of the Gaussian theory. The optical coefficient is an intrinsic parameter of the polymer, independent of the crosslinking density and the solvent used (except for calculation of $\bar{n}_0$).

EXPERIMENTAL

Preparation of samples

All samples were prepared by anionic copolymerization of styrene with divinylbenzene (DVB) according to a method described by Weiss *et al.*[7].

The polymerization initiated by the disodium tetramer of α-methylstyrene, takes place in inert atmosphere in an equilibrium mixture of toluene and tetrahydrofuran (THF)

at $-78°C$. A mould is fitted under the multi-necked lid of the reactor, so that seven parallelipipedic samples (135 x 42 x 4 mm) and one cylindrical sample (120, ϕ 27 mm within the reactor) can be obtained simultaneously.

All these samples were prepared in highly dilute solution (7.5%) with three DVB molecules per living end.

The gel obtained in this way was deactivated by a solution containing 10% THF and tetrahydrofurfuryl alcohol; its alcoholates were removed by successive washings and it was swollen to equilibrium in benzene and cyclohexane.

A sample of the related polystyrene before DVB was added made it possible to measure the molecular weight of the linear chains between crosslinks. Their parameters are given in *Table 1*.

Measurements

Elongation was measured by a cathetometer with a precision of ±1/20 mm in a rectangular glass cell filled with solvent, the samples being held by means of metallic clamps. To measure the stress a calibrated inductive transducer (Model Q11/100gP Hottinger Balwin) was used. The signal of the transducer was amplified by means of a carrier wave amplifier (Model KWS/35-5 Hottinger Balwin) which gives the force after calibration.

Thickness was measured by a microscope with a precision of ±5/1000 mm, and other measurements were taken by means of slide callipers with a precision of 1/20 mm.

Taking into account all the experimental errors previously mentioned the elasticity modulus in extension can be calculated to be ±2.5%.

In compression the samples are pressed in a cylinder by a piston coupled with a transducer (Q11/1kp). The contact surfaces lined with a Teflon film ensure a better sliding on these surfaces under stress. The determination of the initial conditions linked with the parallelism and the surface state of the cross-sections can become inaccurate for weak moduli. Experimental errors of about ±2.5% can then reach ±5% in the most unfavourable cases.

We used the arrangement described by Donkersloot and Gouda[3] to measure the optical birefringence Δn when a unidirectional stress σ is exerted on the gel. A galvanometer linked with a photomultiplier gives the phase retardation with a precision of ±15'.

The determination of the optical coefficient $c = \Delta n/\sigma$ is achieved with a precision of ±2.5%. All these measurements were made at room temperature.

Corrections

In equation (3) σ and q are the stress and the swelling ratio at stress equilibrium. The measurement of σ and q is usually difficult. In order to avoid this difficulty, we have measured the instantaneous stress σ_0, obtained after deformation.

In this case equation (3) becomes:

$$\sigma_0 = A q_0^{-2/3} q_i^{-1/3} \nu_e^* RT [\Lambda_x^2 - \Lambda_x^{-1}] \quad (5)$$

This implies the following expression proposed by Dusek and Prins[18]:

$$\frac{q}{q_i} = \Lambda_x^3 + \frac{f}{f_0}(1 - \Lambda_x^3)$$

where f is the force at equilibrium and f_0 the force measured immediately after deformation.

In order to check the validity of this assumption we have plotted in *Figure 1* the value of σ_0 *versus* $(\Lambda_x^2 - \Lambda_x^{-1})$ and σ *versus* $[\Lambda_x^2 - (q/q_i)\Lambda_x^{-1}]$ for two different values of Λ_x, for the gel no. 853 swollen in benzene. The four experimental points are on the same straight line and give the same value of the modulus G_{ex}. Consequently we have only measured the values of σ_0.

RESULTS AND DISCUSSION

All the results obtained with gels in equilibrium swelling in cyclohexane and benzene are included in *Table 2*, the molecular weight of our gels ranged only from 10 000 to 75 000. For lower molecular weights, the crosslinking speed is too high to obtain a satisfactory homogeneous gel. For higher molecular weights, it proved to be impossible to determine the mechanical properties in good solvents, the gels being too weak.

In *Figure 2*, we have plotted according to equation (5) the values of the stress σ_0 (initial stress per strained swollen cross-section) against $(\Lambda_x^2 - \Lambda_x^{-1})$ for four gels of molecular weights $\bar{M}_n$ = 10 450; 16 450; 19 900; 30 000; swollen in cyclohexane and benzene. The other gels give the same linearity. In all cases we observed a linear variation of σ_0

Figure 3 Compression measurement for gel 743 swollen in benzene

against $(\Lambda_x^2 - \Lambda_x^{-1})$ with an ordinate of zero. The slope allows us to calculate the experimental modulus $G_{ex} = \sigma_0 (\Lambda_x^2 - \Lambda_x^{-1})^{-1}$ of our samples whose values are given in *Table 2*.

In compression, relation (5) can be written:

$$fL^2 = A\nu_e^* RTV_p q_0^{-2/3} q_i^{2/3} \left[\frac{L^3}{L_i^2} - L_i \right]$$

where L and L_i are the lengths of the deformed and un-deformed states; f = force exerted on the sample; and V_p = specific volume of the network in the dry state.

In *Figure 3*, we have plotted fL^2 against L^3 for the gel of molecular weight 19 900 swollen in benzene. We obtained similar curves for all other samples. At low compression ratio a slight deviation from linearity is observed. This is probably due to imperfection in the parallelism of the compressing plates. It can be shown that the slope of the line is $G_{ex}S_0/L_i$, where S_0 is the cross-section of the samples in the swollen undeformed state. The compression moduli G_{exp} for the various gels are given in *Table 2*.

Relation (5) can also be written in the following way:

$$\sigma_0 = A q_0^{-2/3} q_i^{-1/3} \left(\frac{\rho}{M_n} - \nu_i \right) RT(\Lambda_x^2 - \Lambda_x^{-1}) \quad (6)$$

in which ρ is the density of the gels in the dry state and ν_i the number of non-elastic network chains.

Therefore we have plotted in *Figure 4* the values of: $G_{ex}/q_i^{-1/3} = A q_0^{-2/3} [(\rho/\overline{M}_n) - \nu_i)RT]$ against $1/\overline{M}_n$ for the various samples, related to the measurements in benzene and cyclohexane. The experimental points obtained are, to within experimental errors, located on a line going through the origin. We are therefore led to conclude that ν_i is negligible and that consequently $\nu_{e1}^* = \rho/\overline{M}_n$ is a quantity which can be obtained experimentally.

Consequently the behaviour of the gel is ideal, though it may be thought that there is in fact a compensation between eventual pendant chains and the existence of

entanglements. This seems to be all the more probable as in a certain number of our samples and particularly in those whose molecular weights were high, we were able to measure experimentally a certain ratio of extractible chains whose values are shown in *Table 1*. According to Haeringer[20] those values can be linked with a ratio of pendant chains in the network. The apparently ideal behaviour of the studied samples implies compensation by entanglements.

It can be seen in *Figure 4* that the experimental points corresponding to molecular weights higher than 40 000 deviate appreciably from the straight line. This can be accounted for by the ratio of pendant chains becoming too high.

According to relation (6) the slope of the straight lines in *Figure 4* allows us to calculate the values of $A q_0^{-2/3}$ in benzene and cyclohexane. Those values are equal for both solvents. If we suppose the Flory–Wall–Hermans theory that $A = 1$, we can deduce the value of:

$$q_0^{-2/3} = q_c^{-2/3} \frac{\langle r_c^2 \rangle}{\langle r_{0S}^2 \rangle}$$

$q_c^{-2/3}$ being known we can deduce that $\langle r_c^2 \rangle / \langle r_{0S}^2 \rangle = 0.69$ for both solvents.

It is to be noted that the same memory term value is obtained from modulus measurements in two solvents as different from each other as are benzene and cyclohexane. This then seems to confirm that q_0 is an intrinsic parameter of the gel. Although this value is noticeably different from the one given by Prins[21], it confirms qualitatively the influence of crosslinking on the dimensions of the chains.

543	13100	0.608513	0.3433	5.82		0.479
853	16450	0.602126	0.3701	5.40		0.465
743	19900	0.601316	0.3823	5.23		0.465
13112	29300	0.596492	0.4858	4.12		0.470
2743	30000	0.595303	0.4625	4.32		0.470
15112	40500	0.594145	0.5013	4.00		0.468
3043	45600	0.591702	0.6682	3.00		0.477
553	75000	0.585133	1.6055	1.25		0.479

As could be expected from the Mooney—Rivlin representation:

$$\sigma_0 = (C_1 + C_2\Lambda_x^{-1})(\Lambda_x^2 - \Lambda_x^{-1})$$

the C_2 term is nul in all cases. The C_1 term is then equal to the theoretical modulus defined by the theory of elasticity, in compression as well as elongation. This result could be expected, if we consider the importance of dilution in the crosslinking process and the low polydispersity of the chains[22].

Using equation (2) in which we introduce the value of $\Lambda q_0^{-2/3}$ and v_e^* given by the experimental modulus, we obtain a relationship between functionality of the crosslinks f and the polymer—solvent interaction parameter χ, if we suppose that $B = 2/f$. It has been shown for linear polystyrene solution in cyclohexane that χ is independent of the molecular weight and that for polymer concentration identical to those in our gel, this parameter is the same for a linear and a star polystyrene[6]. In that case we can use the value of χ given by the equation of Scholte[23] for our gels:

$$X_\phi = 0.2975 + \frac{62}{T} + 0.306\phi + 0.30\phi^2$$

where ϕ = volume fraction of polymer in the solvent.

In *Table 3* we have given the calculated value of χ for each gel and the corresponding value of B and f given by equation (2).

The functionality decreases with the molecular weight between crosslinks. This can be due to the kinetics of the crosslinking process which may depend on the viscosity of solute and consequently on the molecular weight, or on the number of pendant chains in the gel which obviously increase with the molecular weight. For the last two gels with the highest molecular weight f is 3 and 1.25. These values are anomalous because the average values of f should be higher than 3. This is probably due to the non-ideality of those gels which appears in all the measurements.

In the case of the gels swollen in benzene we cannot apply the same type of calculation, because the value of χ is unknown and probably dependent on molecular weight, swelling ratio and molecular structure. Using the value of f obtained from the measurements in cyclohexane, we have calculated the value of χ in benzene, using equation (2). The values are given in *Table 3*. The parameter χ seems to be independent of the molecular weight and in accordance with the value that could be expected.

In *Figure 5* for the sample 2743, Δn has been plotted against σ_0 and the slope of the straight line is equal to the stress optical coefficient c as defined in the Kuhn and Grün relation[19]. From this value we were able to calculate the anisotropy of the statistical link $\Delta\alpha_c$ which is plotted against $\bar{M}_n$ for the different samples swollen in cyclohexane and benzene. The values are given in *Table 2* and are in accordance with those given by different authors[24-26].

From *Figure 6* we can conclude that, as was predicted by equation (4), $\Delta\alpha_c$ is independent of the molecular weight, except for the highest molecular weights where the presence of pendant chains has been shown by other measurements. As has been found by other authors[27-30], the
Figure 5 Δn *versus* σ_0 for the sample 2743
Figure 6 $\Delta\alpha_c$ *versus* M_n for different samples

values of $\Delta\alpha_c$ depend on the solvents. Concerning our experiments, it seems most unlikely that the small difference in optical anisotropy between cyclohexane and benzene might account for our results. On the other hand, the anisotropy differences measured in those two solvents can be linked to the important difference in the swelling ratios. In fact it can be supposed that either the chain statistic is modified when another solvent is used[31] or the short-range interactions between chains depend largely on the swelling ratio of the network.

In conclusion it appears that the behaviour of these networks is in good agreement with Gaussian theory. That could be expected knowing the fact that the networks were formed from diluted solutions. The same type of measurement in the dry state is actually in process to verify if the behaviour is still in agreement with Gaussian theory and to check the influence of the short range interaction in the bulk.

Increase of the melt viscosity of polycaproamide by chromium (III) ions

A. Szafner and J. Karger-Kocsis
Research Institute for the Plastics Industry, Budapest, H-1950, Hungary
(Received 28 April 1975)

The melt viscosity of polycaprolactam can be enhanced by incorporation of chromium (III) ions into the resin. As a possible interpretation of this phenomenon, formation of a mixed complex is suggested by X-ray diffraction, infrared and uv. absorption spectroscopic studies. By comparison with a model compound, it was found that the carbonyl oxygen and the water occurring in the polymer appear to be the coordination centres of chromium (III) ions. The hypothetical composition of the mixed complex is $[Cr(CO_{amide})_n(H_2O)_{6-n}]^{3+}$ where $2 \leqslant n \leqslant 6$.

INTRODUCTION

The majority of commercial polyamides cannot be used for extrusion of profiles because of their low melt viscosity. The melt viscosity of these polyamides can be increased by introduction of chromium (III) ions[1]. The polymer product is impregnated with an appropriate chromium (III) compound in alcoholic or aqueous medium then dried, extruded and pelletized. The polyamide prepared in this way is capable of extruding as tubes, films, hollow bodies, and other profiles. The chromium (III) compound can also be added to the system before polymerization or polycondensation.

The present paper aims at the interpretation of the effects of chromium (III) compounds.

Changes in the viscosity are shown in *Figure 1* as a function of the amount of chromium (III) compound added. Measurements were carried out using a plastometer at 250°C, a nozzle of 2 mm i.d. and at a load of 500 g. Water content was determined by a vacuum method at 190°C. Thermal stability, resistance to solidification, and water absorption of the polymer product increased while the mechanical properties such as tensile strength and ultimate elongation decreased by about 20% owing to either the change in crystal structure or to the increased proportion of the amorphous phase. In addition, light resistance and

Figure 1 Melt-flow index of chromium-coordinated polycaproamide as a function of the amount of chromium (III) compound added, at different moisture contents. ○, 0.03%; ●, 0.10% moisture content

thermal stability of the polymer can be improved by incorporation of chromium (III) compounds[2]. In another process, anionic polymerization of caprolactam in the presence of complex-forming metal cations, led to products of lower degree of crystallinity[3].

EXPERIMENTAL AND RESULTS

X-ray diffraction patterns

X-ray diffractograms were recorded by a Phillips Micro III equipment using Ni-filtered CuKα irradiation and operated at 40 kV and 20 mA. It was established that the structure of a polyamide coordinated with chromium was different from that of the original polyamide produced industrially by anionic polymerization at the Borsod Chemical Works *Figure 2*. The X-ray diffraction peaks of the original polyamide at 19.7° and 23.5° were designated according to Roldan[4] as α_I and α_{II} respectively.

For samples containing chromium compound, α_I and α_{II} shifted to 20.3° and 22.8° respectively and a new diffraction band appeared at 21.1° characteristic of a polyamide of γ-structure. The γ-structure is analogous to a polypeptide chain and the molecules are packed more loosely than those of the other crystal forms. This is the reason why polyamide is considered as the model compound for the tanning of collagen after the destruction or weakening of the hydrogen-bonded structure.

Formation of the γ-structure was also observed by infrared spectroscopy through its characteristic band at 975 cm^{-1}[5]. The chromium-coordinated polyamide has a lower crystalline proportion in comparison to the original one.

Infrared spectra

Film specimens were investigated by a Zeiss UR-10 spectrophotometer in the range of 400 to 4000 cm^{-1}. By this method, only the modified crystal structure could be observed. No difference appeared in the carbonyl and amide bands between the original and the chromium-coordinated polyamides owing to the low amount of the chromium (III) ions incorporated. The incorporation of 10^{-3} atomic units to a polyamide unit (having a molecular weight of 113) resulted in changes well below the detection limit of this method. Similar results were obtained in the far infrared range at 0 to 250 cm^{-1}.

In order to clarify this problem, tricaprolactamo-chromium (III) trichloride $[Cr(CLm)_3Cl_3]$ was prepared by the
Figure 2 X-ray spectra for the original polyamide (——) and for a chromium-coordinated polyamide (—————) containing 0.35% of [Cr(H$_2$O)$_6$]Cl$_3$

standard method and studied as a model compound[6]. Although a hexacoordinated caprolactam-chromium (III) complex could also have been synthesized[7], an analogous structure to the polyamide-6 might not be expected since, in the practical application, moisture is also present in similar amount to the chromium (III) ion (related to a polyamide unit) and this favours the formation of a mixed complex as it was demonstrated by the absorption spectra (see below).

Caprolactam as a bifunctional compound can coordinate through both lone electron pairs of the oxygen and the nitrogen. If it coordinated through the oxygen, the carbonyl band should shift towards lower frequencies while a coordination through the nitrogen should result in a reverse effect since the amide groups were partly delocalized.

It was established by the KBr pellet technique that the carbonyl oxygen was involved in the complex formation since the CO frequency of caprolactam at 1662 cm^{-1} shifted to 1625 cm^{-1} for the model compound. According to Bull *et al.*[8] steric factors also give such a coordination preference.

In addition to the shift of ν_{CO}, ν_{NH} is changed from 3305 cm^{-1} of the caprolactam to 3320 cm^{-1}, due to the coordination, indicating the delocalization in caprolactam. This valence vibration band of the NH group corresponds to the *trans* configuration of the amide group which is sterically more favourable for the coordination.

U.v. absorption spectra

U.v. and visible spectra were recorded by a Spektromom 201 spectrophotometer. The $n-\pi^*$ transition of the caprolactam CO group appears at 210 nm in n-hexane (molar extinction coefficient of 1380 1 mol^{-1} cm).

Spectra for the tricaprolactamochromium (III) trichloride and the hexaquochromium (III) trichloride in ethanol are similar and in dimethylformamide are essentially coincident, showing a batochromic shift of about 10 nm from those measured in ethanol. This may be attributed to a stronger complex formation rather than to a solvent effect. Since the chromium compound coordinated with caprolactam shows no considerable red shift as compared to that

coordinated with water, the spectra lead to the conclusion that the combined water (bonded strongly or weakly) in the polyamide and the capillary condensed water are involved in the coordination.

In hexacoordinated chromium compounds, three $d-d$ transitions can be observed within the studied range of wavelength. Two of them at 470 and 650 nm correspond to $(t_{2g})^3 \rightarrow (t_{2g})^2 (e_g^*)^1$ transitions[9].

DISCUSSION

The infra-red spectra of the model compound shows that the carbonyl of the amide group is involved in the complex formation by the lone electron pair of the oxygen. This kind of coordination is considered for the polyamide as well although in this case, there is no proof of a coordination by the lone electron pair of the nitrogen. A coiled polyfunctional polyamide chain can also contribute to the chelate formation. Incorporation of a chromium compound into the polymer by melting, when the original hydrogen-bonded structure is destroyed, results in a polyamide of lower degree of crystallinity with altered structure (γ form) causing higher hygroscopy of the polymer.

Since chromium (III) ion has a coordination number of six it is unlikely that all of the sites are occupied by the carbonyl oxygens in the amorphous regions. It can be established by the absorption spectra that water is competitive in the coordination with the oxygen of the amide group making the formation of a mixed complex favourable.

A similar mixed coordination of chromium (III) ions was observed with ethylenediaminotetraacetic acid or with various amino acids[10].

The structure of the hexacoordinated mixed complex is, therefore, supposed as follows:

$$[Cr(CO_{amide})_n (H_2O)_{6-n}]Cl_3$$
where $2 \leq n \leq 6$.

Since the functional groups of the polymer chains are the ligands of the hypothetical chromium complex, an intermolecular coordination is formed which may explain the changes in the polymer viscosity.

Polymeric coatings on steel produced by the electroinitiated polymerization of acrylic monomers

G. Mengoli* and B. M. Tidswell

Postgraduate School of Studies in Polymer Science, University of Bradford, Bradford, West Yorkshire BD7 1DP, UK
(Received 22 November 1974; revised 23 May 1975)

The results of the electropolymerization *in situ* of certain acrylic and methacrylic esters to produce coherent, continuous coatings on steel sheet cathodes using tetra-n-butyl ammonium perchlorate as supporting electrolyte in either DMF or DMSO under galvanostatic conditions are described. The effect of monomer concentration, applied current and electrolysis time have been considered. It has been found that the coating formation is favoured when the solubility parameter of the growing polymer is sufficiently different to that of the media. Under these conditions insulating deposits form on the electrode, resulting in strong increases of the electric resistance of the system. The parallel increase of voltage recorded under galvanostatic conditions was used to explain the formation of the films in terms of 'throwing power' and coherence. The best coating results for adhesion and hardness were obtained by copolymerizing *in situ* suitable mixtures of methacrylonitrile and isobutyl methacrylate.

INTRODUCTION

Electroinitiated polymerization has been the subject of several review articles[1-4], in many of the examples the cathode behaves as a Lewis acid giving rise to either direct or indirect electron transfer to the monomer resulting generally in the initiation of an ionic process. The electrode is thus entirely concerned with the initiation stage which must therefore be heterogeneous, whilst the propagation reaction takes place homogeneously in the bulk of the solution. Thus the electrode acts as an external source of active species as occurs in photolytic or radiolytic initiation.

For either practical or industrial application electroinitiated polymerization is unlikely to compete with conventional techniques unless the system gives rise to polymers with novel characteristics such as very high molecular weight or controlled programmable molecular weight distributions. However, one aspect of this type of polymerization which may be developed for practical purposes is the polymerization *in situ* of the monomer at the electrode surface when both propagation and initiation occur heterogeneously giving rise to the formation of polymeric coatings which would convert a two stage process, that of polymer preparation followed by a suitable coating technique, into a one stage process.

The patent literature contains examples of successful coating obtained by electropolymerization based on diacetone acrylamide and related monomers[5-7]. Asahara[8-16] has reported the electropolymerization of a wide range of monomers to produce polymeric films on a variety of metal substrates acting as electrodes. This work is exploratory in nature and taking into account the large currents and electrolysis times used may most likely involve the

deposition of a polymeric material produced in the bulk of the solution rather than one produced *in situ* on the metal plate.

Not every monomer capable of undergoing electropolymerization is capable of giving a coating on the electrode. The present work which is restricted to the cathodic polymerization of certain acrylic monomers investigates the conditions that the system should fulfill to be suitable for the production of polymeric coatings as a consequence of the electrode reaction.

EXPERIMENTAL

Materials

N,N'-dimethylformamide (DMF) and dimethylsulphoxide (DMSO) (BDH Ltd reagent grade) were stored, before use, over granules of either magnesium or calcium oxide; no further purification was attempted.

The monomers, isobutyl methacrylate, methyl methacrylate (Koch Light), t-butyl acrylate, t-butyl methacrylate and isoamyl methacrylate (Borden Chemical Co.) and methacrylonitrile (Eastman Ltd) were freed of radical scavengers (50–100 ppm) by distillation. However, because of the ionic character of the polymerization similar results were obtained using the commercial materials as received.

n-Tetrabutyl ammonium perchlorate, the supporting electrolyte, was prepared by the neutralization of tetrabutyl ammonium hydroxide (Fluka Chemicals) with Analar perchloric acid. The precipitated product was recrystallized from ethanol/water and dried in a vacuum oven at 60°C.

The steel sheet electrodes (0.178 mm thick) were cut from samples of tin free steel supplied by Metal Box Co. Ltd.

Other reagents were used as supplied.

Apparatus and procedure

All the polymerization studies were performed by electrolysing the monomer—solvent—supporting electrolyte system in a simple two electrode undivided cell. The platinum anode (1 cm^2) was separated from the steel cathode (11 cm^2) by a distance of 2 cm.

Experiment showed that in view of the short electrolysis times used, poisoning of the cathode by products discharged at the anode was apparently negligible. Because of the possible practical utilization of *in situ* electropolymerization all electrolyses were performed galvanostatically which combines simplicity of operation with adequate control of initiation rate. The constant current unit used was capable of supplying 1—50 mA in 1 mA steps (Sandmar Electronics Ltd). The voltage across the electrodes was monitored, during the electrolysis, by means of a digital voltmeter. Each polymerization was carried out at room temperature ($\simeq 20°C$) with unstirred solutions.

Prior to electrolysis the sheet steel electrodes were degreased using chloroform and acetone. Immediately following electrolysis the metal electrode was quickly withdrawn from the solution and dried both at room temperature and in an oven at $60-70°C$.

The hardness of the polymeric films was metered (relative to a glass standard) using a Pendulum Hardness Rocker to DIN specification 53, 157, equipped with automatic electronic counting (Koenig Pendulum by Sheer Instruments Ltd).

The polymer was recovered from the substrate by dissolution in acetone with subsequent removal of the solvent under vacuum. The molecular weights of the resulting polymer samples were determined using toluene solutions in a Knauer vapour pressure osmometer at $50°C$. Thermal analysis of certain samples was carried out using a Perkin-Elmer differential scanning calorimeter DSC 1B.

RESULTS AND DISCUSSION

Polymerization mechanism

The electroinitiated polymerization of the monomers used in this work have not previously been reported. However, there are some reports in the literature of the electro-initiated polymerization of acrylic esters and particularly for the cathodic polymerization of methyl methacrylate in aprotic medium[17,18]. Acrylic and methacrylic esters are capable of cathodic reduction on a mercury electrode in aprotic medium[3,19] with the formation of radical anions and dianions which can easily initiate anionic polymerization. Although no actual mechanistic studies have been carried out it seems more than likely that the reduction of acrylic monomers on a steel electrode which is relatively inert will lead to the same anionic species as produced on mercury. This is substantiated by the following experimental observations.

I. The polymer film formation is not affected by the presence of radical inhibitors.

II. Coating formation is inhibited by small quantities of water or other protic substances.

III. The molecular weight of the polymers is low, which is peculiar to the anionic polymerization of acrylic monomers.

IV. Samples, obtained by electropolymerization *in situ* of isobutyl methacrylate exhibit, by thermal analysis, a T_g of 284 K which is in good agreement with literature values[20] for poly(isobutyl methacrylate) prepared by anionic initiators.

Polymerization of isobutyl methacrylate (iBMA) in DMF

The results referring to the electropolymerization *in situ* of iBMA in DMF are reported in *Table 1*. Each run was performed using 50 ml of solution containing 2.35×10^{-2}

mol/l of TBAP as background electrolyte and monomer, as shown. The monomer concentrations used are in the range which gave coherent coatings of polymer on the cathode. The first three columns (A, B and C) report the experimental conditions for each run. Column D reports the percentage increase of the potential between the two electrodes $[\Delta V/V_0 \times 10^2 = 100 \times (V_{final} - V_{initial})/V_{initial}]$. Under galvanostatic conditions, the potential increase is due to the increase of resistance of the system as a consequence of the build up of a polymeric film at the cathode surface. Since the polymerization rate is (at least initially) proportional to the number of the active centres, i.e. to the current, the film formation mainly follows the strength of the electric field. When the electric field distribution is modified by the formation of an insulating coating on some part of the cathode, film formation is moved to the points on the electrode when initially the field strength was lower, consequently the greater the increase of resistance of the system with coating the greater will be the homogeneity of the film. As an indication when $\Delta V/V_0 \times 10^2$ approaches 20, coating occurs on both the back and the front of the electrode. The parameter $\Delta V/V_0 \times 10^2$ can be taken as an index of the 'throwing power' of the coating system. From the data of *Table 1*, $\Delta V/V_0 \times 10^2$ increases with electrolysis time, reaching either a limiting value or rising to a maximum with a subsequent slight decrease. This may be ascribed to the interaction of the conductive solvent with the polymer film which results in some solution or swelling of the film. In systems where $\Delta V/V_0 \times 10^2$ reaches a maximum for different conditions of monomer concentration and electrolysis time generally correspond to the best experimental conditions for the formation of a coating.

Column E shows the total amount of polymer formed on the cathode during each electrolysis. With increasing electrolysis time this value initially increases quickly but eventually slows to a limiting value; for the longest times a decrease may be observed. For the same electrolysis time the total polymer deposition decreases with increase of the monomer concentration. The first observation may be

explained by the attainment of some steady state condition between rate of polymer formation and rate of polymer solution. The second observation probably results from a decrease of the polymerization rate consequent on the diminution of the dielectric constant of the system for low solvent/monomer ratios, in addition to any increased film solubility at high monomer concentrations.

The current efficiency (column F), the number of polymer moles formed per Faraday probably approaches unity at the very beginning of the process, i.e. each electron transfer initiates a polymer chain, afterwards it decreases rapidly with reaction time. An apparent decrease of efficiency may be due to solution of some of the polymer formed; on the other hand, the polymerization could be diffusion controlled and the decrease of efficiency could be due to a decreased monomer concentration at the electrode surface. The influence of current intensity on polymer yield further confirms the competition existing between electropolymerization *in situ* and interaction of the polymer coating with the solvent. Comparing runs in which the total charge transferred was of the same order (runs 3 and 8, 5 and 9, 13 and 17, 14 and 18, 21 and 24, 22 and 25) one can realise the difference in current intensity. At the lowest currents the polymerization rate is so slow that the time of interaction of solvent with polymer is such that no film is produced.

The last column of *Table 1* gives the hardness of certain films. For the same weight of coating, that is the same thickness of the film, the hardness is generally similar for different experimental parameters used. This together with the similarity of molecular weights (*Table 2*) would imply similar molecular complexity and features in each of the coatings.

Polymerization of isobutyl methacrylate in DMSO

The experiments in DMSO were carried out using conditions identical to those using DMF except that in all cases the current was maintained at 50 mA. The results are reported in *Table 3*. The main differences between DMF and DMSO as solvent lies in the lower compatibility of poly(iBMA) with DMSO which can be appreciated by comparing the solubility parameters; for the polymer $\delta = 9.2$ with a $\Delta\delta$ maximum = 1.8 [21], for DMF $\delta = 12.1$ [22] for DMSO $\delta = 13.4$ [23]. It is for this reason that in DMSO there is a far greater increase in electrical resistance which is shown in *Figure 1*, where the parameter $\Delta V/V_0 \times 10^2$ is considered in terms of different monomer concentrations as a function of electrolysis time. The coatings show a very good 'throwing power' and in most of the coatings the back of the plate is completely and homogeneously coated.

The lower solubility of iBMA in DMSO allows the formation of coherent coatings over a greater range of monomer concentration. Furthermore it is possible to obtain greater amounts of polymer over longer electrolysis periods which means that the current efficiency shows less variation with time. The results show that the best deposition conditions (with respect to rate and current efficiency) are obtained at a volume ratio of about 1:1 solvent:monomer. Both at lower and higher monomer concentration there appears to be a decrease in polymerization rate as a result of diminished monomer activity (at low concentrations) and to diminished dielectric characteristics of the medium (at higher monomer concentration). The data of column E of *Table 3* allows comparison of the hardness
Figure 1 Percentage increase of electrode potential during the electropolymerization *in situ* of isobutyl methacrylate using different monomer concentrations: O, 5.10; X, 1.91; □, 3.83; △, 2.55; ●, 3.20 mol/l

of samples obtained under different conditions. For the same weight of film an increase of hardness generally follows the increase of monomer concentration. This may be explained in terms of a parallel increase of the molecular weights of the samples (*Table 2*).

Polymerization of t-butyl methacrylate

The data for the electropolymerization *in situ* of t-butyl methacrylate (t-BMA) in DMSO are reported in *Table 4*. The difference between the solubility parameter of this polymer ($\delta = 8.3$) [21] and the solvent is greater than with poly(iBMA). *Figure 2* shows $\Delta V/V_0 \times 10^2$ as a function of electrolysis time for experiments when only the monomer concentration was varied. The increase of resistance accompanying the coating is greater than that seen in *Figure 1* and may be explained by the poor interaction of the insulating film with the conducting solvent. For some monomer:solvent ratios when using the higher current intensities of *Figure 2* a value of the difference of potential between the electrodes is soon reached at which the insulating film is broken with a consequent decrease of potential, under these conditions the coating is not homogeneous but is a powdery deposit. As can be seen from the last column of *Table 4* coherent polymeric films can be obtained by using lower current intensities. It is interesting to note that the current yield of poly(t-BMA) does not generally decrease in applying the same amount of charge by decreasing the current intensities (on the contrary the yield of adherent film formed at low current intensities is greater than that of the powdery deposit obtained at high current intensity).

The hardness of the samples (*Table 4*, column F), generally superior to that obtained for poly(iBMA), may be explained in terms of the higher T_g of poly(t-BMA) since the molecular weights and probably the molecular complexity are very similar for the two polymers (*Table 2*).

The hardest films are generally obtained from polymerizations carried out at the lowest currents, an increase of hardness is generally paralleled by an increase in molecular weight (*Table 2*).

Polymerization of t-butyl acrylate with isoamyl methacrylate

For the sake of conciseness the data for t-butyl acrylate (t-BA) and isoamyl methacrylate (iAMA) are not reproduced, only the related molecular weights are given in *Table 2*.

Both monomers show poor affinity for the solvent and coherent films are obtained; however, because of their low T_g the poly(t-BA) deposits are very soft and the coatings of poly(iAMA) are mainly viscous oils. The molecular weights are in a similar range to those for the other polymers.

Despite the poor mechanical features the coatings obtained with these monomers are mentioned here for two main reasons: (i) under the same experimental conditions the

isomers with a n-paraffin substituent (n-butyl, n-amyl) are far less suitable for electropolymerization *in situ*; (ii) Both monomers may well be the main component of an electropolymerization *in situ* with monomers capable of improving the features of the coatings.

Considerations on the molecular weights of the polymers obtained in situ

The molecular weights reported in *Table 2* were obtained from polymer samples obtained by combining the products of several electrolyses similar in concentration and current but differing in reaction time.

In the electroinitiated polymerization of methyl methacrylate[18] and acrylonitrile[2,3,24] in DMF with tetraalkylammonium salts as base electrolyte, it was shown that the molecular weight was largely independent of active centres electrochemically produced, i.e. from the current intensity and electrolysis time. This means that chain propagation and chain limiting reactions have the same kinetic dependence on active centres. On the other hand, Asahara[9] has found some dependence of molecular weights on electrolysis time and current in the polymerization *in situ* of acrylonitrile in the presence of transfer agents. This disagreement may be explained by the heterogeneity of the reaction *in situ*. In addition working in an undivided cell the termination contribution from anodically generated products might well vary with the amount of charge transferred. The molecular weights obtained for different electrolysis times, averaging the contribution from surface or diffusion phenomena, seem however capable of identifying the parameters which control the chain length.

The number-average degree of polymerization $\bar{X}_n$ of the products can be related to the rate of various stages of polymerization by the Mayo equation:

$$1/\bar{X}_n = R_t/R_p + C_M + C_S [S]/[M]$$

where R_p and R_t are the propagation and termination rates respectively and C_M the transfer constant to monomer and C_S that to solvent. The data for poly(iBMA) of *Table 2* plotted according to the Mayo equation (*Figure 3*) give a

straight line from which $C_S = 6$ x 10^{-3} and $R_t/R_p + C_M = 3.4$ x 10^{-2}. In similar way the Mayo equation applied to the molecular weights obtained for t-BMA *(Figure 3)* gives the values $C_S = 2.5$ x 10^{-3} and $R_t/R_p + C_M = 2.25$ x 10^{-2}. For poly(t-BA) on the other hand, the molecular weight appears to be quite independent of solvent:monomer ratios *(Figure 3)* which suggests that the chain limiting process is that of monomer transfer thus differing from methacrylic esters; this monomer does contain an acidic hydrogen atom in the α-position to the carboxyl group.

Copolymerization experiments

The polymer films so far obtained exhibit satisfactory adhesion but generally lack hardness owing to their low T_g. In order to improve this, copolymerization with a monomer whose homopolymer has a higher T_g was investigated.

From the previous work iBMA was selected as the common monomer. This was first copolymerized with methyl methacrylate (MMA) ($T_g = 105°C$) which is useful for hardening polymeric coatings even when present as the minor constituent; in addition it readily undergoes anionic copolymerization with other acrylic and methacrylic esters[25].

From copolymerization runs carried out in DMSO using conditions identical to those reported earlier it was found that: (1) on increasing the molar ratio [MMA]/[iBMA] from 0.1 to 0.37 both $\Delta V/V_0$ x 10^2 and polymer yield decrease; (2) only for systems containing lower amounts

of MMA some slight increase of hardness was observed.

The following explanation seems the most reasonable: iBMA and MMA are likely to have different reactivities. In iBMA the bulky electron releasing substituent would tend to decrease both the electroinitiation and propagation reactions below those to be expected for MMA in the copolymers. However, the solubility parameter of PMMA ($\delta = 10.2$; $\Delta\delta_{max} = 2.6$) is close to that of the solvent which increase the dissolution of the polymer film. Thus when [MMA] in the feed is low, the coating parameters are affected and the hardness increased. Increasing [MMA] decreases the throwing power and film formation eventually ceases to occur. Unfortunately the usable [MMA] is insufficient to cause a substantial increase in hardness without causing a fall of the other favourable features observed for iBMA homopolymerization *in situ*.

Methacrylonitrile (MAN) the second comonomer to be used is again known to copolymerize readily with acrylic esters[26]. Moreover, PMAN produced anionically does show good hardness characteristics, possibly because of the carbon–nitrogen conjugation present in the structure which also confers increased heat stability. Runs 156–176 *(Table 5)* were performed in DMSO with [MAN]/[i-BMA] in the range 0.04–0.12. Small amounts of MAN have a pronounced effect on both $\Delta V/V_0$ x 10^2 and polymer yield. An explanation similar to that for MMA may be used; however, the higher electronegativity of the nitrile group increases the reactivity of the MAN with respect to both the initiation and propagation processes.

The reaction in DMF is particularly interesting. Mortimer[27] has shown that MAN is particularly suitable for electropolymerization *in situ* in DMF. Despite the fact that DMF is a good solvent for PMAN, coatings of this polymer are resistant to the solvent during the time scale of their formation. The films so formed are of reasonable hardness but with relatively poor adhesion to the substrate.

Using a wide range of comonomer compositions of [MAN]/[t-BMA] leads to some interesting results. When [MAN]/[iBMA] $\leqslant 1$ the polymers produced do not give rise to coherent films nor does the solvent swollen film wet the substrate.

On the other hand, when [MAN]/[iBMA] > 1 films are readily produced *(Table 5, runs 176–188)*. Once dried the films are quite hard and exhibit good adhesion properties and in these conditions the coating could have some applied interest; the 'throwing power', on the other hand, is very poor and the system could only be used to coat simple shapes.

Compositions of copolymers with MAN

Consideration of the polymer composition as determined by nitrogen analysis leads to some surprising results especially when considered in the light of the higher reactivity which is expected for MAN. *Figure 4* shows that for iBMA/MAN in DMF the variation in copolymer composition is almost that of an alternating copolymer for which $r_1 = r_2 = 1$. This is interesting in that a product with less than 50 mol% MAN still exhibits the typical coloration of the conjugated carbon–nitrogen bonds shown by pure PMAN. It may be that initial reaction involves the formation of blocks of MAN and that this reaction is faster than the rate of diffusion of MAN to the electrode surface which enables the iBMA (now in relatively greater concentration) to enter into the copolymerization. In addition when the metal plate is withdrawn from the solution after a short electro-
Figure 4 Copolymer composition diagram. □, t-butyl methacrylate in DMSO; ○, iso-butyl methacrylate in DMF; ●, iso-butyl methacrylate in DMSO. Common comonomer, methacrylonitrile

lysis time, the polymer swollen with the comonomer/solvent mixture will have an average composition very close to that at the onset of reaction. If copolymerization or even homopolymerization proceeds during the drying of the films the resulting products will have a composition similar to that of the comonomer feed.

For longer electrolysis times and lower currents, the different resistance of the products to the solvent at different compositions has to be considered too. This is the case for copolymerization runs carried out in DMSO for the system t-BMA/MAN of which only the data of *Figure 4* are reported here.

CONCLUSIONS

It is clear from the data so far discussed that in order to achieve electrochemical polymerization of acrylic monomers *in situ* (i.e. the formation of polymeric material simultaneous with deposition on the metal substrate) a preliminary condition must be fulfilled; in aprotic media the monomer/solvent couple has to be selected such that the solubility parameter of the polymer is sufficiently different to that of the solvent, or at least the time scale of building up the film should be lower than the time required for the dissolution of the polymer.

The 'throwing power' of the process is related to this condition, once the low conductivity of the insoluble deposition does affect the homogeneity and the morphology of the coating. Although the insolubility of the polymer is a necessary condition it can be a hinderance to obtaining a proper polymeric film; the polymer molecules, because of the poor polymer/solvent interaction will tend to be tightly coiled instead of spreading onto the metal substrate. This effect has to be counterbalanced by other factors: (1) by the existence of some interactions between the growing polymer and the electrode material; (2) by a reduction of the polymer chain length.

An indirect indication of point 1 is that a better coating is formed when the polar monomer contains a bulky secondary or tertiary substituent, n-parafinic substituents lead to far less satisfactory results. This fact requires further investigation, but it is likely that the adsorption and orientation of monomer molecules on the metal electrode before the polymerization is very important for the subsequent process *in situ* to occur.

Point 2 is banal and requires little further comment. It must be observed that not only the polymer chain but also the average kinetic chain length resulting from each electron transfer need not be very high otherwise the overall polymerization reaction will not be confined to the vicinity of the electrode surface. Thus in the anionic systems examined no careful diminution of impurities and moisture which could possibly act as chain terminating agents was necessary. It is clear that the conditions so far discussed for electropolymerization *in situ* represent a strict limit to this technique either for the range of expoitable monomers or for the physical features of the coatings. In particular the low molecular weights obtained *in situ* do not agree with the general rule that the film forming properties of a surface coating improve as the molecular weight or molecular complexity of the polymer increase.

Copolymerization may overcome these drawbacks. Although some relatively satisfactory results have been obtained with suitable MAN/iBMA mixtures, copolymerization of similar monomer pairs does not generally resolve the problems related to molecular weight and molecular complexity. Addition of a small quantity of a divinyl derivative, which would not affect the 'throwing power' of the systems reported here may be capable of introducing crosslinks either during polymerization or during subsequent drying operations.

Crystallinity and fusion of ethylene oxide/ propylene oxide block copolymers: 1. Type PE copolymers

P. C. Ashman and C. Booth
Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 16 May 1975)

Lamella spacings, specific volumes and melting points have been determined for a series of well charac-
terized poly(propylene oxide)/poly(ethylene oxide) type PE block copolymers with E-block length
40 chain units and P-block lengths 0 to 11 chain units. These properties are interpreted in terms of
a stacked lamella model with alternating amorphous and crystalline layers. The crystalline lamella
thickness is found to be about 25 E chain units, i.e. the crystals are predominantly of extended-chain
type. The specific volume of the polymer in the amorphous lamellae is found to be lower than that
of polymer of corresponding composition in the supercooled melt. The melting points are low com-
pared to that of perfectly crystalline poly(ethylene oxide), i.e. 47 to 51°C compared with $T_m^0 = 76°C$.
This is due to the positive free energy of formation from the melt of the amorphous layer ($\sigma_a \sim 3.5$
kJ/mol) and the crystalline/amorphous interface ($\sigma_o \sim 3$ kJ/mol).

INTRODUCTION

The crystalline structure and the melting behaviour of low
molecular weight poly(ethylene oxide) has been extensively
studied. Small-angle X-ray scattering[1-3], electron[4] and
optical[5] microscopy and dilatometry[1,2] have served to show
that the crystalline structure is stacked lamellae, i.e. alter-
nating crystalline and amorphous layers, forming a poly-
crystal. Within the crystalline lamellae the poly(ethylene
oxide) chains are folded to an extent which depends upon
the molecular weight and the crystallization tempera-
ture[1,2,6,7]; samples of molecular weight less than 3000 are
essentially unfolded (extended-chain crystals).

The thermodynamic melting point (i.e. the melting
point of an infinitely large perfect crystal composed of
polymer of infinite molecular length) of poly(ethylene
oxide) is near 349 K [8-10]. Melting points of poly(ethylene
oxide) fractions range downwards from 343 K, the actual
values observed being affected by the average molecular
weight[6-11], the nature of the end group[12-16] and the
nature of the chain folding in the crystalline lamel-
lae[6,7,11,14].

Given that poly(ethylene oxide) is a stacked lamella
structure the melting behaviour can be broadly understood
in terms of the lamella thicknesses and the free energies of
formation (from the melt) of the crystalline and amorphous
lamellae. The free energy of formation of the crystalline
lamellae can be calculated (using the methods of statistical
mechanics[17,18], known molecular and thermodynamic pro-
perties of the polymer, and the lamella thicknesses) and
so it is possible to focus attention upon the free energy of
formation of the amorphous lamellae and the crystalline/
amorphous interface. These two contributions to the free
energy of formation from the melt of the polycrystal are
usually considered together as the interfacial free energy,
σ_e.

For predominantly chain-extended crystals a practicable
way of changing σ_e whilst keeping other parameters un-
changed is to vary the chemical nature of the chain end-
groups[12,13]. If the end-groups are blocks of copolymerized
material, such that the block is confined to the amorphous

lamella by the crystallization of the poly(ethylene oxide)
block[14,15], very marked changes in the nature of the amor-
phous layer are possible.

In order to avoid undue complexity in the interpretation
of the thermodynamic properties of a crystallizable block
copolymer it is essential that the two polymeric components
are compatible in the melt (otherwise the properties of the
crystalline copolymer may be determined in part by the
two-phase structure of the melt) and that only one com-
ponent is crystallizable. Accordingly we have chosen to
study block copolymers of poly(ethylene oxide) and poly-
(propylene oxide) rather than the block copolymers favour-
ed by others, i.e. poly(ethylene oxide) with either poly-
(styrene)[19,20] or poly(ε-caprolactam)[21]. The mixing beha-
viour of low molecular weight poly(ethylene oxide) and
poly(propylene oxide) fractions has been investigated[22,23]
and the results give reason to suppose that the poly(ethyl-
ene oxide)/poly(propylene oxide) block copolymers we have
prepared do not exhibit microphase separation in the melt.

In this paper we report the preparation and properties
of diblock copolymers of ethylene oxide and propylene
oxide. We denote these PE (where P is a propylene oxide
block and E an ethylene oxide block). In subsequent papers
we will report on triblock (PEP) and multiblock [P(EP)$_n$]
copolymers.

EXPERIMENTAL AND RESULTS

Preparation

PE copolymers were prepared by the polymerization of
propylene oxide onto α-methoxy-ω-hydroxy-poly(ethylene
oxide).

Reagents and solvents were purified by the methods
described by Perrin *et al.*[24]. Ethylene oxide was refluxed
over anhydrous calcium sulphate (2 h) and then distilled
through a column of potassium hydroxide pellets. Pro-
pylene oxide was refluxed over calcium hydride (4 h) and
then distilled. Methanol (50 cm³) was reacted with mag-
nesium turnings (2 g), more (200 cm³) added and refluxed
(3 h), and finally distilled and stored over molecular sieves

* Weight fraction of poly(ethylene oxide)

(type 4A). Dioxane (1 dm³), water (100 cm³) and concentrated hydrochloric acid (14 cm³) were mixed and refluxed (12 h) under an atmosphere of nitrogen, the mixture was neutralized with solid potassium hydroxide and refluxed with sodium metal (12 h), and finally distilled and the dioxane was stored over molecular sieves (type 4A). Benzene was dried over and distilled from calcium hydride.

Polymerization was carried out in apparatus similar to that described by Simons and Verbanc[25]. Sodium (2 g) was added to a solution of methanol (46 g) in dioxane (10 cm³) under a blanket of dry nitrogen. When reaction was complete (at room temperature) the temperature was raised to 100°C and ethylene oxide (~250 g) was added at a rate sufficient to maintain the temperature. Boiling of the monomer served to agitate the mixture and also blanket the reaction with ethylene oxide vapour; towards the end of the reaction, and whenever the mixture was cooled, dry nitrogen was used for these purposes. After the required amount of ethylene oxide had reacted (i.e. when the ratio of the weight of ethylene oxide reacted to the number of moles of methonol used as initiator indicated an average molecular weight for the poly(ethylene oxide) of $\overline{M}_n \sim 1750$) the system was flushed with dry nitrogen to remove any remaining ethylene oxide. Thereafter propylene oxide was added in increments to prepare the copolymer.

Samples, withdrawn at intervals, were cooled and neutralized with dilute hydrochloric acid. Dioxane, water and unreacted monomer were removed by rotary evaporation followed by evacuation of the melt. Sodium chloride was removed by dissolving the dry polymer in dry benzene and centrifuging the mixture (15 000 x g for 15 min). Finally the polymers were precipitated from the benzene solution by addition of iso-octane (in such a way as to leave the lower molecular weight molecules in solution[26]) and freeze dried (from benzene solution).

Notation

We refer to samples by their number-average block lengths (expressed in monomer units) as established by their preparation and subsequent characterization. For example, sample 2–40 denotes a PE block copolymer with a poly(propylene oxide) block length of 2 monomer units and a poly(ethylene oxide) block length of 40 monomer units.

Characterization

Average molecular weights were measured by use of a Mechrolab vapour pressure osmometer (benzene at 25°C), by end group analysis (phthaloylation in pyridine)[27–29], and by gel permeation chromatography (g.p.c.). Condi-

tions for g.p.c. were essentially as described earlier[14]; calibration was by poly(ethylene oxide) and poly(propylene oxide) fractions (which gave practically coincidental results); correction was made for instrumental spreading[14]. The copolymer compositions were determined by proton magnetic resonance spectrometry[14,30].

The characteristics of the sample are given in *Table 1*. The measured values of $\overline{M}_n$ for sample 0–40 are in keeping with the value (1750) calculated from the preparative conditions. The values of $\overline{M}_n$ finally adopted (last column of *Table 1*) are calculated from the compositions taking a value of $\overline{M}_n = 1750$ for sample 0–40; this procedure gives internal consistency and also gives substantial agreement with the g.p.c. results for the copolymers.

Dilatometry

Melting points of the samples were determined by dilatometry. The glass dilatometers used have been described elsewhere[31]. A known weight (~0.2 g) of molten polymer was injected into the dilatometer, outgassed (<1 Pa, 4 h), and confined with mercury. Prior to crystallization, the dilatometer was immersed in boiling water (5 min) and then transferred to an oil bath held (to ±0.1 K) at the crystallization temperature. Crystallization was allowed to proceed to completion. The melting point was measured by transferring the dilatometer to a second oil bath held at a temperature 2 K below the expected melting point, and then raising the temperature of the bath at a rate of 6 K/h. The mercury level was observed by means of a cathetometer. The melting point was taken to be the temperature at which the last trace of crystallinity disappeared (as judged by the temperature coefficient of expansion). This melting procedure was chosen so as to avoid[6,8] complications due to overheating and recrystallization.

Melting points, determined for a number of crystallization temperatures (T_c), are listed in *Table 2*. Melting points are seen to be practically independent of T_c. Multiple melting points[6,7,14,15] were not observed.

Picnometry

Specific volumes of the polymers were determined by picnometry. The L-shaped glass picnometers (*Figure 1*) had a sample chamber (1 cm³) joined to a capillary (0.07 cm diameter, 8 cm length) ground to a point at the open end. A dual-bulb apparatus (*Figure 1*) was used to provide a mercury reservoir during expansion and contraction of the dilatometer contents. Once equilibrium had been achieved the mercury could be syphoned from bulb A to bulb B (*Figure 1*) leaving the picnometer exactly full to the point of the capillary. The picnometers were calibrated by filling with mercury.

A small amount of molten polymer (~0.4 g) was injected into the weighed picnometer which was then reweighed.

The polymer was outgassed (<1 Pa, 3 h) and confined with mercury. The picnometer was then attached to the dual-bulb apparatus, immersed in boiling water (5 min), and quickly transferred to a water bath held (to ±0.1 K) at the required crystallization temperature. After 3 days, when crystallization was complete, the picnometer was removed and weighed. Specific volumes (calculated with allowance for buoyancy), measured at two crystallization temperatures (T_c), are listed in *Table 3*.

X-ray scattering

Lamella spacings were determined by small-angle X-ray scattering. Thin films of polymer (thickness ~0.1 cm), supported on Melinex polyester film, were melted at 100°C (5 min) and then transferred to a hot plate held (to ±0.02 K) at the required crystallization temperature. Crystallized films were exposed (at room temperature) to CuKα radiation in a Rigaku—Denki slit collimated small-angle camera. The diffraction pattern was recorded photographically. The camera was standardized with powdered sodium stearate.

The diffraction patterns were observed at room temperature for samples crystallized at 33°C. They were similar to those reported[1,6] for low molecular weight poly(ethyl-

ene oxide) homopolymers, i.e. they consisted of several equally spaced maxima of gradually diminishing intensity. Lamella spacings, calculated directly from the photographs by use of Bragg's law (slit smearing affects being unimportant), are listed in *Table 4*. For purposes of comparison extended chain lengths (nm) are given in *Table 4*; these are calculated assuming a length of 0.28 nm per chain unit (P or E), in keeping with the repeat distance of 1.95 nm for the 7—2 helix of crystalline poly(ethylene oxide)[32]. The spacings indicate that the polymers form predominantly extended-chain lamellae, as is found[1,6,7] for poly(ethylene oxide) homopolymers of comparable chain length.

LAMELLA THICKNESS: SPECIFIC VOLUME OF AMOR-PHOUS MATERIAL

We interpret the lamella spacings and specific volume in terms of a stacked lamella model as depicted in *Figure 2*. Initially we focus attention on poly(ethylene oxide) homopolymers.

Homopolymers

It is assumed that: (a) the amorphous material in the poly crystal is all contained within the amorphous lamellae which are of uniform thickness l_a; (b) the crystalline material is free from defects and is all contained within the crystalline lamellae which are of uniform thickness l_c; (c) the interfaces between the alternating amorphous and crystalline lamellae are discrete. Thus the volume fraction of crystalline material, ϕ_c, is simply given by

$$\phi_c = \frac{l_c}{l} \tag{1}$$

where l is the lamella spacing (measured by X-ray scattering); and the weight fraction of crystalline material, w_c, is

Table 4   Lamella spacings of PE polymers crystallized at 33°C

3—40	12.2	11.9
5—40	12.7	12.6
8—40	13.7	13.5
11—40	14.3	14.2
Figure 2   The stacked lamella model of the polycrystal: see text for definition of symbols
Figure 3 Chain length distribution of sample 0—40: l_c = 26 chain units for T_c = 33°C

therefore given by:

$$w_c = \frac{l_c v}{l v_c} \qquad (2)$$

where v is the specific volume of the polycrystal (measured by picnometry) and v_c is the specific volume of the crystalline material (calculated from unit cell dimensions).

Equation (2) contains two unknown quantities, w_c and l_c. A second relationship between w_c and l_c is available if we extend the model further. We assume that: (d) the ends of the molecules are excluded from the crystalline lamellae, and the amorphous material within the polycrystal arises solely from the discrepancy between the length of the polymer (x) and the thickness of the crystalline lamellae (l_c); (e) the molecules fold to their maximum possible extent (consistent with the crystalline lamella thickness); so that molecules with $x < l_c$ are rejected from the crystalline lamellae, with $l_c < x < 2l_c$ pass through the crystalline lamella once, with $2l_c < x < 3l_c$ pass through the crystalline lamella twice, etc. It may be noted that the assumption of maximum folding implies adjacent re-entry (regular folding) only for those molecules with x near $2l_c$, $3l_c$ etc. As these molecules are only a very small fraction of the total in our samples (see *Figure 3*) the model is not particularly restrictive.

Assumptions (a) to (e) allow us to write:

$$w_c = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)l_c} w(x) \left(\frac{sl_c}{x}\right) dx \qquad (3)$$

where l_c is expressed in chain units, i.e. l_c/chain units = (l_c/nm) (1/0.28) since 0.28 nm is the length of a chain unit in crystalline poly(ethylene oxide) at 25°C [32], and $w(x)$ is the weight distribution of chain lengths (x in chain units) in the sample.

We apply equations (2) and (3) in the following way. The weight distribution of low molecular weight poly(ethylene oxide) samples are narrow (*Table 1*) and so can be well represented by Schulz—Zimm [33] distributions, i.e. by:

$$w(x) = \frac{b^{(a+1)}}{\Gamma(a+1)} x^a e^{-bx} \qquad (4)$$

where $b = a/\bar{x}_n$ and $a = 1/(\bar{x}_w/\bar{x}_n - 1)$, and $\bar{x}_n$ and $\bar{x}_w$ are number- and weight-average chain lengths. The two relationships between w_c and l_c are plotted in *Figure 4* for sample 0—40 for which l = 11.0 nm, v = 0.832 cm³/g at 33°C, v_c = 0.814 cm³/g at 33°C*, $\bar{x}_n$ = 40 chain units and $\bar{x}_w/\bar{x}_n$ = 1.05. The intersection of the two curves represents those values (l_c = 7.4 nm, w_c = 0.68) which satisfy the two equations. We include in *Figure 4* plots of equation (3) for other values of $\bar{x}_w/\bar{x}_n$; it can be seen that the values of l_c and w_c obtained are fairly insensitive to this parameter when $\bar{x}_w/\bar{x}_n \geqslant 1.05$.

Block copolymers

The above treatment is readily extended to block copolymers with a non-crystallizable block, since all of this material will be in the amorphous lamellae. If w_c is redefined as the weight fraction of the poly(ethylene oxide) block which is crystalline, and if w_e is the weight fraction of poly(ethylene oxide) in the copolymer, then the weight fraction of the copolymer which crystallizes is $w_c w_e$ and equation (2) becomes:

$$w_c = \frac{l_c v}{l v_c w_e} \qquad (5)$$

---

* We use v_c = 0.813 cm³/g at 25°C [34] and α_c = 0.00015 cm³/g K [2]. Note that l is measured at about 20°C; the correction to 33°C (~0.1%) is negligible compared with experimental error.
Figure 4 Relationship between w_c and l_c for sample 0—40: ———, equation (2); ————, equation (3) with $\bar{x}_w/\bar{x}_n$ equal to 1.05 (A), 1.10 (B) and 1.20 (C)

Table 5 Characteristics of crystalline PE polymers at 33°C

Sample	l_c (nm)	w_c	l_a (nm)	v_a (cm³/g)	v_s (cm³/g)
0—40	7.4	0.68	3.7	0.870	0.897
2—40	7.0	0.69	4.3	0.886	0.917
3—40	7.1	0.69	4.8	0.898	0.927
5—40	7.0	0.69	5.6	0.908	0.937
8—40	6.8	0.69	6.7	0.937	0.952
11—40	6.8	0.69	7.4	0.940	0.957

Equation (3) can be rewritten:

$$w_c = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)l_c} w(y)\left(\frac{sl_c}{y}\right) dy \qquad (6)$$

where $w(y)$ is the weight distribution of poly(ethylene oxide) block lengths (y).

Solutions of equations (5) and (6) for the PE series of copolymers, using the data of *Tables 1, 3* and *4,* are given in *Table 5*. Given l_c and w_c we can calculate the thickness of the amorphous lamellae (l_a) and the specific volume of the material in the amorphous lamellae (v_a) from the equations:

$$l = l_c + l_a \qquad (7)$$

$$v = v_c w_c w_e + v_a (1 - w_c w_e) \qquad (8)$$

and values of l_a and v_a are also given in *Table 5*.

Crystalline lamella thicknesses (l_c) and degrees of crystallinity of the poly(ethylene oxide) block (w_c) are practically independent of the copolymer composition. The specific volume of the amorphous material (v_a) varies with the copolymer composition mainly because of the changing composition of the amorphous lamellae. The specific volume of a supercooled melt of the same composition as the amorphous lamellae (v_s) can be calculated, assuming no volume change on mixing, from the equation:

$$v_s = (w_e w_a v_e + w_p v_p)/(1 - w_c w_e) \qquad (9)$$

where $w_a = 1 - w_c$ is the weight fraction of the poly(ethylene oxide) block which is amorphous, $w_p = 1 - w_e$ is the weight fraction of poly(propylene oxide) in the copolymer, and v_e and v_p are the specific volumes of supercooled liquid poly(ethylene oxide) and poly(propylene oxide) respectively. We use $v_e = 0.897$ cm³/g and $v_p = 1.007$ cm³/g at 33°C*. Comparison of the specific volume of the amorphous material of the polycrystal (v_a) with that of supercooled melt of the same composition (v_s) is made in *Table 5*: v_a is lower than v_s by 1 to 3%. This finding is in keeping with studies of crystalline poly(ethylene), which have been reviewed recently[38,39] and which indicate an increased density of the amorphous material in the polycrystal over that of the supercooled melt.

END INTERFACIAL FREE ENERGY, σ_e

Two theories[17,18] may be used to interpret the melting points and lamella thicknesses of low molecular weight

* $v_e = 0.891$ cm³/g at 25°C [35]: $\alpha_e = 0.00069$ cm³/g K [2,35].
$v_p = 0.997$ cm³/g at 20°C [36]: $\alpha_p = 0.00077$ cm³/g K [22,37].

polymers and block copolymers. These represent extreme cases of independently located chain ends[17] and of chain ends paired at the crystalline lamella surface[18]. A modification[18] of the end-paired model allows for partial melting of the crystalline lamella and the formation of an amorphous layer in which the chain ends are located.

The two models are depicted in *Figure 5*. In the Flory[17] model of the partly melted system (*Figure 5a*) the crystalline lamellae are surrounded by melt in which the chain ends are uniformly dispersed. In the modified Flory—Vrij[18] model of the partly melted system (*Figure 5b*) the alternating crystalline/amorphous lamella structure is the unit which is surrounded by melt. Consequently there is a contribution to the melting point depression in the Flory treatment which arises from dilution of the chain ends in the melt owing to melting of the crystalline phase (*Figure 5a*), which does not appear in the Flory—Vrij treatment. We have shown earlier[9], in application of these theories to the melting of low molecular weight poly(ethylene oxide), that the difference between the two models is slight. However, the Flory—Vrij model is consistent with the model we have developed (to account for the lamella spacings and specific volumes of our polymers) in the previous section.

It is convenient to start with a description of the Flory—Vrij theory applied to homopolymers.

Homopolymers

The Flory—Vrij theory leads[11] to the following expression for the melting point of a low molecular weight homopolymer in an extended-chain polycrystal:

$$T_m = T_m^0 [1 - 2\sigma_e/\Delta h l_c]/[1 - (RT_m^0 \ln I)/\Delta h t l_c] \qquad (10)$$

where T_m^0 is the thermodynamic melting point, Δh the thermodynamic enthalpy of fusion, and l_c the crystalline lamella thickness in chain units. The end interfacial free energy (σ_e) is the free energy of formation from the melt of the amorphous/crystalline interface and the adjacent amorphous layer. The polymer chains traverse the crystalline lamella t times each *on average*. The parameter I accounts for the

8—40	47.5	0.759	1.14	6.6
11—40	47.1	0.717	1.15	6.7

* At T_m: l_c is negligibly different (<0.1%) from l_c at 20°C

state of order of the chains in the polycrystal[11,18] and is, effectively, the probability that a sequence of chain units sl_c long (where s is a positive integer), folded if $s > 1$, does not contain a chain end. For a polydisperse polymer, where each chain folds to its maximum extent (for a given l_c), I has the form[11,18]:

$$I = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)l_c} w(x)[(x - sl_c + 1)/x]\,dx \qquad (11)$$

where $w(x)$ is the weight distribution of chain lengths which, as before, we can represent by a Schulz–Zimm expression[33]. Similarly:

$$t = \sum_{s=1}^{\infty} \left[\int_{sl_c}^{(s+1)l_c} s\left(\frac{w(x)}{x}\right)dx \middle/ \int_{0}^{\infty}\left(\frac{w(x)}{x}\right)dx \right] \qquad (12)$$

Equations (10) to (12) are consistent with assumptions (a) to (e) of the previous section; however, equations (11) and (12) contain the additional restriction that chain folding must be by adjacent re-entry. The folds are included in the crystalline lamellae.

We apply equations (10) to (12) in the following way. Melting points are calculated for several values of σ_e and compared with the observed melting points to fix σ_e. (Details of this procedure have been given earlier[6].) For sample 0–40 we have $T_m^0 = 349$ K [8-10], $\Delta h = 8.4$ kJ/(mol of chain units)[40], $l_c = 7.3$ nm = 26 chain units, $\bar{x}_n = 40$ chain units and $\bar{x}_w/\bar{x}_n = 1.05$. An observed melting point of 323.9 K (*Table 2*) leads to a value of σ_e of 6.5 J/(mol of chains emerging) while t, the folding parameter, is found to be 1.04.

Block copolymers

For block copolymers equations (10) to (12) must be changed to allow for a changed probability of sequence selection. The molten copolymer chain is considered to be composed of segments of volume equal to that of a molten poly(ethylene oxide) chain unit. The probability that a segment chosen at random is a poly(ethylene oxide) segement is then ϕ_e, the volume fraction of poly(ethylene oxide) in the copolymer melt. This is the probability that the first segment of a chosen sequence is a poly(ethylene oxide) unit*. The probability that the rest of the sequence does not contain a poly(ethylene oxide) block end is then (for maximum folding)

---

* Flory[17] puts this probability equal to the mole fraction of crystallizable polymer units. The use of volume (segment) fraction seems more in keeping with the Flory–Vrij[18] model.

$$I = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)} w(y)[(y - sl_c + 1)/y]\,dy \qquad (13)$$

where $w(y)$ is the weight distribution of poly(ethylene oxide) block lengths (y). A similar equation is written for the folding parameter t. The melting point equation for a block copolymer of type PE is:

$$T_m = T_m^0[1 - 2\sigma_e/\Delta h l_c]/(1 - (RT_m^0 \ln \phi_e I)/\Delta h t l_c] \qquad (14)$$

Values of the volume fractions calculated from

$$\phi_e = w_e v_e/(w_e v_e + w_p v_p) \qquad (15)$$

are listed in *Table 6*, together with the values of t and σ_e obtained by use of these parameters and those listed earlier (note that $\bar{y}_n = 40$ chain units and $\bar{y}_w/\bar{y}_n = 1.05$). Values of t are all near to unity, as expected for predominantly extended-chain polycrystals.

The end interfacial free energy σ_e has a formal interpretation which depends upon the model used to describe the system. This is made clear by reference to *Figure 5*. In the Flory model (*Figure 5a*) σ_e is the free energy of formation from the melt of the crystal/melt interface. In the Flory–Vrij model (*Figure 5b*) σ_e is the free energy of formation from the melt of the amorphous/crystalline interface and the adjacent amorphous layer. So it is convenient, for the polycrystalline model, to write σ_e as the sum of three terms:

$$\sigma_e = \sigma_o + \sigma_m + \sigma_a \qquad (16)$$

which can be identified as follows: σ_o = the free energy of formation from the melt of the amorphous/crystalline interface; σ_m = the free energy change (enthalpy and non-combinatorial entropy changes) due to the concentration, relative to the melt, of chain ends (blocks or groups) in the amorphous lamellae. (The combinatorial entropy change associated with the formation of the amorphous lamellae is accounted for by the Flory–Vrij theory.); σ_a = the free energy increase due to conformational restriction, relative to the melt, of the chains in the amorphous lamellae, i.e. due to the constraint of the crystal surface. It has been shown elsewhere[14] that the attractive energy of the crystalline lamellae contributes negligibly to σ_e, and we assume (in the absence of any compressive force) that the low specific volume of the polymer in the amorphous layer simply reflects the effects of conformational restriction.

Estimation of σ_m

Provided we assume random mixing in the amorphous lamellae and the melt, the non-combinatorial free energy change on mixing per mol of segments can be written:

$$\Delta G_m = RT\chi\phi_e\phi_p \qquad (17)$$

where χ is the Flory–Huggins parameter for chain segments [segment volume equal to that of poly(ethylene oxide) chain unit] and ϕ_e and ϕ_p are volume fractions. The free energy of mixing on forming the amorphous layer from the melt is:

$$\Delta G_m(\text{layer}) - \Delta G_m(\text{melt})$$
Figure 6 Effect of the length of the emerging chains on the end interfacial free energy: plot of σ'_e against $(RT/t) \ln l'_a$ in accordance with equations (23) and (25). Broken line (----) has a slope of 2/3. ●, PE block copolymers; ○, poly(ethylene oxide) homopolymers

If we denote volume fractions in the melt by ϕ_e, ϕ_p and in the amorphous layer by ϕ'_e, ϕ'_p we can write, for the incorporation of 1 mol of segments into the amorphous layer,

$$\Delta g_m = RT\chi \left[\phi'_e \phi'_p - \frac{\phi_e \phi_p}{\phi_a} \right] \tag{18}$$

where $\phi_a = l_a/l$. Δg_m is expressed in J/(mol of chain segments) so that l_a, the thickness of the amorphous lamellae, is in segments. We have already defined a chain segment as having the volume of a poly(ethylene oxide) chain unit in the melt, so that

$$l_a/\text{segments} = (l_a/\text{nm}) \frac{v_c}{0.28 v_e} \tag{19}$$

Equilibrium phase composition and cloud point curves have been determined[23] for mixtures of α,ω-methoxy-poly(ethylene oxide) ($\overline{M}_n$ = 300 or 600) and α,ω-methoxy-poly(propylene oxide) ($\overline{M}_n$ = 1500 or 2000). Analysis of these data, in terms of a binary solution with concentration independent χ, places χ near 0.1. This is in agreement with an earlier[22] estimate of χ.

With regard to the contribution of the hydroxy end-group to σ_m, we note that the melting point of α,ω-hydroxy-poly(ethylene oxide) of molecular weight $\overline{M}_n$ = 2000 differs little from that of α,ω-methoxy-poly(ethylene oxide) of the same molecular weight. [We find[6,41] values of 53.8°C (hydroxy-) and 53.5°C (methoxy-).] Accordingly we set χ = 0.1 and, with sufficient accuracy for our purposes, calculate the values Δg_m listed in *Table 7*, together with the corresponding values of $\sigma_m = l_a \Delta g_m$. The contribution of mixing to σ_e is seen to be fairly small (<10%).

Estimation of σ_o

A simple calculation of the difference in entropy between a free chain and a chain tied at one end to an impenetrable surface can be made for a chain restricted to one dimension (lattice coordination number 2) and with

zero excluded volume[42]. This model leads to:

$$\sigma_a = RT \ln (l'_a)^{1/2} \tag{20}$$

where l'_a is the length of the tied chain. The form of equation (20) is not greatly dependent on the geometry of the lattice[42]. If allowance is made for excluded volume[43,44] the estimate of σ_a is increased; e.g. the calculation of Bellemans[44] suggests that:

$$\sigma_a = RT \ln (l'_a)^{2/3} \tag{21}$$

For a once-folded polycrystal the corresponding expression is:

$$\sigma_a = (RT/2) \ln (l'_a)^{2/3} \tag{22}$$

since half the chains emerging from the end interface of the crystalline lamellae are assumed to re-enter the crystal via a regular fold. In general we have:

$$\sigma_a = (RT/t) \ln (l'_a)^{2/3} \tag{23}$$

where l'_a is given by:

$$l'_a = (t l_a/2) + 1 \tag{24}$$

i.e. the average length of the tied chains which emerge into the amorphous lamellae. If we define a quantity σ'_e so that:

$$\sigma'_e = \sigma_e - \sigma_m = \sigma_a + \sigma_o \tag{25}$$

then σ'_e should be independent of the mixing terms and uniform behaviour might be expected for both block copolymers and homopolymers. In *Figure 6* we plot σ'_e against $(RT/t) \ln l'_a$ for the data of *Tables 6* and 7 and for results obtained for poly(ethylene oxide) homopolymers (see Appendix). These results are consistent with equation (23) and lead to an estimate of σ_o of about 3 kJ/mol. This value is about 30% of the heat of fusion. It is, therefore, a plausible result; the usual prediction[45] of the lateral interfacial free energy is about 10% of the heat of fusion.

CONCLUSIONS

We have interpreted the properties of poly(ethylene oxide)/poly(propylene oxide) type PE block copolymers in terms of a simple stacked lamella model with alternating amorphous and crystalline layers. In our systems (E block length = 40, P block length = 0 to 11 chain units) the crystalline lamella thickness is about 7 nm (25 E chain units). The specific volume of the polymer in the amorphous layer, which is predominantly formed of chains

Table 7 Calculation of σ_m for PE polymers

emerging from the end interfaces of the crystalline lamellae, is lower than that of the corresponding polymer in the supercooled melt. The melting temperatures of the stacked lamella structures are low compared with that of perfectly crystalline poly(ethylene oxide): i.e. 47 to 51°C compared with $T_m^0 = 76$°C. This is due to the positive free energy of formation from the melt of the crystal/amorphous interface ($\sigma_o \sim 3$ kJ/mol, 19 erg/cm^2) and the amorphous layer ($\sigma_a \sim 3.5$ kJ/mol, 23 erg/cm^2). The predominant contribution to the free energy of formation of the amorphous layer from the melt is the reduction in entropy, relative to the melt, of the polymer chain emerging from the crystal surface. This reduction in entropy is quantitatively described by equation (23).

APPENDIX

Poly(ethylene oxide) homopolymers

Lamella spacings and specific volumes of several low molecular weight poly(ethylene oxide) homopolymers have been published[1] and the melting points of these polymers are known[6,46]. Published results for samples which form predominantly extended-chain crystals are summarized in *Table A1*. We take $\bar{x}_w/\bar{x}_n$ to be 1.05 for samples 23 to 45 and 1.10 for sample 68 [6,46].

The characteristics of the polycrystals, calculated from the results of *Table A1* in the manner described heretofore, are listed in *Table A2*. Comparison of these results for homopolymers with those for the PE series of block copolymers (*Tables 5* and *6*) reveals an almost complete correspondence between them. The low value of the folding parameter t for sample 23 (*Table A2*) reflects the rejection from the crystal of the shorter chains in the distribution: in turn this is consistent with higher value of v_a found for this sample.

Table A1 Properties of low molecular weight poly(ethylene oxide)

Sample	$\overline{M}_n$	T = 25°C		T_m (°C)
		l (nm)	v (cm^3/g)	
23	1000	7.1	0.832	39.1
34	1500	9.8	0.826	49.0
45	2000	13.1	0.822	53.8
68	3000	18.5	0.821	59.5

Table A2 Characteristics of crystalline poly(ethylene oxide) homopolymers

34	0.68	6.6	3.2	0.85	10.3	0.99	6.0
45	0.68	8.8	4.3	0.84	13.9	0.97	6.6
68	0.68	12.5	6.0	0.84	19.3	1.04	7.0

* For comparison the specific volume of liquid poly(ethylene oxide) at 25°C is 0.89 cm^3/g

Crystallinity and fusion of ethylene oxide/propylene oxide block copolymers:
2. Type PEP copolymers

P. C. Ashman, C. Booth, D. R. Cooper and C. Price
Department of Chemistry, University of Manchester, Manchester, M13 9PL, UK
(Received 16 May 1975)

Lamella spacings, specific volumes and melting points have been determined for a series of well characterized poly(ethylene oxide)/poly(propylene oxide) type PEP block copolymers with E-block length 48 chain units and P-block lengths 0 to 7 chain units. These properties are interpreted in terms of a stacked lamella model with alternating amorphous and crystalline layers. Both extended-chain and once-folded-chain crystalline lamellae are found, the former with thickness about 32 E chain units and the latter with thickness about 21 E chain units. Compared with the specific volume of supercooled melt of the same composition the specific volume of the polymer in the amorphous lamellae is lower in the extended-chain polycrystals and higher in the once-folded-chain polycrystals. The melting points of the copolymers are low compared to that of perfectly crystalline poly(ethylene oxide), i.e. 37 to 55°C compared with $T_m^0 = 76°C$. This is due to the large positive free energy of formation from the melt of the crystalline/amorphous end interface (σ_o) and the amorphous layer (σ_a). For extended-chain polycrystals we find $\sigma_o \sim 3$ kJ/mol and $\sigma_a \sim 3.5$ kJ/mol; for once-folded-chain polycrystals we find $\sigma_o \sim 6$ kJ/mol and $\sigma_a \sim 2$ kJ/mol. We also find $\sigma_{o,x} = 2.5$ kJ/mol for a completely extended-chain end interface and $\sigma_{o,f} = 10$ kJ/mol for a completely folded-chain end interface.

INTRODUCTION

In Part 1[1], we have described the crystallinity and fusion of predominantly extended-chain crystals of type PE poly(ethylene oxide)/poly(propylene oxide) block copolymers, and interpreted the results in terms of a simple stacked lamella model with alternating amorphous and crystalline layers. Previously[2] we have described the melting of predominantly folded-chain crystals of type PEP copolymers. In that work we used E-block lengths of 70 to 100 chain units [E denotes a poly(ethylene oxide) block, P a poly(propylene oxide) block.] Here we report the preparation and properties of type PEP copolymers with an E-block length of 50 chain units and P-block lengths in the range 0–7 chain units. In this series of copolymers we encounter both extended-chain and folded-chain crystals.

EXPERIMENTAL AND RESULTS

Preparation

The method of base catalysed polymerization, using potassium hydroxide as catalyst and ethylene glycol as initiator described in an earlier paper[2] was used in this work without modification.

Notation

We refer to samples by their number-average block lengths (expressed in monomer units) as established by their preparation and subsequent characterization. For example, sample 2–48–2 denotes a PEP block copolymer with poly(propylene oxide) block lengths of 2 chain units and a poly(ethylene oxide) block length of 48 chain units.

Characterization

Average molecular weights were measured by vapour pressure osmometry (v.p.o.) (Mechrolab, benzene at 25°C), by end group analysis (phthaloylation of hydroxy end-groups[3–5]) and by gel permeation chromatography (g.p.c.). Copolymer compositions were determined by proton magnetic resonance spectroscopy[6] and by hydrogen bromide fusion[6,7]. The application of all these methods to ethylene oxide/propylene oxide block copolymers has been discussed earlier[2].

The characteristics of the series of copolymers are given in *Table 1*. The observed values of $\bar{M}_n$ for sample 0–48–0 are in keeping with that (2100) calculated[2] from the preparative conditions. The values of $\bar{M}_n$ finally adopted (last column of *Table 1*) are calculated from the average composition and the value of $\bar{M}_n = 2100$ assumed for sample 0–48–0.

Dilatometry, picnometry, X-ray scattering

The methods used to determine melting points (dilatometry), specific volumes (picnometry), and lamella spacings (small-angle X-ray scattering) have been described in Part 1[1]. Wide-angle X-ray scattering patterns of the copolymers (Debye–Scherrer camera, CuKα radiation) were identical, except for the amorphous background, to those obtained for poly(ethylene oxide) homopolymers.

The melting point was taken to be that temperature at which detectable crystallinity disappeared: a secondary melting point was defined by the appropriate point of inflection in the dilatometric melting curve (e.g. see Fig.1 of ref. 9).

Melting points, measured for a variety of crystallization temperatures (T_c) are given in *Table 2*. All polymers were

crystallized as completely as possible. At $T_c = 36°C$ samples 5—48—5 to 7—48—7 had a low crystallinity and exhibited a high melting point; presumably these effects are due to fractionation during the slow crystallization process at the small undercooling. Two melting points were observed for samples 6—48—6 and 7—48—7 when crystallized at undercoolings exceeding 5 K. (The absence of a melting point is indicated by a rule in *Table 2*.) The final melting points are practically independent of T_c, but secondary (lower) melting points increase as T_c is increased; this behaviour appears to be characteristic of PEP block copolymers[2] and also of partly isotactic poly(propylene oxide)[8]. In *Table 2* the melting points are assigned to extended-chain, once-folded-chain, and twice-folded-chain polycrystals on the basis of past experience[2,9,10], which suggests that the higher melting point is that of the crystal in which the poly(ethylene oxide) chain folds the least number of times, and upon the evidence of the following small-angle X-ray results.

The samples gave small-angle X-ray scattering patterns which resembled those obtained from poly(ethylene oxide) homopolymers[9,11] and copolymers[1,2], in that the scattering

comprised several equally spaced lines. However, samples 5—48—5 to 7—48—7 gave very much more intense diffraction maxima than did samples 0—48—0 to 2—48—2. Lamella spacings, calculated directly by means of Bragg's Law, are listed in *Table 3*. For purposes of comparison extended chain lengths (nm) are given in *Table 3*: these are calculated assuming a length of 0.28 nm per chain unit (P or E) in keeping with a repeat distance of 1.95 nm for the 7—2 helix of crystalline poly(ethylene oxide)[12]. The spacings are consistent with predominantly extended-chain crystals for samples 0—48—0 to 2—48—2 and predominantly once-folded-chain crystals for samples 5—48—5 to 7—48—7. The temperature dependence of the lamella spacing noted for sample 6—48—6 is curious in view of the constant melting point of the folded-chain crystals (*Table 2*).

Specific volumes are listed in *Table 4*.

LAMELLA THICKNESS: SPECIFIC VOLUME OF AMORPHOUS MATERIAL

We interpret the lamella spacings and specific volumes of the samples in terms of the stacked-lamella model presented in Part 1[1], i.e. in terms of the two equations:

$$w_c = \frac{l_c v}{l v_c w_e} \qquad (1)$$

Table 5 Characteristics of crystalline PEP polymers

Sample	l_c (nm)	w_c	l_a (nm)	v_a (cm^3/g)	v_s (cm^3/g)
T = 35°C:					
0–48–0	8.9	0.68	4.6	0.858	0.898
1–48–1	9.0	0.67	5.6	0.884	0.912
2–48–2	8.5	0.69	6.1	0.912	0.928
T = 29°C:					
5–48–5	6.2	0.77	4.7	0.959	0.952
6–48–6	5.9	0.78	5.0	0.973	0.961
7–48–7	5.8	0.78	5.1	0.990	0.962

and

$$w_c = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)l_c} w(y)\left(\frac{sl_c}{y}\right)dy \qquad (2)$$

where w_c = the weight fraction of the copolymer which is crystalline; w_e = the weight fraction of poly(ethylene oxide) in the copolymer; $w(y)$ = the weight distribution of poly-(ethylene oxide) block length (y); l = the lamella spacing; l_c = the thickness of the crystalline lamellae; v = the specific volume of the copolymer; v_c = the specific volume of perfectly crystalline poly(ethylene oxide).

Equations (1) and (2) can be solved graphically for w_c and l_c, as described in Part 1[1]; we assume that $w(y)$ is well represented by a Schulz–Zimm distribution with parameters evaluated from the molecular weight data in *Table 1*. Values of l_a, the thickness of the amorphous lamellae, and v_a, the specific volume of the polymer in the amorphous lamellae, can then be computed from:

$$l = l_a + l_c \qquad (3)$$

and

$$v = v_c w_c w_e + v_a(1 - w_c w_e) \qquad (4)$$

Values of l_c, w_c, l_a and v_a are given in *Table 5*.* The calculation is straightforward for samples 0–48–0 to 5–48–5 since the information we have (*Tables 2* and *3*) is consistent with the presence of only one type of crystalline lamella. The model underlying equations (1) and (2) assumes only one type of crystalline lamella in the system. For this reason the calculations for samples 6–48–6 and 7–48–7 are not entirely well founded.

For purposes of comparison with v_a, the specific volume of the polymer in the amorphous layer, we list in *Table 5* v_s, the specific volume of a supercooled melt of the same composition as the amorphous layer, as calculated (assuming no volume change on mixing) from the equation:

$$v_s = (w_e w_a v_e + w_p v_p)/(1 - w_c w_e) \qquad (5)$$

where $w_a = 1 - w_c$ is the weight fraction of amorphous polymer in the polycrystal, $w_p = 1 - w_e$ is the weight fraction of poly(propylene oxide) in the sample, and v_e and v_p

are the specific volumes of supercooled liquid poly(ethylene oxide) and poly(propylene oxide) respectively.

The data of *Table 5* fall into two groups: (a) samples 0–48–0 to 2–48–2, which form predominantly extended-chain crystals. For these samples w_c is constant at about 0.68: a value identical, within experimental error, to that found[1] for the PE series of polymers and for poly(ethylene oxide) homopolymers which form extended-chain crystals. Moreover we find that v_a is *lower* than v_s by some 2 to 4% (compared with 1 to 3% found earlier); (b) samples 5–48–5 to 7–48–7, which form predominantly once-folded-chain crystals. For these samples w_c is constant at about 0.78, and v_a is *higher* than v_s by some 1 to 3%.

This difference between extended-chain and folded-chain crystals is consistent with our model[1]. The increase in w_c can be attributed to the reduction both in the number of rejected molecules and in the average length of chain ends emerging from the crystalline lamellae. The high value of v_a, relative to v_s, observed for the folded-chain polycrystals can be attributed directly to the decrease in the number of chains emerging from the crystal into the amorphous lamellae caused by adjacent re-entry of the crystalline lamellae by the folded chains. The high value of v_a is consistent with the high intensity of the X-ray scattering maxima which is a characteristic of folded-chain polycrystals (as mentioned earlier), since there is a large density difference between the amorphous and crystalline lamellae.

END INTERFACIAL FREE ENERGY, σ_e

In Part 1[1] we have justified the use of the Flory–Vrij[18] model for the interpretation of the melting points of low molecular weight polymers and block copolymers. Accordingly we write[1,19]:

$$T_m = T_m^0[1 - 2\sigma_e/\Delta h l_c]/[1 - RT_m^0 \ln \phi_e l/\Delta h t l_c] \qquad (6)$$

where T_m^0 is the thermodynamic melting point of poly(ethylene oxide), Δh is the thermodynamic enthalpy of fusion of poly(ethylene oxide), ϕ_e is the volume fraction of poly-(ethylene oxide) in the melt, and t is the average number of times the chains traverse the crystal (i.e. $t = 1$ for an entirely extended-chain polycrystal, $t = 2$ for an entirely once-folded-chain polycrystal, etc.). In general t is given by the equation:

$$t = \sum_{s=1}^{\infty} \left[\int_{sl_c}^{(s+1)l_c} s\left(\frac{w(y)}{y}\right)dy \bigg/ \int_0^{\infty} \frac{w(y)}{y}dy\right] \qquad (7)$$

Parameter I is the probability that a sequence of poly(ethylene oxide) units of length l_c does not contain a block end, and is given by[1]:

$$I = \sum_{s=1}^{\infty} \int_{sl_c}^{(s+1)l_c} w(y)[(y - sl_c + 1)/y]dy \qquad (8)$$

In formulating equations (7) and (8) we assume that each chain folds to its maximum possible extent (for a given value of l_c) by regular folding, i.e. s is the number of sequences chosen consecutively from a given molecule, and that folds are included in the crystalline lamellae. In using

* We use $v_c = 0.813$ cm^3/g at 25°C [13] and $\alpha_c = 0.00015$ cm^3/g K [11]
$v_e = 0.891$ cm^3/g at 25°C [14] and $\alpha_e = 0.00069$ cm^3/g K [11,14]
$v_p = 0.997$ cm^3/g at 20°C [15] and $\alpha_p = 0.00077$ cm^3/g K [16,17]

the equations we assume that $w(y)$ is described by a Schulz–Zimm distribution with parameters evaluated from the molecular weight data in *Table 1*. The end interfacial free energy, σ_e, is the free energy of formation from the melt of the amorphous/crystalline interface *and* the adjacent amorphous layer.

In calculating σ_e we have used $T_m^0 = 349$ K [20–22], $\Delta h = 8.4$ kJ/(mol of chain units) [23], $\bar{y}_n = 48$ chain units, $\bar{y}_w/\bar{y}_n = 1.10$, and the remaining quantities listed in *Table 6*. The values of σ_e, quoted in *Table 6*, are in kJ/(mol of chains emerging from the end interface). The values of the folding parameter t, also listed in *Table 6*, are consistent with our classification of the crystalline samples into essentially extended-chain and once-folded-chain types.

We have written[1] σ_e as the sum of three terms:

$$\sigma_e = \sigma_o + \sigma_m + \sigma_a \qquad (9)$$

which are identified as follows: σ_o = the free energy of formation from the melt of the amorphous/crystalline interface; σ_m = the free energy change (enthalpy and non-combinatorial entropy changes) due to the concentration, relative to the melt, of chain ends (blocks or groups) in the amorphous lamellae; σ_a = the free energy increase due to conformational restrictions, relative to the melt, of the chains in the amorphous lamellae, i.e. primarily due to the constraint of the impenetrable crystal surface.

The estimation of σ_m, assuming random mixing in the melt and the amorphous layer and assuming a concentration independent Flory–Huggins interaction parameter $\chi = 0.1$, has been discussed earlier[1]. The calculation is set out in *Table 7*: the contribution of σ_m to σ_e is seen to be fairly small (<10%). The quantity l_a in *Table 7* is the thickness of the amorphous lamellae at $T = T_m$ measured in segments, so that:

$$l_a/\text{segments} = (l_a/\text{nm})\frac{v_c}{0.28 v_e} \qquad (10)$$

We define a quantity σ_e' where

$$\sigma_e' = \sigma_e - \sigma_m = \sigma_o + \sigma_a \qquad (11)$$

so that σ_e' should be independent of the mixing terms (if these are properly assessed). We have shown earlier[1] that σ_a depends linearly on the function $(RT/t)\ln l_a'$, where l_a' is the average length of the chains which emerge into the amorphous lamellae given by:

$$l_a' = (tl_a/2) + 1 \qquad (12)$$

A plot of σ_e' against $(RT/t)\ln l_a'$ is illustrated in *Figure 1*, where we include data for type PE copolymers and homopolymers taken from Part 1[1] together with data for once-folded-chain poly(ethylene oxide) 6000 taken from Appendix I to this paper.

The results for the predominantly extended-chain crystals of the PEP copolymers are in broad agreement with those established in Part 1[1] for PE copolymers and E homopolymers. The high value of σ_e' observed for sample 2–48–2 requires further discussion. There is a clear distinction between PEP and PE block copolymers of high poly(propylene oxide) content in that the PEP copolymers form folded-chain polycrystals, e.g.

PEP 5–48–5 $w_e = 0.79$ $l = 10.9$ nm $t = 1.7$
PE 8–40 $w_e = 0.78$ $l = 13.5$ nm $t = 1.1$

The formation of folded-chain polycrystals must be a consequence of the reduced stability of the extended-chain

Table 6 End interfacial free energies (σ_e) for PEP polymers

polycrystal: which is consistent with the high value of σ_e' found for sample 2-48-2. The area per chain emerging from the poly(ethylene oxide) end interface can be calculated from lattice dimensions[13] to be 0.26 nm^2. The area of cross-section of the poly(propylene oxide) chain is similar to this if it is in the planar zig-zag conformation (we calculate an area of cross-section of 0.27 nm^2) but is higher than 0.26 nm^2 if the chain adopts a helical conformation (as would be anticipated for isotactic placements: our chains are atactic). In the case of PE copolymers the extension of one end only of the chain leaves a high proportion of terminated poly(ethylene oxide) chains in the amorphous layer. In the case of PEP copolymers the extension of both ends of the poly(ethylene oxide) chains greatly reduces the proportion of chains terminating near to the end interface. Consequently for PEP copolymers forming extended-chain polycrystals there will be a contribution to σ_e (absent or small in PE copolymers) deriving mainly from intramolecular interactions within poly(propylene oxide) sequences constrained to the planar zig-zag form. We have not attempted to quantify this contribution.

The slope of the broken line in *Figure 1*, which adequately represents the experimental data, is consistent with the theoretical prediction of Bellemans[24] (see Part 1[1] for further discussion of this point). Consequently we would expect a similar dependence of σ_e' on l_a' for the predominantly once-folded-chain polycrystals, though we have no data to test this prediction. However, with this in mind, it is consistent with our model to write for any type of polycrystal:

$$\sigma_e' = \sigma_{o,x}(1/t) + \sigma_{o,f}(1 - 1/t) + \sigma_a \qquad (13)$$

where $\sigma_{o,x}$ is the free energy of formation from the melt of the completely extended-chain crystal/amorphous interface, $\sigma_{o,f}$ is corresponding quantity for the completely folded-chain interface, $1/t$ is the fraction of chains which emerge into the amorphous layer, and σ_a is given by[1]:

$$\sigma_a = (RT/t) \ln (l_a')^{2/3} \qquad (14)$$

as indicated by the broken line of *Figure 1*. Equation (13)

can be rearranged to the form:

$$\sigma_e' - \sigma_a = \sigma_{o,f} - (\sigma_{o,f} - \sigma_{o,x})(1/t) \qquad (15)$$

A plot of $\sigma_e' - \sigma_a$ against $1/t$, for all the samples investigated here and in Part 1, is illustrated in *Figure 2*. The straight line drawn through the data intercepts $1/t = 0$ at $\sigma_{o,f} = 10$ kJ/mol and $1/t = 1$ at $\sigma_{o,x} = 2.5$ kJ/mol.

Two crystalline sequences are involved in the formation of one fold, so the above values indicate a free energy of formation within the crystal of a fold of about 15 kJ/(mol of folds). An estimate of the energy of formation within the crystal of a fold, based on conformational changes alone (see Appendix II), is 13 kJ/(mol of folds).

CONCLUSIONS

We have interpreted the properties of poly(ethylene oxide)/poly(propylene oxide) type PEP block copolymers in terms of the stacked lamella model described in Part 1. Samples with short P-blocks (2 P chain units or less) form predominantly extended-chain polycrystals in which the crystalline lamella thickness is about 9 nm (i.e. about 32 E chain units compared with an E-block length of 48 chain units) and in which the specific volume of the polymer in the amorphous layer, which is predominantly formed of chains emerging from the end interfaces of the crystalline lamellae, is lower than that of the corresponding supercooled melt. Samples with long P-blocks (5 P chain units or more) form predominantly once-folded-chain lamellae in which the crystalline lamella thickness is about 6 nm (i.e. about 21 E chain units) and in which the specific volume of the polymer in the amorphous layer is higher than that of the corresponding supercooled melt.

The melting temperatures of the polycrystals are low compared with that of perfectly crystalline poly(ethylene oxide): i.e. 37 to 55°C compared with $T_m^o = 76$°C. This is due to the positive free energy of formation from the melt of the crystal/amorphous interface (σ_o) and the amorphous layer (σ_a), the latter being primarily due to the reduction in entropy, relative to the melt, of polymer chains emerging from the crystal surface. The magnitudes of σ_o and σ_a for our systems are typically:

	Extended-chain polycrystal	Once-folded-chain polycrystal
σ_o	3 kJ/mol (19 erg/cm^2)	6 kJ/mol (39 erg/cm^2)
σ_a	3.5 kJ/mol (23 erg/cm^2)	2 kJ/mol (13 erg/cm^2)

A value of $\sigma_{o,x} = 2.5$ kJ/mol (16 erg/cm^2) is found for the completely extended-chain end interface and a value of $\sigma_{o,f} = 10$ kJ/mol (65 erg/cm^2) for the completely folded-chain end interface.

APPENDIX I

Poly(ethylene oxide) 6000

Lamella spacings, specific volumes and melting points of poly(ethylene oxide) 6000 have been published[9,11] and are summarized below. This sample forms predominantly once-folded-chain polycrystals at crystallization temperatures below 54°C. We use the data to calculate the characteristics of the polycrystals, in the manner described heretofore. Comparison of these results with those for the PEP copolymers which form predominantly once-folded-chain, i.e. samples 5–48–5 to 7–48–7 (*Tables 5* and *6*) shows an almost complete correspondence. [We note that the specific volume of supercooled liquid poly(ethylene oxide) at 25°C is 0.89 cm³/g so that $v_a > v_s$ for this once-folded-chain polycrystal as was the case for the others: see *Table 5*.]

Experimental data for poly(ethylene oxide) 6000

$\bar{x}_n$ = 136 units; $\bar{x}_w/\bar{x}_n$ = 1.1

$T = 25°C$: $l = 20.6$ nm; $v = 0.834$ cm³/g

$T_m = 60.1°C$ (once-folded-chain polycrystal)

Characteristics of crystalline poly(ethylene oxide) 6000

$T = 25°C$ $w_c = 0.68$

$l_c = 15.9$ nm; $l_a = 4.7$ nm

$v_a = 0.91$ cm³/g

$T = 60.1°C$ $l_a = 15.1$ segments

$t = 1.89$

$\sigma_e = 9.1$ kJ/mol

Table A1   Calculation of the energy of fold formation

Conformational change	Energy increase per change (kJ/mol)	Number of changes	Total energy increase (kJ/mol)
$CH_2-CH_2:g_+ \to t$	3.8	2	7.6
$O-CH_2:t \to g_+$	1.8	2	3.6
$CH_2-CH_2:g_+ \to g_-$	1.5	1	1.5
All changes	–	5	12.7

APPENDIX II

Calculation of the free energy of fold formation for poly-(ethylene oxide)

Equivalent lattice sites on the end surface of a poly(ethylene oxide) crystal are separated by 0.46 nm [13]. The optimum conformation for adjacent re-entry is that involving the least number of chain units without deformation of bond angles or formation of eclipsed conformations. Such a conformation, involving 5 chain units, is illustrated in *Figure A1*. The energy of formation of such a fold from crystalline polymer can be calculated from the data of Flory and Mark[25] summarized in *Table A1*, since the conformational change is from the 7–2 helical form:

$CH_2-CH_2-O-CH_2-CH_2-O-CH_2-CH_2-O-CH_2-CH_2-O-CH_2-CH_2-O-$

g_+ t t g_+ t t g_+ t t g_+ t t g_+ t t
to the folded form:

t g_- t g_- t t g_+ g_+ t t t t t t t

The calculation is set out in *Table A1* and the predicted energy of formation of the fold is 12.7 kJ/mol.

Intrinsically coloured polymers from cellulose carbanilates

Richard Benson, James T. Guthrie and Ransford B. Lartey

Department of Colour Chemistry and Dyeing, University of Leeds, Leeds LS2 9JT, UK
(Received 20 May 1975; revised 19 June 1975)

The synthesis and characterization of intrinsically coloured polymers from cellulose tricarbanilates
has been achieved. Data relating to the intermediate stages are given. Spectroscopy, thermal analysis
and light fastness tests were used to establish some of the physical properties of the products. Infor-
mation was obtained regarding the kinetics of nitration of cellulose tricarbanilate and the nature of
the nitration process has been elucidated. Evidence is presented which indicates that the light fastness
characteristics of coloured compounds are not necessarily governed by energy transfer phenomena
since the system studied is known to exhibit efficient energy transfer yet the light fastness results are
invariably poor. The thermal properties of the products are complex and best dealt with in context.

INTRODUCTION

The topic of intrinsically coloured polymers has received
some attention recently. Various avenues are undergoing
investigation and here we report of developments based on
the use of cellulose tricarbanilate.

Work has been published which deals with the enhanced
protection against radiation induced damage which can be
afforded cellulose through its conversion to the carbanilate[1].
Similar protection has been observed by a variety of aroma-
tic groups and so the procedures outlined here may be ex-
tended to cover these[2-4]. In carbanilation it has been shown
that a degree of substitution >2.0 gives almost complete
protection to cellulose. Lesser protection is observed at
lower levels of substitution. One explanation for the occur-
rence of poor light fastness properties of dyes and pigments
involves the initial absorption of energy which is then trans-
ferred to the chromophore, causing its destruction. Thus
the incorporation of cellulose tricarbanilate into a chromo-
phore system was expected to enhance the light fastness of
the chromophore. This is because cellulose carbanilates
have a capacity as efficient energy 'sinks'.

Since one important outlet for intrinsically coloured
polymers is that of pigmentation it is expedient that this
topic be covered in some detail with an attempted classifi-
cation.

Polymeric pigments can be regarded as largely insoluble
polymers which have a chromophoric centre within the
structure. Immediately four classes arise which could be
further subdivided: (a) polymers, which as a result of secon-
dary reaction become intrinsically coloured. Examples in-
clude the thermal or alkali induced degradation of poly-
acrylonitrile; (b) those polymeric pigments derived from
the formation of colour sites within a substrate where hith-
erto they were absent. The action of reactive dyes on natu-
ral polymers can be considered in this category; (c) the pro-
ducts of addition copolymerization reactions in which one
of the monomers is coloured. Reports of work along these
lines have been published[5,6] and further work is in progress;
(d) those intrinsically coloured products of stepwise poly-
merization reactions. Examples must be legion but perhaps
unthought of in this context. Here we can consider the
products of reactions of multifunctional coloured com-
pounds. Within this category are the anthraquinones, azo
compounds, phthalocyanines etc.

These principles can be extended into related areas such
as intrinsically fluorescent polymers, intrinsically biologi-
cally active polymers, intrinsically antioxidant polymers,
intrinsically flame retardant polymers and intrinsically self-
degrading polymers.

In this study we are mainly concerned with the second
class of intrinsically coloured polymer. Our interests lie in
cellulose tricarbanilates, the coloured materials derived
therefrom and their physical properties.

EXPERIMENTAL

Cellulose nitrocarbanilates

Cotton linters were used as the source of cellulose. The
preparation of cellulose tricarbanilate has been fully des-
cribed elsewhere[1]. Cellulose tricarbanilate (CTC) was partly
converted to the *p*-nitro-derivative through direct nitration
under both heterogeneous and homogeneous conditions.
An alternative route to the nitrocarbanilate from cellulose
was by reaction with mixtures of *p*-nitrophenyl isocyanate
and phenyl isocyanate.

Cellulose *p*-nitrocarbanilate was subsequently reduced
under acid or alkaline conditions (homogeneous and heter-
ogeneous conditions) prior to attempting coupling and ex-
change reactions involving some standard coupling com-
ponents and preliminary diazotization. Certain diazotiza-
tions were heterogeneous and hence of reduced efficiency.

The details involved in the nitration, reduction, diazoti-
zation, coupling and exchange stages are given in *Table 1*.

Product characterization

The intrinsically coloured polymers, together with the
various intermediates were characterized through their
spectroscopic, thermal and light fastness properties. Light
fastness tests were applied only to the intrinsically coloured
products.

RESULTS

Completeness of carbanilation was shown through nitrogen
analyses and by the absence of –OH absorption frequencies
in the infra-red spectrum. The thermal characteristics of

Table 1 Experimental procedures in the preparation of intrinsically coloured polymers

Reaction	Conditions	Reagents
Nitration	heterogeneous/30 min	CTC in CH_3COOH (glacial): H_3PO_4 (87%) HNO_3 (70%)
Nitration	homogeneous/various times used in kinetic study	CTC solution in $C_6H_5NO_2$: HNO_3 (70%) Either H_2SO_4 (98%) or H_3PO_4 (87%)
Indirect nitration	homogeneous/48 h	Cellulose; C_6H_5NCO: $NO_2-C_6H_5-NCO$ as solution in C_5H_5N
Reduction	acidic, 80°C, 8 h	$SnCl_2/HCl$
Reduction	alkaline, 100°C, 8 h	$Na_2S.9H_2O$:S in NaOH (5%)

Diazotization	homogeneous, 1 h, 0°C	Polymer solution in CH_3OH:CH_3COOH (glacial):amyl nitrite
Coupling	10°C, 1 h	β-naphthol in NaOH solution to heterogeneously diazotized CTC
Coupling	10°C, 1 h	(a) β-naphthol in NaOH solution
Coupling	10°C, overnight	(b) pyrazolone in NaOH solution
Coupling	10°C, 1 h	(c) H acid by acid coupling
Coupling	10°C, 1 h	(d) H acid by alkaline coupling
Replacements	Sandmeyer reaction conditions	(a) H_2O at 75°C
		(b) CuCl solution at 60°C

CTC are shown in the differential thermogram (*Figure 1a*) which contains a small endotherm at 125°C, being indicative of incomplete removal of residual solvent, whilst the endotherm at 200°C suggests the beginning of the melting process. This broad endotherm points to the polydisperse character of the sample.

Heterogeneous conditions, normally used in the nitration of cellulose, could not be applied to CTC because of excess charring and the occurrence of degradation. Products from homogeneous nitration of CTC, obtained by reaction in nitrobenzene using phosphoric acid as a catalyst and modifier and nitric acid, were invariably yellow powders. This system was studied in detail to provide information concerning the kinetic features of the nitration reaction. *Figure 1b* shows the differential thermogram of a typical nitrated sample.

Nitrocarbanilation of cellulose using *p*-nitrophenyl isocyanate alone, in pyridine, proved unsuccessful. Only with mixtures of phenyl isocyanate and *p*-nitrophenyl isocyanate was any nitration observed. One explanation involves the reduced reactivity of *p*-nitrophenyl isocyanate relative to phenyl isocyanate whilst a second cause could result from reduced diffusion of *p*-nitrophenyl isocyanate to the reactive sites of the cellulose. Once substituted with appreciable phenyl isocyanate the resulting carbanilate swells considerably in pyridine, thus facilitating access of *p*-nitrophenyl isocyanate. A thermogram of a typical product of indirect

nitration is shown in *Figure 1c*. The thermal stability of samples produced by indirect nitration is considerably greater than those achieved from homogeneous direct nitration (*Figure 1b*). *Figure 1b* indicates the presence of considerable heterogeneity in the product which could arise from the oxidizing nature of the acidic nitration medium.

For further study of intrinsically coloured polymers, only samples from indirect nitration were considered. However, an investigation of the kinetics of direct homogeneous nitration was considered to be in order as a means of obtaining information of the degradation process.

Reduction of the *p*-nitrocellulose carbanilate was carried out under both acid and alkaline conditions (*Table 1*). The reductions under acid conditions were heterogeneous with regard to the reducing medium. A thermogram of aminocarbanilated cellulose is shown in *Figure 2a*. A broad band corresponding to the amino group was found in the infrared spectrum; however, a much reduced absorption corresponding to the nitro group was seen at 850 cm^{-1}. Hence reduction is not complete. Decomposition in these samples is seen to be a complex process (*Figure 2a*). Breakdown occurs at 200°C but there is little evidence of any melting process. The high yields obtained for the reduction and the contradicting evidence of incomplete reduction suggest that the gravimetric process of assessing reaction efficiency is
Figure 1 Differential thermograms of (A) cellulose tricarbanilate, (B) cellulose *p*-nitrocarbanilate (homogeneous nitration), (C) cellulose *p*-nitrocarbanilate (indirect homogeneous nitration). ΔT = 0.2°C/in.
Figure 2 Differential thermograms of (A) *p*-aminocarbanilate produced by reduction under acidic conditions, (B) *p*-aminocarbanilate produced by reduction under alkaline conditions. ΔT = 0.2°C/in.
Figure 3 Differential thermograms of the products of coupling the diazo compound to: A, β-naphthol; B, 3-methyl-1-phenyl-5-pyrazolone; C, H acid. $\Delta T = 0.2°C/in$.

misleading. Positive confirmation of the presence of low concentrations of tin salts in the *p*-amino carbanilates was obtained subsequently. Stannic salts often adhere strongly to reaction products when they are used and even with thorough washing with warm dilute hydrochloric acid it was not possible to completely remove all the tin salts. Such impurities could well enhance the thermal degradation of the aminocarbanilate and explain the lower decomposition temperature. As a consequence of the degradation process, sealed sample containers used with the DuPont 900 Thermal Analyser were usually split apart at the hermetic seal.

Alkaline reduction was largely ineffective. Although no significant reduction of the nitro groups was achieved, this treatment gave a product of improved thermal stability (*Figure 2b*) when compared with the product obtained from reduction of the nitro compound under acidic conditions and the nitro compound itself. Decomposition begins at 315°C compared with 290°C for the nitrocompound.

Diazotization reactions

Samples from direct and indirect nitration, subsequently reduced under acidic conditions, underwent heterogeneous diazotization. Diazotizations in solution were carried out only on samples acquired from indirect nitration of cellulose using *p*-nitrophenyl isocyanate and subsequent acid hydrolysis.

Infra-red analysis showed two new absorption bands from samples prepared above. These are seen at 2210 cm^{-1} and 1580 cm^{-1} and have been assigned to the absorption of the diazonium group.

The diazo compounds were found to have considerable stability in that re-assessment by i.r. spectroscopy after washing, drying and storing for 48 h still showed the absorptions at 2210 and 1580 cm^{-1}.

Coupling reactions were carried out on samples produced both by homogeneous and heterogeneous diazotization. The reproducibility of coupling was checked by repeating each process several times. A different coupling component was used for each diazotization process.

For coupling of the product obtained from heterogeneous diazotization, β-naphthol was used as the coupling component. In every instance red coloration occurred as soon as the diazo solution was added to the coupling component. The final products were red materials of varying colour in-

tensities. The coupling process can be represented in simplified form as:

Diazotized polymer
The arrow indicates where coupling occurs. *x* is some value between 0 and 3 and will be dependent on the extent of nitration, reduction, diazotization and any degradation of the polymer.

In the i.r. spectrum, absorption bands at 1550 and 1600 cm^{-1} indicated the presence of azo groups and β-naphthol respectively, though the absorptions were not distinct. The absence of the peak at 2210 cm^{-1} showed that coupling had taken place at all the available diazonium group sites.

In coupling of those amines diazotized in solution the following coupling components were used, 3-methyl-1-phenyl-5-pyrazolone (I), 4-amino-5-hydroxynaphthalene--2, 7-disulphonic acid (H acid) sodium salt (II) and β-naphthol. The thermograms of the coupled products are given in *Figures 3a–3c* respectively. The structures of the latter two coupling components are:

[Arrows indicate the location of coupling]
A problem met with coupling of the amines diazotized in solution concerns precipitation of the polymer as a consequence of coupling. Thus, the partly coloured polymer precipitated from solution before appreciable coupling could take place. The colour strength of the product intensified gradually on standing. All the i r. spectra indicate the presence of the azo group by absorption at 1460–1570 cm^{-1}, but interference occurs. The thermograms (*Figures 3a–3c*) are complex, though the samples decompose at approximately 300°C as seen in the exotherms.

In the replacement of the diazo group by the hydroxyl group, the yield of product was inversely proportional to the reaction temperature and time of reaction. This is indicative of degradation.

Figure 4a shows complex patterns containing an exotherm at ~127°C, a gradual endotherm (melting) at 175°C and delayed decomposition at 260°C. However, the shift in base line shown in *Figure 4a* after the initial exotherm shows this to be the major event. Hence the product containing
is thermally less stable than the other products in this series. The i.r. spectrum indicated the stability of the diazo group by the presence of the absorption bands at 2210 and 1575 cm^{-1}. However, the broad band at 3000–3700 cm^{-1} showed both $-N-H$ groups and hydrogen bonded $-OH$ groups which could indicate successful replacement.

In the attempted replacement of the diazo group by the chlorine atom, only 84% of the original polymer weight was
Figure 4 Differential thermograms of the products from attempted replacement of the diazo-group in cellulose *p*-diazocarbanilate by: A, —OH and B, —Cl. $\Delta T = 0.2°C/in$
Figure 5 Features of the kinetics of nitration. ○, Variation in the extent of nitration (i.r. spectroscopy) with reaction time; △, variation in the weight of product isolated with the reaction time

recovered. Evidence for replacement is by no means conclusive, hence the yield of the chloro derivative is unknown. The i.r. spectrum showed the residual diazo group absorption bands (2210 and 1570 cm^{-1}) though a reduction in the extent of —OH hydrogen bonding was observed at 3000–3700 cm^{-1}.

The attempted replacement of the diazo groups by chlorine atom results in a product with similar low thermal stability (*Figure 4b*) to that obtained during replacement by the hydroxy group.

Light fastness[5,6] tests on typical paint 'draw-downs' were made from the various polymeric pigments. These included 'standards' obtained by diazotization of *p*-aminoacetanilide and coupling of the diazo product with each of the previously described coupling components. Comparisons between the 'standards' and the pigments obtained from the diazotized cellulose carbanilates through identical coupling, were made. The light fastness of each class of pigment derived from cellulose nitrocarbanilates was disap-

pointing. In every instance a light fastness of 3 or less was obtained whereas those of the standards were at least 5.

It is known that the medium and nature of the sample affects the light fastness properties of a pigment. No attempt was made to investigate these points. Since, from the applications viewpoint, the results from fading are serious, there arises the topic of the mechanism of the fading phenomenon.

DISCUSSION

It is unlikely that pigments produced in the manner described have any real value in traditional areas. Points worthy of consideration include the nitration reaction, the thermal decomposition of cellulose nitrocarbanilates and the significance of the poor light fastness properties. Each of these points will be covered in turn.

The system, cellulose tricarbanilate, nitrobenzene as solvent, phosphoric acid as catalyst and modifier, nitric acid as the nitrating species and extended reaction times, was used in an extended study of the nitration process. All the products were obtained as fibrous yellow materials.

Figure 5 correlates the change in nitration with increasing reaction time. It is apparent that higher extends of nitration are achieved at the cost of increased degradation. This is seen in the lower yields recovered from the longer reaction times. Thus low molecular weight (degraded) species are lost in the 'working up' procedures which are designed to recover higher molecular weight, modified polymer. Under the conditions used, a reduction in both the extent of nitration and also the weight of product obtained occurs beyond 35 h of reaction. Again, the indications are that degradation rather than nitration is becoming increasingly significant.

Figures 6 and *7* show the effect of the extent of nitration
Figure 6 Variation of the temperature of initial melting (T_i, X), ultimate melting (T_m, ○) and decomposition (T_d, ●) with extent of nitration for various samples of cellulose *p*-nitrocarbanilate (homogeneous direct nitration)
Figure 7 Variation of the temperature of initial melting (T_i, X), ultimate melting (T_m, O) and decomposition (T_d, ●) with nitration time for various samples of cellulose *p*-nitrocarbanilate

and the nitrating time respectively on the thermal properties of cellulose nitrocarbanilates. In these Figures the following terminology applies: T_i, initial melting temperature (°C); T_m, ultimate melting temperature (°C); T_d, ultimate decomposition temperature (°C). The extent of nitration is given in arbitrary units (being the height of the resonance peak obtained from the i.r. spectra). These Figures appear to be somewhat contradictory though on closer examination explanations can be proposed. In *Figure 6* the overall trend is one of increasing thermal stability as the extent of nitration increases, although the patterns are not uniform. However, *Figure 7* demonstrates that, as the time of nitration increases, the thermal stability of the resulting nitroderivatives passes through a maximum and then decreases. Similar features are shown in each of the measured physical processes, namely T_i, T_m and T_d. It appears that during the nitration reaction other processes are taking place which eventually result in products with lower thermal stability. Preliminary viscometric data suggest that main-chain cleavage occurs on nitration. Although such cleavage is not instantaneous, it reaches significant proportions within 30 min of commencing nitration. Should any cleavage at the carbanilate linkage have taken place during nitration to produce aromatic nitroamines, then these would have been removed during the 'working up' procedure which was not designed to cope with such a possibility. Hence the yield of product decreases with increasing nitration time (*Figure 7*). It is noteworthy that the extent of maximum nitration

of the polymer does not coincide with the longest reaction time. Hence the interpretation of an increase in thermal stability with increasing nitration is consistent with observed data. Thus the samples with greatest nitration and thermal stability are those which have been exposed to the nitration medium for intermediate times.

In the nitration of cellulose carbanilate there arises the possibility of nitration in either the *o*- or *p*-position of the phenyl group or in both positions. Using acetanilide as a reference it is found that nitration occurs in the *o*- and *p*-positions. Even with alkyl groups in the position *para* to the amide group only *ortho* substitution is obtained. This indicates that the amide group is reasonably strongly *o*- and *p*-directing. However, with cellulose tricarbanilate, steric hindrance would be expected to reduce the extent of *o*-nitration.

During thermal analysis experiments on nitrated cellulose carbanilates, a green/yellow condensation product was observed on the inside of the Dupont 900 Thermal Analyser bell jar. This was analysed by u.v. spectroscopy and proven to be pure *p*-nitroaniline. This rules out any possibility of *o*-nitration which indicates the role of steric hindrance in the nitration reaction.

The light fastness results are puzzling. Cellulose tricarbanilate is very resistant to damage from exposure to high energy electromagnetic radiation. This protection is thought to involve transfer of incident energy to the phenyl group before its localization and the onset of degradation. It is the stability of the protecting groups' linkage to the cellulosic backbone which is the deciding factor as to whether or not protection occurs and not the nature of that linking group. Since fading concerns modification or destruction of the chromophore and we are again dealing with the absorption of electromagnetic radiation though of much reduced energy, one might have expected that the presence of carbanilate groups would protect the chromophore through energy transfer. Clearly from the poor light fastness results, this expectation is not realized. Certain possibilities arise, namely: (i) light fastness properties and radiation protection operate by different mechanisms. Thus, light fastness is not dependent on energy transfer processes; (ii) the incomplete character of each of the reaction stages could leave residues in the final pigment which are themselves sensitive to exposure to light. Chief among these are unreacted nitro groups which are known to produce oxidizing species. These in turn would have a marked influence on the physical properties of the dye chromophore.

Many questions remain unanswered in this field though work is continuing in the Department which should provide some solutions.

Some fatigue characteristics of thermoplastics

R. J. Crawford and P. P. Benham

Department of Mechanical Engineering, The Queen's University of Belfast, Belfast BT9 5AH, UK
(Received 21 April 1975; revised 25 July 1975)

Uniaxial and rotating bending fatigue tests were carried out on polypropylene, polycarbonate, poly(methyl methacrylate) (PMMA), poly(tetramethylene terephthalate) (PTMT) and glass filled PTMT to establish the general régimes of thermal softening and fatigue types of failure observed in earlier tests on acetal copolymer. In the uniaxial testing PMMA exhibited both types of behaviour whereas polypropylene and PTMT were particularly prone to the thermal type of failure over a wide range of cyclic frequency and stress and fatigue failure could not be achieved for endurances up to 10^7 cycles. However, for PC and filled PTMT only the cracking type of fatigue failure was obtained as there was only a slight temperature rise which stabilized and hence did not lead to thermal softening. It was evident that the two types of failure were related to the magnitude of the loss tangent value for the material.

Under uniaxial loading the effect of a sharp notch in each material was to reduce the thermal effect so that, for example, fatigue failures were produced in polypropylene and PTMT under stresses which would only produce thermal failures in plain material. In general fatigue endurances were reduced owing to the presence of the notch. Rotating bar fatigue tests using the same specimen as in the uniaxial tests exhibited both thermal softening and fatigue type failures, but at higher stress amplitudes and frequencies compared with the uniaxial tests since only the outer surface was subjected to the maximum stress. The results of constant strain rate and creep rupture tests on these materials have also been included for comparison.

INTRODUCTION

Nowadays thermoplastics are used in a wide variety of load-bearing applications. In many components the applied load is relatively constant in which case creep deformation or static fatigue are the major design criteria. In some components, however, the loading is of a cyclic nature, which may be either in the form of intermittent creep or more rapid and continuous which may lead to dynamic fatigue failure. The high damping and low thermal conductivity of thermoplastics become important factors when the loading is of a fluctuating nature and this, in conjunction with their time and strain dependent properties, means that the dynamic fatigue behaviour of polymers can be quite different from the more familiar concepts in metal fatigue.

The behaviour of polymers under cyclic loading has attracted an increasing amount of attention in recent years. Andrews[1], Gotham[2] and Plumbridge[3] have all presented good reviews on the subject which describe clearly the extent of the problems involved. Some authors[4,5] have favoured the fracture mechanics approach although the work has been mainly concerned with glassy plastics such as poly(methyl methacrylate). Andrews and Walker[6] have indicated how this type of approach may be used for materials such as polyethylene. A number of authors such as Riddell et al.[7], Tauchert[8], Oberbach[9] and Constable et al.[10] have focused attention on the thermal aspect of fatigue. Few[11], however, have attempted to present polymer fatigue data in a similar way to those used for metals.

Most of the worthwhile dynamic fatigue literature available on plastics has appeared in the past seven years, but in many cases it has been limited to rather narrow and specific conditions of testing, material etc.

PREVIOUS FATIGUE STUDIES ON ACETAL COPOLYMER

When the BSI Committee PLC36 was formulating testing procedures for plastics in 1968 there was insufficient information to enable recommendations to be made on dynamic fatigue testing. At that time the authors felt that there was a need for a phenomenological study to establish some of the distinguishing factors that influenced dynamic fatigue of thermoplastics before it was possible to recommend testing procedures. The authors in their previous work[12-14] decided to use initially one engineering thermoplastic, an acetal copolymer, (ICI Kematal M90–04) to study the broad effects of frequency, waveform, mean stress, load or deformation control, notches and mode of testing (uniaxial and bending). Since many components are injection moulded it was decided to design the test specimen to be injection moulded and suitable for a range of tests, e.g. dynamic fatigue in uniaxial tension or bending, creep and creep rupture in tension, and triaxial stress systems. Furthermore by varying the methods of gating into the mould it was possible for the condition of specimens to range from optimum mouldings to those which included defects and undesirable orientation. The geometry of the specimen and the gripping arrangement for all types of fatigue and rupture testing are shown in *Figure 1*.

Perhaps the principal difference between dynamic fatigue in metals and plastics is the effect of cyclic frequency. On the former there is no effect over a wide frequency range so that duration of laboratory testing can be reduced by increasing test frequency. Plastics, on the other hand, have high damping and low thermal conductivity properties which make temperature rise very dependent on frequency
Figure 1 Specimen and grips

and stress level.

Depending on the combination of the latter two parameters the temperature may rise continuously and lead to failure by thermal softening without crack propagation. Alternatively, for certain limits of frequency and cyclic stress the temperature will rise for a period and then achieve a stable value. A conventional form of fatigue crack can then be initiated and propagated to complete failure. The interdependence of stress amplitude, temperature rise and number of cycles is illustrated in *Figure 2*. There is a complete change in behaviour between stress amplitudes of 21.6 and 22.4 MN/m² the former being the highest level of stress amplitude for which crack propagation fatigue can be obtained, while the latter represents the stress for the onset of thermal softening failure. This transition from thermal softening to brittle cracking fatigue is henceforth termed the change-over stress level. It was found to depend on cyclic waveform and frequency, mean stress, and surface area to volume ratio of material.

There is also a distinct difference as between cycling under load control or strain control. A drop in modulus due to temperature rise during load control causes an increase in the energy dissipation, whereas in strain control the drop in modulus causes a decrease in energy dissipation. This means that in the latter case there is a self-stabilizing mechanism with the result that there are no thermal runaway failures under strain control. It is therefore important for designers to consider this aspect of component operation and to select the appropriate fatigue data.

Full details of the thermal softening phenomenon together with an analytical solution for predicting the change-over stress has been given previously[12].

One of the more important observations in the testing of acetal was the apparent independence of cyclic frequency of the reversed stress—log cycle fatigue cracking relationship and also the limited extent of scatter in results from injec-

tion moulded specimens, as seen in *Figure 3*. The dependence of thermal softening failure on frequency is also clearly evident in that Figure.

It was found that tensile mean stress reduced the allowable stress amplitude to give a particular endurance. Range/mean stress diagrams have the same form as for metals except that creep rupture is the predominant mechanism at high mean stress values.

Stress concentration, for all materials, is the most common cause of fatigue crack initiation. Apart from the well known effects of sudden change in geometry of components causing stress concentration there are also many possibilities resulting from fabrication processes, e.g. voids, sprue marks, flash lines, welds, contaminating particles, surface finish etc. Many of the foregoing situations have been studied for acetal, which it was hoped would give a general indication of behaviour for other engineering thermoplastics, and the results are detailed in ref. 13. The fatigue performance for injection moulded specimens having a circumferential V-notch (elastic stress concentration factor = 8) carefully machined into the mid-section is shown in *Figure 4* together with details of the notch geometry. The fatigue strength reduction due to the notch is not as great as would

be expected compared with the so-called plain material, but then in fact the latter is not entirely notch-free because of micro-voids which initiate failure within the wall thickness. Thermal softening failures can occur in the notched specimens, but owing to the localized volume of high stress, higher frequencies can be operated for the same peak stress compared with the unnotched specimens. The effect of other levels and types of stress concentration have been discussed earlier[13].

All the above work was carried out under uniaxial push—pull stress cycling which, although more satisfactory for instrumented testing, is more costly in equipment for commercial testing. Also many components are subjected to bending deformation rather than simple tension/compression; therefore it was deemed necessary to make some limited study of bending fatigue. Rotating bar fatigue machines for metals were modified to give variable cyclic frequency and to accommodate the same specimen and grips used in the uniaxial fatigue tests. Tests were run at 25 and 50 Hz and the same pattern of thermal softening and fatigue cracking failures as in the uniaxial tests was observed except that since only the outer surface in bending is subjected to the maximum stress, the change-over stress amplitude occurred at much higher values. The basic fatigue curves for plain and V-notched (same as above) material are shown in *Figure 5* in which the comparison is made with the corresponding curves obtained from the uniaxial push—pull testing. Apart from the obvious differences in fatigue strength and thermal softening which were exhibited, it became apparent that the tougher skin obtained in the moulding process would have a more beneficial influence in relation to bending fatigue than for uniaxial cycling because the maximum stress in bending only occurs at the outer surface. Another stress concentrator, a transverse hole, and a weld line defect produced by double end gate moulding were also studied and compared with the uniaxial equivalent tests. The details of these results for acetal copolymer may be found in ref. 14.

All types of specimen used in the fatigue programme described above were also tested for tensile creep rupture (static fatigue) of up to 4 weeks duration[13].

Having produced a fully comprehensive picture of the fatigue behaviour of an acetal copolymer it was decided to study the principal patterns of fatigue behaviour in several other engineering thermoplastics.

EXPERIMENTAL

The following materials were tested: (i) polypropylene copolymer (PP) (ICI GW701M natural): injection moulded; (ii) poly(tetramethylene terephthalate) (PTMT) (ICI TAP10 unmodified polymer) injection moulded; (iii) poly(tetramethylene terephthalate) (PTMT) (ICI TGA50 glass filled polymer) injection moulded; (iv) poly(methyl methacrylate) (PMMA) (ICI Perspex) machined from 100 mm sheet; (v) polycarbonate (PC) commercially supplied: machined from 40 mm diam. rod.

All the injection moulded specimens, which were manufactured by ICI Plastics Division, were fed from a ring gate at one end of the specimen in an attempt to obtain uniform flow and orientation along the gauge length of the specimen as had been previously achieved with the acetal mouldings. The mould cavity and core bar were highly polished to give good specimen surfaces. The machined specimens were carefully polished to give comparable surface finish to that from moulding.

The specimens were all produced to the dimensions given in *Figure 1* and the notch as shown in *Figure 4*.

The uniaxial fatigue tests were carried out on a ±20 kN servo controlled machine on which the frequency could be varied in the range 0.1–100 Hz. The rotating bending tests were carried out on three fatigue machines which had been modified to take the polymer specimens as used in the uniaxial tests. On one of these machines the frequency could be varied from 2.5 to 25 Hz and on the other two machines the frequency was fixed at 50 Hz. The uniaxial machine and extensometry[13] and the rotating bar machines[14] have been described in greater detail elsewhere. The surface temperature rise of the specimens during cycling was recorded using an infra-red radiation thermometer.

TEST PROGRAMME

Constant strain rate tensile tests

As an initial check on the relative behaviour of each material tensile tests were carried out at a constant extension rate of 50 mm/min on the basic specimen. The stress–strain curves are shown in *Figure 6* and generally exhibit the features to be expected.

Fatigue tests

Polypropylene. In load-controlled reversed uniaxial loading (*Figure 7*) this material was very prone to thermal failures owing to its high loss tangent at the testing frequencies, and only at relatively low stress amplitudes did the temperature stabilize. At 5 Hz, for example, the thermal/fatigue failure change-over stress was found to be about 7.5 MN/m^2 and below this the temperature rise did stabilize but no

fatigue failures occurred for endurances up to 10^7 cycles (23 days). At a frequency of 0.5 Hz which allowed stress amplitudes of up to 12.5 MN/m^2 before thermal failures occurred, there were still no fatigue failures up to 7 × 10^5 cycles (16 days). Under these testing conditions therefore only thermal failures were produced in unnotched PP. However, cracking fatigue failure would probably have occurred in those specimens in which the temperature stabilized if the tests could have been continued to longer endurances. Of course, if temperature rise is suppressed by some cooling system then fatigue will occur as found with acetal (Fig. 3[15]). Likewise in a component with large surface area, but small volume, heat transfer would be better and temperature rise would stabilize at lower values and at higher stresses.

A few uniaxial reversed strain cycling controlled tests were conducted since thermal failure does not arise under these conditions. Fatigue failures were obtained in plain specimens as shown in *Figure 7*.

Circumferentially V-notched specimens (as described earlier) subjected to reversed uniaxial stress cycling at 0.5 and 5 Hz did not exhibit any thermal failure since temperature rise was less. Fatigue failures (using net stress values) are included in *Figure 7*. A number of problems were experienced in rotating bending tests owing to the pronounced thermal effect, and relatively low modulus, of polypropylene. At 25 Hz thermal failures were produced for stresses above ±8.5 MN/m^2 and for lower stresses no fatigue failures were produced for endurances up to 6 × 10^7 cycles (28 days). At 50 Hz the thermal/fatigue failure change-over stress was 4 MN/m^2 and no fatigue failures could be produced up to 10^8 cycles (23 days).

Polycarbonate. Owing to the low loss tangent value (~0.01 at 1 Hz) for this material specimen temperature rise was never very significant and no thermal failures were obtained at any frequencies at stress amplitudes as high as ±30 MN/m^2. The fatigue data for plain and notched material are illustrated in *Figure 8*. At the lowest stress ampli-
Figure 8 Reversed load cycling fatigue failures in polycarbonate. G = failure in grips. Uniaxial (plain): ○, 5; △, 10; □, 16.7; +, 25 Hz. Rotating bending (plain): X, 25; ∇, 50 Hz. Uniaxial (notched): ●, 5; ▲, 10 Hz
Figure 9 Reversed load cycling fatigue and thermal failures in PMMA. Uniaxial (plain): □, 1.67; ○, 5.0; △, 10.0 Hz. Rotating bending (plain): X, 16.7 Hz. Uniaxial notched (fatigue failures): ●, 5.0 Hz. T = thermal failure

tude of ±4 MN/m² failure occurred for the plain specimens within the grips owing to the stress concentration there. There was no noticeable effect of frequency of testing for either plain or notched results. The ratio of plain to notched fatigue strength does not reflect the high value of stress concentration used and suggests as with the acetal results that the plain material does contain some form of stress raiser in spite of the fact that the carefully machined surfaces were also thoroughly polished.

Under a rotating bending mode of loading PC exhibited a similar general behaviour to that described for uniaxial loading. There was only a small surface temperature rise even for cyclic frequencies of 25 and 50 Hz. The fatigue curve in *Figure 8* indicates that there is a slight improvement in endurance over the uniaxial results and that there is no frequency effect. Since there was no tough skin on the PC specimens, as they were machined rather than injection moulded, a much closer agreement is obtained between uniaxial and bending fatigue, the latter being slightly better as generally found in metal fatigue.

PMMA. The results of the load controlled fatigue tests on PMMA were in many ways similar to those described for acetal. The loss tangent of ~0.08 at 1 Hz is between those for PP and PC and hence both fatigue and thermal failures were observed in the range of cyclic frequencies 1.67–10 Hz as illustrated in *Figure 9*. However, there is a marked difference in the fatigue behaviour of the two materials when a notch is present, owing to their different levels of fracture toughness. It will be remembered that acetal is not particularly notch sensitive whereas the same geometry of notch in PMMA causes a drastic reduction in endurance. The plain and notched specimen fatigue results for PMMA are compared in *Figure 9* and the difference in endurance is always greater than four decades. It was also found that if the surface of the PMMA specimens was not polished after machining there was a considerable reduction in endurance as a result of the surface markings. If the effect of sharp notches on the fatigue behaviour of PC and PMMA is compared it must be concluded that the polishing of the specimens was much more effective for the PMMA.

The rotating bending tests on PMMA again exhibited a similar behaviour to acetal with both thermal and fatigue

failures occurring over the range of frequencies examined (*Figure 9*). The uniaxial and the rotating bending fatigue strengths agree quite closely in spite of the wide range of test frequencies used.

PTMT. The results of the uniaxial reversed load-controlled fatigue tests on unfilled PTMT are shown in *Figure 10* and it is seen that only thermal failures were produced. For test conditions at which the temperature rise stabilized no fatigue failures occurred up to 9 × 10⁶ cycles at 5 Hz or up to 2.5 × 10⁶ cycles at 1.6 Hz. The pronounced thermal behaviour of this material is similar to that described earlier for PP to which it has a comparable loss tangent and the similarity continued when tests were conducted using load controlled cycling on sharply notched specimens. In these tests fatigue failures were produced using frequencies of 1.67 and 5 Hz as shown in *Figure 10*. Comparing these with the results of tests on plain specimens which produced neither thermal nor fatigue failures it may be concluded that the reduction of endurance, owing to the presence of the notch, is at least in the order of one decade over the range of stresses examined.

In the rotating bending tests thermal failures were again predominant with the thermal/fatigue failure change-over stresses being 21.5 and 28.5 MN/m² at frequencies of 50 and 25 Hz, respectively. At both these frequencies several brittle fatigue failures occurred. However, in each case these were at the specimen grips so that no conclusions could be drawn from them and they have not been included in *Figure 10*.

Glass filled PTMT. In the glass filled PTMT the pronounced thermal effect observed in the unfilled material was not present. This can probably be attributed to the greater stiffness of the filled material and the possibility of improved heat transfer owing to the presence of the reinforcement medium in the matrix material. In load controlled cycling fatigue failures occurred for stresses up to ±40 MN/m² at 5 Hz with negligible increase in surface temperature of the specimen. On a stress basis this is twice the value attainable on acetal using the same test conditions.

The results shown in *Figure 11* indicate that the material tested was generally weak in fatigue with endurances considerably less than those of the unfilled material. This
Figure 10 Reversed load cycling fatigue and thermal failures in unfilled PTMT. T = thermal failure; → = unbroken, stable temperature. Uniaxial (plain): □, 1.67; ○, 5.0 Hz. Notched (fatigue failures): ■, 1.67; ●, 5.0 Hz
Figure 11 Reversed load cycling fatigue failures in glass filled PTMT. Uniaxial: ○, 5 Hz (plain); ●, 5 Hz (notched). Rotating bending (plain): ▽, 50; X, 25 Hz

type of behaviour is probably to be expected in that the presence of the fibres in the matrix will provide sites for fatigue crack initiation. However, it is also evident that this batch of moulded specimens must have contained additional stress concentrations of considerable magnitude, since the V-notched specimens had longer endurances than the plain material. The presence of incipient flaws in the glass filled material is also evidenced by the fact that in the constant strain rate tests described earlier the fracture stresses obtained were about 30% less than the values quoted by the manufacturers of the material.

In the rotating bending tests there was again no significant temperature rise in the material and only fatigue failures occurred at frequencies of 25 and 50 Hz. The endurances (*Figure 11*) were slightly better than the uniaxial results and indeed correspond quite closely to the endurances of the notched specimens.

Creep rupture tests

A series of tensile creep rupture tests were carried out on each material using exactly the same specimen as for fatigue, and the results are shown in *Figure 12*. In the tests on acetal it had been found[13] that brittle failure occurred at stresses which caused fracture in less than 10^3 sec. At lower stresses and for lives up to 10^6 sec it was found that failure was ductile and was preceded by whitening. For endurances in excess of 10^6 sec the whitening was barely detectable but a neck formed in the material prior to fracture. In all cases failure initiated from within the wall thickness and was similar to the fractures observed in the constant strain rate tests.

The creep rupture tests on PP produced ductile fractures over the whole range of stress examined. The material whitened and then necked prior to fracture which initiated from within the specimen wall.

The creep rupture endurances in PC were surprisingly large as compared with the relatively short endurances under dynamic loading. In most tests crazing was observed shortly after the load was applied but this did not indicate that failure was imminent. Even in the longest testing time of approximately four weeks the crazes were present throughout the whole life of the specimen. The fracture surfaces

of the PC specimens which failed as a result of creep rupture or fatigue looked very similar under the microscope in that, at the point of crack initiation both had a very smooth area surrounded by finely spaced striations.

Under sustained static loading PMMA was observed to craze at some point during its life and then form a neck at which fracture occurred. Fracture always initiated at the inner or outer surface and had the typical brittle fracture appearance described earlier.

Both filled and unfilled PTMT failed in a brittle manner over the range of stresses examined and as shown in *Figure 12* the endurances of the glass filled material are always greater by about two decades. As with the failures in fatigue and constant strain rate tests the fracture surface of the filled PTMT specimens was generally featureless and indeed it was difficult to distinguish one type of failure from the others. The creep rupture fractures in the unfilled material, however, were quite different from those in the other tests.

DISCUSSION AND CONCLUSIONS

The behaviour of a thermoplastic under cyclic stress conditions is perhaps even more difficult to interpret and design for than is the case with a metal. First, this can be attributed to the presence in plastics particularly of two distinct failure mechanisms, the thermal softening and the fatigue cracking. The presence of the former is largely related to the loss tangent value for the material at any particular frequency. The larger the tan δ value then the more will thermal softening predominate over fatigue cracking. The present specimen geometry is regarded as quite a good compromise for a representative laboratory specimen to relate to likely proportions of components, injection moulding conditions, usage for various tests, etc. The temperature rise for this specimen can be calculated as a function of stress amplitude, frequency, heat transfer coefficient, surface area, volume, density and phase lag δ[12] and this could similarly be done on an approximate basis for actual components to establish when temperature rise stabilizes and so does not lead to thermal failure. In the present programme it was found that

condition of specimen is of considerable importance and must always be specified.

The notched fatigue results illustrate the care which is necessary in the selection of plastics to resist cyclic stressing as revealed by the high notch sensitivity of PC and PMMA and in contrast the notch-toughness of acetal.

Two further factors in the present work which are worth mentioning again are the relatively low degree of scatter in the fatigue cracking results and reasonable independence of cyclic frequency.

It is seven years ago since the PLC36 Committee was unable to make recommendations for dynamic fatigue testing of plastics and perhaps with the number and variety of fatigue studies that have been undertaken since then it would now be possible and appropriate for BSI to reconsider the case.

the changeover stress, cyclic frequency and surface area to volume ratio were related by a single empirical expression of the form:

$$\sigma_c = \left[\frac{A}{V}\right]^{1/2} \left\{ C_1 - C_2 \log_{10} f \right\}$$

where σ_c is the changeover stress amplitude in MN/m^2, f is cyclic frequency in Hz, surface area A and volume V, are in mm units and C_1 and C_2 are material constants. This equation is illustrated in *Figure 13* for four materials and two A/V ratios. One useful point to note is that the changeover stress value can be pin-pointed quickly and accurately since there is so little scatter with the thermal softening failures.

The dynamic fatigue performance of the six materials is summarized in *Table 1* for a reasonably long endurance (3 × 10^6 cycles) and the constant strain rate maximum tensile strength has been included also for comparison. There is a wide variation in the ratio of fatigue/static strength in which PC is seen to be by far the poorest material and PP the best material in uniaxial dynamic fatigue relative to their static strengths.

The dynamic fatigue strength in bending is in all cases slightly higher than in push–pull, as is generally the case for metals, and of course the thermal softening problem is not as severe in bending owing to the stress gradient through the material. As far as commercial fatigue testing is concerned bending does have the considerable advantage of requiring less complicated and costly apparatus than for uniaxial testing. However, in either type of test, design and

Effect of temperature on the impact fracture toughness of polymers

E. Plati and J. G. Williams

Department of Mechanical Engineering, Imperial College, London SW7 2BX, UK
(Received 9 May 1975; revised 17 July 1975)

A method is described by which the true energy release rate at fracture may be determined from a conventional impact test. This method is then used to investigate the effect of temperature on impact strength and the results are described in terms of a yield stress dependent thickness effect. Blunt notch data are also given and plane stress and plane strain energy absorption mechanisms are postulated to account for the observed behaviour.

INTRODUCTION

Impact testing is of considerable practical importance but suffers from several drawbacks in the test methods currently employed. In the first place, the apparatus used is often not of a good standard resulting in considerable scatter in the data because of poor alignment and friction. Secondly, the test method is designed in such a way that the data are difficult to interpret with any logic. This paper describes an apparatus which overcomes most of these problems so that machine scatter is largely eliminated and an analysis is employed which presents the data in a concise and meaningful form.

The results from conventional impact testing are usually expressed in terms of the specific fracture energy w/A, where w is the energy absorbed to break the notched specimen and A is the cross-sectional area of the fractured ligament. Such an analysis of the data is not satisfactory because the parameter w/A depends on the specimen geometry and the type of test used. There is only a rough correlation between the Charpy and the Izod impact values for the same material. However, some recent publications[1–4] have shown that if elastic deformations are assumed linear fracture mechanics theory can be extended to impact data and G_c, the critical strain energy release rate, can be deduced directly from the absorbed energy. The absorbed energy to failure, w, can be written in the form:

$$w = G_c \cdot BD\phi$$

where B and D are the thickness and depth of the specimen respectively and ϕ is a calibration factor which is a function of crack length and may be calculated or measured experimentally. w is determined for several crack lengths and G_c determined from the linear plot of w versus ϕ. Plati and Williams[4] have determined calibration factors for both the Charpy and Izod tests and G_c for a range of polymers at 20°C in both tests. G_c was shown to be independent of specimen geometry and identical for both test methods. For highly ductile materials a modification of the method was necessary to obtain values which are comparable with those for the more brittle materials[2,4].

The work is extended here by measuring G_c for both sharp and blunt notches over a range of temperatures for several polymers using a temperature control cabinet fitted to the impact machine. The results are analysed in terms

of the concept of a plane stress and a plane strain G_c and changes in G_c with both temperature and specimen thickness are described in terms of yield stress changes.

APPARATUS

The impact testing machine used is shown in *Figure 1* and is of the conventional pendulum type. The machine was made by the Mechanical Engineering Department, Imperial College, from a design supplied by The British Petroleum Co. Ltd. A set of pendulums of various weights are used to give high precision in energy measurements over a wide
Figure 1 Impact machine with temperature box
Figure 2 Low impact strength materials. ○, PVC; ●, PMMA; □, GPPS
Figure 3 Medium impact strength materials. ○, Polycarbonate; □, nylon-6,6 (dry)

range of values and the usual precautions were taken to ensure that the centre of percussion is at the impact point. Different pendulums were designed such that Charpy, Izod and tensile impact tests could be performed.

Special care was taken in the bearing design to ensure a minimum of friction and play since these factors were found to be of particular importance in achieving consistency[1]. The angular measurements are made using a photo-electric device and a transparent disc marked at 9' of arc intervals. The angles are indicated as a number on a digital counter. Windage and friction losses were determined from free swing experiments so that each reading on the counter could be given an energy value for each pendulum and initial pendulum angle. Tables of values were produced for all counter readings. Speed variations from the four original settings available are rather small and all the data given here are at 3 m/s.

The various temperatures were achieved using a split insulated box surrounding the specimen (see *Figure 1*). When the required temperature is reached the front part of the box is withdrawn to allow the pendulum to swing down and strike the specimen. A small fan is used to circulate air through the box from a closed loop containing a heater coil. Low temperatures are obtained by blowing liquid nitrogen into the loop. A thermocouple embedded in a dummy specimen located close to the real one controls the nitrogen flow and the heater via a 'Eurotherm' control unit. The range $-100°$ to $+60°C$ was used and a control of $\pm 1°C$ was achieved. The box is opened for a very short

period (<1 s) in order to break the specimen and no appreciable temperature change was observed.

RESULTS

The G_c values for 6 mm thick specimens notched with a very sharp (<50 μm) cutter are shown in *Figures 2, 3* and *4* for the temperature range $-100°$ to $+60°C$. Each point is obtained from the slope of a w versus ϕ graph and contains the results from 15–20 specimens of various notch lengths as shown for polycarbonate in *Figure 5*. They are grouped as low, medium and high impact strengths and in the low group ($\simeq 1$ kJ/m^2) we have unmodified polystyrene and PMMA as expected. The PVC is also unmodified and behaves as a glassy amorphous polymer but PVC would be expected to be in a higher group when impact modifiers or fillers are added. *Figure 3* ($\simeq 4$ kJ/m^2) includes polycarbonate and dry nylon-6,6 which are classified here as medium strength materials. *Figure 4* gives the high impact strength materials ($\simeq 20$ kJ/m^2) and very large changes

with temperature are apparent. Changes of the order of ten are observed here while in the low and medium category they are two or less. There is a noticeable similarity in the curves in that all are sigmoidal in form between constant high and low temperature values within the temperature range covered. It should be noted that all the points are for brittle failures except for some of the high impact strength materials at the higher temperatures. In these cases, ductile failure occurs and the G_c is calculated from $2w/A$ [4].

A series of tests were also performed on specimens with blunt notches of tip radii 0.25, 0.5 and 1 mm. The G_c determination was as in the sharp notch case and a blunt notch G_c value, termed G_B, was obtained. These are shown in *Figures 6, 7* and *8* for PVC, polycarbonate and PMMA, respectively. PVC and polycarbonate show the expected elevation of the curves and they remain similar in form. For PMMA, however, a peak appears at $-60°C$ which increases with the blunter notches and is totally absent in the sharp notch data. There is no significant

evidence of peaks in the other materials for any notch radius.

THEORETICAL ANALYSIS

It is postulated here that a polymer exhibits different fracture strengths depending on the stress system imposed. The lowest value is when the material is heavily contrained, as in the centre of a notched specimen, and this is termed G_{c1}. The highest value is with no constraint as near the surface of the specimen and this is the plane stress value G_{c2}.

This concept has been used for metals[5] and has been extended to polymers[6,7] but in the form of fracture toughness K_c. Following the same line of argument, however, similar relationships may be derived for G_c. The extent of the plane stress region is assumed to be the plastic zone size r_{p2} which is given by[6]:

$$r_{p2} = \frac{1}{2\pi} \cdot \frac{K_{c2}^2}{\sigma_y^2}$$

and since $K_{c2}^2 = EG_{c2}$ where E is the modulus and σ_y the yield stress, we have:

$$r_{p2} = \frac{E}{2\pi} \cdot \frac{G_{c2}}{\sigma_y^2} \qquad (1)$$

The specimen may therefore be considered as a sandwich of a plane strain region between two plane stress regions of thickness r_{p2}. Since energy is measured in this test an average G_c will be determined (and not K_c as in ref.6) such that:

$$G_c B = G_{c1}(B - 2r_{p2}) + G_{c2}2r_{p2}$$

i.e.

$$G_c = G_{c1} + \frac{2r_{p2}}{B}(G_{c2} - G_{c1})$$
Figure 8 Blunt notch data for PMMA. △, Sharp notches; □, $\rho = 0.25$ mm; X, $\rho = 0.5$ mm; ○, $\rho = 1.0$ mm
Figure 9 Schematic form ot toughness changes with temperature as given by equation (2)

where B is the specimen thickness. Substituting for r_{p2} we have:

$$G_c = G_{c1} + \frac{E G_{c2}}{\pi \sigma_y^2 B} (G_{c2} - G_{c1}) \qquad (2)$$

Since impact fractures are at quite high speeds they would be expected to be adiabatic and therefore G_{c1} and G_{c2} would not be expected to depend on temperature. Similarly, E, which relates K_c and G_c would also be expected to be insensitive to temperature. σ_y, on the other hand, refers to the plastic deformation away from the actual fracture and should be influenced by temperature changes. It would be difficult to determine the σ_y appropriate to impact but the form of the temperature dependence would be expected to be similar to slower rate data. If $1/\sigma_y^2$ as determined in ordinary slow rate tests at various temperatures is plotted as a function of G_c, equation (2) would indicate a straight line extrapolating to G_{c1}. This value should be a reasonably accurate estimate since it is not derived from the particular σ_y values used. It is also clear that when $2r_{p2} = B$, $G_c = G_{c2}$. Since σ_y increases with decreasing temperature the form of curve expected would be G_c remaining at G_{c2} with decreasing temperature until $2r_{p2} < B$ when dependence on σ_y comes into force and G_c tends to G_{c1}. Since the σ_y dependence on temperature is similar (i.e. approximately linear) for most polymers an explanation is provided for the similar form of curves noted previously. *Figure 9* shows the form of equation (2) schematically and also indicated the effect of a thickness change. The deformation properties are contained in the term σ_y^2/E and this may be written as the plane stress elastic work to yielding:

$$w_{p2} = \frac{1}{2} \cdot \frac{\sigma_y^2}{E} \qquad (3)$$

It was suggested[4] that blunt notch data could be analysed by assuming that the same plane strain plastic zone of radius r_{p1} had to form at the tip of the blunt notch at fracture as in the sharp notch. For the condition that the notch tip radius ρ is much greater than this plastic zone then the

relation:

$$G_B = G_c \left(1 + \frac{\rho}{2 r_{p1}}\right)^3 \Big/ \left(1 + \frac{\rho}{r_{p1}}\right)^2$$

becomes:

$$G_B = \frac{G_c}{2} + \frac{2}{\pi} w_{p1} \cdot \rho \qquad (4)$$

where

$$w_{p1} = \frac{\pi}{16} \frac{G_c}{r_{p1}}$$

and is the elastic energy to yield under the plane strain conditions at the notch tip. Assuming that there is no lateral deformation in the constrained region the ratio of w_{p1} and w_{p2} may be expressed in terms of the Poisson's ratio ν so that:

$$\frac{w_{p1}}{w_{p2}} = \left(\frac{1 - \nu}{1 - 2\nu}\right)^2 \qquad (5)$$

As expected, as $\nu \to 1/2$, $w_{p1} \to \infty$ since complete constraint has been imposed on an incompressible material. However, for most polymers ν is around 0.4 giving $w_{p1}/w_{p2} = 9$ so that w_{p1} will be expected to be much larger than w_{p2}.

DISCUSSION OF RESULTS

Figure 10 shows data for PMMA and PVC plotted as G_c versus $1/\sigma_y^2$ and the expected linear relationship is apparent giving the values of G_{c1} and G_{c2}. *Figure 11* shows data for two thicknesses of polycarbonate and *Figure 12* for three thicknesses of polyethylene. The form of the data is in reasonable agreement with equation (2) and when the slopes are plotted against $1/B$ in *Figure 13* good straight lines result. It would seem that equation (2) is a good description of the data given here. *Table 1* gives the values of G_{c1} and G_{c2} for the materials tested. The effect of specimen thickness reported by Wolstenholme *et al.*[9] is also in accord with equation (2) in indicating a decrease in energy per unit area with increasing thickness. The reported proportionality of fracture load and yield stress[9] is also consistent with equation (4).
Figure 10 Variation of impact toughness with yield stress. ●, PVC; ○, PMMA
Figure 11 Variation of impact toughness with yield stress for polycarbonate for two specimen thicknesses: O, B = 3 mm; □, B = 6 mm

stress away from the actual fracture zone does show changes with temperature while G_{c1} and G_{c2} do not is the basis for the observed variations with temperature. Blunt notch data in effect magnify the plane strain yielding process at the notch root and although the plane stress energy w_{p2} shows the dependence on temperature typical of slow rate data the plane strain values, w_{p1}, show peaks.

The strong dependence on volume change is believed to be important here since it seems that it is the changes in
Figure 12 Variation of impact toughness with yield stress for medium density polyethylene for three specimen thicknesses: O, B = 3 mm; □, B = 6 mm; △, B = 11 mm

Since G_{c1} is found by extrapolation and G_{c2} is known it is possible to deduce the parameter w_{p2} from equation (2). The E here is an adiabatic value and constant while σ_y is not so that w_{p2} will be proportional to σ_y^2. *Figure 14* shows w_{p2} as a function of temperature and shows a rapid increase with decreasing temperature consistent with this relationship.

The blunt notch data were plotted in accordance with equation (4) so that w_{p1} was obtained and this is shown for the three materials in *Figure 14*. w_{p1} is much greater than w_{p2} as expected and corresponds to ν values of around 0.45. w_{p1} also decreases with temperature decrease and there is evidence of peaks in all three materials. Peaks in impact data have been widely reported[10-12] and Vincent[8] has observed that they are more usually found with blunt notches. Their correlation with tan δ peaks has been widely discussed but seems to be somewhat variable. The pronounced peak at −60°C here for PMMA and the lesser one for PVC at −20°C could be equated with the β process[13,14]. The more modest peak for polycarbonate does not seem to correspond to any tan δ peak which agrees with the findings of Heijboer[10].

CONCLUSIONS

The basic hypothesis that impact strength is strongly influenced by the constraint imposed by the specimen geometry seems to provide a good description of the sharp notch data. The concept of G_{c1} and G_{c2} coupled with yield stress changes gives an accurate picture of variations with temperature and specimen thickness. The fact that the yield

is likely to be of importance in an understanding of the fundamental processes involved.

ν which dominate over those in σ_y. Data of ν are scarce but it seems likely that there would be some correlation between tan δ peaks and volume changes. However, the origins of the effect may be in other factors such as absorbed fluids which are apparent in tan δ and have a strong influence on volume changes. A $-60°C$ peak in PMMA, for example, is sometimes ascribed to water. This sensitivity to volumetric effects in the fracture behaviour of polymers

Crazing and the creep behaviour of PMMA in methanol

G. W. Weidmann* and J. G. Williams

Department of Mechanical Engineering, Imperial College, London SW7 2BX, UK
(Received 9 June 1975; revised 17 July 1975)

A considerable increase in strain was observed when crazes formed during tensile creep tests on poly-(methyl methacrylate) (PMMA) specimens immersed in methanol. A model of craze growth from surface flaws is proposed which is based on craze growth kinetics, and which shows good correlation with the measured time and stress dependent behaviour.

INTRODUCTION

The phenomenon of crazing is well known and occurs in many glassy thermoplastics. It has been extensively studied since crazes, which although crack-like in appearance are still load-bearing, were first distinguished from cracks[1-3]. Work on the structure of crazes, chiefly by Kambour[4,5] has led to the now generally accepted view that these consist of regions of lower density than the bulk polymer and in which the molecular chains are grouped in aligned bundles separated by voids.

The growth of crazes is dependent both on stress and on environment and many polymers which undergo only slow bulk absorption of organic liquids are very prone to crazing when stressed in the presence of these liquids. This appears to be due to a stress-enhanced preferential absorption of the liquid at the tips of pre-existing surface flaws, leading to local plasticization and subsequent craze growth[6,7]. Studies of the growth of crazes from induced flaws have established growth laws as functions of flaw size and stress level[7,8]. The application of these laws to craze growth in unnotched specimens has enabled estimates to be made of the numbers and sizes of pre-existing flaws[8].

Although there have been previous investigations into the effect of liquids on the tensile creep behaviour of polymeric materials[9] and, more recently, an explanation proposed for the observed accelerated creep rates in terms of the kinetics of bulk diffusion of the liquid into the specimen[10], there has been very little reported on the possible role played by crazing in the process. Menges and Schmidt[11] have postulated that a critical strain is required for the onset of crazing which is the same for air as for craze-promoting liquids, the differences in tensile creep behaviour then arising from the different times at which the critical strain was achieved. However, they did not examine the subsequent effect of crazing on the tensile creep strain.

In this work the most intensively investigated polymer—liquid system in craze growth studies, namely PMMA in methanol, is examined under conventional, uniaxial tensile creep test conditions[12]. A comparison with results obtained under similar conditions in air, where no crazing is found, shows that the creep strain in methanol increases much more rapidly with time after crazes are formed and grow. This increasing difference in strain with time between the two environments is considered in terms of craze growth kinetics.

* Present address: Institut für Festkörpermechanik, 78 Freiburg/Br., Rosastrasse 9, West Germany.

EXPERIMENTAL

The creep tests were performed on ICI-type uniaxial tensile creep testing machines[12] with specimens 5.5 mm wide and 100 mm parallel section (80 mm gauge length) prepared from 1/8 in. ($\simeq$ 3 mm) thick, cast PMMA sheet (ICI Perspex). Strains were determined using modified Lamb's optical extensometers[12] and, for the tests in methanol, the whole specimen-extensometer assembly was immersed in the liquid contained in a glazed tank which was bolted to the machine. In order to calculate the strain from an observed deflection of a light spot on a curved scale, it was necessary to correct for refraction at the methanol—air 'interface' (ignoring refractive effects due to the thickness of glass, which were negligible). The geometry of the situation is illustrated in *Figure 1* and, using the same notation, the true reading for a rotation γ of the light beam would be δ_R whilst, due to refraction it appears as δ_A. Putting:

$$\theta = \delta_A/R$$

γ may be obtained by iteration from

$$R \sin \theta = A \tan \gamma + \frac{\mu \sin \gamma (R \cos \theta - A)}{(1 - \mu^2 \sin^2 \gamma)^{1/2}}$$

and as $\delta_R = R\gamma$ strains may be calculated from the change in δ_R during a test.

Two kinds of specimen surface preparation were used. In some cases the routed edges were left untreated, whilst in others these edges were polished with a very fine emery cloth. Such polishing had a marked effect on creep behaviour, with fewer visible crazes being obtained and smaller strains. Tests were conducted over a range of stress levels for both kinds of surface finish and typical creep curves
Figure 1 Extensometer scale geometry
Figure 2 Creep results at σ = 9 MN/m^2 with 12 observed crazes. □, In air; ○, in methanol

for methanol and air are shown in *Figure 2* at a stress of 9 MN/m^2. The difference between the two curves at various times gives the increased strain due to the effect of the methanol, $\Delta\epsilon$.

Additional tensile tests were undertaken in order to establish the maximum flaw sizes, $\hat{a}$, in the specimens. Three each of the polished and unpolished specimens were strained to failure in air with an Instron testing machine. Taking the stress intensity factor $K = 2\sigma a^{1/2}$ (see later) and the critical K value as 1.6 MN/m$^{3/2}$ [13], the flaw sizes may be deduced from 1.6 = $2\sigma_b \hat{a}^{1/2}$ where σ_b is the stress at failure. Both sets of specimens gave an average value of $\hat{a}$ = 36 μm, indicating that the polishing did nothing to remove these large flaws.

This estimate of $\hat{a}$ does not take into account the possibility of slow growth of the flaw during straining[13]. However, an additional estimate of $\hat{a}$ can be obtained from the creep test data. Preliminary trials showed that no appreciable effect on the strain and no visible crazes were produced at stresses below about 5 MN/m^2 and for times less than about 5000 s (at longer times bulk absorption of the methanol became sufficient to accelerate the creep rate). From previous work, the minimum value of K for initiation of craze growth in methanol is K_m = 0.05 MN/m$^{3/2}$ [7]. Taking this value and using σ = 5 MN/m^2 gives a value of $\hat{a}$ = 25 μm, assuming that such initiation first takes place at the largest flaws. In view of the possibility of slow growth in the fracture tests and of the observed initiation of both the cracks and the crazes from the machined edges, it is a reasonable supposition that both started at the same large flaws, whose size is approximately 25 μm.

Crazes would not grow from the cast surface until the stress had reached 16 MN/m^2. Using the same expression for K and the same value for K_m as previously with this value of stress implies a maximum flaw size of the cast surface of 2.5 μm. However, since there were very large numbers of these crazes, it will be taken that this value represents the mean flaw size for this surface.

CRAZING CREEP IN POLYMERS

In earlier work[7] it was established that, depending on the value of K, two different modes of craze growth in the presence of liquids could occur. At stresses corresponding to values of K below about 0.25 MN/m$^{3/2}$ as was the case in the experiments considered in this paper, craze growth is proportional to the square root of time and the craze

length x after a time t under load is given by:

$$x^2 = (K^2 - K_m^2)\beta t \qquad (1)^*$$

where K_m is the minimum value of the stress intensity factor K below which no craze growth occurs, and β, which is a function of the properties of both the polymer and the liquid, is a constant for any polymer—liquid combination. In the case of PMMA—methanol, β = 2.5 × 10^{-8} m^5 MN^{-2} s^{-1} [6,7].

If the surface flaws from which the crazes initiate can be considered as semi-elliptical flaws of depth a and width $2b$, as illustrated in *Figure 3*, with $b \gg a$, then:

$$K^2 = 4\sigma^2 a \qquad (2)$$

From equations (1) and (2):

$$a = \frac{1}{4\sigma^2} \left\{ \frac{x^2}{\beta t} + K_m^2 \right\} \qquad (3)$$

As a mechanism for the contribution, $\Delta\epsilon$, of the crazes to the creep strain it is postulated that, first, an initial craze nucleated from a surface flaw adds an increment u_0 to the deflection of the specimen when it has grown a distance x_0 and secondly, that the subsequent extension of the craze in the direction of the tensile stress can be modelled by the parallel growth of additional, unit crazes from the original flaw each adding a unit increment u_0 to the deflection. Thus, after n crazes per unit length of the specimen have grown to a length of x_0 or greater, the additional strain in the specimen is:

$$\Delta\epsilon = u_0 n \qquad (4)$$

Although the first postulate might appear somewhat arbitrary it tends to be supported by the observed initiation of crazes during the creep tests at much earlier times than those at which differences in strain between the tests in methanol and those in air could be detected. The divergence between the two creep curves (*Figure 2*) only took place after the crazes had grown to, typically, a length of the order of 1 mm.

The distribution of sizes of the flaws on the surface of a specimen may be expressed by a cumulative exponential distribution of the form[14]:

$$N = N_0 \exp - (a/\bar{a}) \qquad (5)$$

where N_0 is the total number of flaws per unit area, $\bar{a}$ is

---

* This is a slightly modified form to that given earlier[7].
Figure 3 Craze growth from a surface flaw
Figure 4 In $\Delta\epsilon$ as a function of $1/t$ at three stress levels: O, 5.5; X, 9.0; □, 12.0 MN/m^2

the modal flaw size, and N is the number of flaws whose depth is a or greater.

If n is proportional to N then the additional strain $\Delta\epsilon$ after n crazes have grown to a length of x_0 or greater, from equations (3)–(5) is given by:

$$\ln \Delta\epsilon = \ln \Delta\epsilon_0 - \frac{K_m^2}{\bar{K}^2} - \frac{x_0^2}{\bar{K}^2 \beta t} \qquad (6)$$

where $\bar{K}^2 = 4\sigma^2 \bar{a}$.

Equation (6) predicts a linear relationship between $\ln \Delta\epsilon$ and t^{-1} for a given pair of creep tests on PMMA in methanol and air at a constant stress σ, and that the slopes of the lines from different sets of creep tests should show a stress dependence of the form:

$$\frac{d(\ln \Delta\epsilon)}{d(1/t)} = -\frac{x_0^2}{4\beta\bar{a}} \cdot \frac{1}{\sigma^2} \qquad (7)$$

The intercept, $\ln \Delta\epsilon_i$, of a $\ln \Delta\epsilon$ *versus* t^{-1} plot, when $t \to \infty$, should be given by:

$$\ln \Delta\epsilon_i = \ln \Delta\epsilon_0 - \frac{K_m^2}{\bar{K}^2} \qquad (8)$$

where $\Delta\epsilon_0 = u_0 n_0$, the limiting strain when all the crazes are longer than x_0, and n_0 is proportional to N_0.

RESULTS

Polished and unpolished specimens were tested in both air and in methanol at stress levels ranging from 5.5 to 12 MN/m^2. The results of each pair of tests at a given stress level were plotted in the form of $\ln \Delta\epsilon$ *versus* t^{-1}. Three typical sets of such data are shown in *Figure 4*, for which it can be seen that linear relationships are obtained for significant ranges of the points. The divergence from linearity which is apparent at short times represents an approximately constant deflection per observed craze of about 1 μm independent of stress level. This might reflect the short term response of the largest flaws immediately after stressing in methanol, since it seems unlikely that any systematic error could have produced an effect of this sort.

Figure 5 shows the slopes of the linear regions of the $\ln \Delta\epsilon$ *versus* t^{-1} plots as a function of σ^{-2}. The relationship is linear as required by equation (7). However, unlike the theoretical prediction, the line in *Figure 5* does not pass through the origin. The accelerated craze growth found at higher stresses in previous work[5] would provide an explanation of this since such behaviour would tend to displace the experimental points upwards at the lower values of σ^{-2}.

From the slope of the line in *Figure 5* (-6.1×10^5 MN s m^{-4}) and equation (7), x_0 may be calculated. There is, however, an uncertainty in the value of $\bar{a}$, the mean flaw size of the machined surface. Upper and lower limits to its value can be provided by the maximum flaw size deduced from the fracture tests, 25 μm, and the estimated mean flaw size on the cast surface, 2.5 μm. This gives 0.4 mm $< x_0 <$ 1.2 mm which is in agreement with the observed extent of craze growth prior to a detectable contribution to the strain from the crazes.

In order to compare the intercept results from the different tests it is necessary to take into account the effect of different flaw size distributions on the specimens (or, more precisely, different values of N_0, the total number of flaws). However, N_0 was not known. If instead the number of observed crazes N' is taken as an indicator of N_0 then, as can be seen from *Table 1* which summarizes the experimental results, if there is any systematic variation of the intercept values with stress then it is in the opposite sense to that required by equation (8). This could be explained if the relationship between n_0 and N_0 was a stress-dependent one rather than the simple proportionality assumed earlier.

CONCLUSIONS

The postulated model of craze thickening through the growth of a number of additional unit crazes from the original flaws, each contributing an increment to the thickness, and the theoretical expressions based on this model, are successful in their ability to describe not only the rate with which the increased strain due to crazing varies with time, but also the rate with which it varies with stress. The correlation of the model with the magnitudes of the observed strains, and their dependence on stress, is not so successful, requiring as it does a more detailed knowledge of the total numbers of flaws on the specimen surfaces.

The initiation data both from craze growth and fracture tests provide reasonable evidence for a maximum flaw size of 25 μm. The mean flaw size has not been so well established, but the values of the parameter x_0 based on upper and lower estimates of the mean flaw size are consistent with the observed extent of craze growth prior to a detectable increase in craze strain. The parameter x_0 might then be taken to represent the average spacing between a surface flaw and an internal flaw sufficiently severe to activate an increase of strain in a craze.

Influence of high injection pressures on the internal stress level in injection moulded specimens

Josef Kubát and Mikael Rigdahl

Division of Polymeric Materials, Chalmers University of Technology, S-402 20 Gothenburg, Sweden
(Received 17 March 1975; revised 7 July 1975)

Internal stresses in high and low density polyethylene specimens, injection moulded at pressures ranging from 100 MPa to 450 MPa have been measured by a stress relaxation method. The internal stress parameter (σ_i), which is an average value of the internal stress distribution in the samples, changes from a negative value (compressive stresses) at normal injection pressures to a small positive value (frozen-in tensile stresses) at the highest pressures used. The yield stress increases in approximately the same way with the pressure, while the mould shrinkage in the flow direction decreases. It is suggested that the decrease in the absolute value of the internal stress parameter originates from an increase of the melting temperature with pressure, resulting in a more homogeneous solidification.

INTRODUCTION

The magnitude and distribution of internal stresses in injection moulded plastics objects is the result of a complicated interplay of a large number of factors, among which the injection pressure seems to occupy an important place.

The influence of the injection pressure on internal stresses in injection moulded samples does not seem to have attracted much interest. On the whole, the variation of the pressure within the range normally used appears to have little effect on the properties of the mouldings, such as yield strength, shrinkage etc.[1], although some properties, e.g. impact strength, exhibit a somewhat more pronounced dependence on the pressure[1]. In addition there is the well known difficulty of separating the effect of internal stresses and anisotropy. Normally, the properties of the moulding will be determined by a combination of both. In order to measure the influence of the injection pressure Kantz[1] determined the volume proportion of oriented material as dependent on the pressure. Jensen and Whisson[2] determined the degree of orientation and presented the results in terms of a so-called orientation stress. Measured in the flow direction, this quantity decreased only to a minor extent as the pressure was raised. The materials studied were polystyrene, polypropylene, polysulphone and ABS. Similar results were reported by Fett[3] using a hardness method for measuring the combined action of internal stresses and anisotropy. The injection pressures used in these investigations were, however, only moderate.

When the polymer melt solidifies in the mould, internal stresses are frozen-in as a consequence of differences in the solidification rate between the surface parts and the interior of the object. This results normally in compressive stresses at the surface and tensile stresses in the interior. Such effects are well known; they have been analysed both experimentally[3-6] and theoretically[6,7].

This paper gives an account of an experimental study of the influence of injection pressure on the overall internal stress level (σ_i) in LDPE and HDPE samples having the shape of small tensile test specimens.

The range of injection pressures extended to 450 MPa, i.e. far above the normally used interval ending at 150—

200 MPa. Increasing the pressure brought about a decrease in the overall σ_i level for both LDPE and HDPE. The yield stress and the mould shrinkage of the samples were also measured. As expected, an increase in the absolute value of σ_i produced larger shrinkage. Also the yield stress showed a tendency to increase with σ_i. The method used to measure the σ_i values was the stress relaxation method described earlier[8,9].

EXPERIMENTAL

Injection moulding

The injection moulding of the samples at varying injection pressures was performed using a modified machine of conventional type (Engel 500/250 AS). This machine was equipped with a special screw (*Figure 1*). The main feature of this screw was a plunger (diameter 30 mm) at its end, the molten polymer flowing through a central bore in the plunger. Back flow of the melt during injection into the mould was prevented by a non-return valve. In this way injection pressures varying between 100 MPa and 450 MPa could be attained. The holding pressure was identical to the injection pressure. The dimensions of the injection moulded samples are shown in *Figure 2*.

Materials used and processing conditions

The experiments were carried out with LDPE and HDPE samples. The characteristics of these materials were as follows: LDPE (BASF, Lupolen 1800 M), density 0.916—

Non-return valve   Drilled plunger   Screw

0.918 g/cm^3, melt index 6–8 g/10 min (*MFI* 190/2 I6); HDPE (Hoechst, Hostalen GC 7260), density 0.960 g/cm^3, melt index 7 g/10 min (*MFI* as above). The moulding conditions are given in *Table 1*.

Measurement of stress relaxation and stress–strain behaviour. Mould shrinkage

The stress relaxation measurements were performed in the usual way by deforming the sample, keeping the deformation constant and measuring the stress decay. The tensile testing machine used was of a conventional type (L & W Alwetron, TCS 250). The deformation rate was $\dot{\epsilon} =$ 10^{-2} s^{-1}. Every sample was used for a single experiment only.

The measured relaxation curves recorded were transformed into stress–log (time) diagrams and the maximum (inflection) slope of the rectilinear portion of the curves obtained, i.e.

$$F = \left(-\frac{d\sigma}{d \log t} \right)_{max}$$

was plotted against the initial stress σ_0 of the relaxation experiment. The plots were then used for determining the internal stress level σ_i from $\sigma_0 = \sigma_i$ at $F = 0$.

Besides the relaxation measurements, the stress–strain curves of the samples were also recorded. In this case, the deformation rate was $\dot{\epsilon} = 1.6 \times 10^{-2}$ s^{-1}.

The mould shrinkage was determined by measuring with a microscope the distance between two fiducial marks made

in the mould by a Rockwell hardness tester, and the change of this distance when measuring the replicas of these marks on the moulding.

The stress–strain and relaxation experiments were carried out at 22 ± 0.5°C.

RESULTS

Internal stresses

As already mentioned the internal stress data were obtained from an analysis of stress relaxation curves of the various samples. An illustration of the effect of injection pressure on the relaxation kinetics is shown in *Figure 3*. The two curves, typical of the behaviour under study, relate to HDPE moulded at a pressure of 100 and 400 MPa; the magnitude of their initial stresses was about the same. As can be seen, the relaxation rate is greater for the sample moulded at the higher pressure.

The internal stress analysis using data from a series of relaxation curves measured at varying initial stress σ_0 has been carried out in *Figure 4* for HDPE samples moulded at
Figure 3 Stress relaxation curves for HDPE, injection moulded at 100 (△) and 400 MPa (○). The initial stresses (σ_0) were 9.7 MPa and 9.9 MPa, respectively
Figure 4 Determination of the internal stress parameter in HDPE using $F(\sigma_0)$ plots. ○, 100; ●, 400 MPa
Figure 5 Determination of the internal stress parameter in LDPE using $F(\sigma_0)$ plots. $\bigcirc$, 100; $\blacktriangle$, 200; $\bullet$, 400 MPa
Figure 6 Internal stress parameter as a function of pressure for HDPE ($\square$) and LDPE ($\bigcirc$)

100 and 400 MPa. The value of the intercept between the maximum slope F of the $\sigma(\log t)$ curves when plotted against the initial stress σ_0, and the axis $F = 0$ is, as pointed out above, a measure of the internal stress level, σ_i. It can be seen from *Figure 4* that the absolute value of σ_i decreases markedly by increasing the injection pressure from 100 to 400 MPa. At the same time, the slope of the $F(\sigma_0)$ line increases. LDPE samples behave similarly (*Figure 5*).

The relationship between the internal stress parameter σ_i and the injection pressure is shown in *Figure 6* for the two kinds of PE. The σ_i value changes from comparatively large negative values to rather small positive ones. For HDPE, the σ_i value at 100 MPa is larger (negative) than that for LDPE. It should be noted that by a suitable choice of the injection pressure the σ_i value can be reduced to zero.

The yield value

The yield value and its variation with the injection pressure or σ_i is another interesting aspect of the experiments reported here. For HDPE, the yield value can be defined without difficulty by relating the maximum stress to the

initial cross-section area of the sample. Such a simple definition cannot, on the other hand, be applied to a material such as LDPE, which does not exhibit a pronounced yielding behaviour. In such a case, one can rely on for instance the ASTM method D 638, according to which the yield point is defined as the stress at which the initial ('elastic') part of the stress—strain curves starts to depart from a straight line, again related to the initial cross-section.

Figure 7 shows the internal stress σ_i plotted against the yield stress value. It can be clearly seen that these two quantities are interrelated. At least for not too high injection pressures, the yield stress increases with the σ_i value.

Mould shrinkage

The extent of shrinkage was determined by measuring the distance between two marks along the flow direction in the mould and the corresponding distance between the replicas of these marks left on the moulded samples. The shrinkage value ϵ_s was calculated from:

$$-\epsilon_s = \frac{a_s - a_m}{a_m}$$

where a_m and a_s denote the distance between the points in the mould and on the sample, respectively.

Figure 8 shows the relationship between internal stress and the mould shrinkage. It follows from this diagram that the lower the absolute value of σ_i, the lower is also the shrinkage. On the other hand, a simple proportionality does not seem to exist.

DISCUSSION

When discussing the results obtained, one should keep in mind the complexity of the various factors influencing the residual stress distribution in an injection moulded specimen. In the first place, such stresses are not homogeneous. Normally, their distribution forms a pattern, the characteristics of which depend on processing and material parameters[4,8]. For specimens of the type used here, one usually finds relatively high compressive internal stresses in the surface layers and weak tensile stresses in the interior[7].
Figure 7 Internal stress parameter vs. yield stress for HDPE ($\square$) and LDPE ($\bigcirc$)
Figure 8 Correlation between internal stress parameter and mould shrinkage for HDPE

The σ_i values presented above are thus to be considered as averages over the various layers having different internal stress levels and also different relaxation behaviour due to the variation of anisotropy over the cross-section[1,10]. As the average σ_i level is evaluated from certain parameters of stress relaxation curves, it is to be assumed that also these parameters in their turn are averages. The course of the stress relaxation is thus the result of a superposition of relaxation processes in the different layers of the specimen having different σ_i values and different relaxation behaviour[10].

Despite the complications mentioned, the analysis of the relaxation curves and the overall σ_i values obtained from them, point at some interesting results when the general influence of the injection pressure on the properties of the specimen is considered. The first result to be noted is that the residual compressive stress obtained in normal injection moulding practice is reduced by increasing the pressure. At the highest pressures used this compressive stress is reversed into a weak tensile one. It thus appears possible to reduce the average σ_i value to zero by an appropriate rise in the injection pressure (*Figures 4* and *5*).

The mechanism behind the appearance of an internal stress distribution in an injection moulded specimen has been discussed previously[6,7]. Here, it may suffice to say, that these stresses are due to a temperature gradient during cooling. The outer layers solidify in the initial stage of the cooling process. Owing to differences in specific volume between melt and solid, compressive stresses are frozen into the solidified surface layers when the interior of the specimen becomes solid. For balance reasons, weak tensile stresses prevail in the interior. With regard to the effect of pressure on this process the following may be said. It is known that the melting point of a polymer is relatively sensitive to pressure, an increase of about $20°C/100$ MPa having been found for polyethylene[11,12] Increasing the pressure on the melt in the mould is thus equivalent to an overall increase of the melting point of the polymer. In principle, when the mould has been filled and the peak pressure reached, the whole cavity content can be brought to solidify simultaneously. In normal moulding, the solidification (crystallization) takes place when the temperature in different parts of the mould passes a critical value (T_m). The important thing

to note is that this critical temperature is reached in different parts of the specimen at different times. Contrary to this, when using high pressures the crystallization can take place simultaneously in the whole of the specimen. It is thus possible to ascribe to the injection pressure the role of a crystallization regulator, a role not taken advantage of hitherto in the production of stress-free mouldings.

Looking at *Figure 6* one may see that the injection pressure corresponding to zero level of σ_i is approximately the pressure by which the melting points of HDPE and LDPE are raised to a temperature[11,12] equal to that of the melt leaving the cylinder.

Another effect which probably contributes to the reduction of the σ_i level on increasing the pressure is a decrease in the thermal shrinkage occurring in the vicinity of T_m[7,11].

As could be expected, the average σ_i value correlates well with mould shrinkage. Again, it should be kept in mind that we deal with averages which preclude an exact analysis of these findings. The same is true of the relationship between σ_i and the yield stress. Nevertheless, the results have a clear technical significance, as the samples used have been prepared according to normal practice. For a closer study of the phenomena involved it is, however, necessary to resolve the different components contributing to the average σ_i level and also to compare such results with experiments performed on samples containing a homogeneous internal stress. In a forthcoming paper we will report on a simple mathematical model relating to a distribution of internal stresses in specimens of simple shape with a varying degree of anisotropy over their cross-section[10]. It will be shown that this model will handle the effects of an internal stress distribution on the parameters of stress relaxation curves, which are used in determining the σ_i values. In the first place this applies to the variation of the $F(\sigma_0)$ relationship and to the value of the $F(\sigma_0)$ intercept with the σ_0 axis (i.e. the σ_i value). For instance, it will be shown that the results of the present paper can be simply handled by assuming a 3-layer model with compressive and tensile internal stresses.

The influence of injection pressure on the σ_i level has been illustrated here using LDPE and HDPE as examples. For other crystalline polymers the melting temperature is shifted in a similar way, e.g. for polypropylene T_m increases from about $175°C$ at atmospheric pressure to about $245°C$ at a pressure of 220 MPa[13] and for polyamide-6 and polyoxymethylene a change in melting temperature of $38°$ and $44°C$ per 100 MPa, respectively, in the pressure range 0–200 MPa has been reported[14,15]. The role played by the increase in the melting temperature with pressure is, on the other hand, not restricted to crystalline polymers. It is known, that the corresponding critical temperature for amorphous polymers, i.e. the glass transition temperature, also rises when the pressure is increased, e.g. for polystyrene, PVC and PMMA a shift of T_g of $32°$, $16°$ and $29°C$ per 100 MPa, respectively, has been determined[16]. As this increase per 100 MPa is of the same order of magnitude as that in T_m for crystalline polymers, the effect of increasing injection pressure in reducing the overall internal stress level appears to be a rather general one.

As the main purpose of this paper was a first demonstration of a possible practical significance of increasing the injection pressure, we have not analysed a number of factors which may influence the results. For instance, the concept of melting and crystallization, and their dependence on super-cooling has been treated in qualitative terms only. With regard to the distinction between true internal stresses and anisotropy, the relaxation method used for the mea-

surements of the overall σ_i level does not clearly distinguish between the two contributions. On the other hand, the method is known to produce data consistent with normal practical experience[8,10]. It may also be pointed out that, in the present experiments, the injection rate was kept constant, independent of the final pressure attained. For this reason, the contribution of the anisotropy should be about the same at the different pressure levels.

Rather naturally, a number of problems remain to be solved. Of particular interest would be measurement of the σ_i level in different directions of the sample as well as careful following of the pressure and temperature variation in the mould. It is intended to describe such studies in a forthcoming publication.

It may be pointed out that the present work is a part of an investigation of the properties of specimens injection moulded at high pressures. The experiments cover a pressure range up to 500 MPa under conditions of normal injection moulding practice. The results of this investigation will be published elsewhere.

Notes to the Editor

Crystallization of isotactic poly(methyl methacrylate) from the melt

A. de Boer, G. O. R. Alberda van Ekenstein and G. Challa

Department of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands
(Received 19 May 1975; revised 20 June 1975)

INTRODUCTION

In 1958 Fox et al,[1] reported the possibility of crystallizing isotactic poly(methyl methacrylate) (i-PMMA). Stroupe and Hughes[2] determined the unit cell of crystalline i-PMMA: a pseudo orthorhombic cell with the lattice distances $a = 21.08$, $b = 12.17$ and $c = 10.55$ Å. Coiro et al,[3] concluded from X-ray fibre diagrams that i-PMMA crystallizes in a (5_1) helix conformation. Tadokoro et al,[4] refined this picture by X-ray diffraction and far infra-red measurements and suggested that the ester side groups of i-PMMA in the (5_1) helix conformation are rotated somewhat inwards. Also Tanaka et al,[5] and Klement and Geil[6] investigated crystalline i-PMMA. In all cases the crystalline i-PMMA was obtained by means of borderline solvents or by annealing stretched thin films. In this note we present some results on the growth rate, shape and melting temperature of crystals of i-PMMA crystallized from the melt.

EXPERIMENTAL

The sample of i-PMMA was prepared according to a known procedure[7]. Some data of the polymer (sample no. 109) are: isotactic/heterotactic/syndiotactic triads 94:5:1, $\bar{M}_v = 213 \times 10^3$, $T_g = 40°C$. The tacticity was measured on 5 wt% o-dichlorobenzene solutions at 150°C by 60 MHz n.m.r. spectroscopy with a Varian A 60 instrument. $[\eta]$ was measured in chloroform at 25°C. For the calculation of $\bar{M}_v$, the relation[8] $[\eta] = 4.8 \times 10^{-5} \bar{M}_v^{0.8}$ was used. The glass transition temperature was measured with a differential scanning calorimeter (Perkin-Elmer DSC IB) at a heating rate of 8°C/min.

Films with a thickness of about 10 μm were obtained by evaporation of a 3 wt % chloroform solution of i-PMMA on a glass slide. To remove all solvent, the films were dried afterwards at 50°C *in vacuo* for 30 min. For crystallization temperatures (T_c) below 110°C the films were first heated at 180°C for 5 min and then cooled down to T_c. This was done because otherwise there exist too many nuclei for detecting separate crystals. Temperature control of the crystallization oven was within 0.2°C. A Zeiss polarization microscope with phase-contrast condenser and objective was used for light microscopic measurements on crystals grown in the films.

Because of the very low growth rate (G) of i-PMMA crystals phase-contrast photographs were taken over seve-

ral days. After enlarging the photographs it was possible to measure the diagonal of the crystals with an accuracy of about 0.6 μm. The magnifications were calibrated with a micrometer. Melting temperatures, T_m, were determined both with d.s.c. and a hot-stage light microscope. We used a hot stage plate (Mettler FP 5) with a heating rate of 0.2°C/min.

RESULTS AND DISCUSSION

In *Figure 1* the average values of the longest diagonals of the crystals are plotted against the crystallization time for various T_c. From these lines the average growth rates G were calculated and plotted against crystallization temperature in *Figure 2*. This Figure shows that i-PMMA has a maximum value G_{max} of about 1×10^{-3} μm/min at about 120°C. For isotactic polystyrene (i-PS) maximum values of about 300×10^{-3} μm/min were reported[9]. In the literature[10] i-PS is considered a slowly crystallizing polymer. Comparing the maximum values of G it is clear that i-PMMA should be called a very slowly crystallizing polymer. However, it should be kept in mind that the given maximum value for i-PMMA is not a general one. It will be influenced by molecular weight and tacticity of the sample.

Figure 3 shows some typical photographs of crystals of
Figure 1 Longest diagonal (μm) of crystals of i-PMMA against crystallization time (min) for various T_c: O, 90°; X, 100°; △, 110°; ●, 120°; □, 130°C
Figure 2 Average growth rate G (μm/min) of i-PMMA crystals against crystallization temperature T_c

i-PMMA taken at different stages of growth at 120°C. Initially only hexagonal structures were observed, which showed only little birefringence (*Figures 3a* and *3d*), while in later stages skeletation to starlike structures occurred and finally the crystals became rounded.

Hexagonal structures have also been reported for polyoxymethylene[11], isotactic polypropylene[11] and isotactic polystyrene[12]. Besides the above mentioned hexagonal structures spherical structures were also observed, especially at lower T_c, e.g. 90 and 100°C. The spherical crystals had about the same value of G as the hexagons. In accordance with the literature[11,13] these spherical structures showed more birefringence than the hexagonal structures. At 130°C no spherical structures could be observed at all.

The above results are in agreement with those of Keith[13] for i-PS. However, we observed hexagons of i-PMMA at crystallization temperatures 100–120°C below the melting temperature, whereas Keith could detect hexagons of i-PS only at 30–40°C below the melting temperature. Moreover, the hexagons of i-PMMA could become much larger than those of i-PS, e.g. 65 μm in *Figure 3a versus* 5 nm reported for pure i-PS.

According to Keith[14] δ can be considered as a characteristic length for the growing crystal. ($\delta = D/G$; D = diffusion coefficient for 'impurity' in the unsolidified medium; G = growth rate of the crystal face). At crystal sizes smaller than δ, impurities can easily diffuse out of the way of oncoming growth fronts. In this stage single crystals grow from the melt, producing hexagons which are multilayers of single crystals, also called hedrites.

In the literature no melt viscosity data were available for i-PMMA to calculate D and it seems troublesome to use the
Figure 3 Various stages of crystal growth of i-PMMA at 120°C. (a), (b) and (c) are phase-contrast photographs. (d), (e) and (f) are bright field photographs between crossed Nicols. Crystallization times: (a) 10 days; (b) 14 days; (c) 18 days; (d) 10 days; (e) 14 days; (f) 18 days (magnification 640 ×)
Figure 4 Phase contrast photograph of i-PMMA crystallized at 130°C during 25 days (magnification 640 X)

available data of atactic PMMA. For δ = 65 μm, the limiting value of the diagonal (*Figure 3a*) and a G value of 1×10^{-3} μm/sec (*Figure 2*) we calculate a D value of about 10^{-9} cm^2/sec, which is a quite reasonable value. So, it may be assumed that the differences in supercooling and sizes of hexagons for i-PMMA and i-PS are predominantly caused by the much lower growth rate of i-PMMA compared with i-PS.

Figure 4 shows a photograph of a sample crystallized at 130°C. At this temperature δ has a larger value than at 120°C because D increases and G decreases with temperature (*Figure 2*). So, we expected to observe still larger hexagons, but even in very early stages no purely hexagonal structures could be observed, only structures with strong skeletation. Maybe, more faceted growth takes place at 130°C.

Finally, *Figure 5* shows the $T_m - T_c$ diagram of i-PMMA. Melting temperatures T_m were recorded with a d.s.c. at various heating rates. To correct for super heating (maximum effects of 8 and 20°C for crystals grown at 90 and 130°C, respectively), T_m values were extrapolated to zero scan speed. T_m values were also estimated on the hot stage light microscope (*Figure 5*). The middle of the melting range (4–8°C) of the crystals was chosen as T_m. The difference with d.s.c. values can be explained by the fact that especially for samples crystallized at 90°C and 100°C the beginning of the melting process is not exactly detected as a result of which too high T_m values are found. Since it is very time consuming to crystallize i-PMMA at temperatures above 130°C, the line in the $T_m - T_c$ diagram had to be extrapolated over a large distance. This means that the extrapolated melting temperature $T_m{}^0$ can only be found approximately. *Figure 5* shows that $T_m{}^0$ of i-PMMA is about 220°C.
Figure 5 Melting temperatures T_m of i-PMMA as a function of crystallization temperature T_c. ●, Recorded by d.s.c. extrapolated values with zero scan speed; ○, estimated by light microscopy with a heating rate of 0.2°C/min

Upper and lower theta temperatures for solutions of *cis*- and *trans*-1,4-polybutadiene

J. M. G. Cowie and I. J. McEwen
Department of Chemistry, University of Stirling, Stirling FK9 4LA, UK
(Received 21 July 1975)

Variations in polymer dilute solution behaviour due to microstructural differences are now well documented[1]. When polymer tacticity is the variable the differences are most clear in pseudo-ideal solvents and become less apparent as the solvent quality improves. In the 1,4-polydienes, where *cis–trans* isomerism is the important feature, structurally dissimilar polymers can be readily distinguished in good solvents in which the polymer coil is highly expanded. Thus the Mark–Houwink equations derived for *cis*- and *trans*-1,4-polybutadiene dissolved in toluene are quite distinct[2]. While some work has been reported on the behaviour of pseudo-ideal solutions of *cis*-1,4-polybutadiene[3,4] we are unaware of any comparable studies for the *trans*-polymer. Vanzo[5] has reported lower critical solution temperatures (*LCST*) for two fractions of a polybutadiene sample in hexane, but the polymer had a mixed structure.

Commercial samples of *cis*- and *trans*-1,4-polybutadiene were used in this work. Infra-red analysis[6] showed that the structures were respectively, 93% *cis*, 4% *trans*, 3% 1,2-addition, and 94% *trans*, 6% 1,2-addition. The samples were fractionated from cyclohexane solutions using isopropyl alcohol as precipitant. The fractions were separated, dried and then stored under vacuum until required for measurement. Viscosity-average molecular weights, M_v, were calculated from established Mark–Houwink equations by measuring the limiting viscosity number $[\eta]$ in toluene at 303K for predominantly *cis* samples[3a], and in cyclohexane at 313K for the *trans* fractions[7]. The results are shown in *Table 1*.

Cloud point curves for all fractions were determined in three solvents, ethyl propyl ketone, diethyl ketone and propylene oxide. These were established, in both the upper and lower critical regions, by preparing several solutions of each fraction in the concentration range 0.5 to 12% w/v, sealing these in capillary tubes and observing the liquid–liquid phase separation temperatures using methods described elsewhere[8]. As the samples were not monodisperse,

Table 1 Limiting viscosity numbers and molecular weights for *cis*- and *trans*-1,4-polybutadiene fractions

Samples	$[\eta]$ (cm^3/g)	$M_v \times 10^5$
cis-1,4-polybutadiene:		
1,1(A)	520	6.92
1,1(B)	386	4.57
1,2	256	2.60
2,2	175	1.53
2,3	135	1.08
trans-1,4-polybutadiene:		
3	177	1.93
4	110	1.37
5(a)	95	1.00
5(b)	53	0.47
Figure 1 Plots of T_{th} against $r^{-1/2}$ for *cis*-polybutadiene (O) and *trans*-polybutadiene (●) in the solvents ethylpropylketone (———), diethyl ketone (————) and propylene oxide (·····). *r* is the ratio of the molar volumes of polymer and solvent at 298 K

the maxima and minima of the cloudpoint curves represented threshold temperatures, T_{th}, rather than true critical points, but the difference is probably small in every case because of the flatness of the experimental curves.

In *Figure 1*, T_{th} has been plotted against $r^{-1/2}$, where *r* is the ratio of the molar volume of the polymer to that of the solvent. The data have been extrapolated to $M = \infty$ in both the upper and lower critical solution regions to obtain θ_U and θ_L respectively. It can be seen from the summary in *Table 2*, that the solvent quality varies quite considerably from a miscibility range $\Delta\theta$ of 109K in propylene oxide to $\Delta\theta = 259$K in ethyl propyl ketone. Also shown is the ratio (θ_L/T_c), estimated for each polymer-solvent pair, where T_c is the critical temperature of the solvent. The values are similar to those reported for other systems. A value of $\theta_U = 283.5$K for *cis*-polybutadiene in diethyl ketone has been reported by Abe and Fujita[4] in reasonable agreement

Table 2 Upper and lower theta temperatures for *cis-* and *trans-* 1,4-polybutadienes

Solvent	Polybutadiene	θ_U(K)	θ_L(K)	(θ_L/T_c)
Ethyl propyl	*cis*	251	510	0.884
ketone	*trans*	—	513	0.889
Diethyl ketone	*cis*	287	481	0.847
	trans	—	486	0.856
Propylene oxide	*cis*	308	414	0.836
	trans	—	419	0.842

with our value, considering that there are slight differences in structure between the samples.

While the *cis* and *trans* forms of the polymer can be distinguished in the lower critical region, the differences in θ_L are really quite small. In all cases, θ_L for the *trans* form was slightly higher than that for the *cis*. This is consistent with the simple explanation which attributes the existence of the *LCST* to differences in free volume between the rapidly expanding solvent and the more slowly expanding polymer, as the critical temperature of the solvent is approached. The expansion coefficients of 1,4-polybutadienes appear to be almost independent of the *cis–trans* content[9], although the results do indicate that the expansion factor for the *trans* form is marginally higher than the *cis*. Thus one would expect both forms to exhibit very similar *LCST*'s, but with the *trans* form having the higher value.

Unfortunately a similar comparison of θ_U values could not be made because the *trans*-1,4-polybutadiene consistently crystallized from all three solvents before liquid—

liquid phase separation could occur. The temperature at which the liquid–crystal phase separation took place was in the range 290–295K and was independent of the sample chain length. For this reason measurement of the *LCST* would be a more general means of distinguishing between the *cis* and *trans* forms of 1,4-polybutadiene, but because of the small differences observed this would not provide a particularly reliable method of analysis. Consequently, in contrast to polymers with different tactic forms, *cis–trans* isomerism is most easily detected when polymers are dissolved in good solvents.

Effects of oxygen on vinyl polymerization systems: limitations of conventional dilatometry

A. Garton* and M. H. George

Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK
(Received 10 July 1975)

INTRODUCTION

Small scale dilatometry is a widely applied technique for following the course of polymerization reactions[1] and many simple, and more complicated types of dilatometer have been described previously[2,3]

Some of the descrepencies associated with the interpretation of dilatometric results may involve the improper use of monomer and polymer densities or the heating effects occuring within dilatometers[4] However, although the need for adequate stirring of dilatometer contents has been stressed when studying emulsion polymerizations[5], little attention has been paid to the effect of inadequate reactant mixing in other polymerization systems. We have found in our laboratories that adequate mixing of dilatometer contents was crucial when examining the effect of the gaseous additive, oxygen, at low concentrations, on several free radical vinyl polymerizations.

EXPERIMENTAL AND RESULTS

For example, the effect of oxygen on the liquid-phase polymerization of vinyl chloride at 55°C in the presence of an added initiator, bis(4-t-butylcyclohexyl) peroxydicarbonate (Perkadox 16) has been studied[6]. Initial experiments were conducted in a conventional manner similar to that reported in several earlier studies. Thick walled dilatometers were used, each with a bulb volume of about 2.5 cm³ attached to 2 mm precision-bore capillary. Known amounts of oxygen were added to the previously purified and degassed monomer/initiator mixtures inside each dilatometer bulb. After freezing in liquid nitrogen, the dilatometers were sealed off under vacuum. The dilatometer contents were shaken vigorously at 0°C prior to clamping vertically in a thermostated bath at 55°C. The relationship between the initial oxygen content (0–600 ppm w/w) and the resulting induction period, τ, recorded as the time taken for polymer to precipitate from solution, was studied. If ideal solution behaviour of oxygen in vinyl chloride is assumed, at least 98%

Table 2 Upper and lower theta temperatures for *cis*- and *trans*-1, 4-polybutadienes

Solvent	Polybutadiene	θ_U(K)	θ_L(K)	(θ_L/T_c)
Ethyl propyl	*cis*	251	510	0.884

with our value, considering that there are slight differences in structure between the samples.

While the *cis* and *trans* forms of the polymer can be distinguished in the lower critical region, the differences in θ_L are really quite small. In all cases, θ_L for the *trans* form was slightly higher than that for the *cis*. This is consistent with the simple explanation which attributes the existence of the *LCST* to differences in free volume between the rapidly expanding solvent and the more slowly expanding polymer, as the critical temperature of the solvent is approached. The expansion coefficients of 1, 4-polybutadienes appear to be almost independent of the *cis–trans* content[9], although the results do indicate that the expansion factor for the *trans* form is marginally higher than the *cis*. Thus one would expect both forms to exhibit very similar *LCST*'s, but with the *trans* form having the higher value.

Unfortunately a similar comparison of θ_U values could not be made because the *trans*-1, 4-polybutadiene consistently crystallized from all three solvents before liquid–

liquid phase separation could occur. The temperature at which the liquid–crystal phase separation took place was in the range 290–295K and was independent of the sample chain length. For this reason measurement of the *LCST* would be a more general means of distinguishing between the *cis* and *trans* forms of 1, 4-polybutadiene, but because of the small differences observed this would not provide a particularly reliable method of analysis. Consequently, in contrast to polymers with different tactic forms, *cis–trans* isomerism is most easily detected when polymers are dissolved in good solvents.

Effects of oxygen on vinyl polymerization systems: limitations of conventional dilatometry

A. Garton* and M. H. George

Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK
(Received 10 July 1975)

INTRODUCTION

Small scale dilatometry is a widely applied technique for following the course of polymerization reactions[1] and many simple, and more complicated types of dilatometer have been described previously[2,3]

Some of the descrepencies associated with the interpretation of dilatometric results may involve the improper use of monomer and polymer densities or the heating effects occuring within dilatometers[4] However, although the need for adequate stirring of dilatometer contents has been stressed when studying emulsion polymerizations[5], little attention has been paid to the effect of inadequate reactant mixing in other polymerization systems. We have found in our laboratories that adequate mixing of dilatometer contents was crucial when examining the effect of the gaseous additive, oxygen, at low concentrations, on several free radical vinyl polymerizations.

* Present address: Applied Chemistry Division, National Research Council, Ottawa, Ontario K1A OR6, Canada.

EXPERIMENTAL AND RESULTS

For example, the effect of oxygen on the liquid-phase polymerization of vinyl chloride at 55°C in the presence of an added initiator, bis(4-t-butylcyclohexyl) peroxydicarbonate (Perkadox 16) has been studied[6]. Initial experiments were conducted in a conventional manner similar to that reported in several earlier studies. Thick walled dilatometers were used, each with a bulb volume of about 2.5 cm³ attached to 2 mm precision-bore capillary. Known amounts of oxygen were added to the previously purified and degassed monomer/initiator mixtures inside each dilatometer bulb. After freezing in liquid nitrogen, the dilatometers were sealed off under vacuum. The dilatometer contents were shaken vigorously at 0°C prior to clamping vertically in a thermostated bath at 55°C. The relationship between the initial oxygen content (0–600 ppm w/w) and the resulting induction period, τ, recorded as the time taken for polymer to precipitate from solution, was studied. If ideal solution behaviour of oxygen in vinyl chloride is assumed, at least 98%

by wt of the gas should be dissolved in the liquid monomer at 55°C under typical conditions. Any positive interactions between vinyl chloride and oxygen would increase the solubility of the gas.

Nevertheless, irreproducible measurements of induction periods were obtained by this simple 'static' dilatometric method. It was considered that the irreproducibility was largely caused by the existence of an oxygen rich phase within the dilatometer capillary. The restricted rate of diffusion of oxygen from the capillary would therefore result in polymerization occurring within the bulb before the oxygen had been completely consumed. Conventional stirring of the contents of dilatometer bulbs would be of little use in these circumstances.

The filled, sealed-off dilatometers were inverted, therefore, in subsequent experiments to allow the gas phase to enter the bulb and then rotated slowly in the theromstated bath. Typically, the dilatometers were rotated about an axis 45° to the vertical at a speed of about 30 rev/min. The oscillation of the gas phase within the bulb coupled with the movement of the liquid reactants within the dilatometer ensured efficient mixing. This tumbling was periodically stopped to allow drainage and refilling of the capillary stem. When polymer precipitation was observed, the dilatometer was returned to its conventional vertical position. The induction period, τ, was recorded and the subsequent rate of polymerization was observed, if necessary after cooling to allow drainage of the contents remaining in the capillary stem.

Using this method of 'tumbled dilatometry', the induction period measurements were reproducible, and at constant initiator concentration were proportional to the square root of the initial oxygen concentration. Some typical induction period results obtained by conventional and tumbled dilatometry are shown in *Figure 1*. The extent of peroxide formation during the induction period was also increased by tumbling the dilatometers which again indicated the incomplete oxygen consumption in conventional dilatometry. Further details of experimental procedure are reported elsewhere[6,7]

Further studies have been made of the effects of oxygen on the polymerization of bulk acrylonitrile initiated by 2,2'-azobisisobutyronitrile (AIBN) at 50°C, and of acrylamide dissolved in ethanol initiated by AIBN at 80°C. In general, induction periods measured by conventional (static) dilatometry were irreproducible and less than those recorded by tumbled dilatometry.

CONCLUSIONS

The method of tumbled dilatometry reported here is applicable to systems in which the onset of polymerization is associated with polymer precipitation. The technique enables reproducible measurements of induction periods to be made due to the presence of added oxygen. The results serve to emphasize the importance of efficient mixing of dilatometer contents involving gaseous additives. Vigorous shaking of reactants at temperatures below that at which
Figure 1 Induction periods, τ, for the polymerization of vinyl chloride at 55°C, as a function of initial oxygen concentration (ppm w/w). Perkadox 16 concentration = 0.05 g/dm³. ○, Tumbled dilatometry; ●, conventional dilatometry

polymerization is finally studied may prove to be insufficient because of inhomogeneities produced when the reactants inside a dilatometer bulb expand into the capillary stem.

Anomalous melt elasticity of isotactic ethylene–propylene block copolymers

In comparing the processing properties of polypropylene homopolymers with those of certain ethylene–propylene 'end-block' copolymers containing up to 25 wt % of ethylene at constant melt flow index (MFI) [1], one obvious difference is that the copolymers have lower swelling ratios than the homopolymers. Within a given manufacturer's series, swelling ratio decreases with increasing ethylene content. Examples are given in Table 1.

At least part of the ethylene in the 'end-block' copolymers considered here, is present as a high molecular weight tail of polyethylene or polyethylene-rich molecules[2]. The apparently reduced elastic response (i.e. lower swelling ratio) is contrary to expectation and common experience in homopolymers with wide molecular weight distribution. However, we have also observed that at stress levels much lower than those used to measure swelling ratio, the copolymers do appear to become more elastic.

The following series of experiments clearly demonstrates the difference between the two types of polymers. Samples were stabilized with 1% Topanol OC and the tests were performed at 210°C under a nitrogen blanket in all cases. All measurements compared the same two polymers: a standard homopolymer and a copolymer containing 15 wt % ethylene.

Dynamic elastico-viscosity

In dynamic measurements an alternating strain of low amplitude is imposed in an oscillation which is sinusoidal with respect to time. For this experiment we used the Contraves balance rheometer interpreting the results in terms of the apparent Maxwell parameters as recommended by Benbow[3]. The inverse of the angular frequency may be interpreted as a time scale.

The Maxwell model comprises an elastic spring of modulus G, in series with a dashpot of viscosity, η. The ratio viscosity/modulus can be interpreted as the natural time of the material; if the time of deformation is less than the

natural time of the material then the majority of the deformation will occur in the elastic element. It follows that the combination of higher viscosity with lower modulus allows the qualitative interpretation of greater melt elasticity.

The apparent Maxwell parameters over the angular frequency range 10^{-3} to 10^{2} sec^{-1} (time scale 10^{3} to 10^{-2} sec) are shown in Figure 1.

At time scales of less than 10 sec the modulus of the copolymer is slightly higher than that of the homopolymer but at a time scale of about 10 to 100 sec the two polymers have similar moduli. They then diverge rapidly so that at a time scale of 1000 sec the modulus of the copolymer is only one quarter that of the homopolymer sample; this, combined with the higher viscosity of the copolymer sample, implies a longer natural time (an apparently more elastic response) for that material at these long time scales.

Steady state flow

Cone and plate rheometry is used to study the steady state flow at stress levels in the range $10^{2}-10^{4}$ N/m^{2}; the experiments are again interpreted in terms of the apparent Maxwell parameters as described by Benbow[3]. Capillary rheometry, including studies of converging flow, is used to investigate the rheology at high stress[4]. The steady state flow measurements (Figure 2) show two distinct regions for the copolymer sample. At stress levels above 10^{3} N/m^{2} the melt viscosity and elastic modulus follow a similar pattern to that of the homopolymer response; below 10^{3} N/m^{2} there is a separate region of high viscosity and low modulus. Thus in both dynamic and steady state measurements we observe a change in rheological behaviour in going from high to low stress (or rapid to slow deformations).

The transition from highly elastic response to less elastic response is clearly seen in Figure 3 which depicts the strain recovery after steady state simple shear. The recovery of the homopolymer sample increases approximately in proportion to the applied stress and reaches saturation within about 50 sec. At recovery times of about 10 sec the copolymer recovers a similar amount of strain to the homopolymer but then continues to recover even after 500 sec.
Figure 2 Rheology of polypropylene at 210°C by constant shear rate cone and plate and by capillary extrusion rheometry. Material properties evaluated according to ref 3 for cone and plate measurements and ref 4 for extrusion rheometry. η, viscosity under simple shear; λ, viscosity under extension; G, modulus under simple shear; E, modulus under extension. ——, Homopolymer; – – – –, copolymer

Figure 3 Strain recovery following 100 sec creep under constant shear stress. ——, Homopolymer; – – – –, copolymer. Creep stress for 100 sec: A, B, 7.4 x 10^3; C, D, 1.5 x 10^3; E, F, 3.7 x 10^2; G, H, 1.5 x 10^2 N/m^2

	MFI (190°C/10 kg)		MFI (230°C/2 kg)		Swell ratio at 100 sec^{-1}	
	MFR	Swell ratio	MFR	Swell ratio	B_1	B_0
Copolymer	11.5	1.51	1.0	1.20	1.5	2.3
Homo-polymer	13.0	1.87	1.3	1.36	2.0	3.1

At higher stress levels this long time scale behaviour does not occur and the recovery curve reverts to a shape which is similar to that of the homopolymers albeit of lesser magnitude.

Discussion

Qualitatively similar viscosity results have been described by Arnold and Meier[5] for styrene–butadiene–styrene block copolymers and by Lee[6] for polypropylene with a dispersed elastomeric phase. Those authors, who did not report any detailed observations of the elastic response, attribute the differences in rheological behaviour to phase separation effects.

Our results form a picture of a highly entangled high molecular weight polymer (polyethylene) dissolved in a different polymer (polypropylene) of lower molecular weight such that at stress levels above 10^3 N/m^2 the high

molecular weight material becomes completely disentangled. After disentanglement the high molecular weight polyethylene chains appear to act solely as a filler, inhibiting the matrix from developing its full melt elasticity. In this respect the high molecular weight polyethylene 'tail' is behaving differently from what would be expected of a comparable high molecular weight polyethylene 'tail' in polyethylene as evidenced by a common experience with wide molecular weight distributions, where the tail enhances the elasticity at all stress levels.

There are several possible mechanisms for a disentanglement process. The two polymers may be sufficiently incompatible in the melt to favour separation on the molecular scale. They are certainly incompatible in the solid state and crystallize in different forms. Other alternatives are the physical separation of 'thin' from 'thick' or 'smooth' from 'barbed wire' structure molecules; in both of these cases separation of unlike molecules might occur in a shear gradient.

Extension of this hypothesis as a basis for achieving easily processable 'alloys' may be feasible if a sufficiently large number of different molecular types can be made available.

Anomalous behaviour of benzoyl peroxide as an initiator of polymerization

Benzoyl peroxide initiates the polymerization of N-vinylcarbazole (VCZ) at 60°C but the process does not have the kinetic characteristics of a radical polymerization[1,2]. The polymer from a polymerization initiated by the peroxide has a molecular weight much lower than that of a polymer from a polymerization performed under similar conditions and proceeding at the same rate but initiated by azobisisobutyronitrile. The average numbers of initiator fragments per polymer molecule are quite different for polymers made using the azonitrile and the peroxide suggesting that the two polymerizations have quite different mechanisms[3]. Further, for the polymers prepared using the peroxide, there is an exceptionally high proportion of benzoyloxy groups among the incorporated initiator fragments. It has been concluded that benzoyl peroxide with VCZ promotes a polymerization most of which is essentially cationic in nature but a small part of which has the characteristics of a radical reaction[2].

VCZ is very susceptible to cationic polymerization and engages readily in electron-transfer processes; correspondingly, its behaviour in free radical systems is such that it has been assigned a large and negative value (-1.34) for e[4]. It seemed desirable, in view of the unusual behaviour of this monomer with benzoyl peroxide, to examine carefully polymerizations involving the peroxide with other monomers known to be active in cationic polymerization and having large and negative values of e. There is no evidence of abnormalities in the case of styrene $(e = -0.8)$ and so
Figure 2 Variation in the relative numbers of benzoyloxy and phenyl end-groups in polymers with the concentration of monomer prevailing during polymerization at 60°C. ————, Methyl methacrylate; —·—·, styrene. ●, N-vinylcarbazole (polymers believed to have been formed in genuine radical polymerizations[2]); ×, N-vinylcarbazole; ○, N-vinylpyrrolidone

attention was paid to monomers with more negative values of e, including N-vinylpyrrolidone (NVP) and p-methoxystyrene (MOS) for which values of -1.14 and -1.11 respectively have been quoted[4,5].

The polymerization at 60°C of NVP in benzene with azobisisobutyronitrile shows no abnormalities. Polymerizations at 60°C with benzoyl peroxide do not have steady rates (see *Figure 1*); even at low conversions and after quite short reaction times, the rates fall off markedly as would be so if the peroxide were consumed much more rapidly than expected by comparison with systems containing monomers such as styrene and methyl methacrylate. The polymers resemble those produced from VCZ under similar conditions in that the proportion of benzoyloxy end-groups is unexpectedly high (see *Figure 2*). It has been reported[6] that benzoyl peroxide fails to initiate the polymerization of NVP; evidently, this report is wrong but a suggestion that the peroxide is destroyed in a rapid redox reaction with the monomer is essentially correct.

Kinetic abnormalities are not immediately apparent in the polymerization at 60°C of MOS in benzene with benzoyl peroxide but rates seem rather high by comparison with those of polymerizations initiated by azobisisobutyronitrile. The molecular weights of polymers prepared using the peroxide are very much lower than expected by consideration of those of polymers produced with the azonitrile. There is almost as high a proportion of benzoyloxy end-groups as in the cases of VCZ and NVP. The slope of the line in *Figure 2* for VCZ and NVP is 20.5 dm^3/mol; the slope of the corresponding line for MOS is 15.8 dm^3/mol.

It is clear that unusual behaviour of benzoyl peroxide an an initiator of polymerization is not confined to VCZ as monomer. Further studies, some with substituted benzoyl peroxides, are in progress.

Figure 1 Conversion/time plots for polymerization at 60°C of N-vinylpyrrolidone in benzene. Concentration of monomer = 2.81 mol/dm^3. Concentrations of benzoyl peroxide: ○, 0.41 × 10^{-2}; ●, 1.24 × 10^{-2}; △, 2.07 × 10^{-2}; ×, 3.02 × 10^{-2}; □, 6.16 × 10^{-2} mol/dm^3

Book Review

Antioxidants, syntheses and applications
J. C. Johnson
Noyes Data Corporation, Park Ridge, NJ. 1975.
$36.00

This book reviews the US patent literature since 1972 on the subject of antioxidants. It provides detailed technical data, taken directly from patents, on the synthesis and evaluation of antioxidants in a wide range of substrates which include polymers, lubricating oils and foodstuffs. By eliminating the legal jargon, the essential technical information has been abstracted from the patents which have been selected from the patent literature apparently on a quite random basis.

The book contains a vast amount of information which will be of value to the practicing antioxidant technologist and the subject index lists the contents both in terms of classes of antioxidant (e.g. phenols, amines, sulphur compounds, etc.) and in terms of the substrates in which they are used (e.g. petroleum products, lubricating oils, elastomers, polyolefins, etc.).

A major deficiency of the book is that it is almost impossible to use it as a reference work as was clearly intended due to the absence of a useful subject index. There is a 'Product stabilisation index' which is little more than an elaboration of the list of substrates in the contents. There is a patent number index which is of value only if the relevant patent number is known. There is a Company index and an Inventor index which are of value if the owners or inventors of the patents are relevant starting data.

Perhaps the most important limitation of this book is its uncritical approach to the patent literature. A forward to the book states its philosophy as follows:

> *'The US patent literature is the largest and most comprehensive collection of technical information in the world. There is more practical, commercial, timely process information assembled here than is available from any other source. The technical information obtained from a patent is extremely reliable and comprehensive . . .'*

This is a point of view which is not shared by many users of the patent literature. Unlike the periodical journal literature with which the patent literature is compared favourably by the author, there is no obligation on the part of the inventors to unequivocally establish the nature of the products reported or the reproducibility of the processes described. Claims as to the usefulness of classes of products are frequently exaggerated to provide adequate legal protection of the invention and the emergence of practically useful

products from the plethora of patents in the antioxidant field is the very rare exception rather than the rule. The author of this book makes no attempt to distinguish between the small number of patents which have been exploited commercially and the remainder which have not.

This book will be of interest to the industrial chemist who is primarily interested in synthesizing new antioxidants and testing them empirically. It will be of little value to the mechanist who is concerned with the design of new antioxidants on the basis of modern theories of antioxidant action.
