Some effects of formaldehyde crosslinking on the kinetics of water vapour sorption in cellulose

A. C. Newns

Department of Pure and Applied Physics, University of Salford, Salford M5 4WT, UK
(Received 28 November 1973; revised 30 May 1974)

New data are presented on the variation in the fraction sorbed with activity in the initial stage of the two stage sorption process for a crosslinked cellulose and compared to those for the original material and analysed in terms of the water–cellulose interaction. For both original and crosslinked material the fractions sorbed in the initial stage depend on the amount sorbed in the first sorption from dryness. The amounts sorbed in the initial stage starting at a given activity and varying the activity increment bear a similar relation to the activity increment as the amounts sorbed at equilibrium bear to activity.

INTRODUCTION

It has been shown[1-3] that the sorption and desorption kinetics of the cellulose/water system may be explained in terms of a diffusion–relaxation mechanism and under certain circumstances the kinetics separate into two distinct stages. The initial stage is mainly governed by simple diffusion of the water through the polymer matrix, the swelling of the matrix being relatively rapid compared to the diffusion process, whereas the second stage is mainly governed by slow relaxation of the polymer matrix under the swelling stress, for relatively small activity increments, diffusion being the controlling rate when the activity increment is relatively large.

The results in this paper amplify previous work. New facts are presented concerning the fractions sorbed in the initial stage, the variation in the amount sorbed in the initial stage with activity increment and the effect of a crosslinking treatment.

EXPERIMENTAL

The materials and procedure were the same as those described in previous communications[1,2]. The cellulose was prepared by hydrolysing cellulose acetate films; some specimens were soaked in a solution of formaldehyde + ammonium chloride to induce crosslinks, and the kinetics were determined by weighing on a sensitive quartz spring in water vapour under controlled conditions of temperature and pressure. The experiments reported in this paper were all performed at 15°C and started from equilibrium on the lowest sorption limb of the hysteresis loop.

RESULTS

The kinetics of water sorption by the cellulose show features similar to those observed for the sorption of small solvent molecules by other polymers at temperatures below the glass transition region[4]. For example, for relatively large concentration changes the curves for the fractional amount sorbed plotted against the square root of the time show a pronounced inflection, and the initial rates of

desorption are far more rapid than the corresponding rates of sorption. If, however, one observes the kinetics for successive small increments of activity then, under certain circumstances, a high initial sorption rate is followed by a low rate of sorption, and the desorption kinetics also exhibit a two-stage behaviour[1].

Successive sorptions from dryness

Estimates of the fractions F_i sorbed in the initial stage as a function of the activity operative during an experiment are shown in *Figures 1* and *2* for the original cellulose and the crosslinked material respectively. The total amounts sorbed during the initial and final stages for successive small sorption increments, together with the overall totals, are shown in *Figure 3*.

Figure 1 Fraction F_i sorbed in initial stage as a function of the activity, a of water vapour for original cellulose. Specimen 2: thickness, 26.2 μm; X, First cycle; •, third cycle; ▲, fourth cycle. Specimen 5: thickness, 12.4 μm; □, fourth cycle; ○, fifth cycle; △, eighth cycle. The number against a point is the number of the interval in a given sequence of measurements

Amounts sorbed in the initial stage with varying activity increment

The amounts sorbed in the initial stage with a given initial activity and varying final activity are plotted against the final activity in *Figure 4*. The sorption isotherms for the original and crosslinked cellulose are shown in *Figure 5*.

DISCUSSION

Successive sorptions from dryness

The curve in *Figure 1* is for small successive increments in activity starting from zero activity of the water. They show that at an activity of about 0.2 the fraction F_i sorbed in the initial stage decreases rapidly as the activity increases up to an activity of about 0.4, thereafter remaining roughly constant as the activity increases.

This curve may be explained in terms of the water–cellulose interaction. At low activities the water is sorbed onto 'active' sites of the cellulose with the formation of hydrogen bonds. At first the swelling of the cellulose is smaller than the volume of water sorbed, the latter occupying a certain amount of 'free space' in the system available owing to the steric hindrance of the cellulose, and improves the 'packing' of the system. As the activity of the water increases the cellulose swells under the osmotic stress which

Figure 4 Sorptions in the initial stage from equilibrium at a given activity. ○, Original cellulose (initial activity, 0.5); X, crosslinked cellulose (initial activity, 0.4). Thickness of the films, 12.4 μm

Figure 5 Sorption isotherms. ○, Original cellulose; □, crosslinked cellulose

overcomes the forces (e.g. hydrogen bonds) holding the chains together. It has been suggested that the kinetics may be interpreted in terms of a coupled diffusion relaxation mechanism in which the increase in free energy during sorption may be separated into the sum of an increase in free energy caused by swelling against unrelaxed internal forces. The kinetics are primarily controlled by diffusion of the water through the system, and an increase in free energy due to mixing as these forces relax, and by the rate of relaxation of the system under the osmotic stress[1].

Thus an explanation of the curves shown in *Figure 1* is that the water is first sorbed onto active sites. As the 'free space' available to the water is filled, stress is placed on the internal 'bonds' and relaxation occurs producing more free space. Thus, up to an activity of about 0.2, corresponding to the part of the sorption isotherm which is concave to the activity axis (*Figure 5*) the water goes largely onto active sites and gradually fills some 'free space' in the system. Between activities of ~0.2 and 0.4 the water diffuses into 'free space' in the system during the initial stage but an increasing proportion of the 'free space' filled is that due to thermal motion. The activity of the water in solution reaches the activity of the water in the vapour phase as a result of the restricted swelling of the solution owing to internal cohesive forces, e.g. interchain hydrogen bonds. In this way stress is placed on the internal cohesive links which then 'break' and the polymer solution relaxes at a slow rate governed by the relaxation times of these 'links'.

It is to be expected that the relaxation times relevant to the two processes are comparable with those involved in the initial rapid rate of strain followed by the slow rate of strain, or creep, accompanying an external stress applied to the polymer alone. However, as the solution relaxes new 'thermal space' is formed, the activity of the water tends to drop, and the water diffuses in to maintain, as closely as possible, thermodynamic equilibrium throughout the system. This process proceeds until there is sufficient water in the solution for its activity to be constant throughout the system. At this stage the activity of the solution will be governed by the thermodynamics of mixing of the molecular species. At low concentrations the sorption process is diffusion controlled[3] and it would seem that, although there is some relaxation of the polymer matrix, the rate of relaxation is lower than or comparable with the rate of diffusion. Also it would seem that a large proportion of the water is sorbed in the initial diffusion-controlled stage, in which there is sorption with little, if any, breaking of inter- or intra-chain bonds. However, the values of F_i are uncertain at these low concentrations, and further measurements may clarify the picture. Above a water activity of about 0.4 the fraction sorbed in the final stage bears a roughly constant ratio to the fraction sorbed in the initial stage of 5:1. In this region the sorption isotherm is convex towards the activity axis, as for the rubber/benzene system.

There is a similar variation of F_i with activity for the crosslinked material (*Figure 2*). However, there are some differences between the results for the two materials. At the higher activities the fraction sorbed in the final stage bears an approximate ratio of 8:1 to the fraction sorbed in the initial stage for the crosslinked material. There are also some differences at lower activities but more data are needed to clarify the picture in this region. The amount of water sorbed at a given activity is less for the crosslinked material than for the original cellulose, as shown in

Figure 5. Thus the lower initial stage fraction at high activities means less sorbed in the initial stage by the crosslinked material at these higher activities. The amount sorbed by the crosslinked material in the final stages is also less than that sorbed by the original material as will be seen from *Figure 3*. The crosslinking holds the chains together in the amorphous regions. For this material a smaller amount sorbed will produce the same internal stress resisting swelling as for a larger amount sorbed by the uncrosslinked material. Also the amount of rearrangement of the polymer will also be more restricted for the crosslinked material than for the original material, reducing the amount sorbed in the second stage by the former compared with the latter.

A significant feature of *Figures 1* and *2* is that, although the values of F_i obtained for successive small increments of activity appear to lie on the lines drawn, if the first sorption is a large one, then the data for F_i against activity lie to the right of the data for successive small increments. This phenomenon seems to depend on the size of the initial sorption. The greater the value of this, the farther to the right do the points lie for successive small sorptions. If the initial stage corresponds to multilayer sorption, then there must be proportionally more sorbed in the initial stage after a large initial sorption than after a small one. Perhaps this may be due to a relatively smaller proportion sorbed in multilayers in the large initial sorption, the large swelling stress tending to open up the structure more so that a higher fraction is sorbed in the initial stage during the following successive sorptions.

Amounts sorbed in the initial stage with varying activity increments

The results plotted in *Figure 4* are for two series of measurements starting at equilibrium on the lowest sorption limb of the hysteresis loop, one for the original cellulose and the other for the crosslinked material. For each of the measurements the activity of the water was increased and the subsequent sorption was allowed to continue until the end of the initial stage. The activity was then decreased to its original state. For the crosslinked material the initial activity was 0.4, and it will be seen that the amount sorbed in the initial stage varies in a linear manner with the activity increment. For the original cellulose the initial activity was ~0.5, and the plot of the amount sorbed in the initial stage against the activity increments is somewhat convex towards the activity axis. Over the activity range covered for the crosslinked material the sorption isotherm (*Figure 5*) is roughly linear whereas over the activity range covered for the original cellulose the isotherm is convex to the activity axis. Thus, for the data presented here the amounts sorbed in the initial stage starting at a given activity and varying the activity increment bear a similar relation to the activity increment as the amounts sorbed at equilibrium bear to the activity. This does not appear to hold for some other systems which exhibit two-stage behaviour (Kishimoto, A. and Fujita, H. personal communication).

Persistent polarization in a carotenoid polymer, β-carotene

P. K. C. Pillai and Malti Goel

Department of Physics, Indian Institute of Technology, New Delhi 29, India
(Received 18 February 1974; revised 3 June 1974)

Charge retention properties of a carotenoid polymer, β-carotene, have been investigated under photo-
and thermal-polarization conditions. Total stored charge has been evaluated. Analysis of thermal
current spectra of a polarized sample has been made by obtaining activation energies and relaxation
times. The process of ionic and electronic charge trapping is mainly responsible for high charge den-
sities retained for longer times in this polymer. The dipolar contribution is comparatively small.

INTRODUCTION

It has been suggested[1] that photoconductivity should occur
in carotenoid compounds since they have a highly conjugat-
ed structure. β-Carotene is a member of the C_{40} carotenoid
group and it has a hydrocarbon composition. It is believed
to take part in photosynthesis and phototropic processes.
It has also been considered as a precursor of retinene pig-
ment which is involved in all visual receptor systems.

Rosenberg[2-4] has experimentally investigated electronic
conduction properties of β-carotene and has determined
activation energies. Photoconduction studies in β-carotene
single crystals, have been carried out by Chapman *et al.*[5]
who reported interesting spectral results. Transient effects
in photoconduction of β-carotene glass have also been
investigated[6] recently. Thus although photoconduction is
an established property of β-carotene, almost nothing has
been reported about its charge retention properties observ-
ed under suitable experimental conditions. An attempt has
thus been made to investigate the persistence of space
charge polarization in this polymer.

EXPERIMENTAL

To study the polarization phenomena in β-carotene, an
apparatus in which studies can be made under controlled
atmospheric conditions has been designed. The arrange-
ment is shown in *Figure 1*. A sample is placed between two
electrodes A and B. The lower electrode is of Nesa-coated
glass which enables the sample to be illuminated, while an
electric field is applied. The upper electrode is movable and
is connected to an insulated micrometer head. The sample
is surrounded by an electrostatically shielded heating
arrangement[7] which provides a uniform or a variable tem-
perature, changing at a linear rate, as required. A thermo-
couple (C, D) is placed near the sample for reading the
temperature.

For the sample preparation, a thin layer of β-carotene
glass was coated on the lower transparent electrode and the
upper electrode was pressed over it in such a way that glass
film adhered to both electrodes. The photopolarization
process has been studied by applying an electrostatic field
across the sample and illuminating it in a perpendicular
direction. The phenomenon of photodepolarization has
been studied in the absence of an external field by observing

Figure 1 Apparatus for polarization and depolarization studies

the decay of current when the photoelectret (polarized
sample) was re-illuminated. For each measurement separate
samples were used and all these measurements were carried
out at room temperature.

For the study of thermal polarization, a sample was
heated to a uniform higher temperature and an electrostatic
field was applied to it. This process of polarization was
continued for a certain period of time and polarization
current as a function of time was measured on a sensitive
electrometer. The samples were then cooled to room tem-
perature in the presence of an external field. Thermal
depolarization currents of the thermoelectrets, so formed,
were observed on reheating the samples at a uniform rate,
in the absence of the field.

The essential feature of the present system is that the
study of photopolarization and depolarization as well as
thermal polarization and depolarization can be carried out
without disturbing the sample.

Aplab stabilized power supply Type HV1 was used for

applying high electrostatic fields across the sample. Current measurements were carried out on a 610C solid state electrometer (Keithley Instruments) and a Hewlett–Packard 7035 B, X–Y recorder was used for studying thermal currents as a function of temperature.

RESULTS AND DISCUSSIONS

Thermal polarization in β-carotene

A study of β-carotene was made when thermal and electrostatic energies were supplied to it simultaneously. The thermal polarization currents were observed at constant temperature as a function of time. The results are shown in *Figure 2* at a forming field strength of 2 kV/cm for two samples polarized at 343 and 363 K respectively. A dis-
continuity was observed at about 10–15 min for both samples.

Polarization current attained a constant value in about 75 min. The samples were then slowly cooled to room temperature under the influence of the electrostatic field. The process of polarization was thus continued for a total of 150 min and then the field was switched off. Thermal depolarization studies of these thermoelectrets were carried out by reheating at a uniform rate of 6°C/min. A thermal depolarization current so observed has been plotted as a function of temperature for samples prepared at different temperatures.

In these curves (*Figure 3*) two peaks, one at 335 K and another at 400 K have been observed. Analysis of the second peak at 400 K has been made by calculating thermal activation energies and relaxation times. According to the initial rise method of Garlick and Gibson[8] the slope of the straight line plot of log *i* vs. 1/*T* (*Figure 4*) for the first lower half of the peak gives activation energy, since:

$$\log i(T) = \text{const} - \frac{E}{KT}$$

where *E* is activation energy, *T* is absolute temperature, and *K* is Boltzmann's constant.

Relaxation time of polarization[9] created by ionic motion or by orientation of dipoles is given by the Arrhenius equation:

$$\tau = \tau_0 \exp\left(-\frac{E}{KT}\right)$$

where τ_0 is a constant corresponding to total charge stored and can be written as,

$$\tau_0 = \frac{KT_m^2}{T_1 E \exp(E/KT_m)}$$

where T_1 is the heating rate and T_m is the peak temperature.

The activation energies and relaxation times obtained from thermal current spectra of *Figure 3* are shown in *Table 1*[10]. The result of activation energy level is in agreement with the result obtained by photoconduction methods. An energy level at 0.356 eV has been postulated[3] as trapping level below triplet state.

τ at T_m (min)	6.386	6.277

current has been found to increase with increasing forming field the total charge stored in a sample calculated by extrapolating decay curves, does not show a similar dependence[12]. The initial current and total charge of various photoelectrets polarized at different fields is shown in *Table 2*.

Irradiation with non-monochromatic light generates electric carriers at the surface as well as in the bulk of the sample. Under the influence of the external field carriers migrate in the bulk and subsequently get trapped. If the trapping levels are sufficiently deep, the substance gets polarized and polarization pertains even after the external field is removed and the radiation is switched off. The process of charge decay is dependent on mutual interaction and annihilation of carriers, but it can be accelerated by again irradiating the sample. The discontinuous decay of the kind shown in *Figure 6*, suggests the presence of various trapping levels in the material. The persistence of thermal polarization also suggests trapping of charge by ionic and

Figure 5 Photopolarization current in β-carotene at various forming field strengths: □, 1; △, 1.8; X, 2.5; ○, 3.3 kV/cm

Photopolarization in β-carotene

The photopolarization currents observed in β-carotene in an apparatus described previously are shown in *Figure 5* for different field strengths. Non-monochromatic mercury light without any filter has been used for illumination.

Currents have been found to increase and then show a saturation with polarizing time. The polarization time required for attaining saturation depends upon the applied field and irradiation intensity. The positive electrode was illuminated in all the measurements.

The polarization process was carried out for 30 min and then the samples were stored in short circuited condition in the dark[11]. Photodepolarization currents observed on re-illuminating the photoelectret are shown in *Figure 6*. Currents have been observed as a function of time for various forming fields. Discontinuities in the current—time curves suggested the presence of various decay modes in the substance. While two decay modes are observed at low field, an additional discontinuity is present at higher fields.
Although the initial value of the photodepolarization

Figure 6 Photodepolarization decay curves of β-carotene photoelectrets fabricated as in *Figure 5*. ○, 1; △, 1.8; □, 2.5; X, 3.3 V

electronic movements and the trap level activated by the thermal process has been computed as 0.352 eV.

However, β-carotene exists in various isomeric forms. Its *trans* configuration has a minimum dipole moment while the 15—15′ configuration has a maximum dipole moment along the perpendicular axis. β-Carotene glass is a combination structure and hence the dipoles will be scattered in all directions in the neutral sample. During polarization processes the external field will exert a force on the dipoles and the orientation will result in dipolar alignment along the external field axis. This dipolar alignment will contribute to persistent polarization, the relaxation of which will depend upon re-orientation of dipoles. The lower peak, observed at 335 K in thermal current spectra (*Figure 3*) is attributed to dipolar polarization. The contribution of dipoles seems to be comparatively smaller than ionic and electronic polarizations which show a larger relaxation peak at 400 K (*Figure 3*).

CONCLUSIONS

The photopolarizing technique produces charge densities in excess of 10^{-6} C/cm^2 in β-carotene, which are retained for reasonably longer times, compared to inorganic substances. This property of retaining high density of charge for longer time, of β-carotene, is possibly correlated with high light sensitivity and memory effects of retinal systems in vertebrates. Thermal polarization technique has also resulted in excessive charge trapping. Analysis of thermally stimulated currents has helped to determine activation energies and relaxation times.

Conformational study of the sequential (Tyr–Glu)$_n$ copolymer in aqueous solution

Yves Trudelle

Centre de Biophysique Moléculaire, CNRS, 45045 Orleans-Cedex, France
(Received 23 April 1974)

Conformational properties of the sequential poly(Tyr–Glu) copolymer in aqueous solution were investigated as a function of pH. No transition could be detected over the range pH 13–10.5. Below pH 10.5 an aggregation process takes place, causing a drastic change in all optical properties of the polymer (optical rotation, c.d. and u.v. spectra). By means of i.r. spectroscopy in D$_2$O, aggregates were found to be in antiparallel β conformation. The c.d. spectrum of β-aggregates is very similar to that of α-helical poly(L-tyrosine) in organic solvents, except in the 280 nm region. In addition the aggregation process is accompanied by a strong hyperchromic effect in the 277 nm absorption band. Using space-filling models, different arrangements of the chains in the β-aggregates were shown to be realizable. All result in a close stacking of tyrosyl phenyl groups, which can explain the drastic changes in all optical properties.

INTRODUCTION

In the present paper we report conformational studies in aqueous solution of the sequential copolymer (Tyr–Glu)$_n$, whose synthesis was described elsewhere[1]. This copolymer was expected to form aggregates; thus, tyrosyl and glutamic acid side chains could be brought into close contact and held in a well-defined position, which could induce some enzyme-like activity. Actually, the active site of carboxypeptidase *A* involves cooperativity of both 248-tyrosine and 270-glutamic acid side chains as well as a Zn^{2+} cation.

It is relevant to the present work to give a brief survey of the present state of investigations on poly(L-tyrosine) and poly(L-glutamic acid) and on their copolymers. Since the investigations of Fasman *et al.*[2,3], poly(L-tyrosine) was considered for a long time to undergo a helix–coil pH-induced transition at about pH 11.5. Fasman[2] pointed out that this transition occurred only when pH was lowered very slowly. If not, the random coiled conformation is retained by entanglement of tyrosyl rings. However, recent results contradict those of Fasman. Patrone *et al.*[4,5] demonstrated convincingly by means of infra-red spectroscopy in D$_2$O that poly(L-tyrosine) undergoes a random coil–antiparallel β pH-induced transition. They suspect also that the α-helical form would exist only in ethanol–water mixtures. Senior *et al.*[6] are in agreement with Patrone and state that the antiparallel β-structure of poly(L-tyrosine) is in the form of β-hairpins. Comparing the c.d. spectra of poly(L-tyrosine) in water and in organic solvents such as trimethylphosphate or methanol, Friedman and Ts'o[7] were led to decide in favour of an α-helix rather than in favour of a β-structure in water as solvent. They emphasized that theoretical calculations of Chen and Woody[8] predicted a c.d. spectrum for α-helical poly(L-tyrosine) very similar to that obtained in aqueous solution. It must be pointed out, however, that the c.d. spectrum reported by Friedman and Ts'o is different from that of Fasman. In addition, the u.v. spectra reported by both investigators reveal some discrepancy between degrees of ionization of tyrosyl side chains at pH 11.2.

Hence conformational transition of poly(L-tyrosine) in aqueous solution is not yet unambiguously explained. Although the existence of β-structures has been clearly established by Patrone *et al.*[4,5], it cannot yet be ruled out that poly(L-tyrosine) in water could exist also under certain circumstances in the α-helical form.

The pH-induced α-helix–coil transition of poly(L-glutamic acid) is now well established. In addition, when pH is lowered below 4.6, poly(L-glutamic acid) begins to aggregate[9].

Few investigations have been devoted to L-glutamic acid/L-tyrosine copolymers. In this connection, it is relevant to mention the fluorescence studies of Fasman[10] concerning glutamic acid-rich copolymers (95%). These exist in α-helical form at acidic pH. Doty and Gratzer[11] prepared the same random copolypeptide and found that the helix–coil transition causes a blue-shift of the u.v. absorption band at 277 nm of tyrosyl side chains. This effect was identified with the transfer of tyrosyl residues from a helical environment to that of the random coil, which is predominantly that of the solvent. Ramachandran *et al.*[12], and Schechter *et al.*[13] reported conformational studies on poly(Tyr–Ala–Glu) which would be α-helical at neutral pH. Tyrosyl and glutamyl side chains would be kept in well defined positions by hydrogen bonding between carboxylate and phenolic groups.

EXPERIMENTAL

Materials

The sequential polymer (Tyr–Glu)$_n$ was obtained by polymerizing *O*-benzyl-L-tyrosyl-γ-benzyl-L-glutamyl-*O*-benzyl-L-tyrosyl-γ-benzyl-L-glutamyl hydroxyphenyl ester hydrochloride, and subsequent removal of protecting groups by hydrobromic acid in 6.5 N acetic acid, as described previously[1]. This method has been proved to be racemization-free. Molecular weight of the sample was estimated from osmotic pressure measurements at pH 10
Figure 1 Potentiometric titration of poly(Tyr—Glu): 5.7 mg in 20 ml 0.0025 N NaOH (——); 6.5 mg in 20 ml 0.0025 N NaOH, 0.1 N KCl (— — —)

and thermostated at 22°C. I.r. spectra were measured on a Beckman IR 11 spectrophotometer, using the transmittance expanded scale.

Analytical gel chromatography was performed on Sephadex G 200, 40—120 μm, at room temperature and using a 2.5 X 45 cm column. Eluants were the same dilute buffers in 0.1 M KCl as used for solutions. The column was monitored by recording the absorbance at 275 nm using a 1 cm flow-cell and a Beckman Acta III spectrophotometer.

RESULTS

Potentiometric and spectrophotometric titration studies in water and in D_2O

Potentiometric titration curves of poly(Tyr—Glu) are reported in *Figure 1*. It can be seen that carboxylic species began to be titrated below pH 8. Below pH 6.5 the polymer began to precipitate; nevertheless titrations were achieved on turbid solutions. As expected, ionic strength increased markedly the degree of ionization. *Figure 2* shows ionization curves of tyrosyl side chains obtained from u.v. spectroscopic measurements. The degree of ionization was estimated from optical density at 294 nm. Tyrosyl side chains are completely ionized above pH 12.4 (pD 14), while they are fully protonated below pH 8 (pD 8.5). Direct and back titration curves were not exactly superimposed. This resulted probably from a slight difference in ionic strength between both experiments.

Optical rotation

When a polymer solution was titrated over the range pH 12.4—10.5 no significant variation of optical rotation could be detected. At lower pH values, the optical rotation under-

to be 15 700. This value may be somewhat overestimated owing to the presence of some aggregated molecules. Intrinsic viscosity was 35.5 ml/g in 0.2 M NaCl, pH 12.

Solutions were prepared by dissolving the polymer in the stoichiometric amount of 0.1 N NaOH evaporating to dryness and adding the adequate dilute buffer in 0.1 M KCl. Buffers were 0.01 M carbonate—bicarbonate (pH 10.5 to 9.5), 0.01 M glycine—NaOH (pH 10 to 8.6), 0.01 M Tris—HCl (pH 8.6 to 7.5) and 1/150 M phosphate (below pH 7.5). The solution was then titrated with 0.1 N NaOH or 0.1 N HCl to the required pH value. For measurements in D_2O, DCl and NaOD were used instead of HCl and NaOH. No experiments could be performed below pH 6.5 because the polymer begins to precipitate. Concentrations of polymer solutions were determined from the optical density at 294 nm in 0.2 N NaOH as solvent assuming an extinction coefficient of 2200 l mol^{-1} cm^{-1} per tyrosyl residue.

Methods

Potentiometric titrations were carried out under nitrogen and at room temperature using a Radiometer 26 pH-meter and a GK 2321 electrode. For measurements in D_2O, pD was considered to be equal to $pH_{app}. + 0.4$.

Optical rotations were measured at 546 nm using a 141 M Perkin—Elmer Polarimeter, in a 1 dm microcell.

Circular dichroism (c.d.) spectra were recorded on a Roussel—Jouan 185 model II dichrograph using 1, 0.2, 0.1 and 0.01 mm cells according to the wavelength range. Concentrations of the solutions were in the range 0.05 to 0.2%.

U.v. spectra were recorded on a Beckman Acta III spectrophotometer.

For i.r. spectroscopy, deuteration of the polymer was carried out as described by Patrone *et al.*[4]. Concentrations were in the range 0.1 to 0.8%. Cells were equipped with CaF$_2$ windows, having an optical path length of 0.05 mm,

Figure 2 Spectrophotometric titration of 0.2% poly(Tyr—Glu) in 0.1 M KCl in water (●, ○) and in D_2O (△)
Figure 3 Variation of specific rotation of poly(Tyr—Glu) in 0.1 M KCl, 1/150 M phosphate buffer as a function of time; ●, 0.194%, pH 7.27; ○, 0.056%, pH 7.1

went a slow change with time (*Figure 3*). At each pH value, two days at least were necessary to reach equilibrium. However the rate of change in optical rotation at a given pH was not reproducible from one run to another and depended also on polymer concentration. Dilute polymer solutions (0.05%) only underwent a small and very slow change. In a few cases, no change at all could be detected. Plotting the optical rotation of a set of equilibrated 0.2% solutions as a function of pH shows (*Figure 4*) a strong sharp change from pH 10.2 to about 9.5 followed by a less steep change. This pH range corresponds to the protonation of the remaining unprotonated tyrosyl side chains (i.e. 25% of the whole). When titrating an equilibrated solution (solution 1, pH 7 in *Figure 4*) towards alkaline pH, the optical rotation describes a curve (*Figure 4*) which is similar to the former, but depends on whether titration was performed slowly or rapidly.

Gel chromatography

Two different sets of runs were carried out. In the first one, samples were applied immediately after pH adjustment (*Figure 5b*). In the second, solutions were titrated to the desired pH value and kept for 4 days at room temperature before being applied to the column (*Figure 5c*). Chromatograms show that the material was eluted into two fractions. One of them appeared with the hold-up volume which indicates the presence of high molecular weight species. Another fraction was eluted afterwards as a broad peak and corresponds to low molecular weights. As shown in *Figure 5b*, the peak of high molecular weight increases as the pH becomes more acidic. The same effect can be observed in *Figure 5c*, but the ratio of high molecular weights to low ones is much larger. This denotes the occur-

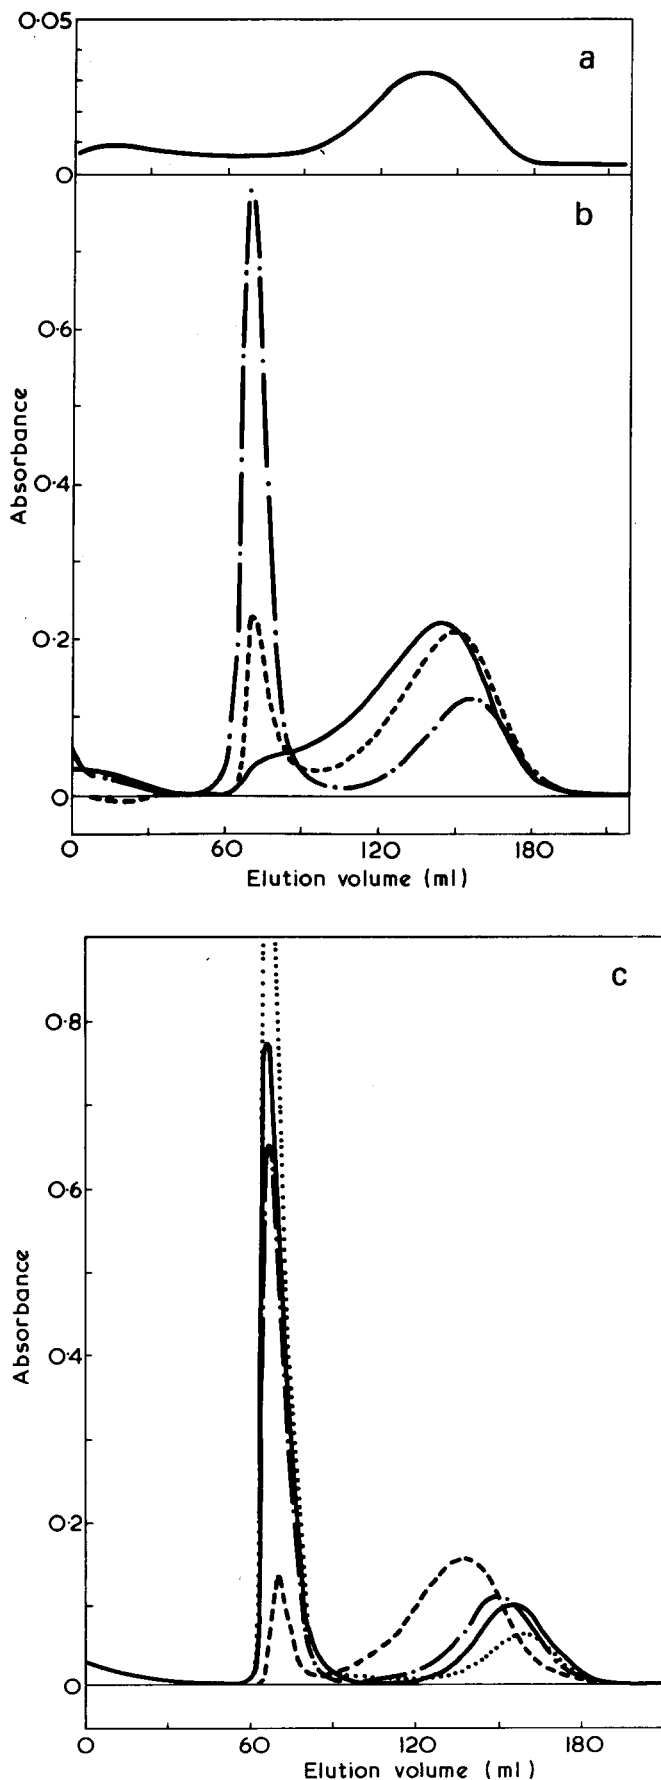
rence of a slow aggregation process, occurring below pH 10.5, which must be related to the change in optical rotation described above and in *Figure 3*. *Figure 5a* shows pH 6.82, whose optical rotation remained unchanged after pH adjustment, even a few days later. No aggregates could be detected in this solution.

I.r. measurements in D_2O

Figure 6 shows i.r. spectra of a 0.8% solution of polymer. At pD 13.37, amide I' band is located at 1648 cm^{-1} amide II' around 1459 cm^{-1} with a shoulder at about 1440–1450 cm^{-1}. When the pH was lowered to 11.16, no shift could be detected either in amide I' or in amide II' bands. However, another amide I' sharp band lying at 1620 cm^{-1}, as well as a shoulder around 1685 cm^{-1} developed with time. These are typical of antiparallel β-structures. *Figure 7* shows spectra of a dilute (0.18%) solution of polymer at various pD values. In spite of large noise and of parasitic bands of atmosphere, owing to high expansion factor, the typical bands of antiparallel β-structures are still quite visible. We observed that these bands formed slowly and they were found to appear below pD 11 in 0.2% solutions. In addition, the higher the concentration, the faster they formed.

Circular dichroism studies

Figure 8 shows the c.d. spectra of a 0.2% solution of poly(Tyr—Glu) at various pH. In alkaline medium (pH 12.05), tyrosinate chromophores give rise to two positive bands located at 285 and 243 nm. The strong negative band at 197.5 nm is probably due to the $\pi \rightarrow \pi^*$ transition of peptide chromophore in unordered conformation. At

Figure 4 Variation of specific rotation of poly(Tyr—Glu) in 0.1 M KCl as a function of pH; 0.2% solutions (1 to 9) equilibrated for 4 days at room temperature at various pH values in adequate buffer (see text) (○); rapid titration of the equilibrated solution 1 with 1 N NaOH (——); very slow titration of the equilibrated solution 2 with 1 N NaOH (— · —)


pH 10.56 where the tyrosyl side chains are about 60% protonated, contributions of both tyrosine and tyrosinate are quite visible at 230 and 245 nm respectively. In the 255—300 nm range both contributions seem to overlap and cannot be resolved. The strong negative band is only slightly blue shifted to 196 nm, while its ellipticity decreases slightly. At pH 9.47, tyrosyl side chains are nearly fully protonated and the c.d. spectrum began to undergo a slow and drastic change as a function of time. However, a few minutes after pH adjustment the essential features of the c.d. spectrum remained practically the same as at pH 10.56, except that the 245 nm tyrosinate band vanished completely. A few hours later, the 230 and 273 nm bands were considerably enhanced, while the negative 195 nm one was replaced by a strong positive peak located at 200 nm. Limit spectra (i.e. spectra of solutions equilibrated a few days at a given pH value) as shown in *Figure 9* depend on pH. However, the pH affects only the magnitude of c.d. bands but not the shape of the spectrum, which is predominantly that of aggregates. In D_2O, all phenomena were just the same as in water.

U.v. spectroscopy

U.v. studies were carried out on the 277 nm tyrosyl band which is not overlapped by contributions of the peptide chromophores. When titrating rapidly an alkaline solution to neutral pH, in the same way as in c.d. measurements a slow enhancement of the 277 nm band took place (*Figure 10*). However, this hyperchromic effect occurred without simultaneous shift in wavelength, and the shape of the band remained practically unchanged (*Figure 11*). The molar absorptivity per tyrosyl residue was increased from about 1320 to more than 1600 in the case of 0.2% solutions. For 0.05% solutions the enhancement was much less pronounced; sometimes no change at all could be detected.

DISCUSSION

In alkaline media, at above pH 12, c.d. spectra of poly(Tyr—Glu) exhibit a strong negative band ($\theta \sim -20\,000$) located at 197.5 nm. This band is probably due to unordered structures. However, its ellipticity seems rather low as

Figure 5 Gel chromatograms of poly(Tyr—Glu) on Sephadex G 200. c.d. spectrum still exhibits a negative 196–197.5 nm band, the only change in c.d. spectrum arising from the protonation of chromophoric tyrosyl side chains. We are thus led to conclude that this polymer undergoes no conformational change over this pH range. Hence, poly(Tyr–Glu) appears to behave quite differently from poly(L-tyrosine), in which lowering of pH induces a sharp transition at pH 11.2.

Below pH 10.5 a slow aggregation process takes place. This process is clearly evidenced by gel chromatography. Molecular weights of aggregates were not estimated. However, since aggregates are eluted with the hold-up volume, these are of the order of 10^5–10^6 at least. The aggregation process causes drastic changes in all optical properties of the polymer. Optical rotation (*Figure 4*) undergoes a sharp change around pH 10–10.2, which corresponds to 15–25%
Figure 9 C.d. spectra of two 0.2% solutions of poly (Tyr–Glu) in 0.1 M KCl, equilibrated for two days at room temperature: − − −, pH 9.55; −−, pH 7.29

compared to usual values of unordered structures (−30 000 to −40 000). This difference could result from some positive contribution of tyrosyl side chains. The location of the amide I′ (1648.5 cm^{-1}) and amide II′ (1459 cm^{-1}) bands are also in agreement with such a conformation. In the range pH 12 to about 10.5, which corresponds to ~0–60% protonated tyrosyl side chains, no conformational change can be detected. First, the optical rotation undergoes no variation. Second, no significant shift can be observed either on amide I′ or amide II′ band. Third, the

Figure 10 Variation of molar absorptivity at 277 nm of poly (Tyr–Glu) in 0.1 M KCl, 1/150 M phosphate buffer as a function of time. ○, 0.21% solution, pH 7.47; ●, 0.051% solution, pH 7.06

of ionized tyrosyl side chains. When tyrosyl side chains are fully protonated (below pH 8), further lowering of pH gives still rise to a change in optical rotation, probably owing to protonation of some carboxylate groups. It must be pointed out that fast and slow titration curves of *Figure 4* are not exactly superimposed. This discrepancy can be easily explained. Actually, addition of 1 N NaOH causes a local but deep pH increase so that a few aggregates are disrupted, which can form again slowly. As expected for such an intermolecular process the concentration has a great effect upon both the rate and the extent of aggregation. This is evidenced in *Figures 3* and *9*. In a few cases, as already mentioned, no aggregation could be observed on dilute solutions (0.05%). We found that this happened when alkaline solutions were very quickly titrated to the desired pH value. As stated above, Fasman *et al.*[2] found a similar behaviour in the case of poly(L-tyrosine).

From the c.d. spectra, the aggregation process seems to proceed directly from unordered structures, without involvement of any intermediate form. Actually, when an alkaline solution is titrated to pH 9.47, its c.d. spectrum recorded a few minutes later shows that the polymer remains essentially unordered. As the aggregation spreads out, the spectrum changes gradually into that of aggregated species. In addition, unaggregated dilute solutions (0.05%) at neutral pH, present the same c.d. spectra as the unordered form. These lead us to conclude that an intermediate form, if any, is quite unstable. On the contrary, poly(L-tyrosine) would undergo a two-step transition: random coil ↔ antiparallel β-monomolecular structures ↔ β-aggregates[4,6]. However, in a recent paper Patrone *et al.*[5] seem to suspect that the transition could be intermolecular only.

I.r. spectroscopy has clearly evidenced that aggregates were in antiparallel β conformation. It is very interesting to compare the c.d. spectrum of such antiparallel β structures to c.d. spectra of poly(L-tyrosine). It can be seen in *Figures 8* and *9* that c.d. spectra of poly(Tyr—Glu) in antiparallel β conformation are very similar to spectra of α-helical poly(L-tyrosine) in trimethylphosphate[14,15] or in methanol[16]. All spectra exhibit actually strong positive bands located at 195—200 nm and at 230 nm, as well as a trough at about 216 nm. The only qualitative difference lies in the 280 nm region, in which antiparallel β-structures give rise to a weak positive band at 272.5 nm, while for poly(L-tyrosine) Damle[13] found a splitting into a negative and a positive band located at 260 nm and 282 nm respectively. Hence, we should emphasize that much care must be taken in the interpretation of c.d. spectra when rotational strength induced by chromophoric side chains is of utmost importance.

Using space-filling models, two essentially different structures of antiparallel β pleated sheets of poly(Tyr—Glu) could be built up. In the first one (I), aromatic rings are equally distributed on both sides of the pleated sheet. Aromatic rings of a chain will be directed towards one side, those of another chain towards the other. In this structure, aromatic rings are stacked along the chain, and are separated by about 6.9 Å. In the second structure (II), all aromatic rings point to the same side of the pleated sheet, and carboxylates to the other. In this case, one side of the pleated sheet is covered with a compact stacked layer of aromatic rings, which are as distant as ~6.9 Å along the chain and 4.7 Å along the perpendicular direction. This aromatic region is likely highly hydrophobic, and it can be suggested that hydrophobic sides of two pleated sheets would come close together, leading to a bi-layer micelle. We cannot, at present, choose between the two structures.

Figure 11 Evolution of the u.v. spectrum of a 0.21% solution of poly(Tyr—Glu) in 0.1 M KCl, 1/150 M phosphate buffer, as a function of time. – – –, Immediately after pH adjustment; ——, 20 h after pH adjustment

However, in both cases, tyrosyl side chains are arranged in a regular and compact stacking so that they can interact strongly, and give rise to the strong bands observed in the c.d. spectrum. The hyperchromic effect (*Figure 11*) is rather difficult to explain. As a rule, denaturation of proteins or of polypeptides, as copoly(Tyr, Glu) (5 mol % tyrosine)[2], induces a blue shift in the 277 nm absorption band of tyrosyl side chains[17]. In addition, Bailey *et al.*[18], observed that a change of solvent from ethanol to water can lead to a large intensity change in the 277 nm band of tyrosine as well as to a blue-shift, and explained this effect by a decrease of the strength of hydrogen bonds between phenolic groups and the solvent. As pointed out before, as the aggregation of poly(Tyr—Glu) takes place (*Figure 11*) no shift could be observed, but only a strong hyperchromic effect. This could result from the occurrence of two opposite effects. As aggregation proceeds, interaction between tyrosyl aromatic rings are enhanced, thus leading to a blue shift, as well to a hypochromic effect. At the same time, the hydrogen bonding system of the phenolic groups may change leading to a red shift and to a hyperchromic effect.

CONCLUSION

Poly(Tyr—Glu) has been found to undergo a random coil-β-aggregates transition by lowering the pH. No intermediate form could be detected. Optical properties of β-aggregates indicate that tyrosyl chromophoric side chains interact strongly. Two models of aggregates could be built up using space-filling models, each one resulting in a close stacking of tyrosyl aromatic rings. In one of these models (II), the β-framework is sandwiched between a hydrophobic layer (tyrosyl side chains) and a hydrophilic one (carboxyl groups). Such a structure could lead to the formation of a micelle. However, as yet no experimental evidence can permit the choice of either of these two models.

Circular dichroism study of poly(L-tyrosine), poly(L-glutamic acid) and of random and sequential copolymers of L-glutamic acid and L-tyrosine in trimethylphosphate

Yves Trudelle and Gérard Spach
Centre de Biophysique Moléculaire, CNRS, 45045 Orléans-Cedex, France
(Received 23 April 1974)

Random and sequential copolypeptides containing L-glutamic acid and L-tyrosine, as well as poly(L-tyrosine) and poly(L-glutamic acid) were investigated by means of c.d. spectroscopy in trimethylphosphate as solvent. In random copolymers, variation of ellipticities at 202.5 and 230 nm *versus* tyrosyl content follows a smooth curve, without any sharp change. This led to the conclusion that poly(L-tyrosine) α-helix is right-handed. From c.d. studies on sequential copolymers we were able to recognize that the 230 nm contribution of tyrosyl side chains is closely related to the array in which tyrosyl residues are arranged in the chain. For instance, it was found that $(n, n + 2)$ and $(n, n + 3)$ pairings of tyrosyl side-chains in $(Tyr-Glu)_n$ and $(Glu-Tyr-Glu)_n$ respectively, were poorly effective, while the $(n, n + 4)$ pairing in $(Glu-Glu-Tyr-Glu)_n$ is more. However, the strongest contribution at 230 nm was observed on the alternating-pairs copolymer $(Glu-Tyr-Tyr-Glu)_n$. This result suggests a new conformational arrangement of tyrosyl side chains in sequential copolymers, as well as in poly(L-tyrosine) and other aromatic polypeptides, based on a regular pairing of the aromatic groups, arranged in two contiguous superhelices.

INTRODUCTION

Several investigators[1-4] have demonstrated the α-helical structure of poly(L-tyrosine) in trimethylphosphate solution. Among these studies, measurements reported by Damle[1] afford the most convincing proof. Actually, Damle could calculate from viscometric and light scattering determinations the geometrical parameters of the equivalent rod, which are in good agreement with the parameters of an α-helix.

Theoretical studies of Chen and Woody[5] on circular dichroism (c.d.) supported an α-helical structure for poly-(L-tyrosine). In addition, their calculations give precise details about the sense of the α-helix which appears to be right-handed. However, such calculations do not take into account the influence of the solvent which can be of importance. For instance, as stated recently by Bradbury *et al.*[4], poly(L-tyrosine) is likely to be in a random coil conformation in dimethylsulphoxide, contrary to previous assumptions[6]. Moreover, in our opinion, such theoretical predictions must be considered with caution. For example, it was recently shown by infra-red spectroscopy that poly(L-tyrosyl-L-glutamyl) gives β-structures in aqueous solutions below pH 10, whereas its c.d. spectrum (strong positive band at 230 nm, very strong positive band around 200 nm, trough at 216 nm) looks like the one of the poly(L-tyrosine) α-helix in trimethylphosphate[7].

The peculiar optical properties of poly(L-tyrosine) are considered to arise from strong excitonic interactions between neighbouring tyrosyl chromophoric side chains. It was of interest to find out what arrays of tyrosyl residues are able to lead to strong rotational strength. In the present paper we have tried to elucidate this problem by studying sequential copolypeptides.

Another question refers to the sense of the α-helix. Some controversy still stands about this. Damle[1] reported that the amide I band for poly(L-tyrosine) films cast from trimethylphosphate solution lies at 1662 cm^{-1}, which seems a somewhat high frequency for a right-handed α-helix and would rather correspond to a left-handed one. Other results, obtained by Bradbury *et al.*[4] and by Quadrifoglio *et al.*[2] contradict those of Damle. These authors found that the amide I band for films or solutions in trimethylphosphate is located at 1657 cm^{-1}. Such discrepancies do not seem to be ascribable to differences between wavenumber calibrations and still remain unexplained.

Theoretical predictions are not fully consistent either. Applequist and Mahr[8] predicted a left-handed α-helix. By another method, Ooi *et al.*[9], Yan *et al.*[10] and Chen and Woody[5] found the opposite sense.

MATERIALS AND METHODS

Poly(L-tyrosine) was prepared by polymerization of *O*-benzyloxycarbonyl-L-tyrosine-*N*-carboxyanhydride (NCA)[11] and subsequent removal of the protecting groups by hydrobromic acid in acetic acid.

Samples of random copolymers of L-glutamic acid and L-tyrosine were prepared by copolymerizing *O*-benzyloxycarbonyl-L-tyrosyl NCA and γ-benzyl-L-glutamate NCA[11]. Side chain protections were removed as above.

Synthesis of sequential copolymers, i.e. poly(L-tyrosyl-L-glutamyl), poly(L-glutamyl-L-tyrosyl-L-glutamyl) and poly(L-glutamyl-L-glutamyl-L-tyrosyl-L-glutamyl) is reported elsewhere[12]. Poly(L-glutamyl-L-tyrosyl-L-glutamyl) was obtained following the same experimental procedure.

Table 1 Viscosity and infra-red data for polymer samples

	Tyrosyl content	$\eta(ml/g)$[b]	Amide I[c] frequency (cm^{-1})
Poly (L-glutamic acid)	0	16.5	1654
–	0	95.5	1654

(Glu–Tyr–Tyr–Glu)$_n$	0.50	22.1	1657

[a] Estimated from acid titration of carboxylic groupings in TMP–water as solvent and from spectrophotometric measurements assuming an extinction coefficient of $2200 \ l \ mol^{-1} \ cm^{-1}$ at 294 nm, in 0.1 M NaCl, 0.2 N NaOH

[b] In 0.2 M NaCl, pH 12, at 25°C

[c] Determined on 1% trimethylphosphate solutions with a Beckman IR 11 spectrometer, carefully calibrated on water vapour

Data for all samples are collected in *Table 1*.

Most of the samples being not directly soluble in trimethylphosphate, they were first dissolved in dimethylsulphoxide. After exhaustive vaporation of dimethylsulphoxide, the polymer readily dissolved in trimethylphosphate.

C.d. spectra were recorded on a Roussel-Jouan 185 model II dichrograph at 22–24°C.

RESULTS AND DISCUSSION

Figure 1 shows the c.d. spectrum of our sample of poly(L-tyrosine), which is in complete agreement with those reported by others.

The c.d. spectra of random copolymers are also collected in *Figure 1*. In the 205–240 nm range a gradual overlap of the α-helix spectrum with the poly(L-tyrosine) one is quite clear. When plotting ellipticities at 230 nm and at 202.5 nm against tyrosyl content no sharp change (*Figure 2*) can be observed. Such a smooth variation allows us to conclude in favour of a right-handed poly(L-tyrosine). It must be also pointed out that the curves of *Figure 2* are not straight lines. This indicates the likely presence of interactions among tyrosyl side chains. However, when plotting ellipticity at 230 nm as a function of the square of tyrosyl content (*Figure 3*) a straight line was obtained. Extrapolation of the straight line towards zero tyrosyl content gave an ellipticity of −20 000, which is in agreement with the expected value for a right-handed α-helix.

Assuming that the contribution at 230 nm of a non-interacting tyrosyl side chain, considered as isolated, is negligible, we can suppose that the rotational strength arises solely from pairing between tyrosyl aromatic rings. It is quite clear in this case that the only effective interactions will occur between neighbouring side chains included in a short *n*-mer segment. Thus, the rotational strength induced by a *i*th tyrosyl residue will be:

$$R_i = \sum_{-n/2}^{n/2} k_j(nx) = nx \sum_{-n/2}^{n/2} k_j = Knx$$

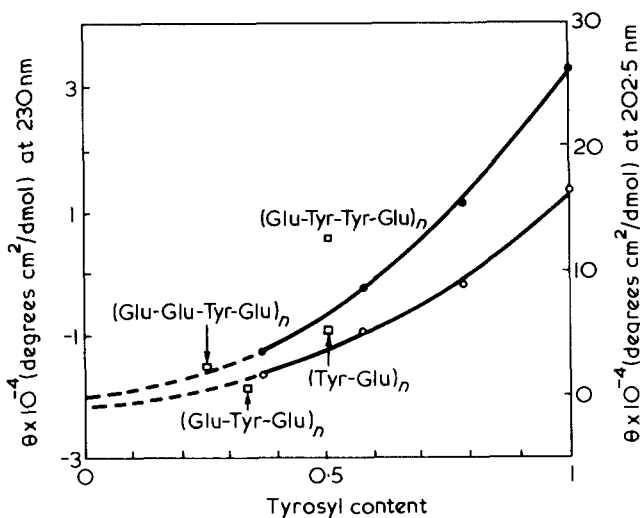
where k_j represents the contribution of the $(i, i+j)$ pair and (nx) the probability to find a tyrosyl residue at any
Figure 1 C.d. spectra in TMP of poly (L-tyrosine) (– ·–) and of random copolypeptides (Tyr, Glu)$_n$ of various tyrosyl contents: 0.78 (——); 0.57 (. . .); 0.36 (– – –). Concentrations, ~1 mg/ml


Figure 2 Ellipticities at 230 (●) and 202.5 (○) nm of random copolypeptides (Tyr, Glu)$_n$ as a function of tyrosyl content. □, ellipticities at 230 nm of sequential copolypeptides. Concentrations, ~1 mg/ml in TMP

given position in the *n*-mer. Summing over the whole chain (*N* residues) gives:

$$R = Nx \times Knx = NKnx^2$$

Hence, the observed linear relationship is consistent with the hypothesis made above, that the contribution of a

Figure 3 Variation of the ellipticity at 230 nm of random copolypeptides $(Tyr-Glu)_n$ against the square of tyrosyl content. Concentrations, ~1 mg/ml in TMP

Figure 4 C.d. spectra of sequential copolypeptides in TMP: $-\cdot-\cdot-$, $(Tyr-Glu)_n$; $---$, $(Glu-Tyr-Glu)_n$; $-\!-\!-$, $(Glu-Glu-Tyr-Glu)_n$; ...., $(Glu-Tyr-Tyr-Glu)_n$. Concentrations, ~1 mg/ml

non-interacting tyrosyl residue is negligible and that interaction between two residues is the only effective mechanism. However, further accurate experiments are required before concluding definitely to the validity of this hypothesis.

In the region below 205 nm, the maximum of the positive band is red shifted from 190 to 202.5 nm as the tyrosyl content increases, whereas the ellipticity first decreases then increases (compare *Figures 1* and *5a*). This effect results probably from the existence of a strong negative band of poly(L-tyrosine) below 190 nm, which has been already pointed out by others[3]. The 280–285 nm negative band cannot clearly be related to tyrosyl content. There may be two reasons for this. First, it seems that this negative band is overlapped by a positive contribution below 270 nm, which is detectable on the spectrum of poly(L-tyrosine). Secondly, theoretical calculations of Chen and Woody[5] have shown that the 280–285 nm negative band is

very sensitive to the orientation of the aromatic tyrosyl rings.

The c.d. spectra of sequential copolymers are reported in *Figure 4*. The shapes of poly(Glu–Glu–Tyr–Glu), poly(Glu–Tyr–Glu) and poly(Tyr–Glu) spectra are very similar to the typical spectrum of a right-handed α-helix. However, ellipticities seem somewhat low compared to the usual values of an α-helix. This is probably due to the low molecular weights of our samples. Indeed the effect of molecular weight on the c.d. spectrum of poly(L-glutamic acid) is actually quite clearly shown in *Figure 5a*. More noteworthy seems to be the alternating-pairs copolymer poly(Glu–Tyr–Tyr–Glu) in which the tyrosyl contribution at 230 nm is much enhanced as compared to that of the poly(Tyr–Glu) isomeric copolymer.

Ellipticities of the sequential copolymers are represented in *Figure 2*. None of the points fit the random copolymer curve, indicating that the rotational strength at 230 nm depends on the tyrosyl residues array.

In *Table 2* are listed all the possible pairings between
Figure 5a C.d. spectra of poly(L-glutamic acid) in TMP. $-\!-\!-$, $[\eta]$ = 16.5; $-\cdot-\cdot-$, $[\eta]$ = 95.5. Concentrations, ~1 mg/ml
Figure 5b Difference spectra calculated as outlined in the text, with θ_H corresponding to the ellipticity of poly(L-glutamic acid) of $[\eta]$ = 95.5 (. . .), 16.5 ($---$), as compared to the c.d. spectrum of $(Glu-Tyr-Tyr-Glu)_n$ ($-\!-\!-$)

Table 2 Pairing possibilities and c.d. data for poly(L-tyrosine) and sequential copolymers

		θ_{230}	Ellipticity contribution per tyrosyl at 230 nm
poly(L-tyrosine) $(Tyr-Glu)_n$	all pairing possibilities	32 000	52 000
$(Tyr-Glu)_n$	$(n, n + 2)$ $(n, n + 4)$ $(n, n + 6)$	−9 500	21 000
$(Glu-Tyr-Tyr-Glu)_n$	$(n, n + 1)$, $(n, n + 3)$ $(n, n + 4)$, $(n, n + 5)$	5 500	51 000
$(Glu-Tyr-Glu)_n$	$(n, n + 3)$ $(n, n + 6)$	−19 000	3 000
$(Glu-Glu-Tyr-Glu)_n$	$(n, n + 4)$	−15 500	18 000

tyrosyl side chains for each sequential copolymer. For this purpose interactions which could occur between side chains separated by more than five residues were neglected. *Table 2* also shows the ellipticity contribution per tyrosyl residue calculated assuming a right-handed α-helix ellipticity of −20 000 at 230 nm.

As observed in *Table 2* and in *Figure 2*, the contribution of tyrosyl side chains at 230 nm in poly(Glu−Tyr−Glu) is small. That means that both interactions ($n, n + 3$) and ($n, n + 6$) as well as the contribution of isolated tyrosyl residues are weak. Comparison of poly(Tyr−Glu) and poly-(Glu−Glu−Tyr−Glu) tends to indicate that the ($n, n + 4$) interaction is rather effective whereas the ($n, n + 2$) is not. But the strongest contribution at 230 nm is obtained with the alternating-pairs copolymer, and is nearly the same as in poly(L-tyrosine). In this connection, *Figure 5b* shows that, in the range 205−240 nm, at least, the spectrum of this copolymer is similar to a 'reconstituted' spectrum obtained by adding the α-helix contribution (θ_H) to the half of tyrosyl side chains contribution of poly(L-tyrosine):

$$\theta = \frac{\theta_{\text{polytyr.}} - \theta_H}{2} + \theta_H = \frac{\theta_{\text{polytyr.}} + \theta_H}{2}$$

However, the same agreement is not observed below 205 nm (*Figure 5b*) where the tyrosyl contribution in the 'reconstituted' spectrum is higher than for the alternating-pairs copolymer. Nevertheless, it seems reasonable to assert that the 230 nm c.d. band in poly(L-tyrosine) arises mainly from the array ($n, n + 1; n + 4, n + 5$). The ($n, n + 1$) interaction is likely very effective, but it cannot yet be decided whether interaction between tyrosyl pairs ($n, n + 1$), ($n + 4, n + 5$) etc. is of importance or not.

Using CPK space-filling models as well as Dreiding models, we tried to find out whether some special geometrical arrangement of tyrosyl side chain could be built to account for the c.d. spectrum of the alternating-pairs copolymer as compared to the spectrum of poly(L-tyrosine). It was then found that if the tyrosyl side chains are alternatively orientated according to the two sets of χ_1, χ_2 angles reported in *Table 3*, this will result in the formation of two contiguous side chain superhelices ($n, n + 4, n + 8 \ldots ; n + 1, n + 5, n + 9 \ldots$ respectively) in which the aromatic rings are nearly parallel to the α-helix axis and overlap to some extent.

The values of angles χ are located near the minimum in the energy map calculated by Ooi *et al.*[9] for poly(L-tyrosine).

In this conformation, consecutive aromatic rings in the same superhelix (i.e. corresponding to $n, n + 4$ residues) are distant by about 6.5−7 Å, while contiguous rings of two different superhelices are nearer (5.5−6 Å). In addition, these contiguous rings are nearly parallel (*Figure 6*). Each of the superhelices wraps right-handed around a Pauling−Corey α-helix (18 residues in 5 turns) with a pitch of 54 Å and 9 side chains per turn. We suggest that such a

Figure 6 Scheme of the proposed arrangement of the side chains in $(\text{Glu−Tyr−Tyr−Glu})_n$

model also holds for poly(L-tyrosine). In this case, a tyrosyl side chain held for instance in the conformation ($\chi_1 \sim 170°, \chi_2 \sim 35°$) will pair with one of its two next neighbours held in the other conformation ($\chi_1 \sim -60°, \chi_2 \sim 120°$). The four superhelices thus make two ribbons each wrapping one side of the α-helical framework. In the free space between the ribbons the α-helical framework appears to be quite open to the solvent while the other part is hindered.

This can help us to understand why the c.d. contribution at 230 nm in poly(L-tyrosine) is twice that of the alternating-pairs (Glu−Tyr−Tyr−Glu)$_n$ copolymer. Superhelical ribbons in poly(L-tyrosine) actually are too distant to interact strongly. This newly proposed conformation of tyrosyl side chains can also be valid for other polypeptides bearing aromatic groups. In the same manner, contiguous aromatic side chains included in α-helical segments of proteins may adopt the same pairing conformation.

CONCLUSION

Assuming that poly(L-tyrosine) in trimethylphosphate is in α-helical form which is now largely evidenced, comparison on the basis of c.d. spectra in trimethylphosphate of poly(L-tyrosine) with random copolypeptides of various tyrosyl contents leads to the conclusion of a right-handed helix sense for poly(L-tyrosine).

C.d. studies on sequential copolypeptides ($\text{Tyr}_x-\text{Glu}_y$) showed that some tyrosyl residues arrays are able to promote strong rotational strength at 230 nm. We found that ($n, n + 2$) and ($n, n + 3$) arrays were of poor effectiveness, while the ($n, n + 4$) one was much more effective. But the strongest rotational effect arises from the alternating-pairs array ($n, n + 1; n + 4, n + 5$).

Table 3 Proposed conformations of tyrosyl side chains

Order of the residue*	χ_1	χ_2[†]
$n, n + 4 \ldots$	~165°	~35°
$n + 1, n + 5 \ldots$	~−70°	~110°

* Numbering the residues from the amino end
[†] χ_2 value does not take into account the orientation of the phenolic −OH group

Using atomic models, we have built up the alternating-pairs copolymer ($x = y = 2$) in the form of an α-helix in which the tyrosyl side chains are arranged as a compact superhelical ribbon wrapping on one side of the α-helical framework with a pitch of 54 Å. This structure corresponds to two different conformations of the tyrosyl side chains each being defined by a couple of conformational angles χ_1, χ_2. When building up poly(L-tyrosine) in the same way a two-ribboned structure resulted. Such a structure fits well our c.d. results in the range 205–240 nm at least, and may be valid for other aromatic polypeptides.

Phosphonitrilic chloride: 23. Substitution reaction of phosphonitrilic chloride trimer with sodium hydroxymethylphenolate and polymerization of substitution products

M. Kajiwara and H. Saito
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan
(Received 11 January 1974; revised 1 March 1974)

Chlorine substitution reactions of phosphonitrilic chloride trimer $(PNCl_2)_3$ with 2-, 3- or 4-$HOH_2CC_6H_4ONa$ and $2\text{-}NaOH_2CC_6H_4ONa$ were carried out in dioxane solvent under various experimental conditions. All reactions were completed in 40–200 min in the temperature range $60°$ to $100°C$. The chemical shifts of P atom were measured by ^{31}P n.m.r. spectroscopy of $P_3N_3(2\text{-}HOH_2CC_6H_4O)_6$ (I), $P_3N_3(3\text{-}HOH_2CC_6H_4O)_6$ (II), $P_3N_3(4\text{-}HOH_2CC_6H_4O)_6$ (III) and $P_3N_3(2\text{-}OH_2CC_6H_4O)_3$ (IV). The ^{31}P n.m.r. spectra showed the singlet peak. Water vapour and formaldehyde were detected by gas chromatography and polymers were formed when (I), (II) and (III) were heated from $150°C$ to $250°C$. The polymers were stable towards water. Further, thermal balance measurements showed that the polymer formed from (I) was the most stable. The resistivity of films formed when (I), (II) and (III) were heated at about $300°C$ for 2 min was $1-10 \times 10^{13}$ Ω-cm. Thermal decomposition occurred rather than ring cleavage reaction when (IV) was heated from $150°C$ to $250°C$.

INTRODUCTION

Various substitution products of cyclophosphazene have been synthesized with cyclophosphazene dichloride trimer $(PNCl_2)_3$ and aromatic, aliphatic mono- or di-functional reagents[1]. However, most of the products were not polymerized with ring cleavage on heating as with $(PNCl_2)_3$, cyclophosphazene pseudohalogen compounds or a few substitution products of $(PNCl_2)_3$[2,3]. In recent years, the formation of cyclophosphazene linear or cyclophosphazene matrix polymers has been studied from substitution products of $(PNCl_2)_3$. This paper describes a synthesis of cyclophosphazene derivatives from $(PNCl_2)_3$ and sodium hydroxymethylphenolate, and cyclomatrix or cyclolinear phosphazene polymers from a condensation reaction with $-CH_2OH$ groups. The physical properties of the polymers are described.

EXPERIMENTAL

Preparation of cyclophosphazene dichloride trimer (PNCl₂)₃

Cyclophosphazene dichloride trimer $(PNCl_2)_3$ was prepared by the modified method of Saito and Kajiwara[4]. Pure trimer (m.p. $112°C$) was obtained by repeated fractional crystallization from light petroleum ether.

Preparation of hydroxybenzyl alcohol and mono- or disodium salts of hydroxybenzyl alcohol

$2\text{-}HOH_2CC_6H_4ONa$ was synthesized from phenol and formaldehyde[5]. 3- or 4-$HOH_2CC_6H_4OH$ were synthesized from *m*- or *p*-hydroxybenzoic acid methyl ester by reduction with $LiAlH_4$ or $NaAlH_2(OCH_2CH_2OCH_3)_2$. Hydroxy-

benzyl alcohols were purified by recrystallization from benzene. The melting point of the products were $86°C$ ($2\text{-}HOH_2CC_6H_4OH$), $73°C$ ($3\text{-}HOH_2CC_6H_4OH$) and $125°C$ ($4\text{-}HOH_2CC_6H_4OH$), respectively. The mono- or di-sodium salts of hydroxybenzyl alcohols were prepared by adding Na (2.3 g) into anhydrous ethanol (13% w/w) dropwise to the ethoxide solution. The mixture was refluxed on a water bath for 1 h and then the ethanol was evaporated under reduced pressure. $2\text{-}HOH_2CC_6H_4ONa$, $3\text{-}HOH_2CC_6H_4ONa$, $4\text{-}HOH_2CC_6H_4ONa$ and $2\text{-}NaOH_2CC_6H_4ONa$ were examined using ^1H n.m.r. The area ratio of $-CH_2$ or $-OH$ calculated from the spectra, and amounts of sodium determined by chemical analysis were in fair agreement with the theoretical values. It was concluded from the analytical data that the products were formed by this reaction.

Substitution reaction of cyclophosphazene dichloride trimer with sodium salts of hydroxybenzyl alcohols

The reaction of cyclophosphazene dichloride trimer $(PNCl_2)_3$ and the sodium salts of hydroxybenzyl alcohols were carried out in dioxane at various reaction temperatures. $(PNCl_2)_3$ (6.86 g) was dissolved in dioxane (200 ml), and was added to a solution of the sodium salt of hydroxybenzyl alcohol in dioxane (19.5 g/100 ml) or the di-sodium salt of hydroxybenzyl alcohol (20.2 g/100 ml). The resulting solutions were warmed on an oil bath at $60°-100°C$ with vigorous stirring. The reaction mixture was separated by filtration, and the filtrate was distilled under vacuum. The product obtained from this reaction was purified from dioxane containing active carbon. No hydrogen chloride gas was evolved. The dioxane insoluble products removed by filtration after the reaction was over, showed the pre-

sence of sodium chloride by X-ray diffraction analysis. The dioxane insoluble products were washed with ethanol several times to remove the unreacted mono- or di-sodium salts of hydroxybenzyl alcohols and the residue was dissolved in distilled water. The degree of conversion was calculated from the quantity of sodium chloride determined with 0.01 N AgNO$_3$.

Polycondensation of products

The substitution products were heated in an electric furnace at 150°C or 200°C in air for various times and it was found by gas chromatography analysis that water vapour or formaldehyde was formed. After the polycondensation reaction was over, the heat treated materials were separated into the dioxane soluble fraction (a) and the insoluble fraction (b) and their composition was determined by elemental analysis.

Molecular weight of products

Molecular weights of the substitution products or polymers obtained with the substitution reactions or polycondensation reaction were measured by the cryoscopic method, or g.p.c. using dioxane.

Determination of water and formaldehyde

Water and formaldehyde were determined by gravimetric analysis of an oxidation/reduction titration method using I$_2$.
Instrumentation

^{1}H n.m.r. spectra were measured with a Nihon Denshi JNMC-60 type spectrometer for 60 MHz at 20°C using TMS as internal standard. ^{31}P n.m.r. spectra were measured with a Nihon Denshi JNMC-60HL type spectrometer using chloroform or DMSO as solvents and H$_3$PO$_4$ as the reference. X-ray diffraction photographs was measured using a Shimazu Co. VDF-1 type instrument and powder diffraction method. Infra-red absorption spectra were measured with a Shimazu Co. IRG-2 type spectrometer using the KBr disc technique. The gas chromatograph used was a Shimazu Co. GC-5A type instrument.

RESULTS AND DISCUSSION

Activation energy of the substitution reaction

Since sodium chloride is formed in the reaction between cyclophosphazene dichloride trimer and the mono- or di-

sodium salts of hydroxybenzyl alcohols and no hydrogen chloride was detected, the following reaction mechanism is proposed:

$$(PNCl_2)_3 + 6HOH_2CC_6H_4ONa \rightarrow P_3N_3(OCC_6H_4CH_2OH)_6 +$$

$$6NaCl$$

$$(PNCl_2)_3 + 3NaOH_2CC_6H_4ONa\text{-}2 \rightarrow P_3N_3(OCC_6H_4CH_2O)_3 +$$

$$6NaCl$$

The extent of the reaction was measured by the amount of sodium chloride formed under various experimental conditions. It was found that the reaction was second order and using equation (1) the value of k was determined:

$$k = 1/(n-1)t(1/C^{n-1} - 1/C_0^{n-1}) \qquad (1)$$

in which n is the reaction order, t is the time, C_0 is the total sodium chloride when the reaction is complete, C is the amount of sodium chloride at reaction time t, and k is the velocity constant. The values for the activation energies, ΔE, determined from Arrhenius plots, are summarized in *Table 1*.

The solubilities of the mono- or di-sodium salts of hydroxybenzyl alcohols used are also shown in *Table 1*.

From *Table 1* it is apparent that the activation energy of the substitution reaction between cyclophosphazene dichloride trimer and 2-HOH$_2$CC$_6$H$_4$ONa or 3-HOH$_2$CC$_6$H$_4$ONa is the lowest; this is believed to be due to its much higher solubility.

Analysis of the substitution reaction products

The products obtained at completion of the reaction are shown in *Table 2*.

The values for both elemental analysis and molecular weight are in fair agreement with the calculated values. ^{31}P n.m.r. spectra of the various products are summarized in *Table 3*.

The ^{31}P n.m.r. spectra give a singlet peak only for all the products and also, bands characteristic of P=N or P−O−R appeared in the region 1200 cm^{-1} or 980−1100 cm^{-1}, respectively. The structure of the products are postulated as I−IV respectively. They are soluble in most organic solvents, but insoluble in water.

Polycondensation reaction of the substitution products

I–III were examined by differential thermal analysis (d.t.a.) and thermogravimetry (t.g.). Peaks for exothermic reactions appeared at 170°, 410°, 630°C (I); 160°, 510°C (II); 180°, 360°, 510°C (III), and peaks for endothermic reactions appeared at 460°C (I), 350°C (II), 450°C (III), respectively. It is proposed that the exothermic reaction at 160°–180°C is the polycondensation of –CH$_2$OH groups present in the substitution products. On heating I–III from room temperature gas chromatographic analysis of the gas formed showed the water vapour or formaldehyde gas was liberated at 160–200°C. The results of d.t.a. and gas chromatography, indicate that polycondensation reaction occurred both intermolecularly or intramolecularly. The results of molecular weight measurement of (a), the soluble fraction obtained by heating at 200°C for 5 h are summarized in *Table 4*.

Thus, polycondensation of I–III could be brought about most readily. The higher molecular weight of III may be attributed to a symmetrical –CH$_2$OH group in III. The infra-red absorption spectra of (a) and (b) obtained from I–III showed that the P=N frequencies of (a) and (b) which appeared at 1200 cm^{-1} shifted to the long wavenumber by about 10 cm^{-1} for the substitution products I–III. On the other hand, the P=N frequency of the rubberlike polymer formed by heating dichlorocyclophosphazene is at 1365–1300 cm^{-1} whereas for the trimer the P=N frequency is at 1218 cm^{-1}. Also, the –CH$_2$–O–CH$_2$– bond formed by the polycondensation reaction of –CH$_2$OH groups appeared at 1150–1060 cm^{-1}, but the –Ph–CH$_2$–Ph– bond formed by polycondensation of –CH$_2$–O–CH$_2$–, –CH$_2$OH groups is no longer distinguishable from the other –CH$_2$– groups. The structure of the polymers (a) and (b) could be deduced from the analytical data as follows:

Table 5 Resistivity of films obtained from various substitution products by heating at 300°C for 2 min

Formula of substitution product		Thickness of film (mm)	Resistivity at 20°C × 10^{-13} (Ω-cm)
(I)	$P_3N_3(2\text{-HOH}_2CC_6H_4O)_6$	0.014	2–10
(II)	$P_3N_3(3\text{-HOH}_2CC_6H_4O)_6$	0.015	1–3
(III)	$P_3N_3(4\text{-HOH}_2CC_6H_4O)_6$	0.029	2–4
Ring cleavage polymerization reaction of $P_3N_3(2\text{-OH}_2CC_6H_4O)_3$ (IV)

The onset of ring cleavage was investigated by d.t.a. and t.g. The exothermic reaction peaks appeared at 160°, 280° and 390°C and the endothermic reaction peaks at 320° and 450°C, respectively. The endothermic reaction at 160°C is due to melting of IV. The nature of the reaction taking place at the other peaks was studied using gas chromatography. It was found that carbon monoxide, carbon dioxide, water vapour, formaldehyde, benzene and methanol were formed when the temperature was raised to 280°C. Thus decomposition occurred without cleavage of the P$_3$N$_3$ ring, although the mechanism of decomposition cannot be explained.

Properties of the polymers

The degree of hydrolysis of polymers (a) and (b) formed from I–III was estimated by heating in water at 100°C for 30 min. The extent of hydrolysis was about 0.2–1.6%. By comparison dichlorocyclotriphosphazene is completely hydrolysed to phosphoric acid, hydrogen chloride and
Figure 1 T.g. curves of polymers obtained by heating at 200°C for 300 min in air at the rate of 5°C/min. (a) $P_3N_3(2\text{-HOH}_2CC_6H_4O)_6$; (b) $P_3N_3(3\text{-HOH}_2CC_6H_4O)_6$; (c) $P_3N_3(4\text{-HOH}_2CC_6H_4O)_6$

ammonium chloride. The polymers were stable against dilute H_2SO_4, HNO_3 or NaOH solution. In air the weight loss by heating was measured on a thermobalance, and the results are shown in *Figure 1*.

Further, it can be seen from the t.g. curves that the most stable polymer is the polymer formed from III, and the stability is related to the degree of condensation. The degradation products formed by heating at 200°C for 300 min are H_2O, CH_2O, CH_3OH (main product), C_6H_6 (main product), CO and CO_2.

Although it is found that main products were methanol and benzene, the mechanism of decomposition is uncertain.

The resistivity of films formed from the substitution products of I—III by heating at 300°C for 2 min are shown in *Table 5*.

The role of electrical conduction of macromolecules in certain biomedical problems

Stephen D. Bruck
National Heart and Lung Institute, National Institutes of Health, Bethesda, Maryland 20014, USA
(Received 26 March 1974)

The electrical properties of selected macromolecules are reviewed in terms of their physico-chemical structures, and these properties are related to interactions with blood. It is suggested that the electrical conduction and semiconduction properties of some natural and synthetic macromolecules may be involved, among other factors, in preventing the initiation of adverse effects on blood components, such as loss of compatibility.

INTRODUCTION

Electrical conduction and semiconduction can be found in a variety of natural biopolymers and synthetic polymers. In 1946, Szent-Györgyi[1,2] suggested that proteins may have an electronic structure similar to that of semiconductors. Based on his ideas, Evans and Gergely[3] calculated that such conditions may exist in proteins. In 1953, Eley et al.[4] reported semiconductivity in albumin, fibrinogen, and edestin, and found that water present in these molecules could decrease the energy gap for the movement of electrons. Later, Cardew and Eley[5] showed that haemoglobin and globin exhibit electrical conductance. Electrical conduction phenomena were also investigated by Rosenberg[6] and Postow and Rosenberg[7], confirming that electronic conduction and semiconduction exist in a number of proteins. Electrical conduction in collagen has been reported by Eley and Spivey[8] and by Bardelmeyer[9,10].

Among synthetic polymers, Winslow et al.[11,12] showed that the non-volatile pyrolytic degradation products of poly(vinylidene chloride) and pre-oxidized poly(vinyl benzene) exhibit semiconducting properties. Such properties were also reported for the pyrolytic condensation product of polyacrylonitrile by Topchiev[13], for polymers of phthalocyanine by Marvel and Rassweiler[14], and for poly(*p*-phenyl) by Mainthia et al.[15]. In 1965, Bruck[16] reported a specific electroconduction of 20 ohm^{-1} cm^{-1} at 25°C for the pyrolytic condensation products of a polypyromellit-imide, which is among the highest ever observed in synthetic polymers. With non-polymeric organic substances, Kepler[17] observed very high conductivity of 100 ohm^{-1} cm^{-1} for salts of tetracyanoquinodimethane (TCNQ).

The role of electrical conduction and semiconduction in various biochemical phenomena has attracted considerable attention since the original suggestion by Szent-Györgyi[1,2] that proteins may have electronic structure resembling semiconductors. For example, it is possible that proteins may be able to conduct electrons in the cytochrome systems of cells[18], that the transfer of energy may cause chemical reactions to occur in distant protein molecules[5], and that electronic conduction may be involved in muscle contractions[19]. Bruck[20], in 1973, suggested that intrinsic semiconduction and electronic conduction may be involved in blood com-patibility of polymeric systems and described observations *in vitro* in support of such a role with the pyrolytic conversion products of an aromatic polyimide[16,20,21].

SOME FUNDAMENTAL CONSIDERATIONS

Electrical conductivity may be either electronic or ionic. Electronic conduction is characteristic of metals in which electrons are the current carriers. On the other hand, ionic conduction is characterized by the presence of charged atoms or groups of atoms, which are the current carriers. Typically, polymers are insulators rather than conductors of electricity. Some polymers, however, can be made 'conductive' by the dispersion of finely powdered metal particles or carbons, or by coating them with metal oxides. Semiconductors are characterized by two energy bands, one that is filled with electrons (valence band), and the other that is empty (conduction band). These two bands are separated by a forbidden energy gap. If an electron acquires sufficient energy, it can jump into the upper conduction band. Electronic conduction may occur that is accompanied by the removal of electrons from the valence bands leaving empty levels and creating the appearance of a flow of positively charged electrons (holes). In a perfect intrinsic semiconductor, the number of electrons in the conduction band is equal to the number of holes. In such a case, electrical conduction will depend on the inherent atomic and crystal structure of the material. On the other hand, in an extrinsic semiconductor, electrical conduction by electrons and holes is caused by impurity atoms present in the crystal lattice. Depending on whether or not the impurity atom (or atoms) donates or accepts an electron (or electrons) from the valence band, the semiconducting material will be *n*-type (because of the negative charge of the carriers) or *p*-type (because of the positive charge of the holes).

Electrical conductivity, σ, which is the reciprocal of resistivity, may be expressed as:

$$\sigma = |e|n(\mu_h + \mu_e) \tag{1}$$

$$= |e|n_h(1 + c) \tag{2}$$

$$= \sigma_0 \exp(E/2kT) \qquad (3)$$

where $|e|$ = electronic charge, n = concentration of current carriers, $\mu_{h,e}$ = mobilities of holes and electrons, $c = \mu_e/\mu_h$, σ_0 = pre-exponential factor, E = activation energy to form charge carriers, k = Boltzmann constant, T = absolute temperature, e = base of natural logarithm. The value c (the ratio of the mobilities of electrons to the mobilities of holes) can be obtained from thermoelectric measurements. These yield the so-called thermoelectric power or Seebeck coefficient, Q. This represents the thermoelectric force per degree that arises when two different conductors are joined at both ends and the two junctions are kept at slightly different temperatures. By convention, the thermoelectric power is positive when the current flows from the sample to the reference metal at the cold junction. The Seebeck coefficient may be expressed by the following relationship[22]:

$$Q = -\frac{k}{|e|}\left(\frac{c-1}{c+2}\right) - \left(\frac{E}{2kT}\right) + 2 \qquad (4)$$

This permits the calculation of the ratio of the mobility of electrons to holes, c, because E can be obtained from a study of the temperature dependence of conductivity. If the carrier mobilities are only slightly dependent on temperature, a plot of $\log \sigma$ vs. $1/T$ (refer to equation 3) should yield a straight line with a slope of $-E/2k$.

Another important effect arises when a current-carrying conductor is placed in a transverse magnetic field, thus producing an electric field, E_H, that is perpendicular to both the magnetic field and to the flow of current. This is called the Hall effect[23,24]. To understand this phenomenon, consider that when an electric field, iE_L, is applied, the current carriers moving with a velocity of $\pm iv$ are deflected by the magnetic field, kB_z, where i and k are unit vectors in the directions of x and z, respectively. As a result, the excess electrons create an electric field having a force eE_H which, in a steady state, equals the force on the electrons caused by the magnetic field. Hence, $eE_H = \pm evB_z$. Since the velocity of the electrons is $v = \mu E_L$, then $E_H = \mu E_L B_z$. The current density, J, can be expressed as:

$$J = nev = ne\mu E_L \qquad (5)$$

hence,

$$E_H = \pm(1/ne)BJ \qquad (6)$$

where the term $(\pm 1/ne)$ is called the Hall coefficient, R. Information can be thus gained on the concentration and sign of the charge carriers. Furthermore, in conjunction with conductivity data, the mobilities of holes and electrons can be calculated.

ELECTRICAL CONDUCTION IN DEHYDRATED PROTEINS

A number of proteins and synthetic polymers in the dry state exhibit electrical semiconduction. In the case of β-proteins, the energy gap (ΔE) between the top of the filled bands and the bottom of the unfilled bands leads to a value of 3.05 eV according to Evans and Gergely[3]. Such β-proteins are characterized by hydrogen bond structures that presumably enable the movement of electrons and holes through the system. Cardew and Eley[5] have suggested

that α-proteins would be expected to have similar electrical properties facilitiated by the helical structure of the polypeptide chains. Synthetic polyamides also exhibit hydrogen-bonded structures, but the density of such hydrogen bonds is less than in proteins. In such systems, evidence indicates that the observed conduction is caused by protons rather than by electrons[25,26]. Protonic conduction is explained in terms of increased rotational freedom of the polyamide chains caused by the lesser degree of hydrogen bonding in these systems[26].

The activation energies (energy gaps) for semiconduction of several dry proteins are summarized in *Table 1* as calculated from equation (3) above. The data indicate that the activation energies of these proteins fall within the range of ~2.3 to 3.0 eV. The mobility of charge carriers, μ, representing the average mobilities of electrons and holes, $\mu_e + \mu_h$, as calculated by Eley and Spivey[8] are between 10^3 and 10^5 cm^2 V^{-1} sec^{-1} at 400 K. These values are much larger than those of many synthetic aromatic compounds and compare favourably with those of inorganic semiconductors[8]. Although proteins exhibit small electroconductivities in comparison to some synthetic materials, the values are reproducible. *Table 2* shows the calculated specific electroconductivities of selected proteins and polymeric materials. These electroconductivities can be explained in the case of proteins by the movements of the π-electrons in the hydrogen-bonded C=O- - -H–N systems[8]. In the case of synthetic polymers and their pyrolytic conversion products, the electroconductivities will be also influenced by increased carrier mobilities due to π-orbital overlap in the unsaturated condensed ring structures[12,13,16]. In either case, electroconduction is facili-

tated by increased order in the chemical structure of the molecules.

ELECTRICAL CONDUCTION IN HYDRATED PROTEINS

Several investigators have shown that the electrical conduction of proteins, such as plasma albumin[26] and haemoglobin[6,27], are influenced by their water content. In particular, it was observed that the main effect of the adsorbed water is manifested in the lowering of the activation energy of conduction. In the case of haemoglobin, Rosenberg[6] proposed that this is due to an increase in the dielectric constant of the protein. This serves to lower the energy needed for charge separation and to stabilize the charge carriers (electrons and holes) so that their numbers will increase. Eley and Leslie[26] considered Rosenberg's hypothesis involving the effect of the dielectric constant as an 'intrinsic mechanism', and they have suggested an alternate 'impurity mechanism' to explain the experimental observations. According to this latter view, the water molecules are adsorbed on polar groups including the C=O- - - -H—N hydrogen bonds to yield a so-called 'charge transfer adsorbed state'[26]. These authors performed experiments to distinguish between the 'intrinsic mechanism' and the 'impurity mechanism' by using various adsorbents such as CH_3OH (dielectric constant = 33), D_2O (dielectric constant = 78.7), and H_2O (dielectric constant = 80.0). There was no significant difference between the activation energy of conductivity between deuterated and non-deuterated proteins, as seen in *Table 3*. Also, only minor changes were observed in the electrical conductivity of these deuterated and non-deuterated proteins. The specific electroconductivities measured as a function of the surface at low adsorbate concentrations were found to increase in the order: $H_2O < D_2O < CH_3OH$, that is in the direction opposite of their respective dielectric constants. Consequently, Eley and Leslie[26] proposed that this increase in the conductivity may be due to the order of decreasing ionization potentials, rather than to the effect of changes in the dielectric constants as proposed by Rosenberg[6].

At higher water contents, several authors proposed protonic instead of electronic conduction for proteins[26,27]. This view stems from polarization phenomenon which is manifested by a slow increase of the resistance with time owing to the build-up of a reverse electromotive force. Such a polarization effect has been observed at a water content of 0.9 mol/100 g protein in both native and denatured haemoglobin[26] and in collagen[27]. On the other hand at water contents below 0.9 mol/100 g protein, there are practically no changes in the resistance with time for other proteins, such as bovine plasma albumin and globin[26]. Therefore, it appears that in dry proteins or in proteins at low water contents, the conduction is electronic, whereas at higher water contents, the conduction may be due to protons. Such protons may be transferred between the

adsorbed water molecules, or from the C=O to the H—N groups. This later process would be mediated by the water molecules which may have entered the inside structure of proteins.

In the case of collagen, Bardelmeyer[27] has recently proposed that the current carriers are probably protons rather than electrons when this protein has a water content of about 20 to 45%, and by small inorganic ions beyond a water content of about 65%. He found that at water contents of below 20%, there was good linearity between current and voltage, and the currents were not time-dependent. Above that water content, however, polarization effects predominated. Furthermore, a sharp brake was observed in the plot of the activation energy vs. water content between 45 and 65% water content[27]. This indicates that at the higher water contents, the main charge carriers may not be electrons but protons. Such protonic conduction may occur along the chains of collagen mediated by water molecules adsorbed on polar groups and the C=O- - - -H—N hydrogen bond system[27,28].

Several authors have used nuclear magnetic resonance (n.m.r.) spectroscopy to study the state of water in collagen[29-31]. Dehl[31] found that about 0.54 g of water/g of collagen does not freeze and retains high mobility to −50°C which represents about 2.6 molecules of unfreezable water per residue of the collagen molecule. Further work by Dehl[32] with $MgCl_2$ and $MgSO_4$ in conjunction with n.m.r. spectroscopy and the use of D_2O suggested that neither the so-called two-state nor the structured-water concept can satisfactorily explain the D_2O n.m.r. doublet spectrum or the effect of salts on it. The existence of 'structured' water has been invoked previously to explain the n.m.r. spectra of water in anisotropic collagen fibres[28-30]. According to the two-state concept of water in collagen, there would be a rapid exchange between bound and free water in collagen, and furthermore, the n.m.r. doublet splitting, $\Delta\nu$, should vary linearly with water content. However, Fung and Siegel[33] have recently shown that this is not the case. In view of these results, it is unlikely that the amount of adsorbed (anisotropic) water in collagen is sufficient to be in equilibrium with an isotropic liquid phase, and that there is a significant quantity of 'structured' water present in collagen[32].

The existence of 'structured' water to explain the blood compatibility characteristics of some hydrogels has recently been postulated by Bruck[34-36], and subsequently by Andrade and colleagues[37,38]. It should be pointed out, however, that the structure of collagen fibres is quite different from synthetic hydrogels, so that no generalization is possible. Nevertheless, it is interesting to speculate on the role of water in electroconduction in biopolymers in conjunction with blood compatibility. In the case of collagen, it is well known that when the endothelium of blood vessels is damaged, the underlying collagen attracts platelets which liberate adenosine diphosphate (ADP). The liberated ADP in turn attracts more platelets and the blood vessel might become completely occluded with the formation of a temporary haemostatic plug which is subsequently converted into a mechanically stable thrombus by the activation of the blood coagulation mechanism. The red cells can also release ADP as the result of haemolysis caused by stimuli such as alteration of blood flow patterns, exposure to damaged vascular wall areas or artificial surfaces. Consequently, platelets are apparently not the only formed blood elements which participate in thrombogenesis. Recently, Ganguly[39] presented evidence that while human

Table 3 Activation energies of conduction of selected deuterated (D) and non-deuterated (N) proteins (compiled from ref 26)

platelets bind thrombin, this by itself is insufficient to cause platelet aggregation and that other reactions seem to be also involved. He also suggested that the receptor of thrombin on platelets may be a protein having a molecular weight in excess of 200 000 [39]. The property of collagen to activate and aggregate the platelets appears to be related to its native, triple-helical structure because denatured (random coil) collagen neither promotes the aggregation of the platelets nor initiates the clotting mechanism. It has also been shown that the activation of the Hageman factor may be related to the free carboxyl groups of collagen because esterification of these groups prevents the activation process[40]. Furthermore, the ability of native collagen to aggregate the platelets may be related also to the particular architecture of the collagen molecule. For example, it has been shown that when the positively charged free amino groups are replaced by neutral groups, the aggregation of platelets is drastically diminished[40]. Vertebrate collagens contain small quantities of carbohydrate that constitutes less than 2% by wt of the total weight of the molecule[41]. Butler and Cunningham[42] studied soluble collagen from guinea pig skin and have shown that glucose (glc) and galactose (gal) are linked to the hydroxyl group of hydroxylysine (Hyd) in the peptide chain as follows:

$$-A-B-Hyd-A-C-D-$$
$$|$$
$$(glc, gal)$$
where A = glycine, B = methionine, C = histidine, and D = arginine. Recent studies by Bosmann[43] and by Barber and Jamieson[44] have indicated that platelet-bound glycosyl transferases seem to be needed for the adhesion of platelets to native collagen as the primary step in haemostasis.

The fundamental structural unit of collagen is believed to be the tropocollagen molecule with a diameter of 15 Å, length of 2800 Å, and molecular weight of about 300 000. The tropocollagen molecules are organized into fibrils (~5000 Å long) in such a way that they overlap by about one-quarter of their length[45]. The tropocollagen molecule forms a triple-helix, the structure of which was established by Rich and Crick[46] and Ramachandran[47]. The individual chains are nearly extended with only *intermolecular* hydrogen bonding possible between them. One-third of collagen is glycine, and an additional one-quarter is composed of proline and hydroxyproline. According to Ramachandran and Chandrasekharan[48], collagen contains one intermolecular hydrogen bond via the N–H- - -O=C group plus one intermolecular hydrogen bond via a water molecule per three residues. This is in contrast to other proteins, the architecture of which permits a greater amount of hydrogen bonding to occur. Chang and Chien[49] have recently shown that a variety of electrolytes can affect the stabilization and destabilization of the rod-like superstructure of reconstituted collagen. They showed that ions influence the structural order of reconstituted collagen both at the micron level (association–disassociation of tropocollagen–supermolecular rods of collagen) and at the molecular level (helix–coil transition).

Considering the particular water organization in collagen, Dehl[32] concluded that most of the water in collagen is 'bound' rather than 'free'. In other words, the bound water molecules are oriented by the polar groups of collagen and do not have the freedom of motion characteristic of liquid water. It should be pointed out that 'oriented' or 'bound' water is not equated with 'structured' water[32].

Collagen, as has been shown above, exhibits electrical conductivity both in the dry and hydrated states. At low water adsorption levels, the conductivity is electronic, but when the water uptake exceeds approximately 10%, the conduction appears to be protonic[27]. Any disturbance to the native structure of this protein (such as increased salt concentration and dehydration) would be expected to affect its triple-helical structure and disrupt at least some of the hydrogen bonds. This in turn should be reflected in increased ion binding propensity and changes in the electrical conduction of the molecule. As a speculative argument, it is proposed that a sufficient alteration in the water structure and hence electrical conductivity may be brought about also as a result of injury to the endotheliur of blood vessels by exposing the underlying collagen and the subendothelial components to the inorganic ions and organic polyelectrolytes of blood. The adsorption of these could subsequently affect the platelets which normally carry a net negative charge density and affect the coagulation factors. In other words, fundamental changes may occur in the native collagen molecule when it changes from the milieu that prevails underneath the normal endothelium to the one that becomes operative when collagen is exposed to blood constituents as the result of injuries to the endothelial lining of the blood vessel. These changes are by themselves apparently insufficient to cause denaturation of collagen, but sufficient to initiate the complex biochemical events that lead to platelet adhesion and aggregation. Similar considerations may affect the other subendothelial components in addition to collagen. The question may be raised in what way does electrical conduction influence the nature of the adsorption process of blood constituents and the activation of the blood clotting factors and platelets, leading to thrombosis?

ELECTRICAL CONDUCTION IN HYDROPHOBIC SYNTHETIC POLYMERS

It should be pointed out that blood compatibility cannot be related alone to the presence of 'bonded', 'structured', or 'free' water. For example, low-temperature isotropic carbons (so-called *LTI* carbons) have excellent blood compatibility[36]. Also, certain perfluorinated cellulose acetate derivatives have shown very promising *in vivo* non-thrombogenic behaviour[50]. Among synthetic hydrophobic polymers, Bruck[20,36] has recently suggested a possible relationship between intrinsic semiconduction, electronic conduction and blood compatibility.

In general, there are three approaches to the preparation of electroconducting and semiconducting polymers: direct synthesis, modification by complexing and chelation, and pyrolytic conversion of suitable polymers having particular types of chemical structures. In this latter area, Bruck has previously reported the thermal conversion of a specially purified aromatic polyimide, poly [*N,N'*-(*p, p'*-oxydiphenylene)pyromellitimide], into semiconducting and conducting condensation products at temperatures well below the graphitization conditions[16,21]. The thermal conversion process between 500° and 800°C is accompanied by the development of an electron paramagnetic absorption (e.p.r.) spectrum caused by free radicals. The calculated free spin concentration is in excess of 10^{19}/g and the relative e.p.r. absorption curves show characteristic maxima as functions of time and temperature of pyrolysis. Initially, there is a decrease in the density owing to the cleavage of the carbonyl bonds and the loss of carbon monoxide and lesser

Table 4 Physical and *in vitro* biological properties of insulating, semiconducting and electroconducting polypyromellitimides (PPMI) (compiled from refs 16 and 20)

Sample	Specific electro-conductivity at 25°C (ohm^{-1} cm^{-1})	No. of spins (g^{-1})	Lee—White coagulation index*	PTT index*	Platelet aggregation and activation
Unmodified PPMI	<10^{-12}	—	0.3	0.5	Heavy and activated
Pyrolytic PPMI	0.1	>10^{19}	2.1	1.3	Very light to none, not activated
Pyrolytic PPMI	11.1	>10^{19}	2.6	1.3	Very light to none, not activated
Pyrolytic PPMI	20.0	>10^{19}	2.5	1.4	Very light to none, not activated

* Expressed as ratio of clotting times for test specimens and those of siliconized glass (average of three)

quantities of other materials. As the pyrolysis progresses, there is an increase in the density of polymer owing to a polycondensation reaction that gives rise to a condensed polynuclear aromatic and heterocyclic system. This system permits an enhanced π-orbital overlap, and a consequent increase in the mobility of electrons.

It seemed of interest to carry out some *in vitro* biological testing procedures with both control (non-pyrolysed) and pyrolysed samples. These tests consisted of the Lee—White blood coagulation times, partial thromboplastin times (*PTT*), and platelet activation and aggregation with human platelet-rich plasma[51]. The Lee—White blood coagulation times and *PTT* were compared with those of siliconized glass[52]. The data summarized in *Table 4* indicate that the semiconducting and conducting pyrolytic polymers have clotting times two to three times longer than those of siliconized glass, whereas the non-conducting (control) sample has a clotting time of approximately one-third that of siliconized glass. Similarly, the electroconducting and semiconducting pyropolymers show very low or no platelet aggregation with no evidence of activation in contrast to the control sample. It seems possible that the electroconducting and semiconducting propensities of these pyropolymers may influence the adsorption and conformation of plasma proteins. This possibility remains to be confirmed experimentally. Although the above observations are preliminary and should not be generalized, they may have importance to the general area of the interactions of blood components with both natural and synthetic surfaces, possibly to the better understanding of the molecular properties of the vascular endothelium, and may also have implications to the pathogenesis of arteriosclerosis.

CONCLUDING REMARKS

Electroconduction in natural products such as melanins has recently been suggested by McGinness *et al.*[53] to be related to diseases such as Parkinsonism and schizophrenia. Melanins are polymeric pigments occurring in the skin, hair, retina of the eye, midbrain, and inner ear. They have condensed, unsatured ring structures, and are formed by the polymerization of oxidation products of tyrosine and dopa (3,4-dihydroxyphenylalanine). McGinness and colleagues have shown that melanins exhibit threshold switching, which until now has been restricted to amorphous inorganic semiconductors. Typically, at the critical threshold voltage, switching occurs that is manifested by 'on' and 'off' states in the current vs. voltage plots. Such electrical switching was also observed with equine cytochrome *c*, but not with bovine serum albumin, myoglobin,

and oxidized cholesterol. The electroconductivity of melanins is in the order of 10^{-5} ohm^{-1} cm^{-1} that increases greatly in the 'on' state[53]. Water absorbed by these pigments is necessary for electrical switching to occur, since dried samples lose this property, apparently due to the alteration in the dielectric constant of the system[53]. However, as it was mentioned in the section on hydrated proteins, ionization potentials could be involved instead in line with the findings of other investigators with deuterated and non-deuterated proteins[26].

The phenomena of electrical conduction and semiconduction in macromolecules are thus apparently of great significance in a variety of biomedical problems ranging from the pathogenesis of disease to the design of synthetic macromolecules with specific biological effectiveness. The systematic study of selected naturally occurring electroconducting macromolecules offers a rewarding approach towards the better understanding of these problems.

(Received 26 March 1974)

The cationic polymerizations of methyl-, 2-chloroethyl-, ethyl-, cyclohexyl- and t-butyl- vinyl ethers initiated by cycloheptatrienyl hexachloroantimonate in methylene chloride solutions have been studied in detail. Reaction rates were measured by an adiabatic calorimetric technique and rate constants for propagation of each of the monomers, k_p (obs), were determined by appropriate kinetic analysis of the experimental curves. The results obtained are discussed in terms of current theories regarding ion pair/free ion equilibria in non-aqueous solvents. Although ethyl-, cyclohexyl- and t-butyl- vinyl ethers behave very similarly to isobutyl vinyl ether, and their reactivities are comparable [k_p (obs) $\sim 3 \times 10^3$ M^{-1} sec^{-1} at 0°C] both methyl- and 2-chloroethyl- vinyl ethers show markedly different characteristics to the others, and in particular exhibit a reactivity approximately one order of magnitude less [k_p (obs) $\sim 2 \times 10^2$ M^{-1} sec^{-1} at 0°C]. These variations in reactivity are discussed in terms of preferred monomer conformations, and the resulting differences in activation energy which are likely to arise when such conformers are approached by an electrophile.

INTRODUCTION

The detailed results from a kinetic study of the cationic polymerization of isobutyl vinyl ether (IBVE), initiated by preformed stable carbonium ion salts, have been reported previously[1]. This present work represents an extension of that study to include a series of alkyl vinyl ether monomers, namely methyl- (MEVE), ethyl- (ETVE), cyclohexyl- (CHVE), t-butyl- (TBVE) and 2-chloroethyl- (CEVE) vinyl ethers. Together with IBVE this group of compounds has aroused considerable interest over the past few years because of the possibility of correlating reactivity with structure. Alkyl vinyl ethers are particularly susceptible to attack from electrophilic reagents, and a number of chemical reactions involving such species have been investigated[2-13] in order to establish some sort of reactivity sequence. In addition various n.m.r. analyses[14-18] have been undertaken to see if such a sequence is compatible with any electronic or structural trends arising within the group.

The aim of the present investigation was to elucidate the absolute reactivity of each of these monomers with respect to polymerization, and in particular to evaluate where possible the rate constants for propagation by free cationic intermediates. It was anticipated that such data might provide an unambiguous comparison of the reactivities of the monomers, since the propagation reaction is a simple bimolecular one, and dissociated free cations should reflect solely on their precursor monomers, and not on any other species in the system (e.g. counter-ions).

Polymerizations were carried out homogeneously in methylene chloride solutions under high vacuum conditions. Initiation was achieved by using preformed cycloheptatrienyl hexachloroantimonate ($C_7H_7^+SbCl_6^-$) as a catalyst, and where possible initiator concentrations were chosen such

that the salt was present predominantly in the form of free ions. Reaction rates were measured by an adiabatic calorimetric method similar to that already reported[1,19]. The technique is most accurate for reactions with half lives $\sim$ seconds, and in order to effect such rapid polymerization of some of the monomers, notably MEVE, ETVE and CEVE, catalyst concentrations were used such that appreciable proportions of propagating ion pair species may have been present. This possibility and its likely effect on the data is discussed later.

EXPERIMENTAL

Materials

Cycloheptatrienyl hexachloroantimonate was prepared and purified as previously reported[1]. Methylene chloride[1], acetonitrile[19], ETVE, IBVE, CHVE and TBVE were dried and purified also as already described[5]. CEVE (Koch Light) was washed several times with alkaline water and dried overnight with potassium hydroxide. It was distilled first from fresh potassium hydroxide and then from freshly extruded sodium wire. Finally it was stored *in vacuo* over calcium hydride. MEVE (BDH Ltd) gas was condensed *in vacuo* onto freshly crushed calcium hydride at 0°C, before a known volume was metered into the reaction calorimeter. A mercury monomer was used to ensure that the vapour pressure of the monomer was constant when volume readings (at −62°C) were taken. The density of MEVE was determined at the same temperature (0.856 at −62°C) and the value agreed with that extrapolated from data reported by Schildknecht[20].

It was also found necessary to determine the densities of ETVE (0.784 at 0°C) and CHVE (0.912 at 20°C), since adequate data were not available in the literature.

Adiabatic calorimeter

The adiabatic calorimeter differed in three main features from those used earlier[1,19]. A conventional magnetic stirrer and follower replaced the previous mechanical stirring arrangement, a thermistor (Stantel U23US) was used in place of the platinum resistance thermometer, and the two calorimeter sections were united by a large cone and socket joint, rather than ground glass flanges.

The thermistor consisted of an unmounted semi-conducting device, and had a time constant in solution of $\sim 10^{-3}$ sec. It was held in the calorimeter within a perforated glass envelope. This provided physical protection, yet allowed the reaction mixture to circulate efficiently around the temperature probe. The thermistor formed one arm of a resistance bridge, and a Sefram Gravispot recorder (type GRVAC) measured the small off balance potentials, arising from changes in resistance (i.e. temperature) of the thermistor. Unlike the resistance thermometer used previously, the thermistor was found to have a highly non-linear (exponential) temperature coefficient over the range say -20°C to $+20^{\circ}$C, though for the temperature rise associated with the polymerization reactions studied ($\sim 0.5^{\circ}$C), it did approximate to a constant (for a particular reaction temperature). Calibration was achieved by using a Beckmann thermometer at the temperature required. The thermometer and temperature probe were immersed in a stirred methanol bath, and temperature changes were related to resistance changes of the thermistor. Freezing water was used to calibrate the Beckmann thermometer.

The heat capacity, H, of the reaction vessel and contents was determined by polymerizing IBVE under the same conditions as kinetic runs involving the other monomers. The heat of polymerization of OBVE is known[1], and hence from the rise in temperature on polymerization, H was calculated.

Kinetic technique

Initiator phials were prepared and placed in the calorimeter as before[1,19]. The catalyst solvent was methylene chloride or a methylene chloride/acetonitrile mixture (96 : 4% v/v). The latter was required for complete dissolution of initiator salt at some of the higher concentrations

of catalyst. Since only ~ 1 ml of this solution was added to 99 ml of methylene chloride in the calorimeter, the effective concentration of acetonitrile in a polymerization reaction never exceeded $\sim 0.04\%$. The calorimeter and contents were equilibrated at the required temperature by surrounding the vessel either with a bath of ice/water at 0°C, or freezing dioxane at $+11.8^{\circ}$C. Polymerizations were carried out essentially as before[1,19], and after quenching the reaction mixture with methanol, the product was transferred quantitatively to a 250 ml flask. Most of the solvent was removed on a water pump, and the concentrated solution was filtered and transferred to a pre-weighed flask. Removal of the last traces of solvent in a vacuum oven overnight allowed the polymer yield to be determined. Molecular weights were calculated from vapour pressure measurements using a Mechrolab osmometer (model 301A).

RESULTS

Calibration of the calorimeter

Kinetic runs were carried out at 0°C and $+11.8^{\circ}$C, and the resistance of the thermistor, R_T, and its temperature coefficient, θ, at each of these temperatures is shown in *Table 1*. The corresponding mean values of the calorimeter heat capacity, H, are also shown.

Kinetic data on ETVE, CHVE and TBVE monomers

ETVE, CHVE and TBVE produced S-shaped recorder traces similar to those from IBVE polymerizations[1]. Without exception the curves were characterized by a relatively slow build up to a maximum gradient at $\sim 15\%$ conversion, followed by a steady decay to a horizontal straight line on completion of polymerization. All solutions became coloured after polymerization had ended, with each monomer displaying its own particular succession of colours. The most common sequence observed was a decay from blue, through green, to brown. Similar changes were reported in the case of IBVE, and some speculation concerning the chromophores responsible has been forwarded[1]. Certainly the effect is largely a post-polymerization one and does not constitute a termination reaction. Indeed polymer yields were always >80% showing termination to be almost totally absent during kinetic lifetimes. The chart recordings were analysed, therefore, by a mathematical treatment described in detail elsewhere (see Appendix to ref 1), and based on a simple two-stage mechanism involving only initiation and propagation reactions. Such analysis produced the data for rate coefficients for propagation, k_p (obs), summarized in *Tables 2–4*.

Kinetic data on MEVE monomer

The recorder traces from the kinetic runs using MEVE proved to differ markedly from all the others. First, the overall reaction was more sluggish than those involving the previous three monomers, and some of the higher catalyst concentrations required the use of traces of acetonitrile to maintain solubility, as already described. Secondly, the traces were found to rise sharply as soon as the initiator phial was broken, thus making the rate of polymerization a maximum at zero conversion; similar to the situation found in the polymerization of N-vinylcarbazole[19]. Again polymer yields were always >80%, and this apparent absence of ter-mination together with the facile rapid initiation process (compared to subsequent propagation), permitted direct evaluation of the rates of polymerization, R_p, from the initial slopes of recorder traces. Observed propagation rate coefficients, k_p (obs), were then obtained from the expression, $R_p = k_p$ (obs) $[C_7H_7^+SbCl_6^-]_0[MEVE]_0$. The results of these calculations are summarized in *Tables 5* and *6*.

Kinetic data on CEVE monomer

The kinetic traces obtained from the polymerization of this monomer were similar in shape to those of ETVE, CHVE and TBVE. However, polymer yields rarely exceed-ed ~50% indicating significant termination during kinetic lifetimes. Moreover, unlike any other vinyl ether polymeri-zations the decaying colour sequences were not visible immediately after polymerization was complete. In order to establish some approximate estimate for the rate con-stant for propagation it was assumed that initially termina-tion was minimal and the curves were analysed in a manner similar to that used for MEVE. It is recognized, however, that even larger error bars must be associated with these data than for any of the other evaluations. A summary of the figures obtained is shown in *Table 7*.

DISCUSSION
Polymerization mechanism

The homogeneous polymerizations of ETVE, CHVE and TBVE initiated by cycloheptatrienyl hexachloroantimonate in methylene chloride parallel exactly those of IBVE[1]. They are characterized by a relatively slow initiation process, followed by a rapid propagation reaction. Termination appears to be insignificant during kinetic lifetimes, as indicated by plots of $\log_{10}[M]_t$ versus t, where $[M]_t$ is the concentration of monomer at time t (see ref 1). These attain a maximum negative gradient corresponding to the situation where all initiating cations are converted to propagating polymeric species. Since beyond this point, the gradient falls only slowly, the total concentration of active centres in each of the systems, $[P_n^+]_t$, thereafter remains constant, to a reasonable approximation, i.e.

$$\frac{-d \ln[M]_t}{dt} = k_p(obs)[P_n^+]_t$$

The molecular weights of polymers are low, a typical average degree of polymerization being ~25, and there seems no reason to indicate that the major chain limiting reaction is anything other than a simple proton transfer to monomer.

In the case of CEVE recorder traces are superficially similar to the others; however, polymer yields are always low and a significant termination reaction must be present. This most likely involves the readily ionizable chlorine atom in the alkoxy substituent. In the polymer the electron lone pairs of the oxygen are no longer conjugated as in the unsaturated monomer, and are therefore much more basic. As a result these may participate in a neighbouring group type reaction to produce chloride ion. The latter

is highly nucleophilic and will readily terminate electrophilic active centres, i.e.

The oxonium ion so formed is likely to be inactive in the kinetic lifetimes of these vinyl polymerizations. Clearly this termination process must compete with transfer mechanisms as the main chain limiting reaction in this case.

The traces from MEVE polymerizations differ most from the remainder, and indicate a fast initiation reaction. In fact as far as the kinetics are concerned initiation can be considered as instantaneous when compared with the subsequent propagation reaction. It would seem that such a

difference could only arise as a result of a different mechanism of initiation, and this argument is reinforced by the data for k_p(obs) for the various monomers where that for MEVE has the *lowest* value (see later). In the case of MEVE it might be, for example, that initiation takes place via a fast electron transfer, followed by radical combination processes, i.e.

$$C_7H_7^{+}SbCl_6^{-} + CH_2{=}CH\atop{|}\atop{OCH_3} \longrightarrow C_7H_7^{\cdot} + \dot{C}H_2{-}\dot{C}H\atop{|}\atop{OCH_3}\; SbCl_6^{-}$$
whereas for the other monomers it seems more likely that a simple addition reaction takes place[1,21,22]:

$$C_7H_7^{+}SbCl_6^{-} + CH_2{=}CH\atop{|}\atop{OR} \longrightarrow C_7H_7CH_2\dot{C}H\atop{|}\atop{OR}\; SbCl_6^{-}$$
The higher reactivity of MEVE (over e.g. IBVE) towards the planar initiating cation could be ascribed to the uniquely planar *cis*-conformation (see later discussion) of MEVE, facilitating reaction (whether by primary electron transfer or by direct addition) following ready formation of a charge transfer complex.

Significance of kinetic data

A summary of the rate coefficients for propagation and enthalpies of polymerization for the various monomers is shown in *Table 8*. For completion the corresponding information for IBVE from ref 1 is included, and estimated activation enthalpies are also listed.

The initial concentrations of catalyst used in the polymerization of CHVE and TBVE were such that the salts could be assumed to be fully dissociated to a first approximation. The arguments in support of the assumption that the propagating species will be at least as dissociated as the initiating species at these low concentrations have already been expounded in detail[1], and since the experimental conditions were almost identical for these two monomers, the discussion will not be repeated here. The observed propagation coefficients can therefore be taken directly as reasonable estimates of the rate constants for the propagation of the free cations derived from these two monomers in methylene chloride solution, i.e. k_p^{+}.

In the case of MEVE, and to some extent ETVE, the values of initiator concentrations were of the same order as values of the ion pair dissociation constant, K_d, for cycloheptatrienyl hexachloroantimonate in methylene chloride[23]. Although the corresponding growing polymeric salts are likely to be more dissociated than the initiator salt at these concentrations, nevertheless, the possibility of some ion pair contribution to propagation cannot be entirely discounted. For these two monomers the observed propagation coefficients, k_p(obs), may in fact represent composite data for the rate constant for free ionic propagation (k_p^{+}), and that for propagation by some type (or types) of ion pair species ($k_p^{\pm}$). The simple relationship, k_p(obs) = $k_p^{\pm}$ + αk_p^{+}, may be assumed to hold, where α = degree of dissociation of the propagating salt. In anionic systems it has now been clearly demonstrated[24] that polymeric ion pairs propagate several orders of magnitude more slowly than the corresponding free carbanions ($k_p^{-}/k_p^{\pm} \sim 10^2$–$10^3$). There seems every reason to suppose that a similar differential exists in cationic systems (i.e. $k_p^{+}/k_p^{\pm} \sim 10^2$–$10^3$), though unequivocal experimental evidence confirming this is still lacking. Thus providing free propagating carbonium ions

are dominant in these polymerizations (i.e. $\alpha k_p^{+} \gg k_p^{\pm}$ or $\alpha > 10^{-2}$–10^{-3}) then the ion pair contribution can be ignored. Under these circumstances the expression for k_p(obs) collapses to k_p(obs) = αk_p^{+}. As far as MEVE and ETVE are concerned, therefore, k_p^{+} may exceed the data for k_p(obs) by a factor $1/\alpha$. A minimum value of K_d for the propagating species in these two polymerizations would be that for the simple cycloheptatrienyl salt in methylene chloride[23] ($\sim 3.0 \times 10^{-5}$ M at $0°$C). This can be shown to yield a minimum value of α of ~ 0.2 (i.e. 20% dissociation) for the concentrations of active centres used in these polymerizations. This figure lies well within the limit described above. On these grounds the values of k_p^{+} for MEVE and ETVE may be, at a maximum, a factor of ~ 5 larger than the data for k_p(obs).

A similar argument can be made in the case of CEVE. However, since a much larger uncertainty already exists in these data owing to the approximate nature of the kinetic analysis used, no quantitative estimation will be included here.

Apart from the possible relative variations considered above, all the data as a whole may be affected in a systematic way by the presence of adventitious impurities. As a result, this set of data should be considered as a valuable guide to orders of magnitude, and no doubt with more refined experimental techniques, more accurate absolute data will eventually emerge. For the time being, however, these values seem to agree well with predictions from the sparse literature which already exists concerning free cationic rate constants in vinyl polymerizations, and indeed represents a very significant addition to the list of numerical data currently available[1,19,25-32].

Relative reactivities of alkyl vinyl ethers

Inspection of the data of *Table 8* shows that whilst there may be little significance in the apparent differences between k_p(obs) (and hence k_p^{+}) for some of the vinyl ethers, there is a significant difference (approximately one order of magnitude) between the data for MEVE and CEVE on the one hand, and the remaining vinyl ethers on the other hand. This result is clear even taking into account the discussion in the previous section. The comparative lack of reactivity of MEVE and CEVE is also reflected in reactions with other electrophiles notably hydronium ion[4,5] and dichlorocarbene[6], and indeed has been reported before in cationic homopolymerization[9]. Generally reactivity appears to parallel the increased energies required for electronic[11], charge transfer[11] and photoelectron[35] spectroscopic transitions. More recently the relative rate differences for alkyl vinyl ethers have been highlighted in a detailed study[12] of their 2 + 2 cycloaddition reactions with diphenyl ketene. Although this reaction proceeds with a mechanism exhibiting many features of concerted cycloadditions[34], the transition state involved has undoubted dipolar character[35], as shown below, and hence the structural and electronic factors affecting reactivity will be similar to those observed for reactions with electrophiles.

$$Ph_2C{=}C{=}O \atop{+} \atop{ROCH{=}CH_2} \longrightarrow Ph_2C{-}C{-}O^{-} \atop{} \atop{R\dot{O}{=}C{-}CH_2\atop H} \longrightarrow Ph_2C{-}C{=}O \atop{} \atop{RO{-}C{-}CH_2\atop H}$$

In this study a marked increase in reactivity occurs on going from CEVE to TBVE as shown in *Table 9*.

Considering all the available information it appears that

Table 9 Relative reactivities of alkyl vinyl ethers with diphenyl-ketene in 1,2-dichloroethane at 25°C

Vinyl ether[a]	Relative reactivity
CEVE	1.0
ETVE	10
IPVE[b]	74
TBVE	250

[a] Experimental conditions precluded the use of MEVE and hence CEVE is used here as its structural model (see subsequent discussion)

[b] Isopropyl vinyl ether

reactivity towards electrophiles increases in the series: methyl-, 2-chloroethyl- < primary alkyl- < s-alkyl- < t-alkyl- derivatives, with the greatest difference occurring, as in the present study, between methyl and 2-chloroethyl derivatives on the one hand and branched alkyl derivatives on the other.

The greatly enhanced (general) reactivities of alkyl vinyl ethers, compared with simple alkenes, arises from resonance delocalization, viz:
and the contribution of the dipolar canonical structure has the effect of increasing rotational barriers around the R—O—CH= linkage. Resonance in alkyl vinyl ethers contributes to abnormal (for olefins) nuclear magnetic resonance shielding and coupling effects, and since the pioneering study of these monomers by n.m.r. techniques[14], there have been many subsequent investigations[15-18]. However, possibly the most important study of conformational equilibria in alkyl vinyl ethers is that reported by Owen and Sheppard[36]. These authors established by i.r. techniques that alkyl vinyl ethers exhibit s-cis/s-trans conformational equilibria, and that for methyl vinyl ether the planar s-cis form is the dominant form at ambient temperatures even in solutions. All the n.m.r. data and more recent i.r. studies[37] are consistent with this view, and the only point at issue is whether alkyl vinyl ethers other than methyl, have stable planar s-trans or gauche conformations. Certainly, as confirmed by molecular models, branched alkyl vinyl ethers cannot adopt the planar s-cis conformation. A major exception is possible in the case of 2-chloroethyl vinyl ether, which like the methyl derivative, may adopt such a planar s-cis form because of a significant contribution from a favourable gauche interaction between the chlorine and oxygen atoms:
If we now make the generalization that planar s-cis conformations are preferred for methyl- and 2-chloroethyl-vinyl ethers, and that progression through other primary and secondary alkyl derivatives to t-butyl vinyl ether involves a gradual change to stable s-trans conformations,

it is possible to rationalize the relative reactivities of alkyl vinyl ethers in a rather simple manner.

The transition state for reactions of alkyl vinyl ethers with electrophiles must involve overlap of the π-electrons with a suitable vacant orbital on the electrophile as indicated:

reaction with s-cis conformer   reaction with s-trans conformer
Clearly the planar s-cis conformation will offer a greater degree of steric hindrance to the incoming electrophile, than the corresponding s-trans (or gauche) forms, almost irrespective of the nature of the substituent. It is this steric effect which contributes to ground state strain (i.e. inability to adopt planar s-cis conformations) in alkyl vinyl ethers other than methyl- and 2-chloroethyl- derivatives, with a consequent reduction in activation energy for attack by electrophiles, as noted experimentally. In the case of the propagation reaction in polymerization, steric interference in the case of s-cis conformers is likely to be exaggerated, since the electrophilic centre is located on the end of an entangled polymer chain. In addition it is tempting to suggest that the apparently zero value for the activation energy in the polymerization of t-butyl vinyl ether arises from a combination of normal Arrhenius behaviour and the ability of the monomer to assume the more hindered s-cis conformation at higher temperatures.

Preparation and properties of some graft copolymers of the poly(2-chlorocyanurate) ester of bisphenol A

A. G. De Boos* and G. Allen

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 22 March 1974)

Graft copolymers of poly(2-chlorocyanurate)ester of bisphenol A have been prepared by coupling with polymers containing nucleophilic terminal groups. Polystyrene, poly(ethyl acrylate) and poly(methyl methacrylate) have been prepared. Physical properties of the grafts are characterized by two separate glass transition temperatures characteristic of the two homopolymers involved. The thermostability of the grafts increased with increase in weight fraction of polycyanurate in the copolymers.

INTRODUCTION

Poly(2-chlorocyanurate)ester of bisphenol A (PCC) is a highly reactive, lightly branched, polydisperse polar macromolecule formed[1] by the polycondensation of cyanuric chloride and 2,2-bis(p-hydroxyphenyl) propane. The pendant chlorine group undergoes the normal reactions of organic acid chlorides although the reactivity is somewhat lower. Nucleophilic substitution at the active carbon atom readily occurs in the presence of amine, alcohols, phenols and other hydroxy compounds.

The coupling of PCC to polymers with nucleophilic terminal groups will yield graft copolymers. Whilst the nucleophilic chemistry of the polymer is somewhat complex because substitution at the main chain ether links competes with that at the active chlorine atom[1], as the molar quantities involved in condensation coupling are small, it is expected that degradative attack on the PCC by the nucleophilic terminal groups of macromolecules will not be a problem in the formation of graft copolymers.

Condensation coupling has not been widely used in the preparation of graft copolymers, nevertheless there are some excellent examples of this technique in the literature. Grahame[2] developed a method in which amine-terminated polystyrene, prepared using a sodium initiator in liquid ammonia, was coupled with polymers containing small amounts of β-isocyanato-ethyl methacrylate as comonomer. Coupling was rapid and efficient, requiring no catalyst. Mutual transesterification between poly(methyl methacrylate) (PMMA) and low molecular weight aliphatic polyesters has also been used[3] to prepare graft copolymers. Similarly by converting the carboxyl end groups of natural and synthetic rubbers to acid chloride groups coupling of these materials to sodium and potassium derivatives of polyamides to form poly(amide-g-rubber)copolymers has been effected[4].

Polymers with amino-terminal groups have been prepared by a number of workers and a series of such polymers have been prepared in this work for coupling with the PCC.

EXPERIMENTAL

Purification of reagents

The solvent, tetrahydrofuran (THF) and the catalyst, triethylamine were refluxed over calcium hydride then distilled as required. Tetrahydrofurfuryl alcohol was vacuum distilled and stored in the dark. Other reagents, all of AR grade, were used as supplied.

Preparation of poly(2-chlorocyanurate)ester of bisphenol A

The polymer was prepared by interfacial polycondensation in the presence of a cationic emulsifying agent by the method described elsewhere[1].

Preparation of amino-terminated polymers

The polymers were prepared by free radical solution polymerization in the presence of mercaptoethylammonium hydrochloride[5]. Alcohols were used as solvents for the polymerization because of their low radical transfer constants and because they were solvents for both polymer and the radical transfer agent. Tetrahydrofurfuryl alcohol was used as solvent in the polymerization of styrene, butyl and methyl methacrylates and methyl acrylate while propanol was used in the polymerization of ethyl and butyl acrylates. A 3:1 propanol/water mixture was also found to be a suitable solvent for the polymerization of methyl acrylate and methyl methacrylate. Polymers prepared in the different solvents did not differ significantly.

In a typical preparation the initiator, azobisisobutyronitrile (AIBN) (0.1% on weight of monomer) and the transfer agent (1% on the weight of monomer) were dissolved in the appropriate solvent (200% on the weight of monomer) and the required amount of monomer was distilled into the reaction vessel which was then sealed under vacuum and held at 80°C for 24 h. The polymer was precipitated by the slow addition of the polymerizing mixture to an excess of non-solvent (methanol for polystyrene and polymethacrylates and petroleum ether for the polyacrylates), then redissolved in chloroform, r precipitated and dried under vacuum.

Because of the low molecular weights of the amine-terminated polyacrylates, purification and drying was a considerable problem and consequently characterization was limited to gel permeation chromatography.

Preparation of graft copolymers

Because, in the presence of a base catalyst, water caused gelation of PCC[1], rigorous drying of polymers and solvents was essential before coupling was attempted. In a typical preparation a solution of PCC (10 g) in anhydrous THF (100 ml) was added to a solution of the amine-terminated polymer (20 g) in THF (200 ml). To this mixture was added triethylamine (0.5 ml) and the final mixture was stirred for 24 h. The solution was then added to an excess of acetone [poly(CC-*g*-DDA) and poly(CC-*g*-S)] or petroleum ether. The precipitated polymers were redissolved in chloroform, the solutions were filtered to remove triethylammonium chloride and the polymers were reprecipitated in petroleum ether and dried under vacuum.

Purification of the graft copolymers

Because of the limited chemical stability of the triazine polymer, selective elution was the only technique used to purify the polymers. The procedure adopted for each graft copolymer was: (a) poly(CC-*g*-DDA) — none required as dodecylamine was soluble in acetone; (b) poly(CC-*g*-S) — selective elution with cyclohexane (PS soluble) followed by selective elution with butanone (PCC insoluble); (c) poly-(CC-*g*-MMA) — selective elution with acetonitrile (PMMA soluble) followed by selective elution with butanone, (d) poly(CC-*g*-EA) — selective elution with diethyl ether (PEA soluble) followed by selective elution with butanone.

No suitable selective solvent could be found for the purification of poly(CC-*g*-MA).

CHARACTERIZATION

The polymers were characterized using established techniques. Osmometric measurements were made with a Melabs recording osmometer (Model CSM-2) using THF as solvent. The specific refractive index increments of the polymers in the various solvents were determined using a Brice-Phoenix differential refractometer, which had been previously calibrated with an aqueous sucrose solution. Light scattering studies were performed in a Sofica light scattering photometer, which used monochromatic light (λ = 546 nm) and which was thermostated at 25°C. Viscosity measurements were made in a Desreux—Bischoff viscometer at 25°C, the kinetic energy correction of which was negligible for the solvents used. G.p.c. was performed in a Waters Associated Model 200 gel permeation chromatograph, which had been calibrated with low dispersity linear polystyrene and THF was used as solvent. End group analysis was done by labelling the amine terminal groups using fluorodinitrobenzene followed by spectroscopic analysis of the polymer in chloroform solution (at 350 nm), and comparison with a suitable calibration. The end group frequency σ was defined as the number of functional end groups per molecule:

$$\sigma = AM_n$$

where A = mol end groups/g polymer.

Four techniques were used to determine the composition of the graft copolymers: (1) microanalysis — the polymers

were analysed for chlorine and nitrogen which were specific for the triazine component; (2) ultra-violet spectroscopy — since the polyacrylates, polymethacrylates and dodecylamine do not absorb in the u.v. above 240 nm the extinction coefficient of the copolymers at 254 nm was used as a measure of composition. This could not be applied to poly(CC-*g*-S); (3) differential refractometry — as the specific refractive index increments of the components of a graft copolymer are usually additive, the specific refractive index increment was used to determine the composition; (4) infrared spectroscopy — from the absorbances of the copolymer at wavelengths specific for the components (PCC at 1540 cm^{-1}; PS at 690 cm^{-1}; and PMMA at 1730^{-1}) it was possible to obtain a measure of the composition of the copolymers. The method was calibrated using the spectra of homopolymer mixtures.

The various techniques used to determine the composition of the graft copolymers gave quite consistent results and so the uncertainty in composition was quite small (*Table 1*)

The problems and errors associated with the solution characterization of the graft copolymers are great, the major ones being due to the products of the side reactions that occurred during the coupling reaction and to the long term degradation of the copolymers during storage. Low molecular weight fragments of PCC are formed when the terminal amino groups attack the main chain ester links of the backbone polymers. These fragments appeared as a low molecular weight tail on the gel permeation chromatograms of poly(CC-*g*-MMA) and poly(CC-*g*-EA) but not on that of poly(CC-*g*-S). These chromatographs are shown in *Figure 1*. The fragments made impossible any extensive characterization of the copolymers, particularly the determination of number-average molecular weight by osometry.

Light scattering measurements of the graft copolymers, poly(CC-*g*-MA), poly(CC-*g*-MMA) and poly(CC-*g*-EA) were performed in THF. As the specific refractive index increments of these copolymers in this solvent were high, the apparent molecular weight determined[6] was expected to be close to the true weight-average molecular weight of the copolymer. The molecular weight of poly(CC-*g*-S)-42, determined in benzene, was very close to the true weight-average molecular weight since the specific refractive index increments of the two components were almost identical[6]. The results are shown in *Table 2*. Although the molecular

§ Apparent second virial coefficient

weight of the graft copolymer was greater than that of the reactive prepolymers the difference was not as great as was expected. This was further evidence that scission of the backbone polymer occurred during coupling.

The intrinsic viscosities of the copolymers (*Table 3*) were determined in three solvents: chloroform, a good common solvent; benzene, a good solvent for the side chains and a very poor solvent for the backbone; butanone, a good solvent for the acrylate side chains, a poor solvent for the polystyrene side chains and a non-solvent for PCC. The solutions of the copolymers in butanone had the characteristic cloudy appearance of micellar solutions. As expected, the order of intrinsic viscosities of the copolymers were: [η] in butanone > [η] in benzene > [η] in chloroform, a consequence of the collapse of the backbone to the 'intramolecular precipitated'[7] state in butanone, which resulted in a contraction of the macromolecules in solution.

In summary, although the graft copolymers have been

partly characterized the instability of the backbone and complications due to side reactions during preparation preclude any application of graft copolymer solution theory.

PHYSICAL PROPERTIES

In this work, we have concentrated on only three aspects of polymer behaviour, the glass transition temperature, the dynamic mechanical properties and the tensile properties.

The glass transition temperatures of the polymers were determined by differential scanning calorimetry (d.s.c.) using a Dupont 900 Differential Thermal analyser fitted with a DSC cell, at a heating rate of 20°C/min. All polymers were scanned from −100°C to 150°C or higher and duplicate samples were run. The thermal stability of the polymers was determined by thermogravimetric analysis (t.g.a.) in a nitrogen atmosphere at a heating rate of 6°C/min.

Because thermal moulding of PCC and those graft copolymers in which the weight fraction of PCC exceeded 0.5 was not possible even at a temperature of 200°C in a 20 ton (1 ton = 1.016 t) hydraulic press, mechanical testing was performed on films cast on to a clean mercury surface from THF and from butanone. The solvent was allowed to evaporate slowly in air protected from draughts. The films (0.05 cm) were then dried at room temperature under continuous vacuum for 2 months. The residual solvent was determined by heating the films at 150°C to constant weight in an evacuated oven. This caused the films to blow out so that the remnant material was useless for tests. The shear modulus of the cast films and its temperature dependence were determined using a Weissenberg Rheogoniometer. The sample (1.0 × 3.0 × 0.05 cm) was placed between two clamps, one of which was oscillated at 1 Hz and with a maximum amplitude of 1.42°. The movement of the other clamp was measured electronically and output and input signals fed into a computer which calculated the real modulus and the dissipation factor (tan δ). These parameters were measured at 5° intervals until the shear modulus was too low to detect. From a plot of the shear modulus and the dissipation factor against temperature the transition temperature of the film was determined (*Figure 2*).

The tensile properties of the polymeric films were determined by stretching the samples (1.0 × 0.1 × 4 cm) to break in a tensometer. Duplicate and often triplicate samples were run. As many of the samples were glassy polymers the clamps were modified to prevent any slippage of the sample by placing a strip of emery paper between the sample and the clamp jaws as shown in *Figure 3*. The samples were stretched at 1 cm/min and a chart to crosshead ratio of 16:1 was used. Samples were conditioned in the testing

Table 3 Intrinsic viscosities of graft copolymers

atmosphere (22°C) for more than one hour before they were tested.

RESULTS AND DISCUSSION

The transition temperature observed by d.s.c. (*Table 4*) for the triazine homopolymer agreed with that observed by other workers at ~140°C. The graft copolymer, poly(CC-*g*-DDA) was found to behave like a random copolymer rather than a true graft copolymer, probably because the dodecyl chains were too small to act independently as low molecular weight polyethylene branches. Consequently only one thermal transition was observed at 135°C, the lower thermal transition of the poly(2-chlorocyanurate) ester of bisphenol A, a result of the plasticizing action of the aliphatic side chains. Similar effects have been observed in the poly(acrylic acid) esters, the poly(methacrylic acid) esters and the poly(*p*-alkyl styrenes).

All the true graft copolymers of poly(2-chlorocyanurate) ester of bisphenol A had multiple thermal transitions corresponding to the glass transitions of the component homopolymers. Poly(CC-*g*-S) copolymers displayed the thermal transitions of the individual components except for poly(CC-*g*-S)-83 where the weight fraction of the polystyrene component was quite low. Here the transition temperature of the polystyrene component was slightly higher than that

of the polystyrene hompolymer. The polyacrylate and polymethacrylate components of the respective graft copolymers tended to lower the thermal transition of the triazine component. The effect of an increase in grafting frequency on the thermal transisiton temperature of the backbone can be easily seen from the results obtained from the poly(CC-*g*-EA) copolymers. Since the molecular weight of the poly(ethyl acrylate) side chains were the same in each case, the grafting frequency was proportional to the weight fraction of the PEA component. The relationship between the thermal transition temperature and the weight fraction of the poly(2-chlorocyanurate) ester of bisphenol A component is shown in *Figure 4*.

The results derived from the dynamic mechanical testing of the cast films of poly(2-chlorocyanurate) ester of bisphenol A and its graft copolymers shown in *Table 5* mirrored the d.s.c. results. The mechanical transitions all represented plasticized glass transitions of the component polymers. The polyacrylate rich phase of the poly(CC-*g*-MA) film appeared to be almost unplasticized, probably a consequence of the prolonged drying (under vacuum) of the copolymer which allowed most of the solvent to be removed from the rubbery PMA rich phase but not from the glassy phase. The lower mechanical transition of the poly(CC-*g*-EA)-67 copolymer was below the temperature range investigated.

The d.s.c. and dynamic mechanical result indicated that PCC and polystyrene were incompatible and that microphase separation occurred in the solid state. However, a solvent cast film of the polymer mixture was clear, behaviour not normally observed when polymers are highly incompatible. This apparent anomolous observation was a result of the similar refractive indices of the two materials which prevented any appearance of cloudiness in the blend, even when phase separation had occurred. PCC and the acrylate polymers were much less incompatible and some interaction between the components occurred, probably accompanied by less extensive microphase separation in the bulk state.

Table 4 Thermal transitions of poly(2-chlorocyanurate) graft copolymers

modulus and low extensibility while poly(CC-*g*-EA)-30 was a soft rubbery material of lower modulus and higher extensibility. The effect of the casting solvent on the modulus of the polymers can easily be seen from *Table 6*. The films cast from THF had a higher modulus than those cast from butanone, a consequence of the more extended configuration of the poly(2-chlorocyanurate) backbone in the films cast from THF. The difference in moduli of copolymers, in which the weight fraction of the triazine polymer was low, was much greater than that of polymers in which the weight fraction was high and where poly(2-chlorocyanurate) ester of bisphenol A formed the continuous phase irrespective of solvent. The increase in modulus of films of poly(CC-*g*-EA)-30 occurred without a large decrease in the extensibility of the material.

The high thermal stability of poly(2-chlorocyanurate) ester of bisphenol A and other triazine polymers has been reported by several other workers[8,9]. The stability of the graft copolymers (by t.g.a.) was much lower than that of the poly(2-chlorocyanurate) homopolymer (*Table 7*). A second shoulder, shown in *Figure 5* was observed in the thermograms of those copolymers in which the weight fraction of the triazine polymer was high, corresponding to the degradation of the backbone. We conclude that the lower stability of the graft copolymer is a simple consequence of the low stability of the side chains (the thermal stability of which has been well documented)[10] rather than of any destabilization of the backbone polymer.

Polymerization of acrylonitrile in the presence of vinylsulphone dyes

N. S. Batty and J. T. Guthrie
Department of Colour Chemistry, University of Leeds, Leeds LS2 9JT, UK
*(Received 15 March 1974; revised 25 June 1974)*

Information regarding the effect of vinylsulphone dyes on the kinetics of polymerization of acrylonitrile is presented in detail. Some of the physical properties of the products, polyacrylonitrile/vinylsulphone dye copolymers, are discussed, although the subject of their thorough characterization is reserved for a later publication. Considerable detail is given concerning the experimental procedures, to ensure ease of understanding of the techniques involved. ^{60}Co γ rays were employed as the polymerization initiator whilst the effect of γ radiation on the chromophore was noted, where relevant.

INTRODUCTION

The concept of polymeric pigments or colouring matters bound to polymers is an attractive one, since such pigments should be free from many of the problems which bedevil other pigments, for example migration and flocculation. Polymeric pigments could also eliminate the grinding operation which is always necessary in the production of more conventional pigments[1]. Outlets should also exist in moulding, spinning or casting operations, avoiding some of the difficulties involved in the production of intrinsically coloured articles and in mass coloration. These developments would depend largely on the nature of the components of the polymer.

This is an account of some preliminary studies of one possible route to this type of pigment.

Certain commercially available dyes contain vinyl groups, sometimes in the free vinyl form, but often as an addition compound such as the β-sulphatoethylsulphone derivative. For this study three Remazol® (Farbwerke Hoechst) dyes were used — a yellow, a red and a blue. The Remazols are reactive dyes intended primarily for dyeing cellulosic fibres. They are sold as β-sulphatoethylsulphones. Under mild alkaline conditions used in dyeing they release the bisulphate anion to yield the free vinylsulphone[2], thus:

$$\text{Dye}-\text{SO}_2\text{CH}_2\text{CH}_2\text{OSO}_3^- \xrightarrow{\text{OH}^-} \text{Dye}-\text{SO}_2\text{CH}=\text{CH}_2 + \text{HSO}_4^-$$

Under alkaline conditions cellulose ionizes and reacts with the vinylsulphone by adding to the β carbon atom of the activated double bond[3]. The reaction is completed by protonation of the α carbon atom. The sequence of reactions is essentially reversible.

The structures of a number of the Remazol dyes have been elucidated and published[4]. The structures of the free vinyl forms of the three dyes used in this work, Remazol Gold Yellow G (I), Remazol Red B (II) and Remazol Brilliant Blue B (III), are given as:

A number of copolymers containing a dye as one of the comonomers have been reported. Lovrien and Waddington[5] copolymerized acrylamide azo dyes with acylic and methacrylic acids to study the effect of the polymeric environment on the photochromic *cis–trans* isomerism. BASF patented copolymers made from dyes containing polymerizable vinyl groups together with one of a wide range of vinyl monomers[6]. The products are stated to be suitable

for making shaped articles, films, sheets, fibres etc. The concept was extended to include such features as grafting the comonomers to cotton resulting in coloration and modification of the physical properties of the substrate in one operation[7].

ICI have shown considerable interest in the printing of textiles using dyes containing an acryloylamino group. The dye is polymerized within the interior of the fibre[8].

There have been a number of papers describing the use of a dye to initiate polymerization. Usually the chromophore becomes attached at one end of the polymer chain. Sometimes it becomes modified during the initiation process and the colour is either changed or destroyed. Kämmerer[9] used a coloured peroxide:
to initiate polymerization. The number of initiator fragments in the polymer were then determined colorimetrically. This was claimed to be a more convenient method of determining the concentration of initiator fragments in the polymer than the more familiar radioactive tracer techniques.

Dyes have also been used as photosensitizers so that polymerization can be initiated by visible light[10]. Much work has been carried out along these lines involving triarylmethane dyes such as fluorescein[11-14]. The colour of the dye is destroyed during the reaction although it has been shown that the dye molecule becomes bound to the polymer[15]. Simionescu *et al.*[16-18] have used various dyes to photosensitize the polymerization of acrylonitrile. They reported that coloured polymers were produced.

In this study an attempt has been made to copolymerize acrylonitrile with vinylsulphone dyes and to determine the nature of the polymerization process. This has been achieved mainly by considering the effect of the dye on the polymerization reaction.

EXPERIMENTAL

Reagents

Acrylonitrile was supplied by BDH Ltd. The inhibitor, 0.005% *p*-methoxyphenol, was removed with potassium hydroxide. An excess of potassium hydroxide pellets was added to the acrylonitrile and it was allowed to stand overnight. The liquid was decanted and distilled from fresh potassium hydroxide, under reduced pressure, at 50°C.

The dyes were all samples from the Remazol range of Farbwerke Hoechst AG and were supplied by Hoechst—Cassella Dyestuffs Ltd, Manchester, UK. The commercial dye was purified and treated to produce the free vinyl form as follows[19].

Dissolution in a minimum of water at 40°C was followed, on cooling, by titration with 5% sodium hydroxide solution until the pH, measured on a glass electrode, was greater than 10.5. After 10 min (30 min for the blue dye) the pH was checked to ensure that it was still above 10.5. This process liberates the vinylsulphone from the β-sulphatoethylsulphone form of the dye. Caution is needed to maintain the pH of the mixture below 11.5 to 12.0. Above pH 12.0 an essentially irreversible reaction occurs, resulting in the formation of the β-hydroxyethylsulphone from the vinylsulphone form of the dye. Precipitation was completed by the addition of 67% (w/w) potassium acetate solution. The dye

was filtered using Whatman's No.5 filter paper, redissolved in water and precipitated again with potassium acetate. The dye was filtered and this process of dissolving and salting out was repeated. At this stage potassium acetate was the only impurity in the free vinylsulphone dye. The potassium acetate was removed by washing the precipitate repeatedly with ethanol until the washings gave no precipitate with 0.1 M silver nitrate solution. The dye was finally dried in a vacuum desiccator. This purification procedure was used for each of the three vinylsulphone dyes used.

Pre-irradiation procedure

Polymerizations with each of the dyes were carried out *in vacuo* and in air. The monomer solutions were prepared by dissolving the dye in warm water, cooling and then adding the appropriate amount of acrylonitrile. The mixture was shaken until the acrylonitrile dissolved. Vacuum irradiated samples were sealed off at 1.33×10^{-3} N/m^2, stored in the dark at 0°C until required and brought to room temperature prior to irradiation.

Irradiation procedure

Polymerization was initiated by γ radiation from the ^{60}Co source located in the Department of Physical Chemistry at the University of Leeds. The absorbed dose rate was determined by Fricke dosimetry. The dose rates at the four positions used in this work were 5.03, 5.45, 5.27 and 4.75 rad/sec. Owing to difficulties arising from the source design it was not possible to obtain identical dose rates for all the positions used. Hence kinetic data are presented later in terms of rad^{-1} as well as sec^{-1}.

Post-irradiation procedure

Post-irradiation polymerization was reduced to a minimum by pouring the contents of each tube, as soon as possible after removal from the irradiation unit ($\geqslant$10 min), into an excess of cold (0°C) methanol containing 50 g/dm^3 of dissolved potassium acetate. The potassium acetate enables the polymer to be separated from the solution. The mixture was centrifuged at approximately 200 m/sec^2 for 20 min. This produced a compact sediment and clear supernatant liquor. The liquor was decanted and passed through a tared sintered crucible (porosity grade 4). The sediment was mixed with 50 cm^3 of methanol and centrifuged again. The clear liquor was passed through the original crucible and further methanol was added to the sediment. This procedure was repeated until no colour was apparent in the solution and until it gave no precipitate with 0.1 M silver nitrate. Thus, removal of all the potassium acetate and dye was ensured.

The resulting sediment was transferred quantitatively to the crucible, washed with methanol and dried to constant weight in a vacuum desiccator. The weight of polymer obtained in each instance was recorded.

RESULTS AND DISCUSSION

In all the systems irradiated there was an initial period during which no visible change occurred. This was followed by a period of rapid polymerization during which the polymer, being insoluble in the monomer, precipitated as a milky suspension.

Polymer made in the absence of dye was easily filtered from its monomer solution. However, polymers made in
*Figure 1* Polymerization of acrylonitrile. $\bigcirc$, *in vacuo*; $\triangle$, in air

Figure 2 Polymerization of acrylontrile in the presence of the yellow dye. $\bigcirc$, *in vacuo*; $\square$, in air

the presence of the dye were extremely difficult to filter. For these, it was necessary to add an electrolyte to coagulate the suspensions before they could be filtered.

The initial period of the polymerization process was not examined at all in this study. In every instance an induction period was observed. This was greatest for irradiations carried out in air and of minor proportions for vacuum irradiated samples. According to Dainton et al.[20] and Peebles et al.[21] this initial period of polymerization is the time during which the concentration of the propagating species builds up to its steady-state value. When the steady state is reached, the rate of polymerization becomes independent of the monomer concentration up to high conversions. Here, deviations from the steady state will take place.

Some observations were made on the polymerization of acrylonitrile in the absence of dye (*Figure 1*). The reaction rates in the linear portions of the graphs, corresponding to the steady state period are 27% and 6.9% (w/w) conversion to the polymer per 10^4 rad for the reactions *in vacuo* and air. In reality the number of points available in *Figure 1* are insufficient to justify a claim that the steady state is reached. Previous workers[20] have found that a steady state is reached after the initial period. This has been assumed in our work and from *Figure 1* the conversion rates are seen to be 3.6×10^{-5} and 9.1×10^{-6} mol converted to polymer dm^{-3} rad^{-1} respectively.

Figures 2, 3 and *4* demonstrate the effect of vinylsul-

phone dyes on the polymerization of acrylonitrile *in vacuo* and in air. In every instance there is the same initial behaviour as observed with pure acrylonitrile. From this stage, the rate of polymerization is seen to fall off steadily because of monomer depletion. Here we would expect deviation from steady state conditions. The data are shown in *Figures 5, 6* and *7* as plots of log $([M]/[M]_0)$ *versus* dose, where [M] denotes the concentration of total monomer (dye + acrylonitrile) in the system at any time and $[M]_0$ is the original total monomer concentration (dye + + acrylonitrile). Reasonably linear plots are shown for the section of the graphs corresponding to the steady state period. This strongly suggests that the steady state process is first order with respect to monomer. If we assume the existence of steady state conditions and that the change in relative monomer concentration is insignificant over the period of investigation then:
$$R_p = k\,[M]$$

Figure 3 Polymerization of acrylonitrile in the presence of the red dye. $\bigcirc$, *in vacuo*; $\square$, in air

Figure 4 Polymerization of acrylonitrile in the presence of the blue dye. $\bigcirc$, *in vacuo*; $\square$, in air
Figure 5 Log (monomer depletion) *versus* total dose, yellow dye with acrylonitrile. ○, *in vacuo*; □, in air

*Figure 6* Log (monomer depletion) *versus* total dose, red dye with acrylonitrile. ○, *in vacuo*; □, in air

Figure 7 Log (monomer depletion) *versus* total dose, blue dye with acrylonitrile. ○, *in vacuo*; □, in air

where R_p denotes the rate of polymerization and k is the first order rate constant. For any other dependence of the form $R_p = k$ [M]^x where k and x are constants, a plot of log ([M]/[M]$_0$) against log (dose) should give a straight line. Plots given in *Figures 8* and *9* can be seen to exhibit continuous curvature. Therefore it is assumed that the reaction is first order in monomer. Here we have a simple method of determining the dependence of the reaction rate on the monomer concentration using data from polymerizations carried out at one monomer concentration. Hence, this affords a much speedier method of acquiring the monomer dependence than is possible using several monomer concentrations in the usual manner. However, the method depends on the validity of the assumptions described.

Polymerizations in air give considerably more scattered points than those carried out *in vacuo*. No attempt was made to control the amount of dissolved oxygen. Oxygen is known to have a marked retarding effect on free radical polymerizations so changes in the concentration of oxygen may account for the observed scatter.

Table 1 First order rate constants for acrylonitrile (AN) polymerization in the presence of dye, in vacuum and in air

Copolymer	Vacuum		Air	
	$k \times 10^6$ (rad^{-1})	$K' \times 10^6$ (sec^{-1})	$K \times 10^6$ (rad^{-1})	$K' \times 10^5$ (sec^{-1})
AN/yellow dye	2.1	10.0	1.7	8.5
AN/red dye	0.6	3.0	0.35	1.7
AN/blue dye	1.4	7.0	0.8	4.0

The first order rate constants have been calculated for the three dye–acrylonitrile systems, both in air and *in vacuo*, from the slopes of the log $([M]/[M]_0)$ *versus* dose plots and are presented in *Table 1*.

From the nature of the reactions it would seem that the polymerization of acrylonitrile, with or without the dye, follows a similar mechanism. However, there is a considerable difference in the initial reaction rates as shown by the time taken for turbidity to develop. The overall reduction in the polymerization rate, with the dye present is further complicated by the fact that these rates become dependent on the monomer concentration. For concentrated solutions, as used here, the rate of polymerization of acrylonitrile in the absence of dye is independent of the monomer concentration to high conversions. This is explained by assuming that most of the polymerization occurs on the surface of the polymer particles and involves only adsorbed monomer. It is also assumed that the polymer particles become saturated with monomer at concentrations well below the saturation limit of acrylonitrile in water. Provided that the concentration of monomer in the solution is sufficient to ensure saturation of the surface of the polymer particle, the rate should not change significantly with the monomer concentration. Depletion of adsorbed monomer at the surface will result in a corresponding reduction in the polymerization rate. The amount of monomer adsorbed, and hence the polymerization rate, becomes proportional to the concentration of monomer in solution.

If this model is accepted, then the dependence of the polymerization rate on the monomer concentration must mean that the polymer particles are not saturated, even in the more concentrated monomer solutions.

The particles of dye–polymer are stabilized with a smaller size than the particles in the absence of dye, and so would be expected to have a greater total surface area. However, it is difficult to imagine that this could so greatly affect the adsorption. We feel that a more likely explanation involves the increased hydrophilic nature of the polymer resulting from the incorporation of ionic groups. This would promote competition between water and acrylonitrile for the surface sites. Then the greater the acrylonitrile concentration the greater will be its occupation of the surface sites and the faster the polymerization process. Hydrolysis of the cyano groups in the homopolymer results in the formation of acid groups which will be hydrophilic.

Polymerization was carried out without prior degassing of the monomer solutions, to determine the role of air in the process. The results are plotted in *Figures 1–7* on the same axes as those of the corresponding degassing reactions, to facilitate comparison. The rates of reaction during the 'steady-state' period are lower in the presence of air. The ratios of the rate constants for vacuum and air are 1 : 0.8,

1 : 0.58, 1 : 0.57 respectively for the yellow, red and blue dye systems, respectively.

Oxygen is well known to have a retarding effect on radical polymerizations. This usually takes the form of almost complete suppression of polymerization until all the oxygen is used up. In the absence of secondary events, polymerization proceeds as normal thereafter.

Figure 10 displays the effect of the concentration of the yellow dye on the rate of polymerization. In spite of the paucity of data, the results show clearly that the rate of polymerization decreases with increase in the dye concentration, at a constant concentration of acrylonitrile. One effect of incorporation of dye into the polymer is to reduce the adsorption forces between the monomer and the polymer. Incorporation of more dye into the polymer would further reduce the extent of adsorption.

One possibility is that the growing polymer radical reacts with a dye molecule to produce a less reactive species. This is supported by the fact that all the polymers made in the presence of dye were highly coloured and the colour was not removed by repeated dissolution and precipitation. This lesser reactivity will arise because of the steric protection of the radical on the dye molecule by the bulky chromophore.

Alternatively, the radical could be less reactive because of resonance stabilization. The styryl radical, for example, is markedly deactivated in this way[22]. The sulphur–oxygen bonds in vinylsulphones, however, have very little double bond character[23,24]. Hence the degree of resonance with the aromatic part of the molecule cannot be great. There is no measurable stabilization of phenyl vinylsulphone radicals.

We cannot rule out the possibility of attack by the polymer radical of the dye molecule at positions other than the vinyl group. If the attack were to occur at some part of the conjugated system, the resulting radical would almost certainly be stabilized and unreactive.

Ham has suggested that polymerization of acrylonitrile occurs by a stereospecific helical mechanism[25]. If this is so, a comonomer, such as a vinylsulphone dye, would upset the regularity and reduce the rate of reaction. We feel that the reduced rate of reaction in the presence of dyes is due primarily to reduced adsorption of the monomer onto the polymer particles. However, we appreciate that any one of,
Figure 10 Effect of the acrylonitrile: dye ratio on polymerization, yellow dye in air. X, acrylonitrile only; ○, 40 : 1 acrylonitrile dye; □, 20 : 1 acrylonitrile dye; △, 10 : 1 acrylonitrile dye

or a combination of, the other mechanisms may also take part.

The polyacrylonitrile/dye copolymers were formed as emulsions or suspensions in water. These emulsions were stable. The copolymers could not be removed from the suspension by centrifuging or filtering through a No.4 porosity sinter. This observation is in marked contrast to the precipitates of acrylonitrile produced in the absence of the dyes, which were very easily separated by the sinter.

Every polymer particle produced during the polymerization of acrylonitrile carries a negative charge. The suspension becomes stable when the particles are large enough to carry a charge sufficient to repel other particles and so prevent agglomeration[20]. Molecules of the polymers containing dye have sulphonate groups which are almost completely ionized in water. Hence, the polymer particles have a further inherent negative charge such that repulsion between the particles and stabilization of the suspension can occur at a smaller particle size. This repulsive effect is reduced in the presence of methanol where ionization is inhibited, or in the presence of an electrolyte such as potassium acetate, where it is partly screened by the excess of ions. This facilitates aggregation, allowing the coloured polymer to be separated from its solution. If water is added to the polymer it reforms the emulsion immediately. Once it has been dried, however, the polymer loses its emulsion forming characteristics. On drying, strong intermolecular bonds must form, as in polyacrylonitrile.

The coloured polymers are insoluble in water, alcohols, ethers, hydrocarbons and halogenated hydrocarbons. They are soluble in *N,N*-dimethylformamide and dimethylsulphoxide. If a solution of the polymer in *N,N*-dimethylformamide is poured slowly into water, the polymer is precipitated as a stable suspension. The overall insolubility of the coloured polymers, produced by the methods outlined, should be of value in pigment applications. The stability of their emulsions in aqueous systems is an added advantage. Evidence is available to suggest that copolymerization renders the chromophore more light fast, than the unmodified dyestuff, on normal substrates.

Melting of thermoplastics in single screw extruders

I. R. Edmondson* and R. T. Fenner
*Department of Mechanical Engineering, Imperial College of Science and Technology,
London SW7 2BX, UK*
(Received 3 May 1974)

Some experiments on the melting of thermoplastic polymeric materials in single screw extruders are
described. Although these were of the now familiar screw extraction type, special care was taken to
distinguish between material melted by screw rotation and that melted during the subsequent cooling
operation. A barrel which could be split longitudinally was also used, thus avoiding some of the dis-
advantages of axial extraction. A theoretical model is proposed which, unlike previous models,
allows the solid bed of material in the screw channel to accelerate naturally, and also allows for the
presence of a film of molten material between the bed and the screw. This model gives satisfactory
predictions of melting performance. Comparison with experimental results shows that break-up of
the solid bed occurs when the model predicts rapid acceleration of the bed. Bed break-up and the
resulting surging may be reduced or prevented by the use of screw cooling which has the effect of
inhibiting the formation of a melt film at the screw surface.

INTRODUCTION

Since most thermoplastic polymeric materials pass at least
once through a single screw extruder, there is considerable
interest in the design of such machines. Early attempts to
understand and analyse the process were concentrated on
the flow of the material after melting[1,2]. Attention has also
been given to the behaviour of solid feedstocks in the feed
sections of screws[3,4]. It is generally agreed, however, that
the melting process is often the most important in that it
determines the maximum output rate of acceptable quality
extrudate. Most experimental work on melting has involved
the extraction of the screw from the barrel while still full
of polymer, in order to study the melting mechanism[5-8].
Based on the observations, various theoretical models have
been proposed[7,9-11], though all are of a similar type.

The purpose of this paper is to report some improvements
to both the experimental techniques for studying melting
in extruders and the theoretical analysis of the process[12].
In particular, the latter makes it possible to predict when
melting is likely to become unstable, leading to surging of
both the output rate and pressure.

EXPERIMENTAL TECHNIQUE

The essence of the experimental method, both past and
present, for studying the melting process in single screw
extruders is to first achieve the required steady operating
conditions and then to stop the screw and cool the barrel
as rapidly as possible. The material in the screw channel is
thereby frozen. The screw is then extracted from the barrel
and the helical strip of solid polymer removed and sectioned.

Two practical difficulties are usually encountered: first,
in achieving a sufficiently rapid rate of cooling to minimize
the amount of material melted by thermal conduction after
the screw has stopped, and secondly in applying a large
enough axial load to the screw to perform the extraction.

* Present address: Imperial Chemical Industries Limited,
Billingham, Teesside.

It is normally necessary to use water cooling on the barrel,
and if possible on the screw as well, to achieve an adequate
cooling rate. Powerful screw extraction equipment is also
needed, since not only is the screw channel full of polymer,
but the extraction must be carried out at as low a tem-
perature as possible. In the present experiments on a 38
mm machine with a screw length-to-diameter ratio of 20, a
maximum extraction force of about 10 t was applied by
means of an electrically driven screw jack. On larger
extruders the required force would be increased in propor-
tion to at least the square of the screw diameter. Even so,
it is not always possible to extract the screw at ambient
temperature, and the barrel must be partly reheated.

If reheating of the barrel is necessary the softened
material near the barrel surface may be disturbed when the
screw is extracted. This difficulty was overcome by using
a longitudinally split barrel, the two halves being bolted
together in use. The barrel heating and cooling jackets
could be removed, the barrel split and the screw removed
with minimum disturbance of the polymer. In most of the
experiments, however, the axial extraction procedure was
used, having first established that the barrel splitting
method gave the same results.

Owing to the low thermal conductivities of most ther-
moplastics, a significant amount of melting by conduction
after the screw has stopped is unavoidable. While the
barrel may be rapidly water cooled, polymer not in contact
with the barrel responds much more slowly. During nor-
mal extrusion, melting occurs almost exclusively in the
regions of intense shear that exist between the solid
material and the screw and barrel surfaces. Consequently
it is possible to distinguish between extrusion melting and
the subsequent conduction melting by whether or not shear
deformation is also involved. This is best achieved by
adding colouring matter to the solid feedstock. One method
is to add a small proportion of granules of the same material
and physical form, to which a distinctive colour has been
imparted. Another method, and the one that was used in
the present experiments, is to mix a very small amount of

powdered dry colouring with the feedstock which clings to the surfaces of the granules. When material from the screw channel is sectioned after extraction it is possible to distinguish conduction melting where the outlines of the original granules are still visible, from extrusion melting where the colouring has been distributed by shear.

Pressures at a number of points along the barrel were measured with the aid of Dynisco transducers, Model PT 420, the outputs from which were amplified and recorded by an ultra-violet recorder. The response of this system was sufficiently rapid to follow in detail the variations of pressures as the screw rotated. The back pressure at the delivery end of the extruder was varied with the aid of a range of dies of different diameter.

The materials used in the experiments included a granular and a powdered low density polyethylene (LDPE), granular high density polyethylene, granular polypropylene, crystal polystyrene, plasticized poly(vinyl chloride) (PVC) granules and rigid PVC powder.

THEORETICAL MODEL

Figure 1 shows part of the screw and barrel of a typical single screw extruder, where the direction of flow of polymer is from left to right. The coordinate directions z and x are respectively parallel and normal to the screw flight, while the third coordinate y is in the radial direction. *Figure 2* shows the screw channel cross-section normal to the flight, looking in the downstream z direction. Also shown is the commonly observed form of melting mechanism. The unmelted material is compacted into a solid bed which is approximately rectangular in cross-section (in practice the corners are somewhat rounded). The bed is continuous in the downstream direction and lies just behind the trailing face of the screw flight. Melting occurs mainly at the interface between the upper surface of the solid bed and the narrow melt film between bed and barrel. Much of the melt so formed is swept by the relative motion of screw and barrel into a melt pool formed in front of the leading face of the flight. If the screw is hot enough there may also be melt films formed between the bed and screw surfaces. As melting proceeds the model assumes that the cross-sectional area of the bed decreases until either the bed width or thickness approach zero. In practice the bed may break into discrete pieces as described later.

Figure 2 shows the view from the screw with the barrel moving relative to the observer. A further simplification is to assume that the channel and contents may be unrolled and treated as rectilinear. The solid bed is assumed to move relative to the screw with a velocity V_{sz} which is independent of x and y but may vary with z. *Figure 3* shows the relative velocity diagram for the solid bed, the velocity of

Figure 2 The melting model

Figure 3 Relative velocity diagram for the solid bed

the barrel relative to the bed using V_r at an angle β to the downstream direction. In practice the magnitude of V_{sz} rarely exceeds half that of V_z.

All the melting models mentioned in the introduction are of the form shown in *Figure 2*. The earliest ones[7,9] neglected the existence of the lower melt film and assumed the bed velocity, V_{sz}, to be constant. Apart from small corrections for channel curvature and leakage flow over the screw flights[10], the main improvement to the basic model has been to allow the bed velocity some freedom to vary. For example, Donovan[11] introduced an empirical 'solid bed acceleration parameter' which allowed V_{sz} to increase in a prescribed manner along the screw.

In the present model the solid bed velocity is allowed to vary naturally, and the lower melt film is introduced as soon as the screw temperature exceeds the melting point of the polymer. The thicknesses of the melt films at the screw root and flight surfaces are assumed to be the same, in accordance with experimental observations.

Mass and force balances

There are four distinct regions in the channel cross-section, namely the upper and lower melt films, the solid bed and the melt pool. Equations for conservation of mass can be stated for each region. For the upper melt film:

$$\begin{bmatrix} \text{Rate of change} \\ \text{of downstream} \\ \text{mass flow rate} \end{bmatrix} = \begin{bmatrix} \text{Rate of melting} \\ \text{over interface} \\ \text{with solid bed} \end{bmatrix} - \begin{bmatrix} \text{Net trans-} \\ \text{verse flow} \\ \text{rate out of} \\ \text{melt film} \end{bmatrix}$$

$$\frac{d}{dz}(m_{1z}X) = \omega_1 X - (m_{1x} - m_{fx}) \quad (1)$$

where the leakage flow rate over the flights may be approximated by assuming a linear velocity profile in the clearance

Figure 1 Typical screw extruder geometry

as:

$$m_{fx} = \frac{1}{2} \rho_m V_x c \tag{2}$$

In the case of the lower film all the melt is retained in the film.

$$\frac{d}{dz} [m_{2z}(X + H_s)] = \omega_2(X + H_s) \tag{3}$$

The downstream mass flow rate in the solid bed decreases owing to the loss of material by melting into the surrounding melt films:

$$\frac{dM_{sz}}{dz} = -\omega_1 X - \omega_2(X + H_s) \tag{4}$$

$$M_{sz} = \rho_s V_{sz} X H_s \tag{5}$$

Since the downstream mass flow rate in the melt pool, M_{mz}, is required to make up the total mass flow rate which remains constant along the screw, the overall mass balance may be stated as:

$$M_T = m_{1z}X + m_{2z}(X + H_s) + M_{mz} + M_{sz} \tag{6}$$

Neglecting the shear stress at the interface between the melt pool and the solid bed, the downstream force balance for the bed may be used to relate the pressure gradient to the stresses at the interfaces between the bed and the melt films.

$$H_s X(dp/dz) = \tau_{1z}X - \tau_{2z}(X + H_s) \tag{7}$$

Further analyses of the four regions are necessary to obtain the mass flow rates m_{1z}, m_{1x}, m_{2z} and M_{mz}, melting rates ω_1 and ω_2, and shear stresses τ_{1z} and τ_{2z}.

Analysis of the melt films

The flows in both the upper and lower melt films may be treated as being entirely due to the motion of the solid bed relative to the barrel and screw surfaces. While pressure gradients certainly exist in practice, they are not large enough to significantly affect the velocity profiles in the thin films. It is also assumed that the velocity and temperature profiles within the films are locally fully developed. A typical film cross-section is shown in *Figure 4,* where the relative velocity between barrel or screw and solid bed . is U in the direction denoted by s. The shear stress, τ, in the same direction is independent of y and may be assumed
to be a power-law function of shear rate and an exponential function of temperature[2].

$$\tau = \frac{\mu_0}{\gamma_0^{n-1}} \left(\frac{du}{dy}\right)^n \exp[-b(T - T_0)] \tag{8}$$

where μ_0 is the effective viscosity at a reference shear rate γ_0 and temperature T_0. The temperature profile may be obtained from the energy equation for fully developed flow:

$$k_m \frac{d^2T}{dy^2} = -\tau \frac{du}{dy} \tag{9}$$

The boundary conditions are

$$u = 0, T = T_m \text{ at } y = 0$$
$$u = U, T = T_w \text{ at } y = \delta \tag{10}$$

where T_m is the melting point of the polymer and T_w is the metal wall temperature. This is essentially the problem solved by Martin[13] by a largely analytical technique which may be readily adapted to the present situation[12]. For a given film thickness and relative velocity it is possible to derive parameters such as flow rate, shear stress, temperature gradients at the film boundaries and mean melt temperature.

In the case of the lower melt film the relative velocity, V_{sz}, is in the downstream direction. The main difficulty is in defining the boundary temperature at the screw surface. In the present work axial screw temperature profiles were assumed, based on the observed points at which lower films were formed as the screw temperature exceeded the polymer melting point. The relative velocity in the upper film is V_r (equivalent to U in *Figure 4*) at an angle β to the downstream direction as shown in *Figure 3*. Since melted material is entrained in the direction of V_r, there must be a corresponding increase in film thickness. Consequently δ_1 is really a function of both x and z. In many melting models δ_1 is assumed to be independent of x, which is in good agreement with many experimental observations. While δ_1 must vary across the width of the bed, the variation is often sufficiently small for an average value to be used for analytical purposes. The variation in film thickness in the downstream direction may be substantial, and the present model treats δ_1 as a function of z.

From the analysis of the upper film may be obtained the mass flow rate relative to the bed, m_1, and the shear stress, τ_1, both in the direction of V_r. The required mass flow rate and stress components may therefore be obtained as:

$$m_{1x} = m_1 \sin\beta \tag{11}$$

$$m_{1z} = m_1 \cos\beta + \rho_m \delta_1 V_{sz} \tag{12}$$

$$\tau_{1z} = \tau_1 \cos\beta \tag{13}$$

Analysis of the solid bed

Heat transfer in the solid bed is due to a combination of thermal conduction through the thickness of the bed and downstream thermal convection, and is governed by the following energy conservation equation:

$$\rho_s C_{ps} V_{sz} \frac{\partial T}{\partial z} = k_s \frac{\partial^2 T}{\partial y^2} \qquad (14)$$

with $T = T_m$ at the upper and lower faces of the bed. The thickness of the bed slowly diminishes, an effect which amounts to a convection of material into the melting interfaces which can be taken account of in determining the melting rates as described below. Equation (14) is a parabolic partial differential equation for which standard numerical methods of solution are available. The temperature profile at successive bed cross-sections may be found, hence the temperature gradients at the melting interfaces.

Analysis of the melt pool

Much of the polymer melted on the upper surface of the solid bed is dragged into the melt pool alongside the bed. The flow patterns in this pool region are very difficult to analyse accurately[14]. So long as the size of the pool is small compared to the channel cross-section, however, a simple but rather inaccurate method may be used without serious effects on the usefulness of the overall model. Assuming the melt to be Newtonian, the total mass flow rate in the pool may be found by superimposing the rates due to the drag flows induced by the motion of the barrel and bed relative to the screw, and the pressure flow due to the downstream pressure gradient.

$$M_{mz} = \rho_m W_m H \left\{ \frac{1}{2} V_z F_D(H/W_m) + \frac{1}{2} V_{sz} F_D(W_m/H) - \frac{H^2(dp/dz)}{12\bar{\mu}} F_P(H/W_m) \right\} \qquad (15)$$

where $F_D(H/W)$ and $F_P(H/W)$ are respectively the drag and pressure flow shape factors[2] for flow in a rectangular channel of width W and depth H. The mean viscosity, $\bar{\mu}$, may be evaluated for the mean shear rate in the pool and bulk mean temperature of the melt entering from the upper film.

Determination of the melting rates

The melting rates at the interfaces between the solid bed and melt films may be determined from the known temperature gradients:

$$\omega_1 \lambda_1 = k_m \left(\frac{\partial T}{\partial n_1} \right)_m - k_s \left(\frac{\partial T}{\partial n_1} \right)_s \qquad (16)$$

$$\omega_2 \lambda_2 = k_m \left(\frac{\partial T}{\partial n_2} \right)_m - k_s \left(\frac{\partial T}{\partial n_2} \right)_s \qquad (17)$$

where n_1 and n_2 are the outward normals to the solid bed surface in the two films. Thermal convection in these directions in both the solid and melt may be accounted for by using modified latent heats of fusion.

$$\lambda_1 = \lambda + C_{ps}(T_m - \overline{T}_s) + C_{pm}(\overline{T}_1 - T_m) \qquad (18)$$

$$\lambda_2 = \lambda + C_{ps}(T_m - \overline{T}_s) + C_{pm}(\overline{T}_2 - T_m) \qquad (19)$$

where $\overline{T}_s$, $\overline{T}_1$ and $\overline{T}_2$ are the bulk mean temperatures in solid bed and upper and lower films respectively. The use of these equations assumes that the polymer has a unique

melting point and a definable latent heat of fusion. While this is reasonable for crystalline polymers it is less so for the more amorphous materials. Also it is assumed that the enthalpy is a sufficiently linear function of temperature in the solid and melt regions for mean values of specific heat to be used.

Solution of the overall problem

The mathematical problem to be solved is defined by equations (1), (3), (4) and (7), the remaining equations being used to define the various terms appearing in these simultaneous first-order ordinary differential equations. Various combinations of primary variables may be used, for example δ_1, δ_2, X and p, or m_{1z}, m_{2z}, M_{sz} and p. In the present work the former set was used. The equations may be integrated numerically with the aid of a digital computer to yield the values of both the primary and secondary variables at intervals along the helical path of the screw channel.

The initial conditions required to start the solution procedure are often difficult to define. At the beginning of the feed section of the screw the temperatures of both screw and barrel are below the melting point of the polymer, owing to the cooling normally applied to the feed pocket. The formation of melt films is therefore delayed until the metal surfaces are hotter than the melting point. This normally occurs first at the barrel surface after two or three turns of the screw. Formation of the melt film on the screw usually occurs several turns later, or may not occur at all if the screw is cooled. Accumulation of molten material in the melt pool does not start until the thickness of the upper film exceeds the radial clearance between the screw flight and barrel. In the present work the starting points for the melt films were based on experimental observations. In the absence of such films it is assumed that Coulomb friction governs the relative motion between the solid bed and metal surfaces.

The downstream solid bed velocity, V_{sz}, is obtained as a function of z, and it is assumed that the bed is capable of undergoing the necessary deformation. In practice, excessive acceleration of the bed cannot be sustained and it breaks as described later. Clearly, the present model is inappropriate after break-up of the solid bed has occurred. Also it does not provide a good description of behaviour towards the end of melting when the material is predominantly molten.

EXPERIMENTAL RESULTS AND COMPARISON WITH THE THEORETICAL MODEL

Space considerations forbid the presentation of more than a small sample of the experimental results obtained in the present work[12]. Attention is therefore confined to those results which demonstrate particular aspects of the melting process in practice or the theoretical model used to describe it. The main data obtained from the experiments are the pressure variations with time sensed by the pressure transducers, and sections of the frozen helix removed from the screw showing the regions previously solid and molten.

Pressure profiles

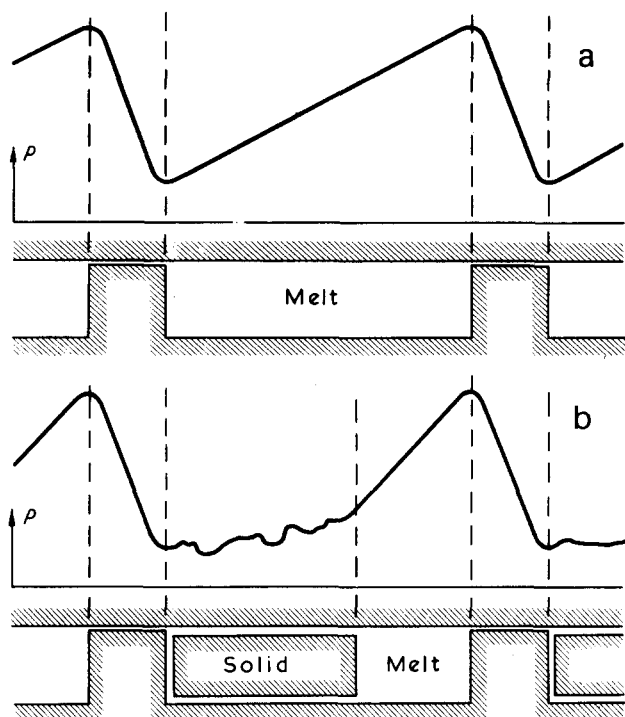
The variation of mean pressure along the screw is considered in the next section, while this section is concerned with variations detected as the screw rotated. *Figure 5* shows typical types of pressure profiles in the absence and


Figure 5 Typical pressure profiles in (a) the absence and (b) the presence of a solid bed

Figure 6 Results and theoretical predictions for an experiment with granular LDPE. ——, theoretical predictions. Screw had a compression ratio of 4.0 over an axial length of 10 turns (diameters), and $c = 0.16$ mm. Barrel temperature = 150°C, $N = 40$ rev/min, $M_T = 5.0$ kg/h

presence of a solid bed. The finite areas of the sensing diaphragms of the transducers had the effect of rounding any sharp pressure peaks or troughs. In the metering section of a screw where the polymer is completely molten the profile took the form of a relatively smooth saw-tooth shape as shown in *Figure 5a*. An approximately uniform

pressure gradient was developed in the melt in the channel and a correspondingly steeper gradient was observed in the much narrower flight clearance. In the presence of a solid bed the behaviour was much less regular. Over the bed itself the pressure generally fluctuated more severely and randomly, presumably owing to the passage of individual granules past the diaphragm (powdered feedstocks gave much smoother traces). The mean pressure either remained reasonably uniform as indicated in *Figure 5b* or rose significantly before the melt pool was reached. Over the melt pool the trace became smoother and the pressure gradient greater.

In principle it is possible to distinguish between melt and solid in the screw channel from the pressure traces alone, based on a combination of change of pressure gradient and smoothness of the profile. This facility is particularly useful on production machines where it is not possible to stop and extract the screw.

Solid bed profiles and pressure development

There are at least three ways of comparing measured and theoretical extruder melting performance: in terms of either relative mass flow rates of solid and melt at particular positions along the screw, relative widths or relative cross-sectional areas. The first of these is unsuitable as it requires a knowledge of the solid bed velocity which is not measured. Of the other two, the relative width criterion is easier to apply and is the one used here. Melt film thicknesses are difficult to measure with sufficient accuracy for comparison with the theoretical model.

Figures 6, 7 and *8* show experimental results and the corresponding theoretical predictions for three tests on LDPE granules, LDPE powder and plasticized PVC granules.

Figure 7 Results and theoretical predictions for an experiment with LDPE powder. ——, theoretical predictions. Screw had a compression ratio of 4.0 over an axial length of 10 turns (diameters), and $c = 0.16$ mm. Barrel temperature = 150°C, $N = 80$ rev/min, $M_T = 13.3$ kg/h
Figure 8 Results and theoretical predictions for an experiment with plasticized PVC granules. ——, theoretical predictions. Screw had a compression ratio of 2.25 over an axial length of 10 turns (diameters), and $c = 0.16$ mm. Barrel temperature = 160°C, $N = 80$ rev/min, $M_T = 22.0$ kg/h

Experimental results are only shown for relative solid bed widths at half-turn intervals along the screw, and mean pressures measured at a limited number of axial locations. The agreement between the measured and predicted solid bed widths is good, particularly during the early stages of melting where the theoretical model is most applicable. The significance of the experimental points showing zero solid bed width in the case of LDPE (*Figures 6* and *7*) is discussed later. It is worth noting that the end of melting occurs much more rapidly in the case of PVC (*Figure 8*) than for LDPE, owing to the much lower latent heat of fusion. Once the average temperature of the PVC solid bed is near its melting point very little more heat is required to completely melt it.

The predicted melt film thickness profiles suggest that the upper film grows rapidly at first until the rate of melting is balanced by the rate at which melt is swept into the pool, when the thickness stabilizes (at about twice the radial clearance between the screw flight and barrel). In both the LDPE experiments there is a subsequent rapid reduction in upper film thickness associated with high solid bed acceleration. The mass flow rate in the upper film changes relatively slowly, so an increase in bed velocity must be accompanied by a reduction in film thickness. The lower melt film thickness, on the other hand, shows a more gradual but sustained rate of increase, all the melted material being retained in the film. The predicted lower film thicknesses tend to be rather greater than those observed in practice. This is probably due to the choice of temperature boundary condition at the screw. Estimated screw temperature profiles were employed which took no account of the necessary heat conduction along the screw.

The agreement between the predicted and measured pressure profiles is abnormally good for the LDPE experi-

ments and poor for the PVC. Taking into account other results not reported in detail here, the predicted axial pressure profiles are rather unreliable, although this appears to have very little effect on the quality of the solid bed profile predictions. The computed pressure gradients depend mainly on the melt pool analysis and the force balance on the solid bed. The latter depends on the shear stress in the lower film and hence on the film thickness which, as already mentioned, tends to be overestimated. Also, the melt pool analysis is inaccurate for non-Newtonian melts.

Solid bed velocities

Figures 6 to *8* suggest that solid bed velocities do not remain constant along the screw, as has been assumed by previous workers, nor are they generally subject to uniform acceleration. While in the case of PVC the solid bed velocity increased fairly steadily along the screw, with LDPE it tended to remain nearly constant until a region of high acceleration was reached. The differences observed between the two types of materials may be due as much to the difference in screw design as to the materials themselves.

Bed break-up and surging

In many of the experiments breaks in the solid bed normal to the screw flights were observed, usually in the compression section of the screw or at the beginning of the metering section. For example, *Figures 6* and *7* show bed breaks at 0.9 m and 1.0 m along the channel respectively, whereas in *Figure 8* the bed was continuous. Both these and other results show a very high correlation between the onset of bed break-up and high bed acceleration. Breaks generally occurred at regular intervals giving separate pieces of solid bed with lengths between about one and four times, their widths, with regions of melt between. Further evidence for high bed acceleration being the cause of bed break-up is provided by the fact that the lengths of the melt regions between pieces of bed increased as they moved downstream. Since melting was still largely confined to the upper and lower melt films, this suggests acceleration of the pieces.

In the theoretical model no account is taken of the deformation characteristics of the solid bed beyond conserving its mass. This is reasonable so long as the bed remains compacted and continuous, and under these conditions the model appears to be equally applicable to all types of materials in either granular or powder form. If the stresses acting on the solid bed were analysed in detail, a fracture criterion such as the presence of tensile stress might be applicable. In practice, however, high bed acceleration provides an adequate criterion for bed break-up.

Bed break-up in extruders is particularly important because it gives rise to a form of pressure surging. In the present experiments the measured pressures, particularly after bed break, fluctuated at frequencies of the order of 5 to 10 times lower than the variations of the form shown in *Figure 5*, associated with the screw rotation. This lower frequency could be correlated with the frequency with which bed breaks occurred[12].

Surging associated with bed break-up has been observed by other workers. For example, Klein[15] reported both this type and another form associated with 'plugging' or wedging of the solid bed in the taper of the screw channel. This latter phenomenon was not observed in the present experiments which used relatively gently tapered screws. In general, surging in extruders appears to be of three main types: (i) variations associated with the rotation of the
$H = 2.03$ mm

$H = 8.13$ mm

Figure 9 Measured pressure profiles and theoretical solid bed velocities for two experiments with granular polypropylene showing the effects of screw cooling. Screw as in *Figures 6* and *7*. Barrel temperature = 250°C, N = 80 rev/min, M_T = 10.7 kg/h (---, uncooled) and 8.6 kg/h (——, cooled)

screw and occurring at the same frequency; (ii) fluctuations due to instabilities in the feeding or melting processes and occurring at rather lower frequencies; (iii) very slow variations of temperatures and pressures over periods of minutes or even hours may be caused by instabilities in the temperature control systems.

Effects of screw cooling

It can be shown, both experimentally and theoretically, that rapid bed acceleration, and hence break-up, does not normally occur in the absence of a melt film between the bed and screw. One way to prevent the formation of this film is to cool the screw. *Figure 9* shows measured pressure profiles and predicted solid bed velocity profiles for two experiments with polypropylene, one with and the other without cold water cooling on the screw. In the case of the cooled screw no lower melt film was formed until melting was nearly complete: the predicted solid bed velocity is nearly constant and the bed was unbroken. With the uncooled screw rapid bed acceleration and break-up occurred. The pressures generated during melting were also much lower, which accounted for the lower output, a lower delivery pressure being available to force melt through the die.

CONCLUSIONS

The present theoretical model for the melting of thermoplastics in single screw extruders is an improvement on previous models in that it allows for the formation of a melt film between the unmelted solid bed and the screw, also for the downstream velocity of this bed to vary. It provides adequate predictions of melting behaviour in terms of the reduction in the proportion of solids present at various positions along the screw. It also provides a

simple means of predicting when break-up of the solid bed is likely to occur, namely when the bed is subject to high acceleration. In its present form the model does not provide very accurate predictions of pressure generation although this does not appear to impair its ability to predict melting rates.

Changes in the theoretical model are required to predict melting behaviour after bed break-up, although if this occurs at all it tends to occur towards the end of melting. There is also considerable scope for improvement in the analysis of flow in the melt pool alongside the bed, particularly if the model is to give accurate predictions in the later stages of melting. As has been suggested previously, solid bed break-up gives rise to a form of pressure surging at a frequency lower than that of the screw rotation. One method of controlling the surging is to apply screw cooling which prevents the formation of a melt film on the screw surface, which in turn inhibits bed acceleration. Screw cooling, however, also has the effect of reducing both pressure generating capacity and output from the extruder.

NOMENCLATURE

b	temperature coefficient of viscosity
c	radial clearance between screw flight and barrel
C_{ps}, C_{pm}	specific heats of solid and melt
D	diameter of the barrel
F_D, F_P	drag and pressure flow shape factors
H	depth of screw channel
H_s	depth of solid bed
k_s, k_m	thermal conductivities of solid and melt
M_{mz}	downstream mass flow rate in melt pool
M_{sz}	downstream mass flow rate in solid bed
M_T	total mass flow rate in screw channel
m_{fx}	leakage mass flow rate per unit length of flight
m_1	mass flow rate per unit width in upper melt film
m_{1x}	transverse mass flow rate per unit length of solid bed, in the upper melt film
m_{1z}, m_{2z}	downstream mass flow rates per unit bed width in the upper and lower melt films
N	screw speed
n	power-law index
n_1, n_2	directions of outward normals to solid bed in the upper and lower melt films
p	pressure
s	direction of relative boundary motion in a melt film
T	temperature
T_m	melting point temperature
T_w	boundary wall temperature
T_0	reference temperature
$\overline{T_s}$	bulk mean temperature in the solid bed
$\overline{T_1}, \overline{T_2}$	bulk mean temperatures in upper and lower melt films
U	relative boundary velocity in a melt film
u	melt velocity in a melt film
V_r	velocity of barrel relative to the solid bed
V_{sz}	downstream velocity of the solid bed relative to the screw
V_x, V_z	transverse and downstream velocities of the barrel relative to the screw
W	width of the screw channel
W_m	width of the melt pool
X	width of the solid bed
x, y, z	Cartesian screw channel coordinates
β	angle between V_r and the z axis

γ_0	reference shear rate
δ	thickness of a melt film
δ_1, δ_2	thicknesses of upper and lower melt films
θ	helix angle of the screw
λ	latent heat of fusion
λ_1, λ_2	modified latent heats of fusion for the upper and lower melt films
μ_0	effective viscosity at γ_0 and T_0
$\bar{\mu}$	mean viscosity in the melt pool
ρ_s, ρ_m	densities of solid and melt
τ	shear stress in a melt film
τ_{1z}, τ_{2z}	downstream shear stresses in upper and lower melt films
ω_1, ω_2	melting rates per unit area in upper and lower melt films

Broadline n.m.r. studies of ultra-high modulus polyethylenes

J. B. Smith, A. J. Manuel and I. M. Ward

Department of Physics, University of Leeds, Leeds LS2 9JT, UK
(Received 8 April 1974; revised 7 June 1974)

Broadline nuclear magnetic resonance (n.m.r.) measurements have been made for a range of isotropic and drawn high density polyethylene materials with different molecular weight distributions and three well defined thermal treatments during preparation. For the drawn materials the dependence of the n.m.r. spectra on the orientation of the static magnetic field with respect to the draw direction has been studied with respect to both line shape and second moment variation. The spectra in general show three component lines with distinctly different line widths. The broad component shows a high degree of molecular orientation in the drawn samples and can be satisfactorily assigned to the crystalline regions of the polymer. It is proposed that the intermediate component corresponds to high molecular weight molecules which interconnect the crystalline regions and are sufficiently constrained to allow motion about the chain axis only. This component shows an increasing degree of molecular orientation and decreases in intensity with increasing draw ratio. Finally, there is an isotropic narrow component, which is attributed to the mobile fraction. From its intensity in samples of different molecular weight this fraction can be associated with low molecular weight material and the ends of molecules which are rejected from the crystalline regions or the rigid fraction in a drawn sample.

INTRODUCTION

The composite nature of the broadline nuclear magnetic resonance (n.m.r.) spectrum of crystalline polymers has been discussed in many publications[1-5] since it was first reported in low density polyethylene and polytetrafluoroethylene (PTFE) by Wilson and Pake[6]. In isotropic polymers, two components have sometimes been observed, a broad component corresponding to a rigid lattice signal, and a narrow component corresponding to a mobile fraction. To a first approximation, these broad and narrow components could be attributed to molecules in the crystalline and non-crystalline regions of the polymer respectively, although the exact details of this depended very much on defining the morphology of the polymer and the exact meaning of the term 'crystallinity'.

In some oriented polymers[7], and in polymer crystals[8], an additional line of intermediate width has also been observed, to give a signal with three distinguishable components. This remarkable result was first obtained by Hyndman and Origlio for oriented high density polyethylene[7], and it was suggested that the intermediate line was due to oriented amorphous material and imperfect crystalline structures resulting from the drawing process. In polyethylene crystals, Fischer and Peterlin[8] also observed a third component of similar line width, which they attributed to molecules undergoing coherent rotational motions about the chain axis. Bergmann and Nawotki[5] analysed the n.m.r. spectra of a number of isotropic polyethylene samples and found that the spectra could most satisfactorily be decomposed by assuming that they represented the superposition of three lines arising from three phases of different mobility in the samples.

There is also much to be gained from studying the aniso-

tropy of the n.m.r. spectra of oriented polymers. This anisotropy relates to the distribution of molecular orientations[9,10], and where there is motion, can also give considerable insight into the molecular nature of these motions[11,12], and hence structural information concerning the oriented polymer.

In this paper we describe a detailed study of the anisotropy of the composite signals from a series of linear polyethylenes of different structure. The preparation and mechanical properties of four of these materials which have been studied in detail has been discussed in a previous publication[13], where it was shown that oriented polymers of very high stiffnesses can be produced. In addition some measurements have been made on two samples of materials of high molecular weights. There is very considerable interest in gaining an understanding of the structure of such materials. It will be shown that broadline n.m.r. in conjunction with X-ray diffraction can throw light not only on the final structures, but also on the nature of the processes which produce these structures.

EXPERIMENTAL

Preparation of samples

Since the full details and methods used to prepare the samples have been discussed in a previous publication[13], only a summary will be given here. Following the previous work, four commercial grades of Rigidex linear polyethylene homopolymer (BP Chemicals Int. UK Ltd) listed in *Table 1* as samples 1 to 4 were selected for examination. We are indebted to Mr J. M. Squire (BP Research and Development Dept., Grangemouth Division, Grangemouth, UK) for the molecular weight characterization shown in the

Table 1 Molecular weights of polyethylene samples examined

Sample No.		$\overline{M_n}$	$\overline{M_w}$
1	Rigidex Grade 9	6 060	126 000
2	Rigidex Grade 50	6 180	101 450
3	Rigidex Grade 25	12 950	98 800
4	Rigidex Grade 140-60	13 350	67 800
5	Hostalen GUR		3.5 to 4 x 10^6
6	R.N.H.		6 to 8 x 10^6 (est.)

Table. The two high molecular weight samples used were Hostalen GUR (Hoechst AG, Frankfurt (Main), W. Germany) and a sample kindly provided by Professor R. N. Haward (Department of Chemistry, University of Birmingham). These samples are numbered 5 and 6 in *Table 2*. Sample 6 is referred to by the initials R.N.H. Sheets of the polymers of thickness about 0.5 mm were made by compression moulding at 160°C. The sheets were either allowed to cool slowly to 110°C before being quenched in water (notation 160/110/W), directly quenched in water at room temperature (notation 160/W) or allowed to cool slowly to room temperature (notation 160/RT).

Some of each sheet so prepared was kept aside for the n.m.r. investigation of the isotropic sheet. The remainder was used to prepare oriented material in the following manner.

Dumbbell shaped samples with gauge dimensions 2.0 X 0.5 cm were cut from the sheets and drawn on an Instron tensile testing machine at a cross-head speed (*CS*) of 10 cm/min where possible, otherwise at 1 cm/min. The draw ratio, λ, was measured from the separation of small ink dots marked at intervals of 1 mm on the undrawn specimen. Since λ varied slightly with drawing time, its value could be controlled to ±5%. For Rigidex 9 samples of draw ratio 9 only were obtained; for other Rigidex materials draw ratios of 11, 19 and 30 were obtained. The high molecular weight samples (5 and 6 of *Table 1*) showed a markedly different drawing behaviour from the Rigidex materials. The former draw with little or no sign of a neck and the drawn material deforms elastically if the Instron cross-head is allowed to continue its motion. The Rigidex materials develop the usual neck and any attempt at further extension invariably results in the sample breaking.

Table 2 summarizes the preparation procedures for all the samples.

N.m.r. experimental procedure

The n.m.r. investigation of these samples was carried out using a Varian DP 60 spectrometer operated at 56.4 MHz. A time-averaging computer was used to add together the signals from several successive sweeps through a spectrum to improve the signal to noise ratio.

Each drawn sample consisted of a thin strip 10 cm long and 1.0 to 1.5 mm wide, depending upon the draw ratio. Strips of the polymer to be investigated were examined and sections with a uniform draw ratio were cut and packed into a slot machined in 6 mm diameter PTFE rod, so that the draw directions of all the pieces were parallel to each other and perpendicular to the PTFE rod. The orientation of the specimen could be varied by rotating the PTFE rod in the n.m.r. spectrometer coil, the angle between the sample draw direction and the static magnetic field being measured by a goniometer head attached to the rod. The angle measured

by the goniometer head was called γ' and spectra were recorded for the values of γ' in steps of 10° between −30° and +120°. Since the measured angle γ' usually differed by a small systematic error from the true angle γ between the static magnetic field and the sample draw direction, a correction was applied so that the variation of the second moments of the spectra with γ showed symmetry about 0° and 90°. The values of second moments were corrected for the modulation amplitude of 0.62 G, using the Andrew correction[14].

For the isotropic specimens only one spectrum was recorded. A lower modulation amplitude of 0.25 G was used to try to resolve a narrow component.

Wide angle X-ray diffraction measurements

Wide angle X-ray diffraction measurements (WAXS) were used to obtain a direct measure of the orientation of the crystalline regions of the Rigidex samples. As these samples possess fibre symmetry, this can be done most conveniently by observations on the 002 reflection (for previous work of this nature see, for example, ref 15). In this investigation the measurements were carried out with a Siemens Type F wide angle X-ray diffractometer. A sample of length 1 cm was mounted horizontally using Plasticene, and its position adjusted until it was positioned centrally on the goniometer and exactly perpendicular to the X-ray beam. The value of the Bragg angle for the 002 reflection was found by scanning through the diffraction peak at a rate of 0.1°/min. The detector was then fixed at this Bragg angle and the sample rotated in ⅛° steps. At the end of each step the detector switched on and counted for 200 sec, printing out the count rate at the end. Each step brought different 002 planes into a position to satisfy the diffraction conditions, and the count was therefore directly proportional to the number of 002 planes involved. The appropriate orientation functions were then evaluated from the count rate as a function of angle. Errors were evaluated on the basis that the standard deviation of an X-ray count is simply the square root of that count; they were minimized by counting for a long time (200 sec) at the end of each step.

Table 2 Preparation of samples
CS: Instron cross-head speed (cm/min); t_D: drawing time (min)

Sample	160/W	160/RT	160/110/W

RESULTS

General nature of the n.m.r. results

Figures 1a–1d show the room temperature n.m.r. derivative spectra for the isotropic specimens of the four Rigidex materials following three types of thermal treatment after compression moulding. The two Rigidex 50 specimens which were allowed to cool slowly for part of the time after moulding (160/110/W and 160/RT) show a very narrow line in addition to the broad and intermediate components usually seen in isotropic polyethylene. We believe that this line is present in the spectra of the three other Rigidex materials

to a lesser extent, but that it is swamped by the intermediate component. The spectra for the static magnetic field at $\gamma = 0$, 45 and 90 degrees for the drawn materials are shown in *Figures 2a–2d*. The spectra of the isotropic and drawn materials may be compared directly since they have been normalized to give unit (integrated) intensity. The three components are noticeably better resolved in the $\gamma = 0$ spectra of the drawn materials and the narrow component becomes clearly visible in the spectra of Rigidex 50, 25 and 140-60. The spectra of these three materials also show a decrease in the intensity of the intermediate line and an increase in the intensity of the narrow line with increasing draw ratio. However, it should be noted that even at its maximum value the narrow line represents the contribution of only a small fraction of the material.

The existence of three components of differing widths points to the presence of material of three different degrees of molecular motion, both in the isotropic and drawn samples.

The broad component is readily identified as being associated with the crystalline regions and we will show that the observed second moments of the spectra are consistent with this interpretation. The very narrow line is also clearly associated with non-crystalline material. It is the intermediate component which is less easy to be completely certain about. It shows some angular dependence, and has a second moment in a range consistent with hindered rotation of the chain molecules as discussed in detail later.

The spectra were therefore analysed along the following lines. First, the three components can be most readily separated for $\gamma = 0$, and this gives a good value for the mass fraction of the three components. Secondly, the total second moment in each case was divided into contributions from the crystalline and intermediate regions. (The very narrow line makes a negligible contribution to the second moment.) Decomposition of the spectra at various angles, γ, enabled orientation functions for the intermediate component to be obtained, on the basis that this arose from molecules undergoing motion about the chain axis, either as chain rotations or torsional vibrations, which can be

The abscissae are in G and the ordinates in arbitrary units normalized to the same integrated intensity. The scale shown is purely to indicate the height of the maxima in the undrawn materials

shown to be a reasonable assumption. The procedures outlined above will be described in detail in the following paragraphs.

The spectra for the materials of high molecular weight (samples 5 and 6 of *Table 1*) are shown in *Figure 3*. The derivative spectra of these materials before drawing show a much smaller broad component than the materials discussed earlier, and a narrower component of considerably greater intensity which overlaps the regions in which the narrow and intermediate components of the Rigidex materials occur. The main effect of drawing is to reduce the height and broaden the narrower line giving it a form closer to that of the intermediate line of the Rigidex materials.

Determination of the crystalline, intermediate and mobile mass fractions of the specimens

The proportions of crystalline, intermediate and mobile material in each sample were determined from their spectra. The crystalline mass fraction f^c is given by the ratio of the integrated intensity of the crystalline component to the total integrated intensity. The mass fractions of the intermediate (f^i) and mobile (f^m) material were determined in a similar manner. The spectra of the materials were each decomposed into their three components as accurately as possible, those for γ = 0 being used for the drawn materials because they show the best resolution of the components.

Separation of the narrow components in the drawn material is straightforward. In the isotropic samples it is somewhat more difficult, but the narrowness of the line still ensures that the errors involved will be small. Separation of the broad component from the remainder of the spectrum was, however, rather more difficult. In the isotropic case the room temperature spectrum of an isotropic sample of Rigidex 075-60 grade (*Figure 4*) prepared by cooling from the melting point (251°C) at a pressure of 5.2 kbar was used as a guide. In this material of high crystallinity the broad component is dominant and can easily be separated to give the room temperature spectrum of an isotropic aggregate of crystalline material. The line shape obtained in this way agreed well with that given by Bergmann and Nawotki[5] and used by them in their work on the decomposition of the spectra of a number of isotropic polyethylene specimens. This shape was used in the decomposition of the spectra of the isotropic Rigidex specimens by matching it to the outer part of the experimental spectrum where the other line components were expected to make no contribution, using a least squares computation. In the drawn case use was made of the results of the X-ray measurements which showed that the crystalline regions of the materials were virtually

fully oriented for the range of draw ratios under consideration. It was therefore possible to use an approximate theoretical calculation[16] (see Appendix and *Figure 4*) of the rigid lattice line shape for the crystalline material as a guide to decomposing the spectral lines. The theoretically calculated shape was modified to take account of the modulation amplitude and allowance was then made for the effect of some motional narrowing in matching the outer parts of the broad component to the experimental spectrum by the least squares procedure. It was assumed that motion present in the crystalline regions at room temperature would not change the line shape qualitatively. This assumption is most likely to be true for γ = 0. The line shape which gave the best fit in decomposition of the γ = 0 spectrum for the 140-60 grade at λ = 30, for which the best resolution occurred, is also shown in *Figure 4*, and this shape was used in the decomposition of the remaining γ = 0 spectra. The doublet structure is partly resolved for the γ = 0 direction because for all the CH_2 groups the internuclear vector joining a pair of protons is closely perpendicular to the direction of the static magnetic field.

Evaluation of the angular dependence of the second moment of the crystalline component

The variation with γ of the second moments of the crystalline components of the spectral lines was evaluated from the decomposition of a series of spectra of the Rigidex 140-60 grade for draw ratio 30. This specimen showed the most highly resolved broad component, and it was assumed that because the X-ray results showed the crystalline regions of all the drawn materials to be virtually fully oriented, the second moment variation of the broad component obtained from the spectra of this specimen would be typical of all the other drawn samples. The decompositions were of necessity rather arbitrary, especially for values of γ around 45°. However, the shape of the broad component for an assembly of fully oriented crystals was calculated for each required value of γ (see Appendix) and used as a guide in the decom-

Figure 4 Derivative wideline n.m.r. line shapes for crystalline polyethylene: —·—·—, Rigidex 075-60 prepared by cooling from the melting point of 251°C at a pressure of 5.2 kbar; ...., modification assumed for isotropic crystalline material in the decomposition of the spectra of *Figure 1*; —— rigid lattice line shape for the static magnetic field along the c axis as calculated in the Appendix; ———, line shape giving the best fit to Rigidex 140-60, λ = 30 for γ = 0 in *Figure 2*, after allowing for modulation broadening and smoothing and some motional narrowing
Figure 5 Variation of the second moment ($\langle \Delta H^2 \rangle^c$ for crystalline high density polyethylene with full c axis orientation along the draw direction and transverse isotropy: – – –, determined from decomposition of spectra of Rigidex 140-60 at draw ratio $\lambda = 30$; –––, calculated by McBrierty and Ward[9] for a rigid polyethylene lattice at $-196°C$

positions. Again it was assumed that motion present in the crystalline regions at room temperature would not change these line shapes qualitatively. Each decomposition was checked by verifying that the ratio of the integrated intensity of the broad component to the total integrated intensity remained constant and equal to the crystalline mass fraction of the specimen.

The variation of second moment of the fully oriented crystalline material obtained in this manner is shown in *Figure 5*.

Determination of orientation distribution functions for the intermediate material

The distribution of orientations of the molecular axes of the material giving rise to the intermediate line may be characterized by the values of $\langle \cos^2 \Delta \rangle^i$ and $\langle \cos^4 \Delta \rangle^i$ where Δ is the angle between the molecular axis and the draw direction of the sample. These two quantities were determined from the variation of the second moment of the intermediate component of the spectra with γ. Since the narrow component arising from the highly mobile fraction gives negligible contribution to the second moment, the second moment of the intermediate component $\langle \Delta H^2 \rangle^i$ can be obtained from the total second moment $\langle \Delta H^2 \rangle$ and the second moment of the broad component $\langle \Delta H^2 \rangle^c$:

$$f^i \langle \Delta H^2 \rangle^i = \langle \Delta H^2 \rangle - f^c \langle \Delta H^2 \rangle^c \qquad (1)$$

The variation with γ of the second moments for the four Rigidex samples is shown in *Figure 6* and the corresponding $\langle \Delta H^2 \rangle^i$ deduced from them using the data of *Figure 5* and equation (1) are shown in *Figures 7a–7d*.

The shapes of the curves of *Figure 7* show qualitative similarity with the theoretical calculations of Folkes and Ward[12] for the second moment variation of an assembly of oriented chains undergoing a rotational motion about their axis. The expression obtained by Folkes and Ward[12] may be written:

$$\langle \Delta H^2 \rangle = (G/32) S \{ (11 - 30\cos^2 \gamma + 27\cos^4 \gamma) +$$

$$\langle \cos^2 \Delta \rangle (252 \cos^2 \gamma - 270 \cos^4 \gamma - 30) +$$

$$\langle \cos^4 \Delta \rangle (315 \cos^4 \gamma - 270 \cos^2 \gamma + 27) \} \qquad (2)$$

where S is a lattice sum given by:

$$S = \frac{1}{N} \sum_{j>k} r_{jk}^{-6} (3\cos^2 \theta_{jk} - 1)^2 \qquad (3)$$

in which N is the number of protons over which the sum is taken, r_{jk} the distance between protons j and k, θ_{jk} the angle between the vector r_{jk} and the c axis of the crystalline material and $G = 3/2 [I(I + 1)g^2 \mu_n^2]$. I is the nuclear spin number, g the nuclear g factor and μ_n the nuclear magneton. The present treatment follows closely that adopted by McBrierty and Ward[9], and Folkes and Ward[12]. The expression (3) for S is identical to that quoted in these papers, although the factor $1/N$ was erroneously omitted previously.

The intramolecular contribution to the lattice sum S for

Figure 7 Second moments $\langle \Delta H^2 \rangle^i$ of the intermediate components of the drawn samples of Rigidex high density polyethylene as function of orientation angle γ, deduced as described in the text. (a) Rigidex 9, $\lambda = 9$; (b) Rigidex 140–60; (c) Rigidex 25; (d) Rigidex 50. –––, draw ratio $\lambda = 11$; ...., draw ratio $\lambda = 19$; –·–·–, draw ratio $\lambda = 30$

a system of rotating chains in a polyethylene crystal has been evaluated using (3) as 0.0321. This value has been reduced to 0.030 in our calculations to allow for other motions such as vibrations excited at room temperature. This is consistent with the previous work, but the actual value is approximately one-half that quoted in ref 12. This is because in the earlier papers[9,12] the lattice sums calculated for the two non-equivalent protons of polyethylene have been added together instead of averaged.

In the actual computation, the lattice sum is calculated for N protons on a crystalline lattice with n non-equivalent positions, i.e. N/n of each type. The term in the Van Vleck second moment formula:

$$\frac{1}{N} \sum_{k>j} r_{jk}^{-6}(3 \cos^2 \theta_{jk} - 1)^2$$

may thus be written as:

$$\frac{1}{2} \frac{N}{n} \frac{1}{N} \sum_{m=1}^{n} \sum_{k \neq m} r_{mk}^{-6}(3 \cos^2 \theta_{mk} - 1)^2$$

$$= \frac{1}{2} \frac{1}{n} \sum_{m=1}^{n} \sum_{k \neq m} r_{mk}^{-6}(3 \cos^2 \theta_{mk} - 1)^2$$

where the index m runs over the n non-equivalent protons. This means that for each non-equivalent proton m the sum

$$\sum_{k \neq m} r_{mk}^{-6}(3\cos^2 \theta_{mk} - 1)^2$$

is found and one-half of the average of these sums gives the required lattice sum. We have elaborated on this point because the exact connection between the Van Vleck second moment formula and its computation has led to some confusion in previous papers. In one of these[12] it is even incorrectly stated that N in the second moment formula refers to the number of non-equivalent protons.

Equation (2) was fitted to the experimental results of *Figure 7* by a least squares procedure, to give values of $\langle \cos^2 \Delta \rangle^i$ and $\langle \cos^4 \Delta \rangle^i$ for the intermediate fraction of the material. The values of these parameters are shown in *Table 4*.

DISCUSSION

Figures 6a–6d show the variation of the total second moments with γ for the drawn Rigidex materials at different draw ratios. There is a very clear increase in the total second moment at all orientations as the draw ratio is increased. For any given γ, the second moment of the broad component in the drawn materials will be independent of draw ratio, because the X-ray data show that the crystalline regions are very close indeed to full orientation, even at the lowest draw ratios examined. Moreover, the second moment of the very narrow component is negligible. The increase in total second moment with increasing draw ratio must therefore be due to a change in the fraction of the intermediate component.

We will now attempt to give a more detailed analysis by considering the orientation and proportion of each component separately.

Broad component

As previously described, the starting point for analysing the broad component was to fit theoretically calculated line shapes for a fully oriented lattice to the room temperature spectra of the Rigidex 140-60 for $\gamma = 30$. The second moment variation evaluated from these decompositions is shown in *Figure 5* together with the theoretical variation for a fully oriented rigid lattice using the results of McBrierty and Ward[9] for high density polyethylene. The two curves are quite similar, and the observed reduction in second moment with increasing γ is characteristic of the onset of motion about the chain axis. This rotation is, however, clearly very restricted, which is consistent with the view that 'gear wheel' hindrances[12] prevent full rotation below 60°C. The broad component can therefore be confidently attributed to the crystalline regions of the polymer.

The values of $\langle \cos^2 \Delta \rangle^c$ and $\langle \cos^4 \Delta \rangle^c$ characterizing the orientation of the crystalline regions obtained from WAXS measurements are given in *Table 3*. There is clearly a high degree of orientation in all the drawn specimens so that the line shapes of the components of the spectra due to the crystalline fractions are effectively the same. The mass fractions, f^c, of the crystalline material obtained from the n.m.r. spectra are also given in *Table 3*. In the drawn materials there is a steady increase in crystalline mass fraction with increasing draw ratio. Although we believe that this is a genuine increase in crystallinity, it is possible that some

chains are rigid and fully extended without being incorporated into the crystalline lattice.

It can be seen from *Table 3* that the crystalline mass fraction of the drawn samples correlates with the draw ratio, and not with the crystalline mass fraction of the isotropic starting material. For example, the highest level of crystalline mass fraction amongst the isotropic sheets is to be found in these materials allowed to cool slowly from 160°C to room temperature, whereas amongst the drawn samples it is to be found at the highest draw ratios for the 140-60 and 50 grades. This would seem to imply that, as far as crystallinity is concerned, the drawn materials do not retain any direct memory of the initial isotropic material from which they were drawn. This would be consistent with the morphological evidence that a complete breakdown of the initial morphology takes place when material is drawn to very high draw ratios.

Intermediate component

In discussing the results for the intermediate component it is necessary to consider whether our knowledge of the crystallization behaviour of polyethylene can throw any light on the nature of the intermediate component in the isotropic material. Crystallization studies on fractionated samples of linear polyethylene[17] indicate that the half life for crystallization as a function of molecular weight shows a minimum value at a molecular weight of about 20 000. This minimum is most pronounced for crystallization temperatures of ~110–120°C. If we accept that in an unfractionated sample such considerations also apply[13], then particularly in the case of samples 160/110/W, the broad crystalline component will consist primarily of molecules of intermediate molecular weight. It is plausible to associate the narrow line with those molecules of low molecular weight, which do not crystallize. These molecules would be expected to be highly mobile; consequently this component is narrow and isotropic even in the drawn materials.

The intermediate component can then be associated with the high molecular weight molecules. It is quite possible that parts of these molecules are included in the crystalline regions, so that the intermediate component arises from interlamellar material. Such material would consist of molecular chains whose ends were constrained, their degree of mobility being greater than that of the crystalline regions but much less than that of the mobile fraction. The n.m.r. component from such molecules would be isotropic and of

intermediate linewidth. On drawing, these molecules would become oriented towards the draw direction to an extent depending on the draw ratio. If we accept that the intermediate component corresponds to high molecular weight molecules which are sufficiently constrained by the crystalline material present to allow motion about the chain axis only, the following tentative explanation of effect of draw ratio can be put forward.

The drawing process decreases the proportion of intermediate component (*Table 4*) and correspondingly increases that of the broad (*Table 3*) and narrow components (*Figure 2*). This suggests that a proportion of the high molecular weight chains now become rigid. This probably occurs by their becoming incorporated in the crystalline regions although it is possible that some chains are fully extended and held under stress in a crystalline structure with some imperfections.

The drawing process also increases the orientation of the high molecular weight molecules, i.e. the intermediate component (*Table 4*), this increase being greater for the narrower molecular weight distribution. This result is to be anticipated on purely geometrical grounds, since a given degree of stretching would be expected to produce greater overall orientation in the case where the structure is more homogeneous. The orientation of the intermediate material appears to approach a limiting value at high draw ratios, and it is possible to speculate that this is the limiting degree of orientation possible in these structures by drawing processes alone. Any further orientation could only take place by a recrystallization process, since attempts to produce further alignment and pulling out of molecules will only initiate fracture of the material.

Narrow component

Inspection of *Figures 2a–2d* shows that the isotropic narrow component, which is attributed to the mobile fraction, increases markedly with increasing draw ratio in the range from draw ratio 9 to 30. The magnitude of the narrow component is also greater in the samples with lower number-average molecular weight. These results are consistent with the assignment of the mobile fraction to the low molecular weight material which does not crystallize during the cooling or quenching processes, when the isotropic sheets are produced. The increase in the narrow component with increasing draw ratio is also consistent with the breakdown of the initial morphology on drawing. It suggests that both

low molecular weight material and the ends of molecules can be rejected from the crystalline regions or the rigid fraction in a drawn structure.

In the isotropic samples the narrow and intermediate components are only separated in the case of sample 2. Now the intensity of the narrow component relates to $\overline{M_n}$, and increases as $\overline{M_n}$ decreases. The intensity of the intermediate component on the other hand, relates to $\overline{M_w}$ and increases as $\overline{M_w}$ *increases*. We therefore require a broad distribution as well as a low value of $\overline{M_n}$ to separate the two components, and this situation is best achieved in our samples by sample 2.

High molecular weight materials

Figures 3a and 3b show the derivative wideline n.m.r. spectra for the two high molecular weight samples (5 and 6 of *Table 1*) before and after drawing. The spectra of the drawn materials are for $\gamma = 0$. As before, selective crystallization of a small molecular weight range produces a broad component. Of the molecules left, those with a molecular weight too large to crystallize will produce an intermediate component. These molecules are probably undergoing rotation about their chain axes when there is sufficient crystalline material present to otherwise constrain their motion. This will not be true for high molecular weight samples such as these; there is simply not sufficient crystalline material present to constrain all of the free ends of the long chains. In this case, motion in the intermediate region will be of a more general type, and the corresponding component becomes comparatively narrow. The remainder have a molecular weight too small to crystallize and will give rise to a narrow component; this is swamped by the intermediate component in these spectra and is therefore not resolved. A comparison of the $\gamma = 0$ spectrum with that of the undrawn material shows that, as before, the broad component increases in intensity and the intermediate component broadens when the material is drawn. This is interpreted as an increase in the crystalline mass fraction and orientation of the intermediate region on drawing. Since there is a relatively small proportion of crystalline material present in the isotropic material, the deformation of these samples will be as a network of entangled long chains. The orientation of the molecules in the intermediate region will be limited since there are so few 'anchor' points available for the ends of the chains.

APPENDIX

Calculation of the n.m.r. line shape for polyethylene crystal assemblies

In a solid such as polyethylene the n.m.r. absorption line shape, $g(\omega)$, is mainly determined by the magnetic dipolar interactions between the precessing nuclear spins. These dipolar interactions are also responsible for the decay of the transverse magnetization (the Bloch decay or free induction decay) observed in a pulsed n.m.r. experiment. It can be shown[18] that the n.m.r. absorption line shape, $g(\omega)$, is the Fourier transform of the amplitude of the Bloch decay, $G(t)$. The relationship is discussed fully by Abragam[19] where expansion formulae for $G(t)$ based on the theory of Kubo and Tomita[18] are considered in some detail. For polyethylene we have used the results of a perturbation expansion calculation by Evans and Powles[16] for the first two terms of an expansion for $G(t)$:

$$G(t) = G_0(t) + G_1(t) + \ldots \tag{A1}$$

where

$$G_0(t) = \sum_{j=1,2} \prod_{r \neq j} \cos B_{jr}t \tag{A2}$$

$$G_1(t) = \frac{1}{3} \sum_{j=1,2} \prod_{k \neq j} B_{jk} \sin (B_{jk}t) \times$$

$$\left[t \prod_{r \neq j,k} \cos (B_{jr}t) - \int_0^t dt_1 \prod_{r \neq jk} \cos \{B_{jr}t + (B_{kr} - B_{jr})t_1\} \right] \tag{A3}$$

with

$$B_{jk} = \tfrac{3}{4}\gamma^2\hbar(1 - 3\cos^2\theta_{jk})r_{jk}^{-3} \tag{A4}$$

r_{jk} is the internuclear vector between protons j and k and

θ_{jk} is the angle between r_{jk} and the direction of the static magnetic field.

In calculating $G_0(t)$ and $G_1(t)$ for the polyethylene lattice, the crystal structure data of Bunn[20] have been used. The summations over $j = 1,2$ correspond to terms contributed by the two non-equivalent protons in the polyethylene unit cell and the indices r and k have been taken over all neighbours within a sphere of radius 7 Å corresponding to 101 and 103 neighbours respectively for the two non-equivalent protons. The values of $G_0(t) + G_1(t)$ were calculated for intervals of 1 μsec in t. The resulting function has an oscillating decay and the calculations were continued to a value for $t = t_f$ at which the amplitude of $G_0(t) + G_1(t)$ fell to 0.001 of its initial value. These computations were carried out on an ICL 1906A computer. The Fourier transforms:

$$g(\omega) = \int_0^{t_f} [G_0(t') + G_1(t')] \cos\omega t' \, dt' \qquad (A5)$$

where evaluated numerically on a PDP 8 computer.

The whole calculation was carried out for a sufficient number of orientations of the static magnetic field with respect to the polyethylene crystal axes to form averages appropriate to assemblies of highly oriented crystals with their c axes along the draw direction and a random distribution of the a and b axes in the transverse plane, as in the specimens measured in the present work.

The absorption line shape functions $g(\omega)$ were transformed to magnetic field units. The result obtained for the static magnetic field along the c axis is shown in *Figure 4* and discussed in the section on determination of mass fractions.

Since Evans and Powles' work[16], Betsuyaku[21] has extended the calculation of the series expansion of $G(t)$ to give an expression for $G_2(t)$. The calculations for polyethylene are being extended to determine $G_2(t)$ and a more detailed account of this work will be published separately.

Note to the Editor

Chlorination of 1,4-polybutadiene

J. C. Bevington and L. Ratti*

Department of Chemistry, The University of Lancaster, Lancaster LA1 4YA, UK
(Received 2 June 1974; revised 5 August 1974)

INTRODUCTION

A re-examination of the structures of the products from the photo-chlorination of polystyrene has already been reported[1]. A similar study has been performed on the products of the dark chlorination of 1,4-polybutadiene in solution; if addition of chlorine to the double bonds were the sole reaction, the final product would be 'head-to-head' poly(vinyl chloride) (with repeating unit $-CH_2.CHCl.CHCl.CH_2-$) and the number average molecular weight $(\bar{M}_n)$ would rise to 2.3 times the value for the original polymer.

EXPERIMENTAL

Samples of *cis*- and *trans*-1,4-polybutadiene containing respectively 96% *cis* and 93% *trans* units, were obtained from the Phillips Petroleum Company. Chloroform was treated with silica gel to remove ethanol. In most experiments, polymer (0.5 g) was dissolved in chloroform (100 ml); a solution of chlorine (1.5 g) in chloroform (60 ml) was added with stirring over a period of 20 min. The mixture was kept at 20°C in the dark and then purged with nitrogen. The polymer was recovered by precipitation in methanol, purified by solution in tetrahydrofuran followed by precipitation in methanol and finally dried at room temperature in vacuum.

Analyses for chlorine were performed by Strauss of Oxford. For determinations of $\bar{M}_n$, a Mechrolab membrane osmometer (type 501) was used at 37°C with solutions in toluene. Infra-red spectra were recorded for polymer samples in KBr discs using a Perkin–Elmer spectrometer 225. Raman spectra were obtained for polymers as powders using a Cary 81L instrument with a CRL krypton laser (model 52) using the green line at 5208 cm^{-1}. A Varian HR 220 instrument (ICI Corporate Laboratory, Runcorn) was used for n.m.r. studies of polymers dissolved in *o*-dichlorobenzene (at 120°C) or deuterated chloroform (at 55°C). δ values (in ppm) are quoted with respect to tetramethylsilane as internal standard. Areas under peaks were compared by the procedure involving cutting and weighing.

RESULTS

The compositions of polybutadienes chlorinated under the specified conditions reached those corresponding to PVC after about 4 h treatment; reaction, to give higher chlorine contents, continued but at a much lower rate. Results are summarized in *Table 1*. The calculated values of $\bar{M}_n$ were deduced from the values of $\bar{M}_n$ for the original polymers

---

M-2	37.8	263 000	184 000

C series: *cis*-1,4-polybutadiene
T series: *trans*-1,4-polybutadiene
M series: chlorination of *cis*-polymer in the presence of methanol (3 ml added to standard system for M-1 and 16 ml for M-2)

and the chlorine contents, assuming that the only reaction affecting the polymer was addition of chlorine to the carbon–carbon double bonds.

Murayama and Amagi[2] reported the changes in infra-red spectra brought about by addition of chlorine to 1,4-polybutadiene; their results were fully confirmed. Products M-1 and M-2 showed a prominent band at 1095 cm^{-1}, absent from the spectra of products from chlorinations performed in the absence of methanol.

The Raman spectrum of *cis*-1,4-polybutadiene included a strong band at 1643 cm^{-1} with weak bands at 1625 and 1666 cm^{-1}; for the *trans*-polymer, the band at 1666 cm^{-1} was strong and those at 1625 and 1643 were weak. As chlorination proceeded, the intensities of these bands fell but the band at 1666 cm^{-1} persisted even in a C-product containing 68.8% Cl. Product M-2 showed no appreciable absorption between 1700 and 1600 cm^{-1}.

Information on n.m.r. spectra is summarized in *Table 2*.

DISCUSSION

Both crosslinking and degradation have been found during the chlorination of hydrocarbon polymers. The data on $\bar{M}_n$ (*Table 1*) indicate that both processes occur during the chlorination of 1,4-polybutadiene. The values of $\bar{M}_n$ found for products C-1, C-2 and T-1 exceed the calculated values showing that there is linking together of polymer molecules although not to an extent sufficient to cause insolubility. That degradation also occurs during chlorination is shown by the fact that $\bar{M}_n$ found for product C-2 is less than that for C-1 although C-2 has the higher chlorine content.

The Raman bands at 1625, 1643 and 1666 cm^{-1} are associated with pendant $-CH=CH_2$, *cis* C=C and *trans* C=C respectively. It is significant that the band at 1666 cm^{-1} persists even in a product containing nearly 70% chlorine

Table 2 N.m.r. spectra of 1,4-polybutadienes and their derivatives

Polymer	Comments
C-0 and T-0	Peaks at δ = 5.5 and 2.1; areas in ratio 1:2
C-5	No peak at δ = 5.5. Peaks at δ = 4.0, 2.13, 2.00 and 1.85; areas in ratios 1.0:0.5:1.0:0.5
T-1	No peak at δ = 5.5. Peaks at δ = 3.9, 2.33, 2.06 and 1.80; areas in ratios 1:0:0.5:1.0:0.5
M-1 and M-2	No peak at δ = 5.5. Peaks at δ = 4.05, 3.5 and 3.4. Various peaks between δ = 2.5 and 1.5; further information in text

and formed from the *cis*-polymer; *trans* C=C may be involved in the 'over-chlorination', i.e. the introduction of chlorine beyond that required to give 56.8% w/w. It is possible that *trans* double bonds are continuously generated in the system by elimination of hydrogen chloride and that they are subsequently saturated with chlorine to convert some of the repeating units first to $-CHCl.CHCl.CHCl.CH_2-$ and subsequently to more highly chlorinated units. It should be noted that evidence[2] from infra-red spectra pointed to some conversion of *cis* C=C to *trans* C=C during chlorination.

Chlorination of 1,4-polybutadiene in the presence of methanol is expected to introduce methoxy groups into the polymer and there is compelling evidence to this effect. The prominent infra-red band at 1095 cm^{-1} can be attributed to these groups in the M-products. These products, although containing appreciably less than 56.8% chlorine, have no Raman absorption between 1700 and 1600 cm^{-1} so evidently all C=C bonds have been saturated. The n.m.r. spectra also provide clear evidence for the methoxy groups (see later).

The n.m.r. peaks at δ = 5.5 and 2.1 have areas in the ratio 1:2 for the starting polymers and are associated with the groups $-CH=$ and $-CH_2-$ respectively; the peak at δ = 5.5 disappears during chlorination. Protons in $-CHCl-$ give rise to peaks at δ = 4.0 (C-5), 3.9 (T-1) and 4.05 (M-1 and M-2). The various peaks between δ = 2.5 and 1.5 are

associated with methylene groups; the total area for these peaks in C-5 or T-1 is twice the area for the peak at δ = 4.0 for (C-5) or that for the peak at δ = 3.9 (for T-1) confirming that the products can be regarded as having the repeating unit $-CH_2.CHCl.CHCl.CH_2-$. Peaks at δ = 3.5 and 3.4 (areas in the ratio 3:1) are present in the spectra for M-1 and M-2 but not in those for C-5 and T-1; they are assigned to protons in $-CH(OCH_3)$ groups. For M-1 and M-2, the sum of the areas for the peaks at δ = 4.05 and 3.4 (associated with protons in $-CHX-$ where X is Cl or OCH_3 respectively) is close to 50% of that corresponding to the peaks between δ = 2.5 and 1.5 indicating that the original C_4H_6 unit in the polymer is on average converted to $C_4H_6Cl_n(OCH_3)_{2-n}$. The ratios of the areas associated with the peaks at δ = 4.05 and 3.4 are 4.5:1 and 2:1 for M-1 and M-2 respectively; the corresponding values of $n/(2-n)$ are therefore 4.5 and 2.0 and those of n are 1.64 and 1.33. From these results, the calculated chlorine contents of M-1 and M-2 are 47.2 and 38.6% respectively in fair agreement with the values of 43.2 and 37.8% found by direct analysis. Taking the average repeating units in M-1 and M-2 as $C_4H_6Cl_{1.64}(OCH_3)_{0.36}$ and $C_4H_6Cl_{1.33}(OCH_3)_{0.67}$ respectively, the calculated values of $\bar{M}_n$ for these products are 261 000 and 259 000. The discrepancies between the calculated and observed values of $\bar{M}_n$ are much less for these products than for those produced by chlorination in the absence of methanol.

Letters

Solution properties of low molecular weight atactic poly(acrylic acid) and its sodium salt

Below a molecular weight of about 10^4 most acrylic and vinyl polymers[1] show an extended region where the Mark–Houwink exponent assumes the theta point value of 0.50 ($[\eta] = K_0 M^{0.50}$) even though thermodynamic conditions are far from those of a theta solvent. The constant K_0 is very near to K_θ (the characteristic value in a theta solvent) provided specific solvent effects are not large. The only exception to this rule discovered so far is polyethylene[1]. This letter reports another exception — poly(acrylic acid) (PAA) and its sodium salt (NaPA). Viscosity measurements have been performed on characterized samples ranging from the trimer (2,4,6-tricarboxyheptane)[2] to the high polymer (M_w = 360 000).

Low molecular weight PAA was prepared by free radical polymerization in solvents which were chain transfer agents[3], i.e. ethyl benzene and 2-butanol. The latter solvent gave partly esterified polymers ($M_w \sim 3000$) which were hydrolysed to the pure acid with boiling aqueous alkali. Fractions of PAA were prepared by elution chromatography and fractional precipitation. A Sofica instrument was used to measure M_w for PAA samples with 2-propanol as solvent. Experimentally it was found that PAA samples of $M_w < 50\,000$ had zero angular dissymmetry. For each sample the refractive index increment (dn/dc) was measured with a Waters differential refractometer (R403).

Values of M_n, obtained with a Perkin-Elmer 115 vapour pressure osmometer, were used to correct the intrinsic viscosities of the unfractionated samples for the effect of heterogeneity according to the procedure of Kurata and Stockmayer[4]. This correction was small ($\leqslant 8\%$) for the unfractionated samples. It was not applied to the fractions for lack of complete data but in their case it would have been even less important. Intrinsic viscosities were measured for PAA samples in 2-propanol (30°C) and
Figure 1 Intrinsic viscosity/molecular weight plots for poly(acrylic acid) in 1,4-dioxane (30°C) (O) and 2-propanol (30°C) (+)
Figure 2 Corrected intrinsic viscosity/molecular weight plots for the sodium salt of poly(acrylic acid) in 1.5 M NaBr (20°C) (O) and 1.0 M NaCl (30°C) (+)

1,4-dioxane (30°C) and for sodium polyacrylate (NaPA) samples in 1.0 M NaCl (30°C) and 1.50 M NaBr (20°C). Ubbelohde suspended level viscometers with water flow times of 20 min were used with all solvents except 2-propanol for which a shorter flow time viscometer was necessary. The corresponding double logarithmic plots are shown in Figures 1 and 2. The viscosity–molecular weight data in Figure 1 are for the acid form (PAA) but those in Figure 2 have been calculated for the sodium salt taking into account the contribution of the end group to the molecular weight.

The $[\eta]-M_w$ plots are linear above $M_w \simeq 30\,000$. The data in this linear region for 1,4-dioxane and 1.5 M NaBr (both theta solvents) correspond very closely to what would be predicted from the corresponding $[\eta]-M_w$ relationships obtained by other workers[5,6] for higher molecular weight fractions of PAA and NaPA. However, $[\eta]-M_w$ relationships have not been calculated for the linear portions of the other curves because they are defined by only a small number of points. The viscosity data below $M_w \simeq 10\,000$ are characterized by a strong upward curvature so that below $M_w \simeq 1000$ $[\eta]$ is almost independent of molecular weight. The data for NaPA in 1.5 M NaBr appear to show an additional downward curvature in the range $M_w \simeq 30\,000$ to 10 000.

These conclusions depend strongly on the accuracy of the data points for 2,4,6-tricarboxyheptane so these have been checked by repeated careful measurement. There is no evidence to suggest that it is invalid to use 2,4,6-tricarboxyheptane as a model for poly(acrylic acid) but it would be useful to have more data for the region below $M_w \simeq 1000$. What is clear is that although the viscosity of PAA and NaPA becomes independent of solvent power below $M_w \simeq 10\,000$ there is no prolonged region at low molecular weight where the theta point relationship is obeyed. In this respect PAA and NaPAA differ from most vinyl and acrylic polymers so far studied[1] and resemble most closely cellulose and amylose derivatives[1].

Growth of lamellar crystals of poly(γ-benzyl-L-glutamate)

Introduction

It was shown by Padden and Keith[1] that under suitably chosen conditions polyglycine, poly(L-tyrosine), and probably poly(L-alanine) as well, could crystallize from solution to form single crystals with folded molecular chains. The lamellar crystals were found to exhibit many of the morphological features normally associated with single crystals of more conventional synthetic polymers[2]. With poly(L-tyrosine) and poly(L-alanine) it appeared, however, that solvent was complexed with the polymer even in the crystalline state; evaporation of the solvent resulted in the loss of crystalline order. Later studies carried out by the same school included the growth of single crystals of alkaline earth salts of poly(L-glutamic acid)[3] from aqueous solution and crystals of poly(L-lysine)[4] stabilized by divalent anions.

In this communication we report a method for growing lamellar crystals of poly(γ-benzyl-L-glutamate) (PBLG). Because of its solubility in a wide variety of solvents, PBLG has been used by many workers as a useful model compound for investigating the behaviour of fibrous proteins[5]. Numerous dilute solution studies[6-8] have been carried out on the polymer. Crystallization studies have shown that PBLG is able to crystallize from solution in the form of fibrillar aggregates; these may be single strands, ropes, rods or toroids depending on the solvent and precipitation conditions[9]. Also the crystalline structure of the polymer has been analysed by X-ray and electron diffraction studies carried out on stretched solution cast films[10,11]. No direct method of growing lamellar single crystals of PBLG has been reported previously although they have been grown epitaxially on alkali halides from mesitylene solution. In the latter work carried out by Carr *et al.*[12] electron diffraction and microscopy studies indicated that the lamellae contained chain-folded α-helical main-chain backbones, but that the bulky side groups remained disordered.

Experimental and Results

Material

The PBLG was synthesized by polymerizing γ-benzyl-N-carboxy-L-glutamate anhydride in benzene for 24 h at 20°C with n-hexylamine added as initiator[13]; the concentration of the initial solution was 0.015 g/cm^3 and the molar ratio of anhydride to initiator was 76. An 85% yield of polymer was recovered from the reaction mixture. Solutions of the polymer in N,N-dimethylacetamide (0.2–0.5% by wt polymer) were analysed by gel permeation chromatography (g.p.c.) at 50°C; four columns of pore size $7(10)^4$– $5(10)^5$ nm, $5(10)^3$–$1.5(10)^4$ nm, $5(10)^2$–$1.5(10)^3$ nm and $7(10)$–$2(10)^2$ nm were employed. For the unfractionated sample the ratio of the weight-average to number-average molecular weight, M_w/M_n, = 5.8. The presence of a low molecular weight tail accounted for much of this spread, however, and if its contribution was neglected M_w/M_n = 2.0. The weight-average molecular weight of the sample determined by light scattering studies on dimethyl formamide solutions was 97 000.

Fractionation

The polymer was fractionated using methylene chloride/methanol as a solvent/non-solvent system; this system under different experimental conditions has been employed previously for PBLG in fractional precipitation experiments[14,15] and in precipitation chromatography[16,17]. In our procedure, methanol was added slowly with stirring to a solution ($c = 0.0025 \text{ g/cm}^3$) of the polymer in methylene chloride thermostated at 20°C until a persistent turbidity was obtained. Next, the system was heated slowly until the solution became clear (~24°C) and then it was allowed to cool back to 20°C. After a period of 24 h, the crystalline fraction which had precipitated was isolated by syphoning off the supernatant solution through a glass wool plug into another flask. The fraction was collected by dissolution in methylene chloride followed by reprecipitation and filtration, and then it was dried by pumping under vacuum. Fourteen fractions were isolated successively in this manner. G.p.c. analysis showed that all the fractions possessed a narrow molecular weight distribution; the g.p.c. traces of fractions 1, 4, 7, 10 and 12 are shown in *Figure 1*. After making an approximate correction for diffusion broadening[18,19], M_w/M_n of each of the fractions is estimated to lie within the range 1.06–1.09. The results show that the solid–liquid fractionation process was very efficient and suggests an almost guillotine-like selection of chain molecules.

Crystallization from dilute solution

The crystallization results to be reported in the present communication were obtained on fraction 1 for which $M_w = 129 000$ and $M_w/M_n = 1.08$; however, similar results have also been obtained for other fractions. Preliminary results showed that well defined lamellar crystals could be grown from dilute solutions of the polymer in hexafluoro-isopropanol simply by allowing the system to cool slowly from 65°C to room temperature. Crystallization studies were then carried out under more controlled conditions using a self-seeding technique of the type developed by Blundell *et al.* for polyethylene[20,21]. Because of the low boiling point (58.5°C) of the solvent, all experiments were carried out in sealed glass tubes (3 mm diam. × 100 mm length); prior to sealing the solutions were degassed on the

Growth of lamellar crystals of poly(γ-benzyl-L-glutamate)

Introduction

It was shown by Padden and Keith[1] that under suitably
chosen conditions polyglycine, poly(L-tyrosine), and
probably poly(L-alanine) as well, could crystallize from
solution to form single crystals with folded molecular
chains. The lamellar crystals were found to exhibit many
of the morphological features normally associated with
single crystals of more conventional synthetic polymers[2].
With poly(L-tyrosine) and poly(L-alanine) it appeared,
however, that solvent was complexed with the polymer
even in the crystalline state; evaporation of the solvent
resulted in the loss of crystalline order. Later studies car-
ried out by the same school included the growth of single
crystals of alkaline earth salts of poly(L-glutamic acid)[3]
from aqueous solution and crystals of poly(L-lysine)[4] stabi-
lized by divalent anions.

In this communication we report a method for growing
lamellar crystals of poly(γ-benzyl-L-glutamate) (PBLG).
Because of its solubility in a wide variety of solvents, PBLG
has been used by many workers as a useful model com-
pound for investigating the behaviour of fibrous proteins[5].
Numerous dilute solution studies[6-8] have been carried out
on the polymer. Crystallization studies have shown that
PBLG is able to crystallize from solution in the form of
fibrillar aggregates; these may be single strands, ropes, rods or
toroids depending on the solvent and precipitation condi-
tions[9]. Also the crystalline structure of the polymer has been
analysed by X-ray and electron diffraction studies carried out
on stretched solution cast films[10,11]. No direct method of
growing lamellar single crystals of PBLG has been reported
previously although they have been grown epitaxially on
alkali halides from mesitylene solution. In the latter work
carried out by Carr *et al.*[12] electron diffraction and micro-
scopy studies indicated that the lamellae contained chain-
folded α-helical main-chain backbones, but that the bulky
side groups remained disordered.

Experimental and Results

Material

The PBLG was synthesized by polymerizing γ-benzyl-
N-carboxy-L-glutamate anhydride in benzene for 24 h at
20°C with n-hexylamine added as initiator[13]; the concen-
tration of the initial solution was 0.015 g/cm³ and the
molar ratio of anhydride to initiator was 76. An 85% yield
of polymer was recovered from the reaction mixture. Solu-
tions of the polymer in *N,N*-dimethylacetamide (0.2–0.5%
by wt polymer) were analysed by gel permeation chromato-
graphy (g.p.c.) at 50°C; four columns of pore size $7(10)^4$–
$5(10)^5$ nm, $5(10)^3$–$1.5(10)^4$ nm, $5(10)^2$–$1.5(10)^3$ nm and
$7(10)$–$2(10)^2$ nm were employed. For the unfractionated
sample the ratio of the weight-average to number-average
molecular weight, M_w/M_n, = 5.8. The presence of a low
molecular weight tail accounted for much of this spread,
however, and if its contribution was neglected M_w/M_n =
2.0. The weight-average molecular weight of the sample
determined by light scattering studies on dimethyl forma-
mide solutions was 97 000.

Fractionation

The polymer was fractionated using methylene chloride/
methanol as a solvent/non-solvent system; this system under
different experimental conditions has been employed pre-
viously for PBLG in fractional precipitation experiments[14,15]
and in precipitation chromatography[16,17]. In our procedure,
methanol was added slowly with stirring to a solution
($c = 0.0025$ g/cm³) of the polymer in methylene chloride
thermostated at 20°C until a persistent turbidity was
obtained. Next, the system was heated slowly until the
solution became clear (~24°C) and then it was allowed to
cool back to 20°C. After a period of 24 h, the crystalline
fraction which had precipitated was isolated by syphoning
off the supernatant solution through a glass wool plug into
another flask. The fraction was collected by dissolution in
methylene chloride followed by reprecipitation and filtra-
tion, and then it was dried by pumping under vacuum.
Fourteen fractions were isolated successively in this man-
ner. G.p.c. analysis showed that all the fractions possessed
a narrow molecular weight distribution; the g.p.c. traces of
fractions 1, 4, 7, 10 and 12 are shown in *Figure 1*. After
making an approximate correction for diffusion broaden-
ing[18,19], M_w/M_n of each of the fractions is estimated to lie
within the range 1.06–1.09. The results show that the
solid–liquid fractionation process was very efficient and
suggests an almost guillotine-like selection of chain
molecules.

Crystallization from dilute solution

The crystallization results to be reported in the present
communication were obtained on fraction 1 for which
$M_w = 129\,000$ and $M_w/M_n = 1.08$; however, similar results
have also been obtained for other fractions. Preliminary
results showed that well defined lamellar crystals could be
grown from dilute solutions of the polymer in hexafluoro-
isopropanol simply by allowing the system to cool slowly
from 65°C to room temperature. Crystallization studies
were then carried out under more controlled conditions
using a self-seeding technique of the type developed by
Blundell *et al.* for polyethylene[20,21]. Because of the low
boiling point (58.5°C) of the solvent, all experiments were
carried out in sealed glass tubes (3 mm diam. × 100 mm
length); prior to sealing the solutions were degassed on the

Figure 1 Gel permeation chromatograms (uncorrected) for frac-
tions 1, 4, 7, 10 and 12

vacuum line. The polymer/solvent system (w/v = 0.003 g/cm³) was first warmed up slowly (~1°C/min) and held at 65°C until the solution became clear. It was then allowed to cool back to room temperature. The system was then plunged into a thermostat bath at 70 ± 0.01°C and left for 10 min. Finally, it was plunged into a thermostat bath held at the chosen crystallization temperature; crystallization studies were carried out at 20, 25 and 30°C. The relatively large temperature increments which separated the dissolution temperature (T_s) from the crystallization temperature (T_c) made it difficult to achieve completely isothermal growth. So as to facilitate quenching thin walled, narrow bore glass tubes were used in the experiments. Trial runs involving further reductions in bore diameter did not have any noticeable effect on the growth of the crystals.

Lamellar crystals having a basic hexagonal habit were the typical product of growth at each of the crystallization temperatures studied. *Figure 2* shows a lamella as viewed with an AEI 6G electron microscope operating in direct transmission; it is mounted on a carbon substrate and shadowed with Pt/C. The lamella is sub-divided into distinct sectors, there being as many sectors as there are prism faces. Many of the lamellae showed evidence of sectorization in this way. Other lamellae revealed no such features. An array of lamellae is shown in *Figure 3*. This micrograph was selected because the lamellae are heavily fractured. As revealed by many of these lamellae, when fracture occurs it tends to be in a radial direction.

No electron diffraction spots or rings could be observed even when utilizing very low beam intensities, only an amorphous halo was observed. This suggests that the crystals were only stable in the presence of bound solvent. Presumably under the vacuum conditions required for shadowing and electron microscopy the solvent is removed and hence the crystalline order is lost due to local crumpling of chains. A similar argument was invoked by Padden and Keith[1] to explain some of their observations.

The thickness of the lamellae was determined from measurements of shadow lengths. For T_c = 20, 25 and 30°C the average lamellar thicknesses were found to be 23, 23 and 25 nm respectively. Thus the thicknesses are roughly a third of the value expected for an unfolded PBLG chain. (If we assume the chains adopt an α-helical conformation[8] along their whole length then the fully extended length of molecules in fraction 1 would be ~82 nm.) At this stage, however, we cannot rule out the possibility that evaporation of solvent may be accompanied
Figure 2 Electron micrograph of a lamella obtained by crystallizing PBLG from hexafluoro-isopropanol
Figure 3 Electron micrograph of an array of lamellae exhibiting extensive fracturing in the radial direction

by significant distortion of the lamellae such as partial
collapse and thinning. Certainly many of the lamellae had
somewhat rounded edges and this introduced a consider-
able degree of uncertainty into the measurements of
shadow lengths. In future studies it is hoped to obtain
unequivocal evidence concerning crystal thicknesses from
low-angle X-ray studies made on moist mats. In the mean-
time, however, supporting evidence that folding occurs is
provided by the observations that many crystals are sub-
divided into distinct sectors. As pointed out by Keller[22]
for polyethylene crystals, sectorization must be considered
as convincing evidence for the folded-chain model.

Book Reviews

Reactivity, mechanism and structure in polymer chemistry
Edited by A. D. Jenkins and A. Ledwith
John Wiley, London, 1974, 613 pp. £13.00

Jenkins and Ledwith have performed a notable service by collecting articles which will be of real value to many physical-organic chemists. They support the very reasonable view that polymer chemistry should not be regarded as quite separate from the rest of chemistry; indeed, they have included sections dealing with general aspects of radicals, carbonium ions and carbanions with hardly a specific reference to polymerizing systems. These particular sections could just as well have been included in a corresponding book about general organic chemistry but the material in them is of course necessary for proper appreciation of the various types of polymerization process.

The editors have recruited some famous men to write for them but it is refreshing to see contributions from authors who up to now have not been featured in publications of this type. It is often only too apparent that there is a lack of coherence in books written by large teams of authors; there may also be considerable variations from one contribution to another in style of writing and in depth of treatment. These defects seem not to be significant in this case.

It should be noted that the editors have restricted themselves to various aspects of the process of polymerization in spite of the more general nature of the title; only in a sub-section headed 'Photochemistry processes in high polymers' and occupying less than 10 pages is there any appreciable discussion of the behaviour of polymers themselves. If fault is to be found, it should be with the chosen title.

There can be no doubt that this book will be a valuable and stimulating aid to those involved in advanced teaching, and in research. It deserves wide circulation and not just among those who describe themselves as polymer chemists. It would be niggling to comment on obscurities, errors, unnecessary repetition between sections and presentation of material already available in other accessible publications; there are examples of these faults but they are few. The reviewer must however, demonstrate that he really has looked beyond the list of contents and so report that the index contains a very unusual symbol for the velocity constant for termination in the case of the polymerization of N-vinylcarbazole.

Blood compatible synthetic polymers: an introduction
C. C. Thomas, Springfield, 1974, 131 pp. $9.75

The field of biomedical polymers is receiving increasing attention from workers in medical engineering and Dr Bruck has set out to provide a short introductory guide for people of all disciplines, be they physicians, engineers, life or materials scientists involved in the development and use of devices which come into direct contact with blood. What it is that makes some synthetic materials more tolerated by the living environment than others is still the subject of much speculation and consequently this monograph deals only briefly with its principal subject matter, giving a summary of the more promising materials found to date which demonstrate a degree of biocompatibility with blood while discussing the attributes mainly associated with a material's surface which might be responsible for the effect.

Understandably the bulk of the text is taken up with a review of polymeric materials and their many chemical, physical and mechanical properties. The emphasis here is on a direct comparison between synthetic and naturally-occurring macromolecules and on those properties which render the former suitable for use in biomedical applications and which might have a bearing on the various theories of blood compatibility.

Additionally, the author has contributed a useful presentation on the composition of blood and its working environment. This serves to highlight the many vital factors which can either influence or be influenced by the presence of a foreign material. For example, the influence of chemical, physical and mechanical action on the blood's defensive mechanisms are exemplified in relation to the blood coagulation pathways.

The current rate of advance in biomaterials science is such that one can anticipate the appearance of a more comprehensive treatise in the near future. This relatively inexpensive book provides a useful insight into the present state of the art and as the performance requirements expected of synthetic biomaterials increase it will serve to encourage the move from intuitive selection towards the synthesis of macromolecules designed to exist at the interface between a device and both the cellular and non-cellular components of blood.

It must be remembered, however, that while efforts have been made to relate blood compatibility of a material to the composition of that material, the final analysis must take account of the application and the physical form.

Progress in polymer science Japan, Vol 5
Edited by K. Imahori and S. Murahashi
John Wiley, New York. 1973, 308 pp. £8.75

The volume is a continuation of the series in which Japanese scientists review specific aspects of polymer science, usually concentrating on their own contributions to the subject. The articles provide useful coherent accounts of the authors' work in and philosophy of their particular subject and also provide access to information in original Japanese publications and conference proceedings, which are not readily available to the scientific community at large.

Of the five reviews in this volume three deal with chemical and two with physical aspects of the subject. Four articles originate from university laboratories, one from Kyoto and three from the less well-known but major polymer centre in Hokkaido. The remaining article stems from one of the major government laboratories devoted to polymer science.

In the third article in this series devoted to alternating copolymerizations, Furukawa discusses the mechanisms of reactions which involve donor—acceptor complexes of monomers with Lewis acids and those initiated by Ziegler-type catalysts. After a brief summary of other workers' contributions he develops the subject mainly in terms of the contributions of his own group. The characterization and physical properties of some copolymers are described. Noguchi's article on poly(α-amino acids) is mainly concerned with catalytic hydrolyses by the polymers and the nature of reaction sites. The article also describes polymers and copolymers prepared using N-carbothiophenyl derivatives of amino acids and attempts to prepare fibres of poly(α-amino acids) which simulate natural peptide fibres. Hasegawa *et al.* describe four-centre photopolymerizations of diolefinic monomers in the crystalline state. The major monomer used in the work was 2,5-distyrylpyrazine but results obtained with related monomers are also discussed. In a very attractive study of those reactions the authors have investigated they describe various factors which influence the reaction, including the wavelength of the incident illumination, crystallographic effects and, briefly, the properties of some of the novel polymers prepared. In the polymer physics section of the volume Kaneko reviews the viscoelasticity of dilute solutions of flexible and rigid polymers and compares the experimental data with theoretical models. Some data on viscoelasticity of polyelectrolytes are included. Finally, Kobatake and Kamo review transport processes in charged membranes and discuss theoretical mechanisms for transport of ions in terms of experimentally determined parameters existing within the membranes.

The volume is well presented and individual articles will be of value to those working in the specialized areas covered. Unfortunately, but predictably, the price is even higher than that of the preceding volume (see *Polymer* 1974, 15, 255) and is extremely high for most workers who, in view of the spectrum of topics covered, will be specifically interested in only one or two articles.

A far infra-red study of conformational disorder in PTFE

H. A. Willis and M. E. A. Cudby
ICI Plastics Division, Welwyn Garden City, Hertfordshire AL7 1HD, UK

and G. W. Chantry, Elisabeth A. Nicol and J. W. Fleming
National Physical Laboratory, Teddington, Middlesex TW11 0LW, UK
(Received 15 May 1974)

The examination of the 250—350 cm^{-1} region of the infra-red spectrum of polytetrafluoroethylene (PTFE) has been extended by studies of thermally degraded and sintered material. We conclude that a band at 277 cm^{-1} does not arise from a true mode of the crystal but has its origin in regions where the chain has a bent conformation. Our previous speculation that bands at 292 cm^{-1} and 312* cm^{-1} (Raman active only, for the isolated chain) acquire their weak activity in the infra-red through conformational disorder is confirmed. It is likely that the conformational disorder in question arises from chain folding in the polymer crystal.

INTRODUCTION

In our first paper on the far infra-red absorption spectrum of unsintered polytetrafluoroethylene[1], we reported previously unrecognized lattice modes of the polymer crystal. We subsequently observed[2] further lattice modes and also two relatively weak bands at 292 cm^{-1} and 312 cm^{-1} which had not previously been reported. These bands are evidently the counterparts of those observed by Koenig and Boerio[3] in the low temperature Raman spectrum and the two bands can be assigned, according to the calculations of Hannon et al.[4], to the CF$_2$ twisting modes in classes A$_1$ and E$_2$ respectively. In a line group model both should be inactive in the infra-red. We suggested that these bands are present in the spectrum of a sample measured at liquid nitrogen temperature because the low temperature crystalline form has more than one molecular chain passing through each unit cell. Above the 19°C transition, however, the crystal unit cell is thought to contain one chain only and we offered a tentative explanation that the persistence of the bands at 292 and 312 cm^{-1} above this transition might be due to their activation by conformational disorder in the molecule.

Our further experiments on PTFE, which we now report, strongly support the validity of this latter explanation and suggest that the presence of weak bands in the infra-red spectrum, arising from modes which on symmetry grounds should be active only in the Raman effect, is a necessary consequence of the folded chain structure of the polymer crystal[5].

EXPERIMENTAL

Infra-red spectra were measured with a NPL—Grubb Parsons modular cube interferometer[6] coupled to a Golay cell detector. The highly crystalline unsintered powder was cold pressed into discs of suitable thickness and these were heat treated in air to produce the sintered and thermally degraded samples described in the text.

---

* This band is often quoted as 308 cm^{-1} in the literature but accurate measurement shows it to lie at 312 cm^{-1}.

RESULTS

The spectra of a series of samples of PTFE observed in the 250—350 cm^{-1} region for room temperature are presented in *Figure 1*. The samples were measured in their original unsintered state and after a period of heat treatment at 380°C as indicated. The spectra of the same samples but measured at liquid nitrogen temperature are shown in *Figure 2*.
Figure 1 Room temperature spectra of a specimen of initially unsintered PTFE after various periods of heat treatment. A, before heat treatment; B, after 1 h at 380°C; C, after 8 h at 380°C; D, after 32 h at 380°C
Figure 2 Low temperature (160 K) spectra of a specimen of initially unsintered PTFE after various periods of heat treatment. The distinguishing codes used for the profiles have the same significance as in *Figure 1*

DISCUSSION

PTFE is remarkable in that it is very highly crystalline (~95%) as made[7]. However, this form of PTFE, i.e. unsintered, has such poor mechanical properties that it is usual to sinter pre-formed objects, by heating to about 380°C, to make commercial products. If specimens of PTFE are cooled slowly from the sintering temperature, the ultimate crystallinity increases the more slowly the specimen is cooled, although it never reaches that of the original unsintered powder. This is quite different from the behaviour of most partly crystalline polymers where heat treatment generally increases the final crystallinity. The origin of this unusual behaviour lies in the occurrence of mostly chain extended conformers in the unsintered powder[8]. These extended chains pack smoothly side by side to give a high physical density and the predominance of well-aligned regular chains leads to high X-ray estimates of the crystallinity and to low infra-red estimates of amorphous content. This latter estimate is low because the infra-red method is based on measuring the intensity of an absorption band at 770 cm^{-1} which arises from a conformational imperfection in the regular progression of the helix[9].

There is good evidence[10] that in the melt crystallization which takes place on sintering the crystalline habit is changed. The original fully extended helical molecules now pack into chain folded crystals in which, after a succession of monomer units (up to a few hundred) in a regular helical conformation, the conformational order is changed so that

the molecule can bend back and re-enter the crystal in the opposite direction, and once more pack regularly. The 'folds', where the molecule is bending back, lie on a regular surface and a sintered specimen consists of an assembly of these folded chain lamellae, together with interlamellar material which is presumably conformationally irregular. Since the chain folded molecules contain substantial portions which are not packed regularly parallel to other portions the proportion of conformationally irregular units is increased, and consequently both X-ray and infra-red measurements show the sintered material to have a lower crystallinity than the unsintered (i.e. substantially fully extended) original material. It is not surprising that, despite their presumed different crystal habits, the sintered and unsintered materials show similar lattice spectra at low temperatures. For polyethylene, both the extended chain and the folded chain crystals have been shown to have identical lattice spectra[11]. This arises because the segments between folds (100 or so repeat units) are long enough to behave as infinite chains so far as inter-segment motion is concerned. For PTFE one would imagine very similar considerations to apply.

With this background, we may examine *Figures 1* and *2*. In these three major absorption bands at 277, 292 and 312 cm^{-1} will be noticed. The definition of these bands improves as the temperature falls[2] and in the spectrum recorded at liquid nitrogen temperature the bands are very well separated. However, this effect clearly arises only from reduction in the band half-widths as the temperature falls and there are no significant frequency shifts. Hence it may be confidently assumed that all three bands arise from internal molecular motions.

The lowest frequency band of the three, namely that at 277 cm^{-1}, has been well known[12] for some years in infra-red absorption and has been universally assigned to a vibrational fundamental of the macromolecular helix, in fact to the E_1 CF_2 scissors mode. The new data shown in *Figures 1* and *2* introduce, however, some difficulties which call for a re-examination of this common assumption. The band at 277 cm^{-1} increases markedly in intensity in going from the unsintered to the sintered material and from this one can conclude at once that not all of the intensity in the 277 cm^{-1} region, observed for sintered samples, arises from the crystalline regions. Of course the simplest assumption is that none of it does and the weak absorption at 277 cm^{-1} observed for unsintered samples therefore arises entirely from the remaining 5% of conformationally irregular material. At least the bulk therefore of the absorption at 277 cm^{-1} must be connected with molecular motion either in the amorphous (i.e. non-helical) molecules or else in the chain folds, since both these species are more abundant in the sintered material. A similar conclusion can be drawn from close examination of previously published Raman spectra[3,13] and also from our observations[14] of the Raman spectrum of PTFE where a very weak band at 277 cm^{-1} for unsintered material becomes very much stronger after sintering. E_1 fundamentals of the regular helix are allowed, of course, in both the infra-red and Raman spectra but the intensification of the 277 cm^{-1} band on going to a more conformationally irregular material suggests strongly that this band does not arise from a fundamental of the regular helix.

It is established therefore that, apart from the fortuitous coincidence that the absorption profile near 277 cm^{-1} is made up of several components, the band is associated entirely with molecular motion in the conformationally

irregular regions of the crystal. However, it is worth enquiring if it is possible to decide from the spectrum whether the motion in question occurs in the interlamellar amorphous material, in the chain folds or in both. Some light is shed on this question by studies of the effect on the spectrum of prolonged heating of the specimen at 380°C. As the heating time is extended from zero to very long times, the intensity of the 277 cm^{-1} band first increases and then slowly decreases. The increase we have already assumed to be due to chain folding and the subsequent decrease can be readily attributed to the effects of chain scission[15]. This has the effect of increasing the rate at which the polymer crystallizes when it is cooled from the melt so that the specimen will become increasingly crystalline as heating is prolonged and therefore the amount of amorphous material will fall. This interpretation of the behaviour of the 277 cm^{-1} band strongly points to its origin in the amorphous material; however, the possibility that it arises from a conformer present in both chain folds and amorphous material cannot be eliminated. If the band arose from a bent conformation present in both amorphous regions and chain folds it would show somewhat similar behaviour since the small increase in the number of chain folds with increasing crystallinity would be more than offset by the decrease in amorphous material. We conclude therefore that the 277 cm^{-1} band arises from the bent molecular conformation, certainly in the amorphous material but possibly also in the chain folds. This leaves open the question of the identity of the E_1 intersection of B6 this matter will be discussed in a later publication.

The bands at 292 and 312 cm^{-1}, like that at 277 cm^{-1}, are considerably stronger in the spectrum of the specimen heated for 1 h at 380°C than they are in the spectrum of the original unsintered material. In other respects however these two bands may be sharply distinguished from that at 277 cm^{-1}. First, these bands have obvious counterparts in the Raman spectra of both sintered and unsintered materials and they may be assigned with very little doubt to the A_1 and E_2 fundamentals of the helix. They therefore arise in the crystalline regions. Secondly, prolonged specimen-heating produces only slight changes in the intensities of these two bands rather than the dramatic reduction observed for the 277 cm^{-1} band.

If we return to the suggestion which we made in our previous paper[2], that these Raman active modes acquire infra-red activity through conformational disorder in the molecules, we see that this fits very well with the notions developed above. The original polymer is highly crystalline, but it is also conformationally very regular because the macromolecules occur mostly in the chain-extended form. The presence of a conformational irregularity can make all the modes of the chain active and the observed strength of a 'forbidden' feature will depend on the number of such discontinuities. For the chain-extended macromolecules the number of irregularities is small and the bands at 292 and 312 cm^{-1} are weak. After sintering the molecules chain fold, and the ensuing conformational disorder leads to a considerable increase in the intensity of these two bands. Subsequent heating leads to a small increase in the amount

of chain-folded crystalline material and the bands gain in strength. For these two bands, and also for that at 277 cm^{-1} it does not appear necessary to draw a major distinction between the observations at liquid nitrogen temperature and those at room temperature. This is in marked contradistinction to the behaviour of the bands lying below 100 cm^{-1} where the spectra at room and at liquid nitrogen temperatures are completely different. There can be no doubt that the bands at 277, 292 and 312 cm^{-1} are present at both temperatures; all that happens as the temperature falls is that the bands sharpen, become better resolved from one another and therefore more immediately obvious in the spectrum. It therefore seems appropriate to abandon our previous suggestion[2] that the bands are activated by two different processes and instead to conclude that the bands owe their activity solely to conformational disorder and not at all to intermolecular effects. Indeed were the latter significant it would be very difficult to understand why at liquid nitrogen temperature a decrease in crystallinity (subsequent upon sintering) should be accompanied by increasing strength of these bands.

We therefore conclude that the band at 277 cm^{-1} is not a fundamental of a conformationally regular PTFE molecule and that the bands at 292 and 312 cm^{-1} which are fundamentals, but which should be forbidden in the infra-red, owe their activity to the presence of chain folds in the crystalline regions of the polymer. Similar conclusions have been reached by Professor G. Zerbi and his colleagues and we would like to thank them for sending us preprints of their work[16].

Mechanical response of elastomers not too far from equilibrium*

R. F. Fedors and R. F. Landel

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91103, USA
(Received 23 April 1974; revised 30 July 1974)

For any polymer, the mechanical response can be conveniently represented in terms of the three variables stress, σ, strain, ϵ, and time, t. It is shown that under fairly general conditions, crosslinked elastomers which display weak or moderate viscoelastic character, i.e., are not too far from equilibrium conditions, will yield mechanical response curves including the rupture response that can be superposed onto master curves provided the plotting variables are properly chosen. It is shown that these variables should be: (1) the reduced stress, $\sigma T_0/\nu_e T$, where T_0 and T are an arbitrarily chosen reference temperature and the test temperature respectively, and ν_e is the network chain concentration or some other quantity proportional to it; (2) the strain; and (3) the reduced time, $t/a_T a_x$, where a_T is the time—temperature shift factor and a_x is a shift factor which accounts for the effect of ν_e on the time scale.

INTRODUCTION

Previous studies have indicated that the mechanical response of amorphous gum elastomers can be conveniently described in terms of a family of physical property surfaces, each member of which can be characterized by both its shape and its location in stress, strain, and time space. The surfaces are generated by allowing one or more parameters to assume different values. For temperatures that are sufficiently above the glass-transition temperature T_g, only a single parameter ν_e, the concentration of effective network chains per unit volume of elastomer, seems to be required to specify the shape of the surface to a good first approximation[1]. Little information, however, is available on the number of parameters that determine location although recent work of Plazek[2] would indicate that two, one of which is ν_e, may be required.

Fracture in reference to the physical property surfaces represents some limiting boundary or discontinuity to each surface. In general, a distinct space curve is associated with each surface and hence both the shape and location of a space curve might be expected to depend to a large extent on the same parameters that characterize the surface.

The projection of a family of space curves to the stress—time (σ, t) or strain—time (ϵ, t) planes represents the time dependence of fracture, while the projection to the σ, ϵ plane is independent of the time scale. The latter projection, known as the failure envelope, has been shown to be independent of ν_e over wide ranges of temperature provided the reduced variable $\sigma_b T_0/\nu_e T$ is used instead of σ_b itself, i.e. a plot of $\log \sigma_b T_0/\nu_e T$ *versus* $\log \epsilon_b$ produces a superposition of the high-temperature portions of individual failure envelopes to yield a master curve for rupture that is essentially independent of variables such as rate, test temperature, chemical nature of the elastomer, ν_e, and the presence of small amounts of diluent[1]. Here T_0 and T are an arbitrarily chosen reference temperature and the test temperature, respectively.

It is easy to demonstrate that these plotting variables will yield a master curve for that segment of the failure envelope in which the elastomer does not exhibit appreciable viscoelastic character, i.e. for test conditions where the system is close to mechanical equilibrium. However, it is a well-established empirical result that segments of the failure envelope where the elastomer is exhibiting weak to moderate viscoelastic response will also fall on the master curve. No explanation for superposition in this region has, as yet, been advanced.

The purpose of this paper is to show that under fairly general conditions, elastomers which display weak to moderate viscoelastic character will yield failure envelopes that will superpose to the master curve. In addition, the effect of weak to moderate viscoelastic character on the physical property surface as well as on the σ_b, t_b and ϵ_b, t_b response will also be discussed.

THE PHYSICAL PROPERTY SERVICE

General characteristics

In general, for a given test mode, the mechanical response of an elastomer can be conveniently described in terms of at least the four variables $\sigma T_0/T$, ϵ, t, and ν_e (the ratio T_0/T is a temperature correction factor for the stress). If $\sigma T_0/T$, ϵ, and t are selected as the three plotting variables, then the response can be represented in terms of a family of three-dimensional surfaces, called physical property surfaces; the shape of the high-temperature portion of the surface is determined primarily by the value of ν_e.

Rupture can then be defined in terms of a family of space curves that represent some limiting value, boundary, or discontinuity to each surface. Thus, each surface will have associated with it a space curve defining the occurrence of rupture.

The projection of these space curves to the $\log \sigma T_0/T$, $\log \epsilon$ plane produces a family of time-independent failure envelopes as shown schematically in *Figure 1a*, where the arrow denotes the direction of increasing ν_e. For a given value of $\sigma_b T_0/T$, the strain-at-break increases as the network chain concentration decreases. Furthermore, as the test
Figure 1 Projections of physical property space curves to:
(a) σ, ϵ plane; (b) σ, t plane; and (c) ϵ, t plane

temperature or the time scale of the experiment is decreased, i.e. as the system is moved away from mechanical equilibrium with a concomitant increase in the viscoelastic character, the rupture points move along the failure envelope in an anticlockwise direction. At a sufficiently low temperature, ϵ_b passes through a maximum and finally decreases to small values as T_g is approached.

This failure envelope is of great importance because of this time independence and also because it is approximately independent of the test type so that nearly the same envelope is generated in stress—relaxation, creep, or constant strain rate, provided the test temperatures are well above T_g.

The projection of the space curve to the $\log \sigma_b T_0/T$, $\log t_b$ plane provides the time-to-break dependence of σ_b as shown schematically in *Figure 1b*, while the projection to the $\log \epsilon_b$, $\log t_b$ plane provides the time-to-break dependence of ϵ_b as shown in *Figure 1c*. It is apparent that $\sigma_b T_0/T$ increases monotonically while ϵ_b passes through a maximum as t_b decreases. As the system moves away from mechanical equilibrium, the failure points move from right to left in both *Figures 1b* and *1c*. Thus, by increasing the viscoelastic character (by decreasing t_b), both σ_b and ϵ_b increase. The maximum in ϵ_b that is directly related to the network chain concentration ν_e is commonly observed to occur at roughly the same time scale at which the stress—relaxation modulus is entering the transition zone. Note that only two of these projections are independent since the third can be generated from the other two by eliminating the common variable.

Mathematical description

For elastomers which display weak to moderate viscoelastic character, it has been shown that time and strain are factorable[3-5]. Hence, one can express the stress as a product of two factors, one of which depends on time alone and one which depends on strain:

$$\frac{\sigma}{G_e} = \frac{G(t)}{G_e} f(\epsilon, a_1, a_2, \ldots) \qquad (1)$$

where G_e is the shear modulus when the system is at mechanical equilibrium (which may be taken equal to $\nu_e RT$, where R is the gas constant), $G(t)$ is the time-dependent modulus, and f is a function that contains the strain dependence as well as possible dependence on additional parameters $a_1, a_2, \ldots$, as may be required. It is clear from previously cited work that the parameters a_i can be at most only very weakly dependent on time or temperature except for temperatures near T_g.

It is more convenient to express equation (1) in the form:

$$\frac{\sigma T_0}{\nu_e T} = g(t) f(\epsilon, a_1, a_2, \ldots) \qquad (2)$$

where

$$g(t) \equiv \frac{G(t)T_0}{\nu_e T} \equiv \frac{G_p(t)}{\nu_e}$$

and G_e has been taken equal to $\nu_e RT$. As $t \to \infty$ or as mechanical equilibrium is approached, $g(t)$ approaches a limiting value of RT_0. To the extent that both g and f can be taken as universal functions, then equation (2) implies that a single superposed physical property surface will be obtained, provided the plotting variables are chosen to be $\sigma T_0/\nu_e T$, ϵ, and t rather than σ, ϵ, and t.

The conditions under which both g and f can be taken to be universal functions, as a first approximation at least, will now be considered. The time-dependent function g is considered first.

Dependence on ν_e. In addition to the usual time—temperature superposition governed by the WLF relationship[6], Plazek has demonstrated that superposition of the long time or terminal region of the creep compliance curves for both natural rubber (NR) and styrene—butadiene rubber (SBR) gum vulcanizates, having different degrees of crosslinking, can be effected by using ν_e as a reduction variable[2]. This fact implies that ν_e is the dominant variable that controls the viscoelastic response at small strains in the long-time domain.

The superposed or universal creep compliance response is defined by Plazek in the following manner:

$$J_x\left(\frac{t}{a_x}\right) = J_p'\left(\frac{t}{a_x}\right) \frac{J_e(R^*)}{J_e} \qquad (3)$$

where J_x is the universal creep compliance function, J_p is the response for an elastomer with a given ν_e value, $J_e(R^*)$ is the compliance at mechanical equilibrium for an arbitrarily chosen reference system, J_e is the compliance at equilibrium at any other ν_e, and a_x is the shift factor along the time scale. For both NR and SBR, the relationship between a_x and ν_e was found to be:

$$\log a_x = 15.4 \log \frac{C}{\nu_e} \qquad (4)$$

where C is a constant. However, NR and SBR had different C values and this was tentatively ascribed to differences in the monomeric friction coefficients, i.e. to differences in chemical structure for these two materials. Equation (4) indicates the enormous influence of changes in ν_e on the time scale and it implies that for a given time scale, the higher the ν_e value, the closer the system is to equilibrium.

Various methods exist for converting from one experimentally observable viscoelastic function, such as creep compliance to any other function such as stress relaxation, to any degree of approximation desired[6]. Thus, for example, $G_p(t)$ can be estimated if $J_p(t)$ is known by use of the approximate relation:

$$G_p(t) = \frac{\sin m\pi}{m\pi J_p(t)} \qquad (5)$$

where m is the slope of the doubly logarithmic plot of $J_p(t)$ versus t. Using this equation, Plazek converted stress—relaxation data, on both NR and SBR as a function of ν_e,

obtained by Chasset and Thirion to a reduced creep compliance function and this was found to be essentially identical to the one that can be obtained by direct experiment. Hence, a universal creep compliance function implies the existence not only of a universal stress—relaxation function but also of other universal viscoelastic functions that can be derived from creep compliance.

Thus, a universal stress—relaxation modulus may be defined in a similar manner to that of the creep function:

$$G_x \left(\frac{t}{a_x} \right) = G_p \left(\frac{t}{a_x} \right) \frac{G_e(R^*)}{G_e} \tag{6}$$

Since $G_e(R^*)$ is chosen arbitrarily, we can for convenience set it equal to a constant value for all systems and, hence, write

$$\frac{G_p(t/a_x)}{\nu_e} = g(t) = \frac{G_x(t/a_x)}{\nu_e(R^*)} \tag{7}$$

Since G_x is a universal function, then $g(t)$ will also be a universal function. This is contingent on the temperature being sufficiently high so that the response is restricted to the terminal region.

Effect of diluent on g. Another factor, which greatly affects the nature of the viscoelastic response and hence the approach to mechanical equilibrium, is the presence of a diluent. Fujita and Kishimoto[7] have found, for several polymers containing varying amounts of diluent, that master stress—relaxation curves could be obtained by shifting individual curves horizontally along the time axis. The diluent concentration—time shift factor a_c for crosslinked systems can be expressed as[8]:

$$\log a_c = \frac{(1/2.303 f_2)(1 - v_2)}{(f_2/\beta') + (1 - v_2)} \tag{8}$$

where f_2 is the fractional free volume of the polymer, v_2 is the volume fraction of the polymer, and β' is a constant for a given system that may be taken as approximately equal to the fractional free volume of the diluent. Values of f_2 and β' can be estimated from the thermal expansion coefficients above and below the glass-transition temperature. It is expected that equation (8) will only be valid for large v_2, i.e. small diluent concentration. It is of interest to note that as v_2 decreases, the value of $-\log a_c$ increases and hence the effective time scale of the experiment increases; thus the system more closely approaches mechanical equilibrium.

Strain dependent factor, f. Several explicit forms for the function f have been reported in the literature. The simplest is provided by the kinetic theory of elasticity and is given by:

$$f = \left(\lambda - \frac{1}{\lambda^2} \right) \tag{9}$$

where $\lambda = 1 + \epsilon$. This form, however is known to be useful only when ν_e is large and λ is small.

Better fit to experimental data especially at moderate strains is provided by the Mooney—Rivlin expression[9]:

$$f = \left(\lambda - \frac{1}{\lambda^2} \right) \left(1 + \frac{C_2}{C_1 \lambda} \right) \tag{10}$$

The parameter C_1 is commonly taken equal to $\nu_e RT$ and the parameter C_2, of unknown origin, turns out to be an implicit but weak function of both ν_e and T with $C_2 \to 0$ as ν_e and/or T increase.

A theoretical equation, which takes into account the finite extensibility of a polymer chain, and provides a good fit to high λ values is given by:

$$f = \frac{n^{1/2}}{3} \left[\mathscr{L}^{-1} \left(\frac{\lambda}{n^{1/2}} \right) - \frac{1}{\lambda^{3/2}} \mathscr{L}^{-1} \left(\frac{1}{n^{1/2}\lambda^{1/2}} \right) \right] \tag{11}$$

where

$$\mathscr{L}^{-1}(x) = \coth(x) - \frac{1}{x}$$

and n represents the number of statistical segments per network chain. As $\lambda/n^{1/2} \to 1$, $f \to \infty$ and, hence, the magnitude of n furnishes an upper limit to the value that λ can attain.

For an ideal network, i.e., one containing no soluble polymer fraction or dangling chain ends, equation (11) leads to the result:

$$(\lambda_b)_{\max} = n^{1/2} = \left(\frac{1}{\nu_e N} \right)^{1/2} \tag{12}$$

where $(\lambda_b)_{\max}$ is the maximum extensibility at break, and N is the molar volume of a statistical unit, a quantity that is determined solely by the chemical nature of the chain.

When $\lambda \ll n^{1/2}$, equation (11) reduces to the simple kinetic form (equation 9). Hence, equation (11) furnishes a good fit at both small and large strains but a poor fit at intermediate strains; the fit in the latter region improves, however, as ν_e is increased.

Thus it may be concluded that no simple equation for f exists that can provide a fit over the entire strain region. However, since this range can be fitted piecewise by use of these several functional forms, useful deductions can be obtained in the strain region where they are applicable.

For example, for small strains where equation (9) can be employed, the stress—strain response is independent of the chemical structure of the elastomer since f is a function of λ alone. In the intermediate λ range, f as given by equation (10) is again apparently independent of chemical structure since at most the strain function includes a contribution from the parameter C_2, which has been reported to be independent of chemical structure[9]. At high strains, where equation (11) can be employed, the response of an elastomer is now no longer independent of chemical structure since it contains the parameter n which, as equation (12) shows, is directly related to structure.

Although $g(t)$ has been shown to be a universal function in the terminal region, no simple universal form for f apparently exists. However, since the strain region can be fitted at least piecewise by assuming several forms for f, these several forms taken together can be considered to constitute a universal f. As a first approximation then, the use of the reduced variables $\sigma T_0/\nu_e T$, ϵ, and t will superpose at least the high-temperature portions of the family of physical property surfaces to a single surface. The superposed surface for elastomers which differ in chemical struc-

ture will at most differ on the time scale by a factor that depends on differences in the value of the monomeric friction coefficient. If this factor is taken into account by suitable shifts along the time scale, then a single universal property surface, independent of chemical structure, will result.

Effect of test type. Superposition of segments of the physical property surface as described above was limited to a single test type, e.g. creep, stress—relaxation, or constant strain rate tests. In general, it is expected that a different family of surfaces will be generated for each test type. However, if attention is restricted to the high-temperature portion of the surface, then it turns out that the surfaces are approximately independent of test mode.

For example, in stress—relaxation *versus* creep experiments, factorability of time and strain as expressed by equation (1) is still expected to be valid and, hence, we can write for the stress—relaxation experiment:

$$\frac{\sigma T_0}{\nu_e T} = g(t)f(\epsilon, a_1, a_2, \ldots) \tag{13}$$

while for experiments in creep:

$$\frac{\sigma T_0}{\nu_e T} = \frac{1}{j(t)} f(\epsilon, a_1, a_2, \ldots) \tag{14}$$

where $j(t) \equiv J_p(t)/\nu_e$ and f is taken to be independent of test type. Considering equation (5), which provides a relationship between $g(t)$ and $j(t)$, it may be seen that the response obtained in these two test modes will differ only when the factor $\sin m\pi/m\pi$ is appreciably less than unity. For example, $g(t)$ and $j(t)$ differ by 10% when m is less than 0.25. For much of the terminal region, m will most likely be less than 0.25. Hence, in this region, the surfaces and space curves as well are expected to be essentially independent of whether the data are obtained in stress—relaxation or creep experiments.

Considering constant strain rate experiments, Smith[10] has proposed a relationship between the stress—relaxation modulus and the constant strain modulus $h(t)$ in the form:

$$g(t) = h(t) \left[1 + \frac{\partial \log h(t)}{\partial \log t} \right] \tag{15}$$

where the partial derivative can assume values in the interval 0 to −0.67. Here again, if attention is restricted to the terminal zone, the values assumed by this factor should be close to zero and hence $g(t)$ and $h(t)$ will not differ appreciably in value.

Thus, the surfaces generated in these three types of experiments may be considered to be essentially the same; this statement applies to the associated space curves and to their projections in the various planes as well. In support of this, it has already been mentioned that experimental data show the failure envelope to be independent of test type.

FAILURE BEHAVIOUR

Having shown that superposed physical property surface exists at least for a small region in $\sigma T_0/\nu_e T$, ϵ, and t space, it follows that a universal failure space curve also exists over the same region. Thus, it is expected that a universal or master failure envelope will be produced when the uni-

versal failure space curve is projected to the σ, ϵ plane. Likewise, universal curves will also occur in the σ, t as well as the ϵ, t planes.

The first of these predictions (the existence of a master failure envelope) has been adequately demonstrated by a mass of experimental data[1]. The failure envelopes diverge from the master curve, however, for those conditions where the physical property surfaces do not superpose. The existence of universal $\sigma_b T_0/\nu_e$ versus t_b and ϵ_b curves has been established in that studies have indicated that shifts along the time axis (Plazek shift factor a_x) do lead to superposition of segments obtained at high temperatures[11]. This work will be the subject of a future report.

IMPLICATIONS AND PRACTICAL APPLICATIONS

Physical property surface

To the extent that the Plazek shift factor is universally applicable, ν_e can be used as a convenient variable to expand the experimental time scale, i.e. to obtain data for times or temperatures that may not be accessible experimentally. For example, if significant degradation occurs at an elevated temperature for an elastomer having a given ν_e value, then equivalent information in the absence of degradation can be obtained by studying the behaviour at lower temperatures for specimens having higher ν_e values; these data can then be shifted along the time axis to yield the desired information. The same type of information is produced by a study of swollen specimens; these data can also be shifted along the time axis according to equation (8).

Failure behaviour

It is known that both σ_b and ϵ_b decrease monotonically with t_b as mechanical equilibrium is approached. Equations (4) and (8) indicate that increasing ν_e or increasing the quantity of diluent also brings the system closer to mechanical equilibrium. Hence, this implies that increasing ν_e and adding diluent to a system should produce a reduction in both σ_b and ϵ_b; this is in agreement with experimental data.

Equations (4) and (8) can be employed to obtain semi-quantitative estimates of the effect of both ν_e and swelling on failure behaviour. Assuming that the σ_b, t_b and ϵ_b, t_b responses are known at one value of ν_e, then the effect of varying both ν_e and swelling on the effective time scale can be calculated. Knowing the effective time scale, one can then read off from the σ_b, t_b and ϵ_b, t_b plots in the σ_b and ϵ_b values that correspond to the change in ν_e or swelling.

Kinetic studies on the decomposition of polystyrene samples with molecular weights ranging from
900 to 1.8×10^6 have been carried out making use of the differential thermogravimetric and dif-
ferential scanning calorimetric techniques. Changes in molecular weight distributions with decom-
position, at different temperatures or times, have been studied by gel permeation chromatography.
This technique was likewise used to carry out component splitting of the undecomposed polymer
samples. These components have been shown to break down statistically primarily by a process of
random scissions yielding lower molecular weight products. The major portion of the observed
weight loss, by the volatilization of small chain segments, is attributed to a rapid and complete
depolymerization of chains. These interpretations are based on changes in polydispersity occurring
during the decompositions. Similar components, decomposing in a different manner but under iden-
tical operating conditions, are suspected of being different stereoregular forms of the polymer. The
order of reaction as computed from the method of Freeman and Carroll has been found to be zero
for random scissions and one for the process of depolymerization. The activation energy computed
by the method of Coats and Redfern was found to increase with molecular weight reaching a maxi-
mum value in the 10^5 molecular weight range.

INTRODUCTION

The thermal decomposition of polystyrene has been the
subject of many studies[1-4] in the past and still remains the
subject of much discussion. It is generally believed that
decompositions such as this proceed in two steps. In the
first, it is assumed that random thermal scissions break the
polymer chains at weak points[5-7] resulting from factors
such as head-to-head linkages, chain branches and unsatur-
ated bonds. In the second step, the shorter chain segments
depolymerize into volatile products consisting mainly of
monomer and low molecular weight oligomers (e.g. dimers,
trimers and tetramers). It is during this second step that
the major portion of weight loss occurs in the decompos-
ition process. These conclusions have been reached prim-
arily from kinetic data where the two-step decomposition
of polystyrene, attributed to different reaction mechanisms,
is said to have zero order kinetics for the first step and first
order kinetics for the second[8-13]. Different activation
energies for the two processes are also reported in the
literature[9-13].

In thermal decompositions where random scissions and
cleavages of chain-ends take place, chain lengths and their
distribution in the polymer must of necessity be important
factors in determining the course that the reaction process
follows with time or temperature. Indeed, studies have
been reported in this area[14-16], but these are based on
either theoretical considerations or data obtained with
light scattering, osmometry or viscometry which yield
limited information. Recently, gel permeation chromato-
graphy (g.p.c.) has been used to study the decomposition
of polystyrene and detailed information has been reported[17].
In this laboratory, g.p.c. distributions have also been ob-
tained as the decomposition proceeds and they have been

analysed[18] though in a different manner. This has led to
speculations regarding the mechanism of decomposition.
Kinetics of the reactions have also been studied in order to
gain support for the speculated mechanism: the order of
reaction and energy of activation being both computed by
the method of Freeman and Carroll[19] and by that of Coats
and Redfern[20]. The results obtained are discussed in the
light of existing theories.

EXPERIMENTAL

Materials

Anionically prepared polystyrene standards with molec-
ular weights ranging from 900 to 1.8×10^6 were obtained
from the Pressure Chemical Company in the USA. A
thermally prepared polystyrene sample with a weight-
average molecular weight of 4.3×10^5, provided by
Farbwerke Hoechst AG was likewise included in the study.
The samples were used as such without further purification
when preliminary tests with purified (by precipitation) and
non-purified samples yielded the same results.

Apparatus

A Perkin–Elmer model TGS-1 thermobalance, operat-
ing under inert nitrogen atmosphere and at heating rates
of $1.25°$, $5.0°$ and $20°C/min$, was used to study the 1 mg
polymer samples selected. A Perkin–Elmer model DSC-1B
differential scanning calorimeter likewise operating under
inert nitrogen atmosphere and at a heating rate of $20°C/min$
was also used in this work but with samples each weighing
from 2 to 3 mg. The samples were placed between two
layers of 100 mesh stainless-steel screening as suggested by
Ellerstein[21].

Analyses of the polystyrene samples both before and
after the decompositions were carried out with a Waters
Associates model 200 gel permeation chromatograph

---

* Present address: Villa Société Nationale des Pétroles Aquitaines
No: 6, 64370 Arthez-de-Béarn, France.

operated in a constant temperature ($25 \pm 0.5°C$) room.
The separating system consisted of four 4 ft (1.22 m)
columns connected in series, each packed with crosslinked
polystyrene gel having (by the Waters method) pore sizes
of 1×10^6, 1.5×10^5, 3×10^3 and 250 Å respectively.
The flow of solvent, tetrahydrofuran degassed with nitrogen,
was maintained at 1 ml/min while the concentration of
polymer in the samples was limited to 0.125 wt % in order
to render negligible 'concentration effects' on the peak
positions in the chromatograms. The anionic polystyrene
standards were used to plot a g.p.c. calibration curve (log
molecular weight, M versus elution volume V_e) shown in
Figure 1. Molecular weights were then computed by follow-
ing Smith's method[22].

Component splitting of the g.p.c. curves

Splitting of the raw g.p.c. curves into several compon-
ents was carried out as described below for the particular
case of the 1.8×10^6 molecular weight anionic polystyrene
standard.

As can be seen from *Table 1*, at the lower elution volumes
which correspond to the higher molecular weight species
there is a continuous decrease in the relative weights of the
polymer species with reaction temperature, whereas at the
higher elution volumes (or lower molecular weights), the
weights of the lower molecular weight species increase
regularly. If one substracts from the initial distribution
curve of the undecomposed polymer the distribution curve
of any subsequently decomposed polymer, one can readily
visualize the changes that take place resulting from the
decomposition of the higher molecular weight species.

To illustrate the above, the g.p.c. distribution of the
undecomposed (1.8×10^6) polystyrene standard was com-
pared successively with that of two other samples obtained
with the same polymer after it had been decomposed during
50 min periods at 230 and 330°C respectively. In this
manner, it was possible to split the undecomposed polymer
sample into three components: α, β and γ.
Figure 1 G.p.c. calibration curve prepared with polystyrene standard
samples in THF at room temperature at a flow rate of 1 ml/min on
the following Waters Associates Styrogel columns linked in the follow-
ing way: 7×10^5 to 5×10^6 Å, 1.5×10^5 to 7×10^5 Å, 3.0×10^3 Å,
and 250 Å

Summation of relative weights:	20.07	19.94	19.90	19.95	19.40	18.37

An examination of *Figure 2a*, where the distribution
curves of the undecomposed and decomposed (at 230°C)
polymer sample are shown, reveals that a part of the high
molecular weight species marked α in the undecomposed
sample has been changed, upon heating at 230°C, into
the lower molecular weight species α'. *Figure 2b* shows the
components of the undecomposed polymer with those of
the sample decomposed at 230°C and this in terms of
distributions, α and ($\beta + \gamma$) for the former and ($\beta + \gamma$) plus
α' for the latter. These distributions, when derived rigor-
ously from the proportions of their areas, appear as shown
by the solid lines. In reality, however, some overlapping of
the two distributions undoubtedly takes place as is shown
by the broken lines. The tracing of these broken lines is
based essentially on the overall shape of the curves be they
broad, Gaussian or other in distribution; but they are at
best only a first approximation of the true situation.

Figure 2c shows further changes that take place in the
20°C distribution of the 1.8×10^6 polystyrene standard,
when it is heated during a 50 min period at 330°C. It is
clear that a greater part of the original distribution, ($\alpha + \beta$),
has been changed into species ($\alpha + \beta$)' of lower molecular
weight. *Figure 2d* illustrates, in the form of distributions,
the areas of ($\alpha + \beta$) and ($\alpha + \beta$)' again with some overlapping
of the two. Tracing of the broken lines was carried out
by making extrapolations on both the right-hand and left-
hand sides of the ($\alpha + \beta$) and ($\alpha + \beta$)' distributions respec-
tively, keeping in mind that their areas are essentially the
same and that the residual distribution γ, which remains
unchanged by the decomposition, is common to the two
curves. More explicitly, the areas of ($\alpha + \beta$) plus γ and γ
plus ($\alpha + \beta$)' should be equal. When the distribution of γ
has been traced, that of β poses no problem. It can be
obtained by subtracting the distribution of α from that of
($\alpha + \beta$) or by tracing those of γ and α under the distrib-
ution curve of the original undecomposed sample, the
remaining area should be that of β. This is shown in
Figure 2e.

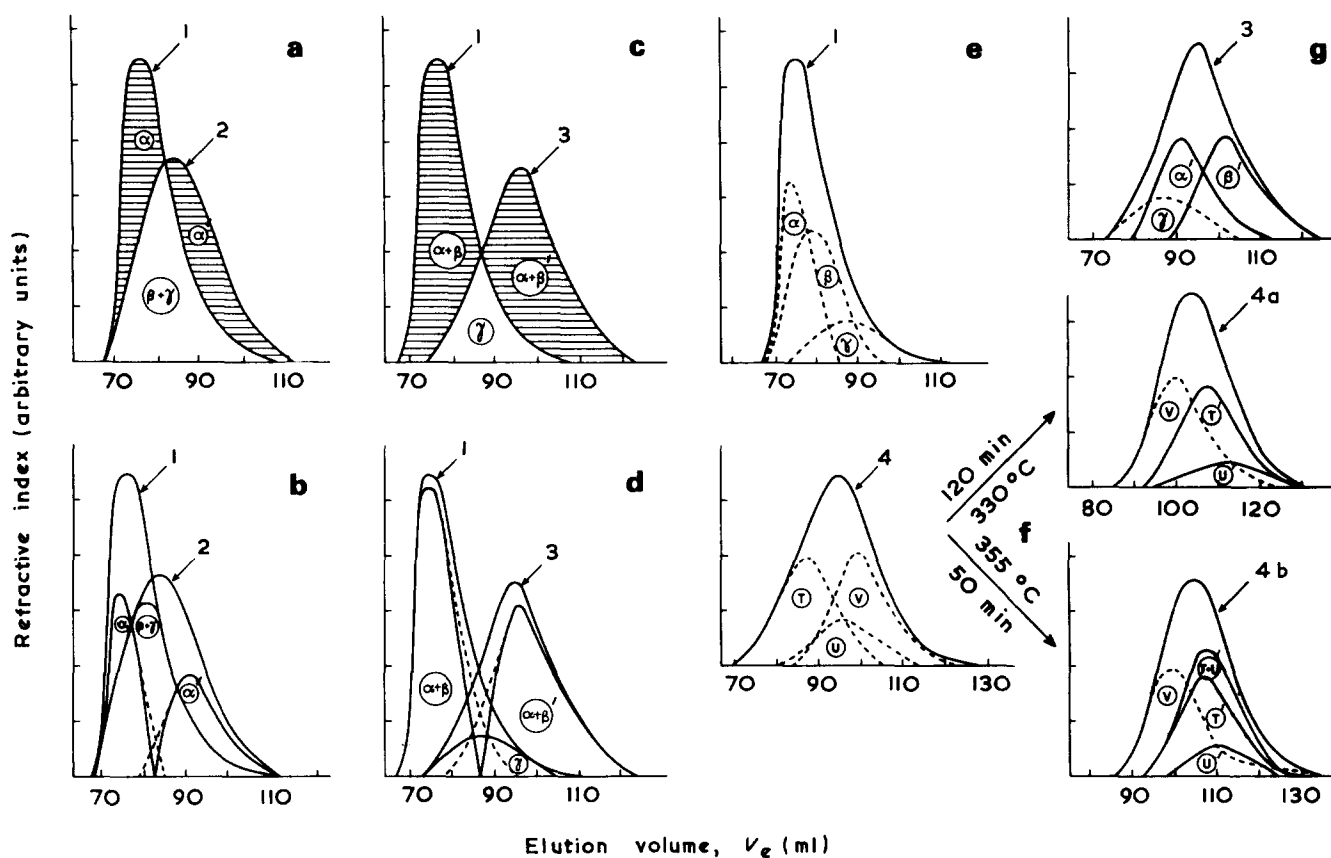
The significance of these components, at this stage, lies
in the fact that one can now say that the distribution of a
polymer sample made up of components α, β and γ at 20°C,
when heated at 230°C for 50 min, changes to a new distrib-
ution involving components β, γ and α'. If the sample is


Figure 2 Graphical method of analysis by which g.p.c. distribution curves are broken down into their components: the case of a polystyrene sample PS ($\overline{M}_w$ = 1.8 x 10^6) subjected to isothermal treatments at several temperatures and for different periods. 1, Undecomposed; 2, 50 min at 230°C; 3, 50 min at 330°C; 4, Hoechst PS ($\overline{M}_w$ = 4.3 x 10^5) undecomposed; 4a, 120 min at 330°C; 4b, 50 min at 355°C

maintained at 330°C instead of 230°C, for a similar 50 min period, yet another distribution is obtained which is the sum of components γ and $(\alpha + \beta)'$. The components β and γ become more meaningful if one finds means to compute their resulting distributions, β' and γ' in a manner similar to that used to evaluate α'.

This would require that the decomposition studies be made in several steps, starting with the undecomposed polystyrene standard at 20°C and decomposing it for a 50 min period at some given temperature. In a second step, one would use a part of the already decomposed sample and subject it to a further decomposition at a higher temperature for a similar period of 50 min. In this way, one would better understand the decomposition process that is taking place.

In practice, one would find this technique long and cumbersome because of the many difficulties involved in handling large quantities of material in the first decomposition that enough material might be left to carry out six or seven successive stages of decomposition. Furthermore, the kinetic parameters (e.g. activation energy) are not necessarily the same when different initial masses are used for the decompositions. This leads one to use a different approach involving: (1) the division of the original undecomposed sample at 20°C into several 1 mg parts; (2) the study of their decomposition at different temperatures for a period of 50 min; and (3) the analysis of the residues by g.p.c.

The disadvantage of this approach is that one must improvise with the results obtained in order to reach meaningful conclusions as far as the changes in distributions are concerned. To illustrate, one may once again consider the case of the decomposition of the 1.8 x 10^6 polystyrene

standard. As mentioned earlier, on heating this polymer at 230°C for 50 min, the component α changes to α' and when the original sample is heated at 330°C for a similar period of 50 min $(\alpha + \beta)$ changes to $(\alpha + \beta)'$. In order to find the value of β', the products of the second decomposition, one is required to show that the distribution $(\alpha + \beta)'$ is equivalent to $\alpha' + \beta'$. This means that one must assume that the g.p.c. distribution curve of the α' products, obtained by heating the undecomposed sample at 230°C, will remain the same when the original sample is heated at 330°C.

This assumption originated from experimental results obtained in this laboratory while working on the decomposition of the thermally prepared polystyrene sample mentioned earlier. *Figure 2f* illustrates the overall distribution of the polystyrene sample and its components T, U and V, their splitting being carried out on a time basis. The use of time as a variable during the decomposition study at a fixed temperature gives meaningful results because these are obtained without having to make assumptions. To illustrate, when considering the changes that occur in distributions on heating a given sample during two different periods (viz. 50 min and 120 min), not only does one obtain results for the two independent times but also information as to what additional decomposition takes place during the latter 70 min. This enables one to trace the distribution of the components in the undecomposed sample; and furthermore it yields the distribution of their decomposed counterparts as shown in *Figure 2f*. It can be seen that when the sample is heated at 330°C for 120 min, the components T and U are changed into T' and U'. Detailed information about components T, U, and V and their decomposition is given later (*Figure 5*). Indeed, it was observed that com-

ponent T changed to T' during the first 50 min and component U decomposed into U' during the next 70 min. When the same undecomposed sample was heated at 355°C but for only 50 min, an identical distribution was obtained which is the sum of the distributions V and (T + U)', the decomposed counterpart of the component (T + U). This distribution has also been shown to be made of distributions V, T' and U' with the only difference that the molecular weight of the decomposed component U' is slightly lower, suggesting that (T + U)' is equivalent to T' plus U'. Based on these results, one can say that the assumption of (α + β)' being equivalent to α' plus β' is not far-fetched. It can be concluded from this observation that time and temperature play similar roles in the decomposition: higher temperatures require shorter times while lower temperatures require longer times. For comparable weight losses the g.p.c. traces may be expected to be very much the same.

Finally, *Figure 2g* illustrates the distribution of the 1.8 x 10⁶ polystyrene standard, decomposed at 330°C during a 50 min period, which is made up of the undecomposed component γ and two decomposed components α' and β'. If one were to carry out further decompositions at higher temperatures, the distribution of the decomposed component γ' could then also be traced.

Nuclear magnetic resonance spectra

N.m.r. analyses of the polystyrene samples were carried out at the Canadian 220 MHz NMR centre, in Sheridan Park, Ontario. N.m.r. spectra of the polymers were obtained with 15% by wt solutions of the polymers in tetrachloroethylene at 100°C; tetramethylsilane was the internal standard used.

RESULTS AND DISCUSSION

A comparison of g.p.c. distributions of the undecomposed (1.8 x 10⁶) polystyrene standard with five of its decom-

posed counterparts, obtained at different temperatures for 50 min periods, is shown in *Figure 3a*. Areas under the curves A' to E' are due to the lower molecular weight decomposition products of components A to E which disappear from the original sample when it is heated at successively higher temperatures. The g.p.c. distributions of the undecomposed sample and its five components A to E are shown in *Figure 3b*. *Figures 3c* to *3g* show successively by g.p.c.distributions the step-by-step decompositions of this polystyrene standard at temperatures ranging from 180° to 355°C where the weight loss reaches an upper value of 8%. Changes in molecular weights and in polydispersities between the decomposed and the undecomposed components are shown in *Table 2*. It can be seen that each decomposition reaction is accompanied by an important drop in the molecular weight of the decomposed species when considered on an individual basis; the bulk molecular weight, however, does not seem to change in such a pronounced way. A similar situation is encountered with the polydispersities. The bulk polydispersity does increase as the decomposition progresses, but it does not reveal the fact that, at each decomposition, the polydispersity of the newly formed products is very close to 2.0. One can safely assume from these results that, for a high molecular weight polystyrene sample of low polydispersity, the mechanism of decomposition resulting in a weight loss of less than 10% should be such as to yield a polydispersity of 2.0, the most probable distribution.

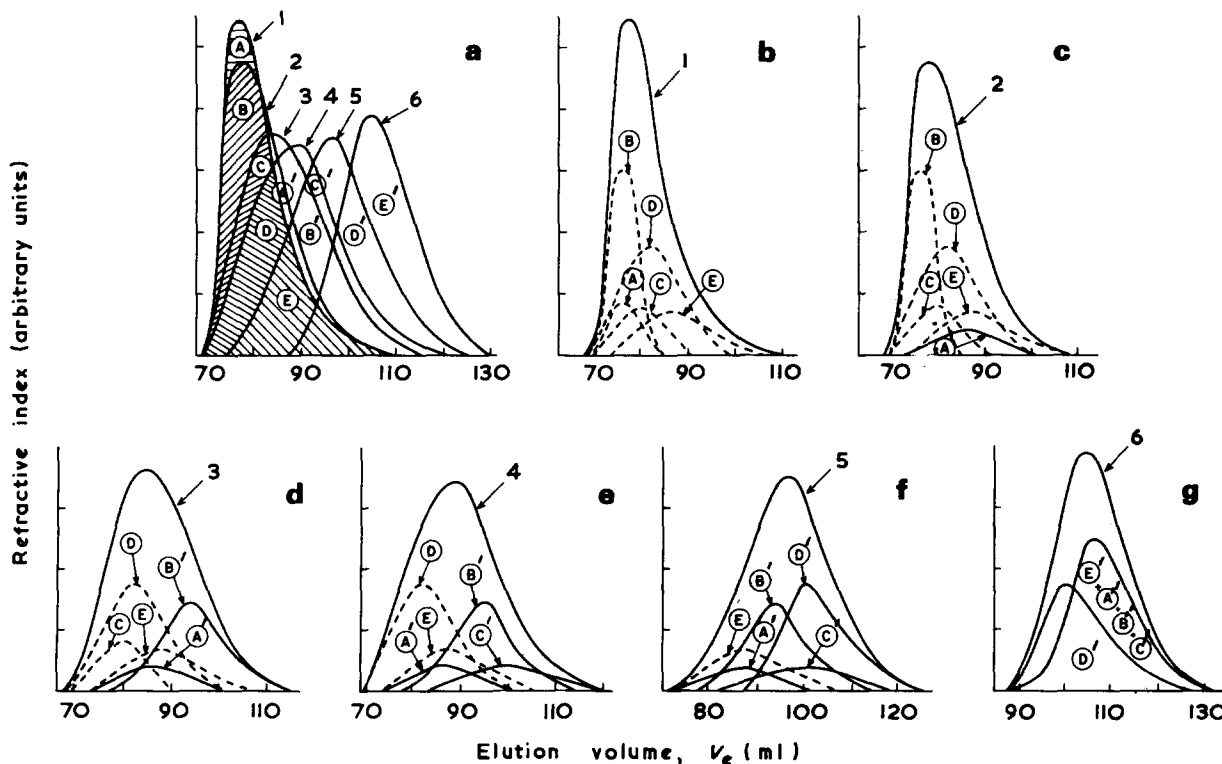
Figure 4a illustrates a comparison of g.p.c. distributions obtained with a thermally prepared polystyrene sample of broad initial distribution and molecular weight, $\overline{M}_w$, of 4.3 x 10⁵ with its decomposed counterparts, where the decompositions were carried out, during 50 min periods, at temperatures of 280°, 330° and 355°C. A fourth distribution of decomposition products was obtained at 370°C but was not included when splitting component parts because of the excessively high polymer weight loss


Figure 3 (a) G.p.c. distributions of PS ($\overline{M}_w$ = 1.8 x 10⁶) subjected to 50 min isothermal treatments at various temperatures; (b) to (g) components of each of the g.p.c. curves shown in (a). 1, Undecomposed; 2, 180°; 3, 230°; 4, 280°; 5, 330°; 6, 355°C
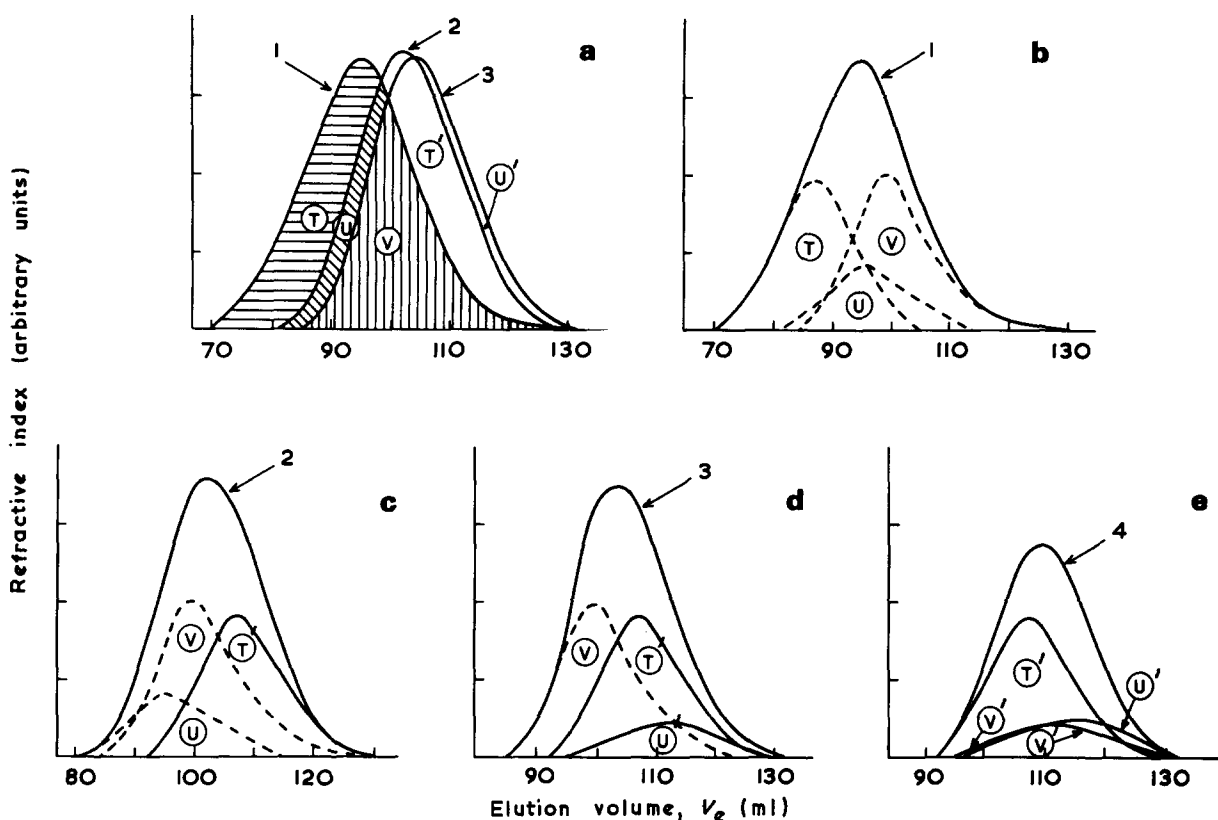

observed (56.5%). In this study, were considered only those decompositions which involved less than 10% weight loss. *Figure 4b* shows the components L to O of the undecomposed distribution while *Figures 4c* to *4f* show successively again by g.p.c. distributions the step-by-step decompositions of this polystyrene sample at the four temperatures mentioned above. The polydispersities of the decomposed components L' to O' are compared in *Table 3* with those of their undecomposed counterparts L to O. The polydispersities of approximately 2.0 remain unchanged after the decompositions.

Figure 5a illustrates g.p.c. distributions obtained with the above mentioned undecomposed polystyrene ($\bar{M}_w$ = 4.3 x 10^5) and with the products of its decomposition at 330°C during different periods. Only three curves were considered for component splitting of the undecomposed polymer since the fourth experiment, lasting 4 h involved an excessive 33% weight loss. *Figure 5b* shows three components T, U, and V while *Figures 5c* to *5e* show the progression of the decompositions. Molecular weight and polydispersity values of the above components, T, U and V,

are shown in *Table 3*. The results show clearly that the decomposition products T', U' and V', have the same polydispersity (2.00) as the parent components.

The process whereby the decomposition of a high molecular weight polymer with a polydispersity of 2.0 or less leads to products of lower molecular weight with a most probable distribution, has been attributed to random scissions by Berlin and Yenikolopyan[15]. The polydispersity results obtained in this laboratory agree well with the theoretical values expected for random scissions.

Figure 6a shows g.p.c. distributions obtained with an undecomposed polystyrene standard ($\overline{M}_w$ = 1.6 x 10^5) and with its decomposed products at 330°C after 50 and 120 min. A third sample treated at 330°C for 4 h was not used for component splitting because of unusually high weight loss (21%). *Figure 6b* shows the components X to Z of the undecomposed distribution while *Figures 6c* to *6e* show successively by g.p.c. distributions the step-by-step decompositions of this sample at the three periods mentioned above. The changes in molecular weight distribution and polydispersity on heating are given in *Table 4*. In this case, the polydispersity values of the decomposed species X' and Y' were all about the same (1.5).

Figure 7a shows a comparison of g.p.c. distributions obtained with the same polystyrene standard ($\overline{M}_w$ = 1.6 x 10^5) but where the decomposition was studied at different temperatures over a fixed time. In *Figures 7b* to *7e* are shown the changes observed in the distributions while the polydispersity values as well as the molecular weights, as computed on the bases of *Figures 7c* to *7e*, are represented in *Table 4*. Here as before, the components P, Q and R are found to change to P', Q' and R' having polydispersities of 1.5. As suggested by Wall and coworkers, this finding requires, in addition to intermolecular transfer, a radical— radical recombination process which probably takes place by some sort of cage recombination[23] as shown below:
The newly formed radicals, $\sim\sim$CH$_2$—C(ϕ)H , must then combine with other radicals.

Figure 8 shows the results of decompositions carried out at different temperatures, as seen through g.p.c. analyses, of a low polydispersity polystyrene standard ($\overline{M}_w$ = 1.03 x 10^4). It is apparent from the g.p.c. traces that there are little or no changes in the molecular weight distributions in the decomposed samples, only weight changes. These are found to decrease. Berlin and Yenikolopyan[15] explain this behaviour by the rapid and complete depolymerization of radical bearing chains. Contrary to chain scissions, depolymerizations invariably occur at polymer chain ends; hence the rate of disappearance of polymer molecules is independent of their length. Thus in depolymerizations, a random proportion of the polymer leaves the reaction medium and this independently of its molecular weight. The number-average and weight-average molecular weights are therefore independent of the extent of the decomposition.

Table 5 summarizes the changes observed in the overall molecular weight and polydispersity values for decompositions carried out at different temperatures and times with the various polystyrene samples discussed individually, in this text, in terms of components. Making use of the values reported, plots of molecular weight with temperature and with fraction decomposed, *a* have been made in *Figures 9* and *10*, respectively. *Figure 9* clearly indicates that the polystyrene standards ($\overline{M}_w$ = 1.03 x 10^4 and 1.6 x 10^5) are very little affected when the temperature is raised up to 330°C; whereas the other two ($\overline{M}_w$ = 1.8 x 10^6 and 4.3 x 10^5) show nearly 5 to 6 fold decreases in their molecular weights. Combining this observation with the results given in *Table 5* and *Figure 10*, the weight loss owing to the decomposition for these two polymers is limited to 9% at 330°C even if there is a substantial drop in molecular weight. As indicated earlier, decompositions involving high

molecular weight samples are termed random scissions when the weight losses are limited to less than 10% and when molecular weights drop by factors of five to six.

When the molecular weights of the fragments drop to a value of around 10^5 or less, the process of depolymerization becomes much more important than that of random scissions. This accounts for the major portion of weight loss observed. It is very difficult, however, to point out the exact moment at which the scission step ends and the depolymerization step begins, because the random scissions which break the polymer statistically alter a nearly monodisperse distribution into a modified most-probable one while depolymerization keeps it as such until all of the polymer has disappeared.

When one follows polydispersity changes solely from overall results, one can erroneously be lead to believe that random chain scissions are the only reactions involved while the overall polydispersity of the products varies but progressively with temperature towards the most probable value of 2.0. This is particularly true in certain cases where most probable values of 2.0 are reached only after intensive periods of reaction during which depolymerization has contributed significantly to the weight loss of the samples. This might explain why one obtains an overall polydispersity of only 1.5 for the decomposition of the component parts of the 1.6 x 10^5 polystyrene standard though both random scissions and depolymerization are known to proceed simultaneously.

Effect of polymer stereoregularity on the decomposition

It has been reported[24] that stereoregularity of polystyrene has little or no influence on its decomposition and indeed investigations[10,12,24] have shown that atactic and isotactic samples have similar activation energy values for their decomposition. Boon and Challa[25] found some differences, though slight, when they computed activation energies from melt viscosity data obtained with non-degraded and degraded samples. They attribute the differences, however, to the temperature dependence of activation energy. Their studies were carried out in the 265–320°C temperature range while most others have worked in the lower 200 to 260°C range[26−28].

In spite of the evidence put forth, it is difficult to visualize that stereoregularity which exerts considerable influence on the mechanical properties of polymers has little or no effect on its thermal properties. Isa and Dole[29] have shown that the heat of fusion of a crystalline polymer is different from that of an amorphous one. One would be led to conclude that, in a mixture made up of isotactic crystalline and atactic amorphous macromolecules of equal molecular weights, one of the two should require less energy to decompose than the other.

With this idea in mind, the decomposition data obtained in this laboratory by g.p.c. were analysed to establish the percentage proportion of isotactic, heterotactic and syndiotactic fractions. The results were compared with those obtained by n.m.r.

Figure 9 Variation of molecular weight with temperature for several PS samples: □, $\bar{M}_W$ = 1.8 x 10^6; ○, $\bar{M}_W$ = 4.3 x 10^5 (thermally prepared Hoechst sample); ●, $\bar{M}_W$ = 1.6 x 10^5; ■, $\bar{M}_W$ = 1.03 x 10^4

Figure 10 Variation of molecular weight with decomposed fraction, a, for several PS samples: □, $\bar{M}_W$ = 1.8 x 10^6; ○, $\bar{M}_W$ = 4.3 x 10^5 (thermally prepared Hoechst sample); ●, $\bar{M}_W$ = 1.6 x 10^5; ■, $\bar{M}_W$ = 1.03 x 10^4

Although the data obtained by the decomposition reactions at different temperatures in the present study have been used to split the g.p.c. curves into many components, there are, in reality, most likely only two or three major components in each case. For example, the components α and β in *Figure 2b* correspond, respectively, to the sum of components (A + B) and (C + D) in *Figure 3b*. This statement is based on the assumption that species of similar molecular weights and identical distributions may actually come from the same parent distribution and thus be combined together. As pointed out earlier, the decomposition reaction itself is random in nature though at any given time, only one component decomposes to lower molecular weight products.

If this is correct, this would mean that the three components α, β and γ in *Figure 2b*, having molecular weights of similar magnitude, decompose at different temperatures and must therefore be different in their formation. Similar

observations have also been made in the case of the 1.6 x 10^5 polystyrene standard shown in *Figure 6b* where the components X and Y have approximately the same molecular weights though component X is the first to decompose. The three polystyrene structures (viz. isotactic, heterotactic and syndiotactic) could be the different formations mentioned earlier.

The validity of this statement can only be checked by the use of n.m.r. spectroscopy; however, the n.m.r. spectra taken even with a 220 MHz instrument at 100°C did not reveal the presence of these stereoregular forms in the four polystyrene samples studied. The n.m.r. spectra in all cases appeared to be identical, indicating that the samples have the same stereoregularity or that the aromatic rings of polystyrene are not sufficiently sensitive to proton spectra. The latter observation is reported in the literature[30] and the possibility that the samples have similar stereoregularities cannot be ruled out. The weight fraction of the least resistant components towards heat, viz. α, X and T,

is very nearly the same in the three cases (~41%), while the corresponding weight fractions of the other more resistant components do not tally quite so well. The use of an ideal polymer, such as poly(α-methyl styrene), because of its ease of detection in n.m.r., should prove most interesting in further studies to confirm the effects of stereoregularity on their decomposition. The polystyrene proton resonances obtained in this work were, nevertheless found to be different from those already reported in the literature. These are listed in *Table 6*, and the experimental spectra, in *Figure 11*. There is a substantial difference in the τ values reported[30] for methine and methylene protons and those observed in the present study. Furthermore, a new resonance peak was found at $\tau = 3.61$. This peak may form part of the proton resonances for $H_{(2)}$ or $H_{(6)}$ for which the values of $\tau = 3.43$ (I) and 3.50 (H) have already been assigned. On the other hand, it may be that $H_{(2)}$ and $H_{(6)}$ are not identical in value as reported earlier[30]; however, the values for the other proton resonances, $H_{(3)}$, $H_{(4)}$ and $H_{(5)}$, show little differences.

Decomposition kinetics

In dynamic thermogravimetry, the rate law for the decomposition of polystyrene can be written in the following general form:

$$\frac{da}{dT} = \frac{k}{q} f(a) \tag{1}$$

where a is the volatile polymer fraction, defined as the ratio of polymer mass, decomposed at a temperature T, to its initial mass; $f(a)$, a function of a; q, the heating rate (in °C/sec); and k, the rate constant said to obey the Arrhenius law written in the form: $k = Z. \exp(-E/RT)$. Here Z is the pre-exponential factor (in sec^{-1}) and E, the energy of activation (in kcal/mol).

For decompositions where weight loss is primarily due to depolymerization reactions, Audebert and Aubineau[31] have shown that $f(a)$ has the following form:

$$f(a) = (1 - a)^n \tag{2}$$

n being the order of reaction. Substituting in equation (1),

Figure 11 N.m.r. spectra for PS samples. 1, $\overline{M}_W = 1.6 \times 10^5$; 2, $\overline{M}_W = 4.3 \times 10^5$; 3, $\overline{M}_W = 1.8 \times 10^6$

one obtains:

$$\frac{da}{dT} = \frac{Z}{q} \exp(-E/RT) (1 - a)^n \tag{3}$$

To compute activation energies, Flynn and Wall[32] have suggested the integration of equation (3) between the limits 0 and a.

Therefore:

$$\int_0^a \frac{da}{(1 - a)^n} = \frac{Z}{q} \int_0^T \exp(-E/RT) dT \tag{4}$$

If one now makes use of the Doyle[33] approximation for the energy of activation E, one gets:

$$E = -4351 \cdot \frac{d(\log q)}{d(1/T)} \text{ (in Mcal/mol)} \tag{5}$$

Freeman and Carroll[19] have suggested another way of using equation (4). Writing it in logarithmic form and in differential terms one obtains:

$$\frac{\Delta\ln(da/dT)}{\Delta\ln(1 - a)} = \frac{E}{R} \frac{\Delta(1/T)}{\Delta\ln(1 - a)} + n \tag{6}$$

Coats and Redfern[20], on the other hand, have shown that the integral

$$\int_0^T \exp(-E/RT) dT$$

is equal to $(RT^2/E) \exp(-E/RT)$. Thus equation (4) can be written as:

$$\int_0^a \frac{da}{(1 - a)^n} = \frac{Z}{q} \cdot \frac{RT^2}{E} \cdot \exp(-E/RT) \tag{7}$$

The expression on the left-hand side of equation (7) may be referred to as $f(a)$ and thus:
Figure 12 Influence of initial mass on thermograms obtained by dynamic thermogravimetric decomposition of PS ($\bar{M}_W$ = 1.03 x 10⁴) at 50°C/min. A, 0.996; B, 3.983; C, 6.066 mg
Figure 13 Influence of heating rate on the dynamic thermogravimetric decomposition of a polystyrene standard ($\bar{M}_W$ = 1.03 x 10⁴). A, 1.25; B, 5.0; C, 20°C/min

$$f(a) = \frac{1 - (1 - a)^{(1-n)}}{(1 - n)} \quad \text{for } n \neq 1$$

$$\text{and} \quad = -\ln(1 - a) \quad \text{for } n = 1$$

If $[f(a)/T^2]$ is plotted as a function of $1/T$ for different values of n, the one yielding a straight line is used to compute the value of the activation energy. Based on these expressions, the factors which are most likely to affect the values of the activation energy seem to be the mass of the polymer being decomposed and the heating rate at which the decomposition takes place.

Figure 12 shows dynamic thermogravimetric curves obtained at a heating rate of 5.0°C/min with three different initial masses of the 1.03 x 10⁴ polystyrene standard. It can be seen that, as the initial mass of the sample is increased, the percentage decomposition at a given temperature decreases. The activation energy values derived from the curves in *Figure 12* increase with sample mass. For initial masses of 1, 4 and 6 mg of polymer, the activation energies were 79, 86 and 89 kcal/mol, respectively.

Figure 13 shows differential thermogravimetric (d.t.g.) curves obtained with the 1.03 x 10⁴ polystyrene standard using initial samples of 1 mg. These were decomposed at three different heating rates (1.25, 5.0 and 20.0°C/min). It is clear from the Figure that the percentage decomposition at any given temperature decreases with increasing heating rate. This, however, creates no particular problem here, since all the activation energy values have been computed for the three heating rates. *Figure 14* shows the d.t.g.

curves of polystyrene standards, with molecular weights ranging from 900 to 1.8 x 10⁶, decomposed at a heating rate of 1.25°C/min, the initial mass of the samples being, in all cases, 1 mg. The curves indicate that, for the polystyrene standards situated between 900 and 1.6 x 10⁵, the decomposition begins between 200 and 350°C depending upon the molecular weight — the higher the value, the higher the starting temperature — but 100% decomposition is achieved at slightly lower temperatures with the two upper molecular weight samples (viz. 1.03 x 10⁴ and 1.6 x 10⁵).

With polystyrene samples having molecular weights of 1.6 x 10⁵ and higher, the decomposition reaction begins around 350°C; but, as in the previous case, the higher the molecular weight, the lower the ultimate temperature for 100% decomposition. This is reflected in the activation energy values which are found to be lower for polymers of molecular weight greater than 1.6 x 10⁵. This point will be discussed in more detail further on.

The volatile polymer fraction, a, for thermogravimetric analyses, was defined earlier in the text. The definition, however, changes when it is used in differential scanning calorimetry (d.s.c.), and must be expressed in terms of enthalpic changes that occur during the process. Keeping this in mind, the order of reaction n can be evaluated with equation (6) proposed by Freeman and Carroll[19] when written in the following form:

$$\frac{\Delta\ln(dH/dT)}{\Delta\ln H_r} = \frac{E}{R}\frac{\Delta(1/T)}{\Delta\ln H_r} + n \tag{8}$$

As with d.t.g., the values of the activation energy are influenced somewhat by the heating rate in the d.s.c. technique. The values, computed with the Borchardt and Daniels[34] expression for different heating rates from d.s.c. thermograms similar to the one shown in *Figure 15* for the 1.03 x 10⁴ polystyrene standard, are given in *Table 7* for first order kinetics as determined with equation (8) in *Figure 16*. As the values obtained change relatively little, a heating rate of 20°C/min was used to study the influence of molecular weight on the activation energy. The values given in *Table 8*, reveal that the activation energies are somewhat higher for the higher molecular weight standards than those for the lower molecular weights. Similar results were obtained with d.t.g. and are reported below.
Figure 14 Influence of molecular weight on the dynamic thermogravimetric decomposition of polystyrene standards at 1.25°C/min (E, thermally prepared sample). B.

Molecular weight, $\bar{M}_w$ x 10⁻³	0.6	0.9	2.03	12.0	160.0
Activation energy (kcal/mol)	45	45	41	50	60

A close examination of *Figure 16* shows that not all of the points fall on the line for a first order reaction. In the initial stages of the process, when the temperature is such that the values of a are less than 0.15, the order of the reaction is indeed zero. This would mean that even if the process were considered exclusively as one of depolymerization, there must of necessity be random scissions taking place for which the order of reaction is zero. It must be pointed out, however, that the zero order process associated with random scissions is more prominent when dealing with higher molecular weight polystyrenes since depolymerization is not a significant factor. All of the plots are not shown because diagrammatically they all resemble the one shown in *Figure 16*.

Activation energy values have nevertheless been computed using the method of Coats and Redfern[20] for the two steps involved (chain scissions and depolymerization) in the decomposition of polystyrene standards with molecular weights ranging from 900 to 1.8 x 10⁶ and heated at rates of 1.25, 5.0 and 20.0°C/min. The results obtained are presented in *Table 8*. For molecular weights up to 1.6 x 10⁵, there is a steady increase in the activation energy values whereas beyond this point they tend to become constant. Increasing activation energy values with increasing molecular weight appear normal if one considers that longer chain lengths can be expected to require more energy for decomposition than shorter ones.

Constant activation energy values with polystyrenes of still higher molecular weights (>1.6 x 10⁵) may be explained on the basis that, for these polymers, very low activation energies are required for their scission into lower molecular weight fragments ($M_w \approx 1.0$ x 10⁵). The values of E, therefore, lie in the same range as those of a sample whose initial molecular weight is 1.6 x 10⁵.

Under certain conditions the activation energy values for very high molecular weights are sometimes much lower than those of other samples having 10 fold lesser molecular weights, but before attempting any explanation of this effect, one must recall that the activation energy varies with many factors among which are: (a) the rate of heating, (b) the order of reaction, (c) the volatile fraction, (d) the nature of the linkages in the polymer, and (e) branching.

Keeping in mind the numerous factors which influence
Figure 16 Variation of $\Delta\ln(dH/dT)/\Delta\ln H_f$ with $[\Delta(1/T)/\Delta\ln H_f]$ based on d.s.c. data obeying first order kinetics

0.9	62	54
Figure 17 Decomposition of a polystyrene standard $(\bar{M}_w = 1.6 \times 10^5)$: variation of activation energy with molecular weight

the values of E, one can ignore minor discrepancies in the experimental data obtained; however, large differences, such as those observed in the case of the 4.3×10^5 thermally prepared polystyrene sample, may be attributed to the presence of weak links in the polymer chains owing to its method of preparation. The exact nature of these weak links is difficult to specify; however, the presence of branching in this polymer can be ruled out on the basis of its n.m.r. spectra where the ratio of benzene protons to that of methine as well as methylene protons compares well with that obtained in the case of anionically prepared standard polystyrene samples.

Computed activation energy values at different stages of the decomposition with the expression formulated by Flynn and Wall[32] are presented in *Table 9*. The results suggest that with the highest molecular weight polymer $(M_w = 1.8 \times 10^6)$, the activation energy increases with increasing volatile fraction whereas, with the other $(M_w = 1.6 \times 10^5)$, the activation energy remains more or less constant during the whole process. This would tend to confirm that with the higher molecular weight ($>1.6 \times 10^5$) polymer, two processes of decomposition are involved. The one termed as random scissions has undoubtedly a lower activation energy and is therefore the dominant step. With lower molecular weight samples ($<1.6 \times 10^5$), there are still two steps involved in the decomposition process but the dominant one, in this case, is the step termed depolymerization, which appears to have a higher energy of activation.

As mentioned earlier, the point at which the process of depolymerization takes over from that of random scissions is difficult to locate. An attempt has, however, been made in this direction in the case of the 1.6×10^5 polystyrene standard by combining the data in *Table 9* where activation

energies are shown to vary with the volatile fraction, a, with that of *Figure 10* where the effect of a on the molecular weights is plotted. These results are shown in *Figure 17* and they clearly indicate that the activation energy values increase until the molecular weight has dropped to around 4.0×10^4 below which E remains constant. This may be the limit at which the random scissions step leaves the way entirely to depolymerization. This value though is at best a rough approximation. Further work in this direction is being carried out and will be reported later.

Grafted polymers from poly(4-vinylpyridinium) salts

Denis Ghesquiere, Claude Caze and Claude Loucheux
Laboratoire de Chimie Macromoléculaire, Université des Sciences et Techniques de Lille, BP 36, 59650 Villeneuve d'Ascq, France

4-Vinyl pyridine can be added via its vinylic double bond to the quaternary nitrogen atom of poly(4-vinylpyridinium chloride). When this reaction is carried out successively, model grafted polymers with grafts of a constant length with a known number of electric charges, have been obtained. Potentiometric measurements, infra-red and ^{1}H n.m.r. spectroscopic studies confirm the structure of the polymers.

INTRODUCTION

Quaternized poly(vinyl pyridines) have been extensively studied[1,2]. These polymers are usually obtained either through the reaction of an acid or a halide with the suitable poly(vinyl pyridine), or through the polymerization of the monomeric vinyl pyridine in the presence of a quaternizing reagent[3-5]. Recently a new way of obtaining quaternized pyridines through the action of an electrophilic vinyl type reagent in the presence of various acids, has been published[6]. The aim of the present work was to apply this type of reaction to the poly(4-vinyl pyridine)/4-vinyl pyridine system, in order to prepare poly(4-vinyl pyridines) bearing ionic grafts of controlled length.

The starting poly(4-vinyl pyridine) (P4VP) was quaternized by hydrochloric acid and the addition of 4-vinyl pyridine (4VP) can be written:

(1)
The process can be repeated after quaternization by hydrochloric acid of the newly introduced pyridine ring, leading to the following series:
Grafted P4VP polymers with $x = 1$ and 2 have been synthesized.

EXPERIMENTAL

Starting materials

4VP was a Merck commercial product. After washing with a 0.1 N NaOH solution to remove the inhibitor, and drying over calcium chloride, the monomeric 4VP was distilled under reduced pressure just before use.

P4VP was prepared by polymerization in methanol at 60°C, using azobisisobutyronitrile as initiator. Its intrinsic viscosity, measured in ethanol at 25°C, corresponded to a molecular weight $M_w = 75\,000$, following the viscosity/molecular weight relationship given by Berkowitz *et al.*[7].

Grafting

The experimental details are described for reaction (1), but they were quite similar for the successive additions of 4VP. The grafting operations were carried out in two steps: (i) quaternization of the polymer. A methanolic solution of P4VP was reacted at 50°C with a methanolic solution of hydrochloric acid. The quantity of HCl was always in excess. The poly(4-vinylpyridinium chloride) was recovered by precipitation in dry ethyl ether. This precipitation was necessary in order to avoid the polymerization of 4VP in the presence of HCl in the following step[8]; (ii) reaction of 4VP with the quaternized P4VP, in methanolic solution, at 50°C, during several hours. Then the grafted polymer was recovered by precipitation in dry ethyl ether. Both quaternized P4VP and grafted quaternized P4VP were white and strongly hygroscopic products.

Characterization of polymers

The potentiometric titrations of Cl⁻ ions were performed in aqueous solutions, using 0.05 N AgNO₃ as reagent. Radiometer equipment consisted of pH meter 28, Titrator 11, Autoburette ABU 1c and Titrigraph SBR2c. The reference electrode was a glass electrode G202c, and the measurement electrode was a silver electrode P4011. The polymer concentration of titrated solutions was 0.5 g/100 cm³. The

Table 1 Identification of polymers and yields of each stage

Polymer	Formula	Yield (%)
A	—Py$^+$H Cl$^-$	100
B	—Py$^+$—(CH$_2$)$_2$—Py Cl$^-$	100
C	—Py$^+$—(CH$_2$)$_2$—Py$^+$H Cl$^-$ Cl$^-$	90
D	—Py$^+$—(CH$_2$)$_2$—Py$^+$—(CH$_2$)$_2$—Py Cl$^-$ Cl$^-$	80

Figure 1 Potentiometric titration curves for polymers A, B, C and D

infra-red spectra were recorded from films of the polymers evaporated on KBr discs using a Perkin–Elmer Model 257 grating infra-red spectrophotometer. The ^{1}H n.m.r. spectra were recorded from D$_2$O solutions of the polymers on a 250 MHz Cameca Model high resolution spectrometer. The concentration range was 2 to 6% and trimethylsilylpropyl sulphonate (TMPS) was used as an internal standard.

RESULTS AND DISCUSSION

Four polymers (A, B, C and D) have been characterized at different stages of grafting. With clear notations, *Table 1* gives the identification of these polymers and the yields of each step of their preparation, determined by potentiometric titration of Cl$^-$ ions.

Figure 1 shows the potentiometric titration curves for A, B, C and D polymers. From the shape of these curves one sees that the functions behave independently along a graft. All products A, B, C and D are water soluble. This criterion excludes the presence of unquaternized P4VP which would derive from the homopolymerization of 4VP in step (ii) described above.

Infra-red study

Figure 2 represents the spectra of A, B, C and D polymers together with the spectrum of P4VP. The spectrum of P4VP exhibits the stretching bands assigned to the pyridine ring[9] at 1600, 1560, 1490 and 1420 cm^{-1}. After quaternization of P4VP, (spectrum A) a shift from 1600 to 1610 cm^{-1} is observed. Two bands at 1640 and 1510 cm^{-1} corresponding to the quaternized pyridine ring and three bands at 2000, 2100 and 2600 cm^{-1}, assigned to the C=NH$^+$ group appear[10]. Furthermore, the bands at 1560 and 1420 cm^{-1} corresponding to the unquaternized pyridine ring disappear. The spectrum of the B product shows that these two last bands are present again, and that the intensity of the bands at 2000, 2100 and 2600 cm^{-1} corresponding to the C=NH$^+$ group decreases strongly. The C product

Figure 2 Infra-red spectra of P4VP and of grafted polymers A, B, C and D

has a spectrum similar to that of the A product. In the spectrum of the D product, one observes the absorptions due to the pyridine ring, but with a decreased intensity.

^{1}H n.m.r. study

The spectrum of A (see *Figure 3*) exhibits three peaks. The assignments of these peaks can be deduced from the previous studies of Noel et al.[11]. The α and β protons of the skeleton have one broad single resonance peak centred at approximately 2 ppm. Such a peak is always observed for atactic samples of P4VP. This peak appears at the same place on the spectra of B, C and D polymers.

α HC
β H₂C

(A)

The resonance peaks at 7.55 and 8.55 ppm are assigned respectively to the protons 2 and 1 of the pyridinium ring. The spectrum of B is more complex:

α HC
β H₂C

(B)

The resonance of γ protons appears as a shoulder at 5 ppm on the flank of the very intense HDO peak. The resonance of the δ protons is a peak centred at 3.7 ppm. These two peaks appear more clearly in the spectrum of polymer C which is obtained by hydrochloric quaternization of B. The assignment of these γ and δ protons is confirmed by the n.m.r. study of the following polymer[12,13]:
The case of the pyridinic protons is more complex. Owing to the presence of the second pyridine ring one would expect two new resonance peaks from 2' and 1' protons. Actually six peaks (or more) are observed. The comparison with the spectrum of polymer C is interesting and suggests that a stacking effect takes place between two neutral

pyridine rings by an intra- or inter-molecular interaction process. This effect disappears in the spectrum of polymer C, when all the pyridine rings are quaternized, excluding such an hydrophobic effect.

For the spectrum of polymer C the resonances can be assigned as follows:

γ and δ protons at 5.05 and 3.65 ppm respectively,
1' and 2' protons at 8.5 and 7.55 ppm, respectively,
1 and 2 protons at 8.80 and 8 ppm respectively.

The spectrum of polymer D shows that the three pyridine rings are not equivalent.

α HC
β H₂C

(D)
The δ and δ' protons appear as unequivalent and give two peaks at about 3.7 ppm, when the γ and γ' protons exhibit one single peak at 5.10 ppm.

CONCLUSION

The data of potentiometric titrations, infra-red and ¹H n.m.r. spectroscopies confirm that the polymers obtained are those expected. Longer sequences of 4-vinyl pyridine units can be bound to the skeleton, the limit being probably imposed by the solubility of the grafted polymers. These grafted polymers are good models for physical chemistry studies. The B polymer seems to have a special structure which will be the subject of future work.

This type of addition reaction may be largely used in order to modify the chemical and physical properties of polymers and copolymers including amine functions.

Solvent effect on cationic polymerization of styrene with α- or β-methylstyrenes

Kenji Yamamoto and Toshinobu Higashimura
Department of Polymer Chemistry, Kyoto University, Kyoto 606, Japan
(Received 26 March 1974)

To investigate the steric hindrance in the cationic copolymerization of styrene derivatives, styrene was copolymerized with anethole or with α-methylstyrene in polar and non-polar solvents by using $BF_3O(C_2H_5)_2$ or $SnCl_4$-trichloroacetic acid as catalyst. As the polarity of the solvent increased, the relative reactivity of α-methylstyrene towards a styryl cation decreased and that of anethole increased. The mode of attack of the propagating carbocation to styrene derivatives in a non-polar solvent is discussed on the basis of these contrasting phenomena.

INTRODUCTION

It is well known that α,β-disubstituted ethylenes are polymerizable by a cationic mechanism in contrast to no polymerizability in radical polymerizations. Thus one can examine the effect of the β-substituent on the reactivity of vinyl compounds in cationic polymerization.

As to vinyl ethers, the introduction of a β-methyl group increased the reactivity of the monomers. In the cationic copolymerization of vinyl ethers with the corresponding propenyl ethers in non-polar solvents, the reactivity of the monomers decreased in the following order[1,2]:

cis-propenyl ether > *trans*-propenyl ether ≥ vinyl ether

However, the relative reactivity of these monomers depends greatly upon the polarity of the solvent, and the reactivity difference becomes smaller in more polar solvents[3,4]. These facts were explained in terms that the location of the attack of a propagating carbocation to a monomer in non-polar solvents differed from that in polar solvents[3,4].

When a β-methyl group is introduced into styrene derivatives, their reactivity in cationic polymerization decreases considerably because of the steric hindrance of the β-methyl group[5-8]. This result is in contrast to that of propenyl ethers, in which the steric effect of the β-methyl group is not important. Therefore, in the cationic copolymerization of styrene with β-substituted styrenes, one can investigate the dependence of the monomer reactivity ratios on the solvent polarity which might give information concerning the steric hindrance of the β-substituent in the propagation reaction.

Several studies concerning the copolymerization of styrene with β-methylstyrene derivatives have been reported but there has been no report concerning how these reactivities are influenced by the solvent polarity. In this study, styrene was copolymerized with anethole (*p*-methoxy-β-methylstyrene) at 30°C in several solvents to investigate the effect of the solvent polarity on the monomer reactivity. In addition, styrene was copolymerized with α-methylstyrene for comparison. On the basis of these investigations, the mechanism of the propagation reaction of styrene derivatives is discussed.

EXPERIMENTAL

Materials

Commercial styrene, *trans*-anethole, and α-methylstyrene were purified by washing and distillation over calcium hydride under reduced pressure before use. The steric purity of *trans*-anethole was found to be more than 99% by gas chromatography. *cis*-Anethole was synthesized by the decarboxylation of *p*-methoxy-β-methylcinnamic acid which was prepared from *p*-anisaldehyde by a Perkin reaction[7,9]. The geometric isomers were separated by fractional distillation through a spinning band column of over 70 theoretical plates (b.p. 99.0–99.5°C at 14 mmHg; lit.[10] 79.0–79.5°C at 2.3 mmHg). After the distillation the monomer contained 98% *cis*-isomer and 2% *trans*-isomer.

Benzene, methylcyclohexane, methylene chloride, and nitroethane as solvents were purified by washing and distillation over calcium hydride before use. $BF_3O(C_2H_5)_2$ and $SnCl_4$ as catalysts and bromobenzene and chlorobenzene as internal standards for gas chromatography were purified by distillation. Trichloroacetic acid (TCA) (Guaranteed Reagent) was used without further purification.

Procedure

Copolymerizations were conducted under dry nitrogen in the same manner as reported previously[11]. The concentration of residual water in the reaction system was determined to be 0.2–0.3 mmol/l by Karl-Fischer titration. 5 vol % of chlorobenzene was used as an internal standard for gas chromatography with styrene/α-methylstyrene copolymerization and 5 vol % of bromobenzene with styrene–anethole copolymerization. Polymer compositions were determined from the amount of residual monomers measured by gas chromatography. Monomer reactivity ratios were calculated according to the improved Fineman–Ross method[12].

RESULTS

Copolymerization of styrene(M₁) with cis-anethole(M₂)

Styrene was copolymerized with *cis*-anethole by BF_3OEt_2 as a catalyst in various solvents at 30°C. *Figure 1*

shows the copolymer composition curves and the monomer reactivity ratios are summarized in *Table 1*. *cis*-Anethole was more reactive than styrene irrespective of the kind of solvent. As the polarity of the solvent increased, r_1 decreased, while r_2 increased. This means that on increasing the solvent polarity *cis*-anethole becomes more reactive than styrene towards either styryl cation or *cis*-anethole cation. However, the influence of the solvent polarity on the monomer reactivity ratio was not so large as in the styrene/*trans*-anethole copolymerization, which will be described below.

Copolymerization of styrene(M_1) with trans-anethole(M_2)

Figure 2 shows the copolymer composition curves and the monomer reactivity ratios are summarized in *Table 1*. *trans*-Anethole was more reactive than styrene irrespective of the kind of solvent. In this copolymerization, in contrast to styrene/*cis*-anethole copolymerization, both r_1 and r_2 decreased as the polarity of the solvent increased, and the product $r_1 \cdot r_2$ was much smaller than unity in polar solvents. This implies that *trans*-anethole becomes more reactive than styrene towards a styryl cation, while the former becomes less reactive than the latter towards a *trans*-anethole cation with increasing the solvent polarity, i.e. the alternating tendency appears in polar solvents.

When $SnCl_4$–TCA was used as a catalyst instead of BF_3OEt_2 in benzene, the monomer reactivity ratios were nearly the same as in methylene chloride (see *Table 1*).

Copolymerization of cis-anethole(M_1) with trans-anethole (M_2)

The effect of the solvent polarity on the copolymerization of *cis*- and *trans*-anethole was investigated with BF_3OEt_2 as a catalyst at $30°C$. *Figure 3* shows the copolymer composition curves and the monomer reactivity ratios are summarized in *Table 1*. *cis*-Anethole was more reactive than *trans*-anethole irrespective of the kind of solvent. As the polarity of the solvent increased, r_2 decreased but r_1 was almost unchanged. This implies that the reaction of *trans*-anethole with a *trans*-anethole cation is difficult in polar solvents.

Copolymerization of styrene(M_1) with α-methylstyrene(M_2)

Styrene was copolymerized with α-methylstyrene at $-78°C$ by use of $SnCl_4$ as a catalyst and TCA as a cocatalyst in methylcyclohexane as a non-polar solvent and in methylene chloride or nitroethane as a polar solvent. It is known that the polymerization of α-methylstyrene accompanies depropagation reactions at high temperatures. However, it is confirmed that in the cationic copolymerization of α-methylstyrene with styrene at a low temperature such as $-78°C$, the contribution of the depropagation reaction

could be negligible[13]. Therefore, styrene was copolymerized with α-methylstyrene at $-78°$C. *Figure 4* shows the copolymer composition curves and the monomer reactivity ratios are summarized in *Table 2*. α-Methylstyrene was much more reactive than styrene irrespective of the kind of solvent. The reactivity difference between the two monomers became small as the polarity of the solvent increased.

DISCUSSION

In the cationic copolymerization of β-methylstyrenes with styrene, the dependence on the solvent polarity of the relative reactivity of β-methylstyrenes was different from that

found in the copolymerization of α-methylstyrene with styrene. Both α-methylstyrene and anethole were more reactive than styrene. But the relative reactivity of α-methylstyrene towards a styryl cation decreased and that of anethole increased, as the polarity of the solvent increased.

In the copolymerization of styrene with α-methylstyrene, the relative reactivity of less reactive styrene towards either styryl cation of α-methylstyryl cation increased with increasing solvent polarity. It is generally accepted that the propagating carbocation becomes more reactive and less selective to attack to monomers when the polarity of the solvent increases[14]. Thus, styrene is much less reactive than α-methylstyrene in non-polar solvents, but competes well with α-methylstyrene in polar solvents. This behaviour may be observed with the transition state for the propagation reaction being free from steric hindrance.

Table 3 summarizes the relative reactivity of styrene and anetholes towards various propagating species in polar and non-polar solvents. A and C in *Table 3* clearly show that the reactivity of anethole towards a styryl cation is higher than styrene, and that the reactivity difference becomes larger with increasing solvent polarity. This is true for either cis- or trans-isomer, and is in contrast to the results of the copolymerization of styrene with α-methylstyrene. If there is no steric hindrance between a propagating styryl cation and the β-substituent of a monomer, the reactivities of the two monomers might be similar in polar solvents, because the reactivity of the propagating carbocation is high in polar solvents. However, the styrene—anethole copolymerization was not the case. Hence, the solvent effect on the styrene—anethole copolymerization seems to be explained in terms of the steric interaction between the propagating carbocation and the β-substituent of the monomer.

In non-polar solvents, we can expect that the propagation reaction of styrene derivatives takes place through a bridged carbocation. However, the propagating carbocation may be very weakly bridged as deduced from the intermediate of the electrophilic halogenation of anethole[15]. This idea is consistent with the mechanism previously proposed by us[4,16] to explain the reactivity of styrene derivatives in terms of open carbocations. The formation of a strongly bridged carbocation from anethole and styryl cation may have been prevented because of the steric repulsion between the substituents. In this respect the reactivity of anethole may have been underestimated in non-polar solvents. As the solvent polarity increases, the propagating styryl cation attacks the monomer from the β-carbon side, so that the steric hindrance between a propagating styryl cation and an anethole monomer diminishes as compared with that in non-polar solvents. Consequently, the reactivity of

Table 3 Summary of relative reactivity of styrene and anetholes towards various propagating species in polar and non-polar solvents (calculated from *Table 1*)

No.	Propagating chain end[a]	Relative reactivity	Solvent

F	trans-An$^+$	trans-An/cis-An	0.45	0.34	0.25

[a] St = styrene; An = anethole

anethole relative to styrene towards a styryl cation increases in polar solvents.

Table 3 also shows that the reactivity towards a styryl cation of *trans*-anethole relative to styrene increases much more sharply than that of *cis*-anethole relative to styrene with increasing solvent polarity. This fact is explained by assuming that the ease of the formation of a bridged carbocation is dependent on the geometric structure of anethole, i.e. in non-polar solvents, the steric hindrance with a propagating styryl cation is larger in the reaction of *trans*-anethole than in the reaction of *cis*-isomer. On the other hand, in the point of view of electronic theory the former is more reactive than the latter[8]. These effects cancel each other so that the reactivities of *cis*- and *trans*-anethole are nearly the same in non-polar solvents. In polar solvents, the propagation reaction proceeds through an open carbocation. In this condition, the steric effect of the β-methyl group of a monomer is not affected by the geometric structure of the monomer[4]. So the reactivities of the two monomers are determined by electronic effect, hence *trans*-anethole becomes more reactive towards a styryl cation.

D and F in *Table 3* show that the reactivity of *trans*-anethole towards a propagating *trans*-anethole cation as compared with the reactivity of styrene or *cis*-anethole does not increase as the solvent polarity increases. When an open carbocation is involved as an intermediate in the propagation reaction, the geometry of the transition state is similar to that in radical polymerizations. When a propagating *trans*-anethole cation approaches a *trans*-anethole monomer, a large steric interference emerges between the β-methyl group of the monomer and the propagating species to reduce the reactivity of *trans*-anethole. On the other hand, the interference is not important in the addition of an anethole monomer to a propagating *cis*-anethole carbocation, which is substantiated in B and E of *Table 3*. These results suggest the different conformations of *cis*- and *trans*-anethole carbocations. Further investigations are necessary for this conclusion to be firm.

In the copolymerization of styrene with *trans*-anethole in benzene with $SnCl_4$–TCA instead of BF_3OEt_2 as a catalyst, the monomer reactivity ratios were nearly the same as those obtained with BF_3OEt_2 in methylene chloride. It has been reported that the catalytic activity of $SnCl_4$–TCA is larger than BF_3OEt_2 in the polymerization of styrene[17] and a propagating carbocation of a loose ion-pair type is formed with $SnCl_4$[18]. The present result is consistent with this view.

As mentioned in the introduction, propenyl ethers are more reactive than the corresponding vinyl ethers and the reactivity difference is more significant in non-polar sol-

vents than in polar solvents. This has been explained in terms of the formation of a bridged carbocation as an intermediate of the propagation reaction in non-polar solvents[3]. On the other hand, it was observed in this study that the reactivity difference between anethole and styrene was somewhat less significant in non-polar solvents than in polar solvents. For this the following explanations were proposed. The β-methylstyrene derivatives form a weakly bridged carbocation as an intermediate of the propagation reaction even in non-polar solvents because of large steric interactions between the substituents. This sort of intermediate makes the reactivity of anethole close to that of styrene in non-polar solvents. Thus, the different effects of solvent on the copolymerizations of vinyl ether derivatives and styrene derivatives could be related to the different modes of attack of a propagating species to a monomer in non-polar solvents.

Dielectric properties of oligomers: 4. Dielectric properties of vinyl acetate and methyl methacrylate oligomers

E. Ikada, T. Sugimura, T. Aoyama and T. Watanabe
Faculty of Engineering, Kobe University, Nada, Kobe 657, Japan
(Received 13 May 1974)

Dielectric properties of vinyl acetate and methyl methacrylate oligomers were studied in order to compare the dielectric properties of an oligomer with those of the corresponding high polymers. The two oligomers showed asymmetric dielectric relaxations at room temperatures. The complex dielectric constants vs. angular frequencies for these oligomers were well represented by the Havriliak—Negami equation:

$$\epsilon^* - \epsilon_\infty = \frac{\epsilon_0 - \epsilon_\infty}{[1 + (j\omega\tau_0)^{1-\alpha}]^\beta}$$

The distribution parameters $(1 - \alpha)$ and β of vinyl acetate and methyl methacrylate oligomer are almost equal to those of poly(vinyl acetate) and poly(methyl methacrylate), respectively. It was concluded that the distribution of relaxation times was independent of the molecular weight of the polymers.

INTRODUCTION

In the principal dielectric relaxations (so-called 'α-relaxation') of the polymer having polar repeating units the dielectric relaxation times show a broad and asymmetric distribution. In this case the shapes of the Cole—Cole plots of these α-relaxations on the complex plane are asymmetric[1]. For example, it is well known that the shapes of the Cole—Cole arcs of the principal relaxations of poly(vinyl acetate) (PVAC)[2] apparently resemble the calculated arc of the well-known Davidson—Cole empirical equation[3]:

$$\epsilon^* - \epsilon_\infty = \frac{\epsilon_0 - \epsilon_\infty}{(1 + j\omega\tau_0)^\beta} \tag{1}$$

where ϵ^* is the complex dielectric constant, ϵ_0 and ϵ_∞ are the limiting low- and high-frequency dielectric constant, respectively. j is the imaginary unit, ω is the angular frequency, τ_0 is the mean relaxation time, and β is distribution parameter of relaxation times. This type of relaxation has in most cases been observed in the hydrogen-bonded liquid diol and triol such as glycol and 1,2,6-hexanetriol[3]. However, it was found that the calculated Cole—Cole arc of equation (1) deviates from the experimental arc of α-relaxations of PVAC[2]. On the other hand, a number of low-frequency α-relaxations of high polymers have been measured at constant temperature. It was reported that these experimental asymmetric flat loss curves of the polymers are well represented by the equation suggested by Havriliak and Negami[4]

$$\epsilon^* - \epsilon_\infty = \frac{\epsilon_0 - \epsilon_\infty}{[1 + (j\omega\tau_0)^{1-\alpha}]^\beta} \tag{2}$$

where $(1 - \alpha)$ is another distribution parameter of relaxation times. The applicability of this equation for α-relaxations of polymers was tested by Havriliak and Negami[4] and Ikada and Watanabe[1]. Further, Williams *et al.*[5] suggested an equation which also fits the α-relaxations as follows:

$$\frac{\epsilon^* - \epsilon_\infty}{\epsilon_0 - \epsilon_\infty} = \mathscr{L}\left[-\frac{d\gamma(t)}{dt} \right], \quad \gamma(t) = \exp(-t/\tau) \tag{3}$$

$\mathscr{L}$ indicates the Laplace transform. $\gamma(t)$ is the normalized decay function.

The low-frequency dielectric relaxations of polar low molecules at the liquid state are attributable to the molecular rotation as a whole[6]. The molecular rotation as a whole in the alternative electric field, however, must become difficult and gradually impossible as the chain length becomes longer beyond the limiting length. This limit cannot be determined definitely. At any rate, the principal dielectric relaxations of long chains differ from those of the low molecules because the relaxing segment of long chains is bound to the neighbouring segment by chemical bonds.

It is interesting to investigate the difference between the molecular rotational relaxation and the segmental relaxation of long chains. As the origins of distribution of relaxation times, several explanations are considered from the characteristic properties of high polymers as follows: (1) the distribution of degree of polymerization in the polymer species yields a distribution of relaxation times; (2) the coexistence of the different relaxation modes in the main chain motions; (3) the relaxation mechanism of segmental motion of main chains consists of the cooperative phenomena; (4) on the relaxation of a long chain the motion is

carried out in the complicated atmosphere.

In order to discuss the above possible deductions, we measured the dielectric relaxations of trifluoromonochloroethylene oligomers $Cl-(CF_2CFCl)_n-Cl$ (n = 2, 3 and 4) which have no distribution of degree of polymerization[7]. It was found that the distribution of relaxation times of this fluoro oligomer was also broad and asymmetric as often seen in the distribution of α-relaxation of high polymers. The distribution parameters $(1 - \alpha)$ and β of the tetramer of these fluoro oligomers are comparatively small and are equal to the small values of high polymers. The experimental Cole—Cole arc of this tetramer is coincident with the calculated arc of equation (2)[7]. This result leads to the conclusion that the distribution of relaxation times is not attributable to the distribution of degree of polymerization. Further, the dielectric relaxations of 1,2,6-hexanetriacetate and glyceryltriacetate were also investigated at the liquid state[8]. These two acetates have three acetate side groups in a chain. This work was carried out to compare the dielectric properties of the low acetate molecules with those of the high acetate molecule such as PVAC. Consequently, the shapes of the Cole—Cole arcs of both the low- and high-molecular acetates resemble closely each other. That is, the distribution parameters $(1 - \alpha)$ and β of equation (2) are almost equal for both the samples although their molecular dimensions are quite different. This result leads to the conclusion that the distribution of relaxation times is independent of the chain length. This unexpected result seems to be very suggestive in the study of the dielectric relaxation mechanism of polymers.

On the other hand, the various properties of poly(methyl methacrylate) (PMMA) have been investigated by many workers[9]. Especially, the dielectric properties of this polymer are of interest because β-relaxation plays an important role in PMMA. For example, first, the relaxation intensity of β-relaxation is larger than that of α-relaxation. Secondly, the temperatures of α- and β-transition are not so isolated rather than submerged. In this work, comparatively low molecular PVAC and PMMA were prepared and the dielectric properties of the two oligomers were studied in order to compare these results with those of the high molecular weight PVAC and PMMA.

EXPERIMENTAL

Preparation of VAC and MMA oligomers

The purified VAC monomer was polymerized in purified acetaldehyde in an ampoule. VAC monomer was added to acetaldehyde in a weight ratio of 1:4. 1 g of benzoyl peroxide was added to 44 g of VAC monomer. Polymerization was carried out in a water bath maintained at 45 ± 0.05°C for 110 h. It was reported that in the VAC polymerization in the presence of acetaldehyde a ketone-type aldehyde or an aldehyde-type carboxyl group should be introduced into a polymer chain-end and that in the telomerization of VAC the ketone-type end groups were more preferential than the aldehyde-type carbonyl end group[10].

MMA oligomer was prepared as follows[11]: purified MMA monomer (0.7 ml) was added to isopropyl alcohol in a volume ratio of 1 to 30 in an ampoule. 0.201 g of di-t-butyl-peroxide was added as initiator. Oligomerization was carried out for 5 h in an oil bath at 130 ± 0.5°C. For removal of the unreacted monomer, solvent and initiator, these volatile portions were evaporated in a hot bath at 42°C under nitrogen gas at the reduced pressure of 60 mmHg.

The residual oligomer, which is an appreciably viscous liquid, was dried in a vacuum drier for a month. The yield of this MMA oligomerization was 72.2%.

Determination of physical constants

Molecular weight. The molecular weight of the oligomers was measured by a vapour pressure osmometer (Mechrolab Inc., model 302). Benzene was used as solvent. *N*-Butylstearate (molecular weight = 340.6) and diphenyl disulphide (M_w = 218.3) were used to determine the calibration factor. The experimental molecular weight of MMA oligomer was 375. As each oligo-MMA molecule has a $(CH_3)_3CO$ end group, the average degree of polymerization was calculated as 3.01 subtracting the corresponding molecular weight of this end group from the whole molecular weight. The number-average molecular weight of oligo-VAC was 446.3. This value is equivalent to the average degree of polymerization of ~5. The density and the refractive index of the oligomers were measured by the Lypkin-type pycnometer and Pulfrich refractometer, respectively. The physical constants of the oligomers are collected in *Table 1*.

Dielectric measurement. The dielectric constants and losses were measured by a ratio arm transformer bridge (Ando Electric Co., type TR-1BK) over the temperature range −70° to +60°C and the frequency range 30 Hz to 3 MHz. The dielectric cell was a concentric platinum glass cell whose vacuum capacity was 13.0 pF. The cell temperature was measured by a Pt—Co vs. Cu thermocouple and a standard thermometer. The glass cell was immersed in a well-stirred alcohol bath at the lower temperatures.

RESULTS AND DISCUSSION

Static dielectric constant

The experimental static dielectric constants are shown in *Figure 1*. The values of static dielectric constants of oligo-VAC and oligo-MMA were larger than those of the corresponding high molecular compounds. The dipole moments were calculated from the static dielectric con-

Table 1 Physical properties of the oligomers

	oligo-VAC	oligo-MMA
Molecular weight	446.3	375
Degree of polymerization	5	3.01
Density, ρ (g/ml)	...	1.038 (17°)

stants by means of the Onsager equation[12]:

$$\epsilon_0 = \epsilon_\infty + \frac{\epsilon_0}{2\epsilon_0 + \epsilon_\infty} \left(\frac{\epsilon_\infty + 2}{3} \right)^2 \frac{4\pi N_0 \mu_0^2}{3kT} \tag{4}$$

where ϵ_0 and ϵ_∞ are the limiting low- and high-frequency dielectric constant, respectively, N_0 is the number of molecules/cm^3, μ_0 is the dipole moment *in vacuo* and kT is the thermal energy. The calculated dipole moments of oligo-VAC and oligo-MMA were 4.8 D and 4.9 D, respectively. These large dipole moments are associated with the dominant quantity of the stretched conformations of the two oligomers. The polar end group (CH_3CO) contributes to the large dipole moment of oligo-VAC.

Dielectric relaxation

The oligomers showed the dielectric dispersion and absorption in the experimental temperature ranges. Frequency dependences of the dielectric constants and losses are shown in *Figure 2* and *3*, respectively. The loss curves of oligo-VAC are seen to be asymmetric. A number of attempts have been carried out to express the experimental asymmetric arcs of α-relaxations by a mathematical

equation. It is still especially difficult to explain the relaxation mechanism of a polymer chain explicitly. Thus at the present stage, it seems to be important to determine an equation to express asymmetric α-relaxation exactly. Applicability of Havriliak—Negami equation was tried for many α-relaxations of polymers. It seems that this equation is the best-fitting equation to represent the dielectric relaxations of polymers. It was reported that the α-relaxation of PMMA[4] and PVAC[8] were represented by this equation. Cole—Cole plots of oligo-VAC and oligo-MMA are shown in *Figures 4* and *5*, respectively. In these Figures, it can be seen that the arcs of both oligomers are as flat as those of the high polymers. The Havriliak—Negami equation was tested for these oligomers. The comparison was shown in *Figures 4* and *5*. The Havriliak—Negami equation, however, is only an empirical equation to express the experimental dielectric relaxation. The mechanism of α-relaxation could not be completely explained by this equation.

Distribution of relaxation times

The relaxation times of the two oligomers are much shorter than those of the corresponding high polymers. The relationship between the two distribution parameters $(1 - \alpha)$ and β in equation (2) and the structure of a polymer is not

−9.3	0.632	0.550

clear. To investigate the asymmetric and wide distribution of relaxation times characteristic of the polymers which is more widely distributed at the shorter time side than at the longer time side is an interesting problem to a polymer chemist. The asymmetry of the distribution of relaxation times may lead to an imaginary existence of cooperative relaxation mechanisms. The values of the two distribution parameters and the relaxation times of MMA and VAC polymers and oligomers are collected in *Tables 2* and *3*, respectively. The oligomers studied are much smaller molecules compared to the high molecular PMMA and PVAC. Nevertheless, the values of the two distribution parameters of PMMA and oligo-MMA do not differ markedly. As described above, the distribution parameters of 1,2,6-hexanetriacetate and glyceryltriacetate were compared with those of PVAC. It was found that the distribution of the dielectric relaxation times of the low molecular triacetates are almost equal to that of high molecular PVAC[8]. These coincidences of the distribution is certainly an interesting result, but this fact does not suggest the significant explanation about the mechanism of the dielectric relaxation of polymers much. As is seen in *Table 3*, $(1 - \alpha)$ of oligo-VAC is smaller than that of PVAC. It was found that this small $(1 - \alpha)$ is due to the polar end groups $(COCH_3)$ of oligo-VAC[13]. The distribution of relaxation times may be more closely related to the molecular structures rather than to the degree of polymerization of the polar polymers. The temperature dependences of relaxation times are shown in *Figure 6*. The activation energies for the dielectric relaxation were calculated by regarding these two curves as straight lines. The calculated values for oligo-VAC and oligo-MMA were 14.35 and 13.1 kcal, respectively. The literature value for PVAC was 60 kcal[14].

Solution properties of poly(propylene sulphide)

D. W. Nash and D. C. Pepper
Chemistry Department, Trinity College, University of Dublin, Dublin 2, Eire
(Received 25 April 1974; revised 7 June 1974)

Poly(propylene sulphide) (PPS) initiated by cadmium bis(phenyl allyl thiolate) was fractionated from benzene—methanol, and the fractions were examined by viscosity, osmotic pressure and light scattering determinations. Gel permeation chromatography with Styragel columns was found unsatisfactory in tetrahydrofuran (THF) and toluene at room temperature. Polymer stored in the dark at room temperature underwent a very slow degradation which broadened the distribution in the fractions. The following quantitative relationships were found at 25°C:

$$[\eta] = 1.40 \times 10^{-2} \overline{M}_w^{0.68} \quad \text{in toluene}$$
$$(\text{ml/g}) \qquad = 2.58 \times 10^{-2} \overline{M}_w^{0.66} \quad \text{in THF}$$
$$= 2.74 \times 10^{-2} \overline{M}_w^{0.63} \quad \text{in benzene}$$
$$= 9.42 \times 10^{-2} \overline{M}_w^{0.50} \quad \text{in 31\% n-heptane/toluene}(\theta\text{-mixture})$$

Extrapolations to derive the unperturbed coil dimensions indicate a possible, but doubtful, solvent effect. The value derived from the θ-mixture gives $A = 696 \times 10^{-11}$ cm mol$^{1/2}$ g$^{-1/2}$ and a steric factor $\sigma = 1.49$, consistent with a high 'chain flexibility' expected from the relatively long C—S—C linkages.

INTRODUCTION

Examination of their solution properties has shown that polymer chains containing C—O—C linkages have smaller coil-dimensions and lower values of the 'steric factor'[1,2] than the corresponding hydrocarbons. This increased 'flexibility' is even more marked in poly(phenylene oxide) chains containing the long 'virtual' bonds ϕ—O—ϕ[3]. The present work was designed to examine the effect of C—S—C links, and also to investigate the discrepancy between different values reported for the Mark—Houwink exponents for poly(propylene sulphide) (PPS) in benzene reported by Eskin[4] and Cooper[5]. The Eskin value of 0.86 is unusually high for a non-cellulosic chain.

EXPERIMENTAL

Monomer purification

Propylene episulphide, prepared conventionally from propylene carbonate and potassium thiocyanate[6,7] was purified from thiols by several successive shakings with an alkaline suspension of litharge (2% PbO in 12% aq. NaOH). After washing to neutrality, it was dried first over MgSO$_4$ and then for several days over CaH$_2$ and fractionated under nitrogen through a 12 in column of glass helices (b.p. 74°C at 1 atm).

Polymerization

The catalyst, cadmium bis(phenyl allyl thiolate) was dissolved in bulk monomer; the solutions were twice degassed and sealed into dilatometer-type Pyrex phials. At the catalyst concentration (10^{-5} to 10^{-6} M) and reaction temperatures ($0°-50°$C) used the time for apparently complete reaction was between 2 and 20 days. The polymer was broken out of the phials, dissolved in benzene and isolated by freeze drying under high vacuum.

Fractionation

Turbidimetric studies using a Hilger Spekner Absorptiometer showed that convenient solvent/non-solvent pairs were benzene—methanol (precipitating over the range 23—30% v/v methanol) and carbon tetrachloride/n-hexane (33—43%). Preparative fractionations were carried out with both these pairs, using 10—15 g polymer samples at ~1% initial concentration, yielding 10—11 fractions and virtually quantitative recovery. N.m.r. spectra, at 100 MHz, indicated that all fractions examined had the same tacticity (55% isotactic) as the unfractionated polymer, providing reassurance that the separation was determined by molecular weight, not tacticity.

RESULTS

Polymer solubility

In a search for θ-solvents, 29 solvents were examined but none were found suitable in the range 0—100°C. At room temperature PPS dissolves easily in aromatic or in chlorinated solvents, and is insoluble in aliphatic hydrocarbons and in very polar solvents. The 'solubility parameter' (cohesive energy density)$^{1/2}$, δ, is only partly helpful for prediction. Thus the value calculated for PPS (via 'molar association constants'[2]) is 9.6 (cal/cm^3)$^{1/2}$. As expected, the 'good' solvents listed in *Table 1* have δ-values fairly close to this

Table 1 Solvents for PPS and solubility parameters (δ). δ (PPS, calc.) = 9.6 (cal/cm^3)$^{1/2}$

Non-solvents	δ	Solvents	δ
methanol	14.5

n-heptane	7.4		
n-hexane	7.3		

value, and the non-solvents mostly have values much higher or lower. But ketone and cycloalkane solvents having δ-values close to that of PPS are nevertheless non-solvents.

By the cloud-point method of Elias[8], a mixture containing 31.5% v/v of n-heptane in toluene, was found to be a θ-mixture for PPS at 25°C.

Polymer stability and intrinsic viscosities

PPS samples prepared by cadmium thiolate initiators are said to be somewhat unstable under exposure to light and oxygen[9]. Wragg[10] found rapid degradation above 200°C but believed the polymer to be stable at room temperature in solution. All polymer samples used in the present work were stored in the dark in vacuum desiccators.

The intrinsic viscosities of a number of samples were measured at intervals over a perod of one month, and no change was detected. Solutions in THF stored in glass or in stainless-steel containers similarly showed no change in viscosity. However, much longer intervals (up to 12 months) often elapsed between the preparation of a fraction and its ultimate molecular weight measurements. Intrinsic viscosities [η] measured then were found to have fallen by varying amounts (3—20%) below the values for 'fresh' fractions. All [η] values quoted are those of the partly degraded samples, measured shortly after the molecular weight determinations.

Viscosities were measured at 25°C in an Ubbelohde-type suspended level viscometer with negligible kinetic energy correction, and [η] values were derived from this common intercept of Huggins and Kraemer plots. Results in toluene, benzene, THF and the θ-mixture are listed in *Table 2*.

Molecular weights and chain dimensions

Attempts to derive molecular weights and distributions by g.p.c. from THF or toluene at room temperature proved unsuccessful (see Appendix).

Number average molecular weights, $\overline{M}_n$, were obtained from measurements of osmotic pressure (π) in toluene at 25°C, using a Mechrolab High Speed Membrane Osmometer with gel cellophane membranes. No evidence for polymer

diffusion was observed and linear π/C vs. $-C$ plots were obtained.

Weight average molecular weights, $\overline{M}_w$, were determined (via Zimm[11] plots) from light-scattering in toluene at room temperature, using the Hg green line at 546 nm, in a Brice-Phoenix photometer, series 100. The refractive index increment in toluene for this wavelength was determined to be 9.6×10^{-2} cm^3/g at 25°C.

The results for three series of fractions are shown in *Table 3*. It can be seen that the ratio $\overline{M}_w/\overline{M}_n$ is often larger than expected for precipitation fractions, and varies erratically; presumably as a result of varying degrees of degradation in different fractions. To make some allowance for this the weight average root mean square end-to-end chain dimensions $\langle L_w^2 \rangle^{1/2}$ were calculated from the experimentally obtained radii of gyration $\langle S^2 \rangle_z^{1/2}$, via the Schultz—Zimm heterogeneity parameter, h, where

$$\overline{M}_w/\overline{M}_n = (h + 1)/h \tag{1}$$

$$\langle L^2 \rangle_w^{1/2} = [6\langle S^2 \rangle_z^{1/2}(h + 1)/(h + 2)]^{1/2} \tag{2}$$

Table 3 shows values for these quantities and for the second virial coefficients, determined from both light-scattering and osmotic pressure.

DERIVED RELATIONSHIPS

Mark—Houwink equations, [η] = KM^a

Plots of log [η] against log $\overline{M}_w$ (*Figure 1*) show good consistency between results from sample 6 (fractionated from carbon tetrachloride—hexane) and sample 21 (from benzene—methanol). Values from sample 17 (from benzene—methanol) scatter more widely and appear to indicate lines of higher slope. The best values of the constant, calculated by linear regression analysis, are listed in *Table 4*.

Chain dimensions in toluene

The heterogeneity-corrected values for the root mean square end-to-end dimensions in toluene (*Table 3*) depend on $\overline{M}_w$ with a scatter similar to that of the [η] values. The

Table 2 Intrinsic viscosities at 25°C

Fraction	[η] (cm^3/g) in			
	Toluene	Benzene	THF	θ-mixture

* From light scattering
† From osmotic pressure
Figure 1 Mark—Houwink relationships for PPS. A, toluene; B, THF; C, benzene; D, θ-mixture. □, points from fractionation no.6; ○, points from fractionation no.17; △, points from fractionation no.21

relationship calculated by linear regression analysis of the points is:

$$\langle L_w^2\rangle^{1/2} = 3.07 \times 10^{-1}\bar{M}_w^{0.575} \qquad (3)$$

Table 4 Constants in the Mark—Houwink equation ([η] (ml/g) = KM^a)

Solvent	$K \times 10^2$	a
31.5% n-heptane/toluene	9.42	0.49$_5$
Benzene	2.74	0.63$_8$
THF	2.58	0.65$_6$
Toluene	1.40	0.68$_3$

According to Ptitsyn's theory[12], the exponent in equation (3) should be related to that of the Mark—Houwink equation, having the value $(a + 1)/3$. The value thus calculated from $a = 0.68$ is 0.56, i.e. in reasonable concordance.

Unperturbed dimensions and steric factor

The intrinsic viscosities in the different solvents were analysed by the usual extrapolation procedures, capable in principle of yielding the polymer—solvent interaction parameter, B, and the 'unperturbed' value of the M—H constant (K_θ) and hence the 'unperturbed dimensions' of a PPS chain.

Figure 2 shows a plot according to the Stockmayer—Fixman equation:

$$[\eta]/\bar{M}_w^{1/2} = K_\theta + 0.51\Phi_0 B\bar{M}_w^{1/2} \qquad (4)$$

Within a considerable experimental error the results in a given solvent can be described by a straight line, but the lines for different solvents do not meet in the theoretical common intercept. Plots of the other extrapolation functions (listed in *Table 5*) showed the same general pattern. Values of K_θ calculated from their intercepts are collected in the Table and show good general agreement between the different procedures, and an apparent effect of solvent on K_θ.

The values of the 'unperturbed dimension' $A = (L_0^2/M)^{1/2}$ shown also in *Table 5* are derived from K_θ via Flory's equation:

$$K_\theta = \Phi_0(\langle L_0^2\rangle/M)^{3/2} \qquad (5)$$

using his now recommended value[13] for $\Phi_0 = 2.6 \times 10^{23}$. A
Figure 2 Stockmayer—Fixman plots for PPS. ▲, THF; ○, benzene; ■, toluene; ●, θ-mixture (31.5% n-heptane in toluene)

theoretical value for this dimension of a 'freely rotating' chain, $A_f = 468 \times 10^{-11}$ cm mol$^{1/2}$ g$^{-1/2}$ has been calculated from Huglin and Stepto's[14] value for poly(ethylene sulphide), allowing for the higher molecular weight of PPS. The derived values of the steric factor, $\sigma = A/A_f$, range from 1.49 to 1.76.

Second virial coefficient, A_2

Table 3 lists values derived from both osmotic pressure and light-scattering measurements. Those from osmotic pressure are appreciably higher, and in one series (from fractionation 17) show an anomalous apparent increase with molecular weight. Those from light-scattering show the normal decrease with $\overline{M}_w$. Log—log plot yields:

$$A_2 = 8.0 \times 10^{-2}\overline{M}_w^{-0.24} \tag{6}$$

the exponent lying within the usual range -0.2 to -0.3.

Coil-expansion factor and excluded volume

Values of the expansion factors α and α_η, derived from intrinsic viscosities by:

$$\alpha_\eta^3 = \alpha^{2.43} = [\eta]/[\eta]_\theta = [\eta]/K_\theta \overline{M}_w^{1/2}$$

are all lower than often found in good solvents; i.e. all lie in the range 1.07 to 1.27 and trend only slightly with molecular weight (compared with α_η ranging from 1.35 to 1.65 for polystyrene in toluene over a similar $\overline{M}_w$ range). The values cover too narrow a range of $\overline{M}_w$ to provide a useful test of the form of the excluded volume function.

The relationship of the α_η values to the virial coefficient is not well defined. They are only slightly less than calculated from the equation of Krigbaum[16]:

$$A_2\overline{M}_w/[\eta] = 217(1 - \alpha_\eta^{-3}) \tag{7}$$

but considerably less than values calculated by the modified expression of Flory, Krigbaum and Orofino[17]. A plot of $A_2\overline{M}_w/[\eta]$ against $(\alpha_\eta^2 - 1)$, often useful[18] to distinguish between these and other functions, proves uninformative because of the narrow range of α values.

DISCUSSION

In view of the partial degradation of the fractions during storage, some discussion is needed of the significance of the measurements for quantitative deductions. As judged by the fall in $[\eta]$ between original fractionation and eventual molecular weight determination, the extent of degradation was variable (3—20%) and unrelated to the original $[\eta]$ value. The breadth of their molecular weight distributions (as indicated by $\overline{M}_w/\overline{M}_n$ ratio) was similarly variable, but also unrelated to $\overline{M}_w$. The corresponding deviations may therefore be expected to be random rather than systematic, and the uncertainties in the derived Mark—Houwink equations and other relationships to depend more on the relatively limited range of molecular weights examined (only ~5-fold) than on the imperfections of particular samples.

The constants of the Mark—Houwink equations listed in *Table 4* are self-consistent, in that for different solvents the K and a values show the expected inter-relationship, K rising smoothly as a falls. The relatively low values of a found in all solvents examined are consistent also with the small coil expansion factors calculated by comparison with their unperturbed dimensions. However, the results found in benzene are appreciably different from those quoted by previous authors, e.g. by Stokes[19]: $[\eta]$ (ml/g) = 5.0 $\times$ 10^{-3} M$^{0.78}$ at 20°C for unfractionated PPS prepared by cadmium thiolates (as here) and by Eskin[4]: $[\eta]$ (ml/g) = 3.3 $\times$ 10^{-3} M$^{0.86}$ at 31°C for fractions of sodium naphthalene initiated polymer.

When all the relationships in benzene are plotted together in the same graph (*Figure 3*) it can be seen that Stokes's results and our own are in reasonable concordance up to moderate molecular weights, but appear to diverge above ~300 000. Stokes's samples were unfractionated, but this would account for the divergence only if his samples had progressively narrower distributions the higher the molecular weight, which seems unlikely. Further examination of high molecular weight fractions are needed to resolve this discrepancy.

Figure 3 suggests that Eskin's results for anionically initiated PPS cannot be accommodated by the relationship found here. His results are very self-consistent but extend only up to molecular weights ~10^5, and it seems possible that over a wider range, an exponent lower than his (un-

usually high) value of 0.86 might apply. But his curve as a whole 'lies high', i.e. corresponds to a value of K considerably lower than found here, so it seems likely that his anionically initiated polymer may be showing genuinely different relationships corresponding to a different chain structure. The only obvious differences are the presence of a central Cd atom in the present (and Stokes's) samples, and difference in chain tacticity. The former would hardly be expected to have much influence on the overall coil dimensions and hence [η]. Differences in chain tacticity have sometimes been found to influence the M—H equations, especially in the poorer solvents, e.g. with PMMA.

Deductions about chain dimensions in the pure solvents are made more than usually uncertain by the limited range of molecular weights and the scatter of points in the Stockmayer—Fixman (*Figure 2*) and similar plots. This raises the question whether the present results in good solvents can give accurate derivations of K_θ, i.e. whether the variation in values derived is a real indication of a true solvent effect. Such effects have been observed[20,21], especially when polymer and solvents differ appreciably in polarity. For PPS, this question must at present be left in doubt, especially in the light of Booth's findings[22,23] that with polyoxides, the extrapolation functions often show considerable curvature towards lower molecular weights.

The results for solutions in the θ-mixture, however, present no problems of interpretation and lead to a well defined value of $K_\theta = 8.6 \times 10^{-2}$ and an 'unperturbed dimension' $A = 696 \times 10^{11}$ cm $\text{mol}^{1/2}$ $\text{g}^{-1/2}$. The derived value for the steric factor ($=A/A_f$) = 1.49 is to be compared with 1.31 derived from Eskin's value of $A = 600 \times 10^{-11}$ for anionically prepared PPS, and with the range of published values for polyoxides listed in *Table 6*.

It is clear that whichever value is to be taken as more realistic for PPS, it is appreciably lower than shown by any of the polyoxides, consistent with orthodox expectations

that steric interactions of adjacent and nearby chain units should be reduced by the longer C—S—C linkage.

APPENDIX

Anomalous behaviour of PPS in gel permeation chromatography

Conventional g.p.c. (Waters Model 200; 5 Styragel columns) proved useless for the present PPS samples in THF or in toluene at room temperature. All chromatograms showed very broad peaks and long 'tails' and indicated apparent molecular weights very much lower than the values derived from light scattering or osmotic pressure. Chromatograms from toluene were less anomalous than those from THF, but still unusable.

In view of the evidence quoted earlier for the slow degradation of PPS it was at first surmised that a faster degradation was occurring in the g.p.c. instrument. Extensive tests of this possibility were made by comparisons of viscosity measurements of solutions stored in presence of the Styragel or in stainless-steel containers. No evidence of degradation could be observed.

It seems likely therefore that the anomalies arise from general adsorption of the polymer on the column material, delaying elution and reducing the resolving power. The fact that Stokes[19] mentions no difficulties in g.p.c. operation in THF at 54°C may be consistent with this conclusion since appreciably less adsorption would be expected at the higher temperature.

Viscoelastic properties of poly(propylene glycols)

A. John Barlow and Aynur Erginsav

Department of Electronics and Electrical Engineering, University of Glasgow, Glasgow G12 8QQ, UK
(Received 3 July 1974)

The relaxational and retardational properties of poly(propylene glycol) liquids, of nominal molecular weights 400 and 4000, are described. The viscoelastic behaviour of each liquid has been determined over a wide temperature range, using high frequency shear wave techniques operating at 30 and 454 MHz. It is found that the complex compliance $J^*(j\omega)$ is described in terms of the viscosity η, the limiting high frequency compliance J_∞, the retardational compliance J_r and a characteristic retardation time τ_r by:

$$J^*(j\omega) = J_\infty + 1/j\omega\eta + J_r/(1 + j\omega\tau_r)^\beta$$

where β is a parameter of the retardation time distribution.

For the lower molecular weight liquid, $J_r/J_\infty = 17.4$, $\beta = 0.45$ and τ_r/τ_m increases with decreasing temperature, reaching a limit of 170 near $0°C$. This liquid shows no evidence of polymeric behaviour.

For the other, $J_r/J_\infty = 85$, $\beta = 0.76$, $\tau_r/\tau_m = 15.4$ and is constant over the temperature range investigated. The main difference between the two liquids appears as an additional retardational or relaxational process for the higher molecular weight material which occurs in the initial or low frequency part of the relaxation region. This process is characterized by a single time, but with relaxation time 1/7 and a stiffness 7 times the values calculated for the first Rouse mode of polymer chain motion.

INTRODUCTION

In previous publications[1-3] the retardational behaviour of several non-polymeric organic liquids and mixtures has been described. The retardational compliance $J_r^*(j\omega) = J_1(\omega) - jJ_2(\omega)$ is related to the complex compliance $J^*(j\omega)$ of a liquid by:

$$J^*(j\omega) = J_\infty + 1/j\omega\eta + J_r^*(j\omega) \qquad (1)$$

where J_∞ is the limiting or high frequency shear compliance $(=1/G_\infty)$, η is the steady flow viscosity and ω is the angular frequency of the shear stress[4]. In turn, $J^*(j\omega)$ is related to the shear mechanical impedance, $Z_L = R_L + jX_L$, by $J^*(j\omega) = \rho/Z_L^2$, where ρ is the density of liquid. $J_r^*(j\omega)$ reaches a limiting value of J_r at low frequency.

For comparatively simple organic liquids, it was found that the retardational compliance could be described by an equation analogous to that used by Davidson and Cole[5] in studies of the dielectric properties of viscous liquids:

$$J_r^*(j\omega) = J_r/(1 + j\omega\tau_r)^\beta \qquad (2)$$

Typically, for pure liquids in the supercooled or highly viscous region, the retardational compliance J_r is 3 to 30 times J_∞, β is 0.5, τ_r is greater than the Maxwell relaxation time τ_m $(=\eta J_\infty)$ at low temperatures but the ratio τ_r/τ_m deceases rapidly with increasing temperature where the viscosity falls to 1 Pa s or less. These measurements were made possible only by the development of a very accurate experimental system for the determination of both R_L and X_L, since $J^*(j\omega)$ is dominated by the term $1/j\omega\eta$ at low

frequencies $(\omega \ll 1/\eta J_\infty)$ and tends to J_∞ at high frequencies $(\omega \gg 1/\eta J_\infty)$.

This paper describes an extension of the previous work. Two poly(propylene glycol) liquids, of nominal molecular weights 400 and 4000, have been investigated. It was considered that whilst the shorter chain polymer might show behaviour similar to that for the non-polymeric liquids, the longer chain was expected to have distinct polymeric characteristics.

EXPERIMENTAL

The two samples were kindly supplied by Dr R. F. Boyer and Mr P. C. Dean of The Dow Chemical Co. Inc., Midland, Michigan, and were designated P400 and P4000. Before use they were dried and degassed under vacuum for 12 h at $40°C$ and subsequently kept in a desiccator with silica gel. The molecular weights were determined by means of a Hitachi—Perkin-Elmer osmometer, and the values obtained are $M_n = 377$ for P400 and $M_n = 3034$ for P4000. These results agree with values determined by gel permeation chromatography, although the accuracy of this latter technique is considered to be inferior. For both liquids M_w/M_n is less than 1.16. It follows that n in the formula $HO(C_3H_6O)_nC_3H_6OH$ is approximately 5 for P400 and 50 for P4000.

The viscosity of each liquid was determined using suspended-level viscometers; the results are estimated to be accurate to within $\pm 0.5\%$. Measurements were made of P400 in the range $74.8°C$ to $-29.3°C$ and of P4000 in the range $79.5°C$ to $-20.1°C$; the results are shown in *Figure 1*.
Figure 1 Temperature dependence of the viscosity of poly(propylene glycols): □, P4000; ○, P400

Above 50°C the viscosity of P400 follows an Arrhenius temperature dependence; below 50°C the data are fitted by the empirical equation[6,7], $\log_e \eta = A + B/(T - T_0)$, with the constants given by:

$$\log_e \eta = -10.7744 + 1047.3/(T - 168.4) \tag{3}$$

For P4000, the data are fitted over the full range investigated by:

$$\log_e \eta = -7.172 + 817.2/(T - 180.1) \tag{4}$$

In these equations, η is the viscosity in Pa s and T is the temperature in Kelvins.

The density, ρ (kg/m^3), of each liquid was also determined, and found to vary linearly with temperature, the results obtained being fitted by the equations:

$$P400: \quad \rho = 1116\,(1 - 0.000727\,(T - 168.4) \tag{5}$$

$$P4000: \quad \rho = 1063\,(1 - 0.000696\,(T - 180.1) \tag{6}$$

The components R_L and X_L of the mechanical shear impedance were determined using plane shear waves at a frequency of 29.426 MHz, and the values obtained are estimated to be accurate to within ±0.5% ± 500 N s m^{-3}. For P400, measurements were made at eight temperatures from 4.4 to 31.8°C, and for P4000, at five temperatures

from 40.1 to 79.5°C. Measurements of R_L alone were made at 454 MHz; for P400 results were obtained from 31.8°C to −70.7°C and for P4000 the range was 40.9 to −65.7°C. Some additional measurements were also made at 30 MHz at low temperatures to determine the extent of the region in which R_L is independent of frequency[8]. The experimental techniques employed have been described in previous publications[9–11].

RESULTS AND ANALYSIS

For each liquid the variation with temperature of $\rho/R_L{}^2$, in the region where it defines the compliance J_∞, is shown in *Figure 2*. As has been found for many other liquids[8,12], J_∞ increases linearly with temperature. The data are fitted by the equations:

$$P400: \quad J_\infty = 1.3 \times 10^{-10} + 1.15 \times 10^{-11}(T - 168.4) \tag{7}$$

$$P4000: J_\infty = 1.0 \times 10^{-10} + 1.85 \times 10^{-11}(T - 180.1) \tag{8}$$

where J_∞ is the compliance in m^2/N. These equations have been used to obtain extrapolated values within the relaxation region.

For the definitions given in the previous section, it follows that:

$$J_1(\omega) = \rho(R_L^2 - X_L^2)/(R_L^2 + X_L^2)^2 - J_\infty \tag{9}$$

$$J_2(\omega) = 2\rho R_L X_L/(R_L^2 + X_L^2)^2 - 1/\omega\eta \tag{10}$$

For each temperature at which both R_L and X_L are known, $J_1(\omega)$ and $J_2(\omega)$ may be determined, using equations (3), (5) and (7) or (4), (6) and (8) as appropriate. Because of experimental limitations which restrict measurement of R_L and X_L to a single frequency ($\omega = 2\pi \times 29.426 \times 10^6$ s^{-1}) it is not possible to determine the temperature dependence of the retardational modulus J_r. Following the procedure adopted in previous work[1–3], the temperature dependencies of J_r and J_∞ are assumed to be the same. Accordingly, the values of $J_1(\omega)/J_\infty$ and $J_2(\omega)/J_\infty$ have been calculated for each liquid and the results are given in *Figures 3* and *4*. In each case the relative variation of these normalized com-
Figure 2 Temperature dependence of ρ/R_L^2 for two poly(propylene glycols): □, P400; ○, P4000. For each liquid the temperature T_g is the value at which $\eta = 10^{12}$ Pa s
Figure 3 Relative variation of the components of the retardational compliance at 30 MHz for P4000
Figure 4 Relative variation of the components of the retardational compliance at 30 MHz for P400

ponents of the retardational compliance is given by a normalized version of equation (2):

$$J_1(\omega)/J_\infty - jJ_2(\omega)/J_\infty = (J_r/J_\infty)/(1 + j\omega\tau_r)^\beta \tag{11}$$

The position of the experimental points on the locus defined by particular values of J_r/J_∞ and β is determined by $\omega\tau_r$; therefore for each point (i.e. at each temperature of measurement) τ_r can be determined.

For P4000, $J_r/J_\infty = 85$, $\beta = 0.76$, the ratio τ_r/τ_m ($=\tau_r/\eta J_\infty$) is 15.4, and is constant over the range 40–80°C. Because of the experimentally limited temperature range of the results these values may be regarded as tentative at this stage of the analysis. However, their use enables a prediction to be made of the properties at other temperatures and frequencies. In particular, R_L and X_L may be calculated by means of equations (4), (6) and (8)–(11). In *Figure 5* the calculated variations of R_L and X_L in normalized form are shown as a function of $\omega\eta J_\infty$. Whilst the agreement between the curves and the data at 30 MHz is simply a consequence of the arithmetical accuracy of the analysis, the good agreement between the $R_L(J_\infty/\rho)^{1/2}$ curve and the 454 MHz data at temperatures from 40.9 to –28.6°C provides substantial confirmation of the predictions, and shows that $\tau_r/\tau_m = 15.4$ over the full range 80 to –28.6°C. Appreciable discrepancies occur between these results and the predicted curve if any one of the above values of J_r/J_∞, β and τ_r/τ_m is varied by more than ±10%. The errors in these values are therefore probably less than ±10%.

For P400, the curve of *Figure 4* is obtained using equation (11) with $J_r/J_\infty = 17.4$ and $\beta = 0.45$. However, τ_r/τ_m is not constant but increases from 30 at 31.8°C to 155 at 4.4°C. It is therefore not possible to draw a single curve which describes the frequency dependence of R_L over this temperature range, a separate curve is required at each temperature. *Figure 6* shows the normalized R_L results plotted as a function of $\omega\eta J_\infty$. The lower curve is

predicted using equations (3), (5), (7) and (9)–(11) for a temperature of 31.8°C at which $\tau_r/\tau_m = 30$. It can be seen that the curve is in good agreement with the measured value at 31.8°C and 454 MHz. The upper curve is plotted for $\tau_r/\tau_m = 170$, and gives a good fit to all the 454 MHz results in the region below 0°C. As in the previous analysis for P4000, the curves are derived using only the data obtained at 30 MHz. The value of $\tau_r/\tau_m = 170$ is a limiting value which is reached at low temperatures. Curves calculated for intermediate values of τ_r/τ_m at temperatures between 31.8°C and 0°C agree satisfactorily with the 454 MHz data at corresponding temperatures; to avoid confusion these are not shown in *Figure 6*.

Figure 7 shows the variation of τ_r/τ_m as a function of temperature.

DISCUSSION

It has been established that the retardational behaviour of each liquid is adequately described by the Davidson–Cole equation (2), and the relaxational behaviour by equations (2) and (1). The properties of the lower molecular weight material P400, as defined by the values of β, τ_r/τ_m and J_r/J_∞ (=17.4), are similar to those of other non-polymeric liquids of comparable molecular weight and chain length. As examples of liquids with similar values of J_r/J_∞, squalane (21.8), tri-β-chloroethyl phosphate (26.0) and benzyl benzoate (27.0) may be cited[1,3]. A decrease in τ_r/τ_m with

J_r/J_∞	17.4	85
J_r (m^2/N)	23.4×10^{-9}	155×10^{-9}
β	0.45	0.76

increasing temperature is also commonly found for non-polymeric liquids; and it may be noted that the variation of τ_r/τ_m above $0°C$ for P400 shows that the time–temperature superposition principle does not hold in this region. The evidence therefore shows that P400 has no specifically polymeric characteristics.

In contrast, the higher molecular weight material P4000 has a much greater value of J_r/J_∞ (=85), a lower ratio τ_r/τ_m and the spectrum parameter β is higher, indicating a narrower retardation spectrum. For comparison, the properties of the two liquids are summarized in *Table 1*: the values are given at $0°C$, thus avoiding the region in which τ_r/τ_m for P400 is temperature dependent. *Figure 8* shows $J_1(\omega)$ for both liquids, calculated using *Table 1* and equation (2), plotted as a function of ω at $0°C$. The difference, $J_1(\omega)$ (P4000) $- J_1(\omega)$ (P400), is also shown, and corresponds very closely to the variation pertaining to a single retardation time. The main effect of the increase in molecular weight from P400 to P4000 can therefore be represented by the addition of a single retardation time process to the distributed spectrum for the short chain material. The retardation time, τ_x, of this additional component is 0.11 μs and its compliance, J_{r_x}, is 132×10^{-9} m^2/N. The apparently anomalous feature of a narrower retardation spectrum for the higher molecular weight liquid can be regarded as due to the introduction of this dominant, high compliance process with a retardation time close to the longest retardation time ($\tau_r = 0.105$ μs) of the distributed spectrum which describes the short-chain retardation processes. A secondary feature is also noticeable in *Figure 8*; in the region $\log_{10}\omega > 8.4$, the compliance $J_1(\omega)$ for

P4000 is slightly less than for P400, indicating a smaller amplitude of the retardation spectrum in this range. In effect. some of the highest frequency components present in the spectrum of the shorter chain liquid are diminished in the higher molecular weight polymer. This occurs only where $J_1(\omega)$ is less than 4×10^{-9} m^2/N. Since the ratio of the retardation times for the two liquids does not change rapidly with temperature below $0°C$, these deductions are not dependent upon the choice of a particular temperature for the comparison, and are valid from $0°C$ to at least $-30°C$.

Previously, because of the lack of accurate data of the retardational properties, analyses of the behaviour of short chain polymers have usually been based upon a relaxational model[13,14]. In this model the shear modulus $G^*(j\omega)$ $[=G'(\omega) + jG''(\omega) = 1/J^*(j\omega)]$ is assumed to consist of the sum of components arising from a 'simple-liquid' type of behaviour and contributions from relaxational modes pertaining to changes in the configurations of long polymer chains, the latter being formulated in terms of the theories of Rouse[15] and Zimm[16]. In principle, it is possible to calculate directly the relaxation spectrum from the retardational behaviour[4]. In practice, even for the simply defined retardational behaviour found for P4000, the analysis is almost intractable unless approximation techniques are used. However, the positions and strengths of the relaxation components are very sensitive to the difference between τ_x and τ_r, and in the present case, where $\tau_x \approx \tau_r$, such approximation techniques are not necessarily reliable. It is preferable to calculate the shear modulus components G' and G'' and to analyse one or both of these. *Figure 9* shows the normalized component G'/G_∞ for P400 and P4000, again calculated at $0°C$. The major difference between the two liquids is seen to be the emergence of a 'plateau region' for P4000. Detailed analysis shows that this feature is almost completely accounted for by a single relaxation time process with $\tau_a = 1/\omega_a = 0.93$ μs and $G_a = 5.2 \times 10^6$ N/m^2. Analysis of G''/G_∞ gives a similar result, and these values are also consistent with approximate values calculated from the retardational results. Above $\log_{10}\omega \approx 8$, the more rapid approach of G'/G_∞ for P4000 to the maximum value of unity is again attributable to a smaller contribution from high frequency relaxations in this region; this effect is naturally more apparent in plots of the shear modulus than of its inverse.
Figure 8 Frequency dependence of $J_1(\omega)$ for P400 (A) and P4000 (B) at $0°C$. $- - -$ shows the difference $J_1(\omega)$ (P4000) $- J_1(\omega)$ (P400); $- \cdot - \cdot -$ is for a single retardation time
Figure 9 Frequency dependence of the normalized shear modulus component, G'/G_∞, for P400 (A) and P4000 (B) at 0°C

The additional single relaxation mode in P4000 is evidence of a 'long chain' mode of relaxation and may tentatively be regarded as the first of the series of 'configurational' modes of the type postulated in the Rouse theory. This theory defines each mode strength as $\rho RT/M$, which for P4000 at 0°C amounts to 7.5×10^5 N/m^2. The observed mode strength G_a, is therefore about 7 times the value for the first Rouse mode, and the observed relaxation time τ_a is approximately $1/7$ of the theoretical time τ_1 (taken as $\eta M/\rho RT$) for this first mode. The Rouse[15] theory postulates modes of motion associated with polymer chain segments, each segment comprising q monomer units with the minimum segmental length defined such that the ends of the segment are spatially related according to a Gaussian distribution. For polydimethylsiloxanes a value of $q \approx 10$ is consistent with the observed viscoelastic behaviour[17,18], and for unbranched polymers with a $-$C$-$C$-$ backbone, a q of 25 has been suggested[19,20]. Since the stiffness G_a for P4000 is greater than the value predicted by the Rouse theory, it may be inferred that the chain length is insufficient for a Gaussian distribution of end-to-end distances, and the value of q is therefore greater than 50. The comparatively high stiffness of the poly(propylene glycol) molecule is surprising in view of the flexibility of the $-$C$-$C$-$O$-$ backbone and the small size of the CH$_3$ side group, and some restriction of possible orientations by intra- or intermolecular forces may be inferred.

Because of this somewhat unexpected result, an alternative to the preceding direct analysis of the experimental results for P4000 has been attempted, in which the Rouse theory is assumed to apply and the number and strength of the modes is chosen to be consistent with the data. Such an approach could not be dismissed without detailed consideration, since it may be argued that because of experimental limitations J_r is obtained only by extrapolation, and the true value of J_r/J_∞ may therefore be quite different

from the value of 85 determined from *Figure 3*. An equivalent statement is that despite the good agreement between the high frequency results (450 MHz) and the predictions obtained by fitting the Davidson—Cole equation to the 30 MHz data there is no confirmation of the predictions at lower frequencies. This alternative analysis shows that if the mode strength is taken as $\rho RT/M$, then the Rouse theory, with any number of modes, is not consistent with the experimental results. If both the mode strength and the number of modes are allowed to be variable, then the best fit to the difference between P4000 and P400 is obtained with one mode, the modulus and relaxation time of this mode agreeing with the values found in the direct analysis of the results.

Monomeric unit distribution and optical activity of copolymers: random copolymers of acrylic acid and *N*-(s-butyl)-*N*-methyl acrylamide antipodes

Christian Braud and Michel Vert

Laboratoire de Chimie Macromoléculaire, Université de Rouen, 76130 Mont-Saint-Aignan, France
(Received 18 March 1974; revised 23 May 1974)

For copolymers of acrylic acid and *N*-(s-butyl)-*N*-methyl acrylamide antipodes as for most copolymers, the dependence of the optical rotatory power was found to be non-linear with regard to their composition. This non-linearity has been discussed generally in terms of conformation or secondary structure. It is proposed that this effect is due to the presence of more than two independent optically active species. The different species were found in terms of triads as the effect of neighbours on the partial specific contribution of a monomeric unit to the total optical activity. A relation was developed for a random copolymer with ideal distribution using eight triads. This relation was applied to acrylic acid/(+) and (−) *N*-(s-butyl)-*N*-methyl acrylamide copolymers which can be considered as ideally random; good independent agreement of the optical purity was obtained. The results are discussed in terms of induced optical activity at the level of the electronic transitions of achiral acid unit chromophores.

INTRODUCTION

The complex optical rotatory dispersion (o.r.d.) of the phenol—formaldehyde type polycondensates of *N*-tosyl L-tyrosine prepared in an acidic medium has been explained by a secondary reaction giving rise to a copolymer of two different optically active monomeric units. The dependence of the specific rotatory power $[\alpha]^{25}_{589}$ on the composition were considered to be anomalous compared to the linear variation shown by mixtures of models of the two types of units[1].

Similar deviations from linearity for the optical rotation of copolymers with regard to comparable mixtures of homopolymers or to optically active species contents have been reported for partly ionized chiral polyelectrolytes[2-6] as well as for copolymers of chiral and achiral monomers[7-9] and for stereocopolymers with chiral centres in the main chains[10,11] or in the side chains[12].

On the other hand, a linear relationship was obtained between the optical rotation at 589 nm and the composition for copolymers of (+) and (−) α-methylbenzyl methacrylates[13], (+) and (−) menthylvinyl ethers[14] and (−) menthyl acrylate and styrene[15].

In most of the cases where linearity was not observed, main chain and/or side chain conformational effects have been invoked[2,3,11]. For copolymers of (−) menthylvinyl ether and arylvinyl ethers[9], the optical anomalies were attributed to some asymmetric conformations of the initially achiral units induced by the adjacent chiral units giving rise to new Cotton effects at the absorption band of the aromatic chromophores. For copolymers of *S*-4-methyl-1-hexene and 4-methyl-1-pentene[7], preferential screw sense of helical conformations in 4-methylpentane units were invoked to render them optically active. Theoretical calculations based on conformational parameters of small

sequences extended to long macromolecules were found to fit experimental data with good agreement when moderately blocked or random distribution of monomeric units was considered[16].

Nevertheless, the above phenol—formaldehyde type polycondensates not being stereoregular, the deviation was assumed to result only from mutual influences of monomeric units attached together since asymmetric preferential conformations are very improbable in this case.

Recently, we have mentioned that o.r.d. of copolymers between acrylic acid and antipodes of *N*-(s-butyl)-*N*-methyl acrylamide are not proportional to the content of chiral units[17]. These copolymers were obtained by partial acidic hydrolysis of the corresponding radical polymerized homopolyacrylamide. Then, as for phenol—formaldehyde type polycondensates, stereoregularity and ordered secondary structure could not be invoked. We have assumed the anomalies should depend only on the monomeric unit distribution:
In this paper, we wish to report the results of our attempt

to correlate specific rotatory power of these copolymers to the content of their two units characterized by the molar fraction of the acidic units β. In order to take into account the neighbouring effects in the calculation of the optical rotatory power of a copolymer, we suggest considering the partial contribution of the different units to the total optical activity at least in terms of triads.

RELATION BETWEEN OPTICAL ROTATORY POWER OF AN IDEALLY RANDOM COPOLYMER AND ITS COMPOSITION

The optical rotation of a mixture of independent species is given by the addition of their partial contributions according to:

$$[\Phi] = \sum_i [\Phi]_i C_i / C$$

where

$$C = \sum_i C_i$$

(as molar concentration).

When only two species are involved as usually considered for copolymers, a linear relationship between $[m]$ * and the composition should be observed. A non-linear dependence compels us to consider more than two independent species. This is the case for a copolymer if we assume that neighbouring units modify the partial contribution of a unit to the total optical activity.

Thus, in a copolymer with a and b units of high optical purity and assuming the long range effects are negligible, changes of the two adjacent units lead to eight different triads: *aaa, aab, baa, bab, aba, bba,* and *bbb,* that is to say four to each central unit.

To these eight triads *iii*, we can associate probabilities P_{iii} (equal to the molar fractions of *iii*) and specific rotatory power $[\Phi]_{iii}$.

Then, the total residue specific rotatory power will result from the sum of the central unit partial contributions of these eight triads according to the relation:

$$[m] = \sum_i P_{iii}[\Phi]_{iii} \qquad (1)$$

(It must be noted that relation (1) expressed for specific rotatory power is also suitable for absorption coefficient of ellipticities.)

The problem is actually to determine the molar fractions which depend on the parameters orienting the distribution of the two units.

An interesting situation is found if it is assumed that the different monomeric units are randomly distributed in an ideal manner along the main chain. This is the case of the copolymerization when the reactivity ratios r_1 and r_2 obey the relation $r_1 r_2 = 1$ for instance[18], but a similar result can be reached when a chemical reaction on a polymer is performed without orienting effects of the different functional groups.

Let us consider such a copolymer with N the total number of monomeric units and n the number of monomeric units of type b, the degree of copolymerization is then $\beta = n/N$. If N is large and $1/N$ negligible compared to 1 and β, the probabilities of finding the different triads can be

calculated and reduced as shown in *Table 1*.

According to the probabilities of the different triads in *Table 1*, equation (1) can be rewritten and reduced to:

$$\langle [m] \rangle = (1 - \beta)^3 [\Phi]_{aaa} + \beta^3 [\Phi]_{bbb} + \beta(1 - \beta)(\beta\delta + \delta') \quad (2)$$

with

$$\delta = [\Phi]_{bba} + [\Phi]_{abb} - [\Phi]_{baa} - [\Phi]_{aab} + [\Phi]_{bab} - [\Phi]_{aba} \qquad (3)$$

and

$$\delta' = [\Phi]_{baa} + [\Phi]_{aab} + [\Phi]_{aba} \qquad (4)$$

Without additional interdependent relations between the $[\Phi]_{iii}$'s, it is impossible to calculate their respective values; nevertheless, δ and δ' can be obtained easily from the slopes for $\beta = 1$ and $\beta = 0$ respectively.

Differentiating equation (2) with respect to β, one obtains:

$$\frac{d\langle [m] \rangle}{d\beta} = 3\beta^2([\Phi]_{bbb} - [\Phi]_{aaa} - \delta) +$$

$$2\beta(3[\Phi]_{aaa} + \delta - \delta') + \delta' - 3[\Phi]_{aaa} \qquad (5)$$

For extreme values of β, relation (5) becomes:

$$\left(\frac{d\langle [m] \rangle}{d\beta} \right)_{\beta=0} = \delta' - 3[\Phi]_{aaa} \qquad (6)$$

and

$$\left(\frac{d\langle [m] \rangle}{d\beta} \right)_{\beta=1} = 3[\Phi]_{bbb} - (\delta + \delta') \qquad (7)$$

Then, relation (2) is completely defined and permits one to correlate experimental data $[\Phi]_{aaa}$, $[\Phi]_{bbb}$, δ, δ', β and $\langle [m] \rangle$ when monomeric units are randomly distributed in an ideal manner.

If there are no adjacent unit effects, all the $[\Phi]_{iai}$'s on the one hand and all the $[\Phi]_{ibi}$'s on the other are identical and relation (2) is reduced to the classical linear law used

Table 1 Probabilities of the different triads found in an ideally random copolymer*

Triads	Probabilities	
aaa	$P_{aaa} = (N-n)(N-n-1)(N-n-2)/N(N-1)(N-2)$	$= (1-\beta)^3$
aab	$P_{aab} = (N-n)(N-n-1)n/N(N-1)(N-2)$	$= \beta(1-\beta)^2$
baa	$P_{baa} = n(N-n)(N-n-1)/N(N-1)(N-2)$	$= \beta(1-\beta)^2$
bab	$P_{bab} = n(N-n-1)(n-1)/N(N-1)(N-2)$	$= \beta^2(1-\beta)$
aba	$P_{aba} = (N-n)n(N-n-1)/N(N-1)(N-2)$	$= \beta(1-\beta)^2$
abb	$P_{abb} = (N-n)n(n-1)/N(N-1)(N-2)$	$= \beta^2(1-\beta)$
bba	$P_{bba} = n(n-1)(N-n)/N(N-1)(N-2)$	$= \beta^2(1-\beta)$
bbb	$P_{bbb} = n(n-1)(n-2)/N(N-1)(N-2)$	$= \beta^3$

* The probabilities P_{iii} calculated in this manner can also be calculated by using the general statistical calculation of the copolymerization reaction in the case of $r_1 r_2 = 1$[19]

for binary mixture of independent optically active species:

$$\langle [m] \rangle = (1 - \beta)[m]_a + \beta [m]_b$$

where $[m]_a = [\Phi]_{iai}$ and $[m]_b = [\Phi]_{ibi}$.

A similar case is obtained if only two types of triads are present as in block copolymers or in mixtures of homopolymers thus explaining the linear dependence of optical rotations on composition in these two cases.

In a more general manner, relation (2) is available only for ideally random copolymers, probabilities of the different triads being different in the other cases when there are preferential enchainments.

It must be noted that for random vinyl copolymers having a chiral centre in the side chain, the triad *abb* is identical to the triad *bba* (and *aab* $\equiv$ *baa*) taking into account the different configurations of the pseudo-asymmetric carbons of the main chain. Then, relations (3) and (4) are reduced to:

$$\delta = 2[\Phi]_{bba} - 2[\Phi]_{baa} + [\Phi]_{bab} - [\Phi]_{aba} \qquad (3')$$

$$\delta' = 2[\Phi]_{baa} + [\Phi]_{aba} \qquad (4')$$

APPLICATION TO ACRYLIC ACID/N-(S-BUTYL)-N-METHYL ACRYLAMIDE COPOLYMERS

Starting homopolyacrylamides

Stereocopolymers of (+) and (−) *N*-(s-butyl)-*N*-methyl acrylamides have been synthesized as optically active homopolyacrylamides, the starting materials for our study on copolymers. Results of radical polymerization of mixtures of the two enantiomers are given in *Table 2*.

Different enantiomer mixtures give roughly the same yield in crude polymer. After purification by coacervation in methanol–water system, samples having viscosities of the same order have been obtained.

Figure 1 represents the variation of the specific rotatory power of these stereocopolymers as a function of the molar fraction of the antipode (+) in the monomer mixture. The linear variation shows that optical rotations are proportional to the optical purity of the monomer as has been mentioned for other stereocopolymers with chiral centres in the side chain far from the main chain[12,14].

Figure 1 Variation of the specific rotatory power $[\alpha]_{270}^{25}$ of stereocopolymers of (+) and (−)-*N*-(s-butyl)-*N*-methyl acrylamides synthesized by radical polymerization as a function of the molar fraction of (+) antipode in the monomeric mixtures (solvent: methanol)

Hydrolysis

The reaction of hydrolysis of poly [*N*-(s-butyl)-*N*-methyl acrylamide] in acidic medium which is independent of the optical purity of the starting homopolyacrylamide has been described in a previous paper[17].

In order to determine the nature of this reaction, we have plotted $\ln 1/(1 - \beta)$ *versus* time, β being the molar fraction of acrylic acid units in the copolymers thus obtained (*Figure 2*).

The straight line obtained for the overall hydrolysis shows that in the chosen condition, the reaction is unimolecular and of the first order with regard to the amide groups according to the kinetic equation:

$$-\left(\frac{d\,AAm}{dt}\right) = k\,(AAm) \qquad (AAm = \text{acrylamide units})$$

with a rate constant $k = 3.15 \times 10^{-2}\,h^{-1}$ and $\theta_{1/2} = 22\,h$.

Then, the reaction of hydrolysis in acidic medium does not depend on the degree of hydrolysis and we can assume that acrylic acid units are randomly distributed in an ideal manner along the copolymer chain.

Figure 3 Experimental rotatory powers of two sets of copolymers of acrylic acid and N-(s-butyl)-N-methyl acrylamide having different optical purities: □, ~93%; ■, ~34% and corresponding variation curves calculated using respectively relation (8) (— — —) and relation (8) multiplied by the optical purity correction factor —25.1/73.5 (——) (solvent: methanol)

Optical activity of copolymers

Figure 3 represents the variation of the specific rotatory power (λ = 300 nm) as a function of the proportion of acrylic acid units β for the copolymers derived from homopolyacrylamides A_1 and A_7 (*Table 2*).

Normally, with independent monomeric units, the curve should be a straight line between the specific rotatory power of the homopolyacrylamide (β = 0) and 0 (β = 1) since poly(acrylic acid) is optically inactive. In fact, we observe in *Figure 3* a large deviation depending on the degree of hydrolysis β for the two sets of copolymers.

Since proportionality between optical activity of the stereocopolyacrylamides and the molar fraction of one antipode as well as ideally random distribution of the two units have been shown respectively in *Figures 1* and *2*, we can apply the treatment based on the influence of only eight triads as stated above to the curves in *Figure 3*.

For the set of copolymers derived from homopoly-acrylamide A_1 $(d[m]\frac{25}{300}/d\beta)_{\beta=0}$ and $(d[m]\frac{25}{300}/d\beta)_{\beta=1}$ are respectively 242 and —72.

Then, using relations (6) and (7), with $[\Phi]_{aaa}$ = —73.5 and $[\Phi]_{bbb}$ = 0, δ and δ' are found to be +50 and +22.

Relation (2) becomes:

$$[m]\frac{25}{300} = -73.5(1 - \beta)^3 + \beta(1 - \beta)(50\beta + 22) \qquad (8)$$

The broken line in *Figure 3* represents the calculated values of $[m]\frac{25}{300}$ for copolymers of different composition. There is a fairly good agreement with all the corresponding experimental data.

Furthermore, the specific rotation of copolymers depends only on their composition and not on the optical purity of the chiral acrylamide units since relation (8) multiplied by the ratio —25.1/73.5 (corresponding to the difference of optical purity between A_1 and A_7) also fits the experimental data obtained for the second set of copolymers very well.

These results confirm that optical activity of random copolymers depends mainly on their composition and not on their conformations because the conformations depend certainly on the proportion and the distribution of R and S antipodes.

For the set of copolymers issued from homopolyacryl-amide A_1, relations (3') and (4') give:

$$2[\Phi]_{bba} - 2[\Phi]_{baa} + [\Phi]_{bab} - [\Phi]_{aba} = +50$$

and

$$2[\Phi]_{baa} + [\Phi]_{aba} = +22$$

To a first approximation, it could be assumed that $[\Phi]_{bba} = [\Phi]_{aba} = 0$ since acrylic acid units are not chiral. So, $[\Phi]_{baa}$ and $[\Phi]_{bab}$ would be respectively +11 and +72. However, the assumption $[\Phi]_{bba} = [\Phi]_{aba} = 0$ is probably erroneous although $[\Phi]_{bbb} = 0$ in homopoly(acrylic acid). Optical activity can be induced at the level of the electronic transitions of the carboxyl chromophores or of those corresponding to the aliphatic backbone.

Such inductions have been previously shown for styrene/R-dimethyl-3,7-octene-1 copolymers[20,21] and model molecules[22]. It has also been observed for copolymers between (—) menthylvinyl ether and aryl vinyl ethers[9].

Unfortunately, electronic transitions of C=O chromophores in amide and carboxyl groups near 200 nm overlap and it is difficult to distinguish their respective contribution to circular dichroism (c.d.) in order to prove the optical activity induction in the C=O of COOH.

The use of a copolymer of acrylic acid and a chiral monomer with no absorption bands above 190 nm should permit one to observe a c.d. band at the $n - \pi^*$ transition of the C=O chromophore of the —COOH groups close to 210 nm. Such a copolymer is not yet available.

Using a maleic acid/S(+) methyl-2 butyl vinyl ether copolymer*, we have effectively observed an optically active c.d. band at 212 nm[23]. However, in this type of copolymer, new chiral centres seem to be induced in the succinic moiety by asymmetric reaction during polymerization[24]. This inconvenience should cancel for copolymers of acrylic acid (or ester) and alkyl vinyl ether if no asymmetric induction occurs in this case. Studies of this type are under investigation.

CONCLUSIONS

The non-linear variation of the optical rotation of the hydrolysed poly[N-(s-butyl)-N-methyl acrylamide] is well

---

represented by:

$$\langle [m] \rangle = (1 - \beta)^3 [\Phi]_{aaa} + \beta^3 [\Phi]_{bbb} + \beta(1 - \beta)(\beta\delta + \delta')$$

This relation takes into account only the distribution of the two monomeric units in terms of triads and the short range interactions between them. Of course, in the $[\Phi]_{iii}$ parameters, local conformational changes of monomeric units are included but no asymmetric structures of macromolecular chains are taken into account.

It now seems that such an interpretation is suitable for most of the copolymers except, perhaps, those with a highly stereoregular main chain where ordered conformations can predominate as for biopolymers.

Under these conditions, the linear dependence observed for some copolymers appears as a limiting case where no neighbouring effects occur. This is the case for block copolymers where the number of triads is practically reduced to the homopolymer triads. A second example is given by optically active copolyamides from (+)-camphoric acid and adipic acid with hexamethylene diamine where asymmetrically perturbed amide groups are separated from each other by achiral long chains[25]. A third case is found in vinylic copolymers when chiral centres are well inside the side chain[12-15]

As shown recently[26], the optical activity of stereo-irregular polyelectrolytes during neutralization depends mainly on the monomeric unit behaviour and not on macromolecular conformation changes. The non-linear dependence of $[m]$ observed for all the synthetic optically active polyelectrolytes during neutralization can then be attributed to neighbouring effects. Partial ionization gives rise to a copolymer of the two optically active units in variable amounts with the degree of neutralization. This seems corroborated by the similarities between the curves observed for polyelectrolytes[2-4] and *Figure 3* in this paper corresponding to acrylic acid/N-(s-butyl)-N-methyl acrylamide copolymers. However, it must be noted that this comparison is only qualitative. By electrostatic repulsions, an ionized group reduces the probability of the ionization of the neighbouring un-ionized groups so the P_{iii}'s cannot be determined by an ideally random distribution and relation (2) should be unsatisfied.

Nevertheless, the knowledge of the triad distributions (by ^{13}C n.m.r. for instance) should permit one to obtain relations between optical activity of copolymers and monomeric unit distribution and confirm our interpretation in the case of polyelectrolytes also.

(Received 29 March 1974; revised 19 June 1974)

From the coherent neutron scattering on dilute solid solutions of the ordinary polymer within the deuterated polymer, conformation parameters of polymer chains in amorphous solid states can be determined. In this way vitreous poly(methyl methacrylate) (PMMA) has been investigated. The chains form unperturbed coils and the radius of gyration is very near to the corresponding value in dilute solutions of the same polymer in the low molecular θ-solvent butyl chloride. The same principle of measurement has been applied to concentrated solutions of PMMA in D-acetone. The solutions contained 50% polymer, the main part of which (98% and more) was deuterated so that the system was optically dilute for neutron scattering on H-PMMA. A monotonic dependence of the radius of gyration and of thermodynamic parameters on the concentration has been found. A first result is presented for a mixture of two polymers. A dilute solid dispersion of poly(α-methylstyrene) (PMS) within D—PMMA has been investigated at $M_w = 250\,000$. The samples are limpid. The PMS forms micelles of 16 molecules (weight average). The radius of gyration of the micelles, r_z is 170 Å.

INTRODUCTION

For the determination of conformation parameters of macromolecules in isotropic phases by diffraction experiments we need a dispersion of the macromolecules in which (i) their coherent scattering length density (= scattering power) differs from that of the environments (contrasting condition) and (ii) no correlations exist between their position and orientation. This can be achieved easily in dilute solutions of macromolecules in low molecular weight solvents; if the refractive index or the electron density of the solute and the solvent differ sufficiently, light scattering or small angle X-ray scattering yield the necessary information. For the elimination of the intermolecular interferences it must be extrapolated to zero concentration. There are many experimental data which have been obtained in this way[1-7].

It is much more difficult to obtain the same information in amorphous solid polymers, in molten polymers or in concentrated polymer solutions. For this purpose a new procedure has been established[8-14]; only a small fraction of the polymer molecules (about 1% or less) contains the normal hydrogen containing compound. All other molecules are perfectly deuterated. Neutron small angle scattering on such a sample yields the required information. A large difference in the coherent scattering length for neutron diffraction between H and D in this way provides the contrast which is needed. The reverse process with a small amount of deuterated polymer molecules dispersed in a large amount of normal hydrogen containing polymer exhibits the same coherent scattering. However, the large incoherent scattering of hydrogen leads to a large background scattering and less accurate results.

From theoretical considerations as well as from experimental data several conceptions have been derived of the conformation of polymer chains in the amorphous solid state and in concentrated solutions[15-19]. Some of these conceptions, however, are highly speculative. Hence new experimental results have become most desirable.

SCATTERING THEORY

If a solved particle is hit by electromagnetic or neutron radiation of intensity, I_0, the coherent scattering intensity, I is given by the equation:

$$(I/I_0)r^2 \equiv R(\kappa) = \left(\sum_i b_{2i} - \frac{v_2}{v_1} \sum_i b_{1i} \right)^2 P(\kappa) \equiv \Delta b^2 P(\kappa) \quad (1)$$

where $R(\kappa)$ is the Rayleigh ratio, r is the distance between scatterer and detector, b_{2i} and b_{1i} are the coherent scattering lengths of the nuclei in the solute and the solvent molecule respectively, v_2 and v_1 are the corresponding partial molar volumes, $P(\kappa)$ is the single particle scattering function and $\kappa = (4\pi/\lambda)\sin\theta$ is the scattering vector; λ is the wavelength and θ is half the scattering angle. The wavelength of neutrons is given by $\lambda = h/mv$, where m and v are mass and velocity of the neutrons respectively and h is Planck's constant. In neutron small angle scattering usually neutrons are taken with λ between 5 and 20 Å [20,21].

If the concentration in g/ml is c then the number of polymer molecules/ml is cN_0/M, where N_0 is Avogadro's number and M is the molar mass of the polymer. Equation (1) has to be multiplied by this value if $R(\kappa)$ is related to the unit of the scattering volume:

$$R(\kappa) = \Delta b^2 P(\kappa) . c . N_0/M \qquad (1')$$

If any non-ideal interaction occurs, one has to take into account the virial coefficients of osmotic pressure. The influence of the thermodynamic solution parameters on the scattering behaviour is well known and has been given by Zimm[22,23]:

$$Kc/R(\kappa) = 1/MP(\kappa) + 2A_2 c + \ldots \qquad (2)$$

K is a constant which depends on the type of scattering and A_2 is the second osmotic virial coefficient. If the solution is ideal, A_2 is zero. By comparison of equation $(1')$ and (2) K can be evaluated for the case of neutron scattering:

$$K = \Delta b^2 . N_0/M^2 \qquad (3)$$

with Δb given by equation (1). From equation (3) K can be specialized easily for our dispersion of the normal hydrogen containing polymer (= solute) within the deuterated polymer. Only the scattering lengths of D and H enter into Δb:

$$\Delta b = \Sigma b_H - \Sigma b_D = N(b_H - b_D) \qquad (4)$$

where N is the number of hydrogen or deuterium atoms in 1 polymer molecule.

To obtain $R(\kappa)$ of the solute one has to subtract the scattering of a polymer sample which contains the same amount of D and H but randomly distributed over all molecules. This sample gives the total incoherent scattering and the small fraction of coherent scattering which is due to the supermolecular structure. It is prepared by suitable copolymerization of the normal monomer with the deuterated monomer.

For the evaluation of the conformation of the polymer molecules $P(\kappa)$ is of greatest interest. It is correlated with the radius of gyration, r, by $P(\kappa) = 1 - r^2\kappa^2/3 + \ldots$. For a more detailed knowledge of the conformation one can perform model calculations and compare them with the experimental results.

EXPERIMENTAL

Preparation of samples

Neutron scattering experiments were made on samples with weight-average molecular weights, M_w = 6100, 34 500, 78 000, 250 000, 505 000 and 1 034 000. Normal poly(methyl methacrylate) (PMMA) fractions of these molecular weights have been prepared in the usual way by radical polymerization[24] with azoisobutyronitrile (AIBN) and sol—gel fractionation. The molecular weight of these samples has been determined by viscometry[25]. M_w/M_n of these samples is about 1.35 (determined by gel permeation chromatography). They contain about 80% syndiotactic diads. The calculated amount (0.3—1.2%) of these PMMA fractions has been solved in monomer deutero methyl methacrylate and the deuterated monomer has been polymerized. This polymerization was initiated by benzoyl peroxide and dodecylmercaptan served as a transfer agent.

The amount of the initiator and of the transfer agent has been apportioned so that (i) M_w of the resulting deuterated polymer coincided with the same quantity of the solved H-PMMA fraction, and (ii) the total amount of initiator + transfer agent was a minimum[24]. The alteration of the kinetic constants by the H/D isotope effect has been determined experimentally and taken into account.

After degassing, the solution was heated for 7 days at 50°C and afterwards for 3 days at 70°C. The reaction was completed by heating for 6 h at 120°C. Tensions occurring in the material were removed by annealing for a short time at 140°C. The temperature was later lowered at a rate of 0.5°C/h. The obtained deuterated polymer has a Schulz distribution[26] with $M_w/M_n \approx 2$.

The samples were rectangular pieces with the dimensions 1.2 cm x 3 cm x 1 cm. The thickness (1 cm) is well known as the optimum thickness of deuterated material (e.g. D_2O) for neutron diffraction. This rough estimation was justified by the experimentally determinated attenuation factor of 2.6 for these samples.

Neutron scattering experiments

The experimental data which are reported in this paper have been obtained with the neutron small angle scattering device of the Institute Max von Laue - Paul Langevin in Grenoble which is described elsewhere[21]. A part of the data is essentially the same as had been determined already earlier[10,11]. The measurements were carried out with different wavelengths, λ, of the neutrons and at different distances, L, between sample and detector. The monochromatizing of the neutron beam was performed by speed selectors. Two different types were used. The half-width of the wavelength distribution was ±17% and ±4% respectively. The neutron scattering data in *Figures 1* and *3* were obtained with both selectors and no perceptible difference was exhibited. The other results were obtained with the broader wavelength distribution. The λ values given in the Tables and Figures are averages.

Instead of the Raleigh ratio the measurement yields a relative scattering intensity $i(\kappa) = k'R(\kappa)$ where k' is a constant of the device. From the scattering intensity of a solution of a polymer with known molecular weight according to equation (2) the Rayleigh ratio has been determined, so that also k' is a known quantity.

RESULTS

Vitreous PMMA

Figure 1 shows difference scattering intensities (sample minus background) for M_w = 250 000 as a function of κ with the concentration c of H-PMMA as a parameter. The background scattering is $\approx 0.1 \times 10^3$ counts in the scale of *Figure 1* almost independently of κ. It does not vary perceptibly if the H/D ratio varies between 0.003 and 0.012. This means that the measured background scattering is mainly due to supermolecular structure and not to incoherent scattering. The drawn lines in *Figure 1* are least error square fits of the theoretical coil scattering function to the experimental values. Debye's expression[27] for monodisperse Gaussian coils has been modified for polydispersity with $U \equiv M_w/M_n - 1 = 0.36$ [22,28]:

$$P(\kappa) = \frac{2}{(U+1)\xi^2} [(1 + U\xi)^{-1/U} - 1 + \xi] \qquad (5)$$
Figure 1 Neutron scattering of PMMA dispersed in D-PMMA (λ = 6.51 Å, L = 8.665 m). ———, Least error square fits of equation (5) to experimental data. X, 1.19%; O, 0.93%; ●, 0.63%; △, 0.31%

with

$$\xi = \frac{\langle r^2 \rangle_z \kappa^2}{1 + 2U}$$

This equation is valid for a Schulz distribution[22,26] of the molecular weight:

$$H(M) = \frac{1}{\Gamma(k+1)} \left(\frac{k+1}{M_w} \right)^{k+1} \cdot M^k \cdot e^{-(k+1)M/M_w} \quad (6)$$

with $k = 1/U$. Adjustable parameters for the fits in *Figure 1* have been the intersection on the ordinate and $\langle r^2 \rangle_z$.

The radii of gyration are converted to the weight average by means of the relation[29]:

$$\langle r^2 \rangle_w = \langle r^2 \rangle_z \cdot \frac{1 + U}{1 + 2U} \quad (7)$$

which is valid for Schulz distributions.

The evaluation has been done in the same way for all experimental data. The result is shown in *Table 1*. It seems noteworthy that the apparent radius of gyration does not vary with the concentration outside the limits of error at $c < 1.2\%$.

The data from *Figure 1* have been drawn into a Zimm plot which is very similar to that which had been published earlier[11].

The second virial coefficient of osmotic pressure A_2 has

been evaluated according to equation (2) from the Zimm plot and the result is that A_2 is zero within the limits of error ($\pm 2 \times 10^{-5}$ cm^3 g^{-2}).

The obtained radii of gyration in the glassy state are compared in *Figure 2* with those in dilute solutions in low molecular compounds. The latter have been determined by light scattering and by small angle X-ray scattering[1-7]. According to a least error square fit the data for the vitreous polymer obey the relation:

$$\langle r^2 \rangle_w = 0.096 \, M_w^{0.98} \quad (8)$$

Thus for the conformation of polymers in the vitreous state all features of unperturbed coils are present, just as it had been predicted by Flory[15,19]. Compared with the results on the θ-solvent butyl chloride the coils in the vitreous state in *Figure 2* are larger by 10—15%. But there is some evidence that this difference is not real. Neutron measurements on PMMA in D-acetone exhibit radii of gyration which are larger by the same factor than the corresponding values from X-ray measurements on PMMA in normal acetone. So the difference is probably due to systematical errors of the used experimental devices. The results on vitreous PMMA are independent of the temperature within the range $20°C < T < 130°C$.

In *Figures 3* and *4* the difference in neutron scattering of one of the samples is shown within a larger range of scattering vectors. The curve shown is the continuation of the curve $c = 1.19\%$ in *Figure 1*. It has been drawn by over-

Table 1 Root mean square radii of gyration ($\langle r^2 \rangle_w^{0.5} \equiv r_w$) from least error square fits of equation (5)

Figure 4 The data of *Figure 3* in the plot $R\kappa^2$ versus κ. – – – –, equation (5) with $R/Kc = M_WP(\kappa)$

lapping of three measurements: the first is that of *Figure 1*. The second has been taken at L = 2.36 m with λ = 3.81 Å and the third at L = 1.33 m with λ = 9.10 Å. A great number of counts per experimental point (up to 4×10^5) has been recorded. The error due to pulse statistics is less than 1 unit in the ordinate scale of *Figure 4*.

The result is compared with small angle X-ray scattering on syndiotactic and isotactic PMMA in two solvents[32]. In *Figure 4* the data of *Figure 3* are plotted as $R\kappa^2$ versus κ. In *Figure 5* a further plot of this kind is shown. From equation (5) one should expect an asymptotic κ^{-2} course of R for Gaussian coils at large κ. As had been pointed out earlier[6,30–32] this behaviour is not found in the case of PMMA. Also Monte Carlo calculations on some special coil models yielded a different result[6,30]. Isotactic PMMA follows

the scattering function of the persistent coil of Kratky and Porod whereas the scattering of syndiotactic and atactic PMMA can be interpreted by the assumption that the coiling of the thread is superimposed by a certain tendency of helix formation.

Concentrated solution of PMMA in acetone and comparison with the dilute solution

The contrast between H and D for coherent neutron scattering can be used also for the determination of the conformation of polymers in concentrated solutions. A preliminary result is shown in *Figure 6*. The 'concentrated solution' consists of 50% polymer and 50% D-acetone. The polymer consists mainly of D-PMMA. The content of H-PMMA is given as the concentration parameter in the Zimm plot. After conversion of r_z to r_w according to equation (7) the result from this Zimm plot is $A_2 = 0.3 \times 10^{-4}$ cm³/g² and r_w = 143 Å.

In the same way a dilute solution of PMMA in D-acetone has been investigated. The result is $A_2 = 2.1 \times 10^{-4}$ cm³/g² and r_w = 158 Å. If one compares these data with the glassy polymer ($A_2 = 0, r_w$ = 129 Å) a monotonic change with the
Figure 5 Neutron scattering on a dilute solution of PMMA in D-acetone (●) (M_W = 34 500); X-ray scattering on a dilute solution of syndiotactic PMMA in acetone (○) (independent of M_W for M_W > 10 000)
Figure 6 Zimm plot of small angle neutron scattering on solutions of 50% PMMA in D-acetone. The concentration parameter indicates the amount of H-PMMA. M_W = 250 000
Figure 7 Small angle neutron scattering on a dispersion of 1% PMS in D-PMMA

concentration can be observed. A_2 in the concentrated solution refers to the chemical potential of D-PMMA + D-acetone as a binary solvent.

Mixture of two polymers

In *Figure 7* a preliminary result of the neutron scattering on a mixture of two polymers is shown. As before the sample consists mainly of D-PMMA. Instead of H-PMMA poly(α-methylstyrene) (PMS) is dispersed within the D-PMMA. The concentration of PMS is 1%, its molecular weight 250 000. It has been prepared by anionic polymerization[33] and therefore its molecular weight distribution is narrow $(M_w/M_n < 1.01)$. The sample for neutron scattering has been prepared in the same way as is described for the PMMA samples of *Figure 1*, the resulting M_w of the D-PMMA being 250 000.

The experimental scattering function in *Figure 7* is not that of a coil. The curve lies between the scattering functions of coil and sphere. The particle weight M_w is ~4 000 000, the radius of gyration r_z is 170 Å.

This result can be interpreted by spherical particles which have a wide size distribution and are aggregates of about 16 PMS molecules. It shows that the two polymers are not really compatible though they form a clear limpid mixture.

(Received 19 April 1974; revised 9 July 1974)

An assessment is made of the information provided by n.m.r. second moment, fourth moment and T_2 measurements on oriented samples of branched and linear polyethylene. Detailed theoretical comparisons are made with the previously reported experimental results of a number of workers in order to derive information about the molecular motions which underlie the α, β and γ relaxations in the two forms of the polymer. Plausible motional models are presented in each case. Particular attention has been given to the β relaxation which is explained in terms of lamellar fold motion. The relative sensitivity of the various n.m.r. measurements to molecular anisotropy and motion in the polymer is discussed.

INTRODUCTION

For many years now the nuclear magnetic resonance (n.m.r.) method has featured prominently among those available for the study of polymers by providing an abundance of information on the molecular motions which underlie the various relaxation processes. The technique is capable of probing a motional spectrum over some eight decades, being limited on the low frequency side by the applicability or otherwise of the Slichter—Ailion conditions[1] (rotating frame $T_{1\rho}$ measurements) and on the high frequency side by the resonant frequency of the spectrometer (spin-lattice T_1 measurements). Second, M_2, and fourth, M_4, moments of the resonance absorption envelope and spin—spin, T_2, relaxation times are sensitive to intermediate correlation frequencies of the order of $10^{4.5}$ Hz. While the theory underlying all these measurements is well established, the precise interpretation of the experimental data is easiest for M_2, M_4 and T_2. The analysis of data on T_1 and $T_{1\rho}$ tends to be complicated by factors such as spin diffusion effects[2,3] and the presence of distributions of correlation frequencies[4].

Fibre materials have been particularly useful in the study of molecular motion as a consequence of the anisotropy which is often observed in n.m.r. measurements when recorded as a function of the orientation, γ, of the fibre axis to the applied laboratory field[5-14]. On the other hand, anisotropic effects may be quite pronounced in some materials[14] and virtually absent in others[15]. In fact the observation or otherwise of anisotropy is dependent on details of the molecular structure of the polymer[16]. Furthermore, M_2 and M_4 may be highly anisotropic when, for the same system, T_2, T_1 and $T_{1\rho}$ exhibit little or no detectable dependence on the angle of orientation[10,16].

It is our intention in this paper to examine, in a general way, the type of information provided by those measurements which tend to be anisotropic. Polyethylene (PE), both linear and branched, has been chosen as particularly suitable for our purposes. The factors which influence this choice are several. First, there is an abundance of relevant published n.m.r. data[3,5-13,16-47]. Second, the crystallographic information required for the various lattice sum computations has been determined for PE over a wide range of temperature[48-51]. Third, even with the extensive relaxation data recorded for PE of widely diverse morphologies, the precise molecular mechanisms which underlie these processes are not yet fully understood. Of particular interest is the observed plateau in the amorphous T_2 component for branched PE[42,46]. Fourth, the orientation statistics of partly drawn PE films have been analysed in detail[41,44]. Finally, the fact that there is no detectable anisotropy ($<10\%$) in the T_2 data from the highly drawn material even though M_2 and M_4 are highly anisotropic is a commonly observed feature of n.m.r. data which requires an explanation.

A recently derived theory of motionally averaged fourth moments will be used[16], in conjunction with the more established theories for M_2 and T_2[2,52,54], to compare plausible molecular motional models with the experimental data on linear and branched PE.

EXPERIMENTAL

An analysis of the broadline spectra for linear PE published by Olf and Peterlin[7] was carried out principally to determine their fourth moments. The material used in their study was Fortiflex A-60-500 (Celanese Corporation of America) for which $M_n \simeq 5$–6×10^3 and $M_w \simeq 8 \times 10^4$. A sheet of thickness 0.5 mm was compression moulded at $+150°C$ and quenched in ice water. Strips 5 mm wide were drawn at $+60°C$ at a rate of 1 cm/min to a draw ratio of 9. The crystallinity of the material was $\simeq 75\%$. Five sets of spectra at orientation angles $\gamma = 0°$, $45°$ and $90°$ within the temperature range $-196°C$ to $+125°C$ are available.

The published spectra of Foulkes and Ward[43] for low density branched PE were also analysed. The material was again in the form of sheets 5 mm thick which had been compression moulded from Alkathene WNF-15 (ICI Ltd) at $+150°C$. The melt flow index of the sample was 7 and its density was 0.917 g/cm^3. Sections of the sheet 10 x 10

cm were cold drawn at a rate of 1.25 cm/min to a draw ratio of 3.7. Five sets of spectra at orientation angles $\gamma = 0°, 45°$ and $90°$ within the temperature range $-196°C$ to $+60°C$ were analysed. The crystallinity was 60%.

In each case photographic enlargements of the spectra were made from which the second and fourth moments were computed. In those cases where the crystalline and amorphous components were clearly resolvable, M_2 and M_4 were determined for each. It is estimated that these experimental moment values have an uncertainty not greater than 10%. As a partial check on our procedures the M_2 values were compared with those quoted in the respective papers and were found to agree satisfactorily. In addition, the results from the two sides of a spectrum agreed to within 5%.

The T_2 data for branched PE reported by McCall and Falcone[42] and by Fujimoto *et al.*[46] are also of interest. Their materials closely resemble the sample studied by Foulkes and Ward specifically with regard to density and branch content.

The T_2 data for a branched PE sample in highly oriented fibre form were recorded in this laboratory as a function of fibre orientation in the magnetic field but no anisotropy was detected; if anisotropy was present in the T_2 measurements it was certainly less than 10%.

BASIC FORMULAE REQUIRED IN THE ANALYSIS

The moment expressions for a semi-crystalline polymer may be written:

$$\langle M_n \rangle = x \langle M_n \rangle_{cryst} + (1 - x)\langle M_n \rangle_{amorph} \tag{1}$$

where x is the crystallinity and $n = 2$ or 4.

The crystalline second and fourth moments for an oriented polymer may be concisely expressed as[16]:

$$\langle M_2(\gamma) \rangle_{cryst} = \sum_{n=0}^{4} C'(\gamma, n) \overline{P_n(\cos \Delta)} \tag{2}$$

$$M_4(\gamma)_{cryst} = \sum_{n=0}^{8} C(\gamma, n) \overline{P_n(\cos \Delta)} + \langle M_4(\gamma) \rangle_{III} \tag{3}$$

$\overline{P_n(\cos \Delta)}$ are distribution functions in the form of Legendre polynomials which describe the orientation statistics in the polymer[16]; $\langle M_4(\gamma) \rangle_{III}$ is a small correction term due to lattice sums of the type

$$\sum_{i,j,k \neq} B_{ij}^2 B_{ik} B_{jk}$$

(usually designated type III terms) in the fourth moment calculation[52]. $C(\gamma, n)$ and $C'(\gamma, n)$ are coefficients which may be determined from a knowledge of the positions of the resonant nuclei in the polymer along with fundamental constants. The summations are taken over even values of n.

The second moment M_{2uo} of an unoriented sample may be determined from calculations on the drawn material according to the relation[8]:

$$M_{2uo} = 1/15\{M_2(0°) + 8M_2(45°) + 6M_2(90°)\} \tag{4}$$

Finally, we shall also make use of the approximate relationship between T_2 and M_2 for solids[42]:

$$T_2 \simeq 1/\gamma M_2^{1/2} \tag{5}$$

where γ here is the gyromagnetic ratio (not to be confused with the orientation angle in the applied field).

REVIEW OF CURRENT INTERPRETATIONS OF DATA ON PE

Linear and branched PE have both been the subject of extensive study by n.m.r.[3,5-13,16-47]. The overall features of the relaxation behaviour are reasonably well established and have been discussed by various authors[8,38]. There would appear to be two crystalline, α_c and γ_c, and two amorphous, β and γ_a, relaxation processes.

The α and γ processes show up clearly in the n.m.r. of linear PE although the presence of γ_a and γ_c contributions to the relaxation can only be inferred. Olf and Peterlin[8,9] have carried out detailed quantitative analyses of the α and γ processes. They observe a linear correlation between the amorphous content and the strength of the γ relaxation as manifested by the fall in M_2 over the temperature range from $-196°C$ to $+20°C$ for a wide range of linear PE materials[8]. The dependence of the observed depth on amorphous content of the T_1 minimum at $-20°C$, which is also attributed to the γ process, supports this conclusion[10]. A number of molecular models have been proposed to account for the γ relaxation: the crankshaft model[55], the kink model[56,57], vacancies associated with chain ends[58] and the 'sandwich model'[59,63]. The results of Olf and Peterlin tend to rule out the first two mechanisms[8].

The α process, which occurs within the temperature range from $\sim +50°C$ to the melting point, is clearly a crystalline one for which a number of models have been proposed[8,38,53]: a flip-flop model which entails rotational jumps through $180°$ between two equilibrium sites coupled with a translation of one CH_2 unit[8,58,64]; a model which involves rotational oscillations of chains about their long axes plus possible torsion[58,67]; and a defect model[56,58]. Quantitative M_2 considerations, again by Olf and Peterlin[8], favour the flip-flop model coupled with a small oscillation ($8°$) about the two equilibrium sites. Their results pertain to single crystal mats. McCall and Douglass[3] have observed little change in the crystalline T_2 from the rigid lattice value until temperatures in excess of $+100°C$ are reached although there is a substantial fall in M_2 for the crystalline component over the same temperature range. This apparent anomaly will be resolved in the appropriate section to follow. The α relaxation is very pronounced in the rotating frame results for linear PE in the form of a well defined minimum at $+95°C$[37].

The pulsed n.m.r. T_1, $T_{1\rho}$ and T_2 data for branched PE[42,46] manifest methyl branch rotations, the γ relaxation, the principal amorphous transition, β, and the α relaxation. The use of multiple pulse techniques[65,66] by Fujimoto *et al.*[46] has enabled them to separate out three T_2 and $T_{1\rho}$ components above $\sim +20°C$ as compared with two components observed by McCall and Falcone[42]. The longer, amorphous, T_2 in the data of McCall and Falcone appears to be a weighted average of the intermediate and long components recorded by Fujimoto *et al.* Schmedding and Zachmann[47] have examined theoretically the crankshaft motion for a single PE chain as a function of the fixed end-to-end distance of the chain. Their results indicate that this mechanism may well be responsible for the intermediate

component observed by Fujimoto *et al.* In both sets of experimental data[42,46] the β relaxation appears as a two stage process as evidenced by an increase in the amorphous T_2 to an intermediate plateau followed by a further increase to a value appropriate to motions of liquid-like proportions.

The α relaxation sets in at much lower temperatures in branched PE as compared with the linear form of the polymer. Typically, the $T_{1\rho}$ minimum for this relaxation occurs at $+50°C$[42] in branched PE and $+95°C$ in linear PE[37]. McCall and Falcone suggest crystalline chain rotation as the mechanism responsible for the α process and state further that the high temperature crystalline phase may not be a true rotor phase in which all the molecules are rotating[42]. This conclusion parallels an earlier discussion by Hoffman[68].

Foulkes and Ward[43], in their analysis of M_2 data for oriented branched PE, have focused attention on the γ relaxation and propose a chain sliding model for its description.

Bergmann and coworkers[39,45] have performed a detailed line-shape analysis of linear and branched PE spectra, recorded as a function of temperature, in terms of three components attributed, respectively, to rigid, microbrownian and hindered mobile behaviour. This approach has the advantage, in principle, of utilizing all the molecular information contained in the absorption envelope in contrast to linewidth, M_2 or M_4 measurements which only monitor part of the information available. This advantage is offset somewhat by the inherent difficulty associated with all curve fitting procedures of assigning values simultaneously to a number of unknown parameters. However, the accurate prediction of the degree of crystallinity of their materials lends general support to their procedures.

The β relaxation in both forms of the polymer is probably the least well understood and will be a central feature of this paper. The absence of a well defined β relaxation in linear PE in experimental measurements tended to support a branch point mechanism. However, Moore and Matsuoka[69] were able to induce a β peak in a linear PE which had been subjected to suitable heat treatment and observed, in addition, that the peak disappeared when the sample was subsequently annealed.

The results of n.m.r. indicate a shift in the β process to higher temperatures in linear PE[3,38] compared with branched PE and consequently becomes so close to the strong α relaxation as to be unresolved. Sinnott's high temperature relaxation peak, which is probably a superposition of the α and β relaxations, was observed to decrease in magnitude when the sample was either annealed or subjected to electron irradiation[40]. A further important conclusion of his work is the observed dependence of the peak upon the motion of the lamellar folds in his single crystal material. The models which are presented later to explain the β relaxation will attempt to reconcile these experimental observations.

The transition maps for linear and branched PE are not superimposable[38] and hence the same molecular mechanisms need not necessarily be responsible for the corresponding relaxations in the two cases.

MODEL CALCULATIONS

The molecular motions which will be considered in our interpretation of the experimental data are: (1) oscillations about the chain axis, leading ultimately to classical rotation; and (2) a flip-flop motion which involves jumps bet-

ween two equilibrium sites plus a translation of one CH_2 unit.

In the oscillation calculation the chains are displaced as rigid rods through $\pm\phi$ from their equilibrium position; all displacements in the range $+\phi$ to $-\phi$ are equally probable. Indeed the choice of specific probability distributions for the displacements has little effect on the results[8]. Classical rotation corresponds to the case where the angle $\phi = 360°$. Chain torsion is neglected.

For the flip-flop calculation the chains are assumed to spend equal time between the two equilibrium sites and, furthermore, all chains are assumed to move coherently. We have not included the refinement of oscillation about the equilibrium sites[8].

The values of the moments were computed for those specific temperatures for which precise crystallographic data are available within the temperature range $-196°C$ to $+100°C$[48-51]. The M_2 and M_4 results are presented in *Figures 1--4* for the crystalline component in the cases of a rigid lattice, flip-flop motion and classical rotation for the two extreme temperatures, $-196°C$ and $+100°C$. The oscillation data are presented in *Figures 5* and *6* for $-196°C$ only, to preserve clarity of presentation. The higher temperature behaviour may be easily inferred from the rigid lattice results, $\phi = 0$, and the classical rotation results at the other extreme, $\phi = 360°$. As already noted by Olf and Peterlin[8], oscillations at angles greater than $\phi = 120°$ are essentially indistinguishable from classical rotation.

RESULTS AND DISCUSSION

Branched polyethylene

Rigid lattice. The rigid lattice n.m.r. of branched PE, draw ratio 3.7, has been the subject of detailed examina-

Figure 1 Theoretical dependence of M_2 for branched PE as a function of orientation in the magnetic field for rigid lattice (——), flip-flop motion (– – –) and classical rotation (– · – · –). The upper curve is for a temperature of $-196°C$ and the lower, $+100°C$ in each case
Figure 2 Theoretical dependence of M_4 for branched PE as a function of orientation in the magnetic field for rigid lattice (——), flip-flop motion (— — —) and classical rotation (— · — · —). The upper curve is for a temperature of −196°C and the lower, +100°C in each case

tion in two earlier papers[41,44]. The chain distribution statistics for this partly drawn polymer have been fully characterized in terms of the following distribution functions:

$$\overline{P_2(\cos \Delta)} = 0.80$$

$$\overline{P_4(\cos \Delta)} = 0.84$$

$$\overline{P_6(\cos \Delta)} = 0.70$$

$$\overline{P_8(\cos \Delta)} = 0.00$$

The angle Δ is the angle between the symmetry axis of a typical structural unit and the draw direction in the polymer. The rigid amorphous contributions, assumed isotropic were assigned the values $M_{2a} = 24.3\ G^2$ and $M_{4a} = 1650\ G^4$, respectively. The theoretical predictions based upon these data (referred to as model BI) are compared with the experimental results in *Table 1*.

γ-Relaxation process. The clearest manifestation of the γ process by n.m.r. is contained in the isotropic data of McCall and Falcone[42] in the form of a small anomaly in T_2 at −100°C (a rise from ~9 μs to ~10 μs), a $T_{1\rho}$ minimum at −85°C and a T_1 minimum at −25°C. The broad-

line M_2 data in the low temperature region display a fairly uniform decrease in magnitude for all orientations without the appearance of a discrete plateau[43].

McCall and Falcone tend to favour the explanation of Hoffman, Williams and Passaglia (HWP)[58] for the γ process in which it is supposed that there is chain rotation in the amorphous regions, $γ_a$, and crystalline chain rotations near row vacancies, $γ_c$. Foulkes and Ward[43] propose chain sliding in the crystalline regions as being the responsible mechanism. Bergmann's results indicate a rigid crystalline component in the region of the γ relaxation process[45].

Our analysis relates to the M_2 and M_4 data at −100°C, that is, the temperature indicated by T_2 measurements[42] and dielectric[45] data for the activation of the γ relaxation. Prompted by the results of Hoffman et al.[58] and Bergmann[45], we have considered two theoretical models. In the first, 20% of the crystalline chains are undergoing flip-flop motion while 75% of the amorphous chains are rotating about their long axes. The model, designated BII, assumes that all the crystalline chains neighbouring row vacancies can undergo flip-flop motion. The second model, BIII, assumes a rigid crystalline component and all the amorphous chains in rotation. The theoretical predictions are compared with the experimental data in *Table 1* from which it is evident that there is little to choose between the two models. In the calculation, the reasonable assumption is made that chain rotation in the amorphous regions reduces the rigid lattice moments by half to the respective values $M_{2a} = 12.1\ G^2$ and $M_{4a} = 825\ G^4$. The result is not overly sensitive to the percentage of amorphous chains in rotation because of the biassing coefficient 0.4, i.e. the amorphous content. The model of Foulkes and Ward is less attractive in that the description of subsequent relaxation at higher temperatures proves difficult on the basis of predominantly *intra* contributions alone, as

Figure 3 Theoretical dependence of M_2 for linear PE as a function of orientation in the magnetic field for rigid lattice (——), flip-flop motion (— — —) and classical rotation (— · — · —). The upper curve is for a temperature of −196°C and the lower, +100°C in each case

Figure 4 Theoretical dependence of M_4 for linear PE as a function of orientation in the magnetic field for rigid lattice (———), flip-flop motion (— — —) and classical rotation (— · — · —). The upper curve is for a temperature of $-196°C$ and the lower, $+100°C$, in each case

required in their analysis. The models considered here predict an increase in T_2 of ~1 μs with the onset of the γ relaxation process, in agreement with the experimental observations[42].

β-Relaxation process. The β relaxation in branched PE corresponds to the conventional glass transition which ultimately indicates liquid-like motions in the amorphous regions. The observation of three components by Bergmann[45] and by Fujimoto *et al.*[46] indicates that there are two discrete types of molecular activity in the amorphous regions. The intermediate T_2 component in the data of Fujimoto *et al.* exhibits a plateau of ~50 μs in the region of $+60°C$ while the long component rises sharply to a value of ~200 μs at the same temperatures which indicates extensive motions of a general character. The relative intensities are ~28% and ~40% for the long and intermediate components, respectively. A single amorphous component is observed by McCall and Falcone which exhibits a plateau of ~65 μs at about $+50°C$. The magnitude of the plateau in each case falls between the expected values for chain rotation, ~20—30 μs, at lower temperatures to values of the order of milliseconds appropriate to motions

of liquid-like proportions at higher temperatures[29]. The problem is to find a discrete motional model which will account for the magnitude of the observed plateau in addition to satisfying the other experimental criteria referred to earlier.

It is most probable that this type of hindered motion is associated with the chain folded regions in the polymer. This view is consistent with current ideas of lamellar morphology which embody the results of a host of experimental observations on PE[59-63]. The morphological feature which is of immediate interest is the presence of loose folds which can spread out in a disordered fashion onto the surrounding environment, in addition to the presence of loose chain ends (*Figure 7*)[63]. These loose folds constitute a sizeable fraction of the amorphous material in branched PE[38]. T_2 data indicate that folds account for about 60%[46]. As the temperature is increased the tendency towards vigorous motion correspondingly increases. However, in the case of folds, the chain ends are anchored at the entry points to
Figure 5 Theoretical dependence of M_2 and M_4 for branched PE as a function of oscillation angle ϕ for $\gamma = 0°$ (———), 45° (— · — · —) and 90° (— — —)
Figure 6 Theoretical dependence of M_2 and M_4 for linear PE as a function of oscillation angle ϕ for $\gamma = 0°$ (——), 45° (— · — · —) and 90° (— — —)

the crystalline interior of the lamellae with the result that the degree of vigour which the motion can achieve is limited.

The calculations of Schmedding and Zachmann[47] demonstrate that their crankshaft model is an obvious candidate for the description of fold behaviour. Typical of their results is a decrease in M_2 from 19 G^2 to 0.5 G^2 when the end-to-end distance decreases to a value of one half of the stretched chain length. This corresponds to a rise in T_2 from 8.6 μs to 53 μs, in agreement with the experimental observations.

A second more idealized mechanism may be envisaged where the chains as a whole are moving in the highly idealized manner shown in *Figure 8*. The chains are already considered to be rotating about their own axes at these temperatures (γ process)[42]. This model has been used to predict successfully the observed anisotropy in the amorphous T_2 data of oriented polychlorotrifluoroethylene

fibres[70]. The fold is divided into straight sections and T_2 is computed for each. The vertical part of the fold will be characterized by a T_2 close to the crystalline value; we assume that those parts of the fold at the angle χ alone contribute to the amorphous T_2. Only *intra* contributions are considered. The T_2 expression for this motion may be written[70]:

$$1/T_2^2 = 1.07 \times 10^{10} P_2^2(\cos\xi) \sum_{l=0,2,4} a_l P_l(\cos\gamma) P_l(\cos\chi) \quad (6)$$

where the numerical coefficient has been adjusted to a value appropriate to polyethylene; $a_0 = 1/5$, $a_2 = 2/7$ and $a_4 = 18/35$, respectively. The angles are defined in *Figure 8*. The expression for an isotropic sample has the much simpler form:

$$1/T_2^2 = 0.214 \times 10^{10} P_2^2(\cos\xi) \quad (7)$$

T_2 is graphed as a function of the angle ξ in *Figure 9*. Notwithstanding the highly idealized nature of the motion, the results again demonstrate that discrete T_2 values of the correct order of magnitude are predicted for reasonable values of the angle, ξ.

The two models discussed involve loose folds on the surface of crystal lamellae and as such describe an amorphous phenomenon. It is not surprizing, however, that the crystalline regions may exert some influence on the process, as hitherto observed[71]. Upon annealing, the loose folds are drawn into the crystalline interior in the lamellar thickening process[72] which would result in the disappearance of the β
Figure 7 Diagram which illustrates loose chain folds and chain ends on the surface of a crystal lamella
Figure 8 Diagram which illustrates the proposed idealized motion underlying the β relaxation process

Figure 9 T_2 as a function of the angle ξ for the motion illustrated in *Figure 8*

relaxation. The crosslinking produced by electron irradiation of the folds[40] would certainly curtail motion severely, if not prevent it altogether, with a consequent elimination of the β process.

α-Relaxation process. The α relaxation shows up as a minimum in the crystalline $T_{1\rho}$ component at +50°C[42]. M_2 and M_4 are decreasing continuously at these higher temperatures although M_2, M_4 ($\gamma = 90°$) become less than M_2, M_4 ($\gamma = 0°$) above room temperature in contrast to the lower temperature region where the reverse is true[43]. This accelerated fall in the values of the moments for $\gamma = 90°$ is reminiscent of the onset of classical rotation (see *Figures 1* and *2*).

In our analysis of the data at +60°C it is noted, initially, that an amorphous T_2 value of 65 μs corresponds to $M_{2a} \simeq 0.4$ G^2; the weighted contribution to the total moment is therefore 0.16 G^2, which may be neglected. M_{4a} is also deemed to be negligible. Attempts to fit any of the proposed motional mechanisms to the crystalline regions lead on the whole to poor agreement with experiment. A reasonable fit may be achieved, however, (see *Table 1*) if 10% of the crystalline regions are assumed to have melted and the remaining 90% of the crystalline component (50% mass fraction in all) to be in classical rotation (model BIV). A further improvement is obvious with the assumption of a less perfect orientation which may well be the case above the glass transition temperature: the vigorous motions in the amorphous regions may have a disordering influence upon the oriented crystalline part. The model is compatible with the rapid decrease in density which is observed with increase in temperature above room temperature[73]. Bunn and Alcock[74] have observed premelting in their X-ray measurements in excess of +80°C. This higher temperature may be due to the different preparative histories of the materials or to the relative sensitivities of the X-ray and n.m.r. methods to premelting.

Linear polyethylene

Rigid lattice. Table 1 shows the optimum agreement which could be achieved between theory and experiment. The polymer was assumed to be fully drawn, in agreement with earlier findings on a comparable sample[41]. The amorphous second and fourth moments were assigned the respective values $M_{2a} = 29.5$ G^2 and $M_{4a} = 1900$ G^4. The model is designated LI. The rather low predicted value at orientation $\gamma = 0°$ and the high value at $\gamma = 45°$ would tend to indicate an oriented amorphous component as suggested by Olf and Peterlin on the basis of the sandwich model[8]. However, the lack of precise morphological information on the amorphous regions precludes a rigorous treatment of amorphous anisotropy for the rigid lattice case. The pre-

dicted rigid lattice T_2 for unoriented material of 7.1 µs, from equations (4) and (5), is in good agreement with the experimental results of ~7 µs obtained at −196°C by McCall and Falcone[42].

γ-Relaxation process. It has been argued that the fall in M_2 from −196°C to +25°C is a manifestation of the γ relaxation process in linear PE[8,9]. Any proposed model to explain the γ relaxation must necessarily be compatible with a number of observations. In the first place, T_2 data would appear to preclude any crystalline motion at +25°C[3,45]. Secondly, the anisotropy in the amorphous regions, implied in the rigid lattice data, would have a more pronounced effect on the measurements if the chains were rotating about their own axes; the anisotropy in M_2 and M_4 as a function of orientation is much greater for rotating chains than for rigid ones[14]. Thirdly, the predicted amorphous moments for the $\gamma = 0°$ orientation at +25°C must agree with the measured values; at this temperature the n.m.r. trace may easily be decomposed into its two components at orientation $\gamma = 0°$. The experimental values are $M_{2a} = 15.4$ G^2 and $M_{4a} = 770$ G^4, respectively, which are consistent with rotation about the chain axis.

The theory presented above to explain the relaxation in branched PE may be used here to quantify the anisotropic effects of an oriented amorphous component in which the chains are rotating. The angle ξ is set equal to zero to confine the motion to rotation about the chain axis alone. The experimental amorphous value of 15.4 G^2 for $\gamma = 0°$ is predicted by the model when the angle χ assumes the value 25°. The corresponding values of M_{2a} for the $\gamma = 45°$ and $\gamma = 90°$ orientations are, respectively, 5.6 G^2 and 4.1 G^2. A rough estimate of the corresponding M_{4a} values may be made if the line shape parameter[11] $p = M_{4a}/M_{2a}^2$ is assumed to be the same for the three orientations. At $\gamma = 0°$, p is experimentally equal to 3.25 which results in $M_{4a}(45°) = 100$ G^4 and $M_{4a}(90°) = 55$ G^4. The theoretical predictions presented in *Table 1* derive from these amorphous values used in conjunction with rigid lattice moments for the crystalline regions. This model is referred to as LII.

We now examine a second model, designated LIII, to demonstrate that a particular model assignment is by no means unambiguous. The second calculation is based upon the impressive arguments of Hoffman *et al.*[58] in which a vacancy defect model is invoked to explain their dielectric data. This model is similar to the one proposed to explain the γ relaxation in branched PE. Crystalline chains near row vacancies are considered to be undergoing classical rotation in addition to chain rotation in the amorphous regions. To illustrate the flexibility of the approach, we have assumed for simplicity that the amorphous regions are isotropic with $M_{2a} = 15.4$ G^2 and $M_{4a} = 770$ G^4, i.e. the measured values for orientation $\gamma = 0°$. The excellent fit achieved with the experimental data, also shown in *Table 1*, is on the basis of 20% of the crystalline chains rotating near defects. Substitution of flip-flop motion for classical rotation coupled with a small adjustment of the number of crystalline chains in motion also leads to an acceptable fit with the experimental data. The predicted bulk T_2 value of 8.2 µs is only 1.1 µs up on the rigid lattice value, i.e., a marginal increase *vis-à-vis* the observations of McCall and Douglass[3].

Thus, while a given model may be in excellent agreement with the experimental data it is nevertheless important to keep an open mind on the possibility of alternative mechanisms.

High temperature relaxation process. This process is usually designated the α-relaxation but we should bear in mind that there exists also the overlapping β process which cannot be resolved by n.m.r. in linear PE. We recall that the predictions of Olf and Peterlin for single crystal mats of linear PE support a model in which all the crystalline chains are undergoing flip-flop motion[8]. McCall suggests rotation of crystalline chains where there exists the possibility that the crystalline regions may not be a true rotor phase[38].

We have analysed the n.m.r. moment data at +120°C and note in the first instance, from those traces which may readily be decomposed into two components, that the amorphous moment values are sufficiently small as to be neglected in our calculations. Attempts to ascribe a particular motion to all of the crystalline regions results in poor agreement between theory and experiment. However, the assumption of 45% of the crystalline component remaining essentially rigid and 55% undergoing classical rotation yields the agreement shown in *Table 1* (model LIV). While it is not our intention to inject detailed morphological conclusions into any particular model we are nevertheless tempted to suggest that there may be appreciable amounts of different types of crystalline material present which exhibit characteristic molecular behaviour (for example, chain folded or extended chain forms)[75].

The predicted T_2 value for the model is 10.8 µs which again is in reasonable agreement with the data of McCall and Douglass[3].

The absence of a well defined β relaxation in mechanical measurements or in n.m.r. data may be due to the presence only of sharp folds which are unable to rotate as in branched PE or, alternatively, to the steric hindrance to fold motion caused by intercrystalline chain units linking neighbouring lamellae[75,76].

CONCLUSIONS

The principal quantitative conclusions of the paper are contained in *Table 1* which summarizes the experimental and theoretical data for the various relaxation mechanisms in linear and branched PE. An interesting and important aspect of these results is the relatively low sensitivity of T_2 to molecular behaviour as compared with M_2 (and M_4). This derives from the square root dependence between M_2 and T_2 as shown in equation (5). In particular, preferred orientation in drawn materials can effect large changes in M_2 as a function of orientation angle γ in the applied field and yet T_2 is essentially isotropic for similarly drawn samples. Typically, the low temperature M_2 data for drawn branched PE are 29.5, 23.9 and 31.0 G^2 for $\gamma = 0°, 45°$ and $90°$, respectively. The equivalent T_2 values, from equation (5), are 6.9, 7.7 and 6.7 µs, respectively. These differences are barely detectible by pulsed n.m.r. as we have experience in this laboratory. Furthermore, the onset of specific motions in the polymer have a much greater effect upon M_2 than on T_2. For example, the fall in M_2 with the onset of the γ relaxation in linear PE is of the order of 7 G^2 while the corresponding rise in T_2 is only of the order of 1 µs. As a result M_2 and M_4 are much more sensitive monitors of the onset of molecular motion than T_2. It is commonly observed that specific motions such as methyl group rotations can remain undetected in T_2 measurements although clearly manifested in M_2, T_1 and $T_{1\rho}$[76].

On the other hand, major experimental difficulties impair the accuracy of M_2 data for magnitudes of the order of a fraction of a $(\text{Gauss})^2$ as is typical above the glass transition temperature. In such cases, T_2 measurements are to be preferred.

In general, it is important to note that while certain intuitive models are in excellent agreement with the experimental observations they need not necessarily be unique in this respect; there may be other models which are in comparable agreement within the accuracy of the experimental n.m.r. data. In practice one tends to choose the model on the basis of available morphological information rather than adopt the reverse procedure of drawing detailed morphological conclusions from a chosen model.

Developments in radiation-induced graft polymerization to cellulosics

J. T. Guthrie

Department of Colour Chemistry and Dyeing, University of Leeds, Leeds LS2 9JT, UK
(Received 19 April 1974; revised 14 May 1974)

INTRODUCTION

Such is the effort afforded studies of grafting to cellulose that several reviews have already been written on this topic. In many ways one can visualize a situation requiring a review of the reviews! As yet, however, industrial interest has been minimal. Whether or not this debility arises from within industry or the research centres is debatable. It is reasonably clear that, despite having many advantages to offer relative to alternative industrial processes, graft polymerization reactions have not been examined to decide their viability. In view of the simplicity of operation, radiation-induced grafting processes appear worthy of much greater attention. Whilst one may attempt to review completely the developments made in radiation grafting in recent times, the advances made are such that the task is beyond the scope of a single publication. Here we are primarily concerned with modern progress in radiation-induced grafting to cellulose and its more common derivatives. Where necessary, however, reference to other substrates may be made for comparison. The theme throughout is publication of the industrial potential of the technique, those applications already in existence and advantages to be gained through their use.

There are in existence reviews which deal with the subject of grafting to cellulose in varying degrees of detail. In some of these radiation dependent methods are considered along with other methods of initiation. The number of reviews devoted to radiation induced processes is very small. Krassig and Stannett[1] set the standard in general reviews of grafting to cellulose which has yet to be matched for comprehensiveness and lucidity. Battaerd and Tregear[2] covered the general and patent literature though their treatment was less comprehensive. More recent reviews have been published by Hebeish[3], Nakamura[4], Matsuzaki and Nakamura[5], Stannett and Hopfenberg[6], Rogovin[7] and Le Gall[8].

Apart from reviews by Moore[9,10] only three other publications are available dealing specifically with the radiation-induced graft polymerization of vinyl monomers to cellulose — by Hoffman[11] and by Arthur[12,13]. The review by Hoffman deals with industrial possibilities whilst Arthur's publications describe advances in the general knowledge of the subject. In the latter instance considerable emphasis is placed on the effects of radiation on the substrate.

As an indication of the interest in grafting processes involving cellulose as the substrate, the proceedings of a symposium held on this topic have recently been published[14]. The field of reference was broad and the treatments given were comprehensive.

In this review a logical progression is followed. Initially, the techniques available in radiation grafting are outlined. Although the coverage is not absolute, much of the recent literature is cited and should be referred to for further details. Thus literature, relevant to radiation-induced grafting to cellulose, is covered in tabulated fashion. This approach enables easy reference to be achieved. Aspects of the subject which have advanced considerably since the review by Krassig and Stannett[1] and those of Moore[9,10] are dealt with in depth in later sections. Emphasis on applications, characterization, grafting to timber and the patent literature is necessary since these areas have been somewhat neglected in the past.

Those interested in cellulose modification through radiation grafting techniques are advised to consult consistently the work of Arthur *et al.*, Dilli and Garnett, Huang and his group, Stannett *et al.* and Usmanov *et al.* Whereas some of the research concerned with grafting to cellulose is of a repetitive nature, that of the above mentioned is invariably of high quality and original.

It is interesting to note that the bulk of the scientific literature relating to grafting arises from research carried out in academic surroundings and that this work is now reaching the patent application stage. Industry has seemed to be hitherto reluctant to investigate the potential of the process. This observation runs contrary to most areas of research. Possible explanations include an unwillingness to change in industries involved in cellulosic products, problems associated with radiation sources, and the relative novelty of the technique. The present time is ideal for the commercial exploitation, on a wide scale, of radiation-induced grafting in a variety of situations.

TECHNIQUES OF RADIATION-INDUCED GRAFTING

All modes of graft copolymerization of vinyl monomers to cellulose require that the substrate be accessible to the monomer. For vapour phase processes this is not a particularly restrictive limitation. However, for both pre-irradiation and simultaneous processes in which the grafting system is heterogeneous, the problem of swelling the substrate arises. For cellulose derivatives this does not present any difficulty provided the derivative is soluble in the monomer or alternatively that both the monomer and derivative are soluble in the solvent selected. This need of access of the monomer into the cellulose substrate is not peculiar to cellulose alone but exists irrespective of the nature of the substrate. In the absence of swelling, grafting is limited to the surface regions of the parent matrix whereas with increased swelling volumetric grafts are obtained.

In general, two fundamental processes are available for radiation-induced grafting.

Pre-irradiation method

Here the substrate is irradiated, either in the presence of air or its absence, before being brought into contact with the monomer whether in liquid, gaseous or solution form. In the absence of oxygen little or no homopolymer is formed whereas in the presence of oxygen, peroxy-radicals are formed within the substrate. These can be made to decompose on heating in the presence of a monomer, giving grafting and some homopolymerization. This homopolymerization occurs through chain transfer to the monomer.

Difficulties often put forward against the use of pre-irradiation as a technique usually centre around the sensitivity of the substrate to radiation damage and factors related to the swelling of the substrate. Features concerning the substrate sensitivity are dealt with in later sections and the second aspect is now considered.

The effect of any cellulose pre-treatment, monomer type and concentration, presence of additives, the dose rate and total radiation dose and the substrate structure all play some part in the ultimate grafting efficiency. However, the major factor is the allowance, in the grafting procedure, for swelling of the cellulose before exposure to the monomer and subsequent grafting. Vapour phase grafting requires that the monomer be applied in a vapour medium which is able to enhance the swelling and reactivity of the cellulose matrix. This is also true of pre-irradiation grafting in heterogeneous systems using either monomer solutions incorporating a swelling agent or a hydrophilic monomer. Walsh[15] has studied, in detail, the effects of swelling on the pre-irradiation grafting of acrylonitrile onto cellulose during which the extent of grafting was noted to increase markedly provided an aqueous medium was employed. This indicates increased access of the monomer into the interior of the cellulose.

Another feature of importance is the nature of the cellulose substrate as seen through the extent of accessibility of the radical sites to the monomer or monomer solution. Grafting is thought to occur initially in the more accessible regions and then, as the substrate becomes modified in these areas, grafting proceeds in the otherwise less accessible regions. Since areas available to the monomer are also amenable to other reagents, for example oxygen, solvents etc., complications may arise. This is seen in the retardation of grafting by atmospheric oxygen. Hence strict interpretations or logic cannot always be applied. An example of this is the lower rate of grafting usually obtained with highly amorphous regenerated celluloses than occurs with substrates of greater crystallinity. This observation is contrary to expectations if accessibility to the monomer is taken as the sole factor of relevance.

The effect of the dose rate and total dose on the ultimate extent of polymerization is less important with pre-irradiation than with mutual techniques. This does not apply to the substrate which may degrade irrespective of the method of grafting employed if excessive doses are used. Within the context of industrialization the pre-irradiation technique is attractive. One may visualize long-term storage of large batches of substrate paper, textile or timber at low dose rates or short term exposure at high dose rates. Either method may be modified to meet particular needs. In this way particular batches can be called upon as required. Advantages to be gained over simultaneous techniques include ease of storage, personnel protection, plant cost and insulation, chemical efficiency, cost effectiveness, etc. Provided certain precautions are taken, as outlined below, there is little excuse for this type

of process not being utilized more readily in the future than it is at the present time.

Recent data concerning pre-irradiation grafting to cellulose and some of its more common derivatives are given in *Table 1*. Being reasonably comprehensive, the outline indicates that the technique is attracting considerable attention. Also of interest is the gradually increasing drift away from the use of the more conventional monomers into areas dealing with improvements to the substrate. This trend is to be encouraged since, to be commercially viable, the products obtained by graft copolymerization must be designed to meet specific needs such as low cost, high efficiency or superior physical characteristics.

Simultaneous irradiation technique

Irradiation of a cellulosic substrate in the presence of the monomer whether in the vapour or liquid phase, bulk or solution system, heterogeneous or homogeneous in nature, is termed the mutual or simultaneous method. Factors of importance to the pre-irradiation technique also apply to simultaneous grafting. These include the nature of the cellulose, its pre-treatments, contributions made to grafting efficiency by swelling agents, transfer agents and additives. Other factors to be considered are the ratio of monomer to solvent in the grafting solution, the ratio of monomer to substrate, diffusion aspects, the possibility of viscosity effects taking place, accurate temperature control, the presence of inhibitors and retarders etc.

Much of the earlier work in grafting has been concerned with mutual techniques, although only recently have the kinetics of the polymerization processes been dealt with in any detail whether qualitatively or quantitatively. Difficulties arose through the inability to determine with accuracy the concentration of monomer in the interior of the substrate during the grafting process. This is of critical significance to monomer/solvent systems since differences may exist between the concentration of monomer within the substrate and the bulk monomer concentration. Use of ultra-violet spectroscopy has resolved these difficulties to a certain extent and has enabled a more reasoned approach to the kinetics to be made.

Extensive volumetric grafting using the mutual process is dependent on swelling of the substrate. Here water has a particular part to play through its ability to break down the hydrogen bonded network in the cellulose. Low concentrations (2%) of water in a monomer/solvent system (assuming that either or both the monomer and solvent are miscible with water) greatly enhances the accessibility of the cellulose to the monomer solution. In the absence of a swelling agent grafting is minimal and is restricted to the substrate surface. From the point of view of general serviceability voluminal grafts are essential.

The swelling behaviour in a given system is dependent on the structure of the substrate cellulose whether cotton, rayon, fibre or film. Equally important is the monomer: solvent ratio which may overide all other contributing factors in the grafting process. Areas of general interest include characterization of products, reaction kinetics in terms of chain transfer possibilities and relationships between experimental results and the composition of the monomer solution.

Data relating to the mutual irradiation technique are presented in *Table 2*. The list of observations made is reasonably comprehensive though a fuller treatment may be found in the text.

Table 1   Recent developments in pre-irradiation grafting to cellulose*

Substrate	M	MP	SA	T (°C)	Remarks	Ref.
Cellulose or derivative	S and AN	solution	Aqueous	RT	i.r. spectroscopy used as means of determining the extent of grafting; samples prepared by KBr pressed disc method; absorption bands at 700 cm^{-1} (styrene) and 2249 cm^{-1} (acrylonitrile) monitored	16,17
Cotton cellulose	EA	solution	CH_3OH/H_2O	25	radical accessibility assessed by e.s.r.; acceleration in rate observed, thought to be due to presence of water; maximum grafting at phase boundary conditions	18
			$(CH_3)_2C=O/H_2O$	25	radical scavenging observed by e.s.r.; grafting less than with methanol/water; no Trommsdorff effect observed	19
			CH_3OH/H_2O	25	effect of oxygen on grafting observed by e.s.r.; effect of temperature increase on the extent of grafting followed; e.s.r. spectra interpreted	20
Cotton cellulose	MA	solution	Aqueous	25	e.s.r. spectra obtained and interpreted; evidence of existence of poly(methacrylic acid) radicals given	21
	S	solution	Both dry and aqueous	50–117	effect of oxygen on degree of grafting; effect of water decreased the amount of grafting when adsorbed; grafting decreases as T increases; e.s.r. measurements analysed; effect of oxygen on the radical yield determined	22
Cotton cellulose	AN + other monomers	solution	H_2O CH_3OH DMSO MEK	25	copolymerization of acrylonitrile and one other monomer from a series of binary mixtures; comprehensive discussion	23
Cellulose fibres	EA	solution	Aqueous	25–35	high grafting yields; grafting yields examined above T_g; levels for elasticity outlined; effect of the comonomer dependent on the functionality of the comonomer; grafting rate increases as temperature increases in the range 25–35°C but not above 60°C; electron microscopic study carried out.	24
Cellulose	MVK	solution	H_2O CH_3OH DMF	25	effect of DMF on grafting assessed and compared with CH_3OH; i.r. band at 5.85 μm used to detect C=O group; mechanical properties determined; tensile characteristics reduced on grafting; other desirable properties imparted to the substrate	25
Cellulose	A	vapour	Aqueous	–	evidence of crosslinking of cellulose by acrolein obtained; strength and flexibility deteriorated on grafting; no homopolymerization observed	26
Cellulose	MMA	vapour	RT→65°C	–	presence of air enhanced grafting; grafting increased with temperature to a maximum at 65°C; beyond this point the rate falls off; E_a = 640 kJ/mol; radical mechanism indicated	27
Cellulose	S V A 2-VP 4-VP	solution	CH_3OH	60	various low dose rates used; small amounts of additives employed and their effect assessed; acridine suppressed, anthracene inhibited and halobenzenes sensitized t..e reaction	28
Cotton rayon	S MMA α-methyl-S	–	–	–	single fibre strength remained unchanged but tenacity in g/denier decreased as grafting increased; apparent degree of grafting > true extent observed	29
Cellulose and cellulose triacetate	S and BA	solution	CH_3OH	0	irradiation in air; monomer mixtures used; reactivity ratios different than with AIBN initiation; trapped radicals in cellulose and peroxide radicals in cellulose triacetate found to be the active initiation species; kinetics studied	30
Cellulose	BMA	solution	Aqueous CH_3OH	25	cellulose copolymerized with butyl methacrylate; distribution of monomer within the fibre investigated; grafted fibre shows better resistance and flexural properties	31
Cotton cellulose rayon, cellulose triacetate	MMA MAA	solution	CH_3OH DMSO	60	polymer structure studies after thorough removal of occluded homopolymers; n.m.r. used to characterize the grafted species	32
Cotton cellulose	VFF	vapour	Aqueous vapour CH_3OH vapour	–	grafting studied in presence and absence of H_2O and CH_3OH; vapours enhanced grafting; excellent laundering and crease resistance characteristics observed; stability to u.v. irradiation increased	33

Table 1 Recent developments in pre-irradiation grafting to cellulose*—cont.

Substrate	M	MP	SA	T (°C)	Remarks	Ref
Ethyl cellulose	MA	vapour	None	25	air retarded the grafting reaction; i.r. used to follow the grafting reaction; identification of the grafted branches attempted; short branches obtained; substrate exposed to vapour of monomer	34
Rayon	EA MMA	solution	H_2O	50	aqueous emulsion medium used; pre-irradiation and chemical initiation compared; effect of temperature on radiation induced methods covered; the morphology of the copolymer investigated; studies show that elastomeric properties require volumetric grafting which expands and disrupts the rayon fibre	35
Cotton cellulose	VF	vapour	—	—	vinyl fluoride grafted onto cotton cellulose	36
Cellulose acetate (DS 1.84—2.25)	S	solution	pyridine	25	e.s.r. used to investigate the grafting process; radical decay rate at 25°C slow; the e.s.r. spectrum does not change on addition of monomer suggesting that chains grow and terminate rapidly compared with the cellulose radical decay rate; high yields and molecular weights of branches anticipated	37
Cotton cellulose	AN	solution	$H_2O/ZnCl_2$	25	an e.s.r. study; effects of various factors including copolymerization on radical yields and the nature of spectra interpreted; suggested radical sites given	38
Cotton cellulose	AN	solution	$H_2O/ZnCl_2$	25	method of separation of grafts from the backbone quoted; grafts analysed for molecular weight characteristics	39
Cotton cellulose	BMA and AN singly and mixtures	solution	—	23	emphasis on structural determinations by electron microscopy; dye uptake used as monitor of uniformity of grafting	40
Cellulose	AN S	solution	benzene DMF	—	radiochemical yields of graft polymerization reactions of cellulose; mutual and pre-irradiation considered	41
Cotton cellulose	AN S MMA VA	solution	various	various	electron microscopic study of various cellulose—comonomer grafts prepared under both pre-irradiation and simultaneous techniques; location of graft partly dependent on monomer grafted	42
Cellulose acetate	S	solution	CH_3OH	50 (in N_2)	radical sites labelled with bromine atoms; methanol remarkably increased the lifetimes of the individual graft radicals but decreased the growth rates	43

* The symbolism used is given in the Appendix

Table 2 Recent developments in the simultaneous (mutual) irradiation technique*

Substrate	M	MP	SA	T (°C)	Remarks	Ref.
Cellulose acetate and others	S AN MA VA	solution	—	—	reactivity ratios in various radiation and redox initiated systems compared and discussed; homogeneous and heterogeneous conditions used; abnormal behaviour at low degrees of grafting which normalized with increased grafting	44
Cellulose (regenerated)	MMA	solution	acetone	RT	samples soaked in monomer then irradiated; acetone as solvent for MMA gave enhanced grafting; effect of AQ (none), hydroquinone (marginal) and oxygen (marginal) on grafting monitored	45
Cellulose	S	solution	H_2O/dioxane	30	quantitative method of determining the concentration of monomer at the grafting sites described in detail using u.v. spectroscopy	46
Cellulose (regenerated)	S	solution	H_2O/dioxane	30	kinetics of grafting investigated; effect of water on the grafting and swelling characteristics of the substrate studied; cellulose degradation studied viscometrically	47
Cellulose (regenerated)	S	solution	H_2O/dioxane	30	ratio k_p^2/k_t was 10^5 greater for grafting than homopolymerization; e.s.r. used to identify radical types and radical decay; values for $G_{(scission)}$ in both air and vacuum obtained	48
Cellulose (regenerated)	S	solution	H_2O/dioxane	30	technique of isolation of grafted branches from the substrate given; other methods discussed	49
Hydroxyethyl cellulose (DS 0.4)	S	solution	H_2O/dioxane	RT	kinetics of grafting discussed; comparisons made with cellulose substrates; effect of physical form on grafting ascertained	50

—cont.

Table 2　Recent developments in the simultaneous (mutual) irradiation technique*—*cont.*

Substrate	M	MP	SA	T (°C)	Remarks	Ref
Carbanilated celluloses (DS 0 → 0.52)	S	solution	H$_2$O/dioxane	30	effect of radiation protection of cellulose on radical yields and grafting behaviour investigated; kinetic appraisal of results made	51
Cellulose	S	solution	CH$_3$OH	20–25	effect of additives on grafting investigated; non-aromatic additives reduced grafting, radical scavengers suppressed grafting; non-aromatics showed little change apart from anthracene and acridine; reaction mechanisms discussed	52
Cellulose rayon	various	solution	—	—	general observation of decrease in the substrate strength with increase in dose	53
Cellulosic textiles	AN	solution	acids alcohols and hydrocarbons	25–50	sensitizers used to enhance grafting; grafting observed to increase with increase number of atoms in the additive both in the presence and absence of air	54
Cellulosic fibres	S MMA	—	none and H$_2$O comparison	various	simultaneous and pre-irradiation methods considered; various factors examined relating to grafting; problems encountered in grafting critically assessed; semi-review	55
Rayon	S	solution	methanol and water	—	comparison between cellulose and poly (vinyl alcohol) as substrates in terms of characterization of grafted chains; methods of isolation of grafts outlined; mutual and pre-irradiation techniques compared	56
Cellulose and others	S 4-VP 5-methyl-2-VP	solution	various polar solvents	—	effect of substrate type on grafting investigated; for S in CH$_3$OH; cellulose exhibited Trommsdorff effect; results interpreted in terms of charge transfer theories	57
Cellulose	S and substituted S MMA VA VP	solution	wetting and non-wetting solvents	—	variety of solvents assessed for effect on grafting; S + o-, m- and p-derivatives investigated; Trommsdorff observed at low doses and dose rates; effect of O$_2$, N$_2$ and vacuum assessed; rate of energy transfer discussed	58
Cellulose	S MMA VA	solution	dioxane DMF acetone	RT	effect of air and vacuum on polymerization investigated; grafting in various cellulose wetting solvents studied; mechanistic interpretation discussed	59
Cellulose	S	solution	CH$_3$OH	RT	grafting at low dose rates studied; effect of oxygen ascertained; evidence of Trommsdorff behaviour noticed	60
Cellulose	S and substituted styrenes and others	solution	CH$_3$OH	various −196 to +40	effect of temperature on the grafting reaction observed as indication of contribution of ionic mechanisms to the process; various monomers used to correlate grafting results with Hammett constants	61
Cellulose	S MMA VA 2-VP 4-VP	solution	non-wetting solvents	RT	poor grafting yields observed; results interpreted in terms of charge transfer theories; methanol enhanced grafting in all cases	62
Cellulose	S MMA VA 2-VP 4-VP	solution	CH$_3$OH	RT	appreciable grafting at room temperature in air and vacuum; dose and dose rate dependence found; evidence of Trommsdorff effect observed; mechanism proposed for the grafting process	63
Cellulose	S	solution	CH$_3$OH	RT	kinetics of grafting studied in a non-quantitative manner; dose dependence observed and effect of air and vacuum on grafting investigated; radical scavenging by methanol proposed for poor grafting yields	64
Cotton cellulose	HEMA HPMA	solution	H$_2$O CH$_3$OH DMF DMSO and combinations	24	kinetic analysis attempted; organic solvents decreased amount of grafting; reactions diffusion controlled and exhibited second order kinetics; various factors investigated, e.g. monomer concentration, dose rate, swelling agents	65
Cotton cellulose	MAA MAN 6-FIPA NVC	solution	1,2-DCE and CH$_3$OH/H$_2$O	25	textile properties of various cellulose graft copolymers and terpolymers investigated and related to the chemical structures of the monomers and the glass transition temperatures of the homopolymers	66
Cotton cellulose	S AN singly and mixtures	swollen substrate	Primary alcohols	—	industrial potential of grafting process assessed; grafts examined for various physical and structural properties	67

KINETICS OF THE GRAFTING REACTION

Until comparatively recently the mechanism of the grafting process was far from well understood. Considerable difficulties arose from the inability to quantify the concentration of monomer at the grafting sites during the grafting reaction. This position has now been improved through u.v. spectroscopic analysis of ungrafted monomer extracted from the substrate prior to and during grafting[46]. Further problems have been overcome by the use of e.s.r. spectroscopy in ascertaining the locations of the radicals within the cellulose substrate (see later).

Attempts have been made to measure the contribution of various solvents for the monomer, to the grafting reaction. This may take the form of swelling the substrate[33], solvency for any homopolymeric species, participation in chain transfer processes and so on. The roles of various additives on grafting have been investigated[28,45,52] as have the effects of temperature[61], viscosity of the grafting medium[47,48], the nature of the substrate and the value of radiation protection[51].

A generalized reaction scheme for the radiation-induced grafting of vinyl monomers (M) to cellulose (P) may be written in a manner which is analogous to that of homogeneous homopolymerization, with equations to represent the various stages.

Initiation (radical formation):

$$P \overset{h\nu}{\to} P^{\cdot} \tag{1}$$

and

$$M \overset{h\nu}{\to} M^{\cdot} \tag{2}$$

Initiation (grafting):

$$P^{\cdot} + M \to PM^{\cdot} \tag{3}$$

and

$$P + M^{\cdot} \to PM^{\cdot} \tag{4}$$

Propagation:

$$PM_n^{\cdot} + M \to PM_{(n+1)}^{\cdot} \tag{5}$$

Termination:

$$PM_n^{\cdot} + M^{\cdot} \to PM_{(n+1)} \tag{6}$$

$$PM_n^{\cdot} + PM_n^{\cdot} \to PM_n M_n P \tag{7}$$

$$PM_n^{\cdot} + PM_m^{\cdot} \to PM_n M_m P \tag{8}$$

$$M_n^{\cdot} + M^{\cdot} \to M_{(n+1)} \tag{9}$$
Certain features of this scheme apply to grafting to cellulose. Steps (1), (3), (5), (7) and (8) are important reactions during pre-irradiation induced polymerization whereas all steps are possible using the simultaneous method. Where the G (radical) value of the monomer is higher than that of the substrate, reaction (2) produces problems through homopolymerization. The converse favours grafting and will be accompanied by correspondingly less homopolymer formation. In the propagation stages, diffusion plays a fundamental part, especially in bulk polymerizations

or polymerizations taken to high conversion. Not allowed for, but equally important, is the part played by the solvent in initiation and termination through transfer. At high extents of grafting, termination reactions become more difficult generally. However, reactions (7) and (8) are likely to be more seriously affected because of restrictions within the matrix.

Before we can proceed further in a kinetic analysis certain assumptions relating to the grafting medium are required. These have been outlined by Guthrie *et al.*[47,48]. Of importance are the nature of the grafting sites in terms of the substrate, the monomer and any swelling agent. One must also consider the effects of radiation on each of the species present in the system. Information required includes the concentration of each of the reactants in terms of the other reagents per unit volume of grafting medium. Thus it is more realistic to express rates of grafting as the number of moles of monomer grafted to the cellulose per unit volume of swollen substrate rather than as amount of add-on per unit mass of original substrate per unit time.

For the grafting process, the following rate equations apply.

Initiation (primary copolymer radicals):

$$R_i = k_i [P^{\cdot}] [M] \tag{10}$$

Propagation:

$$R_p = k_p [PM_n^{\cdot}] [M] \tag{11}$$

Termination:

$$R_t = 2k_t [PM_n^{\cdot}]^2 \tag{12}$$

where $P^{\cdot}$ represents cellulose radicals, $M^{\cdot}$ the monomer and $PM_n^{\cdot}$ the growing polymer radicals respectively. k_p and k_t are the rate constants for propagation and bimolecular termination. Equation (11) gives the rate of polymerization. From this we obtain an equation to represent the rate of change of the graft copolymer radical concentration, $[PM_n^{\cdot}]$ thus:

$$d[PM_n^{\cdot}]/dt = k_i [P^{\cdot}] [M] - 2k_t [PM_n^{\cdot}]^2 \tag{13}$$

At the steady state the rate of change of $[PM_n^{\cdot}]$ is small compared to its rate of formation and disappearance so we may state that:

$$[PM_n^{\cdot}] = (R_i/2k_t)^{1/2} \tag{14}$$

Combination of equations (11) and (14) yields:

$$R_p = k_p (R_i/2k_t)^{1/2} [M]$$

or alternatively:

$$k_p^2/k_t = 2R_p^2/[M]^2 R_i \tag{15}$$

We must now consider the rate of initiation in the grafting process, R_i. Odian[68] has shown that in grafting styrene to polyethylene this rate of initiation is adequately expressed as:

$$R_i = GI\rho/100N_A \tag{16}$$

Equation (16) may be applied to cellulose grafting where

the terms have the following significance: G = the number of radicals formed in the cellulose for each 100 eV of absorbed energy, I = the radiation intensity (eV g^{-1} s^{-1}); ρ = the concentration of accessible cellulose (g/dm^3 of substrate). [M] is the concentration of monomer at the grafting site expressed as mol of monomer/dm^3 of swollen substrate. Factors relating to the determination of ρ and [M] have been outlined by Guthrie *et al.*[48].

Comparison of values of k_p^2/k_t, calculated for grafting and attendant homopolymerization systems, can be used to quantify the autoacceleration known to occur in grafting[68]. This approach has been used in the grafting of styrene to cellulose where the value for grafting was 6.0×10^5 greater than observed in the corresponding homopolymerization[47,48]. Although this is the first quantitative evidence of the Trommsdorff effect in cellulose grafting several qualitative indications have been reported[64,69,70]. Such evidence centres around the fact that in cellulose grafting, grafts have been obtained with very high molecular weights relative to the homopolymer. Data collected indicate that grafts with molecular weights 30 times those of the homopolymer, are not uncommon.

Validity of the procedures adopted to calculate k_p^2/k_t is seen in the close agreement between values obtained by Guthrie[47,48], for radiation-induced styrene homopolymerization (2.0–3.0×10^{-4} l mol^{-1} s^{-1}) and those published by George[72] in bulk styrene homopolymerization (1.0×10^{-4} to 1.8×10^{-4} l mol^{-1} s^{-1}).

Differences in k_p^2/k_t for grafting relative to homopolymerization are usually accounted for by viscosity or Trommsdorff effects. However, when solvents are used, the possibility of chain transfer to the solvent cannot be ignored. This transfer would be greater in the bulk solution than in the polymer matrix if the concentration of solvent were less in the substrate. Hence termination is easier in the bulk solution, which results in lower k_p^2/k_t values being obtained.

In the styrene–cellulose–dioxane–water system extensive transfer to the solvent was demonstrated in homopolymerization[71]. The constant for chain transfer to the solvent (dioxane/water) was $C_s = 1.24 \times 10^{-4}$. Ham[73] has shown that the value of C_s for the styrene–dioxane system is essentially zero. It would seem, therefore, that chain transfer, resulting in lower values of k_p^2/k_t, arises from the presence of water in the mixed solvent. Any water in the cellulose interior is not so readily available for transfer through being tightly bound to the matrix in preferential adsorption. Hence chain transfer within the growing grafted chains is less likely. However, the preponderance of the Trommsdorff effect arises from physical restrictions within the interior of the graft copolymer.

Unless suitable precautions are taken, simultaneous grafting methods may result in excessive involuntary homopolymerization, a potential nuisance factor to commercialization. This can be avoided by considering only those systems in which G (radical) substrate > G (radical) monomer. Other variables such as solvent effects, affinity of the monomer for the substrate and the presence of inhibitors require some attention. Often the proportion of grafting over homopolymerization is improved using comonomers in the grafting process. Examples include butadiene–styrene, styrene–methacrylic esters, styrene–acrylic acid and acrylonitrile–butadiene.

Most kinetic and mechanistic studies of radiation-induced grafting have been carried out at very high dose rates and total doses. There is a lack of data relating to investigations at low dose rates. Available information[46,47,49,60] contains some interesting observations. These include such features as extremely high average molecular weights in branches and homopolymer at low conversion which decrease with increasing total dose, complex molecular weight distribution patterns as shown by gel permeation chromatography (g.p.c.) and ideality in behaviour with regard to the monomer (to the first power) and the radiation intensity (square root of the dose rate) dependence.

The occurrence of post-irradiation grafting and homopolymerization (by transfer from the substrate), involving trapped radicals within the cellulose interior, has been demonstrated. However, most post-irradiation grafting is minimal compared with pre-irradiation and simultaneous grafting.

Free radical grafting reactions undergo classic inhibition and retardation. Air is seen to retard grafting whilst the addition of low concentrations of an inhibitor, for example p-benzoquinone, prevents polymerization by rapid termination of radicals. The interference by oxygen is not well defined though it involves the formation of peroxy-radicals either in the monomer, the cellulose, solvent or any other additive. Subsequent grafting will be dependent on the decomposition of these peroxy-radicals which is a more complex and usually slower process than primary radical formation. Some reports indicate that oxygen plays little part in the grafting process[58,59], findings which are disputed by others[47]. This contention indicates that further controlled work is needed to clarify the position.

Other factors of importance include adequate temperature control, swelling, and the presence of additives. Studies of grafting to cellulose are not always carried out at carefully controlled temperatures. This is surprising since the temperature can markedly affect the grafting medium via diffusion, increased reactivity and accessibility. Grafting at elevated temperatures favours the more amorphous substrates such as cellophane or rayon whereas lower temperatures are more suitable for cotton. A suitable general temperature range for enhanced grafting is 60–70°C. Recent accounts of the effect of swelling agents on grafting[58,59,74–77] indicate that the greater the substrate swelling the more efficient will be the grafting reaction, provided the swelling agent does not chemically interfere. This point has been investigated by Reine *et al.*[74] using aprotic solvents to study the stability of free radicals in γ-irradiated cellulose. Although the substrate becomes highly swollen in solvents such as dimethylformamide or dimethylsulphoxide, the radical concentration is seriously reduced. This suggests that these solvents are unsuitable for cellulose grafting. At elevated temperatures the extent of termination is even more marked owing to greater accessibility of the solvent.

Various additives have been used in cellulose grafting to ascertain their effect on the system. Much of this work has been completed by Dilli and Garnett[52,62–64]. The scope of their investigations incorporated a range of acetone, aniline, benzaldehyde, hydroquinone, thiourea, thiophene, pyridine, benzene, naphthalene, pyrene, phenanthrene, durene, hexamethylbenzene, stilbene, acridine and the halobenzenes. Inhibition was observed when low concentrations (10^{-2} mol) of non-aromatics were used whereas high concentrations sensitized the reaction. Hydroquinone and thiourea suppressed grafting when present in high concentrations. Anthracene, pyrene and acridine gave reduced yields but other aromatics had only marginal effects. Aro-

matic compounds are known to operate by means of energy transfer and radical scavenging. Inhibition by essentially non-aromatic compounds is thought to arise from competitive radical-additive reactions owing to the high G (radical) values of the additive. With high concentrations of non-aromatic, polar additives the grafting yields increase presumably owing either to the effect of the additive on the swelling of the substrate or to indirect activation of the cellulose.

Although work has been devoted to the kinetics of grafting much remains to be done in other areas. Prime among these is the need for methods of producing low molecular weight grafts randomly distributed throughout the substrate in reasonable concentrations. Commercial exploitation is more likely to concern multitudinous grafts of relatively low molecular weights since these will have a greater effect on the properties of the substrate.

EFFECTS OF HIGH ENERGY RADIATION ON CELLULOSE

It is meaningless to speculate on the viability of radiation grafting to cellulose without first considering the effect of radiation on the cellulose. Irrespective of the technique used in grafting, one consequence of exposure to high energy radiation is damage to the substrate. Opinions vary as to the sensitivity of cellulose to high energy radiation. However, it is known that some forms are more prone to degradation than are others. Here we view the problem through changes in physical properties and subsequently show the value of e.s.r. spectroscopy to studies of radical location, cellulose sensitivity and structural interpretation.

Cellulose degradation

Several factors contribute to the overall deterioration including the presence of moisture, oxygen, additives, sensitizers, protecting groups, the dose rate and the total dose. The threshold level for radiation damage is relatively low. Fortunately it is recognized that dose levels needed to encourage grafting are significantly below those likely to cause extensive damage to the cellulose.

The effects of radiation on cellulose can be seen in many ways. These include e.s.r. spectroscopy, changes in thermal and mechanical properties, molecular weight determinations, chemical methods such as end-group analysis and spectroscopic methods.

Factors of importance to any study of radiation damage to cellulose are the reaction conditions, substrate composition and morphology, previous chemical and physical modifications and the presence of trapped radicals. Although the main consequence of irradiating cellulose is degradation, there is growing evidence that some crosslinking takes place when cellulose is irradiated in aqueous media[80-82]. This suggests that the events secondary to initial irradiation are highly complex. However, there is little doubt that the major consequence is chain scission. The formation of carboxyl groups, increase in solubility in alkaline solution on progressive irradiation and the development of characteristic e.s.r. spectra indicate the nature of the scission process. The occurrence of chain cleavage during grafting reactions would result in the product containing varying amounts of block copolymer. This might create difficulties in interpreting the nature of the graft copolymer. Normally chain scission is less using simultaneous irradiation than occurs with pre-irradiation grafting unless both reactions are carried out in the absence of air, when equal cleavage occurs.

Guthrie *et al.* have investigated the degradation of regenerated cellulose, viscometrically, using Cadoxen as a solvent for cellulose. G (scission) values were 24.6 and 13.5 respectively for samples irradiated in air or vacuum. The corresponding threshold values for radiation damage were 10 and 200 J/kg. These threshold values are below previously accepted degradation levels. Exposure of samples irradiated in vacuum or air to the atmosphere at 65% relative humidity gave greatly enhanced degradation even on removal from the radiation source. Examination of samples 21 days after irradiation produced values of G (scission) of 143.0 and 186.5 for vacuum and air irradiated samples respectively. Similar observations have been made by Leuthy in his derivation of the relationship between the total radiation dose and the intrinsic viscosity of the resulting celluloses[83].

Arthur *et al.*[84] have studied the oxidative reactions of cellulose initiated by free radicals. The formation of free radicals increases the reactivity of cellulose mainly through dehydrogenation and oxidative depolymerization reactions. Panchenkov *et al.*[85], in their work on the mechanical properties of filaments of cellulose and its esters, observed reductions in breaking strength and elongation at rupture on irradiation. Decomposition was rapid at high dose rates in either air or vacuum.

In a comprehensive series of papers[86-89] Imamura and Ueno have studied the effects of radiation on a series of dissolving cellulose pulps. The nature of this high energy radiation, whether γ- or X-ray, produced the same chemical and physical effects. The rate of chain cleavage was directly proportional to the dose. Nitration of the irradiated celluloses and their subsequent characterization by g.p.c. gave a decrease in molecular weight and an increase in molecular weight distribution with increase in the total dose. This indicates that the radiation damage is non-random but occurs predominantly in the lower molecular weight regions. Such degradation is enhanced by elevation of the temperature.

Potential industrial processes are suggested from this work especially in aspects of cellulose regeneration. Further investigation has shown that xanthation of these irradiated celluloses, producing useful viscoses, is possible without preliminary ageing. This process is thought to have great practicability provided the total dose is limited to 2 Mrad.

The effect of γ-radiation on the low temperature, dilute acid hydrolysis of cellulose has been investigated by Kunz *et al.*[90] who obtained greater yields of glucose (27%) with irradiated samples than the un-irradiated ones. Such work suggests that low molecular weight products of crude cellulosic materials are obtainable in reasonable yields through preliminary extensive irradiation.

Electron spin resonance spectroscopy

Irradiated celluloses have attracted considerable attention for study by e.s.r. spectroscopy. Many of the parameters thought to influence e.s.r. spectra have been investigated. However, the spectra and their interpretations vary considerably depending on the nature of the substrate, the conditions of irradiation and spectra measurement, decay phenomena, the effects of temperature and so on. Ahmed and Rapson[91] interpreted such spectra in terms of the different crystalline structures used. Khamidov *et al.*[92] obtained G(radical) values for cellulose and some of its derivatives at various temperatures and also studied the kinetics of radical formation. The data indicate that the more crystal-

line celluloses produce a reduction in G(radical) with increases in temperature which is not observed with the more amorphous samples. A possible cause of this difference is the reduction in mobility of excited species, owing to the greater crystallinity giving less substrate interaction.

One feature of this work is that, in the absence of air, no evidence of degradation was observed as a result of irradiation. This finding is substantiated by Guthrie et al.[48], who in studies with regenerated cellulose, observed a doublet in the e.s.r. spectra of samples irradiated under vacuum which is indicative of radicals at C_1 of the anhydroglucose unit. Air irradiated samples produced a quartet, one cause of which could be main chain cleavage. Exposure of samples, irradiated under vacuum, to the atmosphere and monitoring by e.s.r. spectroscopy showed a gradual change from a doublet to a quartet which indicates the role of oxygen and moisture in the degradation process.

Arthur et al.[93] have obtained the e.s.r. spectra of various crystalline modifications of celluloses irradiated in air. Celluloses I, II, III, and IV, partly decrystallized cotton cellulose, ball-milled cotton cellulose, Ramie cellulose and hydrocelluloses of cellulose III and IV were analysed. Radical formation was thought to involve both hydrogenation and chain cleavage. Accessible free radicals were rapidly terminated by water whilst radicals in the inaccessible regions remained unaltered even after long exposure to chemical agents. The e.s.r. spectra were explained in terms of inter- and intra-molecular bonding forces, particularly hydrogen bonding.

The existence of long-lived radicals is supported by Dilli et al.[94] who observed that significant concentrations of radicals remained in the cellulose four years after irradiation and storage at ambient temperature. Elevation of the temperature, in the range $25-70°C$, caused a rapid reduction in the radical concentration to take place. Beyond $70°C$, little effect on the radical decay pattern was noticed. Radical decay was more rapid in vacuum than in air at these elevated temperatures, which again demonstrates the interference by oxygen in decay processes.

Baugh et al.[38,95] chose to interpret the e.s.r. spectra of various types of irradiated cellulose in terms of the possible location of the radicals within the anhydroglucose unit. Radicals in cellulose I (containing regain moisture) dehydrogenation at the C_5 atom; radicals in cellulose II, dehydrogenation at the C_5 atom and also dehydrogenation of the OH group or dehydroxylation at C_6. Since these studies were carried out in air, interference from degradation effects cannot be ruled out. A commonly accepted value for G (radical) of cellulose irradiated in air is 2.88[79] which comprises both the inaccessible and accessible radicals. A value of G (accessible radicals only) of 1.6 has been suggested[51], the residue being inaccessible to chemical attack. Thermal decay of radicals has been shown to be a second order process and the presence of several types of radical of different lifetimes is indicated.

INTRAMOLECULAR ENERGY TRANSFER IN CELLULOSES

Energy transfer processes in the solid state are generally considered to be dependent on the mechanism of energy loss by the incident radiation to the molecules, the initial random deposition and dissipation of the energy within the molecule and the rapid localization of the energy resulting in chemical and physical changes. The time required for this localization process is reported to be not less than 10^{-13} s.

Grafting reactions and chemical substitution have provided considerable information concerning the processes of intramolecular energy transfer of high energy in carbohydrates[97,98]. Such information is important since this concept offers a means of protecting cellulose against otherwise inevitable damage when irradiated. As such, radiation protection may be an important factor in any commercial exploitation. Considerable work has been carried out in this area in recent years.

Arthur et al.[99-102] have investigated the radiation protection given to cellulose through substitution by a wide variety of aromatic groups. These include phenylcarbamoyl, benzoyl, naphthoyl, cinnamoyl, benzyl, benzydryl and trityl groups. All gave protection apart from the benzyl group. The level of substitution required to impart protection was found to depend on the particular group, the nature of its linkage to the cellulose chain and the stability of that linkage. In all cases, in which protection was observed, the substitution affected the localization of energy, reduced both the extent of degradation and also the radical concentration of the substrate. If localization of energy occurs and cleaves the aromatic group from the cellulose chain then the radiation protection of the cellulose chain by the aromatic group is ineffective. Modification of the aromatic group to bring about a reduction in the number of available π electrons results in a corresponding decrease in the level of protection.

Similar studies by Chidambareswaran et al.[103], Guthrie et al.[51] and Singh et al.[104] have confirmed the protective nature of aromatic groups. Chidambareswaran compared benzoylation with allylation and found that, while allylation influenced both the nature and yield of free radicals as seen through e.s.r., benzoylation affected only the yield.

Substitution of cellulose using phenyl isocyanate to give products of low degrees of substitution (DS) have been achieved by Guthrie et al. The carbanilated groups are very effective in protecting cellulose from radiation damage as seen through e.s.r. spectroscopy[51]. Irradiation of the carbanilated celluloses under vacuum produces the cyclohexadienyl radical whose spectrum is shown in *Figure 1*,
Figure 1 E.s.r. spectrum of a typical cellulose carbanilate sample (DS = 2.0), irradiated under vacuum. *DS* determined by analysis for nitrogen

whilst that of the unsubstituted irradiated cellulose is given in *Figure 2*. No cyclohexadienyl radicals were observed in air irradiated samples owing to quenching with atmospheric oxygen and moisture. The lifetime of the cyclohexadienyl radical was approximately five hours after which time spectra similar to those of cellulose irradiated in air were obtained, although of much reduced intensity. Typical G(radical) values were: cellulose (DS = 0.0), 2.86; carbanilated cellulose (DS = 0.3), 2.20; carbanilated cellulose (DS = 1.00), 1.33; carbanilated cellulose (DS = 2.00), 1.19.

In spectra of carbanilated celluloses, irradiated under vacuum, three radical species are indicated, those in inaccessible regions, in accessible regions and the cyclohexadienyl radicals. Quenching of radicals in the inaccessible areas can only be explained in terms of energy transfer to the aromatic group from the cellulose backbone, since the substitution takes place only in the accessible regions. Here we have definite evidence of the contribution made by low degrees of substitution of suitable groups, to the protection of the substrate. Damage to the substrate during further modification can be minimized without altering the nature of the cellulose too drastically. Thus grafting to reasonable extents is easy. Justification for this observation is shown in *Figure 3* which relates changes observed in grafting behaviour to the level of substitution of the cellulose. The decrease in grafting is only marginal when compared with the protection offered the substrate.

Kinetic studies on substituted celluloses indicate that values of k_p^2/k_t decrease with increasing substitution. This suggests that viscosity or Trommsdorff effects are minimized, showing that lower molecular weight grafts are obtained. Such a feature is an asset in radiation-induced
Figure 3 Extent of grafting *versus* irradiation time for various degrees of substitution (*DS*). Styrene monomer used. $\bigcirc$, *DS* = 0; $\triangle$, *DS* = 0.02; $\square$, *DS* = 0.27; $\bullet$, *DS* = 0.50. Temperature = 30°C. Dose rate = 0.37 x 10^{-2} W/kg. Monomer concentration (S) = 20% (v/v) in dioxane (78% v/v) and water (2% v/v)

modifications requiring many low molecular weight grafts rather than a few of very high molecular weight. Owing to the enhanced swelling imparted to the substrate by substitution, mobility of the grafted chains is facilitated, resulting in easier termination.

Singh *et al.*[104] have studied the protection by the furoate group as seen by substitution of cellulose with 2-furoyl, 5-methyl-2-furoyl, or 5-bromo-2-furoyl groups on fibrous cotton cellulose. Radiation sensitivity was reduced as was the energy localized on carbon atoms C_1 and C_4 of the anhydroglucose unit. This work has been patented[105] though the radiation protective effects are similar to those imparted by benzenoid groups.

Graft polymerization reactions may be used to impart stability to radiation damage in certain instances. In an e.s.r. study of cellulose acetate—styrene grafting, Campbell *et al.*[37] observed a slow decay in the trapped radical concentration after addition of the monomer. Such a reduction in radical concentration can only arise through energy transfer to the grafted areas of the substrate. Since grafting only occurs in the accessible regions, energy transfer from the inaccessible to accessible areas is indicated.

More tangible evidence of the effectiveness of aromatic groups in radiation protection of cellulose is seen in the retention of mechanical properties and the corresponding reduction in chain cleavage. Radiation doses required to start deterioration of celluloses substituted to a low degree are usually at least ten times those required for sterilization and thirty times those needed for grafting reactions.

Figure 2 E.s.r. spectrum of a regenerated cellulose sample, irradiated under vacuum

Hence it appears that the presence of bonded aromatic groups in the cellulose substrate leads to selective absorption of the incident radiation by these groups and dissipation of the energy as heat. This minimizes the localization of the energy which would otherwise cause depolymerization and consequent loss of strength. Where non-grafted protective groups are used, care is needed to ensure that this protection does not result in a reduction in grafting efficiency.

COPOLYMER CHARACTERIZATION

Since radiation-induced graft copolymerization is a random process with regard to the mode of initiation, the location of the grafts and their molecular weights, it is reasonable to assume that cellulose graft copolymers prepared in this way will have appreciable heterogeneity of composition and molecular weight. This has led to interest in the solution properties and morphological character of cellulose copolymers and their components.

Solution properties

Prior to any investigation of the copolymer, the backbone or the grafted branches it is essential that each be obtained in a pure state. Hence, techniques have been developed for separation of the branches from the backbone and also for removal of the ungrafted cellulose from the copolymer. Several methods are available for isolation of the grafts. These usually involve acid hydrolysis of the backbone to water-soluble residues. Huang and Chandramouli[70] adopted a simultaneous acetolysis--hydrolysis procedure which was reported to give useful results. Viscometric analysis of polystyrene branches isolated in this way have been shown to exhibit polyelectrolyte behaviour[49]. Sulphur analyses indicated the presence of one sulphonic acid grouping for every thirty polystyrene repeat units. Thus the hydrolysis procedure, which involves the use of 72% sulphuric acid, results in sulphonation of the aromatic nucleus. This problem does not arise when non-aromatic vinyl monomers are used. The alternative method of hydrolysis devised by Morris et al.[39] is satisfactory. This is based on the acid hydrolysis (6 M HCl) of the copolymer, previously swollen in 75% aqueous zinc chloride. The products do not exhibit polyelectrolyte behaviour.

Having isolated the grafts one can evaluate their characteristics. Isolation of the trunk polymer free from grafts is not possible for cellulose substrates, though the position regarding cellulose derivatives is not clear. With unmodified substrates the most satisfactory alternative involves isolation of the ungrafted cellulose and its elucidation. In order to analyse the copolymer, removal of the ungrafted cellulose is essential. This is achieved to some degree by repeated extraction with known solvents for cellulose. Examples include cuprammonium hydroxide, Cadoxen, Cuene etc. The extracted fractions may then be analysed as required. Copolymers of unsubstituted cellulose and vinyl monomers have unusual solubility characteristics. Solvents are unavailable. For this reason it is essential that the cellulose component of the copolymer is converted to some derivative which is soluble in as wide a variety of solvents as possible. Examples include the formation of cellulose acetate or the carbanilate. Unfortunately the substitution of cellulose is accompanied by degradation. Substitution by carbanilate groups is known to give minimum degradation and has been the subject of several investigations[114-117].

It has been conclusively shown by light scattering, osmometry and viscometry that cellulose graft copolymers, prepared by radiation-induced methods, exhibit extreme heterogeneity in composition and molecular weight[71]. Observations from light scattering phenomena were obtained using solutions of the copolymer, the extracted substrate and the branches in a comprehensive series of single solvents and selected mixed solvents. Although the copolymers studied are, without doubt heterogeneous, it is felt that composition deviations arise from the presence within the copolymers of ungrafted cellulose, which is not removed by conventional extraction.

Certain factors ought to be considered regarding the true extent of grafting relative to the apparent value. Much of the substrate remains free of grafting. *Figure 4* shows the apparent and real grafting figures for cellulose–styrene copolymers prepared at low dose rates and total doses. The true extent of grafting is approximately ten times the apparent value at all times. In comparison, *Figure 5* gives the variation in the percentage of extractable cellulose (using Cadoxen) with increase in the percentage of grafting. This latter figure indicates that beyond a certain level of grafting, ungrafted cellulose becomes occluded in the copolymer which cannot be removed by repeated extraction. These observations substantiate the composition heterogeneity found in light scattering measurements. The experimental techniques and definition of the terms real and apparent grafting have been fully dealt with previously[48].

Wellons et al.[118,119] have investigated some of the solution properties of cellulose acetate–styrene graft copolymers. Various types of graft copolymer were analysed. The solubility characteristics of the copolymers were considerably different from those of the copolymer components. These
Figure 4 Variation of the extent of grafting with increasing irradiation time; A (O) = apparent; B (□) = real. Styrene monomer used. Dose rate = 0.37 x 10⁻² W/kg. Monomer concentration = 20% v/v in dioxane (78% v/v) and water (2% v/v)
Figure 5 Variation in the extent of cellulose extraction (O) with increasing apparent degree of grafting. Styrene monomer used. Dose rate = 0.37×10^{-2} W/kg. Ungrafted cellulose isolated using Cadoxen[48,71]

differences include their permeability, diffusion and gas absorption properties. The diffusion and solubility behaviour was closer to that of cellulose acetate, whilst the other physical properties generally lay between those of the two homopolymers.

Regardless of limitations of the available extraction procedures, there is little doubt that with the majority of vinyl monomers, the grafted side chains are of higher molecular weight than the corresponding homopolymer chains. This is further evidence of the Trommsdorff effect. Certain abnormalities in molecular weight distributions have been observed. Conventional, non-radiation induced methods produce branches with broad, but otherwise standard mono-nodal molecular weight distributions. Pre-irradiation methods have been known to produce binodal molecular weight distributions. Such systems continue to attract interest[71]. Even stranger are observations made during simultaneous radiation-induced grafting at very low dose rates, total doses and monomer concentrations. These conditions give rise to trinodal distributions of the molecular weights of the attendant homopolymer. With increasing total dose the distribution became binodal and ultimately mononodal. Such observations are confirmation of the complexity of the grafting process and spotlight the difficulties of interpretation.

In an unusual approach to isolating the components of cellulose–styrene copolymers Ikada et al.[120] obtained samples of grafted fibres which were then acetylated. The substituted cellulose fraction was removed by solution in methylene chloride. Munari et al.[121] isolated grafts from cellulose diacetate and the measured molecular weights were correlated with the kinetics of the grafting process. It was observed that the molecular weights of the grafted chains were controlled by the physical limitations imposed by the matrix. Copolymers of cellulose with methyl acrylate, methyl methacrylate, styrene and vinyl toluene were prepared by Azizov and Afaki[122]. These were acetylated and comparisons made using the ungrafted cellulose as a standard. Acetylation was more rapid with all the

grafted samples than with cellulose alone. Deformation of the copolymers was measured as a function of temperature. The increased rate of acetylation arises from the enhanced accessibility of the substrate, made possible through grafting and the breakdown of the closely knit structure.

Attempts have been made to study the thermal behaviour of cellulose graft copolymers[123] and of ^{60}Co-irradiated cellulose[124]. Thermal analysis techniques indicate that extensive degradation occurs at doses beyond 19 Mrad and that a sensitivity threshold exists at 1 Mrad. Such observations are in close agreement with data presented in earlier sections. Byrne and Arthur[124] have shown that cotton cellulose is marginally more radiation resistant than the more accessible forms of cellulose such as rayon or cellophane. This suggests that post-irradiation damage involves secondary chemical attack by air and moisture.

Morphological properties

Radiation-induced copolymerization of vinyl monomers and cellulose produces copolymers with heterogeneity in composition and molecular weights. Morphological studies should throw some light on the nature of this heterogeneity. Investigations of pure graft copolymers are not usually possible because of difficulties associated with the complete removal of the ungrafted cellulose. Interest has been restricted mainly to the morphology of the grafted fibre, textile, paper, film or powder in its entirety. This approach is justified by the fact that most end uses require only a low degree of grafting to achieve the desired physical properties.

Electron microscopy is particularly useful for locating polymeric grafts within the substrate and many of the factors known to influence the macrostructure have been elucidated. These include the grafting technique (whether simultaneous or pre-irradiation), prior chemical modification of the cellulose, solvent effects, the total dose and dose rate and degradation processes.

The initial irradiation is known to affect markedly the morphology of cellulose graft copolymers irrespective of the original structural form of the cellulose. Such changes correspond to main chain cleavage and overall fragmentation. Arthur et al.[42,102] have correlated these structural changes with modifications in other physical properties such as tensile and elongation characteristics, swelling behaviour and grafting patterns. This group[125] have shown that pre-irradiation grafting of cellulose with acrylonitrile dissolved in zinc chloride shows little change in the natural shape of cotton whereas simultaneous grafting from a solution of the monomer in dimethylformamide causes collapse of the natural fibre shape[111]. Mutual irradiation of cellulose, in the presence of styrene or alkyl methacrylates in methanol solution, produces fibrous structures which are rounded, but not collapsed, existing in a layered network. Here, the extent of layering appears to be dependent on the molecular weight of the original monomer[125]. Copolymerization of cellulose with vinyl acetate from a solution of the monomer in aqueous zinc chloride results in a rounded copolymer structure, though in this instance the poly(vinyl acetate) is evenly distributed throughout the matrix.

Goynes and Harris[40] have used light and electron microscopy to investigate the structure of cotton fibres grafted with butyl methacrylate and acrylonitrile. Uniformity of reaction was indicated by the degree of uptake of dye from solutions of Celliton Fast Red (1% in ethanol) and a Dupont Identification Dye (1% in aqueous solution). Grafting occurred throughout the fibre and increased in uniformity with increase in grafting. Views of highly grafted fibres

showed that coatings of the graft had gradually built up on the surface of the fibre. Similar instrumental techniques were used by Razikov *et al.*[127] on samples of cellulose acetate/poly(methyl methacrylate) copolymers. The overall results suggest globular structures with layering, producing increased flexural strength and lower glass transition temperatures. Using a modified staining technique, dependent on the particular reactivity of osmium tetroxide, Broughton *et al.*[128], studied the location and distribution of *N*-methylolacrylamide brought about during radiation-induced curing processes. This method is useful for locating unsaturated monomers within cellulosic substrates by photomicrography.

Matsuzaki *et al.*[32] applied n.m.r. spectroscopy to their appraisal of the stereoregularity of poly(methacrylic acid) and poly(methyl methacrylate) grafted viscose rayon and cotton fibres. Copolymers prepared by radiation-induced methods were observed to be markedly different from those prepared in chemically initiated processes. Very similar observations were made by Ogiwara and Hitoshi[109] in their n.m.r. study of the water absorption phenomena of poly(methyl methacrylate)/cellulose graft copolymers.

Much of the knowledge of the morphology of cellulose and its copolymers has come from Arthur and coworkers. Details of earlier surveys are to be found in the many publications of this group. Through data of this type, composite pictures of the physical condition of graft copolymers can be built up, especially when correlated with other factors relevant to improving the characteristics of cellulose or its more common derivatives.

APPLICATIONS OF RADIATION-INDUCED CELLULOSE GRAFTING

Considering the attention devoted to applied aspects of radiation-induced grafting to cellulose and the negligible industrialization of such effort, a review of the progress made along these lines is opportune. Much is known of the synthesis, structure, chemical and physical properties, technology, design and fabrication of cellulose copolymers, but few of the original hopes have been realized. Recent international events, the shortage of certain basic raw materials, and the expansion of the textile industries should result in renewed interest in graft copolymerization.

Logic suggests that such interest will be channelled into certain areas. In this section we are concerned with those systems which have particular industrial potential. Technological aspects of grafting were originally discussed by Metz[129], though more recent additions have been made along similar lines[67,130]. Treatments related to wood cellulose are reserved for the next section.

Modification of cellulose, aimed at improving its rot resistance, abrasion resistance, solvent resistance and mechanical stability, has been achieved by grafting with acrylonitrile[131]. Reductions in moisture uptake by grafting with styrene, methylacrylate and other hydrophobic monomers are particularly satisfactory since only low levels of grafting are required to produce the desired change in physical properties.

Dilli *et al.*[134] have investigated the ion exchange properties of radiation copolymerized celluloses. Cellulose–polystyrene systems have been shown to be effective in column and paper chromatography. Examples of their applicability include the separation of dyestuffs, metal cations such as Zn^{2+}, Ni^{2+} and Cd^{2+}, and fatty acids including stearic, myristic and lauric acids. Poly(methyl methacrylate)/cellulose systems separate mixtures of oil-soluble dyes more

readily than does untreated cellulose. Also of interest are the ion exchange properties of grafted celluloses containing $-NH_2$, $-SO_3H$ functional groups or those involving heterocyclic nitrogen. Among the many advantages claimed for these membranes over other adsorbing media are ease of preparation, greater efficiency and resistance to chemical attack, applicability to reverse phase chromatography, greater radiation stability and ease of separation of complex mixtures.

Mares and Arthur[66,135], have considered the textile applications of graft copolymers and terpolymers. A range of monomers was screened and the products were assessed in terms of improvements to the physical properties and serviceability of the substrate. The copolymers retain some of the properties of cellulose and adopt others of the comonomer. Selective application of monomers can produce products which may be thermoplastic, elastomeric, hydrophobic, soil releasing, rot resistant, mechanically and visually superior, radiation resistant, more easily dyed and washed or with better thermal characteristics. Among the monomers grafted to cellulose to achieve specific modifications are acrylic monomers[136], *N*-methacryloylpiperidine[137], acrolein[138] and *N*-methylolacrylamide[139] to induce crosslinking of cellulose; allyl methacrylate *p*-divinylbenzene and ethyleneglycol monomethacrylate[140] to improve the fungus resistance of fabrics; and various monomers designed to improve crease resistance and general usability[141–143]. In most cases the improvement sought in the particular physical property has been achieved.

The use of radiation grafting to provide membranes for studies and applications of osmosis phenomena, particularly reverse osmosis, is gaining in popularity. Hopfenberg *et al.*[144,145] have applied cellulose acetate–styrene graft copolymers to a wide variety of conditions and environments. Similar fundamental studies have been carried out by Dilli and Garnett[134] and Bentvelzen *et al.*[146]. Although still in the experimental stages, this approach seems to hold great prospects for the future.

Ahmed *et al.*[147] have reviewed the potential of radiation grafting with particular reference to its suitability in the developing countries. Substrates considered include wood cellulose, jute, agricultural and stone wastes. The main advantage of the technique lies in the use of materials which are readily available.

Stannett and Stahel[148] have considered the full scale and pilot size plant machinery and isotope sources which would be required for the realistic commercialization of radiation grafting. Among the processes considered are modifications to textiles, curing of coatings and the preparation of wood–polymer composites. Machida[149] has published the results of work concerning the flocculation properties of polyacrylamide–cellulose graft copolymers. A correlation is shown to exist between the length of the grafted chains and the flocculation stability. This work has implications which should be of interest to paint manufacturers in view of the stability of the systems obtained.

The application of radiation-induced graft polymerization to cellulosic textiles has been recently reviewed by Okada[150]. Aspects covered include hydrophilization of the fibres, improvements in the thermal stability, permanent press characteristics and the provision of flame retardant finishes.

Although this survey of recent developments has been brief, the industrial potential of many of the processes outlined is clearly indicated. Further information, relating to earlier predictions of the potential of radiation grafting,

can be obtained from the reviews by Das Gupta[67,130] and Metz[129].

RADIATION-INDUCED GRAFTING TO WOOD

Such has been the recent interest in wood–plastic composites and timber preservation that these materials deserve particular attention. One process, using radiation grafting, has been described by Mott and Stannett[151]. This consists essentially of degassing under vacuum to remove air, nitrogen purging, degassing, exposure to the monomer, impregnation of the timber by the monomer under pressure and subsequent irradiation. Low dose rates and total doses are favoured and a variety of monomers has been investigated. The results of grafting, depending on the monomer applied can be related to those observed during textile modifications. Thus improvements are observed in the moisture uptake, rot resistance, tensile strength, compressive strength, dimensional stability, elastic modulus and overall wood hardness[152–154].

Attempts to fabricate 'wood–plastics' have been successful in certain instances with a wide range of monomers[155]. Much of the research along these lines arises from utilization of natural resources as fully as possible. The outcome is of great interest to the developing nations. In a thorough treatment of the radiation-induced grafting of styrene- and methyl methacrylate-impregnated birch and aspen Shirayeva et al.[156] noted improved compression strength, static bonding strength, shear strength and static hardness. Grafting rates were accelerated by the presence of tributylphosphate resulting in lesser doses being required. Alkenyl phosphates were observed to impart both fire and bio-organic decay resistance.

Another treatment involving impregnation followed by irradiation was used by Basson[157] in a study of grafting to pine and eucalyptus timbers. The degree of monomer uptake by the eucalyptus was less than that of pine. The investigation included microscopic examination, dose rate effects and mechanical and weathering tests. Both types of treated timber were superior to their untreated counterparts in many respects.

Stannett and his group[158–161] have shown a general interest in grafting to wood and wood pulps. Here, however, the aim has been towards a greater understanding of the nature of the grafting process rather than in improving the physical properties of the timber alone. This theme is adopted by Sakata[162] et al. using styrene in grafting to woody fibres. In this instance, the study involved the distribution of grafted polystyrene branches between the lignin and carbohydrate fractions of the parent substrate (1.2 : 4 for lignin : carbohydrate respectively). The branches were removed from lignin sections by treatment with acetic acid and from cellulose by hydrolysis with 72% sulphuric acid (see observations made earlier regarding the use of concentrated sulphuric acid in the acid hydrolysis of cellulose–polystyrene graft copolymers).

Birchwood has attracted attention recently because of the considerable improvements which can be achieved in physical properties by low extents of grafting. Irradiation of unitary and binary monomer impregnated samples has been successfully carried out. Steiners et al.[163] have noted the absence of stress and deformation when birchwood is treated with styrene in carbon tetrachloride and then irradiated. Copolymerized samples have greater dynamic compliance and mechanical properties. Glukhov et al.[164] used styrene–acrylonitrile mixtures and observed that graft-

ing was much easier than polymerization with either monomer alone. Similar observations were made by Oraby et al.[165] in their study of the grafting of these same monomers to wood pulp cellulose.

Modification of timber or wood pulps by radiation-induced grafting offers a simple method of protection against a wide variety of decay-initiating systems. Improvements to physical properties, structural properties and appearance are also achieved. Once grafted, the timber or wood pulp composites are amenable to a much wider range of use than exists for ungrafted materials.

RECENT PATENT LITERATURE

Perhaps the best guide to the progress and success of a novel technique is the patent literature, for it is here that protection of innovations is sought before their commercial baptism. Whether or not radiation-induced grafting techniques achieve success will depend on their viability when compared with existing methods of cellulose modification. On a numerical basis, comparatively few patents applications have been taken out in recent years, especially when the amount of research effort given to the topic is considered.

As in all aspects of grafting studies. Arthur and his coworkers are frequently found in the patent literature. Typical examples include the selective grafting of vinyl monomers to cellulosic materials by radiation-induced grafting with a view to improving the crease resistance. A recommendation that the total dose be restricted to 1 Mrad is made[166]. A second patent[167] involves the copolymerization of binary monomer mixtures with cellulose in order to produce industrial textiles and cellulosic articles having a rigid construction. In outline, the cellulose is dried to a 2% water content, irradiated and then treated with one of several binary monomer mixtures before final washing and drying.

A patent application granted to BASF[168] concerns grafting 1,4-butyleneglycol methacrylate and acrylamide to cellulose. This produces materials whose properties render them useful as leather substitutes. DasGupta and Slobodian were granted patent rights to the grafting of methyl methacrylate or styrene impregnated cotton or paper in roll form in which diffusion of the monomer into the interior of the substrate is assisted by acetone (for methyl methacrylate) or methanol (for styrene).

The flame-proofing of textiles is one aspect of grafting which shows real promise. Miles and Delasanta[170] have claimed a patent governing the grafting of N-methylolacrylamide, acrylamide, acrylonitrile and acrylic acid in binary mixtures with either triallyl phosphate or dimethyl hydrogen phosphite. The addition of the vinyl monomer enhances the flame-proofing action of the phosphate and phosphite.

Improvements to the dyeing properties of rayon (to cationic and acid dyes) as a result of prior modification of the rayon through grafting, is claimed by Igarashi et al.[171] Rayon, among other fibres, was grafted with methyl methacrylate before dyeing. Better light fastness properties were observed than with samples treated with cationic dyes alone. Garnett and Martin[172] claimed general patent rights for the process of the simultaneous, radiation-induced liquid phase grafting of 2-vinylpyridine to cellulose in solvent systems containing alkylolamines. Such a process would broaden the range of dyeability of the substrate by use of acid dyes.

In a Russian patent application Makhkamov et al.[173] describe the bacteriostatic properties of cellulose–acrylonitrile copolymers on treatment with copper acetate and

sodium sulphide. Since similar properties can be acquired by grafting with various vinyl monomers this modification appears to have little to offer over existing selected copolymers. Recent patent applications are more sophisticated than earlier disclosures. Dotson *et al.*[174] hold a patent concerned with the solvent casting of cellulosic films using previously radiation grafted products. Increased processing rates are reported. This is especially so when cellulose ester dopes used in solvent-cast processes in the production of photographic film base, are modified by addition of a vinyl monomer and the whole irradiated. This polymerizes the compatible monomer portion before the cast layer is stripped from the casting web. Another patent relating to cellulose graft copolymer solutions was awarded to Nakao *et al.*[175]. In this application are described processes for the efficient dissolution of a series of cellulose—vinyl monomer graft copolymers.

Dilli and Garnett[176,177] have taken out patents covering the production of cellulose graft copolymers, containing styrene, using low radiation doses, methanol as a swelling agent and a mineral acid (1.1 M sulphuric acid). High levels of grafting are claimed.

CONCLUSION

Several factors need to be taken into account in adopting radiation-induced grafting procedures. Prime among these will be the usability of existing equipment as an alternative to wholesale re-equipping with plant. Adaptation should be possible with little inconvenience and cost when compared with the advantages offered. Major decisions will concern the type of radiation source to be employed, the radiation polymerization technique and personnel protection. High grafting yields, though not essential, offer the greatest scope for versatility. Efforts made to achieve extensive grafting should be carefully considered. Simultaneous irradiation of the substrate in the monomer solution produces greater grafting yields at lower doses than would the pre-irradiation method. However, the pre-irradiation technique may be preferred on expansion to full scale production because of simplicity of plant design, continuity of operation, cost effectiveness, ease of personnel protection and the absence of homopolymeric species which would cause serious problems associated with their removal. Economic viability depends on the total cost of operation. Savings made through the absence of homopolymerization will be considerable. Processes which can operate under aqueous conditions have particular advantages. Storage of batches in radioactive isotope source rooms (^{60}Co or ^{137}Cs) may appear simpler though passage of the conventional substrate under an electron beam lends itself to greater flexibility. The latter technique has disadvantages in terms of stray radiation, maintenance and the initial cost.

The reluctance to change from conventional technology, apparent in the textile and paper industries, must be overcome before the techniques outlined will be accepted. Application to timber preservation seems more hopeful. The greatest potential, in the short term lies in the production of materials for specialist uses. Examples include semipermeable membranes, sterilization without degradation, food preservation and fire-retardant textiles.

Changing world situations could see renewed interest from areas otherwise reluctant to change.

APPENDIX

A key to the abbreviations used in *Tables 1* and *2* is outlined below.

M	monomer used in grafting
MP	grafting conditions of monomer (solution or vapour)
SA	swelling agent used to enhance grafting
T	temperature of the grafting process
S	styrene
EA	ethyl acrylate
AN	acrylonitrile
MA	methyl acrylate
MVK	methyl vinyl ketone
A	acrolein
MMA	methyl methacrylate
VA	vinyl acetate
2- and 4-VP	2- and 4-vinylpyridine
α-Methyl-S	α-methylstyrene
BA	butyl acrylate
BMA	butyl methacrylate
MAA	methacrylic acid
VFF	vinylidine fluoride
VF	vinyl fluoride
5-methyl-2-VP	5-methyl-2-vinylpyridine
HEMA	2-hydroxyethyl methacrylate
HPMA	hydroxypropyl methacrylate
MAN	methacrylonitrile
NVC	N-vinylcarbazole
6-FIPA	hexafluoroisopropyl acrylate
DMSO	dimethylsulphoxide
MEK	methyl ethyl ketone
DMF	dimethylformamide
1,2-DCE	1,2-dichloroethylene
AQ	anthraquinone

Note to the Editor

Synthesis and characterization of a *cis*-1,4-polyisoprene-*b*-poly(methyl methacrylate) copolymer

D. C. Evans, J. A. Barrie and M. H. George
Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK
(Received 22 July 1974)

INTRODUCTION

It was recognized several years ago[1] that anionic polymerization provides a convenient route for the synthesis of block copolymers. Since that time, a considerable amount of work on this subject has been reported. However, recent reviews[2-4] contain no reference to the synthesis of a block copolymer of *cis*-1,4-polyisoprene and poly(methyl methacrylate) using anionic techniques, although a block copolymer has been prepared by mastication of natural rubber swollen with methyl methacrylate[5]. A major difficulty in the preparation of this block copolymer is that anionic polymerization of isoprene produces *cis*-1,4-polymer, only if lithium is used as counter-ion in a hydrocarbon solvent. However, anionic polymerization of methyl methacrylate with a lithium counter-ion does not produce living polymer in the normal sense[6], whereas with a sodium[7] or potassium[8] counter-ion, polymerization proceeds smoothly.

When n-butyl lithium (n-BuLi) was used as a metalating agent in the presence of t-butoxide potassium (t-BuOK), it was proposed[9] that complex formation occurred:
$$\delta^- \text{n-Bu} \cdots\cdots \text{Li}$$
$$\delta^+ \text{K} \cdots\cdots \text{BuO}$$

Further, the presence of t-BuOK during polymerization of dienes, initiated by n-BuLi in hydrocarbon solvents, caused suppression of 1,4-addition[10], suggesting that counter-ion exchange occurred. An attempt has been made to utilize this phenomenon in order to prepare a *cis*-1,4-polyisoprene-*b*-poly(methyl methacrylate) copolymer, as described below.

METHOD

Polymerization of isoprene was initiated by n-BuLi in n-hexane. Since the activation energy for initiation is less than that for propagation in this system[11], the efficiency of initiation was increased by carrying out the polymerization of isoprene at 0°C for 4 h and then overnight at room temperature.

After polymerization of isoprene was complete, t-BuOK was added to the solution of living polyisoprene in order to effect an exchange of counter-ions, as suggested above. This was followed by addition of 1,1'-diphenylethylene (DPE) in tetrahydrofuran (THF) and then sufficient THF to make the final solvent composition approximately 66% (v/v) THF. DPE was added to the living polyisoprene to prevent attack of the ester group by the living polymer upon addition of methyl methacrylate[8]. DPE does not homopolymerize[12] and so only one molecule is added to each of the living polymer molecules.

Polymerization of methyl methacrylate was then carried

out by dropwise addition of the monomer to the reaction mixture at −78°C. The whole reaction was carried out under vacuum in a sealed, all-glass apparatus. The highly purified materials were stored in breakseal ampoules which were attached to the apparatus.

The block copolymer and a sample of homopolyisoprene removed from the reaction mixture on completion of the first stage of the reaction, were fully characterized with respect to molecular weight, composition and microstructure. Full experimental details have been given elsewhere[13].

RESULTS

Molecular weights and composition of the polymers were close to the predicted values. The molecular weight distribution (*MWD*) of the sample of homopolyisoprene, determined by gel permeation chromatography (g.p.c.), is narrow, as shown in *Figure 1*. The *MWD* of the copolymer is relatively broad (*Figure 1*) but the fact that it consists of a single sharp peak suggests that potassium acted as counter-ion during polymerization of methyl methacrylate, since when lithium does so, very broad or bimodal distributions are obtained[6]. Also, the g.p.c. trace of the copolymer suggests that little or no homopoly(methyl methacrylate), possibly initiated by t-BuOK[14], is present.

The microstructure of the homopolyisoprene was determined by proton n.m.r. spectroscopy. Spectra were interpreted according to published data[15]. The polyisoprene microstructure was, approximately: *cis*-1,4-, 78%; *trans*-
Figure 1 Gel permeation chromatograms of (A) homopolyisoprene and (B) *cis*-1,4-polyisoprene-*b*-poly(methyl methacrylate), prepared as described in the text

1,4-, 20%; 3,4-, 2%; and 1,2-, 0%. These values are close to those reported elsewhere[16] for polyisoprene prepared under similar conditions and analysed by proton n.m.r. spectroscopy.

The chain configuration of the poly(methyl methacrylate) block was also determined by proton n.m.r. spectroscopy. Spectra were interpreted according to literature data[17] and the results are summarized in *Table 1*. The triad distribution in the poly(methyl methacrylate) block of the isoprene–methyl methacrylate block copolymer (IMMA) is compared to that in a polystyrene-*b*-poly(methyl methacrylate) copolymer (SMMA), in which polymerization of the methyl methacrylate block was initiated by polystyryl potassium in THF. The triad distribution in each copolymer is similar and is also similar to that in homopoly(methyl methacrylate), prepared by anionic polymerization with a potassium counter-ion in polar solvents, as reported elsewhere[18]. When lithium is the counter-ion the results are quite different[18].

Thus, a *cis*-1,4-polyisoprene-*b*-poly(methyl methacrylate) copolymer of approximately predetermined composition has been prepared. The evidence presented above suggests that counter-ion exchange between polyisoprenyl lithium and t-BuOK does occur under the conditions employed.

Polymer molecular weight methods
(Advances in Chemistry Series 125)
Edited by Myer Ezrin
ACS, Washington D.C., 1973, 350 pp. $17.50

Papers from the symposium entitled 'Recent Trends in the Determination of Molecular Weight' cosponsored by the Analytical and Polymer Chemistry Divisions of the American Chemical Society (ACS) form the contents of this volume. The symposium was held during the 162nd ACS national meeting at Washington D.C. in September 1971.

Methods suitable for the measurement of molecular weights (*MW*) from simple molecules to high polymers are covered. Ebulliometry and mass chromatography have been modified to provide useful methods for measuring lower *MW*. More reliable qualitative determinations are achieved with the twin columns and gas density detectors used in the mass chromatograph. Its adoption to pyrolysis gas chromatography should extend the versatility of this technique also.

Twelve of the twenty six published papers concern the technique of gel permeation chromatography (g.p.c.) in some aspect. Some of these represent small but significant improvements to the technique that enjoyed wider coverage at a previous ACS symposium at Houston, Texas, in February 1970. A welcome emphasis has been placed on the reproducibility of derived parameters, both interand intra-laboratory. Polymer standards, useful in this connection, are described. Other topics include computerized data acquisition and processing, calibration and application to the analysis of polypeptides, cellulose, cellulose nitrate, resole phenol–formaldehyde resins and styrene–butadiene block copolymers.

Another advance, electrospray mass spectrometry (e.m.s.) has enabled particles up to a *MW* of 1.6×10^5 to be examined by mass spectrometry. 'The electrospray process consists of feeding a liquid through a metal capillary which is maintained at a high electrical potential with respect to some nearby surface. As liquid reaches the capillary tip, the liquid is dispersed into fine electrified droplets. If the liquid contains macromolecules then, after the solvent has evaporated completely, the macromolecules are left as gaseous macro-ions'. Here *MW* is expressed in atomic mass units. This unit is equivalent to the less familiar Dalton (1.66×10^{-24} g) used in a previous paper.

Diffusion and sedimentation equilibrium are given a good coverage. Diffusion coefficients are reported to be more readily obtained with the newer technique of self-beat spectroscopy. Two papers explore the mathematics for deriving molecular weight distributions from sedimentation equilibrium experiments.

Other techniques covered include light scattering, X-ray scattering, nuclear magnetic resonance spectroscopy, viscosity and thin film dialysis for isolating substances in the intermediate *MW* range.

This is an excellently produced volume in keeping with the standard of the ACS series of publications. The symposium was successful in conveying the importance of a multidisciplinary approach to *MW* measurement. Generally the papers are highly informative and make a useful and very concise reference book.

On the structure of polybutadiene: 4. ^{13}C n.m.r. spectrum of polybutadienes with *cis*-1,4-, *trans*-1,4- and 1,2-units

Karl-Friedrich Elgert, Gunther Quack and Bernhard Stützel

Institut für Makromolekulare Chemie der Universität Freiburg, D-78 Freiburg, West Germany
(Received 18 June 1974)

^{13}C n.m.r. spectra of polybutadienes with different contents of *cis*-1,4-, *trans*-1,4- and 1,2-units are assigned in the resonance region of the *cis* and *trans* carbon double bond. The observed signals are assigned to configurational triads.

INTRODUCTION

Investigations of the sequence analysis of polybutadienes by ^{1}H n.m.r. spectroscopy indicated triads generated by *cis*-1,4- and *trans*-1,4-units in 1,4-polybutadienes[1,2]. The backbone chain of real polybutadienes, however, consists of sequences of *cis*, *trans* and 1,2-units. ^{13}C n.m.r. spectroscopy offers more detailed information on this structure problem. In previous papers we reported the sequence analysis of 1,4-polybutadiene[3], 1,2-polybutadiene[4] and equibinary (*cis*-1,4-/1,2-)polybutadiene[5] by ^{13}C n.m.r. spectroscopy. In this communication the first results on the determination of the sequence distribution of polybutadienes with different contents of *trans*-1,4-, *cis*-1,4- and 1,2-units are reported.

EXPERIMENTAL

The polybutadienes were polymerized anionically by n-butyl lithium in various n-heptane/tetrahydrofuran mixtures. The polymerization temperatures varied between $-10°$C and $+60°$C.

The microstructure of the polybutadienes was determined by i.r. spectroscopy on a Perkin—Elmer spectrometer 125 in CS_2 solution.

The proton decoupled ^{13}C n.m.r. spectra were obtained in $CDCl_3$ at 35°C with a HX 270 (Spectospin AG, CH-8117, Zürich-Fällanden, Switzerland) at 67.88 MHz. The spectrometer conditions were: sweep width, 12 kHz; acquisition time, 0.67 sec; pulse width, 35 μsec; transients, 8 k; data points, FT interferogram, 16 k. Internal standard was octamethyltetrasiloxane (OMTS) = 0 ppm.

RESULTS AND DISCUSSION

Six polybutadiene samples have been selected. The polymerization conditions of these samples polymerized anionically by n-butyl lithium in suitable n-heptane/tetrahydrofuran mixtures are listed in *Table 1*. The polymerization process is assumed to generate a random sequence distribution of *cis*-1,4-, *trans*-1,4- and 1,2-units. The resonance region of the *cis* and *trans* carbon double bond of the ^{13}C n.m.r. spectra of these polybutadienes is shown in *Figure 1*. The spectra are arranged in succession of increasing content of 1,2-units in the polymer. The observed resonance signals result from influences of neighbouring

1,2-, *cis*-1,4- and *trans*-1,4-units on the signal of a central *cis*-1,4 or *trans*-1,4-unit in a sequence of three structure units, e.g. *cis*-1,4(c)/*trans*-1,4(t)/1,2(v) (c/t/-v):
or 1,2(v)/*trans*-1,4(t)/1,2(v) (-v/t/-v):
Figure 1 demonstrates the multiplicity of the ^{13}C n.m.r. spectra caused by the sequence distribution of the structure units. Spectrum (1) represents the polymer sample 1 whose

Table 1   Polymerization of butadiene by n-butyl lithium in n-heptane/tetrahydrofuran mixtures

Sample	Microstructure (%)			Polymerization temperature (°C)	Tetrahydrofuran (%)
	trans	cis	1,2		
1	54	37	9	30	0
2	45	28	27	60	0.2
3	41	27	32	60	0.3
4	31	16	53	30	0.4
5	9	11	80	−10	1.0
6	5	7	88	−10	100
Figure 1 ^{13}C n.m.r. spectra of the *cis*-1,4 and *trans*-1,4 double bond in polybutadienes with different contents of 1,2-units

1,2-units are mainly isolated. With increasing content of 1,2-units as in samples 2, 3 and 4 the relative intensities of the 1,4-block signals are decreasing whereas the signals of sequences containing 1,2-units are increasing. In spectra (5) and (6), 1,4-units are expected to be mainly isolated.

Figure 2 shows the expanded spectrum of a polymer
Figure 2 Expanded [13]C n.m.r. spectrum of a polybutadiene with 34% *trans*-1,4-, 24% *cis*-1,4- and 42% 1,2-units

sample containing 34% *trans*-, 24% *cis*- and 42% 1,2-units. Within resolution and sensitivity of the spectrometer 16 signals are completely resolved in the resonance region of the *cis*-1,4- and *trans*-1,4-carbon double bond. The assignment of the resonance signals has been performed stepwise using our previous assignment of the [13]C n.m.r. spectra of 1,4-polybutadienes[3]. Signals (8) and (10) are assigned to *trans–trans* and *cis–cis* sequences. Signals (6) and (11) represent *trans–cis* and *cis–trans* transitions. According to our interpretation of the [13]C n.m.r. spectrum of equibinary (*cis*-1,4-/1,2-)polybutadiene[5] the signals (3), (5), (7), (12), (16), (17) and (18) are assigned to sequences of three units containing a central *cis*-1,4-unit. The residual signals are assigned to sequences of three units containing a central *trans*-unit.

If surrounded by 1,2-units the two carbon atoms of the *cis*-1,4- and *trans*-1,4-carbon double bond have different chemical shifts owing to their different distances from the vinyl side group. Head-to-tail addition is highly probable because no signals for other linkages could be verified.

The assignment of the resonance signals of the *cis*-1,4- and *trans*-1,4-carbon double bond is listed in *Table 2*. The assignment of the resonance signals including units with a central *trans*-1,4-unit has been verified by comparison of experimental peak intensities with those calculated by Bernoullian statistics. The intensities in all resonance regions have been calculated from peak areas given by the integration procedure of the spectrometer computer rather than from peak heights. The overall composition of the polybutadienes was determined by i.r. spectroscopy. Within experimental error no difference exists between predicted polymer composition and experimental values from [13]C n.m.r. spectra. By quantitative interpretation of [13]C n.m.r. spectra from poly(α-methylstyrene)[6] it was feasible to calculate the relative abundance of ^{13}C nuclei incorporated in configurational sequences. The quantitative results from [13]C n.m.r. spectra are in excellent agreement with those from corresponding [1]H n.m.r. spectra. Preliminary evidence suggests this procedure may be applicable on polybutadienes as well, if nuclear Overhauser enhancement and relaxation times do not vary in a strong way.

In ^{13}C n.m.r. spectroscopy of low molecular weight compounds the position of a peak in the spectrum is determined by the local environment of the carbon nucleus. The chemical shift of alkanes[7] and alkenes[8] can be calculated from the sum of empirical shift parameters which take into account the environment of a carbon atom. If additivity holds for polymers, too, it should be possible to find an empirical set of shift parameters which take into account quantitatively the influence of a neighbouring 1,2-unit on a given *cis*-1,4- or *trans*-1,4-unit.

As listed in *Table 3* eight parameters are necessary to describe the influence of a neighbouring 1,2-unit on the chemical shift of the resonance signals of the *cis*-1,4- and *trans*-1,4-double bond relative to their block signals at 128.91 ppm and 129.30 ppm, respectively. These parameters hold whether the double bond of the 1,2-unit is three (γ) or four (δ) carbon bonds away from that 1,4-double bond under consideration. The parameters (γ') and (δ') refer to the influence of the vinyl double bond on the opposite side of that double bond atom.

For example, the chemical shift, Δ, of the carbon atoms of the above mentioned examples are calculated as follows:

$$\Delta(C_1)calc. = trans \text{ block} + \gamma' + \delta = 129.30 + 0.46 +$$

$$1.25 = 131.01 \text{ ppm}$$

$$\Delta(C_1)exp. = 131.01 \text{ ppm}$$

$$\Delta(C_{15})calc. = trans \text{ block} + \gamma + \delta' = 129.30 - 1.66 -$$

$$0.19 = 127.45 \text{ ppm}$$

$$\Delta(C_{15})exp. = 127.48 \text{ ppm}$$

$$\Delta(C_2)calc. = trans \text{ block} + \delta = 129.30 + 1.25 = 130.55 \text{ ppm}$$

$$\Delta(C_2)exp. = 130.55 \text{ ppm}$$

$$\Delta(C_9)calc. = trans \text{ block} + \delta' = 129.30 - 0.19 = 129.11 \text{ ppm}$$

$$\Delta(C_9)exp. = 129.11 \text{ ppm}$$

Carbon atoms 13 and 14 of a central *trans*-1,4-unit and carbon atoms 16 and 17 of a central *cis*-1,4-unit differ only in the neighbouring 1,4-unit. The splitting in these cases is of the same magnitude as the splitting of the signals of isomerized 1,4-polybutadienes[3]. The signal of an atom in the *trans* carbon double bond is shifted downfield by 0.11 ppm, if the *trans* unit is next to a *cis* unit on the opposite side of the double bond, whereas the *cis* signal

Table 3 Shift parameters in polybutadienes

Para-meters	cis	trans
γ_i	−1.60	−1.66
γ	+0.48	+0.46
δ_i	+0.48	+1.25
δ'	−0.31	−0.19

is shifted upfield by 0.18 ppm if next to a *trans* unit. Owing to limited resolution and overlapping of signals, however, this splitting is not observable for signals (2) and (5).

As shown in spectra (5) and (6) of *Figure 1* the ^{13}C n.m.r. spectra of polybutadienes containing mainly 1,2-blocks and isolated *cis*-1,4- and *trans*-1,4-units are complicated by an additional fine structure. Signals (1), (15) and (18) split up into two resonance signals. This splitting may be caused by the asymmetric carbon atom of the 1,2-unit or by the influence of the next neighbouring *cis*-1,4 or *trans*-1,4 unit[5]. The shift parameters listed in *Table 3* refer only to the upfield signal. The correct interpretation of these signals is subject to current investigation. An important feature of these parameters is that ^{13}C n.m.r. spectra of polybutadienes can be predicted in the resonance region of the *cis* and *trans* double bond if the sequence distribution generated by the polymerization process is known.

Optimum conditions for electron microscopy of radiation-sensitive polymer crystals

J. R. White
Department of Materials, Queen Mary College, Mile End Road, London E1 4NS, UK
(Received 1 April 1974; revised 2 September 1974)

The use of low electron-image magnifications reduces the electron dose suffered by a specimen during the recording of the image, and can result in a valuable extension of the life-time of a radiation sensitive polymer crystal. At magnifications of approximately 1000x the resolution is determined by the characteristics of the photographic recording plate, and is of the order of 300 Å. It is shown, however, that this is adequate for many of the studies of current interest, and that the benefits resulting from increased lifetime will usually outweigh the detrimental effect on resolution. Particular attention is given to Moiré patterns and dislocation images, and to the problem of focusing when operating at sub-visual levels.

INTRODUCTION

In a recent paper Thomas and Ast[1] conclude that the use of image intensification in the electron microscopy of radiation sensitive polymer crystals brings a modest improvement, namely that damage during focusing can be minimized. They further estimate that the optimum recording magnification for polyethylene crystals is approximately $14\,000\,n^{-1/2}$ in bright field and $4000\,n^{-1/2}$ in dark field, where n is the number of exposures required from the area under observation. Thomas and Ast concentrate on the case where $n = 1$, but it is argued below that very little sacrifice in useful magnification is made when recording images at approximately 1000x, (giving $n \sim 16$). In reaching this conclusion an examination of some of the more important structural features is made, with particular reference to the resolution requirements for adequate observation.

FOCUSING

Focusing procedure

The advantages of image intensification during focusing have been discussed by Thomas and Ast[1]. The majority of electron microscope users do not have access to this facility, however, and are faced with the choice between subjecting a radiation sensitive specimen to considerable damage during focusing, or focusing on an area remote from that subsequently chosen for photography. The latter has been preferred in this laboratory[2] and in others[3-5] and is employed in the current series of experiments. Focusing is performed with an objective aperture displacement corresponding to a polyethylene orthorhombic (110) reflection. (The instrument used in the investigation described here, a JEOL JEM 7, has no high resolution dark field beam-tilting facility.) A small condenser 2 aperture, (100 μm), and the Wehnelt cylinder bias yielding minimum beam current are used throughout, and after focusing the illumination is further reduced by setting both condenser lenses to maximum overfocus. After focusing the specimen is moved at least three grid squares, and thence until finding an area which yields above average brightness — still only a glimmer — indicating crystalline diffraction into the objective aperture. Photographic recording of the selected area on fast plates (Ilford XM) is then performed, making adjustments such as goniometry and selection of the dark field beam rapidly and with the beam intensity switched off as much as possible.

Under the conditions of illumination described, exposures of approximately 30 sec are required even with fast plates and a vibration-free, stable microscope is essential.

Precision of focusing

The focusing precision of the above procedure is limited by the following factors: (a) differences in height between the area focused and that chosen for photography; (b) differences in the intermediate and projector lens excitations caused by hysteresial effects which occur when conditions are altered between diffraction and imaging; (c) imprecision of focusing at low primary magnifications; (d) the spherical aberration term, which will differ from one reflection to another when these are at different inclinations.

The first of these is likely to be the most serious, and the one which offers least chance of correction. At present it is impossible to know the quality of the area or of the focusing until completing the series of exposures and processing the plates. If an image intensifier were available it would be used at this stage to perform a check on the suitability of the area for photography — ideally based on the evidence of a single scan recorded on an image storer (e.g. videotape), with still playback facility. Fine focus adjustment assessed by a small number of single scans might be justified.

Hysteresial effects can be minimized by cycling the lenses through a fixed routine, though they are probably unimportant at the resolution levels accepted here. Similarly low magnification focusing is probably adequate.

In dealing with the spherical aberration term it should first be noted that focusing is performed in dark field. This is important when using simple dark field operation since

beams diffracted away from the optic axis have a different focus from the transmitted beam travelling parallel to the optic axis. If the objective lens is free from astigmatism, however, the same focal length will be shared by all beams of the same deflection independent of their azimuth. Hence all $\{110\}$ reflections will be in focus together, while the $\{200\}$ reflections occur at a different angle, and so should require a different objective lens setting. By inspection of the phase term in the scattered amplitude[6,7] it can be seen that the contribution of spherical aberration of electrons inclined to the optic axis can be expressed in terms of an equivalent defocus. The difference in this equivalent defocus for beams respectively diffracted by (110) planes and (200) planes is approximately 300 Å for an objective lens with spherical aberration coefficient of 3 mm (~focal length), and using 100 keV electrons[8], and is insignificant at the levels of resolution involved here. The effect when using a beam-tilt high resolution dark field attachment should be negligible.

RESOLUTION

Under the conditions of image recording described above, stage drift during the long exposure may limit the resolution. If, on the other hand, this can be neglected, and focusing is likewise good, then resolution will depend on the photographic plate characteristics, and will be approximately 200 Å for images recorded at 1000x magnification[1]. Moiré fringes down to 290 Å spacing have been found in the current series of observations thus confirming that this value is a reasonable estimate. It is now pertinent to examine whether this level of resolution is adequate to yield information of the kind usually sought. It should also be noted that the micrographs of Thomas and Ast contain no detail corresponding to a resolution level approaching their theoretical estimate, such that no benefit has been gained from high magnification recording.

Moiré fringes

The information yielded by Moiré fringes is of two basic types. First, the spacing and orientation of the fringe patterns relate to the relative orientation and relative strains in the superposed lattices which produce them. Secondly defects, in particular dislocations, can often be detected by means of Moiré magnification[9]. In the latter case, the view has been expressed that the detailed shape of the patterns should not be taken as indicative of the strain field associated with the dislocation[9], and our criteria for resolution appropriate to this application will reduce to those for mere observation of the fringes, which result from misorientation or strain differences in the two crystals, and are dealt with below. In examining the resolution requirements of Moiré pattern observation the three types[9-11] will be dealt with separately.

Rotation Moiré patterns[9]

These should show a continuous range of spacings if the angle of misorientation between the two crystals is random. Spacings as small as 40 Å, corresponding to a misorientation of approximately 6°, have been observed in polyethylene[12]. Larger misorientations produce smaller spacings and are hence unlikely to be detected owing to the resolution limitation. This will not be a serious drawback, however, since such patterns would only be useful insofar as their potential for Moiré magnification is realized. At the opposite end

of the scale, i.e. small misorientation/large spacing, the fringe pattern takes on a modified appearance and has attracted the interest of several workers[3,4,12,13]. When the angular misorientation is very small the fringes become kinked and of irregular thickness instead of being straight or continuously and gently curving, and of constant thickness. This has been interpreted to correspond to the formation of an interfacial dislocation network[3-5,13-15], which must have the same (vernier) periodicity as would the rotation Moiré pattern formed at the same misorientation in the absence of any interaction[4,12]. The transition from the regular to the irregular type of pattern has been found to depend on the molecular weight of the sample[13,16] and the time of storage of the crystals (in suspension in the preparation solvent), and to be in the range $0.1°-0.3°$[4]. The exact nature of the interface has not been established, though it seems unlikely that the folds are completely destroyed to yield a true dislocation network. Intermeshing of the crystals has been suggested to occur[13], while an alternative hypothesis is that interaction across tight folds is strong enough to cause mutual alignment of the crystals over large areas, relieved by regions in which corresponding planes in the respective crystals are strongly inclined to maintain the same net misorientation[17]. The strains would hence be qualitatively similar to those envisaged by Niinomi and coworkers for true dislocations, and the image appearance consequently similar. What is relevant here is that the Moiré spacing corresponding to this transition is easily within the resolution capability of the technique under scrutiny.

Parallel Moiré patterns[9]

The dark field parallel Moiré pattern which would be produced by a (110) reflection and a (200) reflection falling within the aperture and produced by polyethylene crystals oriented such that these reflections lie on a common radius would have a spacing of approximately 36 Å. Even if such a pattern could be resolved, it would contain no information which could not be obtained from the diffraction pattern, since the contributing beams would be sufficiently separated to be easily distinguished. Consequently the only parallel Moirés to be considered will be those formed between like planes in crystals maintaining different strains. A parallel Moiré pattern spacing of 300 Å in a dark field image would correspond to a relative elastic strain between the two crystals of ~1.4%. Even if the external restraints could be so arranged to share this between the two, with one in tension and the other in compression, such a strain seems too high to make its occurrence likely. Smaller strains would produce larger spacings which would hence be resolvable by the low magnification recording technique.

Tilt Moiré patterns[10,11]

The range of relative tilt between two crystals which produces a tilt Moiré pattern with observable contrast is restricted, and depends on crystal thickness. For most systems encountered in practice, in particular polyethylene crystals of 100—200 Å thickness, the relative tilt must be small, and the lower limit to the corresponding fringe pattern spacing large, and easily resolved by low magnification recording.

Dislocations

Dislocation detection by Moiré magnification will, in general, be possible whenever the Moiré pattern is resolved,
Figure 1 Dark field images taken in the $(1\bar{1}0)$ reflection of polyethylene crystals on a carbon support film. (a) First exposure; (b) thirteenth exposure. (Goniometer adjustments were made between (a) and (b).)

and the remarks in the sections dealing with Moiré patterns are hence again appropriate. A dislocation will also be rendered visible by the diffraction contrast produced by the associated strain field as long as the burgers vector and the diffraction vector are not mutually perpendicular. Dislocation networks have often been reported, even when recorded at low magnifications[3]. These are generally assumed to lie in the interfacial boundary between two overlying crystals, and to be screw dislocations. Some remarks relating to these networks were made in the section on rotation Moiré patterns above. It will further be recalled that dislocation images are only obtained when the separation exceeds a certain value corresponding to a 'critical angle' of misorientation between the crystals[4]. This separation is fairly large and is easily resolved as has been noted above.

The dissociation of the interfacial dislocations is energetically favourable in many instances[15], and the separation of the partials is often large enough to be easily resolved. In some cases the expected dissociation has not been observed, however, possibly because it is weak and the separation is too small[15]. Better resolution might improve matters, though distinction between an undissociated dislocation image and that of two partials placed close together would not be particularly clear. Care must be taken not to confuse dislocation double images, produced

when $gb = n = 2$, with separated partials. Calculated values for the separation of partials and of dislocation double images are in conflict with observations, possibly owing to inadequate data on the elastic constants of the polyethylene crystal[15], and need improvement before higher resolution can be justified on this account. On the other hand, the reader is reminded of the remarks made earlier regarding the nature of the interfacial dislocations. If the assimilation of the folds into a true twist boundary is incomplete as suggested, the dislocation-like strains might still be expected to dissociate in a manner analogous to that of true dislocations. The difference in strength of the interaction which would occur in a twist boundary at the centre of a crystal of thickness twice the fold period of a monolayer crystal and that present when two monolayer crystals with tight folds are in contact may provide an alternative explanation for the discrepancy between calculated images based on the former model and experimental observations[15].

EXPERIMENTAL RESULTS

The observations presented here are extracted from a broader study reported more fully in another paper[18]. Dark field micrographs of single areas using several beams and at different specimen tilts were required. The number of micrographs with good diffraction contrast obtainable from a single area was found consistent with that claimed by Thomas and Ast, as projected to a magnification of 1000x. *Figures 1a* and *1b* show the same area of a polyethylene crystal preparation grown in xylene and deposited onto a thin evaporated carbon support film. They are respectively the first and thirteenth exposures in a series in which dark field recording at 980x magnification was used throughout, with the exception of one selected area diffraction pattern taken as the seventh exposure (*Figure 2*). The quality of the Moiré patterns in the last of the series is seen still to be very good as long as the large underlying crystal is reflecting, as indicated by projecting the bright bands of the single layered regions into the multilayered parts. This is a pre-requisite applicable to all of the images, of course, and is dependent on the local crystallographic orientation, which is in turn partly governed by the specimen tilt produced by the goniometer stage. The changing location of Moiré images is hence dependent on the diffracted beam used to form the image and on any goniometer adjustments. Loss of Moiré contrast cannot

Figure 2 Selected area diffraction pattern from part of the area shown in *Figure 1*

alone be taken as indication that crystal structure has been destroyed in that area. Parts of this area are shown at higher magnification in *Figures 3a* and *3b*. *Figure 4* shows another area recorded at a primary magnification of 980x at still greater photographic enlargement in which fringe resolution of 290 Å is clearly visible.

The number of exposures possible at higher beam currents (achieved by concentrating the beam somewhat with condenser lens 2) seems to be smaller than with the minimum current available, though no quantitative assessment has been made. This may mean that the heating effect of the beam contributes to the destruction of the crystals, even when working at sub-visual levels. If this is indeed the case, the balancing of low beam currents against the problem of drift and instability during long exposures would again favour low magnification recording, which minimizes the time of exposure.

CONCLUSIONS

In the examination of the resolution requirements of polymer crystal observation in the electron image it has been found that important information is unlikely to be lost when low magnification ($\sim$1000x) is used for recording, with or without the aid of an image intensifier during focusing. The main consequent benefit is improved crystal lifetime, upwards of ten dark field photographs
Figures 3a and *3* Parts of the images shown as *Figures 1a* and *1b* at higher magnification
Figure 4 High enlargement of an image recorded at 980x primary magnification, showing fringe resolution of 290 Å within the circle

being possible from a single area. Additionally, a small magnification means a large field of view, and this is a tremendous advantage when area selection must be made at sub-visual levels.

^{19}F chemical shift anisotropy in aligned PTFE fibres

A. N. Garroway*, D. C. Stalker and P. Mansfield

Department of Physics, University of Nottingham, Nottingham NG7 2RD, UK
(Received 28 May 1974)

By applying a nuclear magnetic resonance (n.m.r.) multiple pulse sequence to a powder of randomly aligned crystallites, the principal values of the chemical shift tensor may be measured. However information about alignment of the chemical shift tensor with respect to the crystal axes is lost. To obtain orientation information in polytetrafluoroethylene (PTFE), we have prepared a bundle of drawn PTFE fibres and observed the ^{19}F line-narrowed n.m.r. spectra for various fibre orientations relative to the direction of the static magnetic field. The data at 77 K indicate that the most screened component of the chemical shift tensor lies along the C—F bond and that the least screened component is aligned at approximately 20° to the molecular chain axis. At 298K the spectrum of a PTFE powder indicates an axially symmetrical tensor whose principal values are consistent with a 20° inclination of the least screened component relative to the chain axis.

ROTATION SPECTRA OF THE CHEMICAL SHIFT TENSOR

In nuclear magnetic resonance (n.m.r.) the chemical shift tensor $\underline{\sigma}$ is observed in the laboratory frame along the z direction, specified by the direction of the static field, H_0. The observed shift is:

$$\sigma_{zz} = (\mathbf{R}^\dagger \underline{\sigma} \mathbf{R})_{zz} \qquad (1)$$

where $\mathbf{R}$ is the transformation matrix from the coordinate system in which $\underline{\sigma}$ is known into the laboratory frame. In the principal axis sytem $\underline{\sigma}$ is diagonal and equation (1) becomes:

$$\sigma_{zz} = \sigma_{11}\sin^2\alpha\sin^2\beta + \sigma_{22}\cos^2\alpha\sin^2\beta + \sigma_{33}\cos^2\beta \quad (2)$$

where α and β are the Euler angles linking the principal axes system and the laboratory frame. For a polycrystalline sample the Euler angles are spatially averaged and equation (2) leads to the familiar powder lineshape[1]:

$$f_3(\sigma, \theta) = \pi^{-1}(\sigma - \sigma_{11})^{-1/2}(\sigma_{33} - \sigma_{22})^{-1/2}K(k)$$

with

$$k^2 = \frac{(\sigma_{33} - \sigma)(\sigma_{22} - \sigma_{11})}{(\sigma - \sigma_{11})(\sigma_{33} - \sigma_{22})} \text{ for } \sigma_{33} \geqslant \sigma > \sigma_{22} \qquad (3a)$$

$$f_3(\sigma, \theta) = \pi^{-1}(\sigma_{33} - \sigma)^{-1/2}(\sigma_{22} - \sigma_{11})^{-1/2}K(k)$$

with

$$k^2 = \frac{(\sigma - \sigma_{11})(\sigma_{33} - \sigma_{22})}{(\sigma_{33} - \sigma)(\sigma_{22} - \sigma_{11})} \text{ for } \sigma_{22} > \sigma \geqslant \sigma_{11} \qquad (3b)$$

$$f_3(\sigma, \theta) = 0 \text{ for } \sigma > \sigma_{33} \text{ or } \sigma_{11} > \sigma \qquad (3c)$$

---

* Present address: Chemistry Division, Naval Research Laboratories, Washington D.C. 20375, USA.

Here $K(k)$ is a complete elliptic integral of the first kind and we have assumed that $\sigma_{33} > \sigma_{22} > \sigma_{11}$. The subscript 3 indicates that equation (2) has been averaged over three dimensions and we shall refer to equation (3) as a three-dimensional powder lineshape.

At the other extreme to a powder is a single crystal. The observed chemical shift is found by first transforming from the chemical shift principal axes system to the crystal frame and then to the laboratory frame:

$$\sigma_{zz} = (\mathbf{R}^\dagger \underline{\sigma}^c \mathbf{R})_{zz} \qquad (4a)$$

with

$$\underline{\sigma}^c = \mathbf{T}^\dagger \underline{\sigma} \mathbf{T} \qquad (4b)$$

From the 'rotation spectra', obtained by rotation about various axes in the laboratory frame, the components of σ^c may be determined and then, by diagonalizing $\underline{\sigma}^c$ may be revealed.

Aligned fibres provide an intermediate to these extremes Here the fibre axis is the only preferred direction and there is rotation isotropy about this axis. A two-dimensional powder pattern is observed, corresponding to a spatial average about the fibre axis. Under favourable conditions, partial knowledge of the orientation of the chemical shift tensor may be extracted from rotation spectra.

ROTATION SPECTRA FOR ALIGNED PTFE

Polytetrafluoroethylene (PTFE) is a long chain polymer. As PTFE is extruded, these chains tend to align. We shall assume that there is a high degree of alignment and further that the molecular chain axis coincides with the macroscopic fibre axis. The formalism of the first section is now specialized to the PTFE fibre case.

In *Figure 1* the principal axes system of the chemical shift tensor is denoted by 1, 2, 3. We assume the 3 axis coincides with the C—F bond. The superscript c indicates
Figure 1 Co-ordinate systems for ^{19}F chemical shifts. The directions 1,2,3 correspond to the chemical shift principal axis system and the directions 1^c, 2^c,3^c to the crystal axes

the crystal axes system and the fibre direction defines the 1^c axis. We shall further assume that the C—F bond is perpendicular to the fibre axis and therefore take the 3^c axis coincident to the 3 axis. The chemical shift in the crystal frame is obtained via equation (4) by a rotation ψ about the 3 axis:

$$\underline{\sigma}^c = \begin{pmatrix} \sigma^c_{11} & \sigma^c_{12} & 0 \\ \sigma^c_{21} & \sigma^c_{22} & 0 \\ 0 & 0 & \sigma^c_{33} \end{pmatrix}$$

$$= \begin{pmatrix} \sigma_{11}\cos^2\psi + \sigma_{22}\sin^2\psi & (\sigma_{11}-\sigma_{22})\sin\psi\cos\psi & 0 \\ (\sigma_{11}-\sigma_{22})\sin\psi\cos\psi & \sigma_{11}\sin^2\psi + \sigma_{22}\cos^2\psi & 0 \\ 0 & 0 & \sigma_{33} \end{pmatrix}$$

$$(5)$$

In *Figure 1* the Euler angles ϕ, θ represent respectively the azimuthal angle about the fibre axis and the inclination of the fibre axis to H_0. By equations (4) and (5) the chemical shift in the laboratory frame is:

$$\sigma_{zz} = \sigma^c_{11}\cos^2\theta + (\sigma^c_{22}\sin^2\phi + \sigma^c_{33}\cos^2\phi)\sin^2\theta +$$

$$2\sigma_{12}\sin\phi\sin\theta\cos\theta \qquad (6)$$

The lineshape is then:

$$f_2(\sigma,\theta) \propto [-\sigma + \sigma^c_{33}\sin^2\theta + \sigma^c_{11}\cos^2\theta + \epsilon^c\cos^2\theta]^{-1/2} \times$$

$$\left\{ [\sigma - \sigma^c_{22}\sin^2\theta - \sigma^c_{11}\cos^2\theta - 2\epsilon^c\cos^2\theta + \right.$$

$$2(\epsilon^c)^{1/2}\cos\theta[-\sigma + \sigma^c_{33}\sin^2\theta + \sigma^c_{11}\cos^2\theta +$$

$$\epsilon^c\cos^2\theta]^{1/2}]^{-1/2} + [\sigma - \sigma^c_{22}\sin^2\theta - \sigma^c_{11}\cos^2\theta -$$

$$2\epsilon^c\cos^2\theta] - 2(\epsilon^c)^{1/2}\cos\theta[-\sigma + \sigma^c_{33}\sin^2\theta +$$

$$\left. \sigma^c_{11}\cos^2\theta + \epsilon^c\cos^2\theta]^{1/2}]^{-1/2} \right\} \qquad (7a)$$

and $f_2(\sigma,\theta) = 0$ $\qquad (7b)$

for σ outside the range for which the radicals are real. Here

$\epsilon^c = (\sigma^c_{12})^2/(\sigma^c_{33} - \sigma^c_{22})$ and the subscript 2 indicates a two-dimensional powder average. This lineshape must then be convoluted by a broadening function to account for relaxation broadening or the residual dipolar interactions not fully reduced by the multiple pulse sequence. These effects, in principle quite complicated[2], are approximated by a simple Gaussian so that the observed lineshape $g_2(\sigma, \theta)$ is:

$$g_2(\sigma,\theta) = \int_{-\infty}^{\infty} d\sigma' f_2(\sigma',\theta)\exp -[(\sigma - \sigma')^2/W^2] \qquad (8)$$

The characteristic broadening width, W, is to be determined experimentally.

In this paper, based in part on our preliminary report[3], we first obtain the chemical shift principal values from a fit to the three-dimensional powder lineshape at 77K and then determine the chemical shift orientation from a rotation study of the aligned fibres. Finally the three-dimensional powder lineshape is measured at 298K to demonstrate the effects of molecular re-orientation about the chain axis.

EXPERIMENTAL

The sample for rotational studies consisted of extruded 0.01 mm diameter PTFE fibres (kindly provided by D. W. McCall and V. J. McBrierty; Du Pont; batch no. 400-60-0) aligned to within ±3°. A specimen of randomly oriented fibres and also a powder of 5 μm particles (BDH; batch no.0943980) were used for the three-dimensional powder lineshapes; within experimental error, no difference in the powder lineshape at 77 or at 298K was observed for these two samples. The PTFE polymer is composed of amorphous and crystalline regions. By measuring the density and also by fitting T_2 relaxation data to a two-phase model, we infer a crystallinity of 60—70% for our fibre sample.

In rigid solids the chemical shift lineshape is generally obscured by the nuclear dipolar interaction which can, however, be reduced by employing multiple pulse sequences. All data were taken on a computer controlled line-narrowing spectrometer operating at 9.0 MHz. The $[132; \overline{132}]$ sequence[4] was used with $\tau = 6.4$ μsec for the low temperature studies. For comparison the ^{19}F resonance linewidth in single crystal CaF_2 aligned along the [111] direction with respect to H_0 was 70—95 Hz at a resonance offset of 2 kHz for this sequence. For the powder lineshape at 298K a new sequence[2], $[132; 1\overline{3}2][123; 1\overline{2}3]$, was used, again with $\tau = 6.4$ μsec. This sequence has a slightly greater line-narrowing efficiency and produced ^{19}F linewidths of 60—70 Hz in CaF_2 at an offset of 2 kHz.

RESULTS AND DISCUSSION

Powder lineshape and rotation pattern at 77K

Figure 2 shows the observed three-dimensional powder lineshape taken at 77K, as well as a computer fit using equations (3) and (8). We find an isotropic chemical shift of —30 ppm measured from a liquid C_6F_6 reference and traceless components of —80, +10 and +70 ppm. These are consistent with previously reported values[4,5]. To achieve a fit, a broadening width of $W = 55$ ppm (500 Hz) was used.
Figure 2   The line narrowed ^{19}F spectrum of PTFE powder at 77K. The solid line represents the theoretical lineshape, equation (3), convoluted with a Gaussian broadening function, for the principal values indicated. ▲, Experimental points

At 77K we obtain the following rotation pattern (*Figure 3*) for the aligned PTFE. Although equation (7) predicts a rather complex spectrum at each θ, owing to residual broadening we see only a single resonance line. The chemical shift plotted represents the first moment of the resonance, with the measured isotropic shift subtracted.

The amorphous region of the PTFE fibre is a complication. If there is indeed no alignment within this region, it follows that the observed spectrum is a superposition of a three-dimensional powder lineshape from the amorphous region and two-dimensional lineshape from the crystalline region; the composite lineshape is:

$$\mathscr{F}(\sigma, \theta) = (1 - a)f_2^c(\sigma, \theta) + af_3^a(\sigma) \qquad (9)$$

where a represents the fraction of nuclei in the amorphous region, and where $f_2^c(\sigma, \theta)$ and $f_3^a(\sigma)$ are the lineshapes of the crystalline and amorphous regions respectively. The first moment M^c of the crystalline region is related to the observed first moment M and the first moment M^a of the amorphous region by:

$$M^c(\theta) = \frac{M(\theta) - aM^a}{(1 - a)} \qquad (10)$$

and the first moments are defined by:

$$M^a = \int_{-\infty}^{\infty} d\sigma \, \sigma f_3^a(\sigma) \qquad (11a)$$

$$M^c(\theta) = \int_{-\infty}^{\infty} d\sigma \, \sigma f_2^c(\sigma, \theta) \qquad (11b)$$

It should be recalled that the first moment is independent of broadening provided the broadening is represented by an even function, as it is here for the dipolar case.

We take $a = 0.30$ and by equation (9) calculate from the data of *Figure 3* the first moment for the crystalline region only; these results are shown in *Figure 4*. We may immediately draw conclusions about the alignment of the

shift tensor. For $\theta = 0$, equation (6) predicts a line centred at σ_{11}^c. Since, by equation (5), σ_{11}^c is a linear combination of σ_{11} and σ_{22} only, then at least one of these components is negative. For $\theta = \pi/2$ the predicted shift is just the average of σ_{22}^c and σ_{33}^c. The observed positive shift indicates that σ_{33} is positive and we assign $\sigma_{33} = +70$ ppm. So the most screened component lies along the C—F bond, as expected. We may arbitrarily assign the -80 ppm value to σ_{11} and now consider the orientation of σ_{11} and σ_{22}.

With the experimental values of $\sigma_{11} = -80$, $\sigma_{22} = 10$ and $\sigma_{33} = 70$ ppm, theoretical rotation patterns generated by equation (7) for various choices of ψ are also shown in *Figure 4*. A reasonable fit to the data is achieved for $\psi \simeq 20°$ and so we infer that the least screened component ($\sigma_{11} = -80$ ppm) is at an angle of $20°$ to the PTFE chain axis. (In our preliminary report[3] the contribution of the amorphous region was not explicitly considered and we found $\psi = 30$ to $45°$ but when the data are corrected for this contribution, a reduced value of $\psi = 20°$ is obtained.)

Figure 4   Experimental and theoretical ^{19}F chemical shift rotation pattern for the crystalline region of PTFE fibres at 77K. The theoretical curves are obtained from equation (7) for various values of ψ, using the measured chemical shift principal values. The data of *Figure 3* are replotted here, after the contribution of the amorphous region of PTFE has been subtracted
Figure 5 A schematic diagram of a short length along the PTFE helix, showing the *gauche* (3 and 4) and isotactic (5 and 6) fluorine positions

To explain properly the orientation of the chemical shift tensor about the C–F bond requires a calculation of the ^{19}F chemical shift tensor in PTFE, a calculation we have not attempted. However, this orientation may be understood qualitatively by examining the location of the near fluorine neighbours since it is their electronic interaction which tends to depopulate the filled *p*-orbitals of the fluorine, giving rise to the chemical shift anisotropy. A short segment of the PTFE helix is shown schematically in *Figure 5*. From X-ray studies[6], the radii of the carbon and fluorine helices are 0.42 and 1.64 Å respectively. Below the 19°C transition adjacent CF_2 groups are related by a rotation of $12\pi/13$ about the axis of the helix and a translation of 1.30 Å along the axis. Between the 19 and 30°C transitions, the helix uncoils slightly so that the pitch angle is $14\pi/15$ but the CF_2 groups are still separated by 1.30 Å. Iwasaki[7] suggests by comparison to the C–F bond characteristics in CF_2H_2 that in PTFE the FCF bond angle is 108.5° and the C–F bond length is 1.36 Å. We shall use these values to estimate the distance to near fluorine neighbours.

The nearest neighbour to the fluorine labelled 1 (*Figure 5*) is the intramolecular fluorine (2) at a distance of 2.21 Å; this distance is of course independent of pitch angle. Since the carbon atoms are arranged on a helix, rather than in a linear zig-zag, the normal to the plane of fluorines 1 and 2 and their associated carbon atom does not coincide with the helix axis but rather makes an angle of 4.5° with this axis. Fluorines 3 and 4 (the *gauche* positions) are at a distance 2.63 and 3.03 Å. Fluorines 5 and 6 are at the isotactic positions at a distance of 2.71 Å.

Other neighbours are further removed. These values are all calculated for the crystal phase below 19°C and will alter slightly when the helix uncoils above 19°C.

The non-bonding *p*-orbitals tend to depopulate preferentially in the direction of the projection of the interacting fluorine onto the plane perpendicular to the C–F bond. Letting χ measure the angle made by this direction with respect to the axis of the helix, we find for the intramolecular fluorine, $\chi_{intra} = -97.5°$ and for the nearest *gauche* fluorine, $\chi_g = 125°$. If the dominant perturbation to the *p*-orbitals were due to only the two nearest neighbours, we should expect that the chemical shift tensor would roughly align along a direction intermediate between 82.5° (180° − 97.5°) and 125° to the fibre axis. The competition of the other *gauche* and two isotactic fluorines will alter this angle. We speculate that the dominant effect does indeed come from the two nearest neighbour fluorines by the following argument.

In the Karplus–Das semi-empirical theory[8] for *p*-orbital chemical shifts, the deviation from filled shells, $p_{ii} = 2$, etc., is represented by:

$$p_{ii} = 2 - \rho_i \tag{12a}$$

$$p_{jj} = 2 - \rho_j \tag{12b}$$

$$p_{kk} = 2 - \epsilon \tag{12c}$$

with

$$\epsilon = 1 - (I + S - IS) \tag{13}$$

and where ρ_i, ρ_j are the double bond characters, kk is defined by the bond direction, and I and S are the ionic character and degree of *sp* hybridization, respectively. The paramagnetic contributions to the chemical shifts are then

$$\sigma_{ii}^p = (3/2)\sigma_0[\epsilon + \rho_j(1 - \epsilon)] \tag{14a}$$

$$\sigma_{jj}^p = (3/2)\sigma_0[\epsilon + \rho_i(1 - \epsilon)] \tag{14b}$$

$$\sigma_{kk}^p = (3/2)\sigma_0[\rho_i + \rho_j - \rho_i\rho_j] \tag{14c}$$

where σ_0 (−863 ppm[8]) is a semi-empirical parameter. Now we have found that the least screened component (−80 ppm) lies at about 20° to the fibre axis. If we identify *ii* with the 20° direction, equations (14a) and (14b) imply then that the deviation from a closed shell is greatest along the 110° direction. This corresponds to an angle approximately intermediate to the intramolecular angle (82.5°) and the nearest *gauche* angle (125°) and so we suggest that the chemical shift orientation about the C–F bond is dominated by the intramolecular and nearest *gauche* interactions. This angle is dependent on the pitch and should change slightly above the 19°C transition. Molecular rotation about the helix axis sets in somewhat below this temperature and produces an axially symmetrical chemical shift tensor. Even with this complication, a rotation spectrum similar to *Figure 4* should in principle reflect the slight change in pitch angle. Our resolution at present is not adequate to determine such a change and we have not produced a high temperature rotation spectrum. However, as the next subsection shows, the experimental three-dimensional powder lineshape above the 19°C transition does provide information about the orientation of the chemical shift tensor.
Figure 6 Line-narrowed ^{19}F spectrum of PTFE powder at 298K. Molecular re-orientation about the chain axis produces an axially symmetrical chemical shift tensor. The theoretical unbroadened lineshape with principal values as indicated is shown as a broken line; the solid line is obtained by convolution with a Gaussian broadening function. ▲, Experimental points

High temperature

Relaxation studies[9,10] in PTFE have suggested that above the 19°C transition, the molecules in the crystalline region begin to rotate rapidly (10^7 Hz) about the chain axis. (In the amorphous region, this rotation may occur at lower temperature[11].) We should then expect that the chemical shift tensor will be in effect temporally, rather than spatially, averaged about the axis of rotation. If the axis of rotation does indeed coincide with the chain axis, then the observed component of the chemical shift tensor is from equation (6):

$$\langle \sigma_{zz} \rangle_\phi = \sigma_{11}^c \cos^2\theta + (1/2)(\sigma_{22}^c + \sigma_{33}^c)\sin^2\theta \qquad (15)$$

where $\langle \ \rangle_\phi$ indicates that an azimuthal average has been performed. This is just the expression for an axially symmetrical chemical shift tensor with parallel component $\sigma_\parallel = \sigma_{11}^c$ and perpendicular component $\sigma_\perp = (1/2)(\sigma_{22}^c + \sigma_{33}^c)$. *Figure 6* shows the observed ^{19}F spectrum from a PTFE powder at 298K, a temperature selected between the 19 and 30°C transition temperatures. Assuming that the principal values of the chemical shift tensor are essentially independent of temperature from 77 to 298K, we may then use the low temperature results to predict the lineshape at this high temperature. Although the uncoiling of the helix above 19°C alters slightly the angle of the intramolecular and nearest *gauche* fluorines with respect to the fibre axis, we shall still compute the averaged chemical shift components using the experimental value of $\psi = 20°$. From equations (15) and (5) we have $\sigma_\parallel = -69.5$ and $\sigma_\perp = 34.7$ ppm. The powder spectrum for an axially symmetrical tensor is generated by a special case of equation (3). The broken line in *Figure 6* represents the theoretical powder spectrum for these principal values, in the absence of broadening. A reasonable fit to the experimental spectrum is achieved for

a broadening width of 27 ppm (240 Hz) and is shown as the solid line in the Figure. The rather asymmetrical lineshape in *Figure 6*, indicative of axial symmetry, should be compared with the more symmetrical lineshape at 77K (*Figure 2*).

CONCLUSIONS

N.m.r. rotation studies of aligned PTFE fibres have shown that the most screened component of the ^{19}F chemical shift tensor lies along the C–F bond and that the least screened component is aligned at approximately 20° to the chain axis. At 298K molecular rotation about the chain axis yields an axially symmetrical chemical shift tensor and the observed powder lineshape is consistent with a 20° orientation of the least screened component with respect to the chain axis. We suggest that the determination of this orientation is dominated by interactions with the fluorine neighbours at the intramolecular and nearest *gauche* positions.

Although we have implicitly assumed a unique fibre direction in the crystalline region, certainly not all the chains are so well aligned. A distribution of alignments will tend to smooth out the observed angular dependence and may well account for the deviation of the experimental results near $\theta = 0$ from the theoretical curve in *Figure 5*. The rotation data are unfortunately too imprecise to warrant invoking an alignment distribution model. With improved line-narrowing resolution, further chemical shift studies of polymer fibres should provide a more sensitive measure of polymer alignment.

Electrical conductivity of PMMA at linearly increasing temperatures

V. Adamec and E. Mateová

Cables and Insulating Materials Research Institute, Bratislava, Czechoslovakia
(Received 16 April 1974; revised 28 August 1974)

The temperature dependence of electrical conductivity in poly(methyl methacrylate), representing polar polymers, has been measured at linearly increasing temperatures in the range from −100 to +100°C. The interpretation by superposition of inherent conductivity and polarization processes is discussed.

INTRODUCTION

The temperature dependence of electrical conductivity of polymer insulating materials used to be determined in two ways. Either the time dependence of current was measured at several fixed temperatures after the d.c. voltage application to the specimen until the steady-state current was achieved and a plot of temperature dependence of steady-state conductivity values was drawn or, after the voltage application, the temperature was steadily increased and simultaneously the current was measured and recorded. In the former case, some of the authors have not found any inflection on the curve in the region of the second order transition temperature[1]; others have found an inflection[2-4]. With the latter method there is always an inflection on the temperature curve[1-5], and the measurement being comparatively simple, this method has been applied several times for the determination of the glass transition temperature, T_g[6].

The interpretation of the temperature dependence of conductivity in insulating polymers is far from consistent. Some hypotheses have postulated that conductivity above and below the inflection is ionic and electronic in nature, respectively, and yet others are based on the analogy with some other materials, according to which intrinsic conductivity exists above T_g and impurity conductivity below T_g. Shishkin and Vershinina[5] and Warfield and Petree[6] explain the inflection at T_g by change in environmental conditions for ion mobility at the transition from the glassy state into a highly elastic one. Herwig and Jenckel[1] and Reddish[2] suppose that the inflection appears as a result of the superposition of polarization effects on the conductivity process at temperatures below T_g, at which the relaxation times become long.

THEORY

The current, I, flowing through the circuit with the specimen connected in after the d.c. voltage, V, application may be expressed as:

$$I(t) = \left(G + \frac{dC}{dt} \right) V \tag{1}$$

where the first term represents the contribution of the

inherent conductance, G and the second one that of the capacitance, C change. From equation (1), the effective conductivity may be deduced:

$$\sigma(t) = \sigma_s + \frac{L}{A} \frac{dC}{dt} \tag{2}$$

where σ_s is the steady-state (inherent) conductivity, L is the thickness of the specimen, and A is the area of the electrodes. At a linear increase in temperature $(dT/dt = b)$ we obtain:

$$\sigma(T) = \sigma_s(T) + \frac{bL}{A} \frac{dC}{dT} \tag{3}$$

Since $C = \epsilon \, \epsilon_0 A/L$ and the relative permittivity $\epsilon = \epsilon_\infty + \Sigma \epsilon_{ai}$, where ϵ_∞ stands for fast polarization processes and $\Sigma \epsilon_{ai}$ for slow processes, and since one may also use the Clausius–Mossotti relation for ϵ_∞, one obtains:

$$\sigma(T) = \sigma_{so} \exp \left(-\frac{W_c}{kT} \right) + b\beta_L \epsilon_0 [\epsilon - (\epsilon_\infty - 1)(\epsilon_\infty + 2)] +$$

$$b\epsilon_0 \sum \frac{d\epsilon_{ai}}{dT} \tag{4}$$

where σ_{so} is the pre-exponential factor, W_c is the activation energy of the inherent conduction process and β_L is the linear expansion coefficient. The second term on the right hand side represents both the temperature dilatation of the specimen and the temperature dependence of ϵ_∞. Its magnitude is of the order 10^{-19} or 10^{-18} mho/cm and therefore it may be neglected in the present consideration.

Using the known differential equation for permittivity $d\epsilon_a/dt = (\epsilon_{as} - \epsilon_a)/\tau$ in the case of a process with a single relaxation time $\tau = \tau_0 \exp(W_a/kT)$, where τ_0 is the pre-exponential factor and W_a is the activation energy of the polarization process, we obtain:

$$\frac{d\epsilon_a}{dT} = \frac{\epsilon_{as} - \epsilon_a}{b\tau_0} \exp \left(-\frac{W_a}{kT} \right) \tag{5}$$

where ϵ_{as} is the static value of the permittivity increment corresponding to the polarization process. Assuming ϵ_{as} to be roughly temperature independent, we have:

$$\epsilon_a(T) = \epsilon_{as} \left\{ 1 - \exp \left[-\frac{1}{b\tau_0} \int_{T_0}^{T} \exp \left(-\frac{W_a}{kT} \right) dT \right] \right\} \quad (6)$$

An anomalous conductivity $\sigma_a(T)$ corresponds to the change of permittivity in the course of the linear temperature rise:

$$\sigma_a(T) = \frac{\epsilon_{as}\epsilon_0}{\tau_0} \exp \left[-\frac{W_a}{kT} - \frac{1}{b\tau_0} \int_{T_0}^{T} \exp \left(-\frac{W_a}{kT} \right) dT \right] \quad (7)$$

The measured effective conductivity at linearly increasing temperatures ought to be determined by both the inherent conductivity and the sum of anomalous conductivities from all relaxation polarization processes in the dielectric.

$$\sigma(T) = \sigma_s(T) + \Sigma\sigma_{ai}(T) \quad (8)$$

EXPERIMENTAL AND RESULTS

A sample of a commercial atactic poly(methyl methacrylate) (PMMA) was chosen for the measurement as a representative polar polymer. A disc shape specimen of 0.5 mm thickness was provided with evaporated gold electrodes of 30 mm diameter and guard rings on both surfaces. The specimen was placed in a shielded oven which was provided with liquid nitrogen cooling and resistance heating controlled by a temperature programmer. A highly stable voltage source of 100 V was used and the current was measured and recorded with a vibrating reed electrometer.

After the specimen had been placed in the oven, it was heated for 3 h at 100°C with short-circuited electrodes. Before the proper measurement started, the background current was checked. It was no larger than 2×10^{-15} A. Also with short-circuited electrodes, the specimen was cooled down to -100°C. Then the voltage was applied and after 10 min, when the effective conductivity was lower than 10^{-18} mho/cm, the temperature began to rise at a rate of 2.3°C/min. At +100°C the temperature rise was stopped and the electrodes were short circuited. A repeated measurement showed very good reproducibility. Further measurements were carried out at the rates of 4.3 and 9.1°C/min. The results are shown in *Figure 1*.

Lastly, the charge, Q accumulated on electrodes during the heating cycle was measured with a capacitor instead of a resistor connected to the input of the electrometer. These results are given in *Figure 2*. At the first measurement, the input of the electrometer was opened and then the voltage was applied ($Q = Q_\infty + \Sigma Q_{ai} + Q_c$), while at the second measurement the reverse procedure was used ($Q = \Sigma Q_{ai} + Q_c$).

DISCUSSION

Three polarization processes have been found previously with a similar sample of PMMA at the measurements of frequency dependences of the permittivity and the loss factor, and of the time dependence of the anomalous conductivity at various temperatures in the range from -30 to $+120$°C [7]. Processes β and α are due to the motion of the parts of molecules carrying a dipole moment. These processes are detectable also with dynamic mechanical methods. The third process, α', which does not have a mechanical analogue, is probably caused by the charge pile-up at the electrodes. The characteristic parameters ϵ_{asi}, τ_{oi}, W_{ai} for

these processes as well as σ_{os} and W_c for conduction have been determined from the measurements mentioned. With these data and with the temperature rates used, the $\sigma_s(T)$ and $\sigma_{ai}(T)$ dependences were obtained by applying equation (7) and by approximate solving of the integral with the aid of a programmable calculator (broken lines in *Figure 1*).

The steeply rising part of the function $\sigma(T)$ is evidently determined by the inherent conductivity and therefore the α' and partly also the α process are masked. The calculated $\sigma_{ai}(T)$ functions are much narrower than the measured ones. This effect may be explained by the existence of a broad distribution of relaxation times instead of a single one. Of course, the equality $\int\sigma_{ai}dt = \epsilon_{asi}\epsilon_0$ must still hold.

A distribution function, which enables one to deduce simple expressions for the time dependence of the anomalous conductivity, and the frequency dependence of the permittivity and the loss factor is based on a uniform distribution of activation energies according to Fröhlich[8]. If the activation energies of the motion of the molecular segments are uniformly distributed in the interval ΔW from W_A to W_B, the relation for $\sigma_a(T)$ would be:

$$\sigma_a(T) = \frac{\epsilon_{as}\epsilon_0}{\tau_0\Delta W} \int_{W_A}^{W_B} \exp \left[-\frac{W}{kT} - \frac{1}{b\tau_0} \int_{T_0}^{T} \exp \left(-\frac{W}{kT} \right) dT \right] dW \quad (9)$$
Figure 1 Temperature dependence of effective conductivity of PMMA at various temperature rates: (A, 9.1; B, 4.3; C, 2.3° C/min); ———, measured; ————, calculated
Figure 2 Accumulated charge and respective permittivity during linear temperature rise. A, $Q_\infty + \Sigma Q_a + Q_c$; B, $\Sigma Q_a + Q_c$

The low temperature tail of the peak in case of a single relaxation time is:

$$\sigma_a(T)_{\text{LTT}} = \frac{\epsilon_{as}\epsilon_0}{\tau_0} \exp\left(-\frac{W_a}{kT}\right) \qquad (7a)$$

and in case of distributed relaxation times is:

$$\sigma_a(T)_{\text{LTT}} = \frac{\epsilon_{as}\epsilon_0}{\tau_0} \frac{kT}{\Delta W} \left[\exp\left(-\frac{W_A}{kT}\right) - \exp\left(-\frac{W_B}{kT}\right)\right] (9a)$$

It follows that the broader the distribution, the less steep is the initial rise of $\sigma_a(T)$, because $W_A = W_a - \Delta W/2$.

From the measurement of absorbed charge (*Figure 2*), one can determine in a simple way the permittivity increment corresponding to the β process: $\epsilon_{\beta s} = 2.0$. This is the same value as has been obtained previously from the measurements of frequency dependence of permittivity[7].

CONCLUSION

The effective conductivity of PMMA determined at linearly increasing temperatures can be interpreted by superposition of the conduction and polarization processes. It follows that the inflection on the $\sigma(T)$ curve does not necessarily correspond to the glass transition temperature T_g, even though the inherent conductivity becomes a predominating component in the vicinity of T_g.

Based on further, unpublished results, it is believed that the concept described in this paper applies not only to PMMA and other polar polymers but also to weak polar polymers, e.g. polyethylene, polystyrene, etc. But, in the latter case, the second term in equation (4) may play an important role.

Light scattering Rayleigh linewidth measurements on some solutions of cellulose trinitrate

D. B. Sellen
Astbury Department of Biophysics, University of Leeds, Leeds LS2 9JT, UK
(Received 31 May 1974)

Light scattering Rayleigh linewidth measurements have been made upon three cellulose trinitrate samples in ethyl acetate by obtaining the autocorrelation function of fluctuations in scattered intensity. The weight average degrees of polymerization (DP_w) were in the range 2400 to 3300 and $DP_w/DP_n \sim 1.3$. Measurements were made at concentrations below 2×10^{-3} g/ml and no concentration dependence was detected within experimental error ($\pm 7\%$). No effects due to internal motion of the polymer chains were observed even though current theories predict that these effects should be quite large. Reasons for this are discussed and it is suggested that the effects of internal motion are diminished when the second virial coefficient is large and positive. Absolute values of translational diffusion constant calculated from the results lie well within the range of those obtained by other authors using conventional techniques. Over the limited range of degrees of polymerization investigated the equivalent hydrodynamic diameter per monomer unit was found to be 0.45 ± 0.03 Å. The effects of polydispersity on the results are discussed.

INTRODUCTION

The diffusion of cellulose trinitrate in solution has been investigated by several authors using conventional techniques[1-6]. During the past decade, however, it has become possible to determine diffusion constants by investigating the spectra of scattered light[7-12], a technique which is particularly advantageous for very large macromolecules where previously a single determination could take more than a week. The relevant theory is set out in a series of publications by Pecora[13]. For high molecular weight polymers spectral broadening due to fluctuations in the particle scattering factor, $P(\theta)$, resulting from configurational changes is predicted, in addition to that resulting from translational diffusion. It is of additional interest therefore to see whether the effects of internal motion can be detected. This paper describes some experiments upon three samples of cellulose trinitrate dissolved in ethyl acetate, each having a low degree of polydispersity.

EXPERIMENTAL

Preparation of cellulose trinitrate samples

Cellulose trinitrate is obtained by nitrating cellulose from a natural source. In most investigations the cellulose has been deliberately degraded so as to render it highly polydisperse. Samples of differing degree of polymerization (DP) with $DP_w/DP_n \sim 2$ can then be obtained by fractional precipitation[14]. A considerable amount of work has recently been done on cellulose nitrate in this Department with a view to investigating the degree of polymerization and polydispersity of native cotton cellulose[15]. During this investigation it was found that direct nitration of cotton by the method of Alexander and Mitchell[16] for periods increasing from 2 to 25 hours at 20°C yielded samples of decreasing molecular weight with $DP_w/DP_n \sim 1.3$ (*Table 1*). Unfortunately the range of degree of polymerization obtainable by

Table 1 Cellulose trinitrate samples

Nitration time* at 20°C (h)	DP_w (light scattering)	DP_n (osmometry)	$D_{20} \times 10^8$† (cm²/sec)
2	3300	2600	5.9
6	2800	2100	7.7
25	2400	1600	9.7

* Nitrogen content was 13.9% in all cases
† In ethyl acetate

this method is somewhat limited. Samples obtained by nitration for periods shorter than 2 h were found to contain microgel and the higher molecular weights rendered osmotic pressure measurements impossible, whilst very long periods of nitration yielded highly polydisperse material. It was thought, however, that in the first instance it would be advantageous to investigate samples with a low polydispersity, so that this method of preparation was used.

Investigation of the spectra of scattered light

The apparatus used and its operation have already been described[11,12]. The autocorrelation function of the photoelectric signal due to the scattered light is obtained. This is given by $\phi(\tau)$ where:

$$\phi(\tau) = \frac{c^2 \gamma^2}{2} [F(\tau)]^2 \qquad (1)$$

τ is the autocorrelation delay time and c the overall photosensitivity of the detecting system. γ is a coherence factor associated with the geometry of the detecting system. $F(\tau)$ is the phase correlation function of the scattered light which for a monodisperse system where spectral broadening is due to translational diffusion alone is given by:
Figure 1 Normalized autocorrelation functions of intensity fluctuations of light scattered from two samples of cellulose trinitrate in ethyl acetate. Concentrations are $\sim 10^{-3}$ g/ml. $\times$, 45°; $\bigcirc$, 60°; ●, 75°; $\triangledown$, 90°
Figure 2 Homodyne beat spectrum for a solution of cellulose trinitrate (DP_W = 3300) in ethyl acetate at a concentration of $\sim 10^{-3}$ g/ml. The solid line is a Lorentzian and corresponds to the exponential shown in *Figure 1*. $\times$, 45°; $\triangledown$, 90°

$$F(\tau) = I \exp\left(-K^2 D\tau\right) \qquad (2)$$

where I is the scattered intensity, D the translational diffusion constant and:

$$K = \frac{4\pi}{\lambda} \sin\theta/2 \qquad (3)$$

where λ is the wavelength *in the solution* and θ the angle of scatter.

In the present experiments γ was increased to 0.3 by using smaller stops than previously[12] and removing all lenses from the light receiver system. The bandwidth of the electronic system was 30 Hz to 14 kHz (*3db* points). The criteria for selection of bandwidth have already been discussed. Corrections were made for any resulting distortion of the autocorrelation function in the manner previously described[12]. The effect of dust in the solutions on measurements of this kind has also already been discussed[12]. Solu-

tions were clarified by centrifuging at 30 000Xg for 2 h and in each case using the top 10 ml of 40 ml in the centrifuge bucket for light scattering measurements[17]. Measurements were made in the angular range 45° to 90°.

At the lower concentrations used in the present work the scattered intensity due to the cellulose trinitrate was approximately equal to that due to ethyl acetate. The Rayleigh linewidth of light scattered from the solvent is, however, very broad compared with that of light scattered from the solute. This was verified experimentally. The autocorrelation function of the photoelectric signal due to light scattered from ethyl acetate, was found to be indistinguishable from that due to light direct from the laser attenuated to the same intensity as the scattered light in the manner previously described[11].

In view of the low scattered intensities involved, a few experiments were carried out in which the power spectrum of the photoelectric signal was obtained directly by scanning with a wave analyser[11]. This was done in order to confirm the validity of the results obtained from the autocorrelation function computer.

RESULTS AND DISCUSSION

Figure 1 shows normalized autocorrelation functions plotted against $\tau \sin^2 \theta/2$ for various angles of scatter for two of the samples. The solid lines are exponentials. The lower molecular weight sample shows a systematic deviation from the exponential curve at longer times independent of angle of scatter. This is the expected effect of polydispersity if the variation in $P(\theta)$ over the angular range is approximately the same for each molecular species, a condition which will hold if the polydispersity is not too high. *Figure 2* shows the results of an experiment on the higher molecular weight sample in which the power spectrum was scanned with a wave analyser. The solid line is a Lorentzian and corresponds to the exponential curve in *Figure 1*.

The variation of diffusion constant with concentration was investigated in detail for two of the samples and the results are shown in *Figure 3*. No variation with concentration was detected. This is surprising in view of the high second virial coefficients associated with the ethyl acetate—
Figure 3 Diffusion constant as a function of concentration for two samples of cellulose trinitrate dissolved in ethyl acetate

cellulose trinitrate system. The author has no explanation to offer at present other than that the effects of thermodynamic and hydrodynamic interaction just cancel out.

In the above discussion the effects of internal motion of the polymer chain have been ignored and the results are in fact those expected for translational diffusion alone. However, the theory due to Pecora[18] suggests that for the samples studied here the effects of internal motion should be quite large. This will therefore be discussed further. The results of Pecora's theoretical investigation into the case of a monodisperse freely draining coil are complicated. The phase correlation function can be expressed in the form:

$$F(\tau) = \frac{I}{P(x)} \left[P_0(x) \exp(-K^2 D\tau) + \Sigma P_A(x) \exp - \left(K^2 D + \Sigma \frac{a}{\tau_n} \right)\tau \right] \quad (4)$$

where $P(x)$ is the particle scattering factor for a Gaussian coil and:

$$x = \frac{K^2 \bar{r}^2}{6} \quad (5)$$

where $\bar{r}^2$ is the mean square end to end distance. The contribution due to translation diffusion alone, $P_0(x)$ is given by:

$$P_0(x) = \frac{\pi}{x} \exp(-x/6) \left[\mathrm{erf}\left(\frac{\sqrt{x}}{2} \right) \right]^2 \quad (6)$$

τ_n denotes a relaxation time of the polymer chain and is given by:

$$\tau_n = \frac{\bar{r}^2}{3\pi^2 n^2 D} \quad (7)$$

where n is an integer. $\Sigma(a/\tau_n)$, where a is an integer, represents permitted combinations of relaxation times which occur, and for each combination there is a function $P_A(x)$ the analytical form of which is in general highly complex. Pecora gives numerical values of these functions for $x < 7$. For $x < 1$ the contribution of internal motion is negligible and $P_0(x) \approx P(x)$. For $x < 3$ the summation is dominated by a single term for which $\Sigma(a/\tau_n) = 2/\tau_1$ and Pecora denotes the corresponding value of $P_A(x)$ by $P_2(x)$. This term also represents approximately half of the contribution of internal modes at $x = 7$, the rest comprising terms for which

$$\Sigma \frac{a}{\tau_n} = \frac{4}{\tau_1}, \frac{2}{\tau_2} \text{ and } \frac{1}{\tau_2} + \frac{2}{\tau_1}$$

A qualitatively similar result to that of Pecora has been obtained by Saitô and Itô[19]. They give an expression which after some rearrangement becomes:

$$F(\tau) = \frac{I}{P(x)} \left[\left(P(x) - \frac{x^2}{45} \right) \exp(-K^2 D\tau) + \frac{2x^2}{\pi^4} \sum_n \frac{1}{n^4} \exp - (K^2 D + 2/\tau_n)\tau \right] \quad (8)$$

The various functions of x have here been expressed as power series and limited to the x^2 term. The expression is not quantitatively valid for $x > 1$.

Experimentally $\varphi(\tau)$ is obtained and the contribution of internal motion will appear principally as terms of the form $P_0(x)P_A(x) \exp - [2K^2 D + \Sigma(a/\tau_n)]\tau$. All of these have decay times which are shorter than that of the term due to translational diffusion alone and will never give rise to a 'tail' on the exponential decay as was obtained for one of the samples in the present work (*Figure 1*). This must be attributed to polydispersity as already indicated. If $P_2(x)$ is assumed to represent the dominant contribution of internal motion then $\phi(\tau)$ is given to a first approximation by:

$$\phi(\tau) = \frac{c^2 \gamma^2}{2} I^2 \frac{P_0(x)}{[P(x)]^2} \left[P_0(x) \exp(-2K^2 D\tau) + 2P_2(x) \exp - \left(2K^2 D + \frac{2}{\tau_1} \right)\tau \right] \quad (9)$$

The ratio of the contribution of the two terms and the ratio of the decay times calculated according to Pecora's theory is shown for the highest molecular weight sample ($DP_w = 3300$) in *Table 2*. The values of x are those obtained from conventional light scattering experiments[15]. At first sight the fourth and fifth columns would appear to indicate that the contributions of internal motion are large. However, if plots are made of the sum of the two terms as a function of $\ln\tau$, it can be shown that within 1% $\phi(\tau)$ is indistinguishable from a single exponential over the experimental range. The factor, R, by which the decay time is reduced from that expected for translational diffusion alone is shown in the last column. Although the effect is less than might be expected a variation of some 25% should have been detectable in the present work. A possible explanation why this was not so is that measurements were made at finite concentrations. A Zimm plot consisting of parallel straight lines may be described by the relation:

$$\frac{KC}{R_\theta} = \frac{1}{MP(\theta)} + 2BC \quad (10)$$

where the symbols have their usual meaning. Hence:

$$\frac{d(R_\theta)}{R_\theta} = \frac{dP(\theta)}{P(\theta)} \frac{1}{1 + 2BCMP(\theta)} \quad (11)$$

so that fluctuations in scattered intensity are less than fluctuations in particle scattering factor for positive values of the second virial coefficient, B. For the highest molecular weight sample at a concentration of 10^{-3} g/ml the factors by which intensity fluctuations would be reduced on the

‡ Taking account of higher order relaxation times
Figure 4 Diffusion constant as a function of degree of polymerization for cellulose trinitrate in ethyl acetate. The author's results are represented by the open squares which indicate the limits of error and have been obtained from light scattering Rayleigh linewidth measurements and conventional light scattering measurements. The results of other authors are as follows: ▽, Muisimann[1]; ✕, Gralen[2]; △, Jullande[3]; ○, Newman *et al.*[4]; ●, Meyerhoff[5,6]. Where measurements were not made in ethyl acetate the points shown are those expected assuming the validity of the Stokes—Einstein equation

basis of equation (11) are 0.51, 0.57, 0.64, 0.69 at 45°, 60°, 75°, 90° respectively. The values of R then become 0.97, 0.93, 0.89, 0.88 so that the variation with angle is reduced by about a half and is approximately the same as the experimental error. At concentrations lower than 10^{-3} g/ml measurements were possible only at 45° and 60° due to the low scattered intensity. It is possible that the translational diffusion constants shown in *Table 1* are systematically high due to the neglect of internal motion but it is believed on the basis of the above discussion that the error involved is of the same order as the random error.

The samples investigated in the present work do not have a wide enough range of degree of polymerization to establish a relationship between diffusion constant and molecular weight. The absolute values can, however, be compared with those obtained by other authors using conventional techniques. Such a comparison is illustrated in *Figure 4* which shows diffusion constants for degrees of polymerization above 1000. The author's results lie well within the range of previous results. The dotted lines have slopes of minus unity and −0.8, the former representing a freely draining coil and the latter representing the minimum value of α in the expression:

$$D = AM^{-\alpha} \qquad (12)$$

consistent with the author's results. The true value of α must therefore lie between these limits for the range of degree of polymerization investigated.

The results of other authors shown in *Figure 4* were obtained by a combination of diffusion and sedimentation velocity measurements. Polydispersity considerations are

therefore complicated and direct comparison of the results is difficult. It has been shown that light scattering Rayleigh linewidth measurements yield a Z average diffusion constant if the autocorrelation function is indistinguishable from a single exponential[12]. The molecular weight to which this diffusion constant corresponds is given by M_D where:

$$M_D = \left[\frac{\sum_i N_i M_i^2}{\sum_i N_i M_i^{2-\alpha}} \right]^{1/\alpha} \qquad (13)$$

N_i is the number of molecules with molecular weight M_i. Thus $M_D = M_w$ when $\alpha = 1$, i.e. in the case of a freely draining coil. Thus within experimental error the author's values of diffusion constant and degree of polymerization correspond directly. Assuming $\alpha = 1$ the equivalent hydrodynamic diameter per monomer unit is 0.45 ± 0.03 Å. This, of course, is merely a parameter determining the diffusion constant at high degree of polymerization and has no physical significance.

CONCLUSIONS

Light scattering Rayleigh linewidth measurements made upon solutions of high molecular weight cellulose trinitrate in ethyl acetate by obtaining the autocorrelation function of fluctuations in scattered intensity, yield diffusion constants which are in good agreement with those obtained by conventional techniques. There is no concentration dependence within experimental error ($\pm 7\%$) and no effects due to internal motion are observed. The latter may in part be due to the high second virial coefficient.

Relationships between T_g and cohesive energy: 1. Dependence of T_g on the composition of copolymers

K. Marcinčin and A. Romanov

Polymer Institute of the Slovak Academy of Sciences, Dúbravská cesta, 809 34 Bratislava, Czechoslovakia
(Received 10 January 1974; revised 3 September 1974)

The possibility of expressing the glass transition temperature of copolymers and homopolymers with an n-alkyl side chain as a function of two parameters (cohesive energy and steric factor) is discussed. An empirical equation representing these two factors is proposed. Calculated values are in good agreement with literature data for the investigated systems.

INTRODUCTION

There are several more-or-less empirical equations available in the literature[1-6] which enable the glass transition temperature of copolymers to be expressed as a function of their composition. Wood[2] proposed an equation of the form:

$$T_g = \frac{k(T_{g_2} - T_g)w_2}{1 - w_2} + T_{g_1} \tag{1}$$

where T_g is the glass transition temperature of copolymer, w_2 is the weight fraction of component 2, k is a non-specified constant and $T_{g_{1,2}}$ are the glass transition temperatures of the corresponding homopolymers.

The equations put forward by other authors are in most cases identical with equation (1) provided the constant k is expressed in a convenient form.

For some copolymers the relationship between the glass transition temperature and composition shows a minimum or maximum. It is not possible to describe such a relationship by equation (1). For this reason, Dyvik[7] proposed the equation:

$$T_g = w_1 T_{g_1} + w_2 T_{g_2} - \phi w_1 w_2 \tag{2}$$

where ϕ is an interaction parameter and its value is a quadruple of the deviation from the linear dependence of T_g on weight composition at $w_1 = w_2 = 0.5$. However, it may be determined only from the relationship between T_g and composition which has been found experimentally.

T_g of polymers is affected by a number of factors among which intermolecular forces and steric hindrance are the most significant. In order to express the relationship between these factors, Wyman[8] put forward the equation:

$$\log T_g = b\Sigma n_i E_i + \Sigma n_i E_{S_i} + C \tag{3}$$

where the symbols b, n_i, C, E_i and E_{S_i} denote the constant ($b = 10^{-5}$), molar fraction of component i, constant ($\log T_g$ of reference polymer — polyethylene), intermolecular interaction parameter of component i which is a quantitative measure of cohesive energy, and intramolecular interaction parameter (steric factor) of component i, respectively.

The values of E_{S_i} calculated from the known values of T_g and cohesive energy have been correlated by Wyman with the solution properties of polymers.

Wyman assumes in his equation that the cohesive energy as well as the steric factor is an additive quantity. It follows from the application of the Wyman equation to copolymers that $\log T_g$ is a linear function of molar composition. Only negative deviation from linear dependence of T_g as a function of composition is possible should the dependence of $\log T_g$ on composition be linear. In fact, this dependence of T_g on composition is observed for many copolymers[2,9]. The Wyman equation, however, fails to describe properly the situation when dependence of T_g on composition shows a minimum (i.e. T_g of copolymers in certain composition range fall below T_g of both homopolymers).

DEPENDENCE OF COHESIVE ENERGY ON THE COMPOSITION OF POLYMERS

The cohesive energy of polymers cannot be determined immediately from heat of evaporation. It is found indirectly by several methods but the individual methods do not quite give identical results[10,11].

The cohesive energy may also be obtained by calculation. In general, the Small method of calculation[12] provides quite good results. The calculations are performed according to the formula:

$$E = \rho \frac{(\Sigma n_i F_i)^2}{M} = \frac{F^2}{V} = F\delta \tag{4}$$

ρ, M, F and δ being density of polymer, molecular weight of repeating unit (monomer), attraction constant, and solubility parameter, respectively. Small[12] published the mean values of attraction constants F_i for individual structural units.

It follows from equation (4) that the cohesive energy E changes linearly with the composition of copolymer only in some specific cases (i.e. provided the solubility parameter is equal over the whole range of composition).

Another factor which occurs in equation (4) is the density of polymer, which is a complicated function of inter-
Figure 1 Relationship between T_g (according to Dyvik[7]) and cohesive energy (calculated according to Small[12] assuming the additivity of volume) on the molar fraction of acrylonitrile (AN) for copolymer methyl methacrylate—acrylonitrile

and intra-molecular interactions. Van Krevelen and Hoftyzer[13], however, showed the possibility of evaluating the density of polymers on condition that the volume increments of individual structural units are additive:

$$\rho = \frac{M}{\Sigma V_i} \qquad (5)$$

They calculated the average values of volume increments and demonstrated that the agreement of the values calculated from average increments with the real ones was rather good.

Other authors[14] calculated the proper volume of the molecules of polymers on the basis of the volume of individual atoms and the lengths of bonds. They showed that the coefficient of packing:

$$K = \frac{\text{proper volume of molecule}}{\text{real volume}} \qquad (6)$$

was approximately a constant quantity, the mean value of which was 0.68. They also calculated the average values of the increments of proper volume for individual atoms considering the kind of atoms to which these atoms were bonded in the molecule.

It follows from the above that the molar volume is approximately an additive quantity consisting of volume increments. The linear dependence of molar volume may be assumed to be still more for copolymers in which the structure of monomer units remains preserved. Provided the volume can be expressed in additive terms corresponding to individual homopolymers, the cohesive energy may be calculated easily for copolymers of different composition on the basis of equation (4).

CORRELATION BETWEEN COHESIVE ENERGY AND T_g FOR COPOLYMERS

According to equation (4) the cohesive energy as a function of the composition of copolymer may even show a minimum. In this respect the copolymer methyl methacrylate—acrylonitrile can serve as an illustration. Both the polymers have nearly equal cohesive energies (7206 and 7245 cal/mol respectively) and glass transition temperatures ($105°$ and

96°C respectively). *Figure 1* shows the dependence of cohesive energy and glass transition temperature on the composition of this copolymer. The course of both these quantities is analogous (they pass through a minimum).

To express T_g dependence on copolymer composition we suggest the equation:

$$T_g = S_F 10^{kES_F} \qquad (7)$$

where

$$S_F = \frac{1}{\rho \cdot S_L}$$

and k is a constant (10^{-6}), S_F and ρ denote the steric factor and density of polymer and S_L is the parameter which is a linear function of molar composition.

The values of T_g calculated according to equation (7) are in good agreement with the values measured for the following examples.

Methyl methacrylate—acrylonitrile

For this copolymer a decrease of T_g below the values of corresponding homopolymers[7,16,19] has been found by several authors. Both the homopolymers show approximately equal and relatively high glass transition temperatures. According to the molecular structure the high glass transition temperature of methyl methacrylate is ascribed to the effect of steric hindrance caused especially by the CH_3 group in the α-position. The high glass transition temperature of acrylonitrile is attributed chiefly to the polarity of polymer. The decrease in the glass transition temperature of copolymer may then be interpreted as a decrease in the steric hindrance occurring in methyl methacrylate by the effect of acrylonitrile units and as a disturbance of polar interactions in acrylonitrile by the effect of methyl methacrylate units. In *Figure 2* the dependence of glass transition temperature calculated for this copolymer according to equation (7) is compared with the course measured by Dyvik[7] ($\psi = 60K$). As is clear from this
Figure 2 T_g as a function of molar composition for copolymers methyl methacrylate—methacrylonitrile (1) and methyl methacrylate-acrylonitrile (2). ——, Calculated on the assumption of a linear relation between S_L and molar composition; — · — · —, according to Dyvik[7] for $\phi = 24K$ and $\psi = 60K$
Figure 3 T_g as a function of molar composition for copolymers methyl methacrylate—styrene (1) and styrene—acrylonitrile (2) calculated on the assumption of a linear relation between S_L and molar composition
Figure 4 T_g as a function of molar composition for copolymer methyl methacrylate—methylacrylate. — · — · —, according to Dyvik[7] ($\varphi = 40$K)

Figure, the decrease in the glass transition temperature may be due to the change in cohesive forces at a practically equal steric factor.

Methyl methacrylate—methacrylonitrile

With the copolymer consisting of this pair of monomers the situation is similar to that one which occurs with the pair methyl methacrylate—acrylonitrile. The dependence of glass transition temperature on composition is well described qualitatively by equation (7) (*Figure 2*). The calculated values are within the whole range of composition smaller than that stated by Dyvik[7] ($\varphi = 24$K) but the difference does not exceed 2K.

Methyl methacrylate—styrene

The properties of the copolymer consisting of this pair of monomers to a certain degree depend on the polymerization conditions. In general, a small negative deviation has been found in the dependence between glass temperature and composition and according to Dyvik[7] at the equimolar composition its value is about 3–4K. The curves

calculated according to equation (7) and presented in *Figure 3* show a negative deviation also.

Styrene—acrylonitrile

The relationship between the glass transition temperature and the composition of this copolymer has been studied previously[15]. They have found that the glass transition temperatures of copolymers are a few degrees higher than those of the corresponding homopolymers. The calculated relation presented in *Figure 3* describes this fact although it shows a positive deviation.

Methyl methacrylate—methyl acrylate

For this copolymer, either a positive (in one case[16]) or negative (in several cases[2,7,17]) deviation has been published for the relation between glass transition temperature and composition. The relationship calculated according to equation (7) shows a negative deviation but it complies fairly well with the values found experimentally for $\varphi = 40$K[7] (*Figure 4*).

Methyl methacrylate—ethyl acrylate

The interaction parameter φ of this pair of monomers varies in the range $\varphi = 60$–80K[7,18]. A similar relation has been also found for mutually crosslinked mixtures of both homopolymers[8]. The relationship calculated according to equation (7) agrees fairly well with the values for $\varphi = 60$K (*Figure 5*).

Change in glass transition temperature due to the prolongation of the side methylene chain

Equation (7) also expresses the change of T_g due to the prolongation of the side methylene chain. *Figure 6* shows the variation of the parameter S_L with the number of methylene groups in the side chain for 6 homologous polymer series. The dependence is linear in all cases presented. By comparing the course of T_g or parameter S_L of the copolymer methyl methacrylate/n-butyl methacrylate[7] and the homologous series of alkyl methacrylates it may be concluded that the effect of a —CH_2— group in the side chain is equal and independent whether a greater number of smal-

ler alkyl groups or proportionally lesser number of longer groups is present.

DISCUSSION

In equation (7), the product of cohesive energy and the steric factor (E, S_F) is taken as the measure of intermolecular forces. The presumption is being introduced that in the case of lower steric hindrances, intermolecular forces of smaller chain section have to be overcome to release molecular motion. The influence of flexible side chain on T_g may be given as an example. In the polymer of this type

side chains of molecules may perform certain kinds of motions even below the glass temperature. Intermolecular forces (potential barriers) which have necessarily to be overcome at the motion of a certain link (section) of the chain will, in this case, be lower when compared with the one, where the motion (rotation) of the side chain due to steric hindrances is not made possible. The mutual dependence of cohesive energy and steric factor is also referred to by Wyman[8].

The glass transition temperatures of polymers of similar composition are different in many cases. This can be shown best with polymer isomers (*Table 1*).

It is interesting that the isomer with lower T_g shows a higher cohesive energy. According to equation (4) the isomer with higher cohesive energy manifests a higher density. By including the density of polymer into the expression for steric factor (equation 7) we obtain an equal value of the parameter S_L for isomers. The value of the constant k in equation (7) was so chosen that this equation might express most accurately the relationship between T_g and composition for the copolymer methyl methacrylate—acrylonitrile. The calculated T_g dependences on composition show quite good agreement even for the other copolymers referred to with experimental results.

Relationships between T_g and cohesive energy: 2. Prediction of T_g of homopolymers

K. Marcinčin and A. Romanov

Polymer Institute of the Slovak Academy of Sciences, Dúbravská cesta, 809 34 Bratislava, Czechoslovakia
(Received 10 January 1974; revised 3 September 1974)

An empirical equation expressing T_g of polymers as a function of cohesive energy and steric factor is suggested so that the parameter V_S in this equation may be considered to be an additive quantity. From the data on 44 polymers including 6 homologous series the increments of V_S were calculated for individual structural units. The agreement of the calculated with the measured values of T_g found for homopolymers and copolymers is discussed.

INTRODUCTION

The prediction of the glass transition temperature of polymers from chemical structure is of remarkable theoretical and practical importance. There are several methods[1-3] which have been proposed for the calculation of the glass transition temperature of polymers from the chemical structure of monomer unit. Some authors[1,2] started from the equations describing the dependence of T_g of copolymers on composition and calculated the additive temperature parameters for individual structural units (groups of atoms). Lee[2] also took into consideration in his calculations how the groups in a molecule of monomer were bonded. Askandskij[3] put forward an empirical equation for the calculation of T_g of polymers in which he assumed the additi-
Figure 1 Parameter V_S as a function of the number of methylene groups in side chain for: ■, poly(alkyl acrylates); ●, poly(alkyl methacrylates); ○, poly(4-alkylstyrenes); △, poly(alkyl chloroacrylates); ▲, polyalkenes; □, poly(vinyl alkyl ethers)

Table 1 Increments V_S of $-CH_2-$ group for individual homologous series

Homologous series	Increment V_S $(-CH_2-)$	Average
Poly(n-alkyl methacrylates)	0.254	
Poly(p-n-alkyl styrenes)	0.272	
Poly(n-alkyl acrylates)	0.270	0.258
Poly(n-alkenes-1)	0.264	
Poly(n-alkyl vinyl ethers)	0.261	
Poly(n-alkyl chloroacrylates)	0.235	

vity of another parameter occurring in this equation (different from temperature). In the equations expressing the relationships between T_g and cohesive energy some additive parameters are also present[4,5].

METHOD OF CALCULATION

In Part 1[7] it has been shown that the parameter S_L in the equation

$$T_g = \frac{1}{\rho S_L} 10^{k(F^2/MS_L)} \qquad (1)$$

increases linearly if the alkyl side is prolonged and assuming the linear dependence of this parameter on molar composition is valid the equation expresses fairly well the glass transition temperature of copolymers. But the parameter S_L does not fulfil the postulate of additivity.

It is known that flexible n-alkyl side chain decreases T_g of polymers more than a non-linear alkyl side chain with the same number of carbon atoms. The polymer with a flexible side chain may be considered as a copolymer consisting of several monomer units. In this case the calculation of steric factor demands that the molar cohesive energy corresponding to such monomer unit be taken into consideration. If we assume for simplification that the number of monomer units is proportional (equal) to molecular weight, equation (1) may be written in the form:

$$T_g = \frac{V}{V_S} 10^{k\,(F^2/MV_S)} \qquad (2)$$

where V is molar volume of monomer unit, V_S is additive parameter $(V_S = MS_L)$ and the constant $k = 10^{-4}$. The

value of constant $k = 10^{-4}$ was chosen so that, for the polymer of molecular weight of monomer unit $M = 100$, equation (2) was numerically equal to equation (1) or equation (7) in Part 1[7].

The values of V, M, F were assigned, experimental T_g being available for 44 polymers including 6 homologous series. The resulting transcendental equations were solved graphically for V_S of these 44 polymers.

The dependence of the parameter V_S on the number of $-CH_2-$ groups in the side chain may be expressed fairly well by a straight line (*Figure 1*). The slope of lines is almost equal (*Table 1*) for individual homologous series and represents the increment of the parameter V_S for methylene groups. Th arithmetic mean for six homologous series is $V_S(-CH_2-) = 0.258$. The glass transition temperature of polyethylene calculated from this value is 196K and complies well with the value obtained by extrapolating the glass transition temperature of a copolymer of ethylene with different monomers[8,9]. Assuming the additivity of parameter V_S is valid, the values of the increments V_{Si} have been calculated for individual structural units (groups of atoms) using least squares procedures. The calculated values of increments V_{Si} are given in *Table 2*. *Table 3* also contains the

† Data after Brandrup and Immergut[11]

differences $V_S - \Sigma n_i V_{S_i}$ and the deviations of the transition temperatures calculated by means of the increments V_{S_i} from the real ones.

DISCUSSION

The assumption that the molecular weight is proportional to the number of monomer units in equation (2) is only approximate. In the case of vinyl polymers the molecular weight of monomer unit is approximately proportional to the number of atomic groups able to rotate freely around simple bonds except polymers containing structural skeletons (rings) or heavier atoms. Owing to this the increment $V_S(-CH_2-)$ (*Table 1*) is the smallest for the homologous series of poly(n-alkyl chloroacrylates) and differs most from the average value. This is also seen in the deviation of the glass transition temperatures obtained from average increments of the parameters V_S from the real values of T_g (*Table 3*, polymers 30–33). For poly(α-methylstyrene) (polymer 8) and homologous series of poly(n-alkyl methacrylates) (polymers 16–22) a positive deviation appears. On the other hand, it is negative in the case of homologous series of poly(n-alkyl acrylates) (polymers 23–26) and poly(p-n-alkyl styrene). It is to a great extent due to the fact that polyacrylonitrile (polymer 3) and polymethacrylonitrile (polymer 4) has also been involved in the calculation of the average values of increments V_{S_i}. For these polymers the difference in the values of V_S is rather higher than that contributed by a $-CH_3$ group of poly(α-methylstyrene) and poly(n-alkyl methacrylate). The deviations occurring with polymers 3 and 4 are also relatively high and of opposite character. High negative deviations also appear in the case of polymers with t-alkyl groups in the side chain (polymers 39–41). It indicates the need of a different evaluation of the $-CH_3$ group according to the kind of bonding in the molecule. For this reason it would be necessary to introduce another rule.

The values of molar cohesive energy are referred to room temperature. For the correlation of T_g with cohesive energy it would be more correct to use values of cohesive energy at T_g of individual polymers. A disagreement may also be due to other factors affecting T_g of polymers (tacticity, crystallinity, symmetry of molecule etc.) the total of which is difficult to express by a single parameter.

The assumption of additivity of the parameter V_S (equation 2) provides fairly good results for T_g of copoly-

Star polymers from styrene and divinylbenzene

Helmut Eschwey and Walther Burchard
Institut für Makromolekulare Chemie der Universität Freiburg, D 78 Freiburg i. Br., West Germany
(Received 28 May 1974)

The principle of anionic block copolymerization of styrene and divinylbenzene, first employed by Rempp and his coworkers, is further developed. Rempp's method (1) of divinylbenzene polymerization with long 'living' polystyrene chains, and our method (2) of the polymerization of styrene with poly-divinylbenzene, bearing a number of 'living' carbanionic groups, are shown to be the two limiting cases of the styrene—divinylbenzene block copolymerization. By preparing 'living' polystyrene of shorter chain lengths than was used by Rempp *et al.* all stages of polymerization within the two limits are realized. In particular, star molecules with a large number of short side chains, according to Rempp's method, are prepared in a first step, and these stars with 'living' nuclei are used to prepare stars (3) according to our method. The number of branches of the original star is doubled by this technique. Also mixed stars with both polystyrene and polyisoprene branches are prepared. The latter are characterized by light scattering in benzophenone, which is isorefractive with the polystyrene moiety. The g' factors of the stars are compared with existing theories, but in no case is satisfactory agreement obtained.

INTRODUCTION

Common block copolymers of the A—B and B—A—B type are usually prepared by anionic copolymerization with either lithium alkyls or sodium naphthalene as catalysts[1]. In these examples lithium alkyls should be regarded as mono-functional initiators while the sodium naphthalene catalyst leads to a bifunctional initiation.

A new type of block copolymer has been obtained by the anionic copolymerization of divinylbenzene (DVB) with styrene or other suitable monomers. By this technique star-shaped block copolymers are obtained consisting of a nucleus of polydivinylbenzene and rays of linear chains, e.g. polystyrene or polyisoprene etc. The structure of this type of block copolymer is represented in *Figure 1*.

Two different methods of preparation of such star molecules have been described in the literature. In the first case[2–5] living polystyrene bearing one carbanionic end group is copolymerized with a small amount of divinyl-benzene resulting in small densely crosslinked nuclei of polydivinylbenzene with several pendant polystyrene chains. By this method Rempp and his coworkers pre-pared star molecules with four to twenty polystyrene branches.

In the second method[6], recently developed in our laboratory, divinylbenzene is anionically polymerized in dilute solution by n-butyl lithium, where densely cross-linked polydivinylbenzene particles are obtained. These particles bear quite a number of living carbanionic groups capable of polymerizing styrene or other monomers yield-ing star molecules. The size and functionality of the poly-divinylbenzene nuclei are increased by increasing the ratio $R = [DVB]/[butyl lithium]$ and the overall concentration of divinylbenzene.

Both methods have different advantages. According to Rempp's method the star molecules are characterized by a relatively narrow molecular weight distribution but the number of branches is highly controlled by a pronounced diffusion control of the reaction. In contrast to Rempp's method any desired functionality of the nuclei ($p = 4 – 4 \times 10^5$) and any length of the side chains can be prepared by the second method but the products are rather polydisperse.

In spite of the differences in principle, these two methods can be considered as two limiting cases of divinylbenzene polymerization. In the first case the initiator is a long 'liv-ing polymer' chain ($PSt^- Li^+$, $DP > 100$),while in the second case it is of low molecular weight ($Bu^- Li^+ = butyl lithium$).

From this point of view all stages in between should be capable of synthesis.

Figure 1 Sketch of a star block co-polymer

EXPERIMENTAL

Materials

Toluene and tetrahydrofuran (both Merck) were dried over sodium. Styrene and isoprene (both BASF) were purified in the usual manner and stored over calcium hydride. Butyl lithium supplied by Merck—Schuchardt as a 20% solution in hexane was used without further treat-ment. The concentration was determined by titration following the description of Gilman and Haubein[7]. *p*-Di-

vinylbenzene was separated from the Merck–Schuchardt commercial mixture by means of its tetrabromide as described by Naumann[8]. Purity was checked by n.m.r. and found to be about 98%. Before use, all solvents and monomers were distilled under high vacuum into flamed breakseal ampoules and sealed off.

Polymerization procedure

Linear living polystyrene was polymerized under high vacuum at room temperature using a mixture of 98% toluene and 2% THF at a monomer concentration of 5%.

In order to prepare star-shaped molecules according to method (1), the solution mixture of living polystyrene was cooled down to $-78°C$ and p-divinylbenzene was added. At this temperature the rate of polymerization can be neglected and the reactants are allowed to mix completely. The reaction vessel was then warmed up to room temperature and was left about 8 h for complete polymerization. An aliquot of this polymer solution was withdrawn under an inert gas atmosphere and terminated with methanol. For the preparation of star molecules according to method (3), styrene or isoprene was added to the remaining part and polymerized to complete conversion. All samples were precipitated in methanol and dried *in vacuo* at 35°C.

Physical measurements

Viscosity. All measurements were performed in toluene at 20°C with an Ostwald viscometer which was dimensioned such that the kinetic energy corrections were negligible. For the determination of the g' factors the intrinsic viscosity/molecular weight relationship of Meyerhoff[9] was used for linear polystyrene.

Light scattering. A Sofica photogoniometer (PDG 43 000) instrument was used. All measurements were performed with light of wavelength 436 and 546 nm using benzene at 20°C as solvent for the polystyrene stars and benzophenone at 60°C for the mixed polystyrene–polyisoprene stars. The molecular weights were calculated as usual from Zimm plots. The refractive index increments of polystyrene in benzene were taken from the literature[10]. The same values have been assumed for polydivinylbenzene. The refractive index increments of polystyrene and polyisoprene in benzophenone were found by extrapolation of a plot of dn/dc in various solvents against the refractive indices of the solvents n_D using data from the literature[10]. The following values were obtained:

$$\lambda_1 = 436 \text{ nm: } dn/dc = -0.0865 \atop \lambda_2 = 546 \text{ nm: } dn/dc = -0.0915 \Bigg\} \text{ polyisoprene}$$

$$\lambda_1 = 436 \text{ nm: } dn/dc = 0.0090 \atop \lambda_2 = 546 \text{ nm: } dn/dc = 0.0055 \Bigg\} \text{ polystyrene}$$

RESULTS AND DISCUSSION

Divinylbenzene polymerization initiated by short 'living polystyrene' chains

To prove the statement at the end of the introduction, living short chain polystyrene of 4 to 160 monomer units in length were prepared and subsequently copolymerized with DVB at almost constant overall concentration (5%). The stars were characterized by light scattering and viscosity measurements and the number of branches, p, and the molecular weight of the nuclei were calculated according to:

$$p = \frac{M_w(\text{star})}{M_w(\text{branch})} \times m(\text{styrene}) \tag{1}$$

$$M_w(\text{nucleus}) = M_w(\text{star}) \times m(\text{divinylbenzene}) \tag{2}$$

where $M_w(\text{star})$, $M_w(\text{branch})$ and $M_w(\text{nucleus})$ are the weight average molecular weights of respectively the stars, the polystyrene branches and the polydivinylbenzene nuclei, and $m(\text{styrene})$ and $m(\text{divinylbenzene})$ are the mass fraction of styrene and divinylbenzene used.

Equations (1) and (2) follow from the three relationships:

$$p = \frac{\Sigma M_w(\text{branch})}{M_w(\text{branch})} \tag{1'}$$

$$M_w(\text{star}) = \Sigma M_w(\text{branch}) + M_w(\text{nucleus}) \tag{2'}$$

$$\frac{\Sigma M_w(\text{branch})}{M_w(\text{nucleus})} = \frac{m(\text{styrene})}{m(\text{divinylbenzene})} \tag{3'}$$

where $\Sigma M_w(\text{branch})$ is the sum of molecular weights of the p branches of one star molecule. It should be noticed that equations (1')–(3') are strictly valid only for the number averages, but for branches of homodisperse chain length these equations may be considered as useful approximations.

The molecular parameters of these stars are collected in *Table 1*. Curve A in *Figure 2* shows the dependence of the number of branches, p, on the degree of polymerization of the initiator. For a better comparison the data obtained by Rempp *et al.*[3] are replotted in *Figure 3*. *Figure 4* demonstrates the interdependence of the size of the nuclei and the number of branches. Line A in *Figure 2* reveals two

striking features: (i) the two series of experiments with R_1 = 3 and R_2 = 5 yield within experimental error the same curve; (ii) the curve of Rempp *et al.* (*Figure 3*) was not correctly extrapolated to short chains, actually the number of branches increases sharply with decreasing chain length of the initiator, arriving at $p \simeq 16\,000$ for *DP*(initiator) = 10.8. The limit of divinylbenzene polymerization with butyl lithium was not accessible in this series of experiments, since under the applied conditions the critical branching is exceeded and gelation occurs. To verify this limit, one has to perform the same series of experiments at much lower concentration[6,11-14].

These experiments demonstrate that, in the range of short chain initiation, the critical point of gelation depends on both, the concentration of divinylbenzene and on the chain length of the initiator. In the present case the critical chain length is found $DP^{\text{crit.}}_{\text{initiator}}$ = 10 from the plot of *Figure 5*.

The sharp decrease of the branch numbers per nucleus with increasing chain length resembles the familiar dependence of the grafting efficiency[15] for star and comb molecules, which in the case of four star molecules has been conclusively interpreted by Roovers and Bywater[16] to be due to a diffusion controlled polymer-polymer reaction.

Applying similar considerations, the correlation between polystyrene chain length and number of branches, *p*, can be interpreted as follows. The reaction may be conveniently separated into three steps. First, each living polystyrene initiates the polymerization of linear poly(*p*-divinylbenzene) chains with the degree of polymerization of the polydivinylbenzene block *DP* = *R* (see *Figure 6*). This is in agreement with studies of Black and Worsfold[17]. In the second step, the pendant double bonds will be crosslinked, where each crosslinking necessarily implies one polystyrene branch. However, with increasing polystyrene chains, crosslinking becomes more and more hindered because now the primary chains have to move through a shield of polystyrene branches before crosslinking can take place. Thus in the third step intramolecular ring formation is favoured resulting in particles with a limited number of branches. It is evident that crosslinking becomes also more hindered with increasing chain length in agreement with our experimental results*.

Figure 4 demonstrates the reasonable finding that for a given *R* the branch number increases with the size of the nucleus. The shift of the M_w(nucleus) *versus p* line to

---

* These difficulties do not occur in method (2)[6], where polydivinylbenzene particles are used as anionic initiators, because in this case neither the branch number nor the chain length hinder the propagation step.

higher values of M_w(nucleus) reflects the simple relationship that with increasing R the polydivinylbenzene block in the primary chain (see *Figure 6*) is increased by the same factor $R_2/R_1 = 5/3$. Thus, *Figure 2* demonstrates that the *number of branches* is determined by the polystyrene chain length, while *Figure 4* shows that the *size of the nuclei* for a given p is controlled by the ratio R. This is of practical importance for the synthesis of star molecules of different nucleus size but the same number of branches. The control of the crosslinking reaction by the chain length can also be recognized from *Table 1*, because the size of the nuclei and the number of branches increase as the polystyrene chains become shorter. Therefore short polystyrene branches correspond to larger molecular weights of the nucleus and large number of branches, p.

Styrene polymerization initiated by star molecules with 'living' nuclei (method 3)

A star molecule with p branches, prepared by Rempp's method, bears p carbanionic groups inside the nucleus, if termination by impurities is excluded. Therefore, it should be possible to use these living nuclei of the star polymers as polyfunctional initiators for the anionic polymerization of styrene or other monomers, in the same manner as we have shown recently for pure polydivinylbenzene particles[6]. This would result in living star molecules and, in the ideal case, the number of branches should be doubled.

The conditions of polymerization were chosen such that the length of the newly polymerized polystyrene branches equal those of the already existing ones. Line B in *Figure 2* shows the results. The increase of the molecular weights agrees well with the values calculated theoretically, with the exception of the stars with very large nuclei, where higher molecular weights and eventually gelation are found. The satisfactory agreement does not necessarily mean that the number of branches is exactly doubled. It is conceivable that the number is smaller, and this would result in longer chains.

To test this, a further quantity defining the number of branches p is needed. According to theories on star mole-

cules[18,19] such a relationship is given by the g' factor:

$$g' = [\eta]_{\text{branched}} / [\eta]_{\text{linear}}$$

where the viscosities of the linear and branched materials have to be taken for the same molecular weight. Strictly speaking, the linear and branched samples should also have the same molecular weight distributions. However, these conditions cannot be realized experimentally. Therefore we determined the g' factors experimentally for stars prepared according to methods (1) and (2)[6] (see *Figure 7*). With the aid of this relationship the number of branches of the stars prepared by method (3) can be estimated independently from their viscosities.

If p_1 is the number of branches of the star prepared due to method (1), and p_2 is the number of branches of the corresponding star prepared by method (3), then (i) $p_2 = 2p_1$ indicates, that all living carbanionic groups of a star 1 have initiated propagation of chains, while if (ii) $p_2 < 2p_1$ some of the living ends were wasted, and finally (iii) if $p_2 > 2p_1$ several stars must have been tied together presumably by free double bonds. *Table 2* shows that p_2 is very close to $2p_1$. The possibilities of preparation as described in this and the preceding section are schematically summarized in *Figure 8*.

We are aware that the experimentally determined g' versus p realtionship cannot be directly compared with existing theories[18,19] mainly for two reasons. First, our samples have a certain molecular weight distribution and secondly, the stars have a more or less extended nucleus and consequently the g'(star) factor is determined by the number of rays of the star and the g'(nucleus) factor of the branched nucleus.

Nevertheless, it is instructive to compare the experimental relationship with the theoretical ones for homodisperse point centred stars. This is done in *Figure 9*.
Figure 7 Plot of g' versus p for star molecules prepared according to methods (1) and (2)

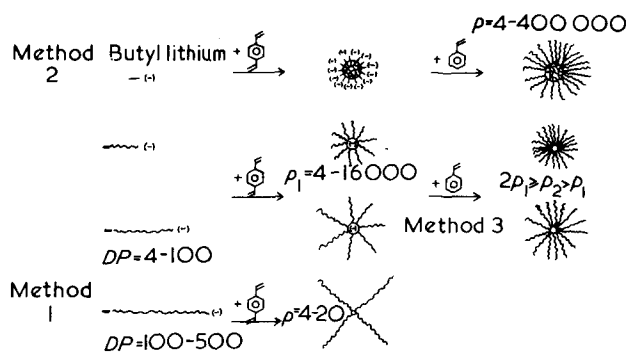
| Sample | Star 1 | | Star 2 | | |
	g'	p_1	$2p_1$	g'	p_2
74	0.69	4	8	0.33	8 ± 2
73	0.09	50	100	0.05	100 ± 25


Figure 8 Principles of the anionic star polymerization demonstrated with the example of *p*-divinylbenzene/styrene
Figure 9 Double-logarithmic plots of g' versus p; $-\bullet-$, Experimental; $-\cdot-\cdot-$, according to Zimm and Kilb[18], $g' = g^{1/2}$; $\cdots$, $g = g$ (free draining case of ref 18); $---$ according to Zimm and Stockmayer[19] $g' = g^{3/2}$. $g = \langle S^2 \rangle_z(\text{star})/\langle S^2 \rangle_z(\text{linear}) = (3p - 2)/p^2$

Measurements of g' performed by Zilliox[20] in the range of $4 \leqslant p \leqslant 20$ using method (1) are not shown in this plot. A similar dependence of g' on p was found but the values are about 20% larger than found by us. The deviations are probably caused by differences in size of the nuclei. Owing to the present state of knowledge on the viscosity of branched materials it appears to be unjustified to draw any conclusions from this comparison[21].

Isoprene polymerization initiated by 'living' polystyrene star molecules

Instead of polymerizing styrene with 'living' polystyrene star molecules as was shown in the previous section, the living polystyrene stars can be used to initiate isoprene branches. This would result in a 'mixed' star bearing the same number of polystyrene and polyisoprene branches. Such stars are of interest not only because of some remarkable mechanical properties to be expected, but also for a check of light scattering theories on block copolymers[22].

Polystyrene has a refractive index of $n_D = 1.59-1.60$[23] while polyisoprene has a lower one of $n_D = 1.5191$[24]. Using benzophenone as solvent with $n_D = 1.5975$ the polystyrene moieties will show no refractive index increment and will therefore scatter no light. Light scattering is caused in such

Table 3 Comparison of the experimental and calculated branch numbers after addition of isoprene to polystyrene stars with living nuclei

Studies on the formation of poly(ethylene terephthalate): 3. Catalytic activity of metal compounds in transesterification of dimethyl terephthalate with ethylene glycol

Kosuke Tomita and Hiroaki Ida
Research and Development Center, Unitika Ltd, 23 Kozakura, Uji, Kyoto 611, Japan
(Received 4 July 1974)

The rate constant of transesterification of dimethyl terephthalate (DMT) with ethylene glycol (EG) in the presence of various metal compounds as catalysts at 197°C, calculated from the quantity of formed methanol, was·used to evaluate each metal compound in its catalytic activity. First, in the case of highly basic metal salts the rate constants were found to be extremely large in the initial stage of the reaction. These values depended on the basicity of the metal salts, but decreased rapidly with the progress of the reaction, and reached values which were not appreciably dependent on the basicity. Secondly, in the case of metal salts of lower basicity such a phenomenon was not observed, and single rate constants were recognized throughout the reaction period. These rate constants were logarithmically correlated by a straight line (mountain-shaped) in a plot vs. stability constants ($\log \beta_1$) of dibenzoyl methane (DBM) complexes of the corresponding metal species. Also in the case of highly basic metal salts, the rate constants in the latter stage followed the same straight line. Consequently, the stability constant of DBM complex of each metal species was found very useful as a forecast of catalytic activity of the metal compound. The compound of metal species with values of $\log \beta_1$ ranging from 9 to 11 was most active as the catalyst.

INTRODUCTION

Poly(ethylene terephthalate) (PET) is produced by poly-condensation of bis(2-hydroxyethyl) terephthalate (BHET) or its oligomers, usually formed by transesterification of dimethyl terephthalate (DMT) with ethylene glycol (EG). This transesterification occurs with removal of formed methanol at a temperature of nearly 200°C under atmospheric pressure, and the presence of a catalyst is essential for the effective formation of BHET or its oligomers.

A knowledge of the catalyst in the transesterification of DMT with EG is important for the polyester—fibre industry, but at the present time little is known about the mode of catalytic activity.

In the present study transesterification of DMT with EG was carried out in the presence of various metal compounds as catalysts, and some rules governing the catalytic activity were found.

EXPERIMENTAL

Reagents

DMT was a commercial 'fibre grade' product, and was used without further purification. EG was also a commercial 'fibre grade' product, and was purified by distillation prior to use.

Most of the catalysts were metal acetates. Commercial products (guaranteed reagent grade) were used without further purification. Antimony(III) acetate was synthesized according to the method of Nerdel and Kleinwächter[1], and aluminium acetate by the method of Pande and Mehrotra[2].

Transesterification

Transesterification was carried out at 197°C (DMT/EG = 0.5 mol/1.0 mol) as described in a previous paper[3], and the progress of the reaction was followed by measuring the quantity of formed methanol.

EVALUATION OF CATALYTIC ACTIVITY

Previously, Griehl[4] and Sumoto[5] investigated transesterification of DMT with EG, and compared the activities of some catalysts from a plot of quantities of formed methanol vs. reaction time. These are, however, too simple as a means of evaluation, and are insufficient to correlate catalytic activity with reaction mechanism.

Catalytic activity must be evaluated from the rate constant but the only study made from such a standpoint is that by Yoda *et al.*[6]. However, this paper is also insufficient in that the rate equation was too simplified, a treatment of highly basic metal salts was left out of consideration, and the study of low active catalysts was insufficient (their rate constants were regarded as zero).

The authors calculated the rate constants according to the kinetic treatment proposed in a previous paper[3], and in the case of low active catalysts the reaction could be followed by using the apparatus described in ref 3, and in the case of extremely low active catalysts rate constants could be calculated according to the relationships given earlier[3].

RESULTS AND DISCUSSION

Figure 1 shows the variation of the reaction with various metal acetates as catalysts (1×10^{-4} mol/mol DMT).

It is noteworthy that highly basic acetates, e.g., alkali metal acetate, give a different curve from others. This problem is discussed first, and a comprehensive view including other acetates is given later.

Catalytic activity of highly basic metal salt

According to ref 3 the rate equation is:

$$k_a t = \frac{V_{100}}{V_0} \left\{ \frac{V_{100}y}{100 - y} + (V_0 - V_{100}) \log \frac{100}{100 - y} \right\} \quad (1)$$

where k_a is an apparent rate constant which depends on the catalyst concentration, y is the degree of conversion (%), V is a volume of the reaction mixture and the subscripts 0 and 100 are used to denote y, 0% and 100%, respectively. By application of equation (1) to sodium or calcium acetate catalyst (*Figure 1*), and plotting the Y values (the right hand term of equation 1) thus obtained against time, *Figure 2* results. The slopes of these rate plots correspond to k_a. In ref 3, the rate plots for zinc acetate and manganese acetate gave straight lines over a wide conversion range, i.e., single rate constants were recognized throughout the reaction. In *Figure 2*, however, the rate constants are found to be extremely large in the initial stage, and then rapidly decrease with the progress of the reaction.

The catalytic activity of highly basic metal salt was further investigated by replacing the anionic species of sodium salt (1×10^{-3} mol/mol DMT). *Figures 3* and *4* show the results.

Figure 4 indicates that as the basicity of anionic species decreases the shape of a curve approaches a single straight

Figure 2 Application of equation (1) to data for sodium acetate and calcium acetate in *Figure 1*: ○, Na; ●, Ca

line, and that after the initial stage the slopes of these rate plots are not appreciably dependent on the anionic species, i.e. the anionic species has an effect mainly on the slopes in the initial stage.

The rate constant in the initial stage and its relationship to the basicity of anionic species are shown in *Figure 5*. In this figure k_{basic} is the rate constant in the initial stage and does not depend on the catalyst concentration: k_{basic} was calculated from k_a in the initial stage. As shown in *Table 1*,

Figure 1 Time—conversion curves of the transesterification of DMT by EG with various metal acetates as catalysts: ●, Zn; ▽, Pb; ⊕, Ce; ○, Mn; △, Co; ⊡, Cd; +, Mg; ◆, Ca; ▲, Li; X, Na; ▪, K; ▼, Sn
Figure 4 Application of equation (1) to data in *Figure 3*
Figure 5 Rate constants in the transesterification of DMT by EG with some sodium compounds against the basicity of the corresponding anionic species

the pK_a value for the conjugate acid of anionic species is used as the value of basicity of anionic species.

Figure 5 shows that according to an increase in basicity of anionic species the rate constant increases, and that a linear relationship exists between log k_{basic} and pK_a. This result suggests that the catalytic species of the sodium salt in the initial stage of the reaction is the base.

The degree of breaking of the linear relationship in the rate plot (*Figure 4*) becomes progressively greater according to the increase in the basicity of anionic species, and becomes negligible with the decrease in the basicity.

This phenomenon may be attributed to the decrease in basicity of highly basic salt with the progress of transesterification. In transesterification of DMT with EG, carboxyl groups will be formed as a result of a side reaction, which may cause the above decrease in the basicity.

On the other hand, after the initial stage of the reaction, the slopes of rate plots are not appreciably dependent on the kind of sodium compounds. Consequently these slopes are considered to show the inherent catalytic activity of sodium compounds. Thus, there are two catalytic species

in a sodium compound: anionic species and another species persisting after the disappearance of basicity.

With regard to the latter, sodium acetate was compared with calcium acetate. Basicity of sodium acetate is evidently higher than that of calcium acetate. This fact corresponds to the relationship between two slopes of their rate plots in the initial stage (see *Figure 2*). After the initial stage, however, it is seen in *Figure 2* that the slope of the rate plot is greater in the later stages contrary to expectation based on basicity. This result suggests that catalytic activity after the initial stage does not depend on basicity but on something of the reverse characteristic, i.e. acidity.

Catalytic activity of other metal salts

Figure 1 suggests that each of the metal salts except for the highly basic metal salts do not show the above tendency. In order to clarify this suggestion, equation (1) was applied to these data as shown in *Figure 6*. Each catalyst gives a linear plot over a wide conversion range, i.e. the rate constant remains constant throughout the reaction period.

Table 1 Basicity of some sodium compounds

Sodium compounds	pK_a values for conjugate acids of anionic species	Ref
ethylene glycoxide	15.4	7
phenoxide	10.0	8
acetate	4.76	8
benzoate	4.20	8
Figure 6 Application of equation (1) to data in *Figure 1*, except for highly basic metal acetates
Figure 7 Time—conversion curves of the transesterification of DMT by EG with some zinc compounds as catalysts: O, phenoxide; ●, acetate; △, benzoate

These metal salts are nearly neutral and therefore, the inactivation of anionic species, as described in the preceding section, may be almost negligible.

In the case of the sodium salt, catalytic activity varies extensively with the kind of anionic species. On the other hand, in the case of the zinc salt (1×10^{-4} mol/mol DMT) *Figure 7* shows that the variation of the anionic species from acetate to phenoxide or benzoate did not influence catalytic activity. The application of equation (1) to these data (*Figure 8*) shows that a linear relationship exists over a wide conversion range with a slope almost independent of the anionic species.

Consequently, the catalytic activity of low basic metal salt seems to be slightly dependent on the anionic species*. Furthermore, these metal salts give single rate constants throughout the reaction period and these values are often higher than those for highly basic metal salts.

From the above point of view, the catalytic species is clearly not basic such as the anionic species, but must be acidic such as the cationic species, i.e., the metal species.

Ordering of catalytic activity

As described above, catalytic activity of a highly basic metal salt is determined by its basicity at least in the initial stage of the reaction, but that of a metal salt discussed in the preceding section is not determined by its basicity. We now discuss the ordering of catalytic activity in the latter.

The only previous related investigation in transesterification of DMT with EG, is ref 6, where electronegativity of each metal species was proposed as the ordering factor of catalytic activity of the metal compound. This proposal is

---

* There are some exceptional cases, e.g., phosphate, etc., which will be discussed in a later paper.

reasonable to a certain degree, but is not entirely satisfactory for the following reasons.

First, catalytic activity changes variously with a reactant, but electronegativity presents only a uniform value regardless of the reactant. Secondly, electronegativity does not accurately follow the change of valency of metal species.

As for the latter, some electronegativities corrected for valency have been proposed[9], but they are also insufficient.

Table 2 shows the rate constants (which do not depend on the catalyst concentration, calculated from k_a) in transesterification of DMT with EG in the presence of various metal acetates as catalysts. These rate constants were logarithmically plotted against electronegativities proposed by Gordy *et al.*[9], as shown in *Figure 9* (the authors consider that the rate constant must be plotted logarithmically, while such a consideration was also overlooked in ref 6). *Figure 9* shows wide scatter and this result suggests that it is not cor-
Figure 8 Application of equation (1) to data in *Figure 7*

Table 2 Rate constants (*k*) in the transesterification of DMT by EG with various metal acetates as catalysts

Cd^{2+}	6.32	Al^{3+}	5.02×10^{-2}
Mg^{2+}	4.18	K^+	4.92×10^{-2}
Ca^{2+}	7.96×10^{-1}		
Figure 9 Rate constants in the transesterification of DMT by EG with various metal acetates as catalysts against electronegativities of the corresponding metal species

rect to apply such a common value as electronegativity to this particular catalytic reaction.

As mentioned above, catalytic activity of these metal salts is considered to depend on its acidity, except for highly basic metal salt in the initial stage of the reaction. Transesterification may proceed by the nucleophilic attack of hydroxyl groups in EG upon ester carbonyl groups in DMT. Consequently, it may be natural to present the following hypothesis. The reaction intermediate is regarded as a complex formed by coordination of the ester carbonyl group to the metal species. This coordination lowers the electron density of carbonyl carbon atom and facilitates the nucleophilic attack of the hydroxyl group upon this positively polarized carbon atom.

Thus, the authors considered adopting the degree of facility of coordination of ester carbonyl groups in DMT to metal species as the ordering factor of catalytic activity of metal salt, e.g., concerning the mixture of DMT and each metal salt, the extent of the frequency shift in the infra-red absorption spectra due to coordination of the carbonyl groups to the metal species. However, it is difficult to estimate exactly the extent of such shifts, since many of the metal salts used in this study are relatively weak Lewis acids. Hence the authors paid attention to a compound that has similar structure to DMT and that can be quantitatively estimated in its facility of coordination to metal species, i.e., dibenzoyl methane (DBM).

DBM has carbonyl groups directly connected to benzene rings although it has no ester groups, and these carbonyl groups form a coordination compound with a metal species.

As to the complexing ability of DBM it is convenient to use a stability constant, and those of DBM complexes ($\log \beta_1$) are shown in *Table 3* with respect to the metal species used in this study. These values were determined by Van Uitert *et al.*[10] except for Sn^{2+} and Sb^{3+}. The values for Sn^{2+} and Sb^{3+} were calculated from the values of the extent of the shift in the frequency of the carbonyl stretch-

ing vibration in the infra-red absorption spectra of xanthone complexes of both metal species ($\Delta \nu_{C=O}$), since an approximately linear relationship exists between $\log \beta_1$ of DBM complexes and $\Delta \nu_{C=O}$ of xanthone complexes[11].

The rate constants in *Table 2* are plotted as $\log k$ against $\log \beta_1$ in *Figure 10* and it is easily concluded that the linear relationship is clearly superior to that in *Figure 9*. Even the rate constants which were regarded as exceptions or wide scatter in *Figure 9* fit the linear relationship in *Figure 10*.

Consequently, it is concluded that the stability constant of the DBM complex is an excellent ordering factor and is very useful as a forecast of the catalytic activity of the metal salt in the transesterification of DMT with EG; further this result is consistent with the hypothesis proposed above in connection with the mechanism of catalytic action.

In addition, this ordering factor has a mechanistic significance because of being the stability constant of the DBM

Table 3 Stability constants ($\log \beta_1$) of DBM complexes of various metal species

Figure 10 Rate constants in the transesterification of DMT by EG with various metal acetates as catalysts against stability constants ($\log \beta_1$) of DBM complexes of the corresponding metal species

complex. The above clear result is not obtained with a stability constant of a common complex not related to the above hypothesis, e.g. a stability constant of metal acetylacetonate.

The straight line in *Figure 10* is mountain-shaped, and its peak appears in the $\log \beta_1$ 9 to 11 region. Thus the compound made of metal ion species ranging in $\log \beta_1$ from 9 to 11 is most active as the catalyst in transesterification of DMT with EG. This relationship suggests catalytic effect of so-called 'volcano-shaped activity order'[12].

Effect of molecular weight on spherulite growth rates of high molecular weight poly(ethylene oxide) fractions

J. Q. G. Maclaine and C. Booth

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 8 July 1974)

Spherulite growth rates have been determined for a set of poly(ethylene oxide) fractions ranging in molecular weight from 10^4 to 10^6. At a given crystallization temperature the spherulite growth rate as a function of molecular weight passes through a maximum. At a given undercooling (as assessed by the method of Mandelkern) the spherulite growth rate is a monotonically decreasing function of molecular weight, and in the range $6000 < \bar{M}_v < 50\,000$ varies roughly as $(\bar{M}_v)^{-3}$. The free energy of formation of the end interface (as assessed by nucleation theory) also decreases as molecular weight increases.

INTRODUCTION

Many features of the crystallization of polymer fractions are affected by their molecular weight, as are many properties of the crystallized polymers. In this paper we report measurements of the spherulite growth rates of poly(ethylene oxide) fractions of moderate and high molecular weight. We are not directly concerned with low molecular weight fractions which crystallize predominantly in extended-chain form[1-3]. Adequate investigations of low molecular weight poly(ethylene oxide) fractions already exist[3-6].

EXPERIMENTAL

We have studied spherulite growth by optical microscopy for a set of well characterized fractions of poly(ethylene oxide) covering the molecular weight range 10^4 to 10^6 (g/mol).

Preparation of fractions

Poly(ethylene oxide) samples with narrow molecular weight distributions were obtained from Hoechst Chemicals Limited (prefix H in *Table 1*) or were prepared, via KOH catalysis with $HOCH_2CH_2OH$ initiator, in a stirred pressure reactor (prefix R in *Table 1*). These samples were purified by dissolving in benzene, filtering, and then precipitating by adding iso-octane. High molecular weight fractions were obtained from samples supplied by Union Carbide Limited, either Polyox WSR-35 (prefix W in *Table 1*) or Polyox N-750 (prefix N in *Table 1*), which were fractionated by the addition of iso-octane to a dilute solution in benzene[7]. Polyox samples contain insoluble alkaline earth salts (catalyst residues) which were removed with the first fraction and discarded. Generally the fractions used in the crystallization measurements were obtained by refractionation of original successive fractions.

Characterization of fractions

The fractions were characterized by dilute solution viscometry and gel permeation chromatography (g.p.c.). Intrinsic viscosities were determined for benzene solutions at

25°C. Modified Desreux–Bischoff[8] or modified Ubbelohde (Fica Model 52 000) viscometers were used. A Kinetic energy correction (+4% of determined intrinsic viscosity) was applied to the results obtained with the Ubbelohde viscometer. Shear corrections were negligible. Viscosity-average molecular weights were calculated using the relation[9]:

$$[\eta] = 0.0397\bar{M}_v^{0.686}$$

Conditions for g.p.c. were: Waters Associates Model 200 GPC; 4 x 4 ft (1.22 m) Styragel columns with nominal pore sizes in the range 10 to 5×10^5 nm; N,N-dimethylacetamide at 80°C and a flow rate of 1 cm^3/min; 2 cm^3 solution of concentration near 5 g/dm^3 injected. Correction for peak broadening was by the method of Aldhouse and Stanford[10]: the standard deviation, σ, resulting from adventitious dispersions was estimated by the method of Tung and Runyon[11] to be:

$$\sigma = 6.72 - 0.026v$$

where v is the elution volume in cm^3. Calibration was by fractions of poly(ethylene oxide) over the molecular weight range 10^3 to 2×10^6. The characterization data are given

in *Table 1*. Fractions are denoted by a prefix (source) and a number (viscosity-average molecular weight). Approximate number-average chain lengths ($\bar{x}_n$, chain units), calculated from the molecular weights and molecular weight ratios, are also listed in *Table 1*.

Spherulite growth rate

Spherulite growth rates were measured on the hot stage[12] of a polarizing microscope. The hot stage could be held at a steady temperature, to ±0.02K, by a proportional controller. Calibration was by 9 melting point standards (checked against standardized thermometers) in the range 35–69°C. Polymer films (0.3–0.5 mm thick) were heated to 100°C for 5 min and then transferred to the stage held at the crystallization temperature. Spherulite sizes were measured by reference to an eyepiece scale, either directly or via photographs. The eyepiece was calibrated against a stage micrometer As a precaution against oxidative degradation a new polymer sample was used for each crystallization. Characterization of certain fractions (W72000, W95000) by g.p.c. after crystallization indicated no degradation, nor did spherulite growth rates of twice-used samples differ from normal.

RESULTS

We made the following observations with the polarizing microscope: (i) spherulites were initiated sporadically with time over the initial part of the crystallization (as noted by Hay *et al.*[13]). Impinged spherulites eventually filled the field of view; (ii) the spherulite number density, ν, varied from fraction to fraction. Generally ν increased as $\bar{M}_v$ increased. For a given fraction ν was reduced by prolonged heating at high temperatures[13]; (iii) the spherulites had a close-textured appearance which did not differ from fraction to fraction; (iv) spherulite radii increased linearly with time up to the point of impingement. Variation of melting temperature (between 80 and 120°C) and melting time (between 2 and 60 min) did not change the spherulite growth rate.

Spherulite radial growth rates (G_S) are listed in *Table 2*. Values are reproducible to about ±10%. In *Figure 1* we present a double logarithmic plot of G_S against $\bar{M}_v$ for selected temperatures. For one crystallization temperature (T_c = 53.4°C) the curve is extended to $\bar{M}_v$ = 6000 by use of data published previously[5]. Plotted in this way the results show broad maxima in spherulite growth rate *versus* molecular weight at constant crystallization temperature. The maxima

are more pronounced at the higher values of T_c. The molecular weights at the maxima are 10^5 or greater, being higher at the higher values of T_c. This variation with $\bar{M}_v$ of G_S is very similar to the variation with $\bar{M}_v$ of the bulk (dilatometric) crystallization rates of polyethylene fractions of moderate and high molecular weight[14].

DISCUSSION

Spherulite growth rate/molecular weight isotherms

The interesting feature of our results is the maximum in the spherulite growth rate, G_S, measured at constant crystallization temperature, T_c, when plotted against molecular weight, $\bar{M}_v$; and particularly the increase in G_S with $\bar{M}_v$ in the low molecular weight range ($\bar{M}_v < 10^5$). This behaviour at low molecular weights is well established for poly(ethylene oxide) fractions crystallized at temperatures near to the melting point[3–6]. Spherulite growth rates measured[15] for polyethylene fractions ($\bar{M}_v$ from 3900 to 87 000) also increase with increasing molecular weight when compared at constant T_c.

By contrast spherulite growth rates measured at con-

stant T_c for many other polymers[16-23] [e.g. poly(tetramethyl-*p*-silphenylene)-siloxane[20], poly(ethylene succinate)[21], *trans*-1,4-polyisoprene[22] and poly(ethylene terephthalate)[23]] decrease with increasing molecular weight within the range of interest. The polymers in this second group all crystallize very slowly compared with poly(ethylene oxide) or polyethylene; at equivalent undercoolings their spherulite growth rates are some 100 times slower than those of poly(ethylene oxide) or polyethylene.

Assuming that crystallization is by a single mechanism, polymer crystal growth rates, G, can be described in terms of a classical rate equation[24-26] which is written (with sufficient accuracy):

$$G = [G_0 \exp(-\Delta F^a/RT_c)] \exp(-\Delta F^*/RT_c) \qquad (1)$$

The term $[G_0 \exp(-\Delta F^a/RT_c)]$ can be thought of as the elementary rate of transport of chain units across the liquid/crystal interface, ΔF^a being the activation free energy for that process. This elementary rate is modified by the term $\exp(-\Delta F^*/RT_c)$ which incorporates the free energy of formation from the melt of a crystal growth nucleus of critical size, ΔF^*. For a given polymer sample and over a limited temperature range well removed from the glass transition temperature, G_0 and $\Delta F^a/RT_c$ can be treated as constant relative to the term $\Delta F^*/RT_c$. For growth of lamella crystals via monolayer nuclei, ΔF^* can be written

$$\Delta F^* = \frac{4\sigma_u \sigma_e T_m^e}{\Delta h(T_m^e - T_c)} \approx \frac{4\sigma_u \sigma_e T_m^e}{\Delta h \Delta T} \qquad (2)$$

where σ_u and σ_e are the free energies of formation from the melt of the lateral (σ_u, J/mol chain units) and end (σ_e, J/mol chains emerging) interfaces of the lamella crystal, Δh is the enthalpy of fusion (J/mol chain units) of bulk polymer crystal, T_m^e is the equilibrium melting point of the sample (i.e. the melting point of the thickest lamella crystal which can be formed from the polymer sample), and ΔT is the undercooling ($T_m^e - T_c$). Parameters Δh and σ_u are properties of the polymer and independent of molecular weight. For practical purposes, over a limited temperature range, they (together with σ_e) may be treated as temperature independent parameters (the temperature range of our experiments is from 324 to 332K).

Provided chain ends are not co-crystallized the equilibrium melting point of a polymer sample is lowered as the molecular weight is lowered. Theory[27] predicts a rapid decrease in T_m^e at molecular weights less than 10^5: by an amount roughly proportional to the inverse molecular weight. Consequently, at a given T_c near to T_m^e, ΔT is reduced as the molecular weight is lowered (particularly at low M) and so, given G_0 and ΔF^a constant, the prediction is that G is reduced as M is lowered. However, it has been argued[20] that the transport term, $G_0 \exp(\Delta F^a/RT)$, is also dependent on the inverse molecular weight; thus, at constant ΔT, the prediction is that G is increased as M is lowered.

Spherulite growth rates of poly(ethylene oxide) fractions bear a one to one correspondence to crystal growth rates over the molecular weight and temperature ranges where the two have been measured[6]. Accordingly we substitute the spherulite growth rate, G_S for the crystal growth rate, G in subsequent discussion. Moreover Kovacs and Gonthier[6] have shown that a single mode of (chain-folded) crystallization probably holds for the molecular weight

and temperature ranges we have examined here, so that the theoretical treatment summarized above can be applied to our data. At high values of the undercooling variation of T_m^e with M is unimportant in determining the value of the nucleation term and consequently G_S at constant T_c will decrease as the molecular weight increases, following the variation of the transport term. The results of Kovacs and Gonthier[6] for poly(ethylene oxide) fractions show that G_S may consistently decrease as molecular weight increases when the undercooling from T_m^e exceeds about 20K. Spherulite growth rates of the slowly crystallizing polymers are rarely measured at undercoolings less than 20K[16-23]. At low values of the undercooling both effects will be important and G_S plotted against M will show a maximum. The position of the maximum (M_{max}) will depend upon the relative importance of the two terms in the rate expression: the greater ΔT the lower M_{max}. Our results (*Figure 1*) are in accord with this prediction.

Temperature dependence of spherulite growth rate

For fractions of the highest molecular weight T_m^e is equal to the thermodynamic melting point T_m^0, i.e. the melting point of a crystal of infinite size formed from polymer of infinite molecular weight. For poly(ethylene oxide) extrapolation methods lead[28,29] to a value of $T_m^0 = 76°C$.

According to equations (1) and (2), and taking the transport term to be relatively insensitive to temperature within our temperature range[†], a plot of $\log_e G_S$ against $1/T_c \Delta T$ should be a straight line of slope $4\sigma_u \sigma_e T_m^e/R \Delta h$. Such a plot, for the fraction of highest molecular weight, is shown in *Figure 2*. The straight line drawn through the points has a slope of $9.2 \times 10^4 K^2$.

Within the experimental error of determination of G_S ($\pm10\%$) a straight line is as adequate a representation of the data of *Figure 2* as any. However, similar plots for fractions of lower molecular weight (but $\bar{M}_v > 5 \times 10^4$ so that $T_m^e \approx T_m^0$) are curved. This is illustrated in *Figure 3*. We shall show later that appropriate plots for low molecular

---

[†] Plots of $\log_e G_S + \Delta F^a/RT_c$, with ΔF^a evaluated by an Arrhenius expression[6] or by a WLF expression[24] [$T_g = -67°C$ for poly(ethylene oxide)[30]] have identical slopes, within the error of our data, to a plot of $\log_e G_S$ alone.

weight fractions ($\overline{M}_v < 5 \times 10^4$) are linear. Ergoz et al.[14] have reported similar deviations from linearity in plots of the logarithm of the bulk crystallization rate against $1/T_c\Delta T$ for polyethylene fractions of similar molecular weight ($\overline{M}_v$ from about 5×10^4 to 7×10^5). This departure from the theoretical prediction for fractions of intermediate molecular weight casts doubt upon a simple model for the crystallization process. However, the deviation from linearity is slight and in subsequent discussion, mainly concerned with the highest and lowest molecular weight fractions, the problem is ignored.

Fractions of molecular weight lower than 10^5 cannot be treated in this way because T_m^e for low molecular weight polymers is lower than T_m^0. The value of T_m^e for a given sample is not generally measurable, nor can T_m^e be calculated independently of σ_e for polymers of narrow molecular weight distribution[27]. Rather than calculate values of T_m^e by assuming values of σ_e, we prefer the method of analysis proposed by Mandelkern[31].

An alternative expression for ΔF^* for monolayer growth is:

$$\Delta F^* = 2\sigma_u \zeta^* \tag{3}$$

where ζ^* is the thickness of the growth nucleus of critical size given by:

$$\zeta^* = \frac{2\sigma_e - RT_c \log_e I}{\Delta h(T_m^0 - T_c)/T_m^0 - RT_c/\overline{x}_n} \tag{4}$$

where $\overline{x}_n$ is the number-average chain length of the polymer and I is the probability that a sequence of length ζ^* chain units does not contain a chain end. The number of sequences in a growth nucleus of critical size is given by:

$$p^* = \frac{2\sigma_u}{\Delta h(T_m^0 - T_c)/T_m^0 - RT_c/\overline{x}_n - RT_c I'/I} \tag{5}$$

where $I' = (dI/d\zeta)$ evaluated at ζ^*. We here assume that chain folding is via adjacent re-entry and write[5,32]:

$$I = \sum_{s=1}^{t} \int_{s\zeta^*}^{(s+1)\zeta^*} w(x) \frac{(x - s\zeta^* + 1)}{x} dx +$$

$$\int_{(t+1)\zeta^*}^{\infty} w(x) \frac{(x - t\zeta^* + 1)}{x} dx \tag{6}$$

where $w(x)$ is the weight fraction of molecules of chain length x units, and where it is assumed that the chains fold to their maximum extent (consistent with $x > s\zeta^*$) up to a maximum of number of sequences t. (If $t = 1$, then the nucleus is composed of unrelated sequences.) Our calculations show that the allowance for the molecular weight distribution is important only when the average chain length is low (comparable with $t\zeta^*$).

We assume that the chain length distributions of our fractions are described by the Schulz–Zimm expression[33], with parameters defined by $\overline{x}_n$ and $\overline{M}_w/\overline{M}_n$ (*Table 1*). For poly(ethylene oxide) at temperatures near 60°C we take Δh to be 8.4 kJ/mol[34]. Use of the relationship[24] $\sigma_u \triangleq 0.1\Delta h$ gives a value of σ_u of 840 J/mol (equivalent to 8 erg/cm²). Equation (1) predicts that a plot of $\log_e G_s$ against $\Delta F^*/RT_c$ has unit slope. Accordingly we calculate ΔF^* for several values of σ_e and determine that value (of σ_e) which leads to unit slope. The procedure is illustrated in *Figure 4*: σ_e is defined to the nearest 0.5 kJ/mol by this method[†].

In *Table 3* we list values of σ_e so determined for two cases: $t = 1$ corresponding to unrelated sequences in the

Figure 4 Logarithm of spherulite growth rate, G_s, against $\Delta F^*/RT_c$ for poly(ethylene oxide) fractions W950000 (O), W190000 (▽), R42000 (△), H23000 (●), H11000 (▼) and 6000 (▲). Values of σ_e used in calculating ΔF^*, with $t = 1$ in equation (6), are given in *Table 3*

nucleus; $t = 4$ corresponding to regularly folded sequences in the nucleus [$t = 4$ is consistent with the values of ρ^* calculated from equation (3)]. The results for fraction 6000 (*Figure 4* and *Table 3*) are obtained using data published earlier[5]. The values we quote have relative significance only, being based upon an assumed value for σ_u: that obtained for the high fraction can be compared with the value of 5.5 kJ/mol obtained from *Figure 2* by use of the same value of σ_u. We note that fractions with molecular weights in the range $5 \times 10^4 < \bar{M}_v < 9 \times 10^5$ cannot be analysed by our method because of the curvature of the $\log_e G_s$ versus $\Delta F^*/RT_c$ plots, but are best fitted (average slope) with σ_e near 5.5 kJ/mol. The data for fraction W190000 are included in *Figure 4* in order to illustrate this point.

We find that σ_e decreases as the molecular weight increases. [We have remarked elsewhere[5] on the difference between our results with poly(ethylene oxide) and those discussed by Devoy and Mandelkern[35].] The values of σ_e obtained for low molecular weight fractions vary with the model used (reflecting the lower entropy of the regularly folded chain nucleus). Kovacs and Gonthier[6] suggest that the crystallization of all our fractions (in the temperature range used) proceeds via a folded-chain nucleus. Accordingly we lean towards the values obtained for $t = 4$.

Spherulite growth rate at constant $\Delta F^*/RT_c$

If $\Delta F^*/RT_c$ is constant then variation in G_s can be attributed to variation in the transport term, $G_0 \exp(-\Delta F^a/RT_c)$, of equation (1). In *Table 4* we list values of G_s estimated (e.g. from *Figure 4*) at $\Delta F^*/RT_c = 18$. The corresponding values of T_c indicate that the undercooling ($\Delta T = T_m^e - T_c$) is about 15K. The precision of an estimate of G_s is no better than ±50% (reflecting the difficulty of defining σ_e to better than 0.5 kJ/mol). The molecular weight dependence of G_s at constant $\Delta F^*/RT_c$ is similar to that found for polyethylene. For example, for polyethylene fractions at constant $1/T\Delta T$ of 1.7×10^{-4} (ΔT near 15K), G_s (μm/min) is 400 for $\bar{M}_v = 3900$ and 5 for $\bar{M}_v = 87\,000$. (These values are taken from *Figure 3* of ref 15.)

The values of G_s at constant undercooling given in *Table 4* vary roughly as $1/\bar{M}_v^3$ provided that $\bar{M}_v < 5 \times 10^4$. This is in keeping with a transport process controlled directly in rate by the viscosity of the melt[36]. At molecular weights higher than 5×10^4, so far as we can judge, G_s at constant undercooling varies very little with

$\bar{M}_v$. These results are not in keeping with the predicted[20] variation of G_s (at constant undercooling).

Crystallization of poly(ethylene oxide) fractions: simultaneous dilatometry and calorimetry

C. Price, K. A. Evans* and C. Booth

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 2 July 1974)

The crystallization of two fractions of poly(ethylene oxide), with molecular weights of 6000 and 360 000, has been studied by simultaneous dilatometry and calorimetry. The crystallization isotherms obtained by the two techniques are identical for the low molecular weight fraction, but differ for the high molecular weight fraction.

INTRODUCTION

The study of the transformation of a polymer from the liquid to the crystalline state requires the measurement of some property of the system which reflects the extent of the transformation[1,2]. Two such properties are the volume and the enthalpy.

Measurements on a partly crystallized polymer are most simply interpreted in terms of a two-phase model consisting of perfect liquid and perfect crystal. Thus the weight fraction of polymer which is crystalline is defined by:

$$X = \frac{P - P_l^0}{P_c^0 - P_l^0} \tag{1}$$

where P represents some property of the system (V, H) and P_l^0 and P_c^0 are the corresponding properties of the system when the polymer is perfectly liquid and perfectly crystalline respectively. Defined in this way P_l^0 and P_c^0 (or their difference, $P_c^0 - P_l^0$) are easily determined[1,2].

It is found that X is always less than unity. This is because polymers crystallize in stacked lamellae and the interfacial regions contain partly ordered liquid and/or partly disordered crystal. Since different properties of the system may be affected in different ways by partial ordering or disordering, it is possible that X will vary according to the property used in its evaluation[1–3].

An alternative representation for the partly crystallized system is a two-phase model comprising liquid and crystalline phases, the crystalline phase being considered as a whole. This model is suited to a single crystalline process occurring at the liquid–crystal (spherulite) boundary. For this model we define a weight fraction of polymer which has been crystallized as:

$$\chi = \frac{P - P_l^0}{P_c - P_l^0} \tag{2}$$

where P_c is the property of the crystallized polymer as it exists in the crystalline phase. When crystallization is com-

plete, all the polymer is within the crystalline phase. Accordingly we can write:

$$\chi = \frac{P(t) - P(0)}{P(\infty) - P(0)} \tag{3}$$

where the property is measured at time zero $(P(0) = P_l^0)$, t, and infinity $(P(\infty) = P_c)$.

Equations (2) and (3) define the weight fraction of polymer crystallized, χ, entirely in terms of the properties of the system as it actually exists. For a single crystallization process, χ is independent of the property used in its determination. If secondary processes occur, i.e. processes of whatever nature which occur behind the primary liquid–crystal boundary, or if fractionation (by molecular weight, chain purity, etc.) results in a proportion of polymer which is not incorporated into the spherulites, then χ may be dependent on the property used in its determination.

In this work we have studied the crystallization of fractions of poly(ethylene oxide) by simultaneously measuring volume and enthalpy changes. The technique of simultaneous measurement by two techniques precludes inconsistencies due to variation in crystallization conditions. A recent study[4] of the crystallization of poly(ethylene oxide) of molecular weight 20 000 by dilatometry and calorimetry has shown that there are differences in the crystallization isotherms obtained by the two techniques. Here we present results for poly(ethylene oxide) fractions of molecular weight 6000 and 360 000. We have good reason to believe, as a result of dilatometric measurements[5,6], that the crystallization of poly(ethylene oxide) of molecular weight 6000 is free from secondary processes whereas that of molecular weight 360 000 is more complex.

EXPERIMENTAL

Preparation and characterization

Samples of poly(ethylene oxide) were Carbowax Methoxy-5000 and Polyox WSR-35, both supplied by Union Carbide Ltd. These samples were fractionated by precipitation from dilute solution in benzene by addition of iso-octane[7]. Characterization was by methods described

fully elsewhere[8]. Characterization data are given in *Table 1*; the fractions are denoted by their approximate molecular weights.

Dilatometry and calorimetry

Simultaneous observation of the crystallization process by dilatometry and calorimetry was by use of a Calvet microcalorimeter.

Dilatometers were constructed of glass. The capillary entered the bulb by an internal seal (after the design of Kovacs and Manson[10]). The bulb volume was about 1 cm^3. The capillary was 0.5 mm internal diameter Veridia tubing, and was of sufficient length (>1 m) to protrude from the top when the dilatometer was inserted into the calorimeter.

The Calvet microcalorimeter (Setram, Lyon) was a standard model (25–200°C). A detailed description of the theory, construction, calibration and operation of the instrument may be found elsewhere[11]. Briefly, the instrument consisted of an aluminium heat sink containing two cavities into which fitted twin cylindrical cells (referred to as 'laboratory' and 'reference' cells). The temperature of the aluminium block was controlled to ±0.001K. In each cavity a thermopile was interposed between cell and block. These thermopiles were connected in opposition and the net output from them was fed to a recorder assembly (Sefram Verispot galvanometer, projection lantern and photodyne spot-follower).

The thermal power, W, developed in the laboratory cell (relative to the reference cell) at time t was estimated by use of the Tian equation. It is assumed that the internal boundary which contacts the pile is at uniform temperature, and that this differs from the temperature of the external boundary by θ:

$$W = p\theta + \mu(d\theta/dt) \tag{4}$$

where p is a constant and μ is the effective thermal capacity of the cell contents. The voltage generated by the heat flux produces a recorder deflection:

$$\Delta = g\theta \tag{5}$$

where g is a constant. Hence we can write:

$$W = (p/g)\Delta + (\mu/g)(d\Delta/dt) \tag{6}$$

$$W = (p/g)[\Delta + \tau(d\Delta/dt)] \tag{7}$$

where $\tau = \mu/p$ is the time constant of the instrument. During the course of an experiment Δ is recorded as a function of time. Equation (7) shows that the actual thermokinetic curve (i.e. W vs. t) can be obtained from the observed curve (i.e. Δ vs. t) by adding at each point an amount $\tau d\Delta/dt$. In

the case of the slow thermal processes (such as the crystallization processes studied here) the correction term is small relative to Δ. Electrical calibration, carried out in the recommended manner using[11] Joule heating, gave values of p/g near 0.966 x 10^{-4} W/cm and τ near 6.0 s for the sensitivity range (lowest) used here.

The twin cells (1.7 cm diameter, 8.5 cm long) were constructed of stainless steel and were held on Teflon tubes. The assembly within a cell is shown schematically in *Figure 1*. The dilatometer bulb (A) was inserted into the cell (B) via the Teflon tube (C). The roof of the cell was formed by a Teflon plug (D) and socket (E). To facilitate heat conduction the dilatometer bulb was immersed in silicone oil (F). The capillary tube of the dilatometer (G) protruded from the top of the instrument through a rubber bung (H).

In practice a known weight of poly(ethylene oxide) (~100 mg) was moulded in high vacuum, sealed into the dilatometer, outgassed and confined with mercury. A similar dilatometer was filled with mercury only, for insertion into the reference cell. In a crystallization experiment the laboratory dilatometer was immersed in boiling water for about 30 min, quickly dried, rinsed in silicone oil held at a temperature a little above the calorimeter temperature, and then inserted into the laboratory cell. At the same time the reference dilatometer was treated similarly and placed in the reference cell. Thermal equilibrium within the calorimeter required about 20 min. This was judged by the movement of the mercury level in the protruding capillary, and also by the establishment of the baseline on the recorder. It was possible to use some of the thermocouples in the pile surrounding the laboratory cell for Peltier cooling and this facility ensured that the temperature of the polymer sample approached the required crystallization temperature fairly quickly. In practice, how-
Figure 1 Experimental assembly of the microcalorimeter cell

ever, our experiments were restricted to very slow crystallizations. The time of transfer was taken as the starting time for the crystallization. The height of mercury in the capillary when steady was taken as the starting height for dilatometry.

The volume contraction was followed by measuring the height of the mercury in the capillary by means of a dilatometer (to ±0.005 cm). Typically the total contraction was about 4 cm, so that we could record changes in degree of crystallinity of about 0.1% by dilatometry. The sensitivity of the microcalorimeter (p/g) was about 10^{-4} J s^{-1} cm^{-1}. Typically the overall heat output was about 20 J, so that the sensitivity in terms of degree of crystallinity was about $5 \times 10^{-4}\%$ s^{-1} cm^{-1} i.e. about 0.2% per hour produced a deflection of 1 mm from the baseline.

RESULTS

In the dilatometric experiment we determine the specific volume change on crystallization $(V - V_l^0, \text{cm}^3/\text{g})$. The specific volume change for perfect crystallization $(V_c^0 - V_l^0, \text{cm}^3/\text{g})$ can be calculated from the following data.

Liquid: $V_l^0(25°\text{C}) = 0.891 \text{ cm}^3/\text{g}^{12}$,

           $\alpha_l^0 = 0.00069 \text{ cm}^3/\text{g K}^{12,13}$

Crystal: $V_c^0(25°\text{C}) = 0.813 \text{ cm}^3/\text{g}^{14}$,

           $\alpha_c^0 = 0.00015 \text{ cm}^3/\text{g K}^{12}$

from which:

$$V_c^0 - V_l^0 = -0.078 - 0.00054(T_c - 298)$$

In the calorimetric experiment we determine the specific enthalpy change on crystallization $(H - H_l^0, \text{J/g})$. This is given by:

$$H - H_l^0 = \int_0^t W\,\mathrm{d}t$$

The specific enthalpy change for perfect crystallization $(H_c^0 - H_l^0, \text{J/g})$ can be calculated from the following data: $H_c^0 - H_l^0(67.9°\text{C}) = -210^{15}$ and $\Delta C_p(\text{J K}^{-1}\text{ g}^{-1}) = 1.23 - 0.0016 T^{16}$.

The value of -210 J/g, for the heat of crystallization of a poly(ethylene oxide) crystal of infinite size formed from polymers of infinite molecular weight, is from measurements on mixtures of benzene with a high molecular weight fraction $(\overline{M}_v = 800\,000)$ of poly(ethylene oxide). The technique is discussed elsewhere[17]. A second estimate is available[18] from extrapolation of the heats of crystallization of extended chain crystals formed from low molecular weight crystals to infinite crystal thickness: i.e. 216 J/g at 75°C.

In *Figure 2* we show crystallization isotherms, X vs. log t, obtained by dilatometry for fraction 360 000 for a selection of crystallization temperatures. The lowest crystallization temperature illustrated in *Figure 2* is 58.8°C. Crystallization isotherms determined at temperatures lower than this (e.g. 57.8°C) overlie that for $T_c = 58.8°\text{C}$; presumably heat cannot be dissipated sufficiently quickly from the dilatometer—cell assembly when the tenth-life of the crystallization is much lower than 100 min. In what follows we con-

fine our attention to slow crystallizations: fraction 6000M at $T_c \geqslant 55°\text{C}$ and fraction 360 000 at $T_c \geqslant 59.5°\text{C}$. The results quoted are typical of many obtained under similar conditions.

Examples of calorimetric records (corrected, W vs. t) are shown in *Figure 3*. The curve for 6000M (*Figure 3a*) shows pronounced bumps. This is due to the low number density of spherulites in the sample; isotherms recorded for 6000M melted at 75°C (rather than 100°C) showed no peculiarities. Similar effects have been noted by Hay *et al.*[19]; presumably the low number density allows the development of large spherulites with consequent changes in crystallization rate when they impinge with one another or with the sample boundary. These adventitious variations in crystallization rate are less apparent when the data are presented as cumulative crystallization curves (see *Figure 4*).

Figure 4 shows the crystallization isotherms (X or χ vs. t) of fraction 6000M determined both by dilatometry and calorimetry. The isotherms are practically identical: the difference between the X isotherms is within the error of their determination (i.e. in the assessment of the numerator of equation 1). The χ-isotherms cannot be separated. The isotherms terminate abruptly, at or about $X = 0.80$, with no indication of a slow secondary process: this is in keeping with other results[5,6].

Figure 5 shows the corresponding crystallization isotherms for fraction 360 000. For this sample the isotherms
Figure 2   Dilatometric crystallization isotherms for fraction 360 000 at crystallization temperatures of: ●, 58.8°; +, 60.0°; ▲, 60.9°C
Figure 3   Calorimetric records for (a) fraction 6000M at 56°C and (b) fraction 360 000 at 60°C

Measurements of volume contraction were stopped after two days. Crystallization isotherms (determined by dilatometry) of comparable fractions of Polyox WSR-35 have been presented elsewhere[6]; provided the molecular weight $(\overline{M}_v)$ exceeds 10^5, a slow decrease in volume is found, continuing long after the primary crystallization has ceased. We would surmise that the volume of our fraction would have contracted further had it been held at 60°C for a few more days. The calculation of the isotherm $\chi(t)$ is therefore somewhat arbitrary; the curve illustrated in *Figure 5* is calculated assuming $V(\infty) = V(8.5 \times 10^4 \text{ s})$.

The data of Godovskii *et al.*[4] for poly(ethylene oxide) of molecular weight 20 000 (χ isotherms only are given) are somewhat intermediate between those of 6000M than 360 000: the dilatometric and calorimetric isotherms are identical up to $\chi \simeq 0.9$; thereafter the dilatometric isotherm lags behind the calorimetric isotherm.

DISCUSSION

For both fractions we find final degrees of crystallinity ($X \simeq 0.80$ for 6000M, $X \simeq 0.7$ for 360 000) which are similar whether estimated by dilatometry or calorimetry. This

Figure 4 Crystallization isotherms for fraction 6000M at 56°C, obtained by dilatometry (+) and calorimetry (●). (a) X vs. t; (b) χ vs. t

determined by the two techniques differ. Two results are noteworthy. First, the dilatometric isotherm lags behind the calorimetric isotherm at all stages of the crystallization. Secondly, the volume of the system continues to contract long after the production of heat at a detectable rate has ceased. From a practical point of view we note that the volume contraction at the time when the heat flow becomes undetectable (8.5×10^4 s) corresponds to a crystallization rate of about 0.5% h^{-1}, i.e. about 2 mm deflection of the recorder*.

* Whilst this should be readily detectable, it is just possible that a systematic baseline drift could affect the measurements and to this extent the second result is tentative. By increasing the amount of polymer in the dilatometer and setting up the experiment so that only the later stages of the crystallization process are investigated, an increase in the sensitivity of the experiment by about a factor of 20 is feasible. In this way we hope at a future time to investigate the thermodynamics of the process in a more detailed manner.

Figure 5 Crystallization isotherms for fraction 360 000 at 60°C, obtained by dilatometry (+) and calorimetry (●). (a) X vs. t; (b) χ vs. t

does not necessarily mean that X has been correctly assessed. It does mean that the volume and enthalpy are similarly affected by partial ordering or disordering in the system.

The observed slow athermal volume contraction at the end of the crystallization of fraction 360 000 (which is absent in fraction 6000M) allows one provisionally to assign the secondary process in high molecular weight poly(ethylene oxide) to a volume relaxation process. The fact that the dilatometric isotherm lags behind the calorimetric isotherm over the whole of the crystallization process implies that the volume relaxation occurs within the spherulites.

It is possible that the volume relaxation process is correctly described by the free volume mechanism assigned to the relaxation of glasses[20] and applied to the crystallization of poly(ethylene) by Banks *et al.*[21]. However, it could only be coincidental that such a process was athermal: changes in the conformational energies of the chain molecules would need to compensate for the energy decrease due to closer packing. We prefer to assign the effect to the formation of macroscopic voids during crystallization[3,22]; the relaxation of a system containing voids will cause a small decrease in enthalpy but a large decrease in volume.

Influence of tacticity of poly(methyl methacrylate) on the compatibility with poly(vinyl chloride)

J. W. Schurer, A. de Boer and G. Challa
Department of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands
(Received 13 June 1974)

Blends of conventional poly(vinyl chloride) (PVC) and poly(methyl methacrylate) (PMMA) with different tacticities were obtained both from the bulk and from solution. The glass transition temperatures (T_g) of the blends were determined with a differential scanning calorimeter and by dynamic mechanical measurements. Some turbidity measurements on films and viscosity measurements on mixed solutions supplied additional information about the state of mixing. From the results it appeared that isotactic (i-)PMMA and PVC form an incompatible system over the entire composition range (two T_g's), whereas blends of syndiotactic (s-)PMMA and PVC form a compatible system up to a composition corresponding with a monomer unit ratio of about 1:1. For higher s-PMMA contents phase separation is observed; one phase corresponding with the 1:1 s-PMMA—PVC associate and the other phase representing the excess of pure s-PMMA. This effect of tacticity is discussed in terms of the differences in chain conformation of i- and s-PMMA.

INTRODUCTION

In the last few decades many polymer blends have been investigated. These studies have been reviewed by Bohn[1], Rosen[2], and Krause[3]. In order to say something more definitely about mixing of polymers the concept of compatible polymer pairs has been introduced. Two polymers were considered to be compatible, when a mixture of these polymers gives a transparent film. However, if two polymers have the same refractive index but do not mix, it is to be expected that such blend also gives transparent films.

Another method to find out compatibility comprises determination of the glass transition temperature, T_g, as a function of the composition of the polymer—polymer system. However, when a polymer—polymer system demonstrates a single T_g, it does not yet definitely mean that mixing occurred on a molecular scale. Thus, Matsuo[4] has shown by electron microscopy that the poly(vinyl chloride)—copoly(butadiene—acrylonitrile 40:60) system contains heterogeneous domains with diameters up to 100 Å, although dynamic mechanical measurements produced only a single T_g.

A next example of the controversy around compatibility of polymer pairs is demonstrated by the poly(2,6-dimethyl phenylene oxide)(PPO)—polystyrene(PS) system. Stoelting[5] has shown by differential scanning calorimetry (d.s.c.) measurements that the PPO—PS system has one T_g. This indication of compatibility was confirmed by Shultz[6] using thermal optical analysis and by Prest and Porter[7] from rheological experiments. However, dynamic mechanical and dielectric relaxation measurements[8] have shown, that PPO and PS form an incompatible system with a PPO rich phase and a PS rich phase.

Another approach to polymer—polymer compatibility starts from well known thermodynamic considerations in terms of solubility parameters δ. If there exists a more favourable interaction between mutual structural units

(smaller difference in δ) the chance of compatibility of the polymer—polymer system will become larger. Some examples of compatible systems are poly(methyl methacrylate)—poly(vinylidene fluoride)[9], polystyrene—poly(vinyl methylether)[10], and poly(vinyl chloride)—poly(ε-caprolactone)[11].

Applying this idea to our studies on association phenomena of tactic poly(methyl methacrylates)(PMMA) we selected poly(vinyl chloride)(PVC) as second polymer because δ has about the same value for both polymers, viz. 9.5 and 9.6, respectively[12]. In view of the large difference of 80°C in T_g between isotactic (i-)PMMA and syndiotactic (s-)PMMA we were interested to know whether the tacticity of PMMA would also have a large effect on the compatibility of PMMA with PVC. To this end we investigated the glass transitions of different blends of i- and s-PMMA with PVC. In some preliminary experiments a commercial sample of atactic (a-)PMMA was used.

EXPERIMENTAL

The polymers i- and s-PMMA were prepared according to known procedures[13,14], a-PMMA was a commodity of ICI (Diakon MO/900), and PVC a commodity of Péchiney et St Gobain (Lucovyl RB 8010). The data of the used polymers are compiled in *Table 1*. The tacticities of PMMA

Table 1 Data of used polymers

	triads i—h—s	$\dfrac{[\eta]}{(dl/g)}$	$\overline{M}_v \times 10^{-3}$
i-PMMA	92—3—5	2.03	630
s-PMMA	2—4—94	1.37	370
a-PMMA	5—32—63	0.40	80
PVC		0.71	55

were measured on 5% solution in *o*-dichlorobenzene[15] at 160°C by 60 MHz n.m.r. spectroscopy with a Varian A60 instrument. $[\eta]$ of the PMMA samples were determined in chloroform at 25°C. For the calculation of $\bar{M}_v$ we used the relationship[16]: $[\eta] = 4.8 \times 10^{-5}\bar{M}_v^{0.8}$. $[\eta]$ of PVC was determined in cyclohexanone at 25°C and $\bar{M}_v$ was calculated[17] from $[\eta] = 173 \times 10^{-5}\bar{M}_v^{0.55}$.

Blends of PMMA and PVC were prepared in three ways: (a) by evaporation of 3 wt% mixed PMMA–PVC solutions in dimethyl formamide (DMF); (b) by precipitation from 3 wt% mixed PMMA–PVC solutions in DMF in an excess of 10:1 water–methanol mixture. The samples were dried in vacuum at 120°C for 1 h. To remove the last traces of DMF, the samples were finally heated at 170°C for 10 min in vacuum; (c) a-PMMA–PVC blends were also prepared by mixing the molten bulk polymers on a two roll mill (Schwabenthan) rotating with 10 and 12 rev/min at 180°C. PVC was first supplied on the mill and after 2 min a-PMMA was added. After 6 min the sheet was removed from the roll. To oppose degradation of PVC, 1 wt% stabilizer, di-n-octyltin-*S,S'*-bisiso-octyl-mercaptoacetate, (Ciba–Geigy) was added. The mixed samples were pressed to bars or d.s.c. tablets at 180°C for 3 min at 50 kgf/cm². The bars or tablets were slowly cooled under pressure.

The glass transition temperatures, T_g, were measured with a Perkin–Elmer differential scanning calorimeter (DSC 1B) at a heating rate of 8°C/min. All samples were first scanned up to 180°C for relaxation of possible stresses. In the second scan reproducible results were obtained. The beginning of the c_p jump was taken as T_g. It appeared from these measurements that the processing conditions had no influence on the course of T_g with composition of the blends. Dynamic mechanical measurements have been carried out on bars of 7 x 0.7 x 0.3 cm with a torsion pendulum of Nonius/TNO at a frequency of ~1 Hz. The measurements have been performed in the temperature range 20–170°C. From the damped oscillations loss tangents tan δ were calculated. The turbidities of some a-PMMA–PVC blends were quantitatively measured at a wavelength of 550 nm with a Jouan spectrophotometer.

RESULTS

Preliminary experiments

In order to tests the expected compatibility of a-, i-, and s-PMMA and PVC we first looked for common solvents yielding homogeneous mixed solutions. It appeared that for total polymer concentrations of about 1 g/dl no phase separation occurred at 25°C in solvents such as DMF cyclohexanone, butanone-2, dioxane-1,4, THF, and *p*-chlorotoluene. Moreover, the reduced viscosities η_{sp}/c of the mixed solutions were practically additive with respect to the values of the separate components.

A further indication of compatibility was obtained from turbidity measurements on 0.6 ± 0.05 mm films of various a-PMMA–PVC mixtures. The results in *Figure 1* show that clear films are obtained for blends up to about 60 wt% a-PMMA. Only at higher a-PMMA contents turbidity arises, passing a maximum value and then falling off to the value of pure a-PMMA. From these solubility and turbidity studies we thought it worthwhile to investigate the compatibility with PVC more thoroughly for both stereoregular PMMA's.

i-PMMA–PVC blends

Some characteristic d.s.c. thermograms are shown in *Figure 2*. T_g values derived from such thermograms are plotted against the composition of the system i-PMMA–PVC in *Figure 3*. Two T_g's are found over a wide composition range, which means that two different phases are present. Moreover, whatever composition is taken the T_g's vary less than should be expected in case of partial mixing of i-PMMA and PVC. So, it is likely that still two phases are present in the extreme composition ranges, but the sensitivity of

Figure 4 Loss tangent tan δ at about 1 Hz versus temperature for the i-PMMA—PVC system. ○, 100:0; □, 50:50; △, 0:100 i-PMMA—PVC

the d.s.c. is too low to detect the T_g of the respective small phases.

In order to check the d.s.c. results dynamic mechanical measurements were performed. In *Figure 4* tan δ is plotted against temperature for three different compositions. From the wide asymmetrical damping curve of the 50:50 sample it seems clear that i-PMMA and PVC form an incompatible system. Asymmetrical curves were also found for 25:75 and 75:25 compositions. Moreover, all the bars of the blends had an opaque appearance pointing to separated phases.

s-PMMA—PVC blends

In *Figure 5* T_g values found by d.s.c.measurements are plotted against composition for the system s-PMMA—PVC. From these data it appears that T_g increases regularly with composition up to 60 wt% s-PMMA. At higher s-PMMA

contents this T_g does not alter anymore, but is accompanied by a second T_g, of about 120°C, i.e. the value of pure s-PMMA. All this does indicate that a compatible system is formed up to 60 wt% s-PMMA, whereas PVC and s-PMMA form an incompatible system at higher s-PMMA contents. One phase of the incompatible system represents the blend 60:40 s-PMMA—PVC, the other one consists of pure s-PMMA.

Figure 6 shows tan δ of some s-PMMA—PVC systems as a function of temperature. It appears that the weight compositions 30:70 and 60:40 s-PMMA—PVC still give symmetrical damping curves, whereas the broad damping curve of the 80:20 s-PMMA—PVC blend seems to be composed of two curves which partly overlap. These results agree with those of the d.s.c. studies. Up to 60 wt% s-PMMA the polymers PVC and s-PMMA form a compatible system, whereas higher s-PMMA contents produce phase separation between a 60:40 s-PMMA—PVC phase and pure s-PMMA. This is also demonstrated by the turbidity of bars with overall compositions between 60 and 100 wt% s-PMMA.

Since the microstructure of a-PMMA is much more syndiotactic than isotactic it is understandable that blends of a-PMMA with PVC give nearly the same d.s.c. and dynamic mechanical results as presented in *Figures 5* and *6*. However, Razinskaya et al.[18] found a much smaller compatibility range for a-PMMA—PVC blends. This might be explained by the three times higher $\bar{M}_v$ value of their PVC.
Figure 5 Glass transition temperatures T_g (determined by d.s.c.) versus wt% s-PMMA for the s-PMMA—PVC system
Figure 6 Loss tangent tan δ at about 1 Hz versus temperature for the s-PMMA—PVC system: ▲, 0:100; ○, 30:70; □, 60:40; ●, 80:20; △, 100:0 s-PMMA—PVC

DISCUSSION

From our studies it can be concluded that i-PMMA and PVC form an incompatible system over the whole composition range, with phase separation between two phases. One phase is very rich in PVC and the other one in i-PMMA. On the contrary, s-PMMA and PVC form a compatible system up to 60 wt% s-PMMA. At higher s-PMMA contents separation occurs between a 60:40 s-PMMA—PVC phase and pure s-PMMA.

Taking into account the different weights of monomer units it appears that the 60:40 s-PMMA—PVC composition corresponds to a monomer unit ratio of nearly 1:1. So, the results show that the interaction between PVC and s-PMMA is so strong that a compatible system is formed up to a monomer unit ratio of 1:1. Possibly, some 1:1 associate is formed from s-PMMA and PVC, which dissolves in excess PVC producing a single T_g but which is not soluble in excess s-PMMA.

As mentioned in the introduction the solubility parameters are about the same for PVC (δ = 9.6) and a-PMMA (δ = 9.5)[12]. Unfortunately, very little is known about the solubility parameters of stereoregular polymers. Only Cowie[19] has reported δ values for i- and s-PMMA, viz. 9.28 and 9.55, respectively. These values are in good agreement with the difference in mixing behaviour of i- and s-PMMA with PVC as found by us. This difference might be attributed to the different chain conformations of i- and s-PMMA. i-PMMA prefers a 5_1 helix conformation[20], while s-PMMA chains have predominantly a planar structure[21]. In the 5_1 helix the ester groups are rotated somewhat inwards and become less accessible to intermolecular interaction than the ester groups of s-PMMA in the planar conformation. Furthermore the ester group of PMMA is considered to be a proton accepting group, whereas PVC behaves like a weakly proton donating polymer by its α-H atoms[22]. So, PMMA and PVC are complementary polymers, for which dipole—dipole or hydrogen bondlike interactions can manifest themselves more strongly when PMMA has a syndiotactic microstructure.

Influence of cure system concentration on crosslink structure in SBR sulphur vulcanizates

C. M. Blow and C. T. Loo*

Institute of Polymer Technology, Loughborough University of Technology, Loughborough, Leics LE11 3TU, UK
(Received 3 June 1974; revised 8 August 1974)

A series of pure gum styrene—butadiene copolymer mixes, compounded with a sulphur/N-cyclohexyl-2-benzothiazyl sulphenamide (CBS) curing system and vulcanized for various times at 150°C has been subjected to extraction and chemical probe treatments to cleave polysulphidic and disulphidic crosslinks. The changes in the value of C_1 of the Mooney—Rivlin equation, obtained from stress—strain data, and the degree of swelling in n-heptane are reported. The weight losses occurring during these treatments have also been determined. If the proportion of vulcanizing ingredients is varied with the ratio of sulphur to CBS held constant, the ratio of monosulphidic to disulphidic crosslinks varies considerably at cure times frôm 45 to 120 min; no polysulphidic crosslinks were present in the vulcanizates examined. The paper contains values of C_2 (Mooney—Rivlin equation) and of χ, the polymer—liquid interaction constant; the latter varies with the cure system and is altered by the chemical probe treatments.

INTRODUCTION

In much of the published work on the study of the properties of rubber vulcanizates in relation to crosslink density, peroxide-cured materials have been employed in which the crosslink is of one type: carbon—carbon.

If the interest, however, is in accelerated sulphur vulcanizates, the problem of selecting a series of mixes to study the effect of crosslink density is complicated by the fact that sulphur forms mono-, di- and poly-sulphidic crosslinks as well as sulphidic ring structures with the polymer chain and pendant accelerator groups[1].

An accelerated sulphur mix vulcanized for a range of times and/or at a range of temperatures will produce a series of vulcanizates with varying crosslink densities but, as is well known, the ratio of monosulphide to disulphide to polysulphide crosslinks varies greatly. An alternative approach is to keep the time and temperature of vulcanization constant and vary the curing system, (a) maintaining a constant proportion of sulphur and varying the accelerator proportion, (b) maintaining a constant proportion of accelerator and varying the sulphur proportion, or (c) maintaining the sulphur to accelerator ratio constant and varying the proportion of total ingredients.

There are statements in the literature[2] to the effect that if the last procedure (c) is adopted the crosslink density will be varied but the proportion of each of the several crosslink types will remain constant. Little evidence has, however, come to light in the present authors' searches, and that is conflicting. Farlie[3] gave data on the mono-, di- and polysulphidic proportions in two series of pure gum natural rubber (NR) vulcanizates with a constant sulphur to accelerator ratio, vulcanized at 140°C for the same time. In the

first series, a conventional sulphur to N-cyclohexyl-2-benzothiazyl sulphenamide (CBS) ratio of 5:1 was used and cure times of 35 min and 120 min representing approximately optimum and overcure respectively. At each cure time the proportions of disulphide and polysulphide crosslinks present in the vulcanizates were substantially constant for a range of sulphur contents from 2 to 4 parts per hundred of rubber (by wt) (phr), there being no monosulphide crosslinks; at the overcure, the monosulphide/disulphide/polysulphide proportions were equal. In the second series, an efficient cure system, sulphur/tetramethyl thiuram disulphide (TMTD)/2-(4-morpholinylmercapto)benzothiazole (MOR) in the ratio 1:1.89:4, was used and a cure time of 50 min. In this case the percentage of monosulphide crosslinks varied from 100 to 85 for a range of sulphur contents from 0.35 to 1.0 phr, the remainder being disulphide links with no polysulphide links.

Studebaker[4] investigated black loaded [50 phr high abrasion furnace (HAF)] NR mixes with the ratio of sulphur to accelerator held constant over a range of sulphur contents from 1 to 6 phr; the accelerators were diphenylguanidine (DPG), MOR, and 2-mercaptobenzothiazole (MBT). Analyses were carried out for polysulphide and monosulphide crosslinks using the lithium aluminium hydride reagent in conjunction with crosslink density estimates from swelling determinations corrected for the carbon black content using the procedure described by Kraus[5]. A decrease in the ratio of polysulphide to monosulphide crosslinks was found to occur with the increasing quantity of curing agents.

In this paper a study is reported of the effect of the proportion of sulphur and CBS (at a constant ratio) on the crosslink types in pure gum styrene—butadiene copolymer (SBR) vulcanizates. SBR mixes were selected because, if the relative proportion of the three crosslink types is con-

stant, they would be of interest as a series for a failure property study.

EXPERIMENTAL

Vulcanizate preparation

The mix formulations are given in *Table 1*, from which it is seen that the sulphur/CBS ratio in the four mixes has been kept constant at 1.81:1. The mixes were prepared on a laboratory mill in a conventional manner and had the same plasticity (Wallace Rapid Plasticity value 29 ± 2); vulcanization was carried out in a steam-heated press at 150°C for a range of times to produce test sheets 150 x 150 x 1 mm, from which the testpieces were cut.

Determination of crosslink density and crosslink type

Dumbbell shaped testpieces were punched from the test sheets and treated with propane-2-thiol (0.4 M) and piperidine (0.4 M) in n-heptane solution to cleave the polysulphidic crosslinks and with a solution of (1 M) n-hexane-thiol in piperidine to cleave the di- and poly-sulphidic crosslinks[6]. Additional testpieces were subjected to extraction in the

[c] After n-hexane-thiol chemical probe treatment
[d] By difference (b — c)
† Testpieces 1, 2 and 3, after n-hexane-thiol treatment were very soft so that C_1 values could not be obtained; the number of monosulphide crosslinks is, therefore, low in these vulcanizates

cold by n-heptane for times and under conditions similar to those given to the testpieces for chemical destruction of crosslinks.

Stress—strain measurements of the original untreated, n-heptane extracted and chemically treated vulcanizates were carried out, using the technique and apparatus described previously[7]. Good straight line plots were obtained of $f/2A_0(\lambda - \lambda^{-2})$ against λ^{-1} enabling the C_1 and C_2 values of the Mooney—Rivlin equation to be calculated, f being the force required to strain a testpiece of cross-sectional area A_0 to an extension ratio, λ.

Weight losses on extraction and chemical treatment

The losses in weight of testpieces during extraction with n-heptane and during treatment with propane-2-thiol and n-hexane-thiol were determined.

Determination of swelling in n-heptane

Portions of some of the dumbbells used for the above-mentioned determination of crosslink density and type were swollen in n-heptane at 20°C for 96 h. From weights in air and liquid, the weight and volume changes were calculated. The weights and volumes of testpieces after removal of the solvent were also obtained so that the volume fraction of rubber in the swollen jelly, v_r, could be calculated, excluding soluble non-rubber ingredients. No correction was made for the small volume (~1%) of zinc oxide and other non-extractable ingredients and residues.

RESULTS

The values of C_1 and C_2 obtained on the vulcanizates in the untreated, extracted and chemically treated state are given in *Tables 2* and *3*. The values of C_2, differing somewhat from some other published values[8], are only included for completeness; they are not relevant to the subject of this paper. The weight losses occurring during the various treatments are plotted in *Figure 1* against the corresponding C_1 values.

The results of swelling tests (*Table 4*) on vulcanizates of mixes B, C and D, cured for 75 min at 150°C, (testpieces 4, 7 and 10), include the untreated vulcanizates, those extracted with n-heptane and dried, and those treated with the chemical probes. *Figure 2* is a plot of v_r against C_1, showing a correlation; the three n-hexane-thiol treated samples appear to lie on a line separate from the other results. Included in *Table 4* are the values of the polymer—liquid interaction constant, χ, calculated according to the Flory—Rehner equation, using the C_1 values as determined above:

$$-RT[\ln(1 - v_r) + v_r + \chi v_r^2] = 2V_1 C_1 (v_r^{1/3} - 1/2v_r)$$

R and T are the gas constant and the absolute temperature respectively, and V_1 is the molar volume of the liquid. It is to be noted that these χ values are all higher than those reported by Bristow and Watson[9] and vary systematically

with the cure system and treatment. The change of χ with curing system, cure time and after probe treatment is well documented[10]. *Figure 3*, a plot of v_r against χ, is included for interest as it shows the linear relation (χ = 0.436 + 0.56v_r) previously pointed out by Kraus[10].

DISCUSSION

It should be pointed out that the probe treatment conditions were those developed for natural rubber vulcanizates. These may not be entirely appropriate for a SBR vulcanizate with

its different backbone structure, and some error may be involved in interpreting the data. Furthermore, no attempt has been made to calculate values for the density of chemical crosslinks because of the absence of data, in the case of SBR, to correct for chain ends and entanglements. Consideration is, therefore, confined to C_1 values. Extraction with n-heptane increases the C_1 value slightly and the chemical treatment with propane-2-thiol increases it somewhat more, the amounts of the increase correlating well with the weight losses (*Figure 1*) which are much in excess of
Figure 2 The C_1 value vs. v_r (the volume fraction of polymer in the rubber swollen in n-heptane at 20°C) of testpieces 4, 7 and 10. A, Untreated, extracted and treated with propane-2-thiol; B, treated with n-hexane-thiol
Figure 3 χ (the polymer–liquid interaction constant) vs. v_r

those normally found in the case of pure gum NR vulcanizates.

Since neither extraction nor chemical probe treatment is carried out at an elevated temperature it can be assumed that no further sulphur crosslinks are added and the possibility of oxidative crosslinking seems remote. The explanation of the increase in C_1 on extraction and probe treatment must lie in the removal of some unbound polymer, which the weight loss data suggest, and in the production of supercoiling and chain entanglements[11]. The lower the state of the cure the more unbound polymer there is likely to be and the greater freedom for the polymer chains to coil and rearrange on its removal.

The v_r values of the pre-extracted samples are somewhat higher than those of the original vulcanizate, although the latter values have been based on the extracted rubber. This fact that an extracted and dried sample swells less than an unextracted one lends weight to the suggestion that increased coiling and entanglement of polymer molecules are present in the extracted vulcanizates.

The conclusion from the data for the samples treated with the propane-2-thiol probe is that there is not a significant number of polysulphidic crosslinks in any of the vulcanizates which is in line with the known lower stability of polysulphides in SBR and their subsequent rapid conversion to monosulphide crosslinks in the case of the semi-efficient curing system employed in this series of mixes[12]. The C_1 values in column 6 of *Table 2* can, therefore, be considered to represent the contribution of the mono- and di-sulphide crosslinks. Correspondingly, the values in column 7, obtained on samples treated with hexane-thiol, represent the contribution of the monosulphide crosslinks.

CONCLUSIONS

It appears justifiable to conclude that the contribution of the disulphide links will be given by the difference between the values in columns 6 and 7. Calculation of the ratio of monosulphide crosslinks to disulphide crosslinks (*Table 5*) shows that keeping the ratio of sulphur to CBS constant in the mix formulation has not maintained this ratio constant at any of the cure times selected in this series.

The energetic contribution to rubber elasticity in the range of small uniaxial compression and moderate elongation

F. P. Wolf* and Geoffrey Allen

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 9 July 1974)

The relative energetic contribution to the retractive force of a deformed rubber sample, f_e/f, has been evaluated from thermoelastic measurements at constant pressure. Extension ratios λ have been studied in the range $0.88 \leqslant \lambda \leqslant 1.70$ at $20°$ and $40°$C. The results are given for a reference temperature, $30°$C. Since data in the transition region from uniaxial elongation to compression were to be evaluated, a new set of equations was derived on the basis of the Gaussian force law, because the usual equation for measurements at constant pressure tends towards infinity when approaching the undeformed state $\lambda = 1$.

Considerable difference between the results obtained by different, though apparently equivalent, equations have their origins in the deviation of the experimental data from ideal Gaussian behaviour. The influence of this inaccuracy on the terms of the equations is discussed and the most reliable functions for small deformations $0.88 \leqslant \lambda \leqslant 1.15$ and for moderate elongation $\lambda > 1.10$ have been identified. With these precautions the Gaussian force law is a satisfactory approximation for the determination of reliable values of f_e/f.

The evaluation of data at small deformations is extremely sensitive to experimental error. Even smoothed polynomials $L(f)$ were not sufficient to eliminate an apparent maximum in the f_e/f vs. λ curve. Therefore the linear thermal expansion coefficient $\beta_{lin}(\lambda)$, which is a major term in all the f_e/f equations at small deformations, had to be scrutinized critically. Although experimental data in this range showed that $\beta_{lin}(\lambda)$ is a slightly S-shaped function, a linear approximation is adequate at moderate elongations.

Using one of the new equations together with the linear approximation for $\beta_{lin}(\lambda)$ in the region of small deformations, and two equivalent equations at moderate elongation, the energetic contribution to the total stress was found to be $f_e/f = 0.18 \pm 0.02$ for lightly crosslinked natural rubber. Little variation in f_e/f was observed over the full range of measurements: $0.88 \leqslant \lambda \leqslant 1.70$.

INTRODUCTION

The retractive force, f, of a deformed rubber sample does not originate entirely from entropy changes due to orientation of the macromolecules in the network. An energetic contribution, f_e, to the total force comes from changes of the conformational free energy of the macromolecules. The relative energetic contribution, f_e/f, can be related to the temperature coefficient of the unperturbed dimensions of the macromolecular chains[1] and thus provides a means of studying molecular processes.

The quantity f_e/f has been reported to be a function of extension ratio[2,3]. Furthermore in elongation the most serious deviations have been detected for small strains, where the experiment ought to be in best agreement with the statistical theory. The deviations at high strains in natural rubber can be ascribed, of course, to the onset of crystallization which can be detected by X-ray analysis[4].

Since the variation of f_e/f in the range of small elongation may be due to experimental methods and their mathematical evaluation, methods currently in use will be discussed against the background of exact thermodynamical relations and the use of Gaussian theory. Then a new

set of equations will be developed for the evaluation of f_e/f from thermoelastic measurements. These equations will be applied to experimental data obtained from a rubber sample under small uniaxial deformation in compression as well as in elongation. The results will be compared with data obtained by one of the conventional methods up to moderate extensions.

THEORY AND REVIEW OF f_e/f DETERMINATIONS

The free energy of a macromolecular network is assumed to consist of two additive terms, the first one accounting for liquid-like intermolecular interactions, the second for intramolecular elastic free energy changes. Thus changes of the conformational free energy can be separated from intermolecular interactions. They are governed by the thermodynamical relationship:

$$dF_{el}(T, V, \lambda) = dU - TdS \qquad (1)$$

U being the internal energy, S the entropy, V the volume of the sample and $\lambda = L/L_0$ the uniaxial deformation ratio (actual length divided by undeformed length).

The retractive force f of the deformed sample is obtain-

ed by differentiation of the free energy with respect to the actual length L at constant temperature T and volume V:

$$f = \left(\frac{\partial U}{\partial L}\right)_{T,V} - T\left(\frac{\partial S}{\partial L}\right)_{T,V} = f_e + T\left(\frac{\partial f}{\partial T}\right)_{V,L} \quad (2)$$

The first term represents the energetic contribution f_e to the total retractive force, and

$$f_e/f = 1 - \frac{T}{f}\left(\frac{\partial f}{\partial T}\right)_{V,L} \quad (3)$$

Instead of measuring the temperature coefficient of the force at constant volume and length, the following relationship uses the corresponding coefficient at constant pressure, p and length, L:

$$\left(\frac{\partial f}{\partial T}\right)_{V,L} = \left(\frac{\partial f}{\partial T}\right)_{p,L} - \left(\frac{\partial f}{\partial V}\right)_{T,L}\left(\frac{\partial V}{\partial T}\right)_{p,L}$$

$$= \left(\frac{\partial f}{\partial T}\right)_{p,L} - \left(\frac{\partial f}{\partial p}\right)_{T,L}\left(\frac{\partial p}{\partial V}\right)_{T,L}\left(\frac{\partial V}{\partial T}\right)_{p,L} \quad (3a)$$

Introduction of the bulk thermal expansion coefficient β_L and the isothermal compressibility κ_L at constant length L of the sample, as given in a previous paper[5], leads to:

$$f_e/f = 1 - \frac{T}{f}\left(\frac{\partial f}{\partial T}\right)_{p,L} - \frac{T}{f}\left(\frac{\partial f}{\partial p}\right)_{T,L}\cdot\frac{\beta_L}{\kappa_L} \quad (4)$$

Equations (3) and (4) have been derived using exact thermodynamical relationships.

Measurements based upon equation (3) are difficult because they require the thermal expansion of the sample to be offset by means of hydrostatic pressure. They have so far been carried out only by Allen *et al.*[6,8] for a few rubbers. Since the apparatus also allowed force vs. pressure measurements to be made, the use of equations (3) and (4) could be compared. The results were in good agreement with one another and although the data showed considerable scatter owing to experimental difficulties, no obvious trend of the f_e/f values in the region of small elongation ratios could be detected. Apart from these direct measurements, all other evaluations require the knowledge of a force vs. elongation relationship.

Application of Gaussian statistics to macromolecular networks leads to a force law which may be expressed as[5]:

$$f = c\left(L - \frac{qV}{L^2}\right)$$

$$= cL_0(\lambda - \lambda^{-2}V/V_0) \quad (5)$$

where the factor V/V_0 corrects for the difference between elongation ratio λ and anisotropic strain[9] α, which because of the very small volume changes on deformation is extremely small and can be disregarded normally. The variable c depends on temperature only and q is a constant determined by the shape of the sample:

$$q = \frac{L_0^3}{V_0} = \frac{L_0^2}{A_0} \quad (5a)$$

(Subscript 0 refers to the undeformed state of the sample, A_0 being the cross-sectional area.)

The slope cL_0 at $\lambda = 1$ for the usual Gaussian plot of force f vs. $(\lambda - \lambda^{-2})$ is related[5] to the shear modulus, G:

$$cL_0 \simeq A_0 G \quad (5b)$$

The following derivatives of the force f obtained from equation (5) will be needed later in the paper:

$$\left(\frac{\partial f}{\partial p}\right)_{T,L} = +\frac{cq}{L^2}V\kappa_L \quad (5c)*$$

$$\left(\frac{\partial f}{\partial L}\right)_{T,V} = \frac{c}{L^3}(L^3 + 2qV) \quad (5d)$$

$$\left(\frac{\partial f}{\partial V}\right)_{T,L} = -\frac{cq}{L^2} \quad (5e)$$

$$\left(\frac{\partial f}{\partial T}\right)_{V,L} = \frac{dc}{dT}\left(L - \frac{qV}{L^2}\right) = f\frac{d\ln c}{dT} \quad (5f)$$

Returning now to equation (4), all pressure dependent quantities in the last term can be replaced in order to yield a formula for the evaluation of thermoelastic experiments at constant p and L. Using equations (5) and (5c) the following expression is obtained for the relative energetic contribution:

$$f_e/f = 1 - \frac{T}{f}\left(\frac{\partial f}{\partial T}\right)_{p,L} - \frac{\beta_L T}{(\lambda^3 V_0/V - 1)} \quad (6)$$

This equation has been derived by Flory[10] who points out that the last term depends strongly on λ, being infinite for $\lambda = 1$. This equation has frequently been used for the evaluation of experimental data, because the conditions of constant p and L are easily realized. Owing to the behaviour of the last term, upturns or downturns of f_e/f when approaching $\lambda = 1$ have been reported in the literature (for a review see refs 2 and 3), and some authors have tried to find molecular interpretations of this phenomenon[11-13].

Another formula, originally given by Flory[10] in terms of the anistropic strain α has been used with[9] $\lambda \simeq \alpha$ for the evaluation of measurements at constant pressure:

$$f_e/f = 1 - \frac{T}{f}\left(\frac{\partial f}{\partial T}\right)_{p,\lambda} + \frac{\beta_L T}{3} \quad (7)$$

It may be verified using the Gaussian force law (5).

Evaluating the same set of data for silicone rubber in the range $\lambda > 1.25$, Ciferri[14] obtained equivalent results within the limits of experimental error by means of equations (6) and (7). Barrie and Standen[15] applied equation (7) to data obtained at constant p and f, conditions which are even more suitable from an experimental point of view than those of constant p and L. Both the above mentioned references, like the majority of the more recent publications, make use of least square method computer programs (LSMCP) to fit expreimental data and to find a reliable value of the unstrained length L_0. Even with

---

* $(\partial f/\partial p)_{T,L} = (\partial f/\partial V)_{T,L}(\partial V/\partial p)_{T,L} = (\partial V/\partial L)_{T,p}$

LSMCP small inconsistencies[15] such as force $f \neq 0$ for $\lambda = 1$ often obtain. This problem has been dealt with in a previous paper[5].

Another type of experiment has been carried out by Treloar[3,16], who employed cylindrical samples subjected to combined torsion and axial extension. This method avoids the sensitivity to an accurate determination of L_0 and the deviations which are introduced by equation (6) in the region of small strains. Effects of the volume changes on deformation are much less apparent. On the other hand, combined torsion and extension involve an inhomogeneous state of strain and thus can be compared with uniaxial deformation only in the limit of zero strain. From the experimental point of view, Treloar's measurements are more complicated than stress—strain investigations in simple elongation.

The relative energetic contribution to the total stress can be calculated from the temperature dependence of the shear modulus, G. Equations (5f) and (5b) yield:

$$f_e/f = 1 - T \frac{\mathrm{d}\ln c}{\mathrm{d}T} = 1 - T \frac{\mathrm{d}\ln G}{\mathrm{d}T} - \frac{\beta_0 T}{3} \qquad (8)$$

The thermal expansion coefficient β_0 (of the isotropic state) has to be taken into account because c is different from the modulus by the dimension 'length'.

Equation (8) has been used by Shen and Blatz[2] in a new attempt to remove the inadequacy of equation (6). They determined G from the initial slopes of Gaussian plots in a way similar to equation (5b). The curves of f/A_0 vs. elongation $(\lambda - \lambda^{-2})$ were calculated by a LSMCP 'forced' through the origin. Since only the 'linear parts' of the Gaussian plots $(\lambda < 1.3)$ were used and one single value of G was obtained for each plot, it was claimed that f_e/f was strain independent in this region.

CHOICE OF EXPERIMENTAL CONDITIONS

Because of the well known difficulties of the constant volume experiment the condition of constant pressure is normally preferred for thermoelastic investigations. Then there remain three variables, one of which must be kept constant: (a) temperature, T; (b) force, f or stress, f/A_0; (c) length, L or elongation, λ (or anisotropic strain α). Alternative (c) presents experimental difficulties. Experiments at constant T were chosen because the apparatus used in the present investigation was designed to allow measurements of length vs. force in the regions of small uniaxial extensions and compressions. Thus the undeformed length $L_0(T)$, the determination of which has proved troublesome in other investigations, is obtained with high accuracy by a LSMCP for $f = 0$. We have not made L vs. T measurements at constant force.

The apparatus and experimental technique have been described previously[5]. The measurements have been evaluated on the basis of varios theoretical relationships which render the resulting f_e/f as a function of either the force f or elongation ratio, λ and also yield a finite value for f_e/f at zero force. For comparison the experimental results have been converted into relations between f and T at constant p and L and an evaluation according to equation (6) has been carried out.

EVALUATION OF f_e/f FROM EXPERIMENTAL DATA

In the analysis of our experimental data we have explored a number of formally equivalent procedures for the evaluation of f_e/f. Without making any assumptions the following equations can be derived from equation (3) using the normal methods of manipulating partial differentials. These manipulations are set out in more detail in the Appendix.

In this section we simply list the equations which have actually been used to interpret the experimental data. Apart from equation (6) these are:

$$f_e/f = 1 + T\left[\beta_{\mathrm{lin}} + \frac{cL_0}{\lambda^2 V_0/V} \frac{3\beta_{\mathrm{lin}} - \beta_f}{f}\right] \qquad (9)$$

$$f_e/f = 1 + T\left[\beta_{\mathrm{lin}} + \frac{3\beta_{\mathrm{lin}} - \beta_f}{\lambda^3 - 1}\right] \qquad (9a)$$

$$f_e/f = 1 + \frac{T}{f}\frac{cL_0}{\lambda^2}\left[(\lambda^3 + 2)\beta_{\mathrm{lin}} - \beta_f\right] \qquad (9b)$$

$$f_e/f = 1 + \frac{T}{f}\left[\left(\frac{\partial f}{\partial L}\right)_{T,p} L\beta_{\mathrm{lin}} - \frac{cL_0}{\lambda^2}\beta_L\right] \qquad (9c)$$

$$f_e/f = 1 + T\left[\left(\frac{\partial f}{\partial L}\right)_{T,p}\frac{L\beta_{\mathrm{lin}}}{f} - \frac{\beta_L}{\lambda^3 - 1}\right] \qquad (9d)$$

SAMPLE SPECIFICATION AND ASSESSMENT OF THE APPROXIMATIONS

The lightly crosslinked sample of natural rubber had a cylindrical shape of 4.2 cm length and 1.27 cm diameter as described in a previous paper[5]. Length vs. force measurements were taken at $20°$ and $40°C$ in the range of $0.88 \leqslant \lambda \leqslant 1.18$, and an individual set of results at $\lambda = 1.70$. Thus thermoelastic quantities could be calculated for a reference temperature of $30°C$ which is convenient for comparison with the literature.

At $30°C$ the cross-section area of the sample was $A_0 = 1.266$ cm^2. For the isothermal compressibility a value of $\kappa_L = 51.4 \times 10^{-6}$ atm$^{-1} \equiv 5.07 \times 10^{-10}$ m^2/N can be extrapolated from ref 18. This quantity is independent of strains[6,19] within an experimental error of 3%.

Two sets of reference marks were attached to the sample, the unstrained distances being about 3.4 cm ('outer marks') and 2.6 cm ('inner marks') respectively. The shear modulus, G was evaluated according to eqution (5b) for $30°C$:

$$G = 0.462\langle0.458\rangle \times 10^6 \text{ N/m}^2$$

for the outer ⟨inner⟩ marks. With the mean value of G the factor $G\kappa_L/\lambda$ was obtained: $G\kappa_L = 2.34 \times 10^{-4}$. This factor appears in several correction terms which have to be assessed.

(a) Uniaxial deformation of a sample is accompanied by volume changes. The quotient:

$$V_0/V \simeq 1 - \frac{\Delta V}{V_0} = 1 - \phi \qquad (10)$$

or its inverse value appears together with some power of λ in the force law (5) and in the f_e/f expressions. The correction ϕ is obtained on the basis of the Gaussian force law as[5]:

$$\phi \simeq \frac{\kappa_L}{A_0} \frac{f}{\lambda + 1 + \lambda^{-1}} \simeq \frac{G\kappa_L}{\lambda} (\lambda - 1) \tag{11}$$

(b) The bulk thermal expansion coefficient under conditions of constant force (A1e) has been assumed to remain constant for moderate elongation. This assumption has been proved for the corresponding coefficient at constant length[6]. The difference between β_L and β_f may be assessed from equations (5c) and (A1d):

$$\beta_L = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_{p,L} = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_{p,f} - \frac{1}{V}\left(\frac{\partial V}{\partial L}\right)_{p,T}\left(\frac{\partial L}{\partial T}\right)_{p,f} \tag{12}$$

$$\beta_L = \beta_f\left(1 - \frac{cq}{L}\frac{\kappa_L\beta_{\text{lin}}}{\beta_f}\right) = \beta_f(1 - \chi) \tag{12a}$$

$$\chi \simeq \frac{G\kappa_L}{\lambda}\frac{\beta_{\text{lin}}}{\beta_f} \tag{13}$$

(c) Comparing equations (A2) and (A2a) in the Appendix the bulk thermal expansion coefficients β_f and β_L have been interchanged, and $(\partial f/\partial L)_{T,V}$ has been replaced by $(\partial f/\partial L)_{T,p}$:

$$\left(\frac{\partial f}{\partial L}\right)_{T,p} = \left(\frac{\partial f}{\partial L}\right)_{T,V} + \left(\frac{\partial f}{\partial V}\right)_{T,L}\left(\frac{\partial V}{\partial L}\right)_{T,p} \tag{14}$$

The derivatives in the last term are replaced through equations (5c), (5d), (5e) thus:

$$\left(\frac{\partial f}{\partial L}\right)_{T,p} = \left(\frac{\partial f}{\partial L}\right)_{T,V}\left[1 - \frac{cq}{L^2}\frac{cq}{L^2}V\kappa_L\frac{L^3}{c(L^3 + 2qV)}\right]$$

$$= \left(\frac{\partial f}{\partial L}\right)_{T,V}(1 - \psi) \tag{14a}$$

where

$$\psi \simeq \frac{G\kappa_L}{\lambda}\frac{1}{\lambda^3 + 2} \tag{15}$$

(d) The Gaussian force law (5) itself is an approximation. To estimate its validity, the experimental data of force and elongation can be inserted so that the experimental correction ω is obtained:

$$\omega = 1 - \frac{cL_0(\lambda - \lambda^{-2})}{f} \tag{16}$$

For values of λ in the range studied here, the corrections ϕ, χ, ψ and ω have been calculated using the experimental results reported previously[5], and are given in *Table 1*.

Although experiments have proved that volume changes exceed the values calculated according to Gaussian behaviour[20] the correction ϕ remains negligible compared with ω. The same applies to χ, and since the experimental accuracy of β_L is about 1%, β_L, β_f and β_0 cannot be discriminated. The correction ψ too can be disregarded, which means that it is satisfactory to carry out force vs. elongation measurements at constant pressure even if the coefficient at constant volume is needed.

Table 1 Values of λ and the corrections ϕ, χ, ψ and ω for the studied range

λ	ϕ(%)	χ(%)	ψ (%)	ω(%)
0.88	−0.003	0.023	0.010	2.15
1.00	0.0	0.008	0.008	0.0
1.18	0.004	−0.010	0.005	−3.83
1.70	0.010	−0.034	0.002	−13.06

The aforementioned corrections have been calculated on the basis of the force law (5), which may only be exact enough when λ is close to 1. The orders of magnitude of ϕ, χ, ψ will remain much the same even for a non-Gaussian equation of state. More troublesome is the influence of ω when the force law is applied to transform the exact equation (A2) for the determination of f_e/f. Even if both derivatives are evaluated by means of the force law (5), there is no guarantee that the deviations cancel out. If, on the other hand, equations with the experimentally determined quantities $(\partial f/\partial L)_{T,p}$ or $(\partial f/\partial T)_{p,L}$ are used there remains the uncertainty of the second term in the force law. If the force law is applied to both terms of equation (A2), for $f = 0$ the difference in f_e/f is zero because $\omega = 0$. Expressions (6) and (9c) and (9d) which contain the force law in one of their terms only can give infinite values of $f = 0$ resulting from even the most minute experimental scatter. Furthermore equation (7) involves the same uncertainties originating from the force law.

Use of the Mooney–Rivlin equation instead of the Gaussian force law would be of little help in the experimental range of the present work because this equation is not applicable in the vicinity of $\lambda = 1$ or in uniaxial compression[5].

RESULTS

The measurements of lengths vs. force at 20° and 40°C have been described previously[5]. Experimental data in the range of small deformation $0.88 < \lambda < 1.18$ were represented by fourth power polynomials $L(f)$ using a LSMCP. From these polynomials mean values for 30°C were calculated giving the constant cL_0 and β_f, and the functions λ, β_{lin} and $(\partial f/\partial L)_{T,p}$ as functions of f. Then equations (9), (9a), (9b), (9c) and (9d) could be applied to the determination of f_e/f. For comparison, another LSMCP was used to fit the experimental data by third power polynomials $f(L)$. Thus the expansion coefficient β_L and the functions f, λ and $(\partial f/\partial T)_{p,L}$ were obtained at constant increments in length. This evaluation allowed the application of equation (6) to determine f_e/f.

Influence of experimental errors in β_{lin}

The linear thermal expansion coefficient β_{lin} is a substantial part of all equations for f_e/f except equation (6). The results turn out to be strongly dependent on any variation in β_{lin} which itself is sensitive to experimental errors. To assess the experimental scatter of β_{lin} this function has been drawn, for the outer and the inner pairs of marks, in *Figure 1*, rendering the computer-calculated curves for small deformations ($\lambda = 0.9$ to 1.15) as continuous lines and an averaged curve for the experimental data at moderate elongation up to $\lambda \simeq 1.70$ as a broken line. The continuous curves are slightly S-shaped, the curve for the inner marks showing a downward curvature above $\lambda \simeq 1.12$ which probably is due to experimental inaccuracies. Therefore
Figure 1 Linear thermal expansion coefficient β_{lin} vs. λ. ●, Outer marks; +, inner marks. ———, Computer calculated curves for small deformations; · · ·, approximated straight line for small deformations; — — —, averaged curve for moderate elongations

of the continuous curves only that for the outer marks which connects satisfactorily with the broken line, was used to calculate f_e/f.

Taking the whole range of measurements and the experimental scatter between inner and outer marks into consideration another method of smoothing out the experimental findings seems reasonable too. In the range of small deformation from $\lambda \simeq 0.90$ to $\lambda \simeq 1.15$, β_{lin} might be approximated by a straight line which joins the broken line and the straight line might even be extended through the experimental points measured at moderate elongation up to $\lambda \simeq 1.50$ (dotted line). Only the last two points, for $\lambda \simeq 1.70$, are not included.

In the isotropic state $\lambda = 1$ the continuous curves yield for the outer ⟨inner⟩ marks $\beta_{\text{lin}}(0) = 2.13_4\langle 2.23_0\rangle \times 10^{-4}$ deg^{-1} whereas from the straight approximation $\beta_{\text{lin}}(0) = 2.14 \times 10^{-4}$ deg^{-1}. According to equation (9f) the bulk expansion coefficient β_f is to be calculated from $\beta_{\text{lin}}(0)$. A comparison with β_L as obtained from the second LSCMP (the constant length evaluation) shows good agreement:

$$\beta_f[\times 10^{-4}\ \text{deg}^{-1}] = 6.40_1\langle 6.68_9\rangle$$

$$\beta_L[\times 10^{-4}\ \text{deg}^{-1}] = 6.40_9\langle 6.69_8\rangle$$

The accuracy of these coefficients has previously been estimated at 3%[5].

Thermoelastic inversion occurs at $\lambda_{\text{inv}} = 1.076\langle 1.079\rangle$ on the continuous curves or at 1.074 in the case of the linear approximation of $\beta_{\text{lin}}(\lambda)$. Because the curve passes through zero the relative accuracy of β_{lin} depends strongly on its absolute value.

From the continuous curve of β_{lin} from the outer marks, f_e/f has been calculated by means of equations (9), (9a), (9b), (9c) and (9d) in the region of small deformation and from the experimental data of either pair of marks in moderate elongation (broken lines). *Figure 2* shows these results together with values obtained according to equation (6) from the constant length evaluation. All continuous functions (9), (9a) and (9b) yield a distinct value $(f_e/f)_0 = 0.26_5$ for $\lambda = 1$ whereas (9c) and (9d) have sharp poles which only become apparent in the interval $0.98 < \lambda < 1.02$. The functions show maxima of different heights for $\lambda \simeq 0.95$ and a rather sharp decrease for smaller λ (more

compression). In elongation there is a negative slope which gradually lessens towards higher λ, being different for each formula and even leading to almost zero slope for (9c) and (9d) in the range of moderate elongation. Equation (6) yields a curve similar to (9c), (9d) but tends towards $+\infty$ on either side of $\lambda = 1$ and shows a small decrease in compression.

Even apart from the differences between functions yielding infinite values for $\lambda = 1$ and the continuous functions in the immediate vicinity of zero deformation, there is a broad scatter of the f_e/f results obtained by different equations. In compression down to $\lambda \simeq 0.92$ the extreme values of f_e/f differ by $\Delta(f_e/f) \leqslant 0.05$. In the range of small elongations $\Delta(f_e/f) < 0.03$ up to $\lambda \simeq 1.12$ but $\Delta(f_e/f) \geqslant 0.20$ at moderate elongations for $\lambda > 1.50$.

In addition to the variation originating from the use of different functions there is an experimental scatter between values for the outer and inner pair of marks, obtained by the same function. This is shown in *Figure 3*, in which f_e/f is represented according to equation (9a) in the range of small deformation as continuous curves and the experimental points for moderate elongation approximated by a broken line. The discrete value $(f_e/f)_0 = 0.29_8$ is found from all continuous functions for the inner marks compared with 0.26_5 for the outer ones.

If, however, the f_e/f calculation is carried out based upon a smoothed function β_{lin}, the resulting curve in the range of small deformation has a completely different shape. *Figure 4* shows f_e/f in the range of small deformation $0.90 \leqslant \lambda \leqslant 1.15$ as a continuous curve obtained from the straight line approximation of β_{lin} using equation (9a).
Figure 2 f_e/f vs. λ calculated from various equations
Figure 3 f_e/f vs. λ for outer (●) and inner (+) marks from equation (9a)
Figure 4 f_e/f vs. λ from equation (9a) with linear approximation of $\beta_{lin}(\lambda)$

Thus f_e/f is almost constant in this range with an average value of 0.18.

Continuation of the straight approximation up to $\lambda \simeq 1.50$ leads to f_e/f values which, by analogy to *Figure 1*, are given by a dotted line. From the broken line in *Figure 1* the broken line in *Figure 4* is obtained. Comparing the broken and dotted lines in *Figure 4* again it is seen that small changes of β_{lin} (see *Figure 1*) cause drastic changes of f_e/f.

We conclude that the influence of experimental errors in β_{lin} on the evaluation of f_e/f at small deformations is most conveniently dealt with by use of a smoothed function for β_{lin} which is linear in λ.

Restrictions on the use of the force law

The poles displayed by equations (6), (9c) and (9d) show that the application of the Gaussian force law to the evaluation of f_e/f must be considered critically. Inspection of these three equations reveal that whereas $-(1/f).(\partial f/\partial T)_{p,L}$ and $(\partial f/\partial L)_{T,p}$, $L\beta_{lin}/f$ can be calculated directly from experimental measurements, the second term in each equation can only be estimated by invoking the force law. At higher elongations they become increasingly important compared with the second terms which can only be determined from the force law. *Figure 5* shows that the magnitude of the second term, underlying the inaccurate force law is roughly equal to the first term for $\lambda \simeq 1.15$ but only $\sim 6\%$ of the first term for $\lambda \simeq 1.70$. Thus increasing inaccuracy of the force law at higher elongations (see correction ω) is offset by the reduced importance of the term. Preference should be given to equation (9d) rather than (9c) for two reasons: first, $\beta_L/(\lambda^3 - 1) < (cL_0/f\lambda^2).\beta_L$ and therefore has less influence on f_e/f, and secondly the determination of the slope cL_0, which may cause additional inaccuracy, is redundant in equation (9d).

Inspection of *Figure 5* shows that both the terms of equations (6) and (9d) tend towards infinity in opposite directions as $\lambda = 1$ is approached. Whereas the increasing influence of the second term is not serious because the force law becomes more and more accurate in this region, it is clear that even minute experimental error causes substantial changes in the sum of both terms. This is the reason why many investigators have found strong upturns or downturns of f_e/f in this region[11-13] and why even a LSMCP does not avoid the appearance of an infinite value for $(f_e/f)_0$ as demonstrated in *Figure 2* for equations (6), (9c) and (9d). Therefore application of equations (6) and (9d) should be restricted to the range of $\lambda > 1.10$ for which range the 'functions' in *Figure 5* have been given as dotted lines, thus allowing the direct estimation of f_e/f.

In equations (9) and (9a) the sum of β_{lin} and the second term are given as dotted lines in *Figure 6*. It must be remembered that both terms of these equations have been derived on the basis of the force law. Therefore the validity of these equations is limited to small deformations up to $\lambda < 1.15$. In compression, the range may be larger because the Gaussian force law is more closely obeyed than in elongation[5]. The second term $(3\beta_{lin} - \beta_f)/(\lambda^3 - 1)$ of equation (9a) should be preferred to the corresponding term in equation (9). Inaccuracy in the determination of cL_0 may be responsible for the non-constancy of f_e/f at small deformations. Therefore the resulting f_e/f can be read more reliably from $F(9a)$ in *Figure 6*, or directly in *Figure 4*.

The rule of de l'Hospital (equation A4) yields a discrete value $(f_e/f)_0$ for zero deformation which may be compared with results obtained by means of measuring the shear modulus G according to equation (8). Owing to the extreme sensitivity of the calculation in the range of small deformations, even a LSMCP rendering smoother $L(f)$ polynomials may cause a fairly large scatter in the
Figure 5 Evaluation of terms in equations (6), (9c) and (9d) vs. λ. $y = -(\beta_L/\lambda^3 - 1)$: $\square$, inner marks; $\lozenge$, outer marks. $y = -(cL_0/f\lambda^2)$. β_L: $\triangledown$, inner marks; $\triangle$, outer marks. $y = (\partial f/\partial L)_{T,p}(L\beta_{lin}/f)$: $\times$, inner marks; $\blacksquare$, outer marks. $y = -(1/f)(\partial f/\partial T)_{p,L}$: $+$, inner marks; $\bullet$, outer marks
Figure 6 Evaluation of terms in equations (9) and (9a) vs. λ. $\bullet$, Outer marks; $+$, inner marks. $y = (3\beta_{lin} - \beta_f)(cL_0/f)$: $\triangle$, outer marks; $\triangledown$, inner marks. $y = (3\beta_{lin} - \beta_f)/(\lambda^3 - 1)$: $\square$, outer marks; $\lozenge$, inner marks

f_e/f results unless an additional smoothing of the coefficient $\beta_{lin}(\lambda)$ is carried out.

From this analysis of results we conclude that of the equations we have used (9a) is most suitable for evaluating f_e/f at small deformations whereas equations (6) and (9d) are best applied at moderate elongations.

DISCUSSION

The selective use of equation (9a) for the range of small deformation and (6) and (9d) for moderate elongation results in a consistent pattern of behaviour of f_e/f in the whole range of the present investigation. *Figure 7* demonstrates that a constant relative contribution $f_e/f \simeq 0.18$ has been measured from compression at $\lambda \simeq 0.90$ up to moderate elongation at $\lambda \simeq 1.70$ for $T = 30°C$. Taking into account the experimental scatter between different sets of marks and different evaluations according to equations (6) or (9d) the accuracy is estimated as: $f_e/f = 0.18 \pm 0.02$.

It is, of course, satisfactory to find that the relative energetic contribution f_e/f is not sensitive to the degree of deformation over a fairly wide range of deformation. Since this holds in the transition region between uniaxial elongation and compression too, any speculation of special 'phenomena' accompanying initial deformation can be discarded.

Volume effects too are not serious in the range of small deformations since disregarding the correction ϕ causes no detectable changes of f_e/f. In the range of small deformation a computer calculation of equation (9) gave differences of $\Delta(f_e/f) < 0.0001$ when ϕ calculated on the basis of Gaussian behaviour was taken into account.

Since in equations (6) and (9d) the influence of the second term which has to be derived from a force law decreases quickly with increasing elongation as shown in *Figure 5*, the Gaussian force law can be used without restriction for $\lambda > 1.10$ to determine f_e/f. Though the Mooney–Rivlin equation is a better representation of the force vs. length relationship in moderate and higher elongation by means of two constants C_1 and C_2, the resulting value f_e/f is not particularly sensitive[8,21] to changes of C_2.

The result that $f_e/f = 0.18$ and is independent of the elongation ratio compares well with data from literature obtained for the most part at larger deformations. The same value 0.18 for lightly crosslinked rubber has been found by Smith *et al.*[4] for $\lambda > 1.30$. Allen *et al.*[8] obtained this value in the range $1.2 \leqslant \lambda \leqslant 2.1$ by use of the Gaussian equation compared with $f_e/f = 0.12$ from the direct experimental determination. Measurements of $L(T)$ at constant f by Barrie and Standen[15] lead to $f_e/f = 0.17$. Treloar's experiments[3] of combined torsion and elongation gave $f_e/f \simeq 0.13$ in the range of axial elongation $1.13 \leqslant \lambda \leqslant 1.25$.

Shen and Blatz[2] found $f_e/f = 0.15$ from $f(T)$ measurements at constant L, and Shen[17] obtained $f_e/f = 0.18$ independent of the degree of swelling by a diluent from measuring $L(T)$ at constant f. These investigations used equation (8), with the shear modulus G determined from the slope of the Gaussian plot f/A_0 vs. $(\lambda - \lambda^{-2})$.

Comparing these data from the literature with the result of the present investigation the suggestion of Shen and Blatz[2] that f_e/f depends on the sample geometry, is at least partly refuted. First, the sample used here is much shorter and thicker than usual samples, and secondly, no uniform trend of f_e/f values measured between the outer
Figure 7 f_e/f vs. λ. $\triangle$, Equation (9a). Equation (6): $\bullet$, outer marks; +, inner marks. Equation (9d): $\square$, outer marks; X, inner marks

('longer sample') or the inner marks ('shorter sample') can be detected.

The amount of deformation (in either direction) read between the marks is relatively larger than that read between the rigidly fixed ends of a sample. A more homogeneous state of deformation is achieved by using the marks. But under the influence of varying temperature, relative changes of the length, and thus f_e/f itself, are not changed apparently.

The geometrical dimensions of samples which are appropriate to uniaxial compression do not favour experiments at high elongation. For this reason the slight decrease of f_e/f which has been reported[13,15] could not be investigated.

APPENDIX

Theoretical calculations

The relative energetic contribution can be transformed from the exact equation (3) into:

$$f_e/f = 1 + \frac{T}{f}\left[\left(\frac{\partial f}{\partial L}\right)_{T,V}\left(\frac{\partial L}{\partial T}\right)_{p,f} + \left(\frac{\partial f}{\partial V}\right)_{T,L}\left(\frac{\partial V}{\partial T}\right)_{p,f}\right] \quad (A1)$$

with the aid of the following relationships:

$$\left(\frac{\partial f}{\partial T}\right)_{V,f} \equiv 0 = \left(\frac{\partial f}{\partial T}\right)_{V,L} + \left(\frac{\partial f}{\partial L}\right)_{V,T}\left(\frac{\partial L}{\partial T}\right)_{V,f} \quad (A1a)$$

$$\left(\frac{\partial L}{\partial T}\right)_{V,f} = \left(\frac{\partial L}{\partial T}\right)_{p,f} - \left(\frac{\partial L}{\partial V}\right)_{T,f}\left(\frac{\partial V}{\partial T}\right)_{p,f} \quad (A1b)$$

$$\left(\frac{\partial f}{\partial V}\right)_{T,f} \equiv 0 = \left(\frac{\partial f}{\partial V}\right)_{T,L} + \left(\frac{\partial f}{\partial L}\right)_{T,V}\left(\frac{\partial L}{\partial V}\right)_{T,f} \quad (A1c)$$

The thermal coefficients at constant pressure p and force f may be represented by the usual symbol β with different subscripts, i.e. the linear thermal expansion coefficient:

$$\beta_{\text{lin}} = \frac{1}{L}\left(\frac{\partial L}{\partial T}\right)_{p,f} \quad \text{A1d)}$$

and the bulk thermal expansion coefficient:

$$\beta_f = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_{p,f} \quad (A1e)$$

In the isotropic state of the sample ($f = 0$) there is by definition:

$$3\beta_{\text{lin}}(f = 0) = \beta_{f=0} \quad (A1f)$$

Whereas β_{lin} strongly depends on f or λ and even changes its sign at a certain elongation λ_{inv} (thermoelastic inversion), the bulk coefficient β_f remains virtually constant because β_f deviates only slightly from the bulk thermal expansion coefficient β_L taken at constant length. Experimental evidence demonstrates that β_L remains constant[6] within the experimental limits of 1% in the range of moderate elongation up to $\lambda = 2.2$. Later the relative difference between β_f and β_L will be shown to be of the order of 10^{-4} deg^{-1}. Therefore either of them can be replaced by the coefficient $\beta_{f=0}$ of the isotropic material[9].

Inserting the thermal coefficients, equation (A1) transforms into:

$$f_e/f = 1 + \frac{T}{f}\left[\left(\frac{\partial f}{\partial L}\right)_{T,V} L\beta_{\text{lin}} + \left(\frac{\partial f}{\partial V}\right)_{T,L} V\beta_f\right] \quad (A2)$$

A force vs. length relationship is required now to express the remaining derivatives in equation (A2) in terms of quantities which can be measured under the experimental limitations imposed by the design of the apparatus. A similar equation:

$$f_e/f = 1 + \frac{T}{f}\left[\left(\frac{\partial f}{\partial L}\right)_{T,p} L\beta_{\text{lin}} + \left(\frac{\partial f}{\partial V}\right)_{T,L} V\beta_L\right] \quad (A2a)$$

is obtained directly from equations (3) and (3a) since:

$$\left(\frac{\partial f}{\partial T}\right)_{p,L} = -\left(\frac{\partial f}{\partial L}\right)_{p,T}\left(\frac{\partial L}{\partial T}\right)_{p,f} = -\left(\frac{\partial f}{\partial L}\right)_{p,T} L\beta_{\text{lin}} \quad (A1g)$$

The first derivative in equation (A2) can be replaced by means of equation (5d) and split into two terms, thus using equations (5) and (5e):

$$f_e/f = 1 + \frac{T}{f}\left[\left(f + \frac{c}{L^2} 3qV\right)\beta_{\text{lin}} - \frac{cqV}{L^2}\beta_f\right] \quad (A2b)$$

This can be re-written in terms of λ using equation (5a) and $\lambda = L/L_0$:

$$f_e/f = 1 + T\left[\beta_{\text{lin}} + \frac{cL_0}{\lambda^2 V_0/V} \frac{3\beta_{\text{lin}} - \beta_f}{f}\right] \quad (9)$$

where cL_0 may be replaced by the shear modulus according to equation (5b).

Equation (11) becomes indefinite for $f = 0$, because according to equation (A1f) the numerator $3\beta_{\text{lin}} - \beta_f$ tends towards zero as $f \to 0$. The influence of the volume quotient V_0/V is negligible.

To evaluate measurements by means of (9) the actual length L has to be known as a function of f and T. The temperature coefficient of the length at various constant forces leads to β_{lin}. An exact determination of length and β_{lin} at zero force is sufficient to calculate λ and β_f and the slope of the Gaussian plot at this point yields cL_0.

Equation (9) is not the only one which can be obtained from equation (A2) by means of the force law (5). There are other similar expressions in which, for simplicity, the volume quotient V_0/V has been omitted:

$$f_e/f = 1 + T\left[\beta_{\text{lin}} + \frac{3\beta_{\text{lin}} - \beta_f}{\lambda^3 - 1}\right] \quad (9a)$$

$$f_e/f = 1 + \frac{T}{f}\frac{cL_0}{\lambda^2}\left[(\lambda^3 + 2)\beta_{\text{lin}} - \beta_f\right] \quad (9b)$$

If experimental data are evaluated by means of a LSMCP and the force is known as a polynomial of the length, $(\partial f/\partial L)_{T,p}$ can be calculated explicitly. Then equation (A2a) may be employed together with the derivative (5e) of the force law to obtain:

$$f_e/f = 1 + \frac{T}{f}\left[\left(\frac{\partial f}{\partial L}\right)_{T,p} L\beta_{\text{lin}} - \frac{cL_0}{\lambda^2}\beta_L\right] \quad (9c)$$

$$f_e/f = 1 + T\left[\left(\frac{\partial f}{\partial L}\right)_{T,p}\frac{L\beta_{\text{lin}}}{f} - \frac{\beta_L}{\lambda^3 - 1}\right] \quad (9d)$$

Returning to equation (9) the undeformed state of the sample may be analysed. In the limit of zero force, $\lambda = 1$ and $V_0/V = 1$. Then the indefinite expression is accessible by means of the rule of de l'Hospital if β_f is assumed to be constant:

$$\lim_{f \to 0} \frac{3\beta_{\text{lin}} - \beta_f}{f} = 3\left(\frac{\partial \beta_{\text{lin}}}{\partial f}\right)_{p,T,f \to 0} \quad (9e)$$

Replacing $\beta_{lin}(f=0)$ by $\beta_f/3$ the relative energetic contribution to zero force is obtained as:

$$(f_e/f)_0 = 1 + T\left[\beta_f/3 + 3cL_0\left(\frac{\partial\beta_{lin}}{\partial f}\right)_{p,T,f=0}\right] \qquad (A3)$$

where equation (5b) may be taken to express $cL_0 = A_0 G$.

Another single value of f_e/f can be calculated using the thermoelastic inversion point. For a particular length L_{inv} the temperature derivative $(\partial f/\partial T)_{p,L_{inv}}$ is zero[17] which is equivalent to the condition that the temperature coefficient of the sample length is zero for the corresponding force f_{inv}:

$$\frac{1}{L_{inv}}\left(\frac{\partial L}{\partial T}\right)_{p,f_{inv}} = \beta_{lin}(f_{inv}) = 0 \qquad (A3a)$$

Inserting this into equation (9a) the quantity f_e/f is obtained at the thermoelastic inversion point:

$$(f_e/f)_{inv} = 1 - \frac{\beta_f T}{\lambda_{inv}^3 - 1} \qquad (A4)$$

which is equivalent to Shen's equation[17].

Depolymerization behaviour of poly-(p-phenylene diacrylic acid diethyl ester)

Fuşae Nakanishi and Masaki Hasegawa

and Takeshi Tasai
Somar Kogyo Co. Ltd, Ginza, Tokyo, Japan
(Received 31 May 1974; revised 2 July 1974)

The photochemical and thermal behaviour of poly(p-phenylene diacrylic acid diethyl ester) [poly(p-PDA-Et)] has been investigated. It was observed that both photo and thermal depolymerization occurs with cleavage of the cyclobutane ring. Photochemically poly(p-PDA-Et) in solution depolymerizes selectively into oligomer, which undergoes cis—trans isomerization without further depolymerization to monomer. On the other hand, it depolymerizes thermally at random into low molecular weight polymer and monomer.

INTRODUCTION

Various types of novel polymers with a cyclobutane ring in the main chain have been prepared by means of four-centre type photopolymerization of diolefinic compounds in the crystalline state[1-3]. It is expected that the presence of a cyclobutane ring in the polymer chain introduces interesting properties to the polymer. Of several cyclobutane derivatives in the solution, it is well known that photocleavage and formation of a cyclobutane ring proceeds reversibly depending on the wavelength of the irradiation. In a polymer system with a cyclobutane ring in the main chain, such a photoreversibility corresponds to the solution photopolymerization and photodepolymerization and such a case was found in poly(2,5-distyryl pyrazine) (PDSP)[4-6].

The present work was undertaken to investigate the photo and thermal behaviour of poly(p-phenylene diacrylic acid diethyl ester) [poly(p-PDA-Et)] which is one typical polymer obtained by a crystalline state photopolymerization:
EXPERIMENTAL

Preparation of poly(p-PDA-Et)

Poly(p-PDA-Et) was prepared according to the method described in an earlier paper[2]. Because of poor solubility of as-polymerized polymer crystal, amorphous polymer which is soluble in organic solvents was used for the study on photochemical behaviour in solution. Amorphous polymer was obtained by reprecipitation of trifluoroacetic acid solution of polymer by adding water. The reduced vis-

cosity of the polymer thus obtained was in the range of between 0.4 and 1.2 ($C = 0.36$ in trifluoroacetic acid).

Preparation of oligo(p-PDA-Et)

Oligo(p-PDA-Et) was obtained by extracting high molecular weight crystalline poly(p-PDA-Et) with chloroform or benzene. Its molecular weight was about 1000 (tetramer), which was measured by vapour pressure osmometry with a Mechro Lab. Model 301 A.

Formation of anhydride from oligo(p-PDA-Et)

Oligo(p-PDA-Et) (100 mg) was hydrolysed by refluxing with 1 N NaOH ethanol solution (10 ml) for 10 h. After removal of ethanol, the residue was dissolved in water and neutralized with dilute hydrochloric acid. The white precipitate obtained was found by i.r. spectroscopy to be hydrolysed oligomer. This acid was refluxed in acetic anhydride for 4 h. After removal of acetic anhydride the residue was washed with ethanol and dried. The obtained product showed the presence of a six-membered ring anhydride by i.r. absorption peaks at 1820 and 1770 cm^{-1}.

Preparation of model compounds

p-PDA-Et crystals (1 g), dispersed in water (100 ml) at 60—65°C, were irradiated with a 100 W high pressure mercury lamp. The crystal gradually became cohesive. After 6 h the product was collected and dried. The dimer content in this product was found to be about 30% by n.m.r. spectroscopy. The dimer was isolated from unreacted p-PDA-Et by washing with n-hexane where the dimer is much less soluble than p-PDA-Et. The residue was recrystallized from ethanol: m.p. 138°C; λ_{max} 287 nm ($\epsilon = 58\,000$ in ethanol). Calculated for $C_{16}H_{18}O_4$: C, 70.05%; H, 6.61%. Found: C, 70.08%; H, 6.68%. The anhydride derivative from hydrolysed dimer showed i.r. absorption at 1820 and 1770 cm^{-1}

Preparation of diethyl α-truxillate

Diethyl α-truxillate was prepared by esterification of α-truxillic acid: m.p. 149°C.

Preparation of poly(p-PDA-Et) film

Relatively low molecular weight polymer (η_{red} = 0.8), the terminal double bonds of which are detectable from the i.r. spectrum was used. The film was obtained by casting a chloroform solution of poly(p-PDA-Et). In order to check the change of film with the u.v. spectrum, the films were deposited on a quartz plate by evaporation of a solution of the polymer in chloroform.

Determination of quantum yield

A solution of diethyl α-truxillate in ethanol (2.49 × 10^{-5} mol/l) was irradiated with monochromatic light of 224 nm wavelength. The number of photons absorbed was determined by use of a calibrated thermopile. The amount of ethyl cinnamate formed was determined by measurement of absorption intensity at 278 nm. The quantum yield thus obtained was 0.2 for the formation of ethyl cinnamate by irradiation with light of 224 nm wavelength in ethanol.

N.m.r. spectroscopy

All spectra were determined in deuterochloroform solution (5%) using a JOEL-C-60HL instrument. These solutions were subjected to photo-irradiation.

D.s.c. and t.g.a. measurements

Differential scanning calorimetry (d.s.c.) and thermogravimetric analysis (t.g.a.) were carried out with Rigaku standard d.s.c. and t.g.a. instruments at a heating rate of 10°C/min under nitrogen. In order to study the thermal behaviour of poly(p-PDA-Et) a few milligrammes of poly(p-PDA-Et) was heated in a cell of the d.s.c. apparatus under an atmosphere of nitrogen for 1 h at various temperatures.

Light source

The monochromatic light was furnished by a spectroscopic irradiator (JASCO CRM FA) composed of 2000 W xenon lamp as the light source and grating monochromator. Other irradiation lights, 100 W high pressure mercury lamp or 17 W low pressure mercury lamp were used as necessary according to the experiment.

RESULTS AND DISCUSSION

Structure of poly(p-PDA-Et), its oligomer and p-PDA-Et dimer

It is difficult to determine the structure of high molecular weight poly(p-PDA-Et) because of poor solubility needed to study the chemical behaviour in solution and the n.m.r. spectrum. However, its oligomer is soluble in common organic solvents and it is easier to study this structure. Therefore, elucidation of the structure was carried out on oligo(p-PDA-Et). The oligomer should have the same steric configuration as that of poly(p-PDA-Et) concerning the cyclobutane ring as any isomerization is not presumed to occur either by crystalline state photopolymerization or during extraction procedure with chloroform. I.r. spectra of anhydride derivatives of hydrolysed oligo(p-PDA-Et) and p-PDA-Et dimer shows formation of a six-membered ring anhydride (1820 and 1770 cm^{-1}). Formation of the six-membered ring anhydride suggests that the configuration of these compounds is one of the following two types:

trans head-to-tail   *cis* head-to-tail
In the case of the former, epimerization is assumed during formation of anhydride. However, the structure of p-PDA-Et dimer and oligo(p-PDA-Et) is most likely to be *trans* head-to-tail from the n.m.r. spectra. The n.m.r. spectra of oligo(p-PDA-Et), p-PDA-Et dimer and diethyl α-truxillate are shown in *Figure 1* together with that of ethyl cinnamate for comparison. The spectrum of oligo(p-PDA-Et) is very similar to p-PDA-Et dimer in each chemical shift. Furthermore, the chemical shifts of ethyl, methyl protons which are in ester residue as substituents on the cyclobutane ring, are in agreement with those of ethyl, methyl protons in diethyl α-truxillate, in which the configuration of its parent acid was established as *trans* head-to-tail type[7]. From these agreements in chemical shifts, the configuration of oligo(p-PDA-Et) and p-PDA-Et dimer is concluded to be *trans* head-to-tail as described in *Figure 1*. In addition the fact that a shear rate dependence of the solution viscosity has been observed for a chloroform solution of poly(p-PDA-Et) supports the view that the structure of poly(p-PDA-Et) is the same as that of oligo(p-PDA-Et)[8].
Figure 1   N.m.r. spectra of (a) oligo(p-PDA-Et), (b) p-PDA-Et dimer, (c) diethyl α-truxillate and (d) ethyl cinnamate and their structures

Photobehaviour of poly(p-PDA-Et) and oligo(p-PDA-Et)

The effect of photoirradiation on polymer solution has been studied by means of measurement of the change in solution viscosity and u.v. spectrum. The change in solution viscosity on irradiation with 100 W high pressure mercury lamp is shown in *Table 1*. When the solution of poly(*p*-PDA-Et) in chloroform was irradiated in a glass tube which is transparent above 300 nm wavelength light, a slight decrease in viscosity was observed (1.28 → 1.06). Thus irradiated polymer did not show any change in n.m.r. spectrum and thin-layer chromatogram compared to those of the original polymer. When a quartz tube was used in place of the glass tube the solution viscosity dropped drastically (1.16 → 0.11). At the same time, the n.m.r. spectrum of thus irradiated polymer showed the appearance of the ethyl cinnamyl group (methyl protons, 1.3 ppm; methylene protons, 4.4 ppm; olefinic protons, 6–7 ppm), which is due to the cleavage of the cyclobutane ring in the main chain. In addition, its thin layer chromatogram gave several spots which are considered to be the fragments with different degree of polymerization. However, no monomer was detected in the u.v. spectrum in this photoirradiated product, i.e. irradiation with light of wavelength shorter than 300 nm, makes poly(*p*-PDA-Et) depolymerize into low molecular weight polymer by cleavage of the cyclobutane ring. This photochemical depolymerization was confirmed by following the change of the u.v. spectrum on irradiation. Poly(*p*-PDA-Et) in chloroform was prepared at a concentration high enough to observe the change in absorption at around 280 nm. The change on irradiation with monochromatic light is shown in *Figure 2*. On irradiation at 287 nm, the absorption intensity decreased slightly and then gradually increased with irradiation time. The first decrease of absorption intensity is due to the isomerization from *trans*-to *cis*-isomer of the terminal ethyl cinnamyl group of the polymer and the subsequent increase is due to a gradual increase in the ethyl cinnamyl group formed by cleavage of the cyclobutane ring in the main chain of the polymer.

Irradiation with the light of wavelength shorter than 287 nm showed the same spectral change; on irradiation at 304 nm, the absorption peak decreased and finally gave a photostationary spectrum. So in this case, only isomerization of the terminal ethyl cinnamyl group occurred.

From these data it may be said that photodepolymerization of poly(*p*-PDA-Et) into low molecular weight polymer is favourable with light that excites the benzene ring, while with light that excits the terminal ethyl cinnamyl group $(\pi-\pi^*)$ isomerization of *trans* to *cis* occurs efficiently.

As the next step the photochemical behaviour of oligo(*p*-PDA-Et) solution has been investigated. When oligo(*p*-PDA-Et) in deuterochloroform was exposed to 287 nm light, its n.m.r. spectrum changed as shown in *Figure 3*. New peaks with a coupling constant of 13 counts/sec were observed at 6–7.5 ppm. With regard to methyl, methylene proton new peaks were found in a slightly higher field. These peaks are assigned to be *cis* protons of the ethyl cinnamyl group.

Almost no change in molecular weight of oligo(*p*-PDA-Et) before (988) and after (995) irradiation supports the occurrence of *cis–trans* isomerization of oligo(*p*-PDA-Et) in solution. The change of u.v. spectrum on irradiation of oligo(*p*-PDA-Et) in ethanol solution is shown in *Figure 4*.
Figure 3 N.m.r. spectra of irradiated (a) oligo(*p*-PDA-Et), (b) *p*-PDA-Et dimer, (c) diethyl α-truxillate and (d) ethyl cinnamate
Figure 4 Change in u.v. spectrum of oligo(*p*-PDA-Et) on irradiation. – – –, Before irradiation; ——, after irradiation

With irradiation of the absorption peak at 287 nm, a decrease of absorption intensity was observed indicating isomerization of the terminal ethyl cinnamyl group. Thus in the case of oligomer, the absorption of light by the ethyl cinnamyl group is predominant, resulting in *cis—trans* isomerization.

It should be noted that PDSP photodepolymerized into the monomer very easily but photodepolymerization of poly(*p*-PDA-Et) into the monomer is rather difficult even on prolonged irradiation.

Photoreaction of model compounds

Two model compounds were prepared in the hope that their photoreaction would provide further information to clarify the photodepolymerization of poly(*p*-PDA-Et). One of the model compounds is *p*-PDA-Et dimer for the terminal unit group of the polymer. The other is diethyl α-truxillate for the repeating unit of the main chain of the polymer. When diethyl α-truxillate in ethanol solution was irradiated at 224 nm, the absorption peak at 278 nm increased gradually (*Figure 5*). This band is due to the appearance of ethyl cinnamate and the reaction is considered to proceed as follows:
The quantum yield was 0.2 for the formation of ethyl cinnamate by 224 nm light in ethanol. Irradiation at 260 nm also caused the same reaction. The n.m.r. spectrum of diethyl α-truxillate in deuterochloroform after irradiation showed the appearance of both the *cis* and *trans* form of ethyl cinnamate (*Figure 3*). *Figure 6* shows the variation of the u.v. spectrum of *p*-PDA-Et dimer in ethanol with irradiation at 224 nm. The decrease of absorption intensity seems to be due to the slow isomerization of dimer as observed in the case of oligo(*p*-PDA-Et). No detectable amount of *p*-PDA-Et was formed by cleavage of the cyclobutane ring and the quantum yield for the formation of *p*-PDA-Et was negligible under the same irradiation conditions as diethyl α-truxillate.

cis—trans isomerization

cleavage of cyclobutane ring
Figure 5 Change in u.v. spectrum of diethyl α-truxillate on irradiation. – – –, Before irradiation; ——, after irradiation. A, 100; B, 300; C, 550; D, 750; E, 950 sec

Cis-trans isomerization was also confirmed by following the change of the n.m.r. spectrum of *p*-PDA-Et dimer in deuterochloroform. After irradiation with 100 W high pressure mercury lamp, no peaks corresponding to *p*-PDA-Et were detected, but peaks corresponding to the *cis* form of ethyl cinnamate were found (*Figure 3*). From the photoreaction of these model compounds it is considered that the absorption of light by a benzene substituent on the cyclobutane ring stimulates photocleavage of the cyclobutane ring, but by substitution of ethyl cinnamyl group on the cyclobutane ring, absorption of light by ethyl cinnamyl group became superior to that of benzene and results in *cis—trans* isomerization of ethyl cinnamyl group. A similar case was found in the photoreaction of 1,2-dicinnamoyl-3,4-diphenylcyclobutane in which *cis—trans* isomerization takes place without cleavage of the cyclobutane ring:

cis—trans isomerization
In summary, the following explanation is reasonable for photodepolymerization of poly(*p*-PDA-Et). There are many benzene rings in the main chain of the polymer and in the first stage they absorb the light resulting in cyclobutane ring cleavage. As a result, the molecular weight of the polymer decreases with an increase in terminal ethyl cinnamyl group. So absorption of light by ethyl cinnamyl group becomes superior to that of benzene and *cis—trans* isomerization takes place efficiently without further depolymerization of poly(*p*-PDA-Et).
Figure 6 Change in u.v. spectrum of *p*-PDA-Et dimer on irradiation. — — —, Before irradiation; ——, after irradiation. A, 90; B, 330; C, 520; D, 720; E, 1000 sec
Figure 7 Change in u.v. spectrum of poly(*p*-PDA-Et) film on irradiation. — — —, Before irradiation; ——, after irradiation at 277 nm; — - — -, after irradiation at 251 nm. A, 1000; B, 2000 sec

Photochemical behaviour of poly(p-PDA-Et) film

It is noteworthy that the film can be produced from poly(*p*-PDA-Et) with a molecular weight of only 2200 as determined by vapour pressure osmometry. The spectral changes in irradiation of poly(*p*-PDA-Et) film are shown in *Figure 7*. With irradiation at 277 nm, the absorption peak disappeared, while with irradiation at 251 nm, the intensity of the peak increased. The former may be due to the decrease of terminal cinnamyl group by cyclo-addition, the latter due to the increase of cinnamyl group by cyclobutane ring cleavage. Actually when the film was irradiated with the light of wavelength longer than 280 nm, the decrease of C=C double bonds (1640 cm^{-1}) in the i.r. spectrum was observed with an increase in molecular weight of the film (mol. wt 3000).

It should be pointed out that the photochemical behaviour of poly(*p*-PDA-Et) film is quite different from that of PDSP which becomes brittle following oxidative degradation on irradiation.

Thermal behaviour of poly(p-PDA-Et)

D.s.c. analysis of poly(*p*-PDA-Et) showed an exothermic peak at 340°C which is the melting point of the polymer. The t.g.a. curve showed slight weight loss near the melting point. Thermal stability of the polymer was examined by heating under a nitrogen atmosphere for 1 h at various temperatures (320, 330 and 360°C). From the heat-treatment at 320°C, the polymer did not show any change in spectroscopic analysis and at 360°C it became insoluble material. This may be due to the occurrence of thermal vinyl-type polymerization which leads to formation of gel[9] At 330°C the polymer became brown material but the result of elemental analysis showed almost no change in composition. Calculated for $C_{16}H_{18}O_4$:C, 70.05%; H, 6.61%. Found: C, 70.74%; H, 6.08%.

Further characterization was carried out on this heat-treated polymer. Several spots which are fragments of different degrees of polymerization were found by thin-layer chromatography. The n.m.r. spectrum showed the appearance of a terminal ethyl cinnamyl group (methylene protons, 4.4 ppm; methyl protons, 1.3 ppm; olefinic protons, 6−7 ppm) and the u.v. spectrum had an absorption peak at 290 nm with tailing absorption corresponding to that of the monomer. In the i.r. spectrum the double bond absorption appeared at 1640 cm^{-1}. From these facts, it is concluded that by heating near its melting point poly(*p*-PDA-Et) thermally depolymerizes into low molecular weight polymer with a small amount of monomer. It should be noted that thermal depolymerization due to cyclobutane ring cleavage seems to occur at any cyclobutane ring in the polymer, while photodepolymerization occurs rather selectively at the cyclobutane ring in the main chain to yield the oligomer without formation of the monomer.

The study of dynamic viscoelastic properties of polystyrene samples shows the influence of molecular parameters on characteristic parameters of linear viscoelastic behaviour. An analysis of complex viscosity in a complex plane shows the influence of polydispersity on the broadness of the relaxation spectrum and on the shape of steady-flow curve $\eta_a(\dot{\gamma})$.

INTRODUCTION

In a previous paper[1], a method for analysing the dynamic viscoelasticity of molten entangled polymers was described. The study of dynamic viscoelasticity of various molten entangled polymers (polyethylene, polystyrene, poly(methyl methacrylate), polyamide) in the low frequency range (20 to 10^{-3} Hz) showed the convenience of representing the variations of real and imaginary parts of the complex viscosity by:

$$\eta^*(\nu) = \eta'(\nu) - j\eta''(\nu)$$

where $\eta''(\nu)$ presents a maximum for a value ν_c of the frequency and $\eta'(\nu)$ goes through an inflection point.

In the complex plane (η', η''), experimental points are located for each product on a circular arc.

There are three parameters, namely: η_0, limiting extrapolated viscosity (intersection of the circular arc with the real axis); τ_0, characteristic relaxation time such as $\tau_0 = 1/2\pi\nu_c$; and h, coefficient such that $(h\pi)/2 = \theta$, angle between diameter going through the origin and the real axis.

Dynamic measurements have been achieved with a Contraves-Kepes Balance-Rheometer. Complex viscosity was measured in the temperature range 150–200°C.

The accuracy of η' and η'' was about 4%. η_0 is known to an accuracy of ±5%, τ_0 to an accuracy of ±10%.

In order to understand the significance of these parameters better, further experiments were carried out on polystyrene samples with a wide range of polydispersity and weight average molecular weight, and are reported in this paper. The results are compared with those obtained in steady-flow experiments.

EXPERIMENTAL

We used polystyrene samples of various types: 3 anionic polystyrene fractions (PSS62, PS50, PSW39); 3 commercial-type polystyrenes (PS550, PS500, PS506); 7 radical polystyrenes with practically the same polydispersity (PS 1,

PS 3, PS 4, PS 5, PS 6, PS 8, PS 9); a polystyrene of polydispersity 4.2, with a very asymmetrical distribution.

The structural parameters of the samples are shown in *Table 1*, in which P represents the polydispersity and M_w the weight average molecular weight.

RESULTS

As an example *Figures 1* and *2* show the results obtained for samples PSW39 (narrow) and PS550 (commercial type). We have reported in *Table 2* the values of the h parameter obtained on all the samples.

Table 1 Structural parameters of polystyrene samples

Sample	M_w	P	Sample	M_w	P
PSS62	125 000	1.25	PS1	257 000	3.38
PS50	160 000	1.10	PS3	311 000	3.52
PSW39	390 000	1.10	PS4	353 000	3.77
PS550	310 000	2.45	PS5	458 000	3.74

Table 2 h parameters of polystyrene samples

Sample	h	Sample	h
PSS62	0.34	PS1	0.41
PS50	0.14	PS3	0.47
PSW39	0.23	PS4	0.44
PS550	0.40	PS5	0.44
PS506	0.39	PS6	0.45
PS500	0.38	PS8	0.48
PSSAM327A	0.48	PS9	0.48

Variation of h *parameter*

We confirm that the h parameter is independent of temperature, whatever the polydispersity value is; it depends greatly on polydispersity, varying from 0.14 for PS50 of polydispersity 1.1, to a value of 0.48 for the SAM 327 A of polydispersity 4.2.

On the contrary it depends weakly on molecular weight at constant polydispersity (PS1 to PS9) and without any correlation.

Figure 3 shows the variation of the h parameter with polydispersity for all the samples.

It can be seen that the h parameter decreases with polydispersity, the variation being small at large values of polydispersity, and large when P tends to 1.

Variation of η_0

We show in *Figure 4* the variation of η_0 (limiting viscosity extrapolated from our dynamic measurements) with weight average molecular weight, M_w, on a logarithmic scale. The full line is the curve proposed by Suzuki[3] for narrow fractions of polystyrene at 192°C (zero shear rate viscosity measured in steady flow experiments: cone and plate rheometry). The plots for narrow fractions, are located on the line, and we will identify η_0 as zero shear rate viscosity.

Variation of τ_0

We previously defined[1] a characteristic relaxation time $\tau_0 = 1/\omega_c$ where ω_c is the frequency corresponding to the maximum of η''. For narrow fractions, $\log \tau_0$ varies linearly with $\log M_w$, following the line: $\log \tau_0 = 3.77 \log M_w - 2.55$. For large samples, at constant polydispersity (PS1 to PS9), the variation is found to be: $\log \tau_0 = 6.22 \log M_w - 33.69$.

DISCUSSION

The results obtained on polystyrene, polyethylene, polyamide and poly(methyl methacrylate) samples in the molten state, led us to represent complex viscosity by an analytical expression such as the Cole—Cole complex permittivity for dielectrics:

$$\eta^* = \frac{\eta_0}{1 + (j\omega\tau_0)^{1-h}} \tag{1}$$

This expression accounts quite well for our experimental results; it is valid for entangled polymers in the molten state, at low and moderate frequencies (20 to 10^{-3} Hz).

Many steady-flow experiments have been carried out on polystyrene (cone, plate and capillary rheometers) and
Figure 3 Variation of the h parameter with polydispersity. ●, Commercial PS; △, PS fractions; ○, constant polydispersity
Figure 4 Zero shear viscosities *versus* weight average molecular weight. T = 192°C, ●, Commercial PS; △, PS fractions; ○, constant polydispersity
Figure 5 Log (apparent viscosity) *versus* log (shear rate), in reduced coordinates. Data of Suzuki, superposed on Graessley's theoretical curve. ○, Linear PS fraction M_w = 1.2 x 10[6]; ●, star PS

it is interesting to compare them with our dynamical results.

Apparent viscosity η_a is compared either with the modulus of complex viscosity, or with the real part of the complex viscosity[5-7].

In *Figure 5* we show the results obtained by Suzuki[3] for a PS fraction (M_w = 1.2 x 10[6]) and star PS approaching the limiting slope. The reduced apparent viscosity is plotted against $\dot{\gamma}\eta_0/\rho T$.

On these experimental results, is superposed the theoretical curve of Graessley[8] calculated for a Schultz—Zimm molecular weight distribution:

$$P(n)dn = \frac{(Z + 2)^{Z+1}}{Z!} \left(\frac{n}{n\omega}\right)^Z \times$$

$$\exp\left[-\frac{n}{n\omega}(Z + 2)\right]\frac{dn}{n\omega} \qquad (2)$$

the polydispersity P being $=(Z + 2)/(Z + 1)$. Z = 10 is chosen, corresponding to a polydispersity index of 1.09, a reasonable value for anionic polystyrene.

The polystyrene of similar polydispersity (PS50) results in a dynamic parameter h of 0.14.

We can calculate from equation (1) the analytical form of η'/η_0 and $|\eta^*|/\eta_0$ as functions of $\omega\tau_0$.

The theoretical curve of log $|\eta^*|/\eta_0$ *versus* log $\omega\tau_0$ according to the Cole—Cole expression (equation 1), with h = 0.14 is plotted in *Figure 6* (curve B). The curve covers a frequency range much larger than the experimental curve.

It appears that the reduced steady-flow curve (η_a/η_0, $\dot{\gamma}\tau_0$) calculated from Graessley's theory (and the experimental data of Suzuki) (*Figure 5*) superimpose quite well with $|\eta^*|/\eta_0$ calculated (and experimental data for PS50) over a large frequency range (with a shift on the frequency scale corresponding to different reducing parameters).

For large frequencies, the curve ($|\eta^*|/\eta_0$, $\omega\tau_0$) calculated with the Cole—Cole expression tends to a straight line with slope equal to (h − 1). For our narrow fractions of polystyrene, this limiting slope varies from −0.77 to −0.86, according to the experimental values of h.

For large samples, the limiting slope depends rather weakly on polydispersity index, since the h parameter depends weakly on $P(h \sim 0.5)$.

We have calculated from equation (1) theoretical curves (log $|\eta^*|/\eta_0$ vs. log $\omega\tau_0$) (*Figure 6*) for various values of h (h = 0; 0.14; 0.5).

We may conclude that the greater the polydispersity index, the sooner the deviation from Newtonian behaviour appears, which is consistent with experiments.

The choice of an analytical expression for $\eta^*(\omega)$ imposes the form of the relaxation time distribution function $H(\tau)$[9]. It is convenient to note that the analytical expression of $\eta^*(\omega)$ is a formal expression without physical analogy in dielectric experiments. This analysis fails at high frequencies, where molecular motions are quite different, but can provide the relaxation spectrum at medium and long times in a very simple way[1,10].

The broadness of the distribution function of the logarithm of the relaxation times depends on h in the experimental frequency range. This distribution, in reduced coordinates ($\tau H(\tau)/\eta_0$ vs. log τ/τ_0) becomes narrower as the polydispersity index tends to 1 (*Figure 7*). According to a more classical scheme, we outlined log$H(\tau)$ *versus* logτ for a commercial PS (PS506, P = 4.62) (*Figure 8*). This distribution has been calculated using the analytical expression proposed here above (full line) and is compared with distribution calculated using the Ferry—Williams approximations (circles)[9].

It is interesting to note that the analytical expression
Figure 6 Calculated curves of log $|\eta^*|/\eta_0$ *versus* log $\omega\tau_0$, for different values of h: A, h = 0; B, h = 0.14; C, h = 0.5
Figure 7 Relaxation spectrum in reduced coordinates. A, PS50 (P = 1.1); B, PSS62 (P = 1.25); C, PSS50 (P = 2.45); D, PSSAM 327A (P = 4.20)
Figure 8 Relaxation times distribution function, in logarithmic scales, for PS506

reproduces the shape of distributions quite well, both for narrow fractions and for samples with broad distributions, in the plateau and terminal zones. It accounts also for the variation of the distribution form with polydispersity[4].

This analysis fails at short times, where molecular motions do not involve entanglement couplings.

CONCLUSION

This study on polystyrene provides the following conclusions: (1) in a complex representation of viscosities, the experimental plots are located on curves corresponding, within experimental error, to circular arcs whose centres are below the real axis, in the frequency range 20 to 10^{-3} Hz; (2) three parameters η_0, τ_0 and h, characterize the behaviour in dynamical experiments; (3) the h parameter is independent of temperature, but essentially depends on polydispersity; (4) η_0 and τ_0 depend on temperature, following a WLF type law and also on molecular weight and polydispersity.

Note to the Editor

Effect of a non-uniform distribution of crosslinks on the analysis of Raman polarization data in stretched networks

J. Maxfield* and I. W. Shepherd

Department of Physics, University of Manchester, Manchester M13 9PL, UK

(Received 20 August 1974; revised 6 November 1974)

In previous work[1] it has been shown that the isomeric populations in a rubber network can be measured as a function of strain using polarized Raman techniques. From these experiments on polydimethylsiloxane (PDMS) it was possible to estimate the value of the constant of proportionality, D_2, in a rotational isomeric theory of elasticity[2]. This value was found to be -8 for *trans* isomers which was nearly an order of magnitude larger than the theoretical prediction of -1.2. For the purposes of the experimental determination a uniform network was assumed, and this assumption is not strictly valid. The purpose of this note is to show that the experimental value of D_2 is strongly dependent on deviations from uniformity in the form of extra short chains in the network and that the Raman data provide evidence for the presence of such short chains.

There is independent evidence of inhomogeneities in the form of highly crosslinked regions within networks. Prins *et al.*[3] have observed resonances in the spectra of light scattered from networks which they attribute to oscillation modes of such inhomogeneities and Baer (personal communication) has seen evidence of such regions in crosslinked polystyrene under deformation. In qualitative terms the presence of such defects has the effect of increasing the number of chains or decreasing the average distance between crosslinks. (Entanglements, in as much as they act as crosslinks, will have a similar effect.) D_2 is connected with the change in population of isomer η through the equation:

$$(\Delta n)_{\eta,\alpha} = \nu D_2 \left[\frac{1}{3} \left(\frac{V}{V_0} \right)^{2/3} \left(\alpha^2 + \frac{2}{\alpha} \right) - 1 \right] \qquad (1)$$

where ν is the number of chains in the network, α the extension and V, V_0 respectively the unstrained and strained volumes. It is clearly important in evaluating D_2 to have the correct value of ν or, equivalently, the average chain length. These quantities, and hence D_2, will be sensitive to the presence of highly crosslinked, short chain regions.

---

* Present address: Polymer Research Center, University of Massachusetts, Amherst, Mass. 01002, USA.

This can be illustrated by using a simple model in which a fraction of short chains L, is introduced into an otherwise uniform network of chains length $L_2 = 10 L_1$. The experimental data of ref 1 can now be used to calculate D_2 as a function of the weight fraction of short chains F. The value of D_2 falls sharply with increasing F and at $F = 0.1$ yields a value of $D_2 = -3.9$ in agreement with recent measurements of PDMS in solution[4]. Agreement with the theoretical value occurs at $F \sim 0.5$. Thus it seems that the presence of short chains can explain the large difference between theory and experiment. Unfortunately, because the Raman technique is only sensitive to the average chain length it cannot be used to study the network inhomogeneities themselves.

In summary, it is clear that an experimental determination of D_2 in networks by Raman scattering depends critically on the network morphology and an accurate value will only be obtained if this morphology is known from an independent measurement. However, the fact that the value of D_2 obtained in solution is much lower than the value obtained assuming a uniform network provides strong evidence that imperfections incorporating short chains exist and confirms the work of Prins *et al.*[3] and Baer.

Letters

Comments on Letter: 'Dilatometric study of monovalent counter-ion association with poly-methacrylate' (J, Komiyama, Y. Takeda, M. Ando and T. Iijima, *Polymer* 1974, 15, 468–470)

In a recent communication, Komiyama *et al.*[1] reported volume changes (ΔV) upon protonation of alkali metal (AM) and tetraalkylammonium (TAA) salts of poly(meth-acrylic acid) (PMA). The results given indicate: (i) that the ΔV upon protonation of AM salts of PMA does not depend on the nature of the alkali metal (ΔV = 19.8 cm^3/mol), except for Li$^+$, and that therefore the binding of AM by polyions cannot be specific; (ii) in contrast, the larger the TAA ion, the larger the volume change upon protona-tion of TAA-PMA salts (ΔV = 26.2, 27.3 and 28.8 cm^3/mol for the protonation of T(Methyl)A, T(Propyl)A and T(Butyl)A-PMA salts, respectively).

From these results as well as results from other studies[2,3] the authors 'suggest that in aqueous solutions, AM salts of PMA do not associate to an extent that the primary hydra-tions of respective ions are perturbed and in contrast, TAA salts are under an interaction leading to the volume con-traction'. Since some of our results[3] were used to reach this conclusion we feel entitled to report several facts which show that the experimental procedure used by Komiyama *et al.*[1] is not very well fitted to the problem investigated and which lead to conclusions opposite to those of these workers.

It must be first remembered that for polyelectrolytes considerable precautions must be taken in both density measurements (to obtain partial molal volumes) and dilato-metry (to obtain volume changes) in order to obtain accur-ate results. These precautions, which have been described at length elsewhere[3], concern more the preparation of the polysalt solutions (thorough purification of the polyacids and hydroxides used to prepare the polysalts, determination of their concentration to within 0.1 to 0.2%, etc.)[3] than the density or volume change measurements which are usually of sufficient accuracy. In particular, an incomplete purifi-cation may lead to large errors (several cm^3/mol on partial molal volumes). The absence of any detail about the ex-perimental procedure by Komiyama *et al.*[1] does not permit us to discuss this point further. It must be pointed out however that the data of Ise and Okubo[2] used by Komiyama *et al.*[1] to further substantiate their conclusion have been shown[3] to be systematically too large by several cm^3/mol. In this respect they certainly do not offer a good experi-mental basis for a discussion on whether the ΔV upon pro-tonation of PMA salts depends on the nature of the counter-ion.

It must also be remembered that the dilatometric study of Strauss and Leung[4] which has provided us with the first evidence of a dependence of the volume change upon counter-ion binding on the nature of the AM counter-ion, consists in the measurement of the ΔV upon addition of an AM-chloride to a TMA polysalt solution at constant ionic strength. If ΔV_{AM} and ΔV_{TMA} are the volume changes upon binding of AM and TMA, respectively, by the polyion, these volume changes would be those measur-ed in an idealized experiment where counter-ions alone are added to a counter-ion-free solution of polyion. The ex-perimental volume change is then given by:

$$\Delta V_{exp} = \Delta V_{AM} - \Delta V_{TMA} \qquad (1)$$

ΔV_{TMA} has been found to be very close to zero[4] (this point is further substantiated below). Therefore ΔV_{exp} is very close to ΔV_{AM}. The variation of ΔV_{exp} for different counter-ions may reach 1 to 2 cm^3/mol for $\Delta V_{exp} \simeq 5$ to 6 cm^3/mol[3]. As the accuracy on ΔV_{exp} is usually of about 5%, the variations of ΔV_{exp} for different counter-ions are well above the experimental error. They can there-fore be measured and have in fact been measured for several polyions[4-6].

Such is not the case when the Komiyama *et al.*[1] proce-dure is used. Indeed these authors measured the ΔV upon protonation of AM-PMA. With the same assumption as above, the measured volume change can be now written:

$$\Delta V_{exp} = \Delta V_H - \Delta V_{AM} \qquad (2)$$

Note that ΔV_H and ΔV_{AM} are positive because they are associated with a release of hydration water. The main drawback of this procedure lies in the fact that ΔV_H has been consistently found to be much larger than ΔV_{AM}[3-7] (20 cm^3/mol compared to 2 to 6 cm^3/mol). As a result, the ion specific contribution to ΔV_{exp}, which shows up only through ΔV_{AM}, represents a much smaller part of ΔV_{exp} than in the Strauss *et al.* procedure. This part is, in many instances, smaller than the experimental error on ΔV_{exp} and can thus go undetected. Also, the purification of the solutions as well as the determination of their con-centration become more critical.

Another minor drawback in the Komiyama *et al.* proce-dure is that the ionic strength, μ, is not held constant dur-ing the experiment. Indeed additions of HCl to AM-PMA increase the AM-Cl content of the solution. This variation of μ depends on the degree of neutralization, α. The in-crease of μ appears to be sizeable since the initial concentra-tion of AM-Cl is 0.01 M and that of AM-PMA 0.046 M. Thus at α = 0 the final concentration of AM-Cl is 0.056 M. Volume changes upon binding have been found to decrease with increasing μ[4,8] and the magnitude of this decrease appears to depend on the counter-ion[8]. This may have been of importance in the work of Komiyama *et al.*

In addition to the dilatometric work of Strauss *et al.*[4-6], there is other evidence of the dependence of the volume change upon binding on the nature of the bound AM ion. This evidence has been obtained through the measurement of the excess ultrasonic absorption of solutions of polysalts, with TMA polysalts used as reference[9]. It must be first recalled that in aqueous solutions, an excess ultrasonic absorption arises from a chemical process such as counter-ion binding, only if a volume change is associated with this process because the enthalpy term is usually very small with respect to the volume change term, owing to the very low value of the thermal expansion coefficient of water[10]. Thus, in water where studies of polyelectrolytes are usually performed, the existence of an excess absorption implies that of a volume change. Upon neutralization of polyacids by TMA hydroxide we have observed very *small* changes

of absorption for weak polyacid solutions and *no* change of absorption for solutions of strong polyacids[9]. The ultrasonic absorption titration curves obtained upon neutralization with AM hydroxides are always above those relative to a neutralization by TMA hydroxide. Finally, additions of AM-Cl to TMA-polysalts (including TMA-PMA) consistently result in an increase of absorption whose magnitude is extremely sensitive to the nature of the counter-ion. All of these results are consistent with the existence of a positive volume change upon binding of AM ions by polyions, and a negligible ΔV upon binding of TMA. The same conclusion was reached by other workers in an ultrasonic study of solutions of chelates of AM and TMA ions[11]. Therefore, in the Komiyama *et al.*[1] report the difference between the ΔV upon protonation of AM and TMA polymethacrylates must not be attributed to a volume contraction due to the interaction between TMA and PMA but to the volume increase upon binding of AM ions by PMA. The negligible volume change upon binding of TMA or formation of chelates including TMA appears to be the result of a compensation between the various contributions to the hydration of TMA ions. As a result, this ion has practically no influence on the volume of the surrounding water molecules[12]. We agree, however, that a small contraction (1 to 2 cm^3/mol) may occur from the interaction of TPA and TBA ions with PMA. We have ourselves observed that the partial molal volumes of the poly(ethylene sulphonic) ion calculated from those of its TEA, TPA and TBA salts are smaller than that obtained from the partial molal volume of the TMA poly(ethylene sulphonate)[13]. Note, however, that this difference cannot be the result of a simple hydrophobic interaction between TAA ions and polyions because a volume increase would be then expected.

Finally, mention must be made about whether the primary hydration layer of AM ions is affected upon binding by PMA and other polyions. We have reported[14] n.m.r. evidence that several polyions, including polyacrylate which is chemically very similar to PMA, appear capable of causing a release of some primary hydration of Co^{2+} upon binding of this ion (4 to 5 water molecules from the Co^{2+} inner hydration shell appear to be released upon binding by polyacrylate[14]). Since the interaction of Co^{2+} with the water molecules constituting its primary hydration is much stronger than in the case of AM ions it seems likely that the primary hydration of AM ions will be affected upon binding. This conclusion is also in contrast with that of Komiyama *et al.*[1].

Study of structural change in linear polyethylene by elongation in view of behaviour of free radicals induced by γ-irradiation

The behaviour of free radicals formed in solid polymers by γ-irradiation has been closely correlated to molecular motions by many investigators. We have reported in a study of γ-irradiation effects on polymers that radicals preferentially form in the non-crystalline phase including defects and the amorphous phase[1,2]. Therefore, the observation of radical behaviour in irradiated polymers may become an invaluable tool for studying the defect of polymer crystals. Actually, we have used this method to elucidate the structural change in the crystalline phase of polyethylene subjected to a cyclic tensile stress[3].

This communication deals with the application of the method for studying the structural change in polyethylene by elongation. Pellets of high density polyethylene(Hizex 1200J, Mitsui Petrochemical Co.) were melted and pressed to form sheets, and then quenched in ice water. The quenched sheets were drawn with different elongations at 60 and 90°C. Additionally, a suspension of solution grown crystals was obtained by maintaining a 0.08% xylene solution of the polyethylene in a Dewar vessel overnight, and then filtering to form single crystal mats. The mats were dried under reduced pressure for more than 3 days. The specimens (0.26 × 3 × 10 mm) were cut out of the original sheets, and sealed in glass tubes under a pressure of less than 10^{-4} mmHg. They were irradiated by ^{60}Co γ-rays to a total dose of about 10^7 rad at liquid nitrogen temperature. The electron spin resonance studies were made with a Nihon Denshi JES–3BSX spectrometer using the x-band and 100 kHz field modulation.

As shown previously[1,2], the amount of radicals formed in the crystalline polymers at liquid nitrogen temperature depends on the polymer morphology. Therefore, we called the radical concentration after γ-irradiation at liquid nitrogen temperature 'radical trapping capacity', which is a measure of polymer morphology. *Figure 1* shows the plots of alkyl radical concentration *versus* elongation. The radical trapping capacity is found to linearly decrease until the elongation reaches 160 and 180% for the samples drawn at 60 and 90°C, respectively. Above these elongations the radical trapping capacity, in turn, linearly increases slightly up to 400%. The capacity of the single crystals was found to be 80% of the bulk sample. The decrease in the capacity with increasing elongation suggests a decrease of non-crystalline phase. Further since little change of density crystallinity by elongation was found, this decrease of radicals may be due to the decrease of crystal defects. It is interesting to compare this fact with the result that the radical trapping capacity increased owing to the increase of crystal defects when linear polyethylene sheets were subjected to the cyclic stress to cause fatigue[3]. In *Figure 1* the radical trapping capacity of the 60°C drawn sample is

of absorption for weak polyacid solutions and *no* change of absorption for solutions of strong polyacids[9]. The ultrasonic absorption titration curves obtained upon neutralization with AM hydroxides are always above those relative to a neutralization by TMA hydroxide. Finally, additions of AM-Cl to TMA-polysalts (including TMA-PMA) consistently result in an increase of absorption whose magnitude is extremely sensitive to the nature of the counter-ion. region II to the localized motion of molecules within the lamellar crystal throughout our recent work[1,3]. This discrepancy originally comes from the interpretation of the γ-process in the mechanical relaxation. The decay datum for the single crystals in the same figure may afford the proof of the above supposition in the present work. Region II almost cannot be seen in the single crystal which is believed to have few defects within it from the Moiré pattern technique[6-8] and n.m.r. data[1]. Similar results were obtained for the 60°C drawn sample.

Figure 3 shows the plots of the step height in the decay curve *versus* elongation for the 90°C drawn sample. It is noteworthy that the amount of decay considerably decreases and the temperature locations are shifted to higher temperatures in region II with increasing elongation, while the amount of decay in region I only slightly decreases.

Figure 3 Plots of decay amount of radicals *versus* elongation. ○, Region I; ●, region II

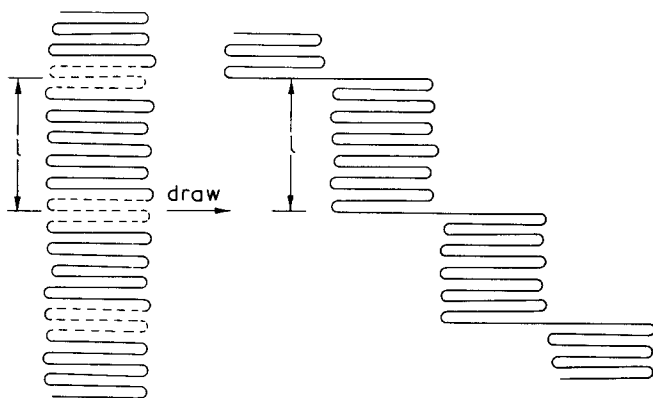
always larger than that of the 90°C drawn sample. This fact can be interpreted by the mechanism that the 60°C drawn sample originally has much larger amount of non-crystalline phase than the 90°C drawn sample because of its low elongation temperature. The fact that the radical trapping capacity becomes almost constant at 160—180% elongation implies that the crystalline texture has settled to form fibre structure above this elongation range.

Further, experiments on radical decay by elevating sample temperature give us valuable information about the cause of change in the radical trapping capacity. *Figure 2* shows the plots of the radical concentration *versus* heating temperature for the bulk, the solution grown and the 90°C drawn samples. These curves were obtained by measuring the radical concentration at liquid nitrogen temperature after heating the samples for 3 min at a regulated temperature increased stepwise from liquid nitrogen temperature. For the bulk sample three stepwise decays are clearly seen. The first step begins at about −160°C (region I), the second one at about −130°C (region II) and the final one at about −80°C (region III). This result is very similar to those obtained by Nagamura[3], Tamura[4], and Nara[5]. The activation energy of the radical decay was estimated to be 0.5, 5 and 15 kcal/mol for regions I, II and III, respectively, by the method described previously[3]. These values are similar to those obtained by Nara[5]. The cause of radical decay in region I has been ascribed to a very small scale motion of the amorphous chains and in region II to the local relaxation mode at the lamellar surface, because the activation energies and the temperature locations of these radical decays are similar to those of molecular motions detected by mechanical relaxation[5]. However, we are inclined to ascribe

Figure 4 Plots of crystallite size *versus* elongation. (a) (110); (b) (200); (c) (020); (d) (002). ○, Drawn at 90°C; ●, drawn at 60°C

From these results it follows that the defects within the crystals which cause region II decreased by elongation. This mechanism agrees well with the result obtained in the study on the radical trapping capacity of the crystalline phase of the drawn polypropylene treated by fuming nitric acid[2]. In this work it was found that the crystal core of drawn sample stripped by etching has little crystal defects. As to the cause of the decrease of defects, one possible mechanism is that the crystal decomposes into smaller ones cleaving from the defects within the crystal. At the cleaved planes of lamellar crystals molecular chains will have larger mobilities, and hence the radical trapping capacity decreases. On the other hand, it has been deduced that elongation causes the remelt–recrystallizing process of crystallites[9,10]. It was found that the long period after elongation was independent on that before elongation, but determined by elongation temperature. This fact seems to be contradictory to the above interpretation, but our experimental range is confined only in the initial stage of elongation where the other data did not cover.

Figure 4 shows the plots of crystallite size *versus* elongation, estimated from the width of wide angle X-ray line profiles using Scherrer's equation. As far as the present data are concerned, both temperature and elongation were found to determine the crystallite size. The progressive increase in crystallite size along the *c*-axis from the original size with increasing elongation is seen, and the abrupt decrease in the size seen earlier[9,10] was not observed. The increase of the size along the *c*-axis may possibly be caused by annealing at elongation temperature and additional heat generation by viscous flow of the microstructure to cause thickening of the lamellar crystals.

From the above considerations we propose here a possible model of the structural change in the early stage of elongation as shown in *Figure 5*. In this model it is emphasized that the lamellar crystal cleaves from the defects within the lamella, shown by the broken lines, to form smaller crystal blocks which have little defects. The model shows the case where complete cleavage occurs, although the actual aspect of the cleavage depends on the draw direction to the lamella. It is comprehensible that the lamellar crystals cleave from the defects within the crystals because the van der Waals force between the crystals plays a predominant role in transmitting the external stress to the element of supramolecular structure in the initial stage of elongation. At this time amorphous tie chains afford to some extent and the external stress acts on the whole unit through van der Waals forces and hence the crystals cleave from the defects. The cleavage from the defects could also


be caused by the thickening process if it proceeds similar to the case of single crystal according to the theory of crystal block formation[1].

Conference Announcement

Rheometry: methods of measurement and analysis of results

Shrivenham, 8–11 April 1975

The British Society of Rheology and the Italian Society of Rheology are organizing the above conference at the Royal Military College of Science, Shrivenham, Wiltshire from April 8 to 11, 1975. The conference will provide a forum for discussion and debate about measuring techniques and the interpretation of rheological data. Further details may be obtained from Dr F. N. Cogswell, 67 Daniells, Welwyn Garden City, Herts. AL7 1QT, UK.

The Proprietors of British Patent No. 1163502, for "Method for activating cycloaliphatic polyamines as curing agents for reaction with epoxide compounds", desire to enter into negotiations for the sale of the patent, or for the grant of licences thereunder. Further particulars may be obtained from Marks & Clerk, 57-60 Lincoln's Inn Fields, London WC2A 3LS.

Book Reviews

The physics of glassy polymers
Edited by R. N. Haward
Applied Science, Barking, 1973, 620 pp. £15

This is a large and ambitious work containing an introduction and ten chapters on various aspects of the structure and physical properties of amorphous polymers at temperatures below their glass—rubber transition. Some sixteen authors are involved and the subject matter is mainly, but not entirely, devoted to mechanical behaviour. Topics covered include thermodynamics of the glassy state, X-ray diffraction studies of amorphous structures, relaxation processes, creep, yield, post yield behaviour, cracking and crazing, and the diffusion and sorptions of gases and vapours. There are also chapters on the behaviour of rubber-modified thermoplastics and regular block copolymers.

Inevitably in a compendium of this sort the style and standards vary from chapter to chapter and there is no progressive, logical development of the subject as one progresses through the book. Indeed each contribution stands on its own as a separate review of a particular subject area.

The nature of the reviews varies considerably; a few are critical, authoritative presentations in which the necessary concepts are presented in a fairly detailed manner which will help the reader achieve some real understanding. Others, less usefully, lack authority and critical appraisal and are little more than an introduction to the literature.

It is perhaps in this latter role, as an up to date introduction to and survey of the literature that the book will be most useful. Each chapter has an extensive bibliography and contains a large amount of experimental data and information on behaviour in the form of numerous diagrams and tables drawn from the literature. There is also an excellent subject index but no author index.

Overall the book will be disappointing to those coming new to the subject and seeking detailed development, basic understanding and critical appraisal. It is likely to have most appeal to those having a good general background in polymer physics who seek mainly a series of 'state of the art' reviews.

The book is well produced and commendably free from editorial and printing errors.

D. W. Saunders

Advances in polymer science
Volume 12
Springer-Verlag, Berlin, 1973, 190 pp. $32.00

This slim volume fully maintains the high standard reached by some of the earlier volumes in this series.

The first chapter by K. Osaki (Kyoto University, Japan) is on the 'Viscoelastic properties of dilute polymer solutions', and is a comprehensive account both of theoretical and experimental studies of dilute polymer solutions. The author sets out to describe systematically the experimental results which have been obtained and to evaluate the success of present molecular-based theoretical explanations. It is of interest to note that in the field of viscoelastic properties of flexible polymers at infinite dilution that several molecular theories were constructed prior to the determination of successful experimental measurements. Considerable attention is paid to the Zimm theory in its different forms as well as to those of Rouse and Ogasa and Imai. Perhaps the most valuable section is that dealing with an evaluation of the experimental validity of the various theories. The final section in this review surveys more recent work on viscoelastic studies at higher frequencies, again considering both theoretical and experimental studies. The author somewhat confidently concludes that sufficient data now exist to allow the theoretical elucidation of the dynamics of polymer solutions on a molecular basis. Certainly an optimistic note on which to end!

The second review is by W. L. Carrick, on the 'Mechanism of olefin polymerization' by Ziegler—Natta catalysts, and attention is naturally paid to the contribution to this field which has come from the Union Carbide Research and Development Department at Bound Creek, New Jersey. The author states that his report is intended to serve as an illustrative, but not exhaustive review of some of the work carried out on olefin polymerization with Ziegler—Natta catalysts. He thus sets out to provide answers to such questions as: what are the co-catalyst interactions?; what is the structure of the active site?; what activates the olefin?; how is stereoregularity achieved? In an area of enormous complexity this is an excellent approach. The answers given are sometimes oversimplified but the author is to be congratulated on the clarity of his account and the considerable insight which he shows into this complex area of polymerization. He rightly stresses the contribution to our present understanding which has come from copolymerization studies and also the role of complex formation reactions between monomer and catalyst so that the necessary degree of stereoregular orientation can be achieved. This brief review should serve as a good introduction to this field of study.

The third review on the 'Applications of infra-red spectroscopy to ethylene—propylene copolymers' is by C. Tosi and F. Ciampelli of the Montecatini Edison Central Research Group in Milan, Italy. It is indeed fitting that this group should be responsible for this review owing to the considerable contribution which they have made to this field. Also, as the authors remark, this is probably the right moment to present a review due to the likely impact of ^{13}C n.m.r. spectroscopy. This is one of the best reviews of its kind and is most readable covering critically the applications of i.r. spectroscopy to C_2–C_3 copolymers up to mid-1972. In dealing with methods for the analysis of composition the authors rightly stress the importance of useful standards and the selection of bands of clear assignment.

The final review on the 'ESR study of photodegradation of polymers' by K. Tsuji of the Sumitomo Chemical Co. Ltd, Osaka, Japan, is timely in view of recent developments in degradable plastics. This is a fairly exhaustive review. The author begins with a consideration of the fundamental steps involved in the photodegradation of polymers. This consideration is followed by a long section on the structure and behaviour of types of free radicals produced after u.v. irradiation of polymers. An exhaustive variety of polymers are examined including polyolefins, poly(vinyl chloride), polystyrene, poly(methyl methacrylate), polyethers, polyamides, polysiloxanes, etc. There is no doubt that this review will be a most useful source of reference to workers in this field.

P. J. T. Tait

The solid state of polymers
Edited by P. H. Geil, E. Baer and Y. Wada
Marcel Dekker, New York, 1974, 708 pp. $47.50

This book contains thirty-three of the forty-one papers delivered at the October 1972 joint seminar in Cleveland, and includes then-current research reports from several leading groups in the USA and Japan. The subject matter divides, somewhat unevenly, into the following sections: deformation of crystalline polymers (3 papers); structure—property relationships in oriented polymers (4 papers); morphology—crystalline polymers (5 papers); morphology—amorphous polymers (3 papers); relaxation behaviour (9 papers); fracture, yield and crazing (8 papers).

The papers individually are of a high standard, but several of the researches are described in outline only; some merely supplement previous publications by their authors whilst others have been superseded by later or amplified papers in journals (this state of affairs is not helped by the appearance of the proceedings nearly two years after the event).

The main value of the work probably lies in the access it provides to some recent Japanese work which might otherwise not have been published in the West. Some of the papers (e.g. Lindenmeyer on Molecular configurations in molten and glassy polymers) will, no doubt, take a significant place in the literature, but the book viewed as a *collection* of papers has no greater coherence than is to be expected from such an exercise. In no way does it constitute a text on, or provide a full coverage of, the solid state of polymers and in that respect its title is somewhat misleading, but research workers in the field will find it a useful reference book.

E. H. Andrews

Sequence peptide polymers: 3. Synthesis and conformational study in solution of poly (L-leucyl-L-leucyl-ε-N-carbobenzyloxy-L-lysine*

L. Bravin and M. D'Alagni[†]

Istituto di Chimica delle Macromolecole, Nucleo di Roma, c/o Laboratorio di Chimica Fisica, Università di Roma, 00185 Roma, Italy
(Received 16 April 1974; revised 5 August 1974)

The synthesis and characterization of poly[Leu-Leu-(ε-Z)-Lys] and its conformational study in organic solvents are reported. The sequential polypeptide has been obtained with a satisfactory optical purity by the self-condensation method of the p-nitrophenyl ester of the corresponding tripeptide derivative according to the general procedure of De Tar *et al*. Poly[Leu-Leu-(ε-Z)-Lys] showed a right-handed α-helical conformation in solution of helicogenic solvents, as displayed by circular dichroism measurements and ultra-violet absorption spectra. The presence of the α-helix has been also detected in the solid state by infra-red spectroscopy. The helix stability of the polypeptide in chloroform—dichloroacetic acid solution is considerably high. This property may be related to the ordered sequence of the bulky leucyl residues which give rise to a screening effect, protecting the chain backbone from the acid solvent molecules.

INTRODUCTION

In order to examine the role of the specific contribution of some factors determining the secondary and tertiary structure of polypeptides and proteins, we have undertaken the synthesis and the conformational study in water and organic solvents of some sequential polypeptides. In previous papers[1,2] we have reported the syntheses and the conformational aspects of sequential poly(leucyl-leucyl-aspartic acid-β-benzyl-ester) (PLLAB), and its acid derivative, poly(leucyl-leucyl-aspartic acid) (PLLAA). This paper describes the synthesis and some conformational features of poly(leucyl-leucyl-ε-N-carbobenzyloxy-lysine) (PLLLZ) in organic solvents. This particular sequence of amino acid residues was chosen in order to obtain a sequential polypeptide which could serve as a model in the study of side chain interactions involving polar as well as non-polar groups. In fact, the investigation in water[3] of the polypeptide with the lysine residue in the unblocked form, poly(leucyl-leucyl-lysine) (PLLL), allowed us to extend the previous work[2], i.e. to examine in aqueous solution and at different pH values the conformation, the charge and the thermal stability of PLLL having the same leucyl-leucyl hydrophobic sequence and, in addition, a residue with an ionizable side chain group further from the backbone than the carboxyl of the aspartic acid of PLLAA.

The polytripeptide PLLLZ was obtained by the poly-condensation of leucyl-leucyl-ε-Z-lysine-p-nitrophenyl ester in dimethylsulphoxide. The conformational study of the polypeptide in organic solvents at different polarity was performed by optical methods and the presence of a right-handed α-helical structure was established by ultra-violet (u.v.) and circular dichroism (c.d.) measurements in TFE and HFI. The surrounding medium affected the conformational state of PLLLZ, an increase of the $[\theta]$ values was obtained in going from HFI to TFE, showing a marked dependence on the α-helical content.

A random coil conformation was exhibited in MSA and a transition from the α-helical conformation to a random coil was displayed in a solution of chloroform—dichloroacetic acid (25:75 v/v).

EXPERIMENTAL

The synthesis of poly[Leu-Leu-(ε-Z)-Lys] was carried out in a similar way to the preparation of poly[Leu-Leu-Asp(OBzl)][1] by polymerization of the p-nitrophenyl ester of the tripeptide and is summarized in the following scheme:

$$\text{Boc-Leu-OH} + \text{HCl} \cdot \text{H-Leu-OBzl} + \text{DCC} + \text{TEA} \rightarrow$$

$$\text{Boc-Leu-Leu-OBzl}$$
$$\text{(I)}$$

$$\text{I} + \text{H}_2/\text{Pd} \rightarrow \text{Boc-Leu-Leu-OH}$$
$$\text{(II)}$$

$$\text{Boc-Lys-OH} + \text{HON}_p + \text{DCC} \rightarrow \text{Boc-Lys-ON}_p$$
$$\overset{|}{\text{Z}}$$
$$\text{(III)}$$

---
* The following abbreviations are used in this paper: Boc = t-butyloxycarbonyl; Z = carbobenzyloxy; OBzl = benzyl ester; TEA = triethylamine; DCC = dicyclohexylcarbodiimide; DCU = dicyclohexylurea; HON$_p$ = p-nitrophenol; TFA = trifluoroacetic acid; DCA = dichloroacetic acid; H-Leu-OH = L-leucine; H-Lys-OH = L-lysine; MSA = methanesulphonic acid; TFE = trifluoroethanol; HFI = hexafluoroisopropanol.

Synthesis of peptides‡

Boc-Leu-Leu-OBzl and Boc-Leu-Leu-OH were obtained as described[1] previously.

Boc-(εZ)-Lys-ON$_p$. DCC (2.713 g; 13.15 mmol) was added to a cooled (0–5°C) solution of Boc-(εZ)-Lys-OH (5.0 g; 13.15 mmol) and of HON$_p$ (1.829 g; 13.15 mmol) in anhydrous and purified ethyl acetate (120 ml) and allowed to react with stirring for 2 h at –5°C and then at 4°C over night. After a thin-layer chromatography control on silica gel, the reaction mixture was filtered to remove the DCU. The filtrate was evaporated *in vacuo* and the residue obtained was crystallized by ethyl acetate/hexane mixture (1:2.5 by vol) (yield 82%). Recrystallization by the same solvent mixture gave a chromatographically pure (chloroform—methanol 95:5 by vol as eluant) crystalline product: m.p. 74–74.5°C; $[\alpha]_D^{25°}$ = –13.80 (c = 0.96% in CHCl$_3$). Calculated for C$_{25}$H$_{31}$N$_3$O$_8$; C = 59.86%; H = 6.23%; N = 8.38%. Found: C = 59.73%; H = 6.31%; N = 8.41%.

TFA.H-(εZ)-Lys-ON$_p$. Boc-(εZ)-Lys-ON$_p$ (3.6 g) was dissolved in 10 ml of TFA, allowed to stand at room temperature for 15 min and then evaporated *in vacuo* at 25–30°C. The viscous product was treated twice with CH$_2$Cl$_2$, removed *in vacuo*; the residue obtained was triturated with ether and the resulting solid was purified by crystallization from acetonitrile—ether (1:2 by vol). After two recrystallizations from acetonitrile a colourless chromatographically pure product (n-butanol/acetic acid/water 60:15:25 by vol and chloroform—methanol 95:5 by vol as eluants) was obtained. Yield 80%; m.p. 124.5–125°C; $[\alpha]_D^{25°}$ = +9.69; $[\alpha]_{546}^{25°}$ = +12.08 (c = 0.720% in CH$_3$CN). Calculated for C$_{22}$H$_{24}$N$_3$O$_8$F$_3$: C = 51.26%; H = 4.69%; N = 8.15%. Found: C = 51.34%; H = 4.67%; N = 7.95% and H = 4.72%; N = 8.02%.

Boc-Leu-Leu-(εZ)-Lys-ON$_p$. TFA.H-(εZ)-Lys-ON$_p$ (1.599 g; 3.1 mmol) was added to a cooled (–5°C) stirred solution of DCC (0.640 g; 3.1 mmol) in acetonitrile (30 ml). A solution of Boc-Leu-Leu-OH (1.074 g; 3.12 mmol) and of TEA (0.432 ml) in 50 ml of acetonitrile was added in portions over a period of 30 min to the suspension previously obtained.

The reaction mixture was kept under stirring for 2 h at –5°C and overnight at 0–4°C. The DCU formed was fil-

---

‡ The elemental analyses were performed by Dr A. Bernhardt of the Microanalytical Laboratory. The melting points were taken on a Kofler apparatus.

tered and the filtrate was evaporated to yield an oily residue which was crystallized from ethyl acetate/ether. Further recrystallizations from ethyl acetate/hexane mixtures gave a chromatographically pure product (chloroform—methanol 95:5 by vol. as eluant) in 58% yield: m.p. 156–157°C; $[\alpha]_D^{25°}$ = – 54.35; $[\alpha]_{546}^{25°}$ = –65.64 (c = 0.780% in chloroform). I.r. spectrum in KBr pellet showed bands at: 1760 cm^{-1} (COON$_p$); 1690 cm^{-1} (Z); 1650 cm^{-1}; 1545 cm^{-1} (CONH); 1530 cm^{-1} (NO$_2$); 1390 cm^{-1} and 1370 cm^{-1} (t-Bu). Calculated for C$_{37}$H$_{53}$N$_5$O$_{10}$: C = 61.43%; H = 7.38%; N = 9.68%. Found: C = 61.25%; H = 7.41%; N = 9.78%; and C = 61.31%; N = 9.75%.

TFA.H-Leu-Leu-(εZ)-Lys-ON$_p$. Chromatographically pure Boc-Leu-Leu-(εZ)Lys-ON$_p$ (0.8 g) was treated with 5 ml of TFA, allowed to stand at room temperature for 10 min, and then evaporated under vacuum at 25–30°C. The residue was dissolved in anhydrous chloroform and concentrated under vacuum to a small volume. This operation was repeated. The solid obtained was crystallized from ethyl acetate/ether.

Further recrystallization from acetonitrile gave a pure compound. Yield 72%: m.p. 142.5–143.5°C; $[\alpha]_D^{25°}$ = –22.50; $[\alpha]_{546}^{25°}$ = –26.87 (c = 0.781% in CH$_3$CN–DMF, 90:10 by vol). Calculated for C$_{34}$H$_{46}$N$_5$O$_{10}$F$_3$: C = 55.05%; H = 6.25%; N = 9.44%. Found: C = 54.92%; H = 6.24%; N = 9.25%.

Poly [Leu-Leu-(εZ)-Lys]. TFA.Leu-Leu-(εZ)Lys-ON$_p$ (0.775 g) was dissolved in dimethylsulphoxide (0.85 ml).

Anhydrous TEA (0.144 ml) was added while stirring for 3 min. The reaction mixture was kept in the dark for five days at room temperature.

The product obtained was solubilized in 500 ml of chloroform, washed several times with trishydroxymethyl aminomethane buffer (pH = 7.2), water, and dried over anhydrous sodium sulphate. The solvent was removed in vacuum and the residue was extracted with dry ether. The polymer was redissolved in chloroform and precipitated with ether, dried to constant weight under high vacuum at 110°C and over P$_2$O$_5$. Yield 85%; m.p. 225–232°C. Calculated for C$_{26}$H$_{40}$N$_4$O$_5$: C = 63.91%; H = 8.25%; N = 11.46%. Found: C = 63.90%; H = 8.28%; N = 11.41%.

Determination of optical purity of the polymer

The optical purity of the polypeptide was established by the hydrolysis procedure on the decarbobenzyloxylated polymer, that is the PLLL·HCl. A treatment with 6 N hydrochloric acid at 106°C for 48 h in degassed sealed tubes gave complete hydrolysis of the polymer. A duplicate comparison was made on the specific rotation of the amino acids solution obtained by the hydrolysed polymer with the specific rotation of the amino acid components exposed to the same treatment. Because of the initial low concentration in PLLL·HCl a wavelength of 297 nm was used. The specific rotations were the following: $[\alpha]_{297}^{25°}$ = +175.31 for the totally hydrolysed solution obtained from the PLLL·HCl, in 6 N hydrochloric acid; $[\alpha]_{297}^{25°}$ = +179.69 and +172.33 for the leucine and lysine solution respectively. The optical purity, calculated from the reported values, was 99.2 ± 2%. This result led to the conclusion that no significant racemization occurred during the synthesis of PLLLZ.

Physical measurements

U.v. absorption spectra were measured on a Beckman DK-2A recording spectrophotometer.

Circular dichroism (c.d.) measurements were obtained on a Cary 61 CD spectropolarimeter. All measurements of u.v. and c.d. spectra below 210 nm were made in 0.01 or 0.50 cm path length quartz cells, so that the total cell absorbances were kept below 1.2. The slit width was maintained sufficiently small to ensure a wavelength accuracy of better than 0.5 nm. Prepurified nitrogen was flushed to remove oxygen from the light path. In calculating ϵ and $[\theta]$ values one-third of the repetitive unit (leu-leu-ϵZ-lys) was used as residue molecular weight of the polypeptide.

Infra-red absorption spectra were recorded by a Perkin—Elmer 257 instrument during the synthesis of peptides, and on a Beckman IR 9 apparatus for the study of the conformational aspects.

Optical rotation measurements were performed using a Perkin—Elmer 141 M spectropolarimeter at 25°C ($c = 0.1$–0.15%) and a 1 dm path length cell.

RESULTS AND DISCUSSION

The reactions leading to the sequential polypeptide PLLLZ are shown in the scheme previously reported.

Information about the molecular weight distribution have been deduced studying the polymer PLLL·HCl. The main fractions obtained on gel filtration, as described elsewhere[3], had an average molecular weight of over 94 000, corresponding to over seven hundred amino acid residues per polypeptide chain. The presence of fractions at such a degree of polymerization and the optical purity of PLLLZ provide further evidence[1] on the usefulness of the polycondensation method of tripeptide p-nitrophenyl esters for obtaining sequential polypeptides[4–7].

The conformational study of PLLLZ was carried out by u.v. absorption spectra and c.d. measurements in solution and by i.r. spectra in solid state.

Figure 1 shows the u.v. spectra of PLLLZ obtained in
Figure 1 Ultra-violet absorption spectra of PLLLZ in MSA (——) and in TFE (— — —)
Figure 2 Circular dichroism spectra of PLLLZ in MSA (— · — ·), in HFI (— — —) and in TFE (——)

two different solvents, in MSA and in TFE. As is evident, the molar residue absorptivity value results are highly dependent on the solvent medium in which the polypeptide is examined. A large decrease in the molar absorptivity and a different spectral resolution ensued in going from MSA to TFE. A different conformational state in the two solvents considered, namely random coil in the former and α-helicoidal in the latter may be assumed to be present. It can be seen that the molar residue absorptivity values are in both cases higher than those reported[8] for these conformational states, being the molar absorptivities of the peptide band at the maximum 7000 ± 100 and 4300 ± 100 $mol^{-1} cm^{-1}$ respectively for a random and α-helicoidal chain. The difference in the values of ϵ_{max} obtained can be ascribed to the side chain ϵ-carbobenzyloxy absorption contribution. In fact considering the molar residue absorption maximum in both curves, $\Delta\epsilon_{max} = 2910 \pm 100$ mol^{-1} cm^{-1} is obtained. This value is equal or very near to that reported[9] in the conformational transition from random coil to α-helix. Moreover, a prominent shoulder between 205 and 210 nm, due to the splitting of the π–π^* peptide transition in the α-helical conformation[9–11], is displayed for TFE. This evidence together with the characteristic hypochromism at 190 nm, may be used as convincing proof for the presence of the α-helical conformation in TFE and of the random coil in MSA.

The results obtained by circular dichroism, where there is no interference from extraneous sources of optical activity contribution, are presented in *Figure 2*. PLLLZ easily dissolves in pure MSA. The dichroic spectrum in this solvent, registered soon after dissolution of the polypeptide,
Figure 3   Infra-red spectrum of PLLLZ: unoriented film cast from chloroform solution

is characterized by a negative dichroic band located at
about 196 nm ($[\theta]_{196}$ = $-15\,260 \pm 1300$ degree $cm^2/dmol$)
and a weak positive dichroic band located at 218 nm. The
profile of the dichroic curve is typical[12-14] of polypeptides
in the random coil conformation, but exhibits absolute
molar ellipticity values lower than those normally obtained
for polypeptides in such conformational state. This
behaviour, which has been already observed in the case
of poly(γ-ethylglutamate)[15] and of polycyclohexylalanine[16]
studied in MSA, is similar to that reported[17] in 0.2 M $NaClO_4$
for the polyelectrolyte poly(L-glutamate) sodium salt
(NaPG) and the non-ionizable poly[N^5-(2-hydroxyethyl)-
L-glutamide] (PHEG). Heating a solution at pH 7.7 in
0.2 M $NaClO_4$ of NaPG and PHEG, which are in random
conformation in this condition, the absolute molar ellip-
ticity gradually decreased and reached at 198 nm the same
limiting value of $-16\,000$ at 90°C for both polymers. Since
the heating at such a temperature of these polypeptides
solutions should increase the randomness of the polymer,
the lower ellipticity values obtained in MSA for poly(γ-
ethyl-L-glutamate), poly(L-cyclohexylalanine) and PLLLZ
may be ascribed as due to a higher degree of randomness
rather than to solvent effects on the $\pi-\pi^*$ peptide
transition[16].

Three ellipticity peaks are displayed by the c.d. spectra
of PLLLZ in HFI and TFE: a positive peak at 190–192 ±
2 nm, and two negative peaks located at 204–205 ± 1 nm
and at 217 ± 1 nm. The c.d. crossover points are obtained
at 197–197.5 ± 1 nm. The ellipticities values, and the c.d.
crossover points, are consistent with the presence of the
α-helicoidal state in HFI and TFE, in agreement, for the
latter solvent, with the u.v. absorption analysis. However,
the substantial differences in the ellipticities values of the
two spectra indicate an α-helical content greater in TFE
than in HFI. Furthermore it should be noted that the c.d.
profiles examined are characterized by a blue shift of the
two negative dichroic bands and by a marked difference
in their absolute magnitudes, i.e., the peak at 217 nm, due[12]
to the $n-\pi^*$ transition is lower than that at 205 nm, owing
to the parallel-polarized component of the $\pi-\pi^*$ transition.
Similar results have been found for α-helical polypeptides
such as polyalanine[18] in TFE–TFA (98.5:1.5 by vol)
and poly(γ-methylglutamate) in TFE[12] and in HFI[19]. These
features found in the c.d. spectra of PLLLZ may be ascrib-
Figure 4 $[\alpha]_{365}^{25°}$ of PLLLZ *versus* solvent composition (chloro-
form/dichloroacetic acid mixtures)

ed, besides the residues forming the main chain, to solvent
effects which may induce changes in the positions and
intensities of the transitions and may cause conformational
variations in the polypeptide chain as is observed in the
comparison between the solutions in TFE and HFI.

The i.r. spectrum of PLLLZ obtained on a film cast
from chloroform is reported in *Figure 3*. Sharp and strong
absorption bands at 1655 ± 2 cm^{-1} and at 1547 ± 2 cm^{-1}
are shown respectively for the amide I and II bands. The
correlation[20] between the amide I and II band frequencies
and the conformations, establishes the prevalence of the
α-helical conformation in the PLLLZ also in the solid state.

The PLLLZ α-helical stability in solution has been
investigated by observing the dependence on the α-helix
random coil transition from the solvent mixture. The
variation of the specific rotation at 365 nm with solvent
composition is shown in *Figure 4* for mixtures of chloro-
form, a helix favouring solvent and DCA, a random coil
favouring solvent. The $[\alpha]_{365}$ of PLLLZ showed a marked
decrease on addition of small amounts of DCA and an
abrupt change is obtained as the proportion of DCA is
increased above 75% (by vol) in the chloroform solution,
thus indicating the helix → random coil transition had

occurred. This last result proves that the stability of the helical structure of PLLLZ in solution is comparable to that of the PLLAB previously studied[1] and, moreover, that the aliphatic hydrocarbon side chains of the leucyl residues provide a more efficient shield for the hydrogen bonded α-helical backbone than those of the poly(ε-carbobenzyl-oxy-lysine), for which the helix → random coil transition occurs at about 36% dichloroacetic acid in chloroform solution[21].

In PLLLZ it is possible to consider that the bulky iso-butyl groups forming a compact hydrocarbon surface decrease the accessibility of the hydrogen bonds of the backbone to the polar hydrogen bond breaker dichloro-acetic acid.

Effect of molecular weight on the morphology and drawing behaviour of melt crystallized linear polyethylene

G. Capaccio and I. M. Ward

Department of Physics, University of Leeds, Leeds LS2 9JT, UK
(Received 16 May 1974; revised 16 October 1974)

The effect of molecular weight on the cold drawing behaviour of melt crystallized linear polyethylene has been studied. It is shown that the draw ratio achieved under comparable conditions rises with decreasing $\overline{M}_w$, very high draw ratios (~36) being possible for optimum morphology of the undrawn polymer. The yield behaviour was also examined, and it is shown that the yield stress is affected in a complex fashion by both crystallization conditions and molecular weight. These results are discussed in terms of the crystallization and morphology of the melt crystallized polymer.

INTRODUCTION

In recent papers, the drawing behaviour of melt-crystallized linear polyethylene (LPE) was discussed[1,2]. The draw ratios obtainable were shown to depend on the molecular weight characteristics of the polymer and on the crystallization procedure, the extent of the effects being markedly dependent on the latter, and hence on the morphology of the undrawn polymer.

The present paper is one of a series in which particular aspects of these discoveries are covered in some detail. Here we consider the molecular weight effects by examining a much wider range of samples than was previously available. On the basis of the previous work two very contrasting crystallization conditions have been chosen, one in which the polymer is rapidly cooled from the melt by directly quenching in water, and one in which the polymer is first slow cooled to 110°C and subsequently quenched. The latter process, when combined with suitable drawing procedures produces oriented material which is substantially different from those previously obtained for comparable draw ratios[3,4], with Young's moduli reaching ~7 x 10^10 N/m². This value is close to theoretical values for fully aligned LPE[5,6] and gives a material of considerable technological potential[7], quite apart from its interest for studies of structure and physical properties.

EXPERIMENTAL

The molecular weight characteristics of the linear polyethylene homopolymers studied are shown in *Table 1*. Both $\overline{M}_w$ and $\overline{M}_n$ were obtained from gel permeation chromatography, unless otherwise stated.

Compression moulded sheets were prepared according to the procedure described previously[2]. As discussed in the introduction, only two thermal treatments were selected; one in which crystallization occurs during rapid quenching in water from 160°C, and a second in which before quenching in water, the sample is allowed to cool from 160°C to 110°C at a rate of 7–9°C/min.

The density of the compression moulded sheets was measured at 23°C in a diethyleneglycol/isopropyl alcohol density gradient column.

Dumbbell samples of dimensions 2 cm x 0.2 cm were cut and drawn in air on an Instron Tensile machine at 75°C at a speed of 10 cm/min for drawing times of either 60 sec or 90 sec

Optical micrographs of the morphology of the isotropic sheets were obtained with crossed polarizers using sections 20 μm thick for sample 4 and 5 μm thick for sample 9.

RESULTS AND DISCUSSION

Density and crystallization

The results of the density measurements (*Figure 1*) will be discussed first as they provide information regarding the crystallization behaviour. All the samples of the present investigation have been crystallized under non-isothermal conditions; they have been cooled very rapidly to room temperature either from the melt or after slow cooling to 110°C. In the latter case, the cooling curves were measured in the previous investigation and from the exotherm at 120–123°C we could conclude that an appreciable amount of crystallization occurred in this temperature range. Looked at superficially this crystallization route gives rise

to an increase in density from ~0.950 to ~0.966 g/cm³ at low molecular weights and from ~0.927 to ~0.936 g/cm³ at high molecular weights. More significantly at this stage the substrate is produced on which further crystallization will take place during the subsequent rapid cooling. It would appear as if this particular phenomenon might be associated with important morphological modifications which are observed in the final product as a function of its thermal history and which will be discussed later in this section. Consideration of the measured crystallization rates of LPE fractions crystallized isothermally[8-10] show that for the rapidly quenched samples negligible crystallization can occur above 120°C, i.e. rapid cooling will not only reduce the extent of crystallization, but cause the initial growth of the lamellae to occur at lower temperatures. We believe that this has important consequences for the proportions of different molecular weight species which take part in the crystallization and hence for the morphology, and this part will be elaborated later.

First, let us consider the effect of molecular weight on density for the different heat treatments. *Figure 1* shows that in both cases there is a clear correlation between the density ρ and $\bar{M}_w$, ρ decreasing monotonically with $\bar{M}_w$, with the samples quenched from the higher temperature showing a systematically lower density, as expected.

The trend is very similar to that found for LPE fractions crystallized isothermally[11]. This would support the view that it is justifiable, at any rate for qualitative considerations, to extrapolate from results on fractionated polymers to polydisperse systems. This conclusion has important consequences, because it implies that the isothermal crystallization data for fractionated polymers can be combined with a knowledge of the imposed thermal history to provide an understanding of the crystallization of an unfractionated polymer for a wide range of arbitrarily selected crystallization conditions.

It is interesting to note that the differences in density between samples of different thermal treatment are somewhat reduced at high values of $\bar{M}_w$. This observation is consistent with the view that the longest molecules are responsible for the decrease of ρ with $\bar{M}_w$. The long molecules are characterized by low mobility which is responsible for two

interrelated effects, a decrease in crystallization rates and increased disorder on the lamellar fold surfaces, both effects reducing the overall level of crystallinity. Molecular weight effects on the interfacial morphology have been observed for isothermally crystallized LPE fractions[12] and could be even more pronounced in unfractionated polymers crystallized non-isothermally.

It is known from other studies that the crystallization of medium and high molecular weight species in LPE is closely related to the transport factor in the kinetic equation[8] and hence to the internal viscosity. It is therefore reasonable that the molecular weight dependence of the crystallization can be so well expressed in terms of $\bar{M}_w$. This is analogous to the strong dependence of the melt viscosity on $\bar{M}_w$.

The importance of the transport factor suggests that the effect of molecular weight and thermal treatment on the rate of crystallization of polymers must be also linked to the development of other important features which are also diffusion-controlled, i.e. the degree of order of the fold surface of the crystals and the morphology of the crystalline aggregates. Thus not only will the slow cooled polymers be more crystalline than the rapidly cooled polymers and the low $\bar{M}_w$ slow cooled polymers more crystalline than the high $\bar{M}_w$ slow cooled polymers, but the concentration of chains folding regularly back into the same crystalline lamellar will also increase.

The optical micrographs in *Figures 2a* and *2b* show how much the morphology of the samples can be affected by the thermal treatment. The rapid cooling clearly produces a conventional spherulitic structure with banded spherulites, whereas slow cooling yields much coarser and often hardly recognizable spherulites.

It is known[13] that in conditions of relatively high viscosity the spherulitic geometry develops in a complex process of radial lamellar growth and/or branching at different angles with the radial direction. At low viscosities, however, the secondary nucleation which gives rise to the branching mechanism becomes less likely and the spherulitic radiation cannot occur in the same fashion.

This is exactly what the optical micrographs confirm. Sample 4 exhibits a spherulitic texture when quenched from 160°C, i.e. crystallized at very high degree of supercooling, hence high melt viscosity (*Figure 2a*). The opposite happens when it is slow cooled, i.e. crystallized at a low degree of supercooling hence low viscosity (*Figure 2b*). At much higher molecular weight (sample 9) where the viscosity of the melt always remains high, differences in crystallization temperature produce a less obvious morphological distinction (*Figures 3a* and *3b*).

Drawing behaviour

In a previous paper it was observed that there was a very considerable increase in the yield stress as the quenching temperature following slow cooling was decreased below 120°C, showing the effect of crystallization on the yield stress. This is confirmed by the present investigation over a much wider range of molecular weights (*Figure 4*). It is, however, at first sight remarkable that the yield stress appears to be independent of molecular weight because we know that there is an appreciable reduction in crystallinity at higher molecular weights. We can therefore conclude that not only does the yield stress increase with crystallinity at constant molecular weight but also that at constant thermal treatment it increases with molecular weight. The
Figure 2 Photomicrographs of sample 4, photographed between crossed polarizers. (a) quenched from 160°C; (b) quenched from 110°C

which are obscured in this very wide span of M_w. Detailed arguments have been presented previously as to how molecular weight distribution can be considered to affect the results[2].

The effect of $\bar{M}_w$ on draw ratio is also shown in the case of the quenched polymers, although the magnitude of the change is considerably reduced and here some effect of $\bar{M}_n$ may also be seen (*Table 2*). It is to be noted in particular that samples 2, 3 and 4 now reverse their order in terms of draw ratio. Without ruling out the possibility that the effect is due to small fluctuations in the crystallinity of the initial materials, a plausible explanation of this fact can also be given along the following lines. When the crystallization occurs under less discriminating conditions from the viewpoint of molecular weight, shorter molecules can become incorporated in more than one lamella. In the case of polymers with a larger low molecular weight fraction this pos-

larger molecules introduce more interlamellar tie molecules and physical entanglements, probably changing the nature of the yield process so that it involves higher stresses in the non-crystalline regions. Although this gives rough equivalence to increasing crystallinity from the phenomenological measure provided by the yield stress, these processes may not be capable of allowing such high degrees of molecular alignment as are produced by the pulling out of chain folds. Hence there is a dramatic effect of molecular weight and crystallization procedure on the draw ratio as we will now discuss.

The results are summarized in *Figures 5* and *6*. The most striking feature is shown by samples quenched from 110°C and drawn for 90 sec. There is a clear correlation between the draw ratio achieved and $\bar{M}_w$. As found previously, but with much less certainty[2], $\bar{M}_n$ does not produce any comparable effect, although there may be points of detail

sibility will be reduced and the draw ratio would be expected to increase with decreasing $\overline{M}_n$ as is observed.

Figures 5 and *6* also show that the draw ratio achieved is dependent on the time of drawing, and this is particularly so at low values of $\overline{M}_w$. At low values of $\overline{M}_w$, and especially for the polymer which was slow cooled to 110°C before quenching, the deformation is very time dependent and the polymer behaves as a viscoelastic material. With increasing values of $\overline{M}_w$, on the other hand, the effect of drawing time becomes less and less pronounced and the deformation proceeds by the movement of a stable neck along the specimen in a manner which approximates to the behaviour of an elastic—plastic material. It is interesting to relate this observation to two possible deformation mechanisms. The first deformation mechanism, yielding lower and less time-dependent draw-ratios, is dominated by the plastic characteristics of a network superstructure originated by the non-crystalline material[14]. It involves limited breakdown and subsequent orientation of crystalline lamellae. In the second mechanism, operative at high draw ratios, we believe that the predominant process is the simultaneous pulling out of chain folds and alignment of much longer lengths of molecular chain. This second process must therefore involve both the breakdown of the lamellar structure and the straightening out of interlamellar material. It is much more time-dependent and dependent on the topology of long lengths of molecular chain. This gives rise to the dependence of the draw ratio achieved on $\overline{M}_w$.

The present results show clearly that, for given drawing conditions, the initial morphology affects the local deformation rate in the necked region, so that for a given drawing time drawn samples can be obtained from slow cooled polymers, which exhibit a draw ratio higher than that for

drawn quenched polymers. It is also evident that the magnitude of this effect decreases with increasing molecular weight. It is, however, not possible at this stage to formulate any definite conclusions regarding the effect of initial morphology on the ultimate draw ratio attainable from a sample of given molecular weight. However, studies which are now in progress do suggest that for intermediate values of $\overline{M}_w$, much higher draw ratios can be obtained than those shown in *Figure 6* simply by extending the drawing time. The isochronal draw ratio/$\overline{M}_w$ curves of *Figure 6* therefore do not represent an absolute upper limit for the plastic deformation. Rather, they indicate different deformation patterns as a function of initial morphology and molecular weight. It seems likely that with increasing drawing times the draw ratios will converge to an envelope curve which defines the limiting or ultimate extensibility of the initial polymer as a function of $\overline{M}_w$. The research required to substantiate or deny this hypothesis is at present being undertaken and will be reported in due course.

CONCLUSIONS

Studies of the influence of molecular weight and thermal treatment on the plastic deformation of LPE polymers suggest that these two factors affect both the morphology of the isotropic polymer and the draw ratio in a similar manner. The differences in molecular weight between different samples manifest themselves as a monotonic increase in draw ratio with decreasing $\bar{M}_w$. This relates to the part played in the morphology by the longer molecules in the molecular weight distribution. These molecules, in comparatively small concentration, can form a network superstructure in which physical crosslinking is supplied by molecular entanglements in the non-crystalline regions and by crystalline domains sharing segments of the same molecule. High values of $\bar{M}_w$, and crystallization under conditions where there are many tie molecules linking the crystalline domains, both affect the morphology in a similar manner and reduce the draw ratio achieved under standard conditions of draw.

Phase equilibria in quasi-binary poly(α-methylstyrene) solutions

J. M. G. Cowie and I. J. McEwen

Department of Chemistry, University of Stirling, Stirling, FK9 4LA, UK
(Received 20 June 1974; revised 7 August 1974)

Upper (*UCST*) and lower (*LCST*) critical solution temperatures have been measured for poly(α-methyl styrene) in four solvents. The extent of solvent—polymer interaction was found to be reflected in the miscibility range exhibited by these systems. The data could be described by theoretical curves derived using the Patterson—Delmas theory, if an arbitrary selection of the reference temperature was made for each quasi-binary system. Curves showing the relative contributions of the cohesive energy and free volume contribution to the polymer—solvent interaction parameter were also derived from this theory; these illustrated that while the free volume factors predominated at the *LCST*, the cohesive energy contribution could still play a significant role.

INTRODUCTION

Phase separation in polymer—solvent systems, owing to the difference in thermal expansion between solvent and solute, occurs as the liquid—vapour critical point of the solvent is approached. By examining this high temperature region one can locate lower critical solution temperatures (*LCST*) which, in conjunction with the well-known upper critical solution temperatures (*UCST*), define the phase—temperature relations for polymer solutions[1-3]. In this paper we report the threshold temperatures for poly(α-methylstyrene) (PαMS) in four relatively poor solvents in which both upper and lower critical phase separation is observable. The solvents are cyclohexane, methylcyclohexane, n-butyl chloride and propylene oxide.

The results are analysed by the Patterson—Delmas theory[4,5] based on the principle of corresponding states as applied to polymer solutions by Prigogine and his associates[6].

EXPERIMENTAL

Four PαMS samples were prepared by anionic polymerization and have been characterized previously[7]; they have a very narrow molecular weight distribution. A sample of PαMS was obtained by polymerization in methylene chloride at 203 K with BF_3 initiator. Two fractions were selected from a seven-fold fractionation of this material and their viscosity-average molecular weights were calculated from the relation[8]: $[\eta] = 7.81 \times 10^{-3} M_v^{0.73}$. Fraction molecular weights are collected in *Table 1*.

The solvents were dried by standard techniques and fractionated before use.

Cloud point curves were established as described elsewhere[1,3] by measuring the temperature of phase separation of polymer solutions in the concentration range 0—20%. Since PαMS degrades at elevated temperatures[9], the validity of the *LCST* obtained was always checked by recooling solutions to the previously determined *UCST* and noting the new temperature of phase separation. In no instance did this differ by more than a degree from the original value. It has been assumed, therefore, that thermal degradation

does not affect the *LCST* values reported when these occur below 530 K.

In the case of the *UCST* in n-butyl chloride and propylene oxide the cloud point curves had to be established by first cooling the solutions to 195 K and noting the temperature at which the polymer redissolved when the solutions were warmed, with constant shaking. This technique gave reproducible cloud points whereas those obtained by noting the temperature of phase separation on cooling were unreproducible and at much lower temperatures than the former. This behaviour has been encountered previously[1] but remains unexplained.

Light-scattering measurements on PαMS/propylene oxide solutions were made in a Sofica P.G.D. 42000 instrument using unpolarized blue light ($\lambda = 436$ nm). Solutions were clarified by passage through Millipore filters, grade 0.45 μm, into Pyrex cells designed to fit standard Sofica cell holders. These were subsequently flame-sealed under vacuum. Readings were made in the temperature range 285—360 K at an angle of $\theta = 90°$.

The specific volume of propylene oxide was measured, as a function of temperature, by standard dilatometric techniques. The propylene oxide used was fractionated, dried over calcium hydride under vacuum for three days, distilled three times on a vacuum line, discarding generous head and tail fractions, and finally flame-sealed, under vacuum, in a calibrated dilatometer with a precision bore (0.05 cm) capillary tube. Measurements were made over the temperature range 288—345 K at approximately 2 K intervals.

The thermometers used in the study were Arno Amarell works certificated thermometers with a quoted accuracy of

RESULTS AND DISCUSSION

Threshold temperatures for PαMS in the four solvents are shown, plotted as a function of *r*, in *Figure 1* where *r* is taken as the ratio of molar volumes of the polymer and solvent at 298 K. The results, as depicted in *Figure 1*, show a considerable variation in type. In cyclohexane, which is an established θ solvent for PαMS[10] the upper and lower θ-temperatures (θ_U and θ_L) are well separated. Extrapolation to infinite molecular weight gives θ_U = 308 K, in good agreement with results reported by Cowie and Bywater[10] and a value of 307.5 K obtained by Kato *et al.*[11]. The value of θ_L for this system is found to be 456 K. The miscibility range, defined by ($\theta_L - \theta_U$) is 148 K which can be compared with ($\theta_L - \theta_U$) = 179 K for the polystyrene–cyclohexane system reported by Kuwahara *et al.*[12].

In contrast to PαMS–cyclohexane, the PαMS/propylene oxide system shows considerable curvature and cannot be unambiguously extrapolated to intercept the *T* axis. In order to clarify this point the second virial coefficient, A_2, was measured by light scattering for two fractions of PαMS in propylene oxide.

If separate θ_U and θ_L exist for this system they should correspond to the two temperatures at which A_2 becomes zero[13] and these temperatures should be identical for fractions of differing chain length. Measurements from light-scattering C/I_{90} vs. *C* plots in the quasi-ternary system polystyrene–methylcyclohexane–diethyl ether have shown[14] that zero slope correlates well with θ-conditions extrapolated from *CST* measurements. The results of similar measurements in the PαMS/propylene oxide system, for two fractions of considerably different molecular weights, are shown in *Figure 2*. The upper limit of temperature was 360 K due to distillation within the light-scattering cell but the slopes of the C/I_{90} vs. *C* plots for the two fractions cannot be sensibly extrapolated to zero slope at the same temperature. For a molecular weight of 1.40 x 10⁶ this temperature is 348 K while for a molecular weight of 1.02 x 10⁵ it is estimated to be about 384 K. Both are shown in *Figure 1* and tend to mirror the threshold temperature curve. Since there is no unique, molecular weight independent temperature where A_2 is zero in the PαMS/propylene

oxide system the *T* vs. $r^{-1/2}$ curve cannot be extrapolated to intersect the *T* axis at separate temperatures corresponding to θ_U and θ_L.

The PαMS/propylene oxide system is thus of the same type as the polystyrene–acetone and polystyrene–ether system[2,3]. In this instance, however, the solvent is relatively 'good' in the sense that it can dissolve quite high molecular weight polymer compared with, for example, polystyrene in acetone where the solubility limit is reached at a molecular weight of about 2 x 10⁴ [2,3]. For the PαMS/propylene oxide system the solubility limit is estimated to be $M \approx 10^7$.

The data for PαMS/methylcyclohexane extrapolate to θ_U = 366 K and θ_L = 431 K, indicating a small miscibility range of only 65 K compared with polystyrene in the same solvent[12] where ($\theta_L - \theta_U$) = 140 K. This reflects the poorer nature of the solvent for PαMS but is not accompanied by the predicted high curvature[15] in the *T* vs. $r^{-1/2}$ plots.

The PαMS/butyl chloride system presents a much higher degree of curvature but ($\theta_L - \theta_U$) has the considerable value of 149 K. It appears that high curvature in these plots is not necessarily indicative of small miscibility gaps contrary to the prediction of the Patterson–Delmas theory[15].

An alternative treatment of *CST* data is given by the Schultz–Flory expression which is based on the original Flory–Huggins theory[16]:

$$\frac{1}{T_c} = \frac{1}{\theta}\left\{1 + \frac{1}{\psi_1}\left(\frac{1}{r^{1/2}} + \frac{1}{2r}\right)\right\} \quad (1)$$

This predicts a linear dependence of T_c^{-1} on $(r^{-1/2} + 1/2r^{-1})$. For the PαMS–solvent systems described here, equation (1) is only valid over the whole molecular weight range in the upper critical regions of the PαMS–cyclohexane and PαMS–methylcyclohexane systems. By drawing tangents to the remaining data, which is curved, θ-temperatures and entropy parameters, ψ_1, for all the systems can be obtained and these are shown in *Table 2*. The thermodynamic condition that the excess entropy of solution should
Figure 2 (a) Slopes (A_2) of C/I_{90} vs. *C* plots for PαMS fraction 2 (1.40 x 10⁶). (b) Slopes (A_2) of C/I_{90} vs. *C* plots for PαMS fraction 1, 3 (1.02 x 10⁵)

Table 2 Schultz—Flory parameters for PαMS—solvent systems studied

Solvent	θ_U (K)	θ_L (K)	ψ_{1U}	$-\psi_{1L}$	θ_L/T_{crit}	$\alpha \times 10^3$ at θ_L

$\alpha_{(polymer)} = 5.72 \times 10^{-4} K^{-1}$

be negative for a *LCST* is exemplified by the negative values of ψ_{1L} shown in *Table 2*. Also tabulated is the ratio θ_L/T_{crit} for each system, where T_{crit} is the solvent—vapour critical temperature.

The original polymer solution theory proposed by Flory[16] and Huggins[17] does not predict the existence of the *LCST*. Patterson and Delmas[4,5] have extended the statistical thermodynamic theory based on the corresponding state principle developed by Prigogine and his coworkers[6] to account for this phenomenon. This theory is essentially similar to that recently proposed by Flory *et al.*[18], and expresses the χ_1 interaction parameter as:

$$\frac{\chi_1(P, T)}{c_1} = \frac{-\widetilde{U}(\widetilde{P}, \widetilde{T})\nu^2}{T} + \frac{\widetilde{C}_p(\widetilde{P}, \widetilde{T})\tau^2}{2} \tag{2}$$

where $\widetilde{U}$ is the reduced configurational energy of the solvent, ν^2 is a parameter describing differences in force fields and segment sizes between polymer and solvent and c_1 is the number of external degree of freedom of the solvent molecule. ν^2 is normally treated as an adjustable parameter although it can be defined by the theory. c_1 and τ are measured directly from experimental expansion coefficients, α_i, and thermal pressure coefficients, γ_i, for the solvent (1) and polymer (2) via the following expressions:

$$c_i = \frac{P_i^* V_i^*}{T_i^* R} \tag{3}$$

$$\tau = 1 - \frac{T_1^*}{T_2^*} \tag{4}$$

$$\widetilde{V}_i^{1/3} = \frac{\alpha_i T}{3(1 + \alpha_i T)} + 1 \tag{5}$$

$$T_i^* = \frac{T\widetilde{V}_i^{4/3}}{(\widetilde{V}_i^{1/3} - 1)} \tag{6}$$

$$P_i^* = \gamma_i T \widetilde{V}_i^2 \tag{7}$$

Characteristic reduction parameters (asterisked) are related to reduced quantities (tilde) by:

$$\widetilde{X}_i = \frac{X_i}{X_i^*} \tag{8}$$

In equation (2) the function $\widetilde{C}_p$ has the property of increasing with temperature to an infinite limit at the gas—liquid critical point. By assuming a smoothed cell model and a van der Walls dependence of the configurational energy on liquid volume, the following expressions for $\widetilde{U}$ and $\widetilde{C}_p$ have been derived[5,18]:

$$\widetilde{U} = -\widetilde{V}^{-1} \tag{7}$$

$$C_p^{-1}(P, T) = \left(1 - \frac{2}{3}\widetilde{V}^{-1/3}\right) - \frac{2(1 - \widetilde{V}^{-1/3})}{(P\widetilde{V}^2 + 1)} \tag{8}$$

Combination of equations (2), (6), (7) and (8) leads to

$$\chi_1 = \frac{T_1^* c_1 \nu^2}{T\widetilde{V}_1} + \frac{c_1 \tau^2}{2\left(\frac{4}{3}\widetilde{V}_1^{-1/3} - 1\right)} \tag{9}$$

at zero pressure. The first term on the right hand side of equation (9) may be regarded as an alternative expression of the Flory—Huggins dependence of χ_1 on temperature. If solvent quality were solely described by such an expression it is predicted to be an ever increasing function of temperature. The second term on the right-hand side of equation (9) expresses the effect of free-volume differences between the components. It is this latter expression which predominates at high temperatures when the solvent is relatively highly expanded compared with the polymeric solute and causes the overall value of χ_1 to increase rapidly near the gas—liquid critical point. The relative contribution of each term to χ_1 is clearly seen in *Figure 3*, as a function of the temperature in each system. Using the Flory—Huggins expression we have

$$\chi_{(crit)} = \frac{1}{2}(1 + r^{-1/2})^2 \tag{10}$$

Equations (9) and (10) can be solved to provide the theoretical dependence of *CST* on chain length, r, when c_1, T_1^*, T_2^* and ν^2 are known. Following procedures described elsewhere[1,3,14] theoretical curves for the four systems described here have been calculated and are shown in *Figure 1*. The equation of state and reduction parameters required have been collated in *Table 3*. Expansion and compressibility coefficients were obtained from the literature for cyclohexane, methylcyclohexane and butyl chloride. Thermal expansion data for propylene oxide was established from the following least squares expression from the results of our own dilatometric study:

$$(11)$$

where here T is in degrees Celsius.

Theoretically T_1^* should be a constant but when measured experimentally is found to vary with temperature[14]. This temperature variation has been used to select a T_1^* value, for each of the four solvents, which provides a close absolute prediction of the experimental CST values. In this and other systems studied[1-3,12] use of T_1^* values calculated from expansion data pertaining to room temperatures has led to theoretical CST vs. $r^{-1/2}$ curves which are displaced by varying amounts from the experimental ones. By selecting T_1^* values at a new, higher reference temperature a fit is obtained which is absolute and no worse than that obtained by displacing the curves calculated from room temperature data. Unfortunately the actual choice of a new reference temperature is completely arbitrary and is governed only by the 'best fit' criterion used previously[14] It is found that the reference temperatures required are normally in the region bounded by the $UCST$ and $LCST$ and in this sense are reasonable. It should be noted we are using extrapolated expansion data which will introduce small unavoidable errors in the selection of the reference temperature.

An indication of the temperature variation of T_1^* values in the four systems can be obtained from *Table 3* where both room temperature and higher reference temperature values are tabulated. In each of the systems it is the second value of T_1^* which is used in constructing the theoretical curves shown in *Figure 1*.

The temperature variation of χ_1, for the four systems, is shown in *Figure 3*. This function has been calculated from equation (9) using the parameters listed in *Table 4*. Since T_1^* is not a constant it has been necessary to generate an artificial dependence of $\tilde{V}_1$, on temperature by solving equation (6) using the chosen value of T_1^* for each of the systems. This artificial $\tilde{V}_1(T)$ function coincides with the experimental $\tilde{V}_1(T)$ function calculated from equation (5) only at the chosen reference temperature. It is, however, the function implicitly used in the calculation of the theoretical CST vs. $r^{-1/2}$ curves shown in *Figure 1*.

In *Figure 3* there are several noteworthy features; χ_1 attains its limiting value of 1/2 at both the theoretically predicted $LCST$ and $UCST$ in the three systems PαMS–cyclohexane, PαMS–methylcyclohexane and PαMS/butyl chloride, whereas in the PαMS/propylene oxide system χ_1 is always greater than 1/2 implying that no distinct θ_U and

Butyl chloride	423	5065	0.128	15.08
Propylene oxide	383	4545	0.124	19.19

θ_L temperatures exist in the system. The two separate components of χ_1, corresponding to the two terms on the right-hand side of equation (9), have been identified here with a free volume contribution and a cohesive energy contribution and correspondingly labelled χ_1^{FV} and χ_1^{CE} in the Figure. In each case χ_1^{FV} is shown to be rapidly increasing at high temperatures. The effect of this, in the PαMS–cyclohexane, PαMS–methylcyclohexane and PαMS/butyl chloride systems, is that there is a more rapid increase in total χ_1 through the $LCST$ region than the corresponding decrease through the $UCST$ region.

The ratio θ_L/T_c gives an indication of how close one must approach the critical temperature of the solvent before phase separation occurs. It is instructive to compare this with the expansion coefficient of the solvent at the θ_L and one finds that they are in the same relative order. While the simple picture of the $LCST$ is one in which the free volume control of the phenomenon is emphasized, this shows that the cohesive energy contribution is still an important consideration. Thus the difference in free volume between solvent and polymer, as reflected in the difference in expansion coefficients, might be expected to be of the same order of magnitude for a polymer in different solvents at θ_L if this was the only contributing factor. This is clearly not the case. In cyclohexane solutions the solvent is much more expanded at the temperature of phase separation than is methylcyclohexane, but the cohesive energy contribution is considerably less favourable in methylcyclohexane. This means that phase separation will take place in methylcyclohexane solutions when the difference in free volume is smaller than that required for phase separation to occur in cyclohexane. This is reflected in the lower value of θ_L/T_c. The ratio θ_L/T_c for butyl chloride solutions has an intermediate value.

Consequently, while the predominant factor governing phase separation is entropic in origin, its effect is tempered by the enthalpic contribution. This is clearly illustrated in the curves shown in *Figure 3*.

Three main points of interest emerge from this study.

The first is confirmation of our previous observations that the Patterson--Flory theory is capable of describing the phase equilibria in a qualitative sense, but that quantitative agreement requires an arbitrary choice of reference temperature. We have not yet been able to rationalize this selection. The second highlights the importance of examining the broader aspects of phase equilibria in polymer solutions. This is exemplified in the propylene oxide solutions where polymer insolubility is manifest only at very high molecular weights. This type of behaviour immediately indicates that the liquid will not act as a theta solvent. This system is unusual, however, in that insolubility as a function of chain length has normally been reported for systems where the polymer solubility limit is much lower[2,3]. The final point is that the miscibility range appears to provide a good indication of polymer–solvent interaction, and this is being investigated further, for other binary systems.

Domain structure and crystalline morphology of AB and ABA type block copolymers of ethylene oxide and isoprene cast from solutions*

Eiji Hirata†, Toshikazu Ijitsu, Toshiichi Soen‡, Takeji Hashimoto and Hiromichi Kawai
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan
(Received 17 June 1974)

The domain structure and crystalline morphology of AB and ABA type block copolymers of ethylene oxide (EO) and isoprene (Ip) were investigated by using two kinds of casting solvents, non-selective (benzene) and selective (ethyl benzene) solvents. The domain structures of both types of block copolymers are identical, as in the case of amorphous block copolymers, depending mostly on the fractional compositions of each block segment but hardly on the sequence arrangements.

When benzene is used as a cast solvent, the change of domain structure with increase of Ip fraction follows, in general, a role established for amorphous block copolymers, except for the fact that the EO segment is crystallizable so that the above role is considerably modified, especially when the EO fraction is dominant, to form spherulitic crystalline texture. The domain structure of mixed system of block copolymer with homo-PEO, cast from benzene solution, also follows the above role, simply depending on fractional composition as a whole, of each component, unless the molecular weight of the homopolymer is much larger than that of corresponding block segment.

On the other hand, when ethyl benzene is used as a cast solvent, the domain structure is quite different from that cast from benzene solution, giving single crystal-like texture of EO segments on which Ip segments are segregated to form Ip layer even for a copolymer having an EO fraction as small as 20%. The above contrast of domain formation mechanism between the two kinds of casting solvents is interpreted in terms of an interrelation of two binodal surfaces, critical concentration of crystallization of EO segments and critical concentration of micelle formation of EO and Ip segments, in the phase diagram of the system at a given temperature.

INTRODUCTION

Thermodynamic incompatibility of A and B block segments of amorphous block copolymers has been shown to involve the microphase separation at a critical micelle concentration[1,2]. The micelles formed at the concentration are believed to be essentially maintained through the solvent evaporation process to result in the domain structures observed in the solid state[2-4]. The shape and size of the micelles, and consequently of the domains, depend upon the incompatibility, molecular weight, and fractional composition of the block copolymers, and solvent used for casting, and temperature of casting[3-8].

When one component of the amorphous block copolymers is replaced by a crystalline polymer, the domains (or crystalline textures) formed by the solvent cast should depend upon, at least, the following two factors: (i) crystalline blocks; and (ii) the microphase separation resulting from the incompatibility of the A and B blocks. The crystalline textures observed in solid state are considered to depend upon a relative contribution of the two factors. It is the purpose of this paper to investigate the role of the casting solvent and fractional composition on the domain structure and domain formation mechanism of AB and ABA type block copolymers of ethylene oxide and isoprene.

EXPERIMENTAL AND RESULTS

Preparation of AB and ABA type block copolymers of ethylene oxide and isoprene

The block copolymers were synthesized by an anionic polymerization technique primarily after the method of Szwarc[9], using cumyl potassium and sodium naphthalene as initiators for ethylene oxide/isoprene (EO/Ip) diblock copolymer and ethylene oxide/isoprene/ethylene oxide (EO/Ip/EO) triblock copolymer, respectively, and varying the fractions of the ethylene oxide and isoprene segments from zero to unity.

Isoprene and ethylene oxide monomers, as well as tetrahydrofuran (THF), the polymerization solvent, were carefully purified by conventional methods and collected under a vacuum (10^{-6} mmHg) in separate ampoules equipped with breakable seals. Polymerization of the isoprene monomer, and then of the ethylene oxide monomer, was performed in a block copolymerization apparatus connected to
Figure 1 Schematic diagram of block copolymerization apparatus: B, purification flask for solvent (THF); Na, sodium lumps; EO, ethylene oxide monomer; Ip, isoprene monomer; A, copolymerization flask; I, polymerization initiator for isoprene (cumyl potassium or sodium naphthalene in THF); T, polymerization terminator (glacial acetic acid in THF)

a vacuum line, as illustrated schematically in the right hand side of *Figure 1*. The THF solvent was further purified by means of the Na mirror technique in flask B, flash-distilled to flask A through stopcock K and main vacuum line L, and stored in the block copolymerization apparatus by fusing off the apparatus at the portion C from the main vacuum line.

The polymerization of isoprene was then initiated by mixing the initiator solution (cumyl potassium or sodium naphthalene in THF), I, and the isoprene monomer, Ip, at dry ice—methanol temperature around −75°C. The reaction, which gave a pale yellow colour of living isoprenyl potassium or naphthalene anion, was allowed to continue for 6 to 24 h, depending on the molecular weight of the isoprene block, until the monomer was completely consumed. Then, block copolymerization of ethylene oxide to the polyisoprene sequence was carried out by adding the ethylene oxide monomer, EO, to the solution containing poly(isoprenyl potassium) or naphthalene anion as the initiator. The reaction rate was usually very low, as reported by O'Malley *et al.*[10] as well as by Richards and Szwarc[9], but the reaction was performed, at first, at relatively low temperature near room temperature for about 24 h and then at gradually elevated temperatures up to 60°C for a period as long as 10 days, to avoid blowing up the ethylene monomer within the copolymerization apparatus. The reaction was terminated by adding a solution of glacial acetic acid in THF, T.

The copolymers thus synthesized were precipitated from the solutions in THF by adding n-hexane for EO rich copolymers, methanol for Ip rich copolymers, or their mixtures for intermediate copolymers. These precipitates were dried under a vacuum (10^{-3} mmHg) at room temperature, followed by freeze drying in benzene to remove traces of the solvents.

Characterization of block copolymers

The block copolymers thus obtained were characterized by velocity ultra-centrifugation, osmotic pressure, and ordinary element analysis in order to investigate the degrees of monodispersity of the copolymers as well as of contamination with corresponding homopolymers, the number-average molecular weight, and the fractional compositions of the block sequences, respectively.

Sedimentation pattern. The sedimentation pattern of the copolymers was observed at 20°C in a Spinco Model E ultracentrifuge of a benzene solution (0.3—0.5 g/l in concentration) at 56 000 rev/min. The pattern exhibited a relatively sharp single peak, as demonstrated in *Figure 2b* in terms of the Schlieren picture, for most of the copolymers, suggesting that the copolymers synthesized must be genuine AB or ABA type block copolymers having considerably sharp distribution of molecular weights. But some of the copolymers gave twin peaks, as demonstrated by the lower pattern in *Figure 2a*, suggesting that the copolymers may be contaminated with homopolyisoprene. The fractionation to remove the homopolymer was repeated by using n-hexane or methanol as a precipitant for relatively dilute solutions (less than 5% in concentration) of EO rich or Ip rich copolymers both in benzene, respectively, until their sedimentation patterns gave a single peak.

Molecular weight. The number-average molecular weights, as determined in a toluene solution at 37.0°C with a high-
Figure 2 Sedimentation patterns from Spinco Model E ultracentrifuge: (a) (lower curve) 0.5 g/l benzene solution of a block copolymer contaminated by homopolyisoprene at 56 100 rev/min; (b) 0.5 g/l benzene solutions of a genuine block copolymer and a well fractionated block copolymer both at 56 000 rev/min

speed membrene osmometer, are listed in *Table 1*, together with specimen codes of the respective copolymers.

Fractional compositions of AB and ABA block sequences. The weight fraction of each block sequence was determined from ordinary element analysis, and was double-checked by using an infra-red absorption of 0.5 g/l solution in CCl_4 in terms of a characteristic band for polyisoprene at 1638 cm^{-1} [11]. The fraction by the infra-red method agreed with that by the element analysis within experimental error, so that their arithmetic mean was listed in terms of wt % fraction of EO sequence in *Table 1*.

Degree of crystallinity and melting point of EO crystal. The degree of crystallinity and melting point of the EO crystal in the film specimens cast from benzene solutions of the block copolymers, were investigated by means of d.s.c. analysis using a Perkin–Elmer Model DSC-1B differential scanning calorimeter, under a given elevating temperature rate $\sim 10°C/min$. The results were also listed in *Table 1*, where the degree of crystallinity and melting point were evaluated from the endothermic peak area over a temperature range from about 40 to 70°C, as illustrated in *Figure 3* for some of the test specimens, by taking a literature value of heat of fusion of homo-PEO crystal, 45 cal/g[12] as a reference and from the endothermic peak position along the temperature scale, respectively.

As can be recognized from the Table, the degree of crystallinity in EO phase decreases linearly, in general, but more rapidly for the ABA series than the AB series, with decrease of the EO fraction. On the other hand, the melting poing of the EO crystals, which are considerably lower than a literature value for homo-PEO crystal, 68.5°C[12], remains almost constant, a little higher than 60°C, unless the EO fraction and the molecular weight of the EO block sequence become extremely small.

Figure 4 shows X-ray diffraction pictures for the series of AB type block copolymers including homopolyisoprene and homo-PEO as extremes. The Figure demonstrates that the crystal system of the block copolymers is identical with that of homo-PEO even for a block copolymer of less crystallinity and lower melting point as EO/Ip 5, and that somewhat diffused characteristics in the X-ray diffraction picture from the EO/Ip 5 must arise mostly from smaller size of less grown crystallites than the others.

Electron and polarized light microscopy

Ultrathin film specimens (~700 to 1000 Å in thickness) were prepared for electron microscopic observations by pouring a drop of 0.1% benzene or ethyl benzene solutions on to the microscope mesh coated by collodion and carbon, and by evaporating the solvents as gradually as possible at 30°C. Ethyl benzene was used as a selective solvent good for the Ip but poor for EO block segments, while benzene

was used as a non-selective solvent good for both block segments. The results for the selective solvent may be compared with those recently studied by Kovacs *et al.*[13,14] and by Kawai *et al.*[15].

The electron microscopic observations were made in the following two ways: (i) the specimens were stained by OsO_4 vapour which selectively stains Ip phase in order to observe the domain structure (the microphase separation) with deep contrast; or (ii) they were shadowed by Pt—Pd in order to observe morphology of crystalline EO phase. It was not possible to prepare ultrathin sections by ultramicrotome even after the OsO_4 fixation treatment proposed by Kato[16], partly because the EO segment is hydrophilic and makes the specimen too ductile to perform the ultrathin sectioning, and partly because there are no adequate liquids of common poor solvent for both segments on which the ultrathin sections are floated in order to mount the sections on the microscope mesh.

Domain structure and crystalline morphology of EO/Ip/ EO tri-block copolymers cast from benzene solutions. In *Figure 5* are shown cross-polarized photomicrographs of the PEO 1, EO/Ip/EO 2, EO/Ip/EO 3, and EO/Ip/EO 4 specimens all cast from 1% benzene solutions at 30°C. It is seen from the Figure that spherulitic texture with negative birefringence becomes less perfect, leading to less clear Maltese-cross, with increasing fraction of the amorphous Ip segments. The texture of the other specimens having EO fractions less than 50% was not clearly observed by the light microscope. Most of the block segments must be considered to locate within the spherulites for the EO/Ip/EO 1 to EO/Ip/EO 4 specimens, since the spherulites are impinged on another. Fine structure of the spherulites, especially location of the

Ip phase within the spherulites was examined as a function of EO fraction by transmission electron microscopy.

The fine structure of the EO/Ip/EO tri-block copolymers cast from 0.1% benzene solution at 30°C are shown in *Figure 6*. These Figures show typical structures of the copolymers having weight fraction of EO segments: (i) greater than 75% (*Figures 6a* and *6b* for EO/Ip/EO 2 stained and shadowed, respectively); (ii) less than 75% but greater than ~40% (*Figures 6c* and *6d* for EO/Ip/EO 3 and EO/Ip/EO 4, respectively); and (iii) less than ~40% (*Figures 6e* and *6f* for EO/Ip/EO 5 and EO/Ip/EO 7, respectively).

The micrograph on the stained specimen of EO/Ip/EO 2 (*Figure 6a*) indicates that the dark spherical domains of ~1000 Å in diameter are dispersed in the bright matrix. The dark and bright phases should correspond to the Ip and EO phases which are stained and unstained by OsO_4, respectively. Texture of the EO matrix is seen clearly to be spherulitic from the micrograph on the shadowed specimen (*Figure 6b*). The spherical Ip domains are not regularly arranged in the spherulitic EO matrix as in the case of amorphous block copolymers.

Upon increasing the Ip fraction, the spherical Ip domains are interconnected to result in the texture of rod-like Ip domains dispersed in spherulitic EO matrix as seen in *Figure 6c*. With further increase of the Ip fraction, the rod-like Ip domains are interconnected to result in both Ip and EO being continuous phases as seen in *Figure 6e*. The EO phase, however, is still seen to be spherulitic, although disordered, from the electron micrographs on the shadowed specimens or in the cross-polarized photograph (*Figure 5d*). Finally a phase inversion occurs in which, as shown, for example in *Figure 6e*, spherical EO domains having average
Figure 5 Cross-polarized photomicrographs of film specimens, a series of EO/Ip/EO block copolymers having relatively large fractions of EO segments, all cast from 1% benzene solutions at 30°C, demonstrating less perfect development of spherulitic crystalline texture with increase of Ip fraction. diameter of ~400 Å are dispersed in an Ip matrix. The spherical EO domains are known to be crystallized, as mentioned before, by wide-angle X-ray diffraction and d.s.c. thermogram investigations on the thin films. The size of the dispersed EO domains, ~400 Å in diameter for EO/Ip/EO 5, ~750 Å for EO/Ip/EO 6, 400 Å for EO/Ip/EO 7, is not necessarily in agreement with that theoretically expected

for amorphous AB and ABA type block copolymers[3-6]. This may be due to an effect of crystallization of one component.

Domain structure and crystalline morphology of AB type block copolymers cast from benzene solutions. Figure 7 shows cross-polarized photographs of EO/Ip 1 to EO/Ip 4 specimens all cast from 1% benzene solutions at 30°C. It is

seen again that spherulitic texture, which becomes less per-
fect with increasing fraction of the amorphous Ip segments,
grows unless the fraction of crystalline EO segments is rela-
tively small, being less than around 50%.

The fine structure of the EO/Ip di-block copolymers cast
from 0.1% benzene solutions at 30°C are shown in *Figure 8*.
The electron micrograph on the stained specimen of EO/Ip 2
(*Figure 8a*) indicates that the Ip spherical domains of
~1300 Å in diameter are dispersed in the EO matrix. Tex-
ture of the EO matrix is seen clearly to be spherulitic from
the micrograph on the shadowed specimen (*Figure 8b*).
With increasing the Ip fraction, the spherical Ip domains are
interconnected to form a texture of irregular rod-like domains
dispersed in spherulitic EO matrix as seen in *Figure 8c*. With
further increase of the Ip fraction up to an extent compar-
able with EO fraction, the irregular rod-like domains of Ip
component become more regular and orient parallel to each
other in the radial direction of the spherulitic texture of EO
component as seen in *Figure 8d* for EO/Ip 4. When the Ip
fraction becomes more dominant, the phase inversion
occurs, as seen in *Figure 8e* for EO/Ip 5, in which the spheri-
cal EO domains are dispersed in a matrix of the amorphous
Ip component.

Comparing the results for the EO/Ip di-block series with
those for the EO/Ip/EO tri-block series, it may be suggested
that the morphological behaviour of the di-block series is
quite similar to that of the tri-block series, depending mostly
on the fractional compositions of the block segments but
hardly on the sequence arrangements, as in the case of amor-
phous AB and ABA type block copolymers[17].

*Domain structure and crystalline morphology of ABA and
AB type block copolymers cast from ethyl benzene solutions.*
Figures 9a and 9c show cross-polarized micrographs of the
EO/Ip/EO 2 and EO/Ip/EO 4 specimens, respectively, both

cast from 1% solutions in ethyl benzene, a good solvent for
the Ip segments but a poor solvent for the EO segments, at
30°C. *Figure 9b* also shows a cross-polarized micrograph of
a thin film specimen, which was obtained by melting and
annealing the EO/Ip/EO 2 specimen cast from the solution
on a microscope deck. As can be seen in the Figures, the
crystalline texture is generally much less developed than
that obtained from benzene solutions.

When the specimens were cast from 0.1% ethyl benzene
solution at 30°C, the texture seen in the electron micro-
graphs for both the stained and shadowed specimens turned
out to be those characteristic of single crystal-like lamellae
(hedrites) having a square shape of a few micrometres in
size, irrespective of the fractions of EO segments if it is
approximately greater than 20%. Typical electron micro-
graphs are shown in *Figure 10* for EO/Ip/EO 2 (*Figure 10a*)
and EO/Ip 5 (*Figure 10c*). Close observation of the micro-
graphs suggests that disc-like domains of Ip segments appear
on the free surface of the EO single crystals. The Ip phase
is considered to exist in interlamellar region, as proposed by
Kovacs *et al.*[13,14] and by Kawai *et al.*[15], when the copolymers
are cast from more concentrated solutions so as to result in
a stack of lamellae.

There is, however, an exception for the copolymers hav-
ing nearly equal fractions of the Ip and EO segments, for
which the development of crystalline texture is quite
unstable, forming either sheaf-like texture, an undeveloped
texture of spherulite as shown in *Figure 10b*, or hedrite
having a square shape of a few micrometres in size. Despite
the exceptions, it must be emphasized that the crystalline
texture of the EO component and, in turn, the domain struc-
ture of the amorphous Ip component obtained by casting
with ethyl benzene are very different from those obtained
by casting with benzene. In the case of casting with ethyl

Figure 8 Electron micrographs of ultrathin films cast from 0.1% benzene solutions of a series of EO/Ip block copolymers at 30°C: (a) EP/Ip 2 stained by OsO$_4$; (b) EO/Ip 2 shadowed by Pt–Pd; (c) EO/Ip 3 stained by OsO$_4$; (d) EO/Ip 4 stained by OsO$_4$; (e) EO/Ip 5 stained by OsO$_4$

benzene, the crystallization of the EO segments must occur in advance of the micelle formation owing to microphase separation of the block segments and/or in association with relatively less entanglements between the EO segments due to contraction of individual EO segments in the poor solvent. These must make the crystallization less dislocated to result in the hedrite with a square shape as large as a few micrometres in size and on which surfaces the Ip segments may be segregated to form the Ip layers. In the case of casting with benzene, on the other hand, the situation may be just the opposite and makes the crystallization much dislocated resulting in the dendritic or spherulitic textures or the spherical domain structure of the EO component dispersed in a matrix of the Ip component for the EO rich or Ip rich copolymers, respectively.

Figure 11 shows wide-angle X-ray diffraction and small-angle X-ray scattering patterns obtained from through radiation (*Figure 11a*) and edge radiation (*Figure 11b*) for a film specimen of EO/Ip/EO 2 copolymer, which was cast from

3% solution in ethyl benzene, at first at a relatively elevated temperature around 60°C and then at gradually lowered temperatures down to 30°C. The patterns indicate preferential orientation of paratropic crystal planes, such as (120) plane, perpendicular to the film surface as well as planar orientation of crystal lamellae parallel to the film surface. The first and second order scattering peaks, which are observed from meridional intensity scanning as shoulders at 33.6 and 67.2 min, arise from a single interlamellar spacing of 157 Å (from the Bragg equation). By assuming the densities of crystalline and amorphous phases of EO component and of amorphous phase of Ip component as 1.234 and 1.130 and 0.913 g/cm^3, respectively, and by using the fractional composition of the EO and Ip segments of the copolymer, the layer thickness of the crystalline and amorphous EO phases and of amorphous Ip phase are calculated to be 96 and 10 and 51 Å, respectively. The thickness of the crystalline EO phase agrees fairly well with that reported for homo-PEO[12].
Figure 9 Cross-polarized photomicrographs of film specimens, EO/Ip/EO block copolymers having relatively large fractions of EO segments, all cast from 1% ethyl benzene solutions at 30°C: (a) EO/Ip/EO 2 (as cast); (b) EO/Ip/EO 2 (molten and annealed); (c) EO/Ip/EO 4 (as cast)
Figure 10 Electron micrographs of ultrathin films cast from 0.1% ethyl benzene solutions at 30°C: (a) EO/Ip/EO 2 shadowed by Pt—Pd; (b) EO/Ip/EO 2 stained by OsO4; (c) EO/Ip/EO 4 shadowed by Pt—Pd; and (d) EO/Ip 5 shadowed by Pt—Pd

Similar investigations of the wide-angle X-ray diffraction and small-angle X-ray scattering were performed for a film specimen of EO/Ip/EO 4 copolymer cast from 3% solution in benzene. Although much less preferential orientiation of (120) crystal plane and planar orientation of crystal lamellae than the above were observed, the meredional Intensity distribution was too monotonous to detect the long period.

Domain structure and crystalline morphology of mixed system of block copolymer with homo-polymer. In order to investigate the solubilization of homo-polymer into the corresponding domains of block copolymer, EO/Ip/EO 6 was mixed with homo-PEA 2 in various fractions and was cast into ultrathin films from 0.1% solutions in benzene at 30°C. The homo-PEO was chosen so that its molecular weight was

comparable to that of the EO segment of the block copolymer[18], and the mixed specimens were designated as Co 90 to Co 30 in accordance with the mixed fractions of the copolymer in wt % from 90 to 30.

Electron micrographs of the stained specimens including EO/Ip/EO 6 itself are shown in *Figure 12*. As can be seen, the morphological behaviour of the mixed system with
Figure 11 Wide-angle X-ray diffraction (30°) and small-angle X-ray scattering (1°) patterns of film specimen cast from 3% ethyl benzene solution of EO/Ip/EO 2, at first, at around 60°C and then at gradually lowered temperatures down to 30°C: (a) through radiation; and (b) edge radiation (film normal is in horizontal and vertical directions for the wide- and small-angle X-ray patterns respectively)

increasing fractions of homo-PEO is very similar to that of the series of EO/Ip/EO tri-block copolymers with increasing fractions of EO segment, as demonstrated in *Figure 6*. When the fraction of the Ip component remains still dominant, the Ip component occupies the matrix phase in which spherical domains of EO component disperse with their diameters increasing with increase of homo-PEO fraction, as seen in *Figures 12a* and *12b*; when the fraction of the Ip component becomes comparable to that of the total fraction of the EO component, the spherical EO domains are interconnected resulting in both Ip and EO phases being continuous and interpenetrating each other, as seen in *Figures 12c* and *12d*; and when the total fraction of the EO component becomes dominant, the EO component occupies the matrix phase in which spherical or rod-like domains of the Ip component are dispersed, as seen in *Figures 12e* and *12f*. Sheaf-like or spherulitic crystalline textures, which are not shown here, can be also observed under cross-polarized microscope for the mixed systems of Co 75 to Co 30. These suggest that the morphological behaviour of the mixed system is mostly affected by the fractional composition of each component, as a whole, in association with a complete solubilization of the homo-PEO into the corresponding domains, unless the molecular weight of homo-PEO is considerably larger than that of EO segment of copolymer, as concluded for the amorphous block copolymer systems[18].

Effect of heat treatment upon the domain structure and crystalline morphology of as-cast copolymers. The effect of heat treatment upon the domain structure and crystalline texture of as-cast films of the block copolymers from benzene solutions was investigated. The ultrathin films were, at first, cast on the electron microscope mesh from 0.1% solutions in benzene, and then heat-treated under vacuum (10^{-3} mmHg) at 70°C for 2 h followed by gradual cooling down to room temperature. *Figure 13* shows the stained and shadowed micrographs demonstrating the effect of the treatment for EO/Ip/EO 4, EO/Ip 4 and EO/Ip 5. By comparing the results with those for the as-cast specimens in *Figures 6d, 8d* and *8e*, respectively, the domains of Ip component are seen to be considerably distorted as the EO crystalline texture is being developed.

DISCUSSION

The domain formation mechanism and structures are shown to be similar to those of amorphous AB and ABA type block copolymers of styrene and isoprene when benzene, a non-selective solvent, is used as a cast solvent except that one phase is now crystallized and that the domain structures are distorted. This leads to irregularities in shape and mutual arrangement of the domains, owing to the crystallization and development of crystalline texture. On the other hand, they are shown td be quite different when ethyl benzene, a selective solvent, is used as a cast solvent.

Origin of this phenomenon may be qualitatively interpreted in terms of an interrelation of two kinds of binodal surfaces in phase diagram, as shown in *Figure 14* in a very simplified fashion, where the curved surface ABC represents a kind of binodal surface for crystallization of EO segments and the curved surface DFEG represents a kind of binodal surface for micelle formation due to microphase separation of EO and Ip block segments. In the phase diagram at a given temperature, as illustrated by the bottom section of the trigonal prism, the curves DFE and CB represent the critical micelle concentration, C_m, and the concentration, C_c, at which crystallization of PEO occurs, respectively, at the given temperature for the system. The critical micelle concentration which depends upon the fractional composition, incompatibility and molecular weight of the copolymer, cast solvent, and casting temperature, is empirically known to be about 5 to 10 wt % at room temperature[1,2,19]. The concentration, C_c, depends on crystallization temperature, solvent and fractional composition of the copolymer. At a particular temperature, 30°C, which is mostly used in this study, C_c should be considerably higher than C_m if the solvent is good for EO segments, but considerably lower than C_m if the solvent is poor for EO segments.

When benzene is used as a solvent, C_c is expected to be higher than C_m as shown in *Figure 15a*, since benzene is a good solvent for EO segments. Hence if a copolymer having fractional composition given by point 'd' is cast from benzene solution, the microphase separation occurs at concentration given by a point 'c' prior to the crystallization of EO segments, and then the crystallization starts at higher con-

centration (at a point 'b') in the crystallizable EO matrix to result in spherulitic texture as shown in *Figures 5a—5d* and *Figures 7a—7d*. Consequently the crystalline texture is affected by the domain structure formed at C_m. For the copolymers having EO fraction less than ~40%, the EO

a

b

Figure 15 Schematic representations of the triangular phase diagram at a given temperature, room temperature ~30°C; (a) benzene, and (b) ethyl benzene as cast solvent

words, the crystallization must occur, in general, more easily than the micelle formation, resulting in the above modifications for the domain structures of (iii) and (iv) having rather higher level of free energy in the micelles than the others, as pointed out by Inoue *et al.*[3]. The effect of heat treatment of the as-cast specimens, shown in *Figure 13*, can be interpreted in terms of the same principle.

On the other hand, if ethyl benzene is used as a cast solvent, C_c is expected to be lower than C_m at room temperature, as illustrated in *Figure 15b*, since the solvent is good for the Ip segments but poor for the EO segments. Therefore, crystallization is a predominant factor which governs the solid texture, and there is little effect of the phase separation on the solid texture. For the EO/Ip/EO 2 copolymer, the EO component is crystallized into single crystal-like texture at point 'b' (*Figure 15b*) and Ip component is segregated into interlamellar region, as schematically shown in *Figure 16a*. This is observed to occur, as shown in *Figure 10d*, even for a copolymer having EO fraction as small as ~20%, such as for EO/Ip 5. It should be, however, noted that the texture is exceptionally ill defined and not single crystal-like but rather a less perfect spherulite for copolymers having nearly equal fraction of the EO and Ip

a

b
Figure 16 Schematic representation of the textures of EO/Ip/EO block copolymers cast from (a) ethyl benzene and (b) benzene solutions

phase is dispersed in a matrix of Ip component, so that the crystallization is limited in the dispersed EO domain. This gives a spherical crystalline texture embedded in the amorphous Ip matrix, as shown in *Figures 6e, 6f* and *8e*. The Ip domains or matrix interrupt crystal growth and may cause disorders in the EO crystal as schematically shown in *Figure 16b*.

In the case of amorphous AB or ABA type block copolymers, the domain structure is regularly arranged in space and varies with increasing A component: (i) A sphere, (ii) A rod in B matrix, (iii) alternating lamellae of A and B, (iv) B rod and (v) B sphere in A matrix. In the case when one component B is replaced by a crystalline component, the domain structure and mutual arrangement of the domain are disordered as seen in *Figures 6* and *8*. The domain structure (iii) is modified to result in *Figures 6d* and *8d*, and structure (iv) is not observed but is modified to result in structure (v). The effect of crystallization on the domain structure occurs because the decrease of free energy level of the system due to the crystallization must be larger than that due to the micelle formation, when a given common stage of high free energy level, if any, is taken as a reference state. In other

segments, as illustrated in *Figure 10c* for EO/Ip/EO 4. This may be interpreted as arising from an effect of the microphase separation on the crystallization, which, in turn, may occur because C_c is close to C_m, as shown in *Figure 15b* in terms of another straight line 'ab'c'd'' for the copolymers.

Solution behaviour of similar block copolymers (styrene/ethylene oxide, and styrene/propylene oxide) in selective solvent of both block chains has been intensively studied by Skoulios and coworkers[20-23]. They give, at high concentrations, highly organized, mesomorphic structures which could be detected by analyses of small angle X-ray scattering. This organization, in the range 100—500 Å, is shown to be of the lamellar, rod-like, or spherical type.

The domain structure of the EO/Ip and EO/Ip/EO copolymers as expected when the selective solvent good for the homo-PEO is used should be similar to that as expected when the non-selective solvent is used, in that the microphase separation occurs prior to the crystallization of the crystallizable EO segment. The domain structure formed by the phase separation would correspond to the mesomorphic organization found in concentrated solutions by Skoulios and coworkers. On the other hand, when the selective solvent good for the non-crystallizable block chain is used, crystallization of the EO block chain is shown to occur at very low concentration, i.e. lower than the critical micelle concentration, and to result in single crystal-like texture. In this case the mesomorphic organization observed by Skoulios *et al.* will be, therefore, expected to correspond to the dispersed single crystal-like texture in solutions.

Our findings on the domain structure and domain formation mechanism are also in rough accord with those by Crystal *et al.*[24,25], although the detailed submicroscopic domain structures were not necessarily fully investigated by them because the osmium tetroxide staining method could not be satisfactorily used on their copolymers of styrene/ethylene oxide.

Thermomechanical heat of deformation studies on *cis*-polybutadiene

C. Price, G. Allen and N. Yoshimura

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 16 August 1974)

Thermomechanical heat of torsional deformation measurements have been made on crosslinked *cis*-polybutadiene by means of a Calvet microcalorimeter operated at 30°C. When corrected for volume changes utilizing the Gaussian statistical theory of elasticity, the data gave a value for the relative energy contribution to the torsional couple, M_e/M, of 0.14 ± 0.02. Measurements were also made on a sample subjected to simple tensile deformations. The relative energy contribution to the tensile force (f_e/f) was found to agree within experimental error with the value obtained for M_e/M, and the two results gave an average value for $d \ln \langle r_0^2 \rangle / dT$ of $4.1 \times 10^{-4} \text{ K}^{-1}$.

INTRODUCTION

The Gaussian statistical theory of rubber elasticity predicts that the equilibrium couple required to maintain a rubber cylinder of length, L in torsion at an angular rotation, θ, is given by[1]:

$$M = (\pi/2)(\nu k T/V_u)(\langle r_i^2 \rangle / \langle r_0^2 \rangle)(\theta/L)a_0^4 \tag{1}$$

where ν is the number of active network chains, k is Boltzmann's constant, V_u is the volume in the stress free state, $\langle r_i^2 \rangle$ is the mean-square end-to-end distance of the chains in the network and $\langle r_0^2 \rangle$ the corresponding value for free chains in the bulk state, and a_0 is the unstrained radius of the cylindrical sample. From a thermodynamic stand-point the equilibrium couple may be considered to consist of an entropic and an energetic (or enthalpic) contribution:

$$M = (\partial U/\partial \theta)_{T,V,L} - T(\partial S/\partial \theta)_{T,V,L}$$

$$= (\partial U/\partial \theta)_{T,V,L} + T(\partial M/\partial T)_{\theta,V,L} \tag{2}$$

and

$$M = (\partial H/\partial \theta)_{T,P,L} - T(\partial S/\partial \theta)_{T,P,L}$$

$$= (\partial H/\partial \theta)_{T,P,L} + T(\partial M/\partial T)_{\theta,P,L} \tag{3}$$

where, to a very good approximation[2],

$$(\partial H/\partial \theta)_{T,P,L} = (\partial U/\partial \theta)_{T,P,L} \tag{4}$$

In terms of the classical theory of elasticity, torsion is a constant volume deformation, and hence $(\partial U/\partial \theta)_{T,P,L}$ and $(\partial U/\partial \theta)_{T,V,L}$ are equivalent[3]. For finite deformations of rubber-like materials, Flory *et al.*[4] indicated this would not hold. Considering the combined case of torsion about a cylindrical axis and extension in the axial direction, Treloar[1] showed from equation (1) that:

$$(\partial U/\partial \theta)_{T,V,L} = (\partial U/\partial \theta)_{T,P,L} + M\beta T \tag{5}$$

where β is the coefficient of cubical expansion.

The correction term $M\beta T$ arises because a torsional deformation at constant pressure is accompanied by a small, but significant, reduction in volume (ΔV) i.e. according to the Gaussian theory:

$$(\partial V/\partial \theta)_{T,P,L} = -M\kappa \tag{6a}$$

and

$$\Delta V = -M\theta\kappa/2 \tag{6b}$$

where κ is the bulk compressibility.

To-date very few studies have been made of the energetics of torsional deformations of rubber-like materials. From torsional couple vs. temperature measurements carried out at constant P, L and θ, Boyce and Treloar[5] determined M_e/M for natural rubber by means of equations (3), (4) and (5). Again from thermoelastic measurements, but using a somewhat refined apparatus, Gent and Kuan[6] determined M_e/M for natural rubber, *cis*-polybutadiene, *trans*-polyisoprene and polyethylene at a series of uniaxial extensions. Recently, the present authors[7] reported a thermomechanical, heat of torsional deformation study of natural rubber from which values of M_e/M could be obtained. In the present contribution we report the results of a similar thermomechanical study for *cis*-polybutadiene. Measurements have also been made of the energetics of simple extension in order to obtain a direct comparison of the analogous quantities M_e/M and f_e/f [$\equiv (\partial U/\partial L)_{T,V}/f$]. All the measurements were made at 30°C at atmospheric pressure.

EXPERIMENTAL

The *cis*-1,4-polybutadiene (BR-01) was obtained from the Japanese Synthetic Rubber Co. (JSR). The polymer was crosslinked in the form of cylindrical rods by the Rubber and Plastics Research Association, Great Britain; the recipe involved heating at 153°C for 60 min with 2 parts by weight of dicumyl peroxide (per 100 parts of rubber). The

cylinders were approximately 21 mm in length and 13 mm in diameter for torsion experiments (and designated BR.A) and 21 mm in length and 3 mm in diameter for simple extension experiments (and designated BR.B). Mild steel endpieces were bonded on to the samples. Uncrosslinked material and excess curing reactant were not extracted.

Before any experiments were made, each sample was relaxed by annealing at 48–55°C for about 65 h at a higher deformation than the maximum deformation to be developed in the experiments.

Thermomechanical studies

On deformation of a rubber sample at constant pressure, the change in enthalpy, ΔH, is given by $q + w$, where q is the heat absorbed by the system and w is the work done on the system other than that arising from volume changes. In torsion,

$$w = \int_{\theta_1}^{\theta_2} M d\theta$$

where θ_1 and θ_2 are the initial and final angles of torsion, and for simple extension,

$$w = \int_{L_1}^{L_2} f dL$$

where L_1 and L_2 are the initial and final lengths in the extension direction. For both torsion and simple extensions q was measured in a Calvet microcalorimeter thermostated at 30°C. Values of w were determined in the first case from torsional couple *versus* angle of twist measurements and in the second from tensile force *versus* extension measurements. Ideally, for any given deformation q and w should have been determined simultaneously. Since this proved difficult to achieve experimentally, values of w were determined in separate deformation experiments carried out under similar conditions to those used in the calorimeter.

A detailed description of the theory, construction and calibration of the Calvet microcalorimeter[8] and the experimental arrangement used in the determination of heats of deformation[7] are fully described elsewhere. Details of the procedures and apparatus used in the force–deformation experiments have also been described[7].

The thermomechanical, heat of torsional deformation, measurements were carried out in an axially unstretched state. A torsional twist was first applied to the sample (BR.A) and the system left for 1 hour to reach equilibrium. The angle of torsion was then reduced and the calorimetric response was monitored until the recorder showed a steady base line. Measurements were made for a number of increments over the range $\theta = \pi \rightarrow 0$ (radians). The heat changes observed were additive, i.e. $q(\theta_A \rightarrow \theta_C) = q(\theta_A \rightarrow \theta_B) + q(\theta_B \rightarrow \theta_C)$.

In the heat of extension measurements the sample (BR.B) was first deformed to a chosen extension ratio and kept at this value for 1 hour. The sample was then allowed to retract to a lower extension ratio. This process was repeated until the sample had completely retracted. A wide range of experiments were carried out starting and finishing at different extensions. As in torsion it was found that the

observed heat changes were additive. A number of exploratory runs showed that the calorimetric results were insensitive to moderate variations in the retraction rate.

As in previous experiments, the arrangement within the 'reference' cell of the microcalorimeter was similar to that employed in the 'laboratory' cell except for the omission of the sample[7]. The microcalorimeter was calibrated in the recommended manner using Joule heating[8].

RESULTS AND DISCUSSION

Torsion

As shown in *Figure 1*, there was found to be a linear dependence of heat of untwisting on ψ^2 over the range studied (i.e. $\psi = 1.57 \rightarrow 0$ rad/cm). The value of $\gamma (= q/a_0^2 V_u \psi^2)$ was calculated to be 0.137 J/cm^3 using the method of least squares.

In agreement with the results of earlier force–deformation experiments on rubber-like materials[9], the plot of torsional couple M *versus* ψ was linear: from the gradient, the shear modulus $[G = (2/\pi a_0^4) ML/\theta)]$ was calculated to be 0.516 J/cm^3. A simple analytical expression for the mechanical work, w, may be obtained by integrating the torque over the angle of twist θ:

$$w = \int_0^\theta M d\theta = a_0^2 V_u G \psi^2 / 4 \qquad (7)$$

Combining expressions for q and w we obtain:

$$\frac{\Delta H}{a_0^2 V_u} = \left(\frac{G}{4} - \gamma \right) \psi^2 \qquad (8)$$
Figure 1 Heat absorbed on untwisting a sample of crosslinked cis-polybutadiene from torsion ψ (=θ/L) to the unstrained state

By partial differentiation,

$$\left(\frac{\partial H}{\partial \theta}\right)_{T,P,L} = \left(1 - \frac{4\gamma}{G}\right)M \qquad (9)$$

Finally, from equations (3)–(5) and (9):

$$\frac{M_e}{M} = \left(1 - \frac{4\gamma}{G}\right) + \beta T \qquad (10)$$

Substitution of the experimental data into this expression yields $M_e/M = 0.14 \pm 0.02$. This result is in satisfactory agreement with the values of M_e/M obtained recently by Gent and Kuan from thermoelastic studies on cis-polybutadiene; they obtained $M_e/M = 0.10 \pm 0.04$ at $\alpha \simeq 1.0$, and $M_e/M = 0.07$ on averaging seven determinations made within the range $\alpha = 1.0 \rightarrow 3.0$. Whilst thermomechanical experiments offer a more direct method of determining M_e/M than thermoelastic experiments, it should be emphasized that both approaches are dependent on a volume correction term derived from the Gaussian statistical theory of rubber elasticity.

Simple extension

Thermomechanical studies were made within the range $\alpha = 1.7 \rightarrow 1.0$. The results are plotted together in *Figure 2*. The mechanical work was obtained by graphical integration of the force–extension curve established under similar conditions to those employed in the calorimetric experiments.

The relative energy contribution to the tensile force at constant volume (f_e/f) may be calculated from the data using one of the following expressions derived from the Gaussian statistical theory:

$$f_e/f = (\partial H/\partial L)_{P,T}/f - \beta T/(\alpha^3 - 1) \qquad (11)^{10,11}$$

$$f_e/f = [\Delta H - VT\beta f'(1 - \alpha^{-1})/(\alpha - \alpha^{-2})]/w \qquad (12)^{7}$$

where f' is the force per unit cross-sectional area of the unstrained rubber, and ΔH and w are the enthalpy changes and the work done on the bulk sample. Estimation of the slope of ΔH *versus* α in *Figure 2* at $\alpha = 1.65, 1.55, 1.45, 1.35$ and 1.25 to obtain $(\partial H/\partial L)_{T,P}$ and correction of these values to constant volume conditions by means of equation (11) gave the following results for f_e/f: 0.12, 0.13, 0.13, 0.13 and 0.11 respectively.

Application of equation (12) provides a more satisfactory method of analysis, however, since any inaccuracies which might be introduced in estimating slopes are avoided. It also circumvents the problem associated with the determination of f_e/f at low extension ratios, since the equation yields an average value for the range covered. Over the range $\alpha = 1.0 \rightarrow 1.65$ we find $f_e/f = 0.11 \pm 0.02$ which is in fair agreement with the results reported from thermoelastic studies. From five thermoelastic studies[12–16] on conventionally crosslinked cis-polybutadiene (cited in a recent review article by Mark[17]) an average value for $f_e/f = 0.13$ is obtained.

For natural rubber it has been established that the Gaussian statistical theory underestimates the magnitude of the volume correction term for the case of simple extension[18]. Whilst the effect on f_e/f is small and barely outside experimental error, it does lead to systematically high values for this parameter. Unfortunately, dilation measurements have only been made on one sample[18] of cis-poly-
Figure 2 Enthalpy change, ΔH, heat absorbed, q, and work done by $(-w)$ a sample of crosslinked cis-polybutadiene on retraction from extension ratio α to the unstrained state; $\bigcirc$, values of q; $+$, values of w, and $\Delta H = q + w$

butadiene; furthermore this sample had a considerably lower shear modulus than those used in the present study. The limited dilation results available, however, suggest that as with natural rubber the Gaussian statistical theory may very slightly underestimate the volume correction term.

On the basis of the Gaussian statistical theory, values of M_e/M and f_e/f should be directly comparable since both quantities are equivalent to $Td \ln \langle r_0^2 \rangle/dT$. In keeping with this prediction, the values obtained in the present study (0.14 ± 0.02 and 0.11 ± 0.02 respectively) agree within experimental error, and give an average value for $d \ln \langle r_0^2 \rangle/dT$ of 4.1×10^{-4} K^{-1}. There do not appear to be any solution data suitable for the calculation of $d \ln \langle r_0^2 \rangle/dT$. Using the rotational isomeric state theory, however, Mark[19] has shown that a positive value for cis-polybutadiene arises because the lowest energy conformations about CH_2–$CH=$ CH–CH_2 rotatable bonds are $\pm 60°$, $\pm 60°$ and $\mp 60°$, $\pm 60°$ states, which are relatively compact.

(Received 4 March 1974; revised 29 July 1974)

Dielectric absorption caused by the molecular relaxation of thermally decomposed poly(vinyl chloride) in air was studied on samples in the form of thin films. It was found that, with the progress of thermal decomposition, the magnitude of α dielectric absorption changes in three stages: (1) initial decrease in magnitude corresponding to the process of the formation of polyene sequences caused by dehydrochlorination; (2) ensuing increase corresponding to the deformation of polyene sequences attributed to oxidation; (3) final decrease corresponding to the formation of crosslinks.

INTRODUCTION

Studies[1-11] on the thermal decomposition of poly(vinyl chloride) (PVC) in air, by means of determining hydrogen chloride evolved, viscosity measurement, infra-red spectroscopy, thermal gravimetric analysis, and Brabender Plastgraph, have so far revealed that both dehydrochlorination and polyene formation take place in the initial stage of the thermal decomposition, then in the second stage, oxidation, and finally in the third stage, crosslinking and chain scission take place.

Kisbényi and Hedvig[12,13] have reported that, by continuously recording the a.c. conductivity and the dielectric spectra, the degradation of sheet PVC samples interposed between electrodes can be kinetically measured and that information on changes in the physical structure of the samples can be obtained.

For the purpose of observing the dielectric absorption due to the molecular relaxation, the usual dielectric method for measuring the decomposition process, however, is unsatisfactory as the absorption is masked from observation by electrical conduction caused by ionic matters resulting from decomposition.

In the present study, thin films of PVC degraded in an air oven were employed, so that most ionic compounds such as hydrogen chloride derived from the decomposition could be released from the film into the air and electric conduction caused by ionic compounds remaining in the film would be minimal, thus eliminating the difficulty mentioned above. From the results obtained, the relation between the dielectric absorption caused by molecular relaxation and structural changes in the thermal decomposition process of PVC is clarified.

EXPERIMENTAL

Sample

PVC films used in the present study were prepared thus; Geon 103 EP (product of Nippon Geon Co.) was dissolved in tetrahydrofuran (THF), and the solution was poured onto a glass plate and left for 2 days until a sheet of film was formed. To remove the remaining THF, the film was steeped in methanol for two days and dried *in vacuo* at $50-60°C$. The films thus obtained were decomposed thermally in a thermal ageing tester (a gear oven produced by Tabai Co., model GS-11) at $150°C$ and $190°C$ ($\pm 2°C$) for a given time. After an appropriate time lag, one of the films was taken out from the oven and then quenched in liquid nitrogen. The thickness of these sample films was 0.04–0.1 mm.

Method

Each sample film was set in an electrode arrangement. The complex dielectric constant ($\epsilon^* = \epsilon' - j\epsilon''$, where real term, ϵ', is the dielectric constant and imaginary term, ϵ'', the dielectric loss) of the sample was calculated from the values of capacitance (C) and conductance (G) measured by the inductive ratio arm bridge (manufactured by Ando Electric Co., model TR-10C) in the frequency range of 30 to 10^6 Hz at varied temperature. The thickness of the sample was not changed during the dielectric measurement. To compare the degradation in the air oven, a thick PVC plate interposed between measuring electrodes (in a closed system) was decomposed in a state in which the decomposition products remained in the sample.

In order to see the physical nature of the degraded films, the dynamic modulus, the d.c. conductivity, the glass transi-
Figure 1 Frequency dependences of ϵ' and ϵ'' at $110°$C for PVC films decomposed at $150°$C in the air oven. Time of decomposition: ○, 0; ●, 0.5; △, 2; ▲, 3; □, 4; ■, 8 h

tion temperature, X-ray diffraction and infra-red absorption spectra were measured.

RESULTS AND DISCUSSION

As for the thin films of the original and those decomposed at $150°$C in the air oven, the frequency dependence of ϵ' and ϵ'' calculated directly from the value measured by the inductive ratio arm bridge (hereafter, a.c. bridge) at $110°$C are shown in *Figure 1*. It is clear that the dielectric absorption observable in *Figure 1* is ascribable not to the electric conduction attributed to the ionic matters derived from the decomposition, but to the molecular relaxation. On the other hand, for the films decomposed in the closed system, the d.c. conduction (G_0) increased with progress of decomposition; for example, the d.c. conductivity, $\sigma(\Omega^{-1}\,cm^{-1})$ $(\sigma = G_0 . d/S$ where d is the thickness of the film and S is the area of electrode) increases as expressed by:

$$\log \sigma = 2.2t - 10.9$$

where t is the time of decomposition (h), and the value of σ for the decomposed film for 3 h was found to be about 10^4 times that of the thin film decomposed in the air oven for the same period and at the same temperature. As for the case of the closed system, the dielectric loss (ϵ_T'') calculated directly from a.c. conductance (G_a) measured by the a.c. bridge, and the loss (ϵ_D'') calculated from the value subtracting G_0 from G_q, are plotted against the frequency in *Figure 2*. Although ϵ_T'' which increases with the progress of decomposition shows no peak of dielectric absorption, ϵ_D'' shows a peak of dielectric absorption which coincides with that observed in *Figure 1*. It is inferred from these results that when the thick plate of PVC sample is being decomposed

thermally, most of the ionic compounds such as hydrogen chloride derived from the decomposition remain in the sample, hence the dielectric loss calculated directly from G_a of the sample plate increases with the decomposition.

In the case of the present study using thin films decomposed in the air oven, it is considered that because of the diffusion of split ionic compounds from the film into the · air, the ionic conduction becomes very small. Thus the dielectric loss ascribed to the orientation of dipoles can be determined directly from G_a without measuring d.c. conduction of the sample, although a small increase of ϵ'' is observed at the low frequency side as shown in *Figure 1*, which is attributed to the electric conduction caused by the ionic compounds remaining in the film.

The analysis of X-ray diffraction patterns measured for the original and decomposed PVC films revealed that the sample films are not crystallized during treatment in the present experiments.

The glass transition temperature, T_g, was found to be $77°$C for the original film, and ranged between $77°$ and $83°$C for the decomposed films. The value of T_g changes to a lesser extent with decomposition.

The frequency dependence of ϵ'' of the films decomposed at $190°$C is shown in *Figure 3*. The dielectric absorptions shown in *Figure 1* and *3*, observed at temperatures above the glass transition region, are the so-called α absorptions ascribed to the micro-Brownian motion of segments in amorphous region[14-17]. The β absorptions which have been considered as deriving from the local motion of frozen main chain below T_g[14-17] were observed at temperatures lower than $70°$C. The discussion with respect to the β absorptions is omitted from this paper, since little influence is caused by the thermal decomposition.

As for the sample films decomposed at $150°$C and $190°$C, the apparent activation energy, H^* of the α relaxation process for each film was determined from the slopes of $\log f_m$ vs. $1/T$ curves (f_m is the relaxation frequency, T is the absolute temperature at which the dielectric constants were measured), and the time dependence of H^* in the thermal decomposition is shown in *Figure 4a*. It is observed in this Figure that H^* changes in three stages.

Figure 4 (a) Change of apparent activation energy, H^* (α relatation process) with the progress of thermal decomposition. ○, Decomposed at 150°C; ●, decomposed at 190°C. (b) Change of $\Delta\epsilon$ at 110°C with the progress of thermal decomposition. ○, Decomposed at 150°C; ●, decomposed at 190°C

In order to clarify the behaviour of the polar groups in PVC, the value of $\Delta\epsilon = \epsilon_0 - \epsilon_\infty$ as a magnitude of the dielectric absorption (ϵ_0 and ϵ_∞ are low and high frequency limiting values of ϵ') was determined from the Cole circular arc plots[18]. The value of $\Delta\epsilon$, here, is independent of the frequency and proportional to $N\mu^2/kT$, as shown in Fröhlich's formula[19] (μ is the mean dipole moment; N, the concentration of dipoles; k, Boltzmann's constant; T, the absolute

temperature). The time dependence of $\Delta\epsilon$ in the thermal decomposition process is shown in *Figure 4b*, which shows the α absorptions for the films decomposed at 150°C and 190°C. The value of $\Delta\epsilon$ in both cases decreases in the initial stage of the decomposition, then increases and again decreases after reaching a maximum. The rate of change in $\Delta\epsilon$ with the decomposition at 190°C is greater than that for those decomposed at 150°C.

At the initial stage of the thermal decomposition of PVC, the predominant reaction is known to be the dehydrochlorination which is accompanied by the formation of a series of conjugated double bonds[4-9]. For the purpose of finding the change in number of conjugated double bonds and the carbonyl groups of PVC during the thermal decomposition, the absorbance at 1600 and 1725 cm^{-1} arising from the conjugated double bonds and the carbonyl groups was measured by i.r. spectroscopy, and these results are shown in *Figures 5a* and *5b*. *Figure 5a* shows that the conjugated double bonds increase at the initial stage of the decomposition. From this fact and that H^* increases at the initial stage, it can be considered that the decrease of $\Delta\epsilon$ in the initial stage corresponds to the decrease of the molecular mobility caused by the formation of polyene sequences.

At the second stage, the decrease of the absorbance due to the conjugated double bonds and the increase of the absorbance due to the carbonyl groups take place at the same time as shown in *Figures 5a* and *5b*. It has been
Figure 5 (a) Change of polyene absorption intensity (1600 cm^{-1}) with the progress of thermal decomposition. (b) Change of carbonyl absorption intensity (1725 cm^{-1}) with the progress of thermal decomposition. (c) Formation of insoluble compounds in the thermal decomposition of PVC films. ○, Decomposed at 150°C; ●, decomposed at 190°C
Figure 6 Change of elastic modulus, E', (at 110°C and at 110 Hz) by thermal decomposition. ○, Decomposed at 150°C; ●, decomposed at 190°C

reported that polyene sequences derived from the decomposition are shorter in the presence of oxygen than in its absence[4,6,9]. Therefore, it is suggested that the deformation of polyene sequences caused by oxidation takes place at the second stage. Further, H^* decreases at this stage in the decomposition as shown in *Figure 4a*. From these facts, it is considered that the segmental motion restricted in the initial stage is restored temporarily by the deformation of polyene sequences caused by oxidation. The increase of $\Delta\epsilon$ at the second stage, therefore, is considered to correspond to the increase of chain mobility attributed to the deformation of polyene sequences caused by oxidation.

In order to examine the decomposition process of the final stage, a portion of the decomposed sample was taken and again dissolved in THF; the solution was then filtered and the residue was dried and weighed. The time dependence of the insoluble matter, as shown in *Figure 5c*, indicates that at 190°C crosslinking commences about 50 min after the onset of decomposition and that at 150°C, it commences about 3 h after the onset, as observed by Collins and Krier[3]. Furthermore, it was found that the T_g of the samples in the final stage above 81°C is greater than that of the original sample (77°C), and that H^* increases at the final stage as shown in *Figure 4a*. These findings support the above observation of the formation of crosslinks in the final stage. Since the segmental motion is restricted by the crosslinks, the decrease of $\Delta\epsilon$ in the final stage can be considered to correspond to the increase of crosslinks.

It is also possible to obtain information on the molecular mobilities from the viscoelastic properties[20–22]. In order to examine the rigidity of the sample, the dynamic modulus, E', was measured by a viscoelastic spectrometer at 110°C and at 110 Hz, for the decomposed PVC samples, and is shown in *Figure 6* as a function of the time of decomposition. Log E' changes in three stages as observed for the case of H^* in *Figure 5a*. This result is evidence in support of the consideration related to the dielectric properties.

Thermal decomposition of a vinyl chloride/vinyl acetate copolymer

Shadi L. Malhotra, Jean Hesse* and Louis-P. Blanchard

Département de Génie Chimique, Faculté des Sciences, Université Laval, Québec, G1K 7P4, Canada
(Received 1 May 1974)

The thermal decomposition of an 85% vinyl chloride/15% vinyl acetate copolymer and its different fractions obtained by precipitation was studied by the thermogravimetric scanning (t.g.s.) technique. Analyses of the t.g.s. thermograms revealed the existence of two major steps in the decomposition reaction. The first occurs between 180 and 380°C during which hydrogen chloride and hydrogen acetate are given off. In the second, which occurs between 420 and 480°C, degradation of the carbon chain takes place. Both the order of reaction and the activation energy were found to be dependent on the molecular weight of the copolymer and on the heating rate at which the experiments were carried out. Analyses of the samples carried out by gel permeation chromatography (g.p.c.) after each decomposition revealed that, besides the two steps mentioned above, yet another step, viz. crosslinking, may be taking place at 180°C or below where the weight loss of copolymer is too small to be detected by t.g.s. The process of crosslinking, however, may take place at other temperatures as well. A higher degree of crosslinking has been associated with a higher acetate content in the copolymer. A comparison of g.p.c. results with those obtained by nuclear magnetic resonance spectra showed that, out of the three steric configurations of the copolymer, syndiotactic sequences are least resistant to thermal treatment followed in order by heterotactic and isotactic sequences.

INTRODUCTION

Studies of the thermal decomposition of poly(vinyl chloride) (PVC)[1] and of poly(vinyl acetate) (PVAC)[2] have yielded very interesting results. The respective decompositions are known to begin around 180°C with the elimination of hydrogen chloride (HCl) from PVC by a free radical mechanism and of hydrogen acetate (HAC) from PVAC by a molecular mechanism. The remaining products in both cases are conjugated residues which can undergo at much higher temperatures (>400°C) further decomposition by carbon chain scissions.

As for the thermal decomposition of vinyl chloride/vinyl acetate copolymers P(VC/VAC), the first investigations reported in the literature are those of Lehrle and Robb[3] who showed that the volatile decomposition products (viz. HCl and HAC) are given off in proportions corresponding to the amounts of each monomer in the copolymers. Vymazal[4] who studied the elimination of HCl from an 87% VC copolymer between 143 and 164°C reports an overall activation energy of 27 kcal/mol in air and 31 kcal/mol in nitrogen.

In a recent study, Grassie *et al.*[5] have shown that once the reaction has been initiated neither HCl nor HAC is given off preferentially. Their studies on the thermal decomposition of these copolymers by pyrotechnique analysis over the full range of compositions showed that copolymers having vinyl acetate contents of 40 to 50% were indeed the least stable. While examining the development of conjugation along the polymer chain, they also found that for a given rate of decomposition, the conjugation sequences were longest for copolymers having vinyl acetate contents of 20 to 30%.

Little is reported in the literature on the thermal decomposition of P(VC/VAC) copolymers by the thermogravi-

metric scanning (t.g.s.) technique. Furthermore little interest seems to have been shown in the second step of this reaction, namely, the thermal decomposition of poly-conjugated chains formed by the acid eliminating step. This is why a t.g.s. investigation[6] was undertaken in this laboratory to elucidate kinetic aspects of the two-step process responsible for the thermal decomposition of an 85:15 wt % VC/VAC copolymer and some of its fractions with differing molecular weights. Changes in distribution resulting from thermal effects were also studied by gel permeation chromatography (g.p.c.). The results of these studies form the subject of this communication.

EXPERIMENTAL

Materials

The vinyl chloride/vinyl acetate copolymer (VS-814) used in this work was kindly provided by the Shawinigan Chemicals Division of the Gulf Oil Company in Canada. The product had been synthesized by suspension polymerization and contained 15% by wt of vinyl acetate. This material was purified by total precipitation from a tetrahydrofuran (THF) solution using distilled water as the precipitating agent. It was then dried at 60°C under vacuum prior to its use in the decomposition study. Fractions with differing molecular weights were also obtained by partial precipitation from a 1% by wt solution of the copolymer in THF. The precipitations were carried out in a large pear-shaped separatory funnel by adding progressively small quantities of distilled water to the well agitated solution. Before withdrawing a precipitated phase, the total solution was allowed to settle for at least 24 h in order to favour equilibrium exchanges between the upper solution and the lower precipitated phase. After drying, each fraction was examined by g.p.c.[7].

Figure 1 G.p.c. calibration curve prepared under normal operating conditions with several P(VC/VAC) copolymer fractions

Apparatus

The decompositions were carried out with a Perkin—Elmer (model TGS-1) thermobalance. It was operated at three different heating rates (1.25, 5.0 and 20.0°C/min), under a dynamic (27 ml/min) nitrogen atmosphere. The samples used weighed approximately 1.0 mg.

Molecular weight distribution analyses of the P(VC/VAC) copolymers, both before and after the decompositions, were carried out with a Waters Associates (model 200) gel permeation chromatograph, operated at a constant temperature of 25 ± 0.5°C.

The separating system, consisting of four 4 ft (1.22 m) long columns connected in series and packed with cross-linked polystyrene gels having nominal permeabilities (by the Waters method) of 1.0×10^6, 1.5×10^5, 3.0×10^3 and 250 Å respectively, was fed with solvent, THF degassed with nitrogen, at a controlled flow rate of 1 ml/min. The concentration of all g.p.c. sample solutions was adjusted to 0.125% by wt in order to render negligible 'concentration effects' on the peak position in the chromatograms. The P(VC/VAC) copolymer fractions, characterized by membrane and vapour pressure osmometry as well as light scattering, were used to plot a g.p.c. calibration curve ($\log M$ versus elution volume, V_e) shown in *Figure 1*. Molecular weight calculations were computed following Smith's method.

Component splitting of the g.p.c. curves

The raw g.p.c. curves were broken down into three distinct components (L, M and N shown in *Figure 2a*) by the method described below for the particular case of the P(VC/VAC) ($\bar{M}_n = 2.8 \times 10^4$) copolymer. The relative weights of the above mentioned copolymer as a function of the elution volume for decompositions carried out during 50 min periods at different temperatures are summarized in *Table 1*. The results show that between 20 and 180°C the weight loss due to decomposition is negligible. Furthermore there is little or no change in the relative weights of the samples treated in this temperature range when compared to those of the initial copolymer. On heating them at 230°C for a similar period of 50 min, over and above the 7% weight

loss, a significant change in the relative weights was observed. At the lower elution volumes (95 to 110 ml), these show a decrease whereas at higher elution volumes (115 to 130 ml), there is a corresponding increase in the relative weights. If one subtracts from the initial distribution curve of the undecomposed polymer, the distribution of any subsequently decomposed polymer, one can readily visualize the changes brought about by the decomposition of the higher molecular weight species. This is shown in *Figure 2b* where the area marked L in the initial undecomposed copolymer is found to disappear at 230°C, while a corresponding area marked L′ appears at a lower elution volume. *Figure 2c* shows these areas (L and L′) in the form of distributions where both meet at a common elution volume of 111 ml. In reality, however, some overlapping is believed to

Thermal decomposition of a vinyl chloride/vinyl acetate copolymer: S. L. Malhotra et al.

take place between the two distributions as shown in the Figure by the broken lines. The tracing of these lines is based essentially on the overall shape of the curves, be they broad, Gaussian or other in distribution; and they are at best only a first approximation of the true situation. This correction, when applied to component L of the undecomposed polymer results in the addition of areas E_A, E_B and E_C to its distribution. A corresponding compensation in the L' distribution is then necessary and is made by using the same areas. *Figure 2d* illustrates two g.p.c. distributions, one obtained with an undecomposed sample, the other after the sample has been heated at 280°C for 50 min. The areas marked (L + M) and N_1 in the original distribution show up in the second as the alternate areas $(L + M)' + N_1'$. This would mean that the higher molecular weight portions (L + M) of the original distribution are decomposed into lower molecular weight species $(L + M)'$, while a lower molecular weight portion N_1 is altered to form a higher molecular weight one N_1' by a process believed to involve crosslinking. Species N_1 could possibly follow an alternative route and decompose completely into volatile products: however, as additional experimental data will show, this is not believed to be the case. Rather, the possibility of crosslinking appears to be the more logical choice.

Figure 2e shows these areas in the form of distributions. As can be seen, the (L + M) and N_1 distributions show abrupt endings at elution volumes of 108 and 111 ml, respectively. Unlike the situation shown in *Figure 2e*, there are no clear guide-lines to indicate how these two distributions might be overlapping; therefore, the broken line extentions based on the Gaussian nature of the overall curves were made by simply tracing the mirror images of the (L + M) and N_1 distributions. The summation of these two distributions when subtracted from the area under the undecomposed copolymer curve yields a fourth distribution N_2, which has remained unchanged until now. Distributions N_1 and N_2 have been considered here as forming a part of a single distribution N rather than introducing a fourth distribution O. This has enabled the number of components to be kept to three, L, M and N, in order that they might be compared with the three possible steric forms of the copolymer. Subtracting the distribution assigned to component L from that of (L + M) yields M, while subtracting that of the (L + M) component from the distribution of the undecomposed copolymer yields an area assignable to N which is also the

sum of the N_1 and N_2 components. If one then subtracts the distribution of N_2 from the distribution of a sample decomposed at 280°C, that of $(L + M)' + N_1'$ poses no problem to trace.

Nuclear magnetic resonance (n.m.r.) spectra

N.m.r. analyses were carried out on several P(VC/VAC) copolymer samples at the Canadian 220 MHz NMR Centre in Sheridan Park, Ontario. Spectra were obtained using solutions of the copolymers (15% by wt) in dichlorobenzene at 100°C, with hexamethyldisiloxane as internal standard.

RESULTS AND DISCUSSION

The changes observed in components L, M and N when samples of the initial copolymer were heated for 50 min periods at different temperatures are summarized in *Table 2*. It is interesting to note that the molecular weights, $\bar{M}_n$ and $\bar{M}_w$, of component L undergo a five-fold drop in value, while its weight loss due to decomposition attains but 26%. Moreover, the polydispersity of the decomposed component does not change significantly. These observations suggest that one of the initial processes responsible for lowering of the molecular weight must be that of random chain scissions. Once these have made their contribution some other mechanism of decomposition invariably takes over. The process whereby the initial polydispersity of the polymeric species is unaffected by decomposition and where changes occur only in the weight of the sample has been explained in detail by Berlin and Yenikolopyan[9] on the basis of complete and rapid depolymerization of the chains. There is yet another condition attached to this depolymerization process: this demands that no abrupt changes take place in the molecular weight of the decomposing species. In the present case, however, the molecular weight of the copolymer did in fact change from 6.05×10^4 to 1.32×10^4. It is therefore difficult to say if this observation should be attributed entirely to the process of random scissions or in part to a chain depolymerization process.

On heating the copolymer at 280°C, component M disappears and is replaced by a new distribution M' having a lower molecular weight and a lower polydispersity. Lowering of both the molecular weight and the polydispersity of component M, coupled with its weight loss attaining between 43 and 90%, suggests that chain depolymerization

Figure 3 (a) to (c) G.p.c. distributions of a P(VC/VAC) copolymer ($\overline{M}_n$ = 2.80 x 10⁴) before and after isothermal treatment (various periods at 180°C) plus distribution tracings of the components (decomposed and crosslinked counterparts). 1, 0; 2, 50; 3, 120; 4, 240 min

increase thereby affecting the polydispersity of the resulting crosslinked component.

In all probability, one should expect the polydispersity to decrease. The change observed (from 1.5 in L to 1.07 in L') supports the concept of crosslinking which is put forth here.

Figures 3a to *3c* illustrate the changes observed in the g.p.c. curves of the initial P(VC/VAC) copolymer when it is heated at 180°C for periods of 50, 120 and 240 min. In *Figure 3a*, it is evident that the thermal treatment of the sample at 180°C during a 50 min period does not affect its g.p.c. distribution; however, on heating it for 120 min, a part of the lower molecular weight species S disappears while higher molecular weight ones S' are found to appear. After 240 min at the same temperature another part T likewise disappears and is replaced by the higher molecular weight species denoted by T'. In both cases the thermal treatment was accompanied by a weight loss on only 1.3 and 1.4%, respectively. It seems evident that intermolecular crosslinking of the conjugated polymeric species yield higher molecular weight products. The decrease in polydispersity observed when components S and T undergo crosslinking again adds support to the existence of such a process.

One should note that the copolymer species which are most susceptible to crosslinking are those that are situated in the relatively lower molecular weight range (0.9 × 10⁴, the approximate molecular weight of components N_1 and T, and 4 × 10⁴, that of component S). In order to verify this observation a study was made on the decomposition of two fractions, C and J, of this copolymer[7] having molecular weights ($\overline{M}_n$) of 6.05 × 10⁴ and 3.18 × 10⁴ respectively.

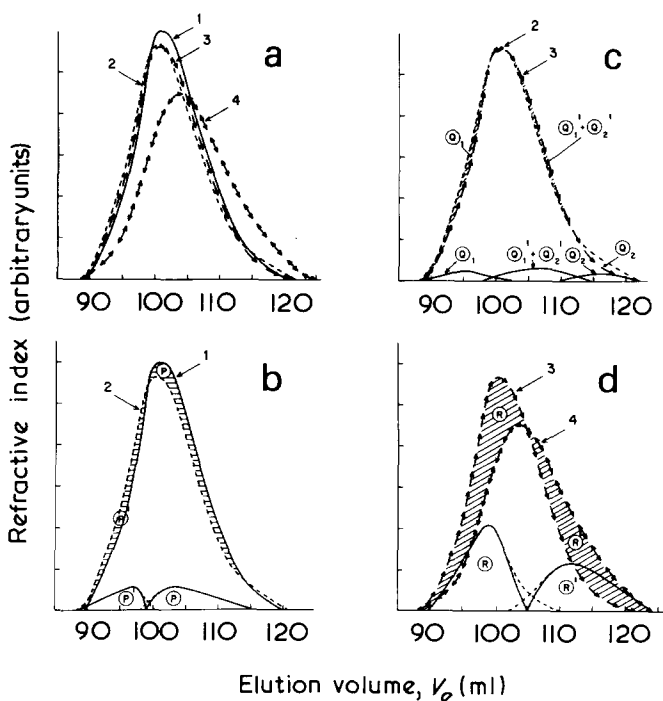
Figures 4a to *4d* and *Table 3* summarize the results obtained for the decomposition of fraction C which was heated at 180°C for different periods of time. In *Figure 4a* are shown the g.p.c. curves of the initial undecomposed sample and of samples treated at 180°C for 50, 120 and


Figure 4 (a) G.p.c. distributions of P(VC/VAC) copolymer fraction C ($\overline{M}_n$ = 6.05 x 10⁴) before and after isothermal treatment (various periods at 180°C); (b) to (d) distribution tracings of components (undecomposed, decomposed and crosslinked counterparts). 1, 0; 2, 50; 3, 120; 4, 240 min

is very much the predominant process in this reaction. Estimation of the weight loss range for M is based on results given in *Table 2* which show that at 280°C the 44% overall weight loss observed in the copolymer comes primarily from components (L + M). The lower weight loss limit (43%) in M is based on the assumption that component L has been completely volatilized, whereas the upper limit (90%) corresponds to the 26% weight loss of L alone recorded on heating the copolymer at 230°C. A part, N_1, of component N may also undergo changes without weight loss when the copolymer is heated at 280°C for 50 min. As suggested earlier in the text, crosslinking may be responsible for the resulting changes observed. If this assumption is valid, the number of chains should decrease and their lengths should

Polydispersity	1.16	1.26	1.46

240 min, respectively. It is difficult to draw definite conclusions from this Figure because, from all appearances, the first three g.p.c. curves shown (viz. that of the initial sample and those of the samples treated for 50 and 120 min respectively) appear to be very much the same. If one attempts to study the changes that occur at each step, however, one observes that during the first 50 min, a component P having a molecular weight of 4.76×10^4 has been converted to a new component P' of higher molecular weight $(M_w = 17.0 \times 10^4)$. On heating the sample for an additional 70 min, a component Q_1 $(\bar{M}_w = 15.8 \times 10^4)$ decomposes and a lower molecular weight component Q'_1 $(\bar{M}_w = 2.01 \times 10^4)$ appears. At the same time, a component Q_2 $(\bar{M}_w = 0.87 \times 10^4)$ undergoes crosslinking to yield Q'_2 $(\bar{M}_w = 2.01 \times 10^4)$. This shows the complexities involved in attempting to study the kinetics of this reaction, where processes take place involving random scissions, chain depolymerizations, crosslinking as well as the decomposition of conjugated residues at higher temperatures (>400°C). *Figure 4d* shows the changes that occur when sample C is treated at 180°C, first for 120 and then for 240 min. Though no additional weight loss is observed, a component R with a molecular weight of 9.86×10^4 is replaced in the 240 min treatment by a lower molecular weight component R' $(\bar{M}_w = 1.89 \times 10^4)$ arising most probably from a random scission process.

Figures 5a to *5d* summarize the results obtained with fraction J. Here as in the case of fraction C, one can see that the distributions, when compared as a group, appear as a cluster *(Figure 5a)*; however, when these are considered on an individual basis, they show trends similar to those observed with the higher molecular weight fraction C. The principal difference appears to be in the greater extent of crosslinking that takes place in the lower molecular weight fraction J. As shown in *Figures 5b* and *5c*, on heating fraction J at 180°C for 50 min, component A is replaced by a new component A' of higher molecular weight whereas on heating it at the same temperature but for 120 min, components (A + B) give rise to a new still higher molecular weight component (A + B)' as a result of intermolecular crosslinking. The changes that occur during the latter 70 min, involving the formation of B' from B are not shown in *Figure 5* but the analytical results are listed in *Table 4*.

The changes that occur to fraction J in the time interval of 120 to 240 min, involve a decrease in molecular weight for species C due, in all probabilites, to random scissions because the polydispersity of the species is found to increase while no additional weight loss is observed during the period.

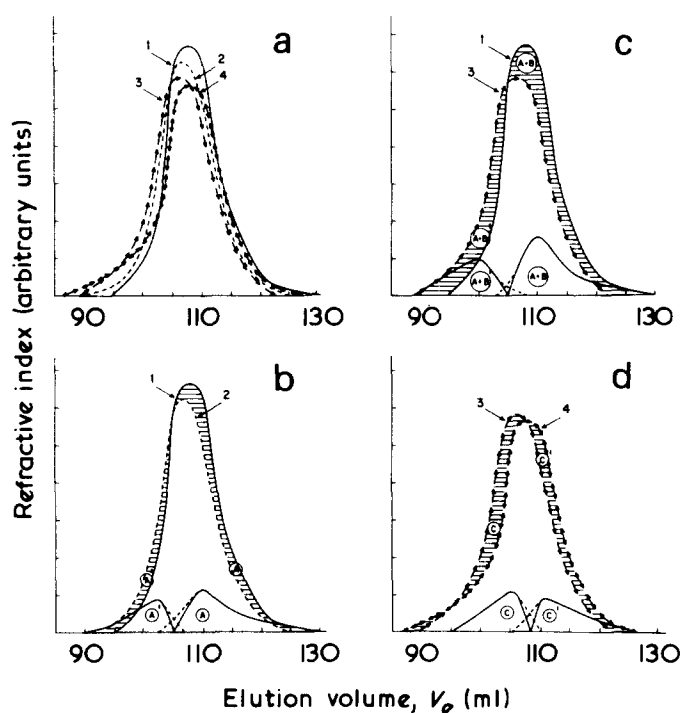
Figures 6a to *6c* show the changes that take place in g.p.c. distributions based on studies of the decomposition of fraction J at 180 and 230°C for periods of 50 min. Here, as before, the lower molecular weight components X and (X + Y) are replaced by the higher molecular weight components X' and (X + Y)' as a result of intermolecular crosslinking.


Figure 5 (a) G.p.c. distributions of P(VC/VAC) copolymer fraction J $(\bar{M}_n = 3.18 \times 10^4)$ before and after isothermal treatment (various periods at 180° C); (b) to (d) distribution tracings of components (undecomposed, decomposed and crosslinked counterparts). 1, 0; 2, 50; 3, 120; 4, 240 min

Table 4 Components of fraction J, $(\bar{M}_n = 3.18 \times 10^4)$ of the initial copolymer P(VC/VAC) and their decomposed counterparts at different times and temperatures

	Undecomposed components				
	X	(X + Y)	A	B	C
$\bar{M}_w \times 10^{-4}$ (g.p.c.)	1.62	2.26	1.81	2.00	5.49
$\bar{M}_n \times 10^{-4}$ (g.p.c.)	1.09	1.49	1.13	1.75	4.91
Polydispersity	1.49	1.52	1.60	1.15	1.12
Decomposition times (min)	50	50	50	120	240
Temperatures (°C)	180	230	180	180	180
True weight loss, α (%)	6.0	9.0	6.0	7.0	7.0

	Decomposed counterparts				
	X'	(X + Y)'	A'	B'	C'
$\bar{M}_w \times 10^{-4}$ (g.p.c.)	8.00	15.2	8.36	15.7	1.37
$\bar{M}_n \times 10^{-4}$ (g.p.c.)	6.55	9.15	6.76	12.8	0.97
Polydispersity	1.22	1.66	1.24	1.23	1.40

Figure 6 (a) G.p.c. distributions of P(VC/VAC) copolymer fraction J ($\overline{M}_n$ = 3.18 x 10⁴) before and after isothermal treatment (50 min periods at various temperatures); (b) and (c) distribution tracings of components (undecomposed and crosslinked counterparts). 1, 20°; 2, 180°; 3, 230°C

The maximum extent of crosslinking observed for these fractions varies between 20 and 24%, the former value being for component (A + B) of fraction J when it is heated for 120 min at 180°C and the latter for component (X + Y) (also of fraction J) when it is heated at 230°C for only 50 min. As mentioned earlier, these values obtained under identical conditions are lower in the case of fraction C, the maximum value not exceeding 8%.

Stereoregularity and crosslinking

It has been shown earlier that the lower molecular weight fraction J shows a greater tendency to crosslink than does the higher molecular weight fraction C. Before attempting to study the effect of molecular weight of the copolymer on its tendency to crosslink, it is necessary to establish initially that all of the samples have the same structure because branching as well as the different steric arrangements in the copolymer may influence its mode of decomposition. In order to elucidate these characteristics, the initial copolymer and its two fractions C and J were subjected to n.m.r. spectroscopy.

The criterion generally used for the determination of stereoregularity through n.m.r. spectroscopy for a P(VC/VAC) copolymer is the triplet yielded by the methyl protons of the acetate $-OCOCH_3$ group. If one obtains a well resolved triplet, then the areas under the three peaks can easily be computed. These correspond, in ascending order of magnetic field, to the proportions of isotactic, heterotactic and syndiotactic sequences in the sample. In the event that the resolution of the triplet is poor, one can alternatively use the methine protons of the vinyl chloride $-CHCl$. units. These yield three pentuplets assigned, in ascending order of magnetic field respectively, to syndiotactic, heterotactic and isotactic sequences. The spectra of the initial copolymer was obtained in order to relate its steric structure with the pattern of its decomposition at different temperatures. *Figure 7* shows n.m.r. spectra of the three copolymers. The assignment of the chemical shifts for the protons of the vinyl chloride part of the copolymer

was based on results reported by Heatley and Bovey[10]; that for the protons of the vinyl acetate part, on the work of Bovey and coworkers[11] and that of Ramey and Field[12]. The chemical shifts observed in this work for the VC part agree well with the literature[10]; however, those for the VAC part are at some variance[11,12]. It is not unlikely that the chemical shifts recorded in the lower magnetic field (τ = 4.70) for the methine protons ($-CH$) of the VAC part of the copolymer and those in the higher magnetic field (τ = 8.40 and 8.69) for the methylene protons ($-CH_2$) are caused by the presence of VC units in the vicinity instead of the VAC units usually present in vinyl acetate homopolymer.

A comparison of the n.m.r. spectra obtained with the C and J copolymer fractions reveals that the percentages of syndiotactic (25%), heterotactic (40%) and isotactic (35%) sequences are essentially the same in both. The acetate content of the lower molecular weight fraction J would seem to be higher than that of the lower molecular weight fraction C. Moreover, there appears to be differences in the proportions and nature of methylene protons (τ = 8.40 and 8.69) in the vinyl acetate part of the copolymer. How these differences bring about an increase in the process of crosslinking is not as yet fully understood.

Grassie and coworkers[11] have made suggestions concerning the role played by the chloride and acetate groups in the elimination of acids. These may be represented as follows.

For the elimination of HAC:
For the elimination of HCl:
The inductive effect of the chlorine atoms weakens the C–H bonds of the methylene group and thus facilitates the elimination of acetic acid. Elimination of HCl on the other hand has been attributed to the participation of acetate groups which finds its support from the role of acetic acid as a catalyst in a study reported on by Capon[13] who showed instances where the elimination of small molecules is assisted by the acetate groups. Grassie and coworkers[11] have shown further that vinyl acetate content in the copolymer controls the chain lengths of the conjugated sequences. It was found that in copolymers with a vinyl acetate content of 20 to 30%, the proportion of long conjugated sequences was at a maximum. This might explain the higher degree of
Figure 7 N.m.r. spectra for three P(VC/VAC) samples. 1, Initial copolymer ($\overline{M}_n$ = 2.80 x 10^4); 2, fraction C ($\overline{M}_n$ = 6.05 x 10^4); 3, fraction J ($\overline{M}_n$ = 3.18 x 10^4)

crosslinking observed in the lower molecular weight co-polymer J, which carries a higher acetate content.

The n.m.r. spectrum of the unfractionated copolymer is also shown in *Figure 7* with the exception of that part situated between τ values of 8.10 and 10.00. Based on the integral of the curve produced by the methine protons (τ = 5.40 and 6.00) of the vinyl chloride units and the specific areas under the three peaks τ = 5.52, 5.62 and 5.75, the syndiotactic, heterotactic and isotactic sequence contents of the copolymer are found to be 25, 40 and 35%, respectively. If one compares these values with the corresponding values obtained for the areas of each of the components L (27%), M (40%) and N (33%) in the initial copolymer, one is lead to speculate that the syndiotactic sequences are the first to decompose followed by the heterotactic and finally the isotactic sequences. It remains very difficult to say whether this is indeed the order followed in the decomposition of the three steric structures present in the copolymer.

Kinetics of the decomposition

In dynamic thermogravimetry, the rate law for the decomposition of a polymer may be written, in a general form,

as follows:

$$\frac{d\alpha}{dT} = \frac{k}{q} \cdot F(\alpha) \tag{1}$$

where α is the fraction of initial polymer volatilized at a temperature T; $F(\alpha)$ is a function of α; q (in °C/sec) is the heating rate; and k is a rate constant presumed to follow the Arrhenius law in the form $k = Z \exp(-E/RT)$. Here Z (in sec^{-1}) is the pre-exponential factor and E (in kcal/mol) is the energy of activation.

It is evident from this expression that the heating rate has a definite influence on the rate of decomposition. *Figure 8* shows, for three specific heating rates, typical thermograms obtained during the decomposition of copolymer samples at temperatures ranging from 220 to 520°C. At first glance, though the shapes of the curves are similar in all three cases, the influence of the heating rate is reflected in variations of the initial and final temperatures of decomposition. The curves are made up of two parts located in successive regions of the temperature scale. This observation agrees well with that of Grassie and coworkers[5] who showed that the first
Figure 8 Influence of heating rate on the dynamic thermogravimetric decomposition of P(VC/VAC) copolymer ($\overline{M}_n$ = 2.80 x 10⁴). A, 5.0°C/min; B, 10.0°C/min; C, 20.0°C/min

region is characterized by the elimination of acid (HCl and HAC) and the second by the degradation of polyconjugated chains. They did not, however, establish the kinetic parameters of these reactions. Keeping this in mind, an analysis of the curves shown in *Figure 8* has been carried out in order to determine, for each part, the order of reaction and the energy of activation, using the expression derived by Coats and Redfern[14]. This method, based on equation (1), consists of plotting $\ln [F(\alpha)/T^2]$ as a function of $1/T$, where

$$F(\alpha) = \left[\frac{1 - (1 - \alpha)^{1-n}}{1 - n} \right]$$

for $n \neq 1$ and

$$F(\alpha) = [-\ln(1 - \alpha)]$$

for $n = 1$. α is the volatilized fraction of the polymer and T (K) is the absolute temperature.

Different values of n are tested and that which yields the most linear correlation is retained as the order of reaction. The slope of the line obtained with the accepted value of n is $(-E/R)$ from which the activation energy is readily obtained.

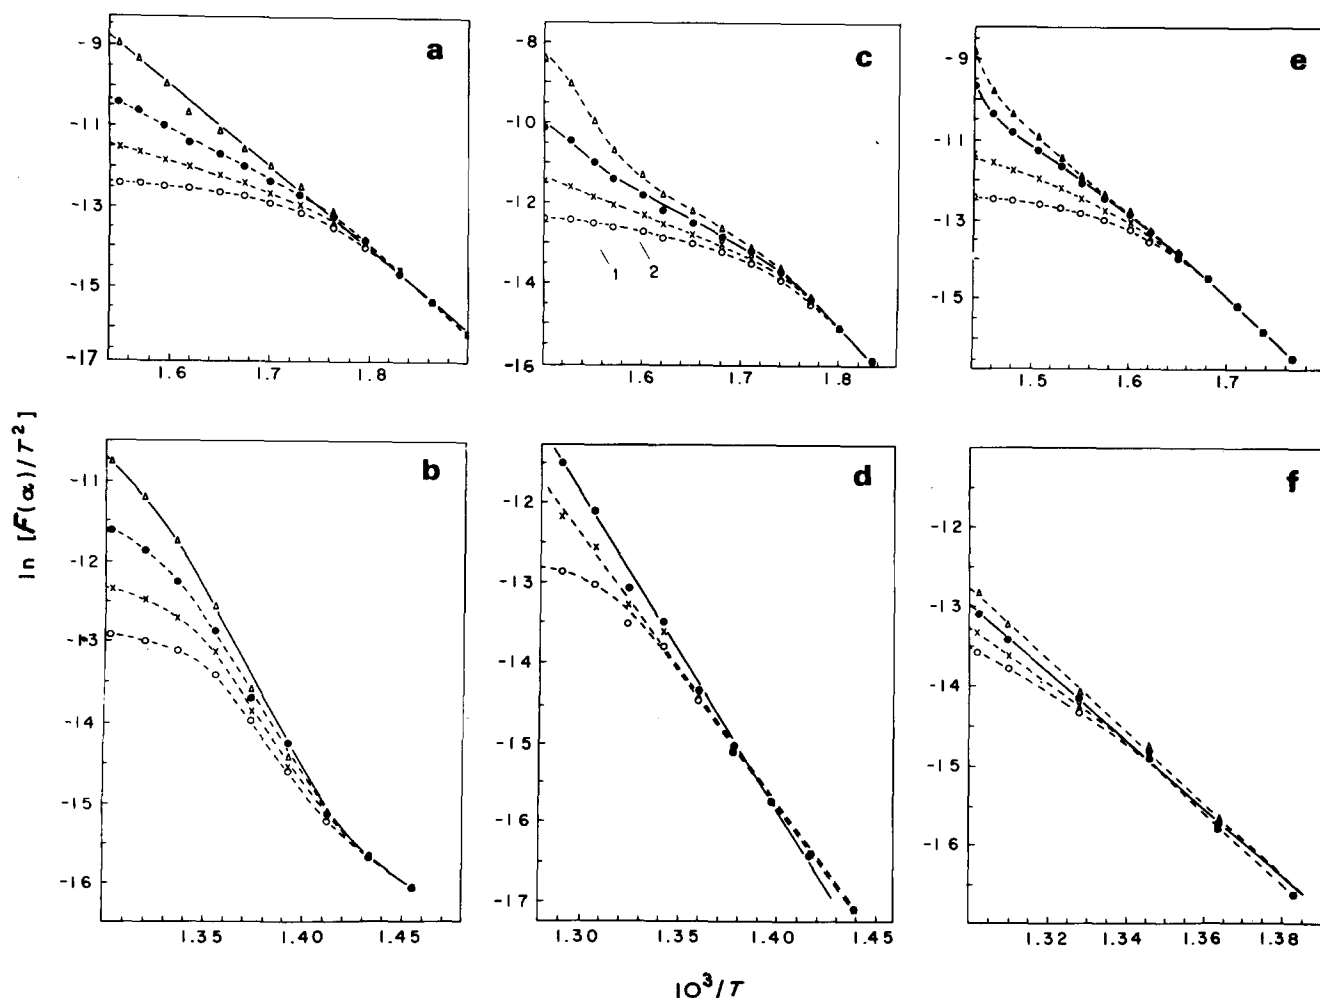
Figure 9 shows, for several values of n, plots of $\ln [F(\alpha)/T^2]$ versus $1/T$ for each of the two parts involved in the decomposition at three specific heating rates of initial


Figure 9 Variation of $\ln[F(\alpha)/T^2]$ with $1/T$ for the two-step decomposition of P(VC/VAC) copolymer ($\overline{M}_n$ = 2.80 x 10⁴) at three different heating rates and several values of n, the order of reaction: 1, 5.0°C/min (first-step in a, second-step in b); 2, 10.0°C/min (first-step in c, second-step in d); 3, 20.0°C/min (first-step in e, second-step in f); O, n = 0.5; x, n = 1.0; ●, n = 1.5; ▲, n = 1.7; △, n = 2.0

copolymer samples. Similar plots have been made (though not shown here) for the two fractions C and J. The order of reaction and the energies of activation have been computed and are presented in *Tables 5* and *6*. It is evident from the data given in these Tables, that the order of reaction for the same phenomenon is different for each of the heating rates. Moreover, the results show a dependency on the molecular weight. In all probability, the principal factor responsible for this dependency lies in the interpretation given to the value of n since in many cases, one can trace near-linear relationships for $\ln [F(\alpha)/T^2]$ *versus* $1/T$ with several values of n and it becomes a difficult problem to select the true value. This also has an effect on the activation energy values which are based directly on the accepted order of reaction n. Based on the data obtained, one can only say that the value of the activation energy for the first part of the decomposition, involving the elimination of acids, lies between 30 and 40 kcal/mol while that for the second (viz. decomposition of polyconjugated chains) lies between 50 and 90 kcal/mol, depending upon the molecular weight of the sample: the lower the molecular weight, the lower the energy of activation.

In conclusion, one can say that crosslinking begins to take place at 180°C even though the weight loss is negligible. This may take place as well at higher temperatures in other stages of the reaction. A higher degree of crosslinking in the lower molecular weight copolymer has been attributed to its higher acetate content. Furthermore during the course of the process leading to the elimination of acids (viz. HCl and HAC) from chain ends, as suggested by Grassie and co-workers[11], random scissions also participate in breaking down the polymeric chains. The activation energy values (*Table 6*) computed for the second step lie in the range of 50–90 kcal/mol assigned to the dissociation of C–C bonds[15], which may be responsible for the decomposition of polyconjugated chains in the copolymer. N.m.r. spectroscopy has lead to speculations that syndiotactic sequences are the least resistant to thermal treatment, followed by heterotactic and finally isotactic sequences.

The experimental limitations and the corresponding interpretations limit the number of conclusions that can be

drawn from this work. Nevertheless, it should prove interesting to establish eventually the role played by the molecular weight and likewise by the heating rate. To do this, other techniques would be required such as differential scanning calorimetry. These would prove more helpful in the lower temperature range (180 to 220°C) where the t.g.s. technique is less effective because of negligible weight losses though other activities, e.g. crosslinking which consumes energy, are operative.

Reactivity ratios for the copolymerization systems styrene/*p*-ethoxystyrene and methyl methacrylate/*p*-ethoxystyrene

D. Margerison, D. R. Bain, K. Lindley, N. R. Morgan and Lindsay Taylor
Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK
(Received 26 July 1974)

Reactivity ratios for the systems styrene/*p*-ethoxystyrene and methyl methacrylate/*p*-ethoxystyrene have been determined at 50°C. The values found by the computational method of Tidwell and Mortimer were 1.08 and 0.74 for the first system, and 0.37 and 0.24 for the second; the 90% joint confidence limit envelopes were also calculated.

INTRODUCTION

The theory of free-radical copolymerization leads to the conclusion that the composition of the copolymer is determined by the reactivity ratios, r_1 and r_2, and the ratio of the concentrations of the two monomers. Since the composition of the polymerization mixture normally changes with time, the theory predicts the composition of the copolymer formed in an infinitesimal period of time in which the two monomer concentrations may be regarded as constant. The result is:

$$y_2 = \frac{x_1 x_2 + r_2 x_2^2}{r_1 x_1^2 + 2x_1 x_2 + r_2 x_2^2}$$

where y_2 is the mole fraction of monomer 2 in the infinitesimal amount of copolymer formed in the time interval in which the mole fractions of monomer 1 (M_1) and monomer 2 (M_2) in the feed are x_1 and x_2. Several authors[1-5] have recently discussed the procedures by which the reactivity ratios can be evaluated from determinations of copolymer compositions at known feeds. Here, we report the application of the Tidwell—Mortimer[1] method to the determination of the reactivity ratios of two systems: styrene (M_1)/*p*-ethoxystyrene (M_2), and methyl methacrylate (M_1)/*p*-ethoxystyrene (M_2).

EXPERIMENTAL

Inhibitor was removed from the three monomers by washing with 10% aqueous sodium hydroxide. After washing with de-ionized water and drying over anhydrous sodium sulphate, the monomers were distilled under vacuum. All polymerizations were carried out at 50°C under vacuum ($<10^{-3}$ mmHg permanent gas pressure) using AZBN as initiator. Toluene was added as a diluent in the methyl methacrylate systems. The polymerizations were followed dilatometrically and stopped at about 5% conversion. The polymers were recovered by precipitation from methanol. Their number-average molecular weights were in the range 5×10^4 to 2.5×10^5.

In the case of the styrene systems, the initial composition of the comonomer mixture was fixed by pipetting accurately known volumes of the two monomers into the reaction vessel; with the methyl methacrylate systems, a weighing technique was used instead.

The composition of each of the copolymers was found by elemental analysis (Alfred Bernhardt, West Germany), or by u.v. spectrophotometry using a peak located at about 279 nm in the absorption spectrum of both the homopolymer of *p*-ethoxystyrene and the two copolymers studied here. Neither polystyrene nor poly(methyl methacrylate) absorb appreciably at this wavelength so that a determination of the absorbance of the copolymer at this point gives directly its composition, once the extinction coefficient for *p*-ethoxystyrene segments is known.

RESULTS AND TREATMENT OF DATA

Extinction coefficient of p*-ethoxystyrene at 279 nm*

The absorbances of 4 solutions of poly(*p*-ethoxystyrene) in CHCl₃ were measured in a 1 cm cell over the concentration range 20—50 mg/l. A simple least squares line constrained to pass through the origin was put through the points and the extinction coefficient calculated to be 1.131×10^4 cm²/g with negligible error.

*Compositions of the monomer feed and the copolymer for the system styrene (*M₁*)/*p*-ethoxystyrene (*M₂*)*

Two groups of four copolymers were prepared. Each copolymer was analysed for carbon, hydrogen, and oxygen by elemental analysis and for *p*-ethoxystyrene by u.v. spectrophotometry. The mole fractions, y_2, of *p*-ethoxystyrene in the products is shown in *Table 1*.

The figures indicate the precision obtainable; *p*-ethoxystyrene contents determined from H analysis do not appear because the precision of the method is inadequate. It will be noted that there is good agreement between the three methods used.

*Compositions of the monomer feed and the copolymer for the system methyl methacrylate (*M₁*)/*p*-ethoxystyrene (*M₂*)*

A similar procedure to that above was employed to determine the copolymer compositions at different feeds

in this system. The results are shown in *Table 2*. Again reasonable agreement between the three analytical methods is observed.

Estimation of r_1 *and* r_2 *and the error envelopes for both systems*

The procedure for calculating the least squares estimates of r_1 and r_2 which was described by Tidwell and Mortimer was found to work very satisfactorily. Usually, only three or four iterations were required to reach more or less stationary values of these quantities. The results are shown in *Table 3*.

The differences in the estimates from one analytical method to another are not significant. This can be seen from *Figure 1* where the 90% joint confidence limit envelopes are plotted. (To construct these envelopes, an extension of Tidwell and Mortimer's approximate procedure was devised to facilitate computation; the method is described in the Appendix.) The numerical values listed in *Table 3* illustrate a well-known difficulty in the estimation of reactivity ratios, namely that r_1 and r_2 cannot be independently estimated from the same set of data; when one estimate is shifted by a change of analytical procedure or the use of an alternative computational method, then so is the other. This fact is the basic reason why joint confidence limits provide the best representation of the experimental error.

It only remains to select final values of the estimates of r_1 and r_2 for the two systems studied. We choose the values associated with the confidence limit envelope with the smallest area. These are:

Styrene/*p*-ethoxystyrene:　　$\hat{r}_1 = 1.08$
　(oxygen analysis)　　　　　$\hat{r}_2 = 0.74$

Methyl methacrylate/*p*-ethoxystyrene:　$\hat{r}_1 = 0.37$
　(u.v. analysis)　　　　　　　　　　　$\hat{r}_2 = 0.24$

These two sets of values are self-consistent in the sense that each gives essentially the same *e* value[6] for *p*-ethoxystyrene; we obtain −1.3 from the styrene system and −1.2 from the methyl methacrylate system. Furthermore, the first pair of reactivity ratios is very similar to the pair found by Ceccorulli *et al.*[7] for the analogous system styrene/*p*-methoxystyrene. These workers found $\hat{r}_1 = 1.16$ and $\hat{r}_2 = 0.82$ using u.v. rather than oxygen content to characterize the copolymers.

APPENDIX

Computation of the joint confidence limit envelope

Using the notation, $\ln \hat{r}_1 = \hat{t}_1$ and $\ln \hat{r}_2 = \hat{t}_2$, Tidwell and Mortimer derived the following approximate equation for the coordinates (t'_1, t'_2) of the joint confidence limit envelope at the $100(1-p)$ per cent level, where $0 < p < 1$

$$(t_1' - \hat{t}_1)^2 a_{11} + 2(t_1' - \hat{t}_1)(t_2' - \hat{t}_2)a_{12} +$$

$$(t_2' - \hat{t}_2)^2 a_{22} = 2s^2 F_p(2, n - 2) \qquad (1)$$

Here, a_{11}, a_{12}, a_{22}, and s^2 are quantities evaluated in the estimation of r_1 and r_2, and $F_p(2, n - 2)$ is the value of the statistic F at the significance level p with $(2, n - 2)$ degrees of freedom, n being the number of copolymers used. Equation (1) represents an ellipse in (t_1, t_2) space with its centre at $(\hat{t}_1, \hat{t}_2)$.

By shifting the origin of the coordinate system to the point $(\hat{t}_1, \hat{t}_2)$ and then rotating the coordinate axes through an angle θ given by:

$$\tan 2\theta = \frac{2a_{12}}{a_{22} - a_{11}}$$

we can reduce equation (1) to the simple form:

$$\frac{x^2}{A^2} + \frac{y^2}{B^2} = 1$$

where

$$\left. \begin{aligned} t_1' - \hat{t}_1 &= x\cos\theta - y\sin\theta \\ t_2' - \hat{t}_2 &= x\sin\theta + y\cos\theta \end{aligned} \right\} \qquad (2)$$

and

$$\left. \begin{aligned} A^2 &= \frac{2}{\alpha + \gamma - \delta} \\ B^2 &= \frac{2}{\alpha + \gamma + \delta} \end{aligned} \right\} \qquad (3)$$

Here, $\alpha = a_{11}/2s^2 F$, $\beta = a_{12}/s^2 F$, $\gamma = a_{22}/2s^2 F$, and $\delta^2 = \beta^2 + (\gamma - \alpha)^2$; F in these expressions stands for $F_p(2, n - 2)$. The virtue of this transformation is that the coordinates of the confidence limit envelope in the new coordinate system can be computed through the expressions:

$$\left. \begin{aligned} x &= A\cos\phi \\ y &= B\sin\phi \end{aligned} \right\} \qquad (4)$$

where ϕ is a dummy variable to be incremented in the range 0 to 2π.

The computation of the confidence limit envelope on $\hat{r}_1$, $\hat{r}_2$ in (r_1, r_2) space thus proceeds as follows: (1) having chosen p, the significance level, compute A and B from equation (3) and the associated definitions of α, β, γ, and δ; (2) compute the locus of the elliptical envelope in (x, y) space using equation (4); (3) calculate the quantities $(t_1' - \hat{t}_1)$ and $(t_2' - \hat{t}_2)$ using equation (2); (4) calculate t_1' and t_2', the coordinates of the elliptical envelope in (t_1, t_2) space; (5) transform to $r_1' = \exp(t_1')$ and $r_2' = \exp(t_2')$ to obtain the joint confidence limit envelope in (r_1, r_2) space.

Vinyl polymerization initiated with alkali metal adducts of triphenylamine and triphenylphosphine

Koichi Yamaguchi, Takero Yoshida and Yuji Minoura
Research Institute for Atomic Energy, Osaka City University, Osaka, Japan
(Received 25 April 1973; revised 3 October 1974)

The polymerizations of styrene, methyl methacrylate, isoprene, butadiene and acrylonitrile initiated with alkali metal adducts of triphenylamine or triphenylphosphine at $0°C$ in tetrahydrofuran take place by an anionic mechanism. Biphenyl alkali metal anion radical and alkali metal adducts of benzene, aniline and diphenylamine are formed in the reaction of triphenylamine with the alkali metal and it was shown that styrene was polymerized with both the anion radical and alkali metal adducts of benzene, whereas methyl methacrylate and acrylonitrile were polymerized by all anion species.

INTRODUCTION

It is well known that alkali metal amides initiate an anionic polymerization of styrene (S), methyl methacrylate (MMA) and acrylonitrile (AN) in liquid ammonia[1], and that alkali metal salts of aniline and diphenylamine initiate the polymerization of AN and MMA in diethyl ether or liquid ammonia[2]. Primary and secondary amines[3,4] or tertiary amines and phosphines[5] [e.g. triphenylamine (TPA) and triphenylphosphine (TPP)] readily react with alkali metals and in this paper, the polymerizations of S, MMA, AN, isoprene, and butadiene with the potassium adducts of TPA or TPP were investigated in tetrahydrofuran (THF) at $0°C$. The difference between the reactivity of TPA and TPP with various alkali metals was examined.

EXPERIMENTAL

Materials

Triphenylamine (TPA) prepared by the reaction[6] of diphenylamine with phenyl iodide was recrystallized from ethyl acetate (m.p. $127°C$). Diphenylamine and triphenylphosphine were purified by recrystallization from benzene and all solvents used were purified by distillation before use.

All vinyl monomers used were dried over calcium hydride, and distilled under nitrogen.

Reaction of triphenylamine with potassium metal

A mixture of potassium (0.0346 mol) and TPA (0.0204 mol) was stirred in 50 ml of dried THF under nitrogen atmosphere at room temperature until the potassium dissolved (about 100 h). The green solution resulting was filtered through the glass filter under a stream of nitrogen gas, and the filterate was used immediately.

Reaction of triphenylphosphine with potassium metal

A mixture of potassium (0.00785 mol) and TPP (0.00308 mol) was stirred in 50 ml of dried THF under nitrogen atmosphere at $-15°C$ until the potassium dissolved (about 40 h). The red solution was used after filtering as described above.

Alkali salts of aniline and diphenylamine

The reaction of aniline (0.052 mol) with potassium (0.0511 mol) in 20 ml of THF to give mono-potassium aniline, and that of diphenylamine (0.041 mol) with potassium (0.043 mol) in 20 ml of THF to form mono-potassium diphenylamine were carried out at $70°C$ for 6 h.

Di-potassium aniline was obtained by the reaction of aniline (0.056 mol) with potassium (0.113 mol) in 20 ml of DG at room temperature for 4 h.

The identification of those products was carried out by elemental analysis and by reaction with benzyl chloride. The products of the latter reaction were benzyl aniline (m.p. $35.0°C$), benzyl biphenylamine (m.p. $88.0°C$) and bibenzyl phenylamine (m.p. $69.5°C$), respectively.

Polymerization

The alkali metal adduct in THF solution was added to the degassed monomer—solvent mixture by means of a syringe. The polymerization was carried out in a sealed tube at $0°C$. The reaction mixture was poured into a large excess of methanol containing dilute hydrochloric acid and the precipitated polymer was filtered off, washed with methanol and dried in vacuum to constant weight.

Measurements

The intrinsic viscosity of polymer was measured in benzene by means of a Ubbelohde viscometer and the degree of polymerization was calculated from:

$$\bar{P}_n = 1770 \times [\eta]^{1.40} \text{ (for polystyrene)}^7$$

$$\bar{P}_n = 2200 \times [\eta]^{1.13} \text{ (for PMMA)}^7$$

Molecular weights of the reaction products and of the oligomers were determined with a Knauer vapour pressure osmometer, using benzene as solvent.

E.s.r. measurements were carried out on a JES ME 3X Type spectrometer (x-band, 100 kHz irregularity) with 100 kilocycles modulation.

The visible absorption spectrum was measured by means of a Hitachi-EPS-2 Type ultra-violet spectrometer and the

infra-red spectra of polymer, oligomer, and reaction products as film or pellets using a Jasco IR-E infra-red spectrometer.

RESULTS AND DISCUSSION

Reaction of triphenylamine with potassium metal

Anion radical. The reaction of TPA with potassium, sodium, lithium was investigated at room temperature, and only the more highly electron donating potassium reacted. The e.s.r. signal of a THF solution of TPA with potassium metal showed a nine line spectrum centred at 3300 G, and each signal split into five fractions at 0.41 G. This signal was the same as that of biphenyl anion radical[8], but e.s.r. signals from triphenylamine anion radical or any radical on nitrogen were not observed. The formation of the reaction product was confirmed by the absorption band at 600 nm from biphenyl anion radical.

Reaction products. By treating the solution obtained by reacting TPA with potassium described above with a few drops of water, followed by hydrogen chloride, aniline hydrochloride (0.41 g, m.p. 192.2°C) was isolated by the filtration. Biphenyl (0.51 g), *N*-phenylcarbazole (0.11 g), benzene (0.4 ml), and unreacted TPA (2.22 g) were isolated from the filtrate by column chromatography on silica gel (developing solvent; mixed solvent of diethyl ether and petroleum ether). The formation of aniline, was confirmed by reaction of the product with *p*-toluenesulphonyl chloride to give phenyl *p*-toluenesulphonamide (m.p. 103.0°C).

From these results, the following reactions are assumed:

$$\left(\left\langle \bigcirc \right\rangle \right)_3 N + K \longrightarrow \left[\left(\left\langle \bigcirc \right\rangle\right)_3 N\right]^{\cdot} K^+ \quad (1)$$

$$\left[\left(\left\langle \bigcirc \right\rangle\right)_3 N\right]^{\cdot} K^+ + K \longrightarrow \left[\left(\left\langle \bigcirc \right\rangle\right)_3 N\right]^{2-} 2K^+ \quad (1')$$

$$\left[\left(\left\langle \bigcirc \right\rangle\right)_3 N\right]^{2-} 2K^+ \longrightarrow$$

$$\left[\left(\left\langle \bigcirc \right\rangle\right)_3 N\right]^{\cdot} K^+ \longrightarrow \left(\left\langle \bigcirc \right\rangle\right)_2 N^{\cdot} + K-\left\langle \bigcirc \right\rangle \quad (2)$$

$$\left(\left\langle \bigcirc \right\rangle\right)_2 N^{\cdot} + K \longrightarrow \left(\left\langle \bigcirc \right\rangle\right)_2 N^{-}K^+ \quad (3)$$

$$\left(\left\langle \bigcirc \right\rangle\right)_2 N^{-}K^+ + \left\langle \bigcirc \right\rangle - K \longrightarrow$$

$$\left\langle \bigcirc \right\rangle - NK_2 + \left\langle \bigcirc \right\rangle - \left\langle \bigcirc \right\rangle \quad (4)$$

$$\left\langle \bigcirc \right\rangle - \left\langle \bigcirc \right\rangle + K \longrightarrow [C_{12}H_{10}]^{\cdot} K^+ \quad (5)$$
As the electronegativity of nitrogen atom (3.0) is larger than that of carbon atom (2.5), alkali metal was thought to react directly at the nitrogen atom. It was found by thin-layer chromatography (silica gel, developing solvent; mixed solvent of diethyl ether and petroleum ether, $R_f = 0.16$ for aniline and 0.41 for diphenylamine), that a little $C_6H_5NH_2$ was formed by the reaction of $(C_6H_5)_2NK$ with n-butyl lithium, which has smaller pK_a than C_6H_5K (>40). Therefore, aniline was assumed to be produced by the reaction of $(C_6H_5)_2NK$ with C_6H_5K, (reaction 4) and that benzene was formed from reaction (2) and *N*-phenylcarbazole by reaction (1), and that the main reaction products were obtained by the reactions (2)-(5) rather than reaction (1).

Polymerization with potassium adducts of triphenylamine

The results are shown in *Table 1*. *J* values[9] of PMMA were 95~100. The microstructure of the polyisoprene and polybutadiene was calculated from the intensity of i.r. spectrum as follows:

	cis-1,4 (%)	trans-1,4 (%)	1,2 (%)	3,4 (%)
polyisoprene	0	0	24.0	76.0
polybutadiene	30.2	28.5	41.3	—

Further, copolymerizations of S–MMA, S–AN, and AN–MMA carried out under the same conditions gave the results shown in *Table 2*.

The results show that the polymerization took place by an anionic mechanism.

In order to confirm the initiation reaction, an oligomer of MMA was prepared by use of high concentration of potassium adducts of TPA (MMA: 0.048 mol; TPA: 0.041 mol; potassium: 0.053 mol). The i.r. spectrum of the oligomer (which had been purified by reprecipitation from petroleum ether) showed an absorption band at 1600 cm^{-1} due to phenyl group, a molecular weight of 1700, and nitrogen content 0.09 wt %. Similarly, an oligomer of S prepared under the same conditions had a molecular weight of 1800, and nitrogen content zero. From these results, it was assumed that the polymerization of MMA was induced

by $C_6H_5NK_2$, $(C_6H_5)_2NK$, C_6H_5K, and $\left\langle \bigcirc \right\rangle - \left\langle \bigcirc \right\rangle^{\cdot} K^+$

and that of S by C_6H_5K and $\left\langle \bigcirc \right\rangle - \left\langle \bigcirc \right\rangle^{\cdot} K^+$

as previously shown by Morton *et al.*[10].

Polymerization with potassium salts of aniline and diphenylamine

In order to elucidate the polymerization with *N*-metal compounds derived from the reaction of TPA with potassium, the polymerizations of vinyl monomer with aniline mono-potassium salt, aniline di-potassium salt and diphenylamine mono-potassium salt were carried out, and the results shown in *Table 3*, include also the copolymerization of AN and MMA with these salts.

AN and MMA were found to undergo polymerization with these potassium salts but S did not polymerize. The PMMA was found to be syndiotactic. The copolymer was found to contain more AN than MMA. The results show that the alkali salts initiate an anionic polymerization of MMA and AN.

In order to confirm the initiation mechanism, the reaction of MMA (0.0472 mol) with aniline (0.0104 mol) and potassium (0.0225 mol) and of MMA (0.0283 mol) with diphenylamine (0.0075 mol) and potassium (0.0071 mol) in 10 ml of THF were carried out at room temperature. The oligomers formed were found to contain phenyl group and nitrogen by i.r. spectrum and elemental analysis and it was concluded that the fragment of $C_6H_5NK_2$ and $(C_6H_5)_2NK$ was linked at the chain end of PMMA.

Reaction of triphenylphosphine with alkali metal

In order to compare the reactivity of TPA and TPP the polymerization of vinyl monomers with TPP–alkali metal adducts were studied. The reaction of TPP with alkali metal in THF or liquid ammonia has been shown[11-15] to lead to the formation of anion radical products.

A study of the reaction of potassium, sodium and lithium with TPP and TPA in THF at room temperature showed that TPP reacted readily with these alkali metals, whereas TPA reacted only with potassium.

It was considered that the difference of reactivity arises from the smaller energy differences in the 4s–3d orbitals of phosphorus relative to that of the 3s–4d orbitals of nitrogen. The former situation would promote electron delocalization into the $p\pi$ system in TPP⁻ thus stabilizing the molecule.

Polymerization with alkali metal adducts of triphenylphosphine

The results are shown in *Table 4*. The *J* values of PMMA were 92–95, and the PMMA had a syndiotactic structure. The micro-structure of polyisoprene and poly-butadiene obtained was calculated from the intensity of the infra-red spectrum as follows:

	cis-1,4 (%)	trans-1,4 (%)	1,2 (%)	3,4 (%)
Polyisoprene	0	0	35–32	65–68
Polybutadiene	25.4	29.6	45.0	—

The results agreed with those of the classical anionic polymerization in polar solvents.

The results of the copolymerizations of S–AN, MMA–S, and MMA–AN were carried out under the same conditions and are shown in *Table 5*.

In order to confirm the polymerization mechanism, PMMA and polystyrene of low degree of polymerization were prepared by use of high concentration of initiator, viz.: ([monomer] = 1.0 mol/l, [I] = 0.162 mol/l) in THF at room temperature. The oligomer of MMA and that of S formed had molecular weights of 1300 and 1800, respectively. The qualatitative analysis for phosphorus[16] was positive for oligomeric MMA, and was negative for oligomeric S. PMMA had an absorption band at 1600 cm⁻¹ due to phenyl group. Therefore, the oligomer of MMA had a

Cloud point curves for poly(vinyl methyl ether) and monodisperse polystyrene mixtures

T. Nishi* and T. K. Kwei

Bell Laboratories, Murray Hill, New Jersey 07974, USA
(Received 14 May 1974; revised 24 July 1974)

The compatibility behaviour of poly(vinyl methyl ether) (PVME) and monodisperse polystyrene (PS) is studied for solution cast films. The molecular weight of monodisperse PS ranges from 2100 to 2 000 000 whereas the PVME used is polydisperse and has weight-average molecular weight of 51 500. When cast from toluene solution, the mixtures undergo phase separation at elevated temperatures. The cloud point curves move to markedly lower temperatures with increasing molecular weight which is similar to the lower critical solution temperature (LCST) behaviour for polymer solutions. They move to lower temperatures until the molecular weight of PS reaches about 51 500.

The effect of molecular weight distribution on the cloud point of equal amounts of PS and PVME mixtures simulated by mixing two monodisperse polystyrenes of different molecular weight for PS part is accurately predicted by using weight-average molecular weight for PS in this range. However, if the molecular weight of PS exceeds about 110 000 the molecular weight dependence of cloud point temperature is reversed and the prediction for polydisperse polymer by using weight-average molecular weight fails. This phenomenon is discussed from several viewpoints including the possibility of the effect of chain entanglement.

Mixtures of PVME and PS of M_w = 20 400 were also cast from an 'incompatible' solvent, trichloroethylene. Compatibility is found to be dependent on composition and even phase-separated samples show at least one cloud point, indicating at least partial mixing of the two polymers. Finally, it is demonstrated that crosslinking of compatible films can be achieved by electron irradiation to form true interpenetrating networks. The cloud point temperatures are increased drastically after crosslinking.

INTRODUCTION

Only a few pairs of polymers that show mutual compatibility are known[1,2] because of the small entropy of mixing for long polymer chains and the positive energy of mixing usually observed between polymers. However, recent results for the mixtures of polystyrene (PS) and poly(vinyl methyl ether) (PVME)[3,4] show their compatibility for a wide range of composition[3] and temperature, although compatibility is reported to depend on the nature of the solvent used. The compatible films show reversible phase separation at high temperatures[4], and this cloud point temperature is associated with the lower critical solution temperature $(LCST)$[5].

Detailed studies of the nature of compatibility of this system have been conducted including density, vapour sorption, diffusion and pulsed n.m.r. measurements[6]. The two different polymer chains in the compatible system are found to mix extensively, although pulsed n.m.r. measurements suggest that the mixture is not completely free of micro-heterogeneity. Negative interation parameters were obtained for certain compositions, and it was also suggested that both $LCST$ and upper critical solution temperature $(UCST)$ appeared to exist for this system.

According to the thermodynamics of mixtures, the most influential factors which determine $LCST$ or $UCST$ behaviour in a polymer–polymer mixture[5] are the interaction parameter, thermal expansion or thermal pressure coefficient,

and molecular weight and molecular weight distribution. Although the contribution of each parameter was calculated for model monodisperse polymer pairs[5], experimental results were too scarce to permit meaningful comparison. This is to be contrasted with the case of polymer–solvent mixtures where the effect of molecular weight and the nature of the solvent on $UCST$ or $LCST$[7,8] have been studied in detail and compared with theory[9,10].

In order to elucidate cloud point behaviour of polymer–polymer mixtures, the PS and PVME system is thought to be ideal since monodisperse PS with widely different molecular weights is available. In this paper, monodisperse PS with molecular weights ranging from 2100 to 2 00 000 are mixed at various compositions with polydisperse PVME of $\bar{M}_w$ = 51 500 and cast from toluene solution to obtain compatible films. The effects of molecular weight and molecular weight distribution on the cloud point curves are studied. The influence of molecular weight distribution is studied by blending monodisperse PS simultaneously with PVME. We have also examined films cast from trichloroethylene solution since the latter was reported to give always incompatible films[3] for high molecular weight PS and PVME. In our case, a low molecular weight monodisperse PS (M_w = 20 400) was mixed with PVME and examined.

PS and PVME can be crosslinked by radiation[11]. This provides a unique opportunity to prepare a truly interpenetrating network from a compatible mixture. To examine the effect of irradiation on cloud point curves, samples were irradiated by 1 MeV electron beam at doses from 5 to 200 Mrad.

EXPERIMENTAL

Materials

The monodisperse PS polymers were obtained from the Pressure Chemical Co. and *Table 1* lists their nominal molecular weights and the ratios of weight-average molecular weight, $\bar{M}_w$, to number-average molecular weight, $\bar{M}_n$. PVME was obtained from Cellomer Associates, Inc. and the intrinsic viscosity was 0.51 (100 cm³/g) in benzene at 20°C. The $\bar{M}_w$ was computed to be 51 500. Both polymers were used without further purification.

Films containing PS and PVME mixtures were cast from toluene or trichloroethylene solution on glass surfaces. Initial polymer concentration was about 3 g/100 ml. The solvent evaporation process has been described elsewhere[6]. Film thicknesses ranged from 0.01 to 0.03 cm.

Electron irradiation

Five samples of films, cut into about 5 mm square, were placed in a chamber with a thin polyethylene window (about 0.005 cm) and irradiated simultaneously at each dosage. A van de Graaff accelerator was used. The electron energy was 1 MeV and the dose rate was 0.5 Mrad/sec. Irradiation was carried out at room temperature under circulating nitrogen gas.

Cloud point measurements

The film was cut into 2–3 mm square and mounted on a glass microscope slide. To ensure good heat transfer during measurements, thin spacers with 0.01 cm thickness were placed around the specimen and a cover glass was applied to protect the sample. The assembly was carefully pressed above the glass transition temperature of the film to get uniform thickness and air bubble free geometry between the glasses and the film. It was slowly cooled down to room temperature to relax residual stress due to the above operation. The assembly was then placed on a microscope hot

stage (manufactured by Reichert Co., Austria). A thermometer attached to the hot stage served as a temperature indicator. Temperature was increased at about 10°C/min and the sample was monitored through a stereomicroscope (manufactured by Bausch & Lomb Co.). The temperature at which blue coloration was first detected was recorded as the cloud point. The heating rate dependence of the bluish coloration temperature of the film was slight[4] and was less than 3°C from 1°C/min to 10°C/min heating rate probably because of good heat transfer for our thin samples. The temperature was increased further until slightly white opalescence appeared. Subsequently, temperature was gradually lowered. Compatible films became transparent again after this treatment. All the measurements were carried out within one week after sample preparation to avoid any effect which may arise as a result of slow phase separation[6].

RESULTS AND DISCUSSION

Effect of molecular weight

Figures 1 and *2* show the cloud point curves of films cast from toluene. The effect of molecular weight and weight fraction, ϕ, of PS on the cloud point curves are typical of the *LCST* phenomena commonly observed for polymer—solvent mixtures. Owing to thermal degradation of PVME above ~240°C the cloud point curves are shown only for PS with molecular weight above 10 000. These are probably the first experimental data to show the molecular weight dependence of cloud point curves for polymer—polymer mixtures of sufficiently high molecular weight.

When the molecular weight of PS is below 51 500 the cloud point curves depend greatly on the molecular weight of PS and the composition of the mixture especially at very low PS or PVME concentrations. It should be noted, however, that the molecular weight dependence of the cloud point curves levels off or even reverses with PS having molecular weight above 110 000. The significance of this unusual observation will be discussed in a later section.

In the case of polydisperse polymer—solvent systems the
Figure 2 Cloud point curves for PVME and monodisperse PS mixture where molecular weight ($\bar{M}_w$) of PS is 498 000 (o) and 2 000 000 (•). ϕ is the weight fraction of PS and broken line shows the result for PS with $\bar{M}_w$ = 200 000 in *Figure 1*
Figure 3 Composition of the extremum point $\phi_{A(ext.)}$ and reduced variables X_A and X_B, where X_A and X_B mean degree of polymerization of PS and PVME, respectively. ————, equation (1); - - - - -, equation (2)

extremum of cloud point curve and critical point does not coincide with each other[21,22]. The critical point tends towards the right-hand branch of the cloud point curve as the poly-dispersity of the polymer increases. However, it may be worthwhile to discuss the extremum of the cloud point curve and the critical point of this system since it is systematically changing with molecular weight of PS.

Figures 3 and *4* show the composition of the extremum point, $\phi_{A(ext.)}$ and the extremum temperature, $T_{ext.}$, plotted against the parameter $(X_A/X_B)^{1/2}$, where X_A and X_B are the degree of polymerization for PS and PVME, respectively. The weight-average molecular weight is used since it is found to be a proper parameter for cloud point curves for polydisperse polymers as will be shown in the next section.

In *Figure 3*, McMaster's data[5] of extremum composition are shown as the solid circle and the agreement with our data is within experimental error. In his experiment, $\bar{M}_w$ of PS and PVME were 236 600 and 13 320, respectively, and both were polydisperse. According to the theory of polymer solution the critical composition $\phi_{A(crit.)}$, can be estimated for monodisperse polymer mixtures from equation (1)[12] based on the Flory—Huggins approximation[13,14]. The calculated values are indicated as a solid line in *Figure 3*.

$$\phi_{A(crit.)} = \frac{1}{1 + (X_A/X_B)^{1/2}} \tag{1}$$

Our experimental data seem to parallel the trend predicted by equation (1), but this always predicts a higher value of $\phi_{A(crit.)}$. One reason for the discrepancy may be due to poly-dispersity of PVME. For polydisperse polymer mixtures Stockmayer's equation[19] is more appropriate:

$$\phi_{A(crit.)} = \frac{1}{1 + (X_{Aw}/X_{Bw})(X_{Bz}/X_{Az})^{1/2}} \tag{2}$$

where subscripts w and z mean weight- and z-average, respectively.

As a first approximation, we assume $X_{Az} \simeq X_{Aw}$ for PS and $X_{Bz} \simeq 3/2X_{Bw}$ for PVME, using Schulz-Flory's most probable distribution[20]. Then the denominator in equation (2) becomes $1 + 1.225 (X_{Aw}/X_{Bw})^{1/2}$ and the calculated values of $\phi_{A(crit.)}$ are represented by the broken line. Although the agreement between equation (2) and experimental results is still far from perfect, the correction for polydispersity is certainly in the right direction.

In *Figure 4*, the data by McMaster and by Bank *et al.*[4] on extremum temperatures are shown and they differ from our data. Bank *et al.* gave only number-average molecular weight $\bar{M}_n$ for PS and PVME. $\bar{M}_n$ for PS was given as 104 000 or 150 000 and $\bar{M}_n$ for PVME as 524 000. They did not specify which PS was used. Therefore their results have less importance in this report. The rather high extremum temperature found by McMaster may be ascribed to the low molecular weight PVME used in his study.

In order to explain the results in *Figures 1—4*, it may be necessary to take into account not only the molecular weight and molecular weight distribution of each polymer but also the difference between the thermal expansion and the thermal pressure coefficients of the two polymers as suggested by McMaster[5]. According to his model calculation, a difference of several per cent in thermal expansion coefficients or thermal pressure coefficients is enough to change $T_{crit.}$ drastically. Whether McMaster's contention is sufficient to account for our observation cannot be assessed at present because of lack of experimental data.

Another possibility which we like to entertain is the influence of molecular entanglement. For PS, the critical chain length for the formation of entanglement is about 300 to 500 $(M_w \cong 30 000$ to $50 000)^{15-17}$. For PVME, the entanglement chain length is not known but it is probably about 300 $(M_w \cong 17 000)$ or less because the chain is more flexible. The two polymers are supposed to be mixed well in toluene and there should be many molecular entanglements between PS and PVME molecules in concentrated solutions, i.e. as solvent evaporates. After evaporation of the solvent, the entanglement between different chains can be preserved and can act to hinder the phase separation at high temperatures although separation is favoured on thermodynamic grounds. This can explain qualitatively the decrease of molecular weight dependence of cloud point curves where $\bar{M}_w$ of PS exceeds 51 000 or 110 000. Based on this reasoning, we have attempted to introduce permanent entanglement (i.e. crosslinks) into the system by electron irradiation. As will be seen later, crosslinking increases the cloud point temperature quite drastically.

The other possibility to explain the reversal in extremum temperatures of the cloud point curves at higher molecular weight range for PS is the polydispersity of the monodisperse PS in the polymer—polymer mixtures. From *Table 1*,
Figure 4 Temperature of the extremum point $T_{ext.}$ and reduced variables X_A and X_B, where X_A and X_B mean degree of polymerization of PS and PVME, respectively. ○, This work; ●, McMaster; ↔, Bank *et al.*

Figure 5 Molecular weight $\bar{M}_w$ dependence of cloud point temperature for PS/PVME = 50:50 mixtures

the polydispersity of the monodisperse PS increases slightly as the molecular weight of PS exceeds 498 000. However, this will cause the sharpening of the cloud point curves and the extremum temperature would decrease with increase in molecular weight distribution of monodisperse PS if we take into account the model calculation for polydisperse polymer—polymer[5] and polymer—solvent[21] systems by McMaster and Koningsveld *et al.* * Their calculations are contrary to our experimental results. Moreover, the results in *Figure 6* for the effect of molecular weight distribution indicate that it may not be the increased polydispersity of the higher molecular weight monodisperse PS that causes this effect.

The last possibility is the influence of the microhetero-geneous structure in the mixture, as described in our earlier paper[6], which was detected by pulsed n.m.r. as two spin—spin relaxation times. This concept is now under investigation and will be reported in the near future.

Effect of molecular weight distribution

Figure 5 shows molecular weight dependence of PS of the cloud point temperature for PS/PVME = 50:50. The effect of molecular weight distribution is simulated by mixing different amounts of two PS polymers of different molecular weights. The composition was always kept at PS/PVME = 50:50. Blends of PS with $\bar{M}_w$ = 110 000 and 10 000 or with $\bar{M}_w$ = 670 000 and 10 000 were chosen since the trend in cloud temperature changes when $\bar{M}_w$ of PS is above 110 000.

* Koningsveld *et al.* calculated the effect of polydispersity for polymer—solvent system with *UCST* and they showed that extremum temperature would increase with the polydispersity of the polymer. On the other hand, our system has lower critical solution temperature behaviour and the extremum temperature would decrease with the polydispersity of the polymer.

Figure 6 shows the results for PS blends with $\bar{M}_w$ = 110 000 and 10 000. As the concentration of PS with $\bar{M}_w$ = 10 000 increases, the cloud point increases as expected from *Figure 5*. Also in *Figure 6*, cloud point temperatures predicted from $\bar{M}_n$, $\bar{M}_w$, and $\bar{M}_z$ for the PS blends are indicated by using equations (3) to (5) and *Figure 5*:

$$\bar{M}_n = \frac{M_1 M_2}{\phi M_2 + (1 - \phi)M_1} \quad (3)$$

$$\bar{M}_w = \phi M_1 + (1 - \phi)M_2 \quad (4)$$

$$\bar{M}_z = \frac{\phi M_1^2 + (1 - \phi)M_2^2}{\phi M_1 + (1 - \phi)M_2} \quad (5)$$

where M_1 and M_2 are the molecular weights for each monodisperse PS respectively and ϕ is the weight fraction of PS with M_1. It is apparent that $\bar{M}_w$ is a good measure for predicting the cloud point curves of polydisperse polymers. It is also consistent with theoretical prediction[5].

Figure 7 shows similar results for mixed PS with $\bar{M}_w$ = 670 000 and 10 000. In this case, however, minima in cloud temperatures appear at ϕ = 0.025, 0.64 and 0.992 for curves predicted from $\bar{M}_n$, $\bar{M}_w$ and $\bar{M}_z$, respectively, because of the minimum cloud point temperature around $\bar{M}_w$ = 250 000 in *Figure 5*. The agreement between the data and those calculated from $\bar{M}_z$ below ϕ = 0.7 is fortuitous. The reason for the discrepancy is not clear, and it might be due to the effect of molecular entanglement or other causes discussed in the previous section.

Effect of solvent

Figure 8 shows the cloud point curve for PS—PVME mixtures cast from trichloroethylene solution. The molecular
Figure 6 Cloud point temperatures for PS/PVME = 50:50 mixture where PS is a mixture of two monodisperse PS (1) and PS (2). The weight fraction of PS (1) is ϕ and the molecular weights of PS (1) and PS (2) are 10 000 and 110 000, respectively. $\bar{M}_n$, $\bar{M}_w$ and $\bar{M}_z$ curves are predicted based on equations (3)—(4) and *Figure 5* for the PS (1) and PS (2) mixture
Figure 7 Cloud point temperatures for PS/PVME = 50:50 mixture where PS is a mixture of two monodisperse PS (1) and PS (2). The weight fraction of PS (1) is ϕ and the molecular weights of PS (1) and PS (2) are 10 000 and 670 000, respectively. $\bar{M}_n$, $\bar{M}_w$ and $\bar{M}_z$ curves are predicted based on equations (3)—(5)

weight of the monodisperse PS was 20 400. Homogeneous, clear films were obtained at room temperature when the PS weight fraction ϕ was lower than 0.25. Films were almost clear yet had slight heterogeneity when ϕ was between 0.25 and 0.30 or when ϕ was higher than 0.97. For PS fractions between 0.40 and 0.93 films were usually heterogeneous.

Upon heating, the clear films gave the same cloud point temperature as that cast from toluene solution. The solid line in *Figure 8* represents the cloud point curve for films cast from toluene solution. For the heterogeneous films two cloud points appeared to exist. If we describe heterogeneities in these films as islands in the sea, then either the sea or the islands became cloudy first and then the rest of the film also turned cloudy at a higher temperature. For films with ϕ between 0.4 and 0.7 the sea part became cloudy first and between 0.8 and 0.93 the island part first. The first cloud point temperature was almost constant ($\sim 157°$C) regardless of the composition of the film. It was difficult to detect accurately the second cloud point temperature except for the film with $\phi = 0.97$ since at higher temperature the sea or the island part which showed first cloud point became too whitish. Upon cooling, all films returned to their original appearances if the temperature was not brought up much higher than the first cloud point temperature.

It is clear from *Figure 8* that the heterogeneous films are not completely phase separated into pure PS and PVME domains. Rather, PVME rich and PS rich phases result upon evaporation of trichloroethylene. In order to explain our observation it seems logical to assume the existence of upper critical solution temperature (*UCST*) for this system. If the *UCST* curve crosses room temperature at $\phi \simeq 0.30$ and $\simeq 0.97$, samples with ϕ between 0.30 and 0.97 should always separate into PVME rich phase ($\phi \simeq 0.30$) and PS rich phase ($\phi \simeq 0.97$). Upon heating, the PVME rich phase which happens to have lower cloud point temperature

would show an almost constant first cloud point temperature.

The experiments reported by Bank *et al.*[3] used PS and PVME of much higher molecular weight than ours and the crossing points between the *UCST* curve and room temperature must have occurred at very low and very high ϕ. Therefore, they obtained all incompatible films and they concluded, quite properly, that phase separation resulted in almost pure PS and PVME as evidenced by their T_g results.

In the next series of experiments, the solvent trichloroethylene was rapidly evaporated and the resulting films $(0.97 > \phi > 0.30)$ became heterogeneous on a very fine scale and looked white. They were found to turn transparent again after annealing at 60–90°C for a period of 10 to 100 min and they showed the same cloud point temperatures as the films cast from toluene solution when heated above 150°C. Apparently, there seems to be a critical size of heterogeneity below which annealing can bring the system to the thermodynamically favoured state. However, it was very difficult to obtain *UCST* curves accurately.

It is known that a small difference in polymer–solvent interaction has a marked effect on polymer incompatibility in the polymer–polymer–solvent ternary system[18]. Therefore, the observed effect of solvent on the properties of solid films can be regarded as an extrapolation of the effect of asymmetry in the polymer–solvent interactions in the ternary system.

Effect of electron irradiation

Figure 9 shows effect of electron irradiation on a cloud point temperatures for PS/PVME = 50:50 mixture where the molecular weight of monodisperse PS has been changed from 51 000 to 2 000 000. The cloud point temperature increases drastically at around 50 to 100 Mrad. In this range it was noticed that the temperature gap between the onset of blue coloration and white opalescence also increased greatly. For samples which show cloud point temperatures higher than 195°C in *Figure 9*, the whitish coloration is limited only to the periphery of the film. The phase separation behaviour observed in this limited area was probably accompanied by oxidative degradation and it was not reversible after cooling.

Both PS and PVME are classified as radiation crosslink-
Figure 8 Cloud point curve for PVME and monodisperse PS with molecular weight 20 400 cast from trichloroethylene solution (o). ϕ is the weight fraction of PS and solid line represents the cloud point curve for the same composition cast from toluene solution
Figure 9 Electron irradiation dose D dependence of cloud point temperature for PS/PVME = 50:50 where the molecular weight of PS has been changed: o, 51 000; •, 110,000; □, 498 000; ■, 2 000 000

able polymers[11] and the irradiated mixtures swell but do not dissolve in toluene. The doses for incipient gel formation are dependent on the molecular weights of monodisperse PS in the mixture and they are about 10, 20, 50 and 100 Mrad for the mixtures with PS molecular weight 2 000 000, 498 000, 110 000 and 51 000, respectively. It is most probable that the crosslinking between PS and PVME has taken place to form an interpenetrating network and the cloud point temperature increases as a result of the restricted mobility of the chains.

CONCLUSIONS

Many aspects of polymer–polymer compatibility behaviour are clarified experimentally by using polydisperse PVME and monodisperse PS samples with molecular weight varying from 1×10^4 to 2×10^6.

The molecular weight dependence of cloud point curves for polymer–polymer mixtures is obtained for the first time for polymer pairs having sufficiently high molecular weight. For PS–PVME mixtures cast from toluene, *LCST* behaviour is observed and the cloud points decrease rapidly with increase in PS molecular weight until about 51 000. However, the molecular weight dependence of cloud point curves levels off or even reverses for mixtures with PS having molecular weight higher than about 110 000. Several possibilities for the phenomena are suggested based on thermodynamic effect, effect of molecular entanglement and effect of microheterogeneous structure in the mixture.

The effect of molecular weight distribution on cloud point curves is simulated by mixing PVME with a blend of two PS fractions of different molecular weight. When the

molecular weight of both PS are lower than 110 000, the cloud point temperature is accurately predicted by using weight average molecular weight. However, if the molecular weight of either PS is higher than 110 000, the above prediction is found to be ineffective and again the possibility of the effect of molecular entanglement is suggested.

The effect of the nature of solvent is studied using trichloroethylene. The compatibility behaviour is dependent on the composition of the mixture and even in heterogeneous films phase separation is incomplete. This is explained adequately by the existence of *UCST* near room temperature. These solvent effects can be rationalized as the consequence of the effect of asymmetry in the polymer–solvent interactions in the ternary system.

Finally, it is demonstrated that the electron irradiation can crosslink compatible films to form an interpenetrating network and drastically increase the cloud point temperature.

Effects of molecular weight and chain ends on glass transition of polystyrene

Alfred Rudin and Dennis Burgin
Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada
(Received 28 May 1974; revised 2 August 1974)

The main glass transition temperatures, T_g of narrow distribution anionic polystyrene samples have been measured by differential thermal analysis (d.t.a.). The d.t.a. data were verified by differential scanning calorimetry. Effects of heating rates were eliminated by extrapolating observed T_g values to a standard heating mode of 1°C/min In a T_g vs. log (heating rate) relation. The variations of T_g peak height and temperature with heating rate and polymer molecular weight (M) agree with conclusions from other reports of d.t.a. work. The T_g values corrected for heating rate effects agree well with figures reported in studies with d.t.a. and other techniques for locating vitrification temperatures.

The volumes attributable to end groups differ significantly between anionic and thermally initiated polystyrenes at temperatures above T_g. A comparison of T_g values of both polystyrene types provides a direct test of the iso-free volume model of the vitrification process. A common T_g vs. M relation was found for anionic and thermally initiated polystyrenes, regardless of chain end nature. This comparison is not consistent with the concept that vitrification is governed by free volume defined as the difference between specific volume of the polymer and a reference volume. Our results are compatible with several other mechanisms which have been suggested for the glass transition.

INTRODUCTION

The glass transition of a polymer sample is observed when the short time limit of viscous response at the particular temperature and pressure is comparable to the time scale of the experiment. The fundamental mechanistic problem involves the means whereby temperature, pressure and molecular weight changes influence the polymer relaxation time. A large number of explanations have been offered[1-3]. This paper focuses on the assumption that the glass transition is an iso-free volume state. Our concern here is not primarily with questions as to whether the glass transition can be related to thermodynamic state variables[4], existence of multiple transitions[2], or even with the choice of a particular reference specific volume in the definition of free volume[5].

Fox and Flory[6] first proposed that the glass transition represents an iso-free volume state. This conclusion has been variously supported and challenged, depending on the particular experimental results[1-5]. Some of the difficulties in this connection are evidently related to experimental inaccuracies and to uncertainties in the meanings of viscosity and free volume at the glass transition.

Particular evidence may tend to favour one view[5] or the other[7], but clear-cut answers evidently require further information. Much of the available evidence can be interpreted in terms of alternate models and a case may even be made[1] that there is no inherent controversy between the various views.

The present report contributes some additional evidence regarding the nature of the transition phenomenon. It is a direct test of current iso-free volume concepts and concerns results on polystyrenes, which formed the initial basis of this model. The influence of molecular weight on the glass transition, T_g, of this polymer is examined in experiments which parallel the important pioneering work of Fox and Flory[6,8].

Free volume derives from three principal sources: motion of chain ends, motion of side chains and motion of the main chain[5]. This study examines the glass transitions of polystyrenes which differ only in the specific volumes assignable to chain ends. The conclusions are independent of the particular model used to estimate free volume from chain end volumes if it is accepted that differences in the latter volumes must lead to free volume variations.

Fox and Flory[6,8] studied the effects of molecular weight on T_g and specific volumes of thermally initiated polystyrenes. A recent study from this laboratory[9] has shown that volumes attributable to end groups differ significantly between anionic and thermally initiated polymers. Specific volumes of end groups in anionic polystyrene liquids are larger and increase more rapidly with temperature in the temperature range (170–237°C) studied. Data of Bender and Gaines[10] which were developed in a different context and extend to lower temperatures, are also consistent with this conclusion. One would expect from the iso-free volume model that T_g values of anionic and thermally initiated polystyrenes would coincide at reasonably high molecular weights and differ significantly at low molecular weights where chain end concentrations are relatively more important. This assumption is tested in this report and it is shown that the two polymer types do not differ significantly in T_g at given molecular weight.

Glass transition temperatures were measured in this work by differential thermal analysis (d.t.a.). Application of this technique for T_g measurements of polymers was first reported by Keavney and Eberlin[11]. Its use in the study of molecular weight effects on polystyrene T_g has been reported once, for whole polymers[12]. A method is described in this report for eliminating d.t.a. instrument effects on T_g and the validity of the present data is established by comparison with results of other workers.

The d.t.a. data obtained here were verified by differential

scanning calorimetry (d.s.c.) measurements. A relation between molecular weight of narrow distribution polymers and T_g is presented here which seems to be universally applicable and which permits estimation of T_g of infinitely high molecular weight samples (T_g^∞) from data on lower molecular weight polymers.

EXPERIMENTAL

Materials

The anionic polystyrenes studied are commercial samples available from Pressure Chemical Co. Molecular weights of these materials are listed in *Table 1*. These values were determined as reported elsewhere[9]. A Dow anionic sample $(S102)$[13] was also included in this study. The influence of uncertainties in molecular weight (M) values on conclusions which can be reached in studies such as this has been noted before[9].

All the usual molecular weight averages coincide within experimental error for samples with molecular weight distributions as narrow as those used in this work. It is not necessary, then, to distinguish between $\bar{M}_w$, $\bar{M}_n$ and so on, although $\bar{M}_n$ is clearly the average which determines specific volume and presumably free volume[6,8,9,14].

Methods

A Du Pont model 900 differential thermal analyser was used. Nitrogen atmosphere was provided by flushing the gas through the sample holder at a controlled rate. Thermocouple contacts were surrounded with glass wool for shielding from drafts caused by the nitrogen flow. Dynamic gas flow has been reported to increase peak heights, without changing peak temperatures[15].

Before each experiment the chromel–alumel sample thermocouple tip was cleaned by burning off contamination in a gas flame. Care was taken to prevent heating of the thermocouple past a dull red colour. Thermocouples and samples tubes were handled with rubber gloves to prevent transfer of moisture from the operator's fingers.

Glass beads were used as the reference substance. The sample cell contained undiluted polymer. The polymer samples were obtained as powders and were used as received. In all cases 3 mm of sample (or reference) was packed as uniformly and reproducibly as possible into 2 mm diameter glass 'micro' tubes supplied with the d.t.a. apparatus. The thermocouples were centred in the tubes and positioned to touch the bottoms of the glass cells.

T_g of polystyrenes was obtained by Martin and Kase[12] from d.t.a. thermograms as the temperature corresponding to intersection of extrapolated base line and peak curves. This procedure, which relates T_g to the temperature of onset of the endotherm in the heating mode, was not applicable in the present experiments because non-linear base lines made extrapolation uncertain. Instead, T_g was defined as the intersection temperature from extrapolation of the longest straight line portions of the peak sides. This is the

* Pressure Chemical Co.

method used to locate phase transitions by Vassallo and Harden[16] and others. Martin and Kase[12] reported T_g = 100°C for an anionic polystyrene with $\bar{M}_w$ 187 000. Our data, given below, indicate a T_g of about 101°C for a narrow molecular weight distribution polymer with the given molecular weight. The agreement between the two studies is thus good, considering the differences in interpretation of the differential thermograms.

It has been reported that annealing was necessary to obtain good thermograms of commercial polystyrenes. This was attributed to the presence of stresses frozen into the polymer during extrusion and subsequent granule cutting[12]. A differential scanning calorimeter study of a commercial polystyrene has also indicated that prolonged annealing at 200°C was required to erase the influence of thermal history on the specific heat of the polymer[17]. The effects on T_g were minimal, however, in the latter report.

In this study annealing was found to be unnecessary and, in fact, undesirable. Duplicate specimens which were not annealed showed excellent reproducibility at fixed experimental conditions. Samples which were annealed by heating to 130°C in an initial experiment and were tested again after cooling had much smaller or no endothermic peaks. When a peak was obtained in second or subsequent heating experiments its location was found to coincide with the endothermic peak in the first experiment, to within the normal experimental error.

The present results appear to be consistent with both cited reports. Our anionic polystyrene samples have very different shear and thermal histories from the commercial polymers studied by Martin and Kase[12]. The anionic polymers have presumably never been heated into the melt temperature range and are free of extrusion and freezing stresses. Thus, annealing does not shift the observed T_g. Inadvertent annealing during the experimental heating cycle does apparently change the relative heat capacities of the material above and below T_g sufficiently to diminish the observed endotherm in the glass transition range. This is qualitatively consistent with the report of Currie and Dole[17]. The apparent elimination of T_g effects with some of our samples is an artifact of the particular sample, the time—temperature conditions during the heating cycle and the sample size and instrument sensitivity.

The effect of sample size on T_g was not investigated. The largest sample size consistent with the use of 'micro' sample tubes in the Du Pont d.t.a. apparatus was used to maximize the endothermic peak observed during heating. This corresponded to a sample depth of 3 mm in the particular cell.

No exothermic peak could be detected during cooling of the polystyrene samples. Two factors seem to be responsible for this observation. In the first place, annealing of the specimens during the heating mode would reduce the magnitude of the cooling mode T_g exotherm for reasons mentioned above. Secondly, the apparatus used limited cooling rates to a maximum of about 20°C/min. These relatively low cooling rates produce smaller d.t.a. peaks. Linear cooling rates were not attainable over the whole temperature range in any event. T_g is most easily detected by this method with lower molecular weight polystyrenes. In these cases the glass temperatures are at lower absolute temperatures where the non-linear cooling rates which could be achieved were even slower. Thus the sizes of the most easily detectable peaks were depressed the most. All T_g values reported here were measured during heating experiments.

The absolute value of the d.t.a. temperature scale was confirmed by measuring melting points of *trans*-azobenzene,

benzil and acetanilide. The respective temperatures cited in the literature are 68.5°, 95.0° and 114.3°C. This range coincides with the limits of the polystyrene T_g values reported here. The melting points were identified as the intersection of the peak sides, in accord with the procedure used to locate polystyrene glass transition temperatures. The measured melting points coincided with the values cited to within 0.5°C at heating rates ⩽ about 10°C. We conclude that the T_g temperatures reported for anionic polystyrenes are free of systematic error.

RESULTS

Peak magnitudes

Subject to certain simplifying assumptions, the temperature difference, ΔT, between a sample of fixed dimensions and the reference in the d.t.a. experiment is expected to be proportional to the heating rate and inversely related to the thermal diffusivity of the sample material[18]. Since thermal diffusivity will be related directly to polymer viscosity and hence inversely to molecular weight, ΔT may be predicted to be less for high than for low molecular weight polymers.

This is indeed the observed effect. *Figure 1* records ΔT (°C) figures for 34.7°C/min heating rate abstracted from the complete set of results in *Table 1*. The shape of the experimental curve is as expected. A sample with molecular weight 1.8×10^6 produced no detectable T_g (i.e. $\Delta T = 0$) under the particular experimental conditions with a heating rate of 34.7°C/min. This datum point, which is consistent with the others, is not shown in *Figure 1*.

The expected increase of ΔT of a given sample at higher heating rates was observed. The data, which are somewhat scattered, are recorded in *Table 1*. A linear relation, however, was not found between ΔT and heating rate. Some of the variations in replicate values of ΔT may be attributed to differences in sample packing and thermocouple placements.

Heating rate effects

As expected, the T_g values measured during the heating mode increased at faster heating rates. *Figure 2* summarizes the experimental data. The data are linear in a temperature/log (heating rate) representation. This relation is as reported by Wunderlich and Bodily[19] for d.t.a. of an annealed polystyrene with $\bar{M}_w$ ~350 000. Our data points for anionic poly-
Figure 1 Endotherm peak height (ΔT) as a function of sample molecular weight at heating rate of 34.7°C/min

styrenes with molecular weights ⩾200 000 fit the heating rate relation given in this reference.

Plots such as those in *Figure 2* allow extrapolation of measured T_g values to standard conditions of 1°C/min heating rates [log (heating rate) = 0]. The estimated T_g at this heating rate is presumably a 'true' value independent of experimental artifacts. Comparison with results of other measurements below indicates that this expectation is realized.

Experimentally, T_g could not be detected at a heating rate of 1.8°C/min even with the molecular weight 2100 polystyrene which yielded the largest endotherms. Thus the only way to determine a true T_g was by extrapolation from faster, experimentally accessible heating rate results. Fortunately, the change in T_g with a given change in heating rate is essentially the same for all the polystyrenes. The extrapolated 1°C/min T_g was 11.6°C less than the T_g measured at 34.7°C/min heating rate with the 2100 molecular weight sample, for example, and the corresponding difference was 11.9°C with the 51 000 molecular weight polystyrene. It was thus assumed that the correction factor depended only on the heating rate and not at all on the polymer molecular weight. The heating rate T_g correction factor curve is shown in *Figure 3*.

Table 1 lists the observed and corrected T_g values. All corrected (to 1°C/min heating rate) T_g figures agreed to within 1.4°C except for the 4000 molecular weight sample. Higher T_g temperatures were observed in replicate experiments which produced larger, sharp peaks than when broader endotherms with lower ΔT values were obtained. This may reflect packing variations in the sample cell. The higher T_g values were used below for 4000 molecular weight polystyrene. These results coincide with d.s.c. figures mentioned below. The corrected T_g value for infinite molecular weight obtained in this study was 101°C. This agrees with the figure reported from other measurement techniques[6,8,14] and is further evidence for the reliability of the present results. Our data on low molecular weight samples seem to be in reasonable agreement with the d.s.c. values given by Bender and Gaines[10] for three Pressure Chemical Co. polystyrenes.

Differential scanning calorimetry

The anionic polystyrene samples mentioned above were also examined with a Perkin Elmer DSC-1B differential scanning calorimeter (d.s.c.). This instrument is superior to d.t.a. for measurement of heat energy interchanges at transitions but was less satisfactory for the primary aim of this research, which was the location of transition temperatures. Some details of the d.s.c. results are nevertheless recorded here as they will be of value to other workers in this area.

A series of standard crystalline materials was examined to calibrate the temperature scale on the d.s.c. instrument. The absolute errors in measured melting temperatures were found to vary with the temperature level, and the effect of heating rate was not strictly linear in a melting point vs. log (heating rate) plot. These effects are shown in *Figure 4*.

All d.s.c. measurements were made in the heating mode to correspond to the d.t.a. procedure. D.s.c. transitions were located at the intersection of the base line and extrapolated peak side. The discrepancy between this temperature and the peak temperature varied with the breadth of the transition, and hence with polystyrene molecular weight.

An average heating rate correction for all polystyrene samples was obtained by a procedure similar to that described above in d.t.a. studies. Apparent polystyrene T_g values were obtained at a standard heating rate of 1°C/min by reference to a heating rate correction vs. log (heating rate) curve similar to the d.t.a. plot in *Figure 3*. A plot of temperature correction *versus* apparent temperature was made from the data shown in *Figure 4* and used to adjust the absolute values of the 1°C/min heating·rate T_g figures.

Table 2 lists the d.s.c. results and corresponding d.t.a. figures. The d.t.a. T_g values are slightly higher, in general, since these are taken from peak side intersections while the d.s.c. temperatures are those at which the peak side intersected the base line. D.s.c. T_g temperatures taken at the peak maxima averaged 3–4°C higher than the figures recorded in *Table 2*.

The coincidence shown in *Table 2* is good, and we conclude that the d.s.c. and d.t.a. measurements are in essential agreement. The d.t.a. figures are taken as reference values since the non-uniform absolute temperature corrections noted above in connection with the d.s.c. values make the latter somewhat more uncertain.

* M from intrinsic viscosity data of Fox and Flory[8] and Mark–Houwink equation of Altares and coworkers[22] for low molecular weight polystyrenes

Effect of molecular weight on T_g

The influence of molecular weight on T_g has been studied by several groups and an inverse[6,8,14,20] relation to molecular weight of fractionated samples has been clearly established.

Our data are summarized in the appropriate form in *Table 3*. A plot of T_g against $1/M$ is not strictly linear. This is shown in *Figure 5*, which also includes data points from the work of Fox and Flory.

Comparison of the present data with those of Fox and
Figure 5 T_g as a function of $1/M$ for polystyrene. •, Present data; x, Fox and Flory[8] as given in *Table 3*

Flory is instructive, since the former are measured with anionic polystyrenes and the latter with fractions of thermally initiated polymers. Fox and Flory determined polystyrene molecular weights from dilute solutions viscosities using a relation given by Pepper[21]. However, the Mark–Houwink constants reported more recently by Altares and coworkers[22] for low molecular weight polystyrenes account for the data of Pepper as well as those of other workers. These latter constants were used for molecular weights of the Pressure Chemical Co. anionic polystyrenes. A consistent comparison of our data with those of Fox and Flory requires use of the same Mark–Houwink relations and this is fortunately possible because the constants appropriate for low molecular weight species do not depend on solvent or end groups[22]. We have therefore recalculated the molecular weights given by Fox and Flory[8] using the Mark–Houwink values reported by Altares and coworkers[22] for molecular weights up to 10 000. These molecular weights and the corresponding T_g values are given in *Table 2*.

A plot of the recalculated data of Fox and Flory coincides within experimental uncertainty with the present data, as shown in *Figure 5*. It is clear that the same T_g/M dependence applies to both the anionic and thermally initiated polymers.

The data of Ubberreiter and Kanig[14], which are also for thermally initiated polystyrene fractions, differ systematically from those shown in *Figure 5* in that T_g at low molecular weights tend to be lower than the values reported here and by Fox and Flory. This discrepancy has been noted by others[2] but its cause is not clear.

The slight inflection in the T_g vs. M^{-1} plot at degrees of polymerization between 100 and 200 is not confined to the present data. The results of Beevers and White[20] for poly-(methyl methacrylate) samples and the polystyrene data of Fox and Flory also reveal a similar tendency. The effects noted are minor but they seem to be general[23].

The observed inverse relation between T_g and M and the occurrence of a limiting value, T_g^∞, of T_g at sufficiently high M suggest the following general relation:

$$T_g x = T_g^\infty (x - \text{constant}) \tag{1a}$$

where x is the degree of polymerization of the particular vinyl polymer. The form of this equation is similar to those derived from different premises by Fox and Flory[6] and Somcynsky and Patterson[24] and others. The constant in equation (1a) is a small number which depends on the particular polymer type. We have found it useful for some applications to assume the form given in equation (1b):

$$T_g x = T_g^\infty (x - 1) \tag{1b}$$

Although this relation is not strictly correct, a plot of $T_g x$ against $(x - 1)$ is always rectilinear through the origin because deviations of the constant from unity are negligible compared to the experimental uncertainties and the range of x. This linear representation facilitates comparison of T_g data from different sources, as shown below. The slope of the relation equals T_g^∞ whether or not a zero intercept is theoretically acceptable. This technique provides a reliable method for estimating T_g^∞ values without measurements of the behaviour of very high molecular weight polymers, which respond sluggishly to changes in experimental conditions.

Polystyrene data are plotted in *Figure 6*, according to equation (1b). The slope yields a value of $100°C$ for T_g^∞. Data of Fox and Flory[8] and of Ubberreiter and Kanig[14] are included in this plot along with the results of this study. Since the ordinate is rather compressed in *Figure 6*, low molecular weight data from the three sources are replotted with an expanded ordinate in *Figure 7*. The degree of polymerization in the latter plot is such that $2 \leqslant x \leqslant 44$. The slope in *Figure 7* is lower than the corresponding value in *Figure 6*, which was equal to T_g^∞. This difference in slopes reflects the non-linearity noted in *Figure 5*.

Figure 7 Plot of equation (1b) for low molecular weight polystyrenes. ○, Present data; x, Fox and Flory[8] as given in *Table 2;* •, Ubberreiter and Kanig[14]

Anionic and thermally initiated polystyrenes fall on the same lines in *Figures* 6 and 7, showing that the two polystyrene types have the same dependence of T_g on molecular weight at all molecular weights which have been studied.

The 82 000 molecular weight polystyrene listed in *Table 1* is the Dow S-102 sample. This polymer has slightly lower T_g than the value expected from the Pressure Chemical Co. samples. Its molecular weight determination is, however, stated to be uncertain[25] from consideration of Newtonian viscosity data. This may be the reason for the minor difference in T_g behaviour noted here with this material.

DISCUSSION

The comparisons with other reports given above establish the validity of the present d.t.a. method for locating T_g. Also, the fact that the T_g/M relation found here for anionic polystyrenes agrees at all M values with figures developed by others for thermally initiated fractions is indirect but nevertheless very strong evidence that the present T_g values are comparable to those obtained by other experimental methods.

This appears to be the first direct study of effect of M on T_g with polymer fractions which differed only in endgroups. The specific volumes attributable to end groups in anionic and thermally initiated polystyrene melts differ significantly[9,10] and it seems unlikely that these discrepancies would disappear under glass transition conditions. Since free volume is defined operationally as the difference between specific volume and a reference volume the two species may reasonably be expected to differ in free volume regardless of the definition of the reference state.

As shown in *Figures 5–7*, the various polystyrene fractions with different end group volumes have the same T_g at equivalent molecular weight. It seems clear, then, that free volume and main glass transition are not cause and effect. This conclusion does not preclude the possibility that the glass transition and an operationally defined estimate of free volume may vary in parallel with changing experimental conditions or polymer structure.

The present results are not consistent with the idea that free volume is a constant at the glass transition. Our comparison of polystyrene fractions with different end group volumes is compatible with a number of other explanations which have been offered for the main glass transition. A recent article by Morley[26], for example, concludes that the nature of end groups should have no strong influence on T_g.

Our data are also consistent with the concept[3,7] of T_g as an isoviscosity state characteristic of segmental rather than molecular movement. This idea is pursued briefly below because it leads to certain interesting conclusions regarding the influence of free volume on melt viscosity.

The iso-segmental viscosity mechanism is compatible with the observation noted above that the T_g vs. M^{-1} relation deviates from linearity at molecular weights at which studies of Newtonian viscosity indicate that segmental flow becomes more important than molecular translation of polymer molecules[25].

In the low molecular weight region the Newtonian viscosities of polystyrene melts are directly proportional to molecular weights of fractions, indicating that molecular rather than segmental flow mechanisms dominate. It might be expected in this region that T_g of anionic and thermally initiated polymers would still differ even if the determining

role in the vitrification process is not the achievement of a constant free volume. This assumes that free volume is related to molecular mobility at given M and T. At sufficiently low molecular weights (which are in the range of the samples examined in this and the cited work[6,8,14] of others) the different end group volumes in the two polystyrene types would be expected to result in different free volumes and hence in different Newtonian viscosities and vitrification temperatures. With these particular oligometric samples in which segmental flow is absent, this model predicts that T_g and end group volume should be related if only indirectly through the influence of free volume on molecular mobility.

In fact, there is no detectable difference in T_g of low molecular weight polystyrenes, as is shown most clearly in *Figure 7*. If the glass transition is an iso-viscosity state then this observation brings into question the role of free volume in viscosity and suggests that Newtonian viscosities of anionic and thermally initiated polystyrenes will not differ at given M and T despite the differences in end group volumes. The two different polymer types have indeed been reported to give equivalent viscosities under these conditions[27], in agreement with the results of the present T_g experiments.

The design of large hot melt extruders*

R. T. Fenner
Department of Mechanical Engineering, Imperial College of Science and Technology,
London SW7 2BX, UK
(Received 14 August 1974)

A method is proposed for the rational design of large single screw extruders for processing hot molten thermoplastics, which is based on a theoretical analysis of polymer flow. A typical design study for an homogenizer for low density polyethylene is examined in detail, with particular attention being paid to the effects of screw diameter, length and channel depths on melt temperatures, degree of mixing, residence time, machine cost and power consumption. Owing to the physical properties of polymer melts, heat transfer by conduction is very inefficient. Barrel cooling serves to draw power from the motor rather than heat from the polymer, and in order to achieve a given level of mixing there is a largely unavoidable increase in melt temperature.

INTRODUCTION

Large single screw extruders for processing thermoplastic polymeric materials are particularly difficult to design and operate because of heat transfer limitations. The amount of heat that can be conducted into or out of the bulk of the flowing polymer is very limited. In the present context 'large' extruders are those with diameters of 200 mm or more. The main application for such machines is in homogenization during polymer manufacture. Although attention is confined here to the design of extruders for homogenizing molten low density polyethylene (LDPE), the method is applicable to other materials. Many of the topics discussed are also relevant to the design of both smaller and plasticating extruders.

The main function of a LDPE homogenizer is to thoroughly mix the melt produced by the polymerization process, prior to granulation. During hot mixing, the melt undergoes shear and thermal degradation which result in a breakdown not only of agglomerates, but also of individual molecules with molecular weights higher than the average, resulting in a change in material properties[1]. The current trend in a number of European countries is to use a single extruder to homogenize up to 10 000 kg/h or more of melt. The diameter of such an extruder would be at least 400 mm, and in some cases machines with length-to-diameter ratios of as much as 40 are in use.

ANALYSIS OF PERFORMANCE

The approach described here for designing large hot melt extruders is based on a mathematical analysis of the melt flow. The complexity of this analysis makes it unsuitable for presentation in the form of algebraic design formulae. Numerical solutions to specific problems may be obtained, however, with the aid of a digital computer. The purpose of the present paper is not to dwell on the mathematical details of the analysis but to concentrate on its application to design problems.

Mathematical model

The details of the mathematical model, which was first proposed and solved by Yates[2], are outlined in the Appendix. This model is sufficiently simple to be used in routine design studies, while retaining all the important features of the melt flow, particularly the developing thermal effects. It has been used successfully to aid in the design of large extruders.

Performance parameters

The flow analysis should ideally provide estimates of the following extruder performance parameters. (1) Output. (2) Mean melt temperature (see equation (A11) in the Appendix). The most useful single temperature parameter is the mean delivery temperature, $\bar{T}_{out}$. (3) Delivery pressure. As indicated later, delivery pressure is closely linked with filled length, the effect of which is examined below. (4) Mechanical power consumption. The power required to drive the screw may be calculated as the rate of working at the interface between the melt and barrel[3]. (5) Heat transfer at the barrel surface. The amount of barrel heating or cooling required to maintain a particular barrel temperature can be estimated from the computed temperature profiles. (6) Mean degree of (distributive) mixing. The degree of mixing imparted by an extruder is one of its most important performance parameters. Mixing is of two main types, namely dispersive and distributive. The former is obtained by applying high stresses to the material to break up inhomogeneous lumps, whereas the latter is obtained by applying large deformations which spread such lumps into thin layers over large areas. In a polymer extruder, distributive mixing is the more important, and the overall degree of mixing imparted may be thought of as: M = (mean shear rate) × (mean residence time). Thus M is the mean shear strain applied to the material. The formal definition of the mixing parameter is given by equation (A12) in the Appendix. (7) Mean shear rate (see equation (A13) in the Appendix). It appears that mixing is best carried out at a reasonable shear rate, generally of the order of 100 s^{-1}. At this level there may be a significant amount of dispersive mixing, but the rate is not so high as

to lead to excessive degradation. (8) Residence time is also important for a readily degradable material.

The mean degree of mixing is just one aspect of extrudate quality. The variation of the degree of mixing about this mean is also significant, as is the variation of thermal history of different particles of material passing through the extruder.

Mixing aids

The screws of some large hot melt extruders are fitted with mixing aids such as dams or rows of cylindrical pins. The main functions of these appear to be to provide some dispersive mixing and to disturb the established flow patterns in the melt. Extrudate quality is thus improved by narrowing the distributions of shear and thermal history

Typical example

Suppose it is required to homogenize a 0.2 *MFI* LDPE supplied at a rate of 5000 kg/h and a uniform temperature of 250°C. In a typical LDPE plant the material range is generally 0.1 to 30 *MFI*, although extruder performance for a 0.2 *MFI* grade is usually the one specified. The physical properties of such a material are:

$$\mu_0 = 16.0 \text{ kNs/m}^2 \text{ at } \gamma_0 = 1 \text{ s}^{-1} \text{ and } T_0 = 250°C,$$

$$n = 0.30, b = 0.01°C^{-1},$$

$$\rho = 750 \text{ kg/m}^3, C_p = 0.80, k = 0.30 \text{ W/m}°C$$

For the remainder of this paper, certain assumptions are made concerning extruder screw geometry. The lengths of the feed and compression sections (L_f and L_c in *Figure 9a*) are chosen as $2D$, where D is the barrel diameter. For melt extruders such lengths are adequate. The flight width, e, is taken to be $0.1D$, and flight lead as D (helix angle θ = 17.65°).

The compression ratio, H_f/H_m, is chosen to be 4, based on the following reasoning. The output of a hot melt extruder is normally determined by the feed section, and practical experience shows that the value of the dimensionless flow rate there, Q/BV_zH_f, is usually very close to 0.10. As indicated later, however, the dimensionless flow rate in the metering section (equation A10) should be about 0.4. A compression ratio of 4 therefore ensures a reasonable balance between the feed and metering sections of the screw.

Initially one set of machine geometry is considered, variations in the main dimensions being examined in the next section. The barrel diameter is chosen as D = 300 mm, overall length $L = 25D$ = 7.5 m, and H_m = 12 mm. A value of π_Q = 0.4 is assumed, from which the screw speed may be determined as N = 97 rev/min. The other operating conditions include barrel temperature, T_b = 250°C, and filled length, $L_{fill} = L_m$.

The performance predicted by the analysis is as follows:

Bulk mean delivery temperature, $\overline{T}_{out}$	= 326°C
Mechanical power consumption (excluding motor and gearbox losses)	= 690 kW
	= 0.138 kWh/kg
Barrel cooling rate	= 200 kW
Mean degree of mixing, M	= 4400
Mean shear rate, $\overline{\gamma}$	= 121 s^{-1}

Figure 1a shows the predicted temperature profile over the channel depth at the delivery end of the screw. The two temperature peaks correspond to the regions of greatest shear rate. Despite the steepness of the profile near the barrel the amount of heat conducted out is comparatively small, owing to the low thermal conductivity of the melt. *Figure 1b* shows the predicted increase in bulk mean temperature along the extruder. Clearly the flow is far from being 'fully developed' (velocities and temperatures independent of distance along the screw channel) even at the delivery end of the machine. Indeed, a machine with a L/D ratio very much larger than 25 would be required to achieve this condition, which is fortunate because excessively high temperatures would be generated.

Melt temperatures actually measured in large extruders generally do not show the considerable increases implied by the predicted profiles. In the author's experience this is largely due to inaccurate measurements. A temperature recorded at the barrel surface is unrepresentative of the bulk of the material, as is the temperature of a small sample leaked through the barrel wall. Most temperature measurements tend to be strongly influenced by the temperature of the metal component on which the thermocouple is mounted, which may be 50°C or more below that of the bulk of the flowing polymer.
Figure 1 (a) Melt temperature profile at delivery. (b) Increase in bulk mean temperature

APPLICATION TO DESIGN

In the above example the method of melt flow analysis is applied to an extruder whose geometry is prescribed. An even more important application for such an analysis is to the design of new machines for particular duties. In order to do this it is necessary to establish the appropriate design criteria.

Design criteria

The constraints to be satisfied in the design of a large extruder for homogenizing a given flow rate of melt include the following: (1) adequate mixing; (2) minimum bulk mean delivery temperature; (3) minimum machine size and cost; (4) minimum power consumption; (5) reasonable screw L/D ratio; (6) reasonable speed and shear rate. These requirements are of course highly interdependent. For example, delivery temperature and power consumption increase with the degree of mixing. It is difficult to predict what constitutes 'adequate' mixing, although trials on laboratory scale equipment can in principle establish the appropriate level. The mean degree of mixing imparted by melt homogenizers is generally between 2000 and 6000, although at the lower end of this range the machines serve as no more than melt pumps.

The last two of the above design criteria are concerned with the mechanical aspects of extruder design. Previous work[4] has shown that large extruders with high L/D ratios tend to be mechanically unstable, owing to a combination of buckling and whirling. High L/D machines are also more difficult and therefore more expensive to manufacture, and occupy large areas of plant. For all these reasons it is desirable to restrict L/D ratios to about 25. Similarly, as speeds are increased, screws tend to whirl and the rates of wear increase. For large extruders, 100 rev/min is a reasonable upper limit. The choice of mean shear rate was discussed earlier, where a figure of about 100 s^{-1} was suggested.

The main geometric variables available to the designer are the diameter, L/D ratio, metering section channel depth and helix angle. For present purposes, secondary variables such as feed and compression section lengths, flight width and compression ratio are fixed as indicated above. Operating variables which affect the design include the screw speed, barrel temperature profile and delivery pressure.

Typical design problem

Suppose it is required to select a suitable screw design for the application described earlier, namely the homogenization of 5000 kg/h of a 0.2 *MFI* LDPE supplied at 250°C. The effects of the various operating variables and helix angle are examined before considering the main screw dimensions.

Figure 2 shows bulk mean delivery temperature plotted against mean degree of mixing, two of the principal performance parameters. The geometric and operating variables are as defined before, except that helix angle, dimensionless flow rate (speed) and filled length are varied in turn over the ranges indicated. For all of these variations there is a direct proportionality between temperature rise and degree of mixing. This result may be interpreted as meaning that the helix angle dimensionless flow rate, and filled length do not significantly affect machine performance, because they do not affect the ratio of temperature rise to degree of mixing. The required level of mixing can be
Figure 2 Effect of varying helix angle, π_Q and filled length.
○, $10° < \theta < 35°$; □, $0.3 < \pi_Q < 0.45$; △, $9D < L_{\text{fill}} < 21D$.
0.2 *MFI* LDPE; 5000 kg/h at 250°C. $D = 300$ mm; $L/D = 25$.
$L_f = L_c = 2D$. $H_f = 48$ mm; $H_m = 12$ mm. $N = 97$ rev/min (when $\pi_Q = 0.4$); $T_b = 250°$ C

equally well achieved by a suitable choice of channel depths, as shown below. It should be noted that the effect of relatively large variations in the filled length, and hence the delivery pressure, have very little effect on performance in terms of melt temperatures and mixing. For the remainder of this paper the values $\theta = 17.65°$, $\pi_Q = 0.4$ and $L_{\text{fill}} = L_m$ are used.

The effects of varying barrel temperature are shown in *Figure 3*, in which the predicted bulk mean delivery temperature, mechanical power input and barrel cooling are plotted. The degree of mixing is not significantly affected by barrel temperature. In practice, the temperature of the barrel is controlled by the amount of cooling applied to it. According to *Figure 3*, the delivery temperature actually decreases as the barrel temperature is increased (eventually reaching a minimum), although the rate of decrease is relatively small. Practical evidence for this phenomenon can be obtained by removing the cooling from one or more barrel zones of a large hot melt extruder, and noting the very small effect on melt temperatures measured beyond the end of the screw. In large extruders the heat generated by the dissipation of mechanical work tends to be convected downstream, causing a continual rise in the bulk mean temperature, rather than be conducted out through the barrel. This can be attributed to the low thermal conductivity, and makes it very difficult to conduct heat into or out of the bulk of the flowing polymer.

Figure 3 also shows the large variations in power input and barrel cooling associated with the changing barrel temperature. In view of the much smaller effects on the main performance parameters, mixing and temperature rise, a number of conclusions may be drawn as follows. The main effect of barrel cooling is to draw power from the motor rather than heat from the polymer. It would appear to be
Figure 3 Effects of varying barrel temperature. $\bigcirc$, $\bar{T}_{out}$; $\square$, power input; $\triangle$, cooling. Same conditions as in *Figure 2*. $\theta = 17.65°$. $\pi_Q = 0.4$ ($N = 97$ rev/min). $L_{fill} = 21 D$

Figure 4 shows the effect of varying screw diameter for a fixed L/D ratio of 25. For each of the diameters there is nearly a direct proportionality between mean temperature rise and degree of mixing, with metering section channel depth as the variable. For a given value of the ratio H_m/D, the degree of mixing is virtually constant. The main point to note is that machine performance is improved by increasing the screw diameter, since a cooler melt can be achieved for a given level of mixing. Considering the relatively massive increases in extruder dimensions however, the temperature reductions are modest. Owing to the difficulty of transferring heat by conduction, increases in barrel surface area have relatively little effect.

According to the design criteria, screw speed and mean shear rate should also be considered. These are shown in *Table 1* for the range of machine dimensions employed in *Figure 4*. Clearly, the use of a 250 mm extruder for the present application would lead to excessive speeds and shear rates, whereas those for 300 or 350 mm machines are reasonable.

Figure 5 shows the effect of varying the length of a 300 mm extruder. For each of the five lengths there is nearly a direct proportionality between mean temperature rise and degree of mixing, with metering section channel depth as the variable. The downward displacement of the

possible to run large melt homogenizers with no barrel cooling and a considerable saving in power consumption. The common practice of quoting specific power consumption as a measure of the degree of mixing imparted can be misleading.

It now remains to examine the effects of the main geometric variables of diameter, length and channel depths.
Figure 6 Effect of machine volume (cost) on bulk mean temperature rise. *L/D*: ○, 15; ☐, 20; △, 25; ●, 30; ■, 40. ——, *D* = 250 mm; ---, *D* = 300 mm; ----, *D* = 350 mm. *M* = 4000; *T_b* = 250°C
Figure 7 Effect of residence time on bulk mean temperature rise. ○, *D* = 250 mm; ☐, *D* = 300 mm; △, *D* = 350 mm. *M* = 4000; *T_b* = 250°C

curves with increasing L/D implies that machine performance is improved by increasing its length, but not by very large amounts. As indicated in the previous section, however, considerations of screw stability and ease and cost of manufacture suggest that L/D ratios should be limited to about 25.

From the point of view of performance, the extruder should be as large as possible. In practice, the costs of building, housing and running such a machine are also important considerations. As a rough approximation, the cost of manufacture is proportional to the volume of the machine, which in turn is proportional to $D^3 \times (L/D)$. *Figure 6* shows the effect of this parameter on the bulk mean delivery temperature for a particular level of mixing, $M = 4000$. There are two main conclusions to be drawn. First, that a long thin extruder is better than a short fat one having the same volume (cost), from the point of view of minimizing melt temperature rise. Secondly, that the delivery temperature tends to become independent of the size of the machine as the latter is increased. In the present example, it is not possible to reduce the delivery tempera-

ture to significantly less than 300°C for the particular level of mixing imposed. A 300 mm, or at most a 350 mm, extruder represents a reasonable compromise between delivery temperature and cost.

With some materials, the residence time in an extruder is important from the point of view of thermal degradation, particularly if elevated temperatures are unavoidable. For a given dimensionless flow rate, the residence time is proportional to $(1/N) \times (L/D)$. *Figure 7* shows the effect of this parameter on the bulk mean delivery temperature, for $M = 4000$. The computed results all lie close to a single curve. A limiting minimum delivery temperature is again reached as the residence time (machine size) is increased. For some materials a thermal damage criterion, possibly based on a product of temperature and residence time, might be appropriate for helping to choose a screw design.

The final choice of screw design is based on $L/D = 25$ for the reasons already given, and $D = 300$ mm for reasons of cost. *Figure 8* shows bulk mean delivery temperature plotted against the degree of mixing for metering section channel depths between 9 and 18 mm. The upper limit of the useful range on this curve is determined by the maximum acceptable screw speed, and the lower limit by inadequate mixing and low shear rate. A channel depth of $H_m = 12$ mm is a reasonable choice, unless a very high degree of mixing is required, and is the case considered earlier.

Range of machines

Attention has so far been confined to extruders for processing 5000 kg/h of LDPE melt. Even larger machines are being designed and built. Following the procedure outlined in the above design study, the range of machine designs show in *Table 2* may be proposed.
Figure 8 Final choice of screw. *D* = 300 mm; *L/D* = 25; π_Q = 0.4; *T_b* = 250°C

Table 2 A range of LDPE homogenizers

Output (kg/h)	D (mm)	L/D	H_m (mm)
5000	300	25	12
10000	400	25	16
15000	450	25	18

All three machines are very similar in terms of mixing performance, bulk mean temperature rise and specific power consumption, for the same barrel temperatures. The screw speeds for the 400 and 450 mm machines are in the range of 80–90 rev/min.

NOMENCLATURE

a	axial component of velocity,
B	screw channel width,
b	temperature coefficient of viscosity,
C_p	specific heat,
D	internal diameter of extruder barrel,
e	screw flight width,
H	screw channel depth,
H_f	screw channel depth in feed section,
H_m	screw channel depth in metering section,
I_2	second invariant of rate of deformation tensor,
k	thermal conductivity,
L	axial length of screw,
L_c	axial length of compression section,
L_f	axial length of feed section,
L_{fill}	axial filled length,
L_m	axial length of metering section,
M	mean degree of (distributive) mixing,
N	screw speed,
n	power-law index,
p	pressure,
Q	volumetric flow rate,
T	temperature,
$\bar{T}$	bulk mean temperature,
$\bar{T}_{out}$	bulk mean delivery temperature,
T_b	barrel temperature,
T_0	reference temperature for viscosity data,
u, v, w	velocity components in (x, y, z) directions,
V_x, V_z	transverse and downstream components of velocity of barrel relative to screw,
x, y, z	Cartesian coordinates,
$\bar{\gamma}$	mean shear rate in metering section,
γ_0	reference shear rate for viscosity data.
θ	helix angle,
μ	viscosity,
μ_0	effective viscosity at reference shear rate and temperature,
π_Q	dimensionless flow rate in metering section,
ρ	density,
τ_{xy}, τ_{yz}	viscous stress components.

APPENDIX

Mathematical model

Figure 9a shows, in very diagrammatic form, the basic geometry of a single screw extruder. From the analytical point of view the difference between single and multi-start screws is very slight, although the latter may offer advantages in terms of mechanical symmetry and improved feeding. Note the choice of x and z for the transverse and down-

stream channel directions respectively. If it is assumed that the channel may be treated as though it were unrolled, then the views from the screw in the z and x directions are as shown in *Figures 9b* and *9c*.

Flow theory

The channel depth, H, changes slowly with z and is small compared with the width, B. Consequently, the local velocity profiles can be obtained from the following simplified momentum equations for slow viscous flow[3]:

$$\frac{\partial p}{\partial z} = \frac{d\tau_{yz}}{dy} , \quad \frac{\partial p}{\partial x} = \frac{d\tau_{xy}}{dy} \tag{A1}$$

where p is pressure and τ_{yz} and τ_{xy} are viscous stresses, given by:

$$\tau_{zy} = \mu \frac{dw}{dy} , \quad \tau_{xy} = \mu \frac{du}{dy} \tag{A2}$$

where μ is viscosity. The velocity components (u, v, w) are in the (x, y, z) directions, and the assumptions imply that $u = u(y), v = 0, w = w(y)$.

The same level of approximation cannot, however, be applied to the melt temperatures because of the dominant effect of thermal convection. Assuming that the only significant thermal conduction is in the y direction, the energy equation becomes:

$$\rho C_p \left(w \frac{\partial T}{\partial z} + u \frac{\partial T}{\partial x} \right) = k \frac{\partial^2 T}{\partial y^2} + \tau_{yz} \frac{dw}{dy} + \tau_{xy} \frac{du}{dy} \tag{A3}$$

<div style="text-align:center">convection   conduction   dissipation</div>
Figure 9 (a) Extruder geometry; (b) view in the z direction; (c) view in the x direction

where ρ, C_p, k and T are respectively the density, specific heat, thermal conductivity and temperature of the melt. As the thermal conductivity is low, heat derived from the dissipation of mechanical work tends to be convected along the screw channel rather than conducted out through the barrel. Unfortunately, it is not possible in the present model to include the effects of transverse convection because of the simplification already applied to the velocity profiles. Thus it is necessary to assume that:

$$u \frac{\partial T}{\partial x} \ll w \frac{\partial T}{\partial z} \tag{A4}$$

so that the second term on the left hand side of equation (A3) may be omitted. The disadvantages of making this assumption can be largely offset by a suitable choice of boundary conditions.

Constitutive equation

The non-Newtonian viscosity of polymer melts can generally be represented empirically as a power-law function of the local rate of deformation and an exponential function of temperature[3]:

$$\mu = \mu_0 \left(\frac{\sqrt{4I_2}}{\gamma_0} \right)^{n-1} \exp\left[-b(T - T_0) \right] \tag{A5}$$

where μ_0 is the effective viscosity at a reference shear rate γ_0 and temperature T_0. n is the power-law index and b the temperature coefficient of viscosity. In the present model, the second invariant of the local rate of deformation tensor is:

$$I_2 = \frac{1}{4}\left[\left(\frac{dw}{dy} \right)^2 + \left(\frac{du}{dy} \right)^2 \right] \tag{A6}$$

Boundary conditions and flow rate

The boundary conditions are assumed to be:

$$u = 0, w = 0, T = T_b \text{ at } y = 0$$
$$\tag{A7}$$
$$u = V_x, w = V_z, T = T_b \text{ at } y = H$$

where T_b is the barrel temperature. The temperature boundary condition at the screw ($y = 0$) is chosen to allow for the omission from equation (A3) of transverse convection, the effect of which is to keep the temperature of the screw close to that of the barrel.

Neglecting leakage over the flights, the transverse flow rate in the channel is zero:

$$\int_0^H u\,dy = 0 \tag{A8}$$

while the downstream volumetric flow rate, which is the output from the machine, is given by:

$$Q = B \int_0^H w\,dy \tag{A9}$$

It is convenient to define a dimensionless flow rate:

$$\pi_Q = \frac{Q}{BV_zH_m} \tag{A10}$$

which can be thought of as the ratio between the actual flow rate and the rate that would be achieved if the melt in the metering section all moved downstream with the same velocity as the barrel relative to the screw. A value for π_Q between about 0.4 and 0.5 corresponds to the drag flow condition, where no pressure gradient is generated. As this represents the maximum output for melt-fed machines, $\pi_Q = 0.4$ is a reasonable value to assume for design purposes.

Filled length

So far it has been implicitly assumed that the channel is always full of melt. In the early part of the screw, before pressure generation starts, the channel is in practice only partly full. This situation can be analysed with only minor modifications to the mathematical model. The axial filled length, L_{fill}, is determined by the pressure required at the delivery end of the screw. As indicated, however, variations of the filled length have relatively small effects on machine performance.

Method of solution

The mathematical equations can in general only be solved numerically, with the aid of a digital computer. Equation (A3) is used to step downstream to compute the developing temperature profiles. At each step equations (A1) are used to find the velocity profiles with the aid of equations (A2), (A5)–(A9). Note that the temperature and velocity profiles are linked by the temperature dependence of viscosity in equation (A5).

Performance parameters

From the computed temperature and velocity profiles may be obtained performance parameters which are of more direct practical use. For example, the temperature profile can be described in terms of a bulk mean temperature at any position along the extruder

$$\overline{T} = \int_0^H aT\,dy \bigg/ \int_0^H a\,dy \tag{A11}$$

where

$$a = w\sin\theta - u\cos\theta$$

is the melt velocity component in the axial direction.

Distributive mixing is discussed in the paper. The mean degree of mixing may be formally defined as[3]:

$$M = \frac{B}{Q} \int_0^{L\,\text{cosec}\,\theta} \int_0^H \sqrt{4I_2}\,dy\,dz \tag{A12}$$

Finally, the mean shear rate in the metering section may be defined as

$$\overline{\gamma} = V_z/H_m \tag{A13}$$

Notes to the Editor

Viscosity of Newtonian suspensions*

R. F. Fedors

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91103, USA
(Received 23 December 1974)

In a recent paper, Nicodemo and Nicolais[1] reported the effect of asymmetric glass fibres (of average length 0.053 cm, average diameter 0.0014 cm and hence of aspect ratio 37.8) on the viscosity of aqueous solutions of poly(ethylene oxide). They showed that the dependence of the relative viscosity, η_r, at zero shear rate on volume fraction of glass fibre, ϕ could be described by an equation of the form:

$$\eta_r = \exp(8.52\phi) \tag{1}$$

A comparison of the experimentally measured η_r and that calculated using equation (1) is shown in *Table 1* where as may be seen, the agreement is quite satisfactory.

It is our purpose to show that the η_r, ϕ response can also be adequately described by an equation proposed previously for the Newtonian viscosity of suspensions of aggregates[2]. It is given by:

$$\eta_r = \left(1 + \frac{1.25\phi}{\phi_m - \phi}\right)^2 \tag{2}$$

where ϕ_m is the maximum volume fraction to which the suspended particles can be randomly packed. In principle, the value of ϕ_m can be estimated independently from measurements such as sedimentation volume or packing fraction. We have used equation (2) to fit the η_r, ϕ data and the results are also shown in *Table 1*. For this fit, ϕ_m was taken to have the value 0.31 which is reasonable for the random packing of high aspect ratio rods. This value means that a randomly packed bed of rods contains 69% void volume.

If we expand equation (1) to the second power in ϕ (which is adequate to fit the experimental data), we have:

$$\eta_r \approx 1 + 8.52\phi + \frac{(8.52)^2}{2}\phi^2 \tag{3}$$

while expansion of equation (2) provides:

Table 1 Dependence of η_r on ϕ for glass fibres in aqueous poly(ethylene oxide)

	ϕ				
	0	0.01	0.03	0.05	0.07
η_r(exp.)	1.0	1.12	1.3	1.5	1.85
η_r(calc. eqn.1)	1.0	1.09	1.29	1.53	1.82
η_r(calc. eqn.2 ϕ_m = 0.31)	1.0	1.09	1.29	1.54	1.86
η_r(calc. eqn.2 ϕ_m = 0.29)		1.09	1.31	1.59	1.95

$$\eta_r \approx 1 + \frac{5\phi}{2\phi_m} + \frac{65}{16}\frac{\phi^2}{\phi_m^2} \tag{4}$$

Equating like coefficients of powers of ϕ, we have ϕ_m = 0.293 from the ϕ term and ϕ_m = 0.334 from the ϕ^2 term. Taking the average of these two values, we get ϕ_m = 0.314 which is in satisfactory agreement with the value of this parameter obtained directly from application of equation (2) to the experimental data.

In a further effort to show that ϕ_m = 0.31 is a reasonable value, packing experiments were carried out using approximately 2500 pieces of steel wire 0.12 cm in diameter and 4.0 cm in length (i.e., wire with an aspect ratio of 34). This size was chosen for convenience in handling as described below. Also it is well-known that ϕ_m does not depend on particle size except in that region where the high surface area to volume ratio causes particle to particle sticking. For example, ϕ_m for large sphere of glass, steel, Plexiglass, nylon[3] 0.32 cm in diameter is 0.63 while ϕ_m for glass spheres 0.003 cm in diameter is also 0.63[4]. Hence, we can reasonably expect that ϕ_m for the 0.12 cm diameter wire should be comparable to ϕ_m for the glass fibre used by Nicodemo and Nicolais.

The ϕ_m value for the wire was estimated as follows. The wire was placed in small, very flexible plastic bags and then immersed in water; the volume of water displaced was assumed to be equal to the total volume, V_T, occupied by the wire. ϕ_m was then taken equal to v/V_T where v is the volume of the wire which is equal to the weight of the wire, 899 g, divided by its density, 7.70 g/cm^3.

The plastic bags were sufficiently flexible so that they for the most part conformed to the outline of the bed of wire. However, in practice, the wire ends usually produced small punctures in the bag. Hence two bags were used one over the other. The inner bag opening was simply twisted closed but otherwise left unsealed while the outer bag was sealed with a rubber band. It soon became apparent that an appreciable air space existed between the two bags. To eliminate the air, small holes were made in the outer bag and the bags and wire were gently kneaded by hand to expel air. The total occupied volume was then taken to be the minimum volume of water displaced. To monitor the quantity of water getting into the bags to the wire, the bags containing the wire were removed periodically and weighed. When the volume of displaced water had decreased and stabilized at 405 cm^3, the difference between the weight after kneading under water and the initial dry weight amounted to less than 4%. This weight increase is equal to the weight of water which had flowed in the plastic bags. From the numerical data obtained, ϕ_m for the wire is estimated to be 0.29, a value in excellent agreement with the value of 0.31 required for fit of equation (2) to the experimental data.

If one takes the ϕ_m value for the glass fibres to have

the same value as estimated for the wire, the η_r, ϕ response calculated using equation (2) and ϕ_m = 0.29 is within 6% of the experimentally determined response. Thus, we have been able to estimate η_r as a function of ϕ to within 6% using equation (2) and independently estimating the parameter ϕ_m by means of an auxiliary experiment.

Evidence for aggregation in solutions of poly(ethylene oxide)

Carla Cuniberti
Istituto di Chimica Industriale dell'Università di Genova, Via Pastore 3, 16132 Genova, Italy
(Received 23 October 1974; revised 18 November 1974)

It was shown in previous papers[1,2] that dilute solutions of high molecular weight poly(ethylene oxide) (PEO) in dimethylformamide (DMF) above room temperature contain supermolecular particles arising from molecular associations. In order to investigate the ability of these particles to act as crystallization centres on cooling, the isothermal crystallization of PEO–DMF solutions with different thermal histories was studied.

Three procedures were used to prepare the solutions: (a) direct dissolution of the sample at a temperature above its solution point; (b) dissolution of the sample at 80°C, followed by full crystallization at 0°C and heating of the suspension up to a temperature above the clearing point (the solution was maintained 30 min at this temperature); (c) dissolution of the sample at 110°C, followed by slow cooling (10°C/h) to lower temperatures.

The time at the dissolution temperature was 1 h and 0.1% diphenylamine was added to avoid polymer degradation.

Quenching from the final temperature reached by the solution, T_d, to the crystallization temperature, T_c, was carried out in each case.

The sample was a well annealed film obtained by evaporation at 50°C of a benzene solution of a PEO fraction with molecular weight 3.5×10^5. Solutions of concentration 0.155% were employed. The dissolution temperature of the appropriate amount of polymer in DMF was 38°C and the clearing point of the crystalline suspension 21.6°C. The crystallization temperature 12.8°C was chosen because it was possible to achieve the complete phase separation within acceptable times in all the cases here studied. The crystallization process was followed by measuring the increase of the turbidity, a method particularly suited to the investigation of the initial part of the phase separation in dilute solutions[3].

In *Figure 1* the measured induction time, t_i, for the crystallization of PEO is plotted against the temperature T_d. The increase of t_i with T_d reveals the presence of destroyable heterogeneities in all the solutions but, while induction times falling approximately on the same curve are obtained by means of procedures (b) and (c), the crystallization is much faster in case (a) at $T_d < 80°C$. Furthermore, in *Figure 1a* curve bc (circles) shows a sensible increase of t_i in two separate intervals of the explored temperature range. The low temperature variation covers about 25 degrees above the clearing point of the suspension and must be connected with crystallization seeds that decrease in number with increasing temperature, as

Figure 1 (a) Dependence of induction time, t_i, on the final temperature of the solution (T_d) reached by procedures (a) ($\triangle$), (b) ($\bigcirc$) and (c) ($\bullet$). (b) Dependence of the reduced viscosity on temperature for solutions 0.155% (A) and 0.082% (B); $\bullet$, points obtained by decreasing the temperature; $\bigcirc$, points obtained by increasing the temperature

was shown for polyethylene in xylene[4]. These seeds are completely destroyed above 45–50°C. On the same line, the increase of t_i between 80° and 110°C gives evidence of a second kind of crystallization seeds that disappear only above 110°C. The stability of these particles above the melting point of the polymer[5] and their reduced ability to grow crystals show that, besides numerical or dimensional differences, a different morphology must be involved. The identical crystallization rates obtained with procedures (b) and (c) show moreover that both kinds of seeds are in equilibrium with dissolved polymer molecules. That non-equilibrium residues give rise to much shorter induction times is shown by curve a (triangles) in *Figure 1a*, obtained when the sample is directly dissolved at T_d. At T_d lower than about 80°C residual seeds from the crystalline film require heating times longer than 1 h to reach equilibrium

the same value as estimated for the wire, the η_r, ϕ response calculated using equation (2) and ϕ_m = 0.29 is within 6% of the experimentally determined response. Thus, we have been able to estimate η_r as a function of ϕ to within 6% using equation (2) and independently estimating the parameter ϕ_m by means of an auxiliary experiment.

(Received 23 October 1974; revised 18 November 1974)

It was shown in previous papers[1,2] that dilute solutions of high molecular weight poly(ethylene oxide) (PEO) in dimethylformamide (DMF) above room temperature contain supermolecular particles arising from molecular associations. In order to investigate the ability of these particles to act as crystallization centres on cooling, the isothermal crystallization of PEO—DMF solutions with different thermal histories was studied.

Three procedures were used to prepare the solutions: (a) direct dissolution of the sample at a temperature above its solution point; (b) dissolution of the sample at 80°C, followed by full crystallization at 0°C and heating of the suspension up to a temperature above the clearing point (the solution was maintained 30 min at this temperature); (c) dissolution of the sample at 110°C, followed by slow cooling (10°C/h) to lower temperatures.

The time at the dissolution temperature was 1 h and 0.1% diphenylamine was added to avoid polymer degradation.

Quenching from the final temperature reached by the solution, T_d, to the crystallization temperature, T_c, was carried out in each case.

The sample was a well annealed film obtained by evaporation at 50°C of a benzene solution of a PEO fraction with molecular weight 3.5×10^5. Solutions of concentration 0.155% were employed. The dissolution temperature of the appropriate amount of polymer in DMF was 38°C and the clearing point of the crystalline suspension 21.6°C. The crystallization temperature 12.8°C was chosen because it was possible to achieve the complete phase separation within acceptable times in all the cases here studied. The crystallization process was followed by measuring the increase of the turbidity, a method particularly suited to the investigation of the initial part of the phase separation in dilute solutions[3].

In *Figure 1* the measured induction time, t_i, for the crystallization of PEO is plotted against the temperature T_d. The increase of t_i with T_d reveals the presence of destroyable heterogeneities in all the solutions but, while induction times falling approximately on the same curve are obtained by means of procedures (b) and (c), the crystallization is much faster in case (a) at $T_d < 80$°C. Furthermore, in *Figure 1a* curve bc (circles) shows a sensible increase of t_i in two separate intervals of the explored temperature range. The low temperature variation covers about 25 degrees above the clearing point of the suspension and must be connected with crystallization seeds that decrease in number with increasing temperature, as

Figure 1 (a) Dependence of induction time, t_i, on the final temperature of the solution (T_d) reached by procedures (a) ($\triangle$), (b) (O) and (c) ($\bullet$). (b) Dependence of the reduced viscosity on temperature for solutions 0.155% (A) and 0.082% (B); $\bullet$, points obtained by decreasing the temperature; O, points obtained by increasing the temperature

was shown for polyethylene in xylene[4]. These seeds are completely destroyed above 45—50°C. On the same line, the increase of t_i between 80° and 110°C gives evidence of a second kind of crystallization seeds that disappear only above 110°C. The stability of these particles above the melting point of the polymer[5] and their reduced ability to grow crystals show that, besides numerical or dimensional differences, a different morphology must be involved. The identical crystallization rates obtained with procedures (b) and (c) show moreover that both kinds of seeds are in equilibrium with dissolved polymer molecules. That non-equilibrium residues give rise to much shorter induction times is shown by curve a (triangles) in *Figure 1a*, obtained when the sample is directly dissolved at T_d. At T_d lower than about 80°C residual seeds from the crystalline film require heating times longer than 1 h to reach equilibrium

with their environment. This behaviour shows that the poly-mer film is characterized by a more extensive order than the crystals grown in solution, since it is presumably the more ordered parts of the crystallites that resist dissolution. Only above 80°C is t_i completely independent of the thermal history of the solution, this suggesting that the aggregation mechanism[3] involved has no connection with crystallization.

The equilibrium between crystal seeds and polymer molecules found for PEO solutions just above the clearing point is different from the behaviour reported for poly-ethylene solutions, where the destruction of crystals has been described as an irreversible process[6]. One must there-fore conclude that in PEO solutions the mechanism for recreating seeds is connected with the high temperature aggregation.

Viscosity measurements on solutions prepared after procedure (c) give further support to this result. *Figure 1b* shows the change of the reduced viscosity for the $c = 0.155$ per cent solution (curve A), together with results previously obtained[2] at higher dilution (curve B). The two maxima at different temperatures indicate that two different aggrega-tion mechanisms are involved[7]; the increased prominence of the maxima with dilution shows that the average size of the two species is different. The larger weight of the peak on the left suggests further that the high temperature aggre-gates must act as nuclei for the growth of the low tempera-ture species.

Dielectric behaviour of ethylene—vinyl acetate copolymers

Previous studies[1-3] of electrical properties of ethylene—vinyl acetate copolymers have demonstrated their use for determining the composition of the copolymers. Eidel'nant et al.[3] designated three relaxations α, β and γ in descending order of temperature at a fixed frequency. The α process was observed only for copolymers with vinyl acetate contents up to 20% by wt and was assigned to crystalline regions and the β relaxation to segmental motion in amorphous regions. The γ relaxation process occurred in the glassy state at about $-100°C$ for frequencies in the audio-region and presumably was associated with local motion on a small scale. The α and γ loss peaks were very small compared with the β one. McNight and Tretault[4,5] in dynamic mechanical and dielectric measurements on ethylene/vinyl acetate/vinyl alcohol terpolymers observed only two relaxations in the relevant copolymers (their samples A_1 and B_1) corresponding to the β and γ relaxations above.

To assist clarification of these mechanisms we have made further studies of these copolymers and describe in some detail, not previously published, the parameters associated with segmental motion in amorphous regions. This includes information about the shape and width of loss curves and activation energies as a function of vinyl acetate content.

The copolymers studied were supplied by ICI Ltd as Evatane 18—02, 28—05, 33—25 and 40—50 (all random with the first number designating the wt/wt concentration of vinyl acetate) with crystallinities of 37, 22, 15 and 4% respectively as deduced from an empirical relationship[6]. The glass transitions T_g of the samples were evaluated from d.s.c. data and fell in the range $-20°C$ to $-30°C$. The average molecular weights of the samples were at least 20 000. The samples were examined in vacuo as discs 5.08 cm in diameter by about 1 mm thick in the form of a three-terminal guarded electrode system, after cleaning and careful drying to constant weight over P_2O_5. They were placed in a shielded electrode assembly in a cryostat controlling temperature to $\pm0.3°C$. Dielectric measurements were made over the frequency range 10^2 to 10^5 Hz using a GR 1615A capacitance bridge.

Careful measurements on the 18—02 sample over the temperature range $-25°C$ to $+40°C$ (and frequency range above) revealed only one (α) relaxation contrary to the results of Eidel'nant et al.[3] and over the temperature range $-90°C$ to $+40°C$ all the copolymers exhibited only 2 relaxations (α and β) corresponding to the β and γ of Eidel'nant et al.[3]. The magnitude of the α relaxation was much greater than that of the β.

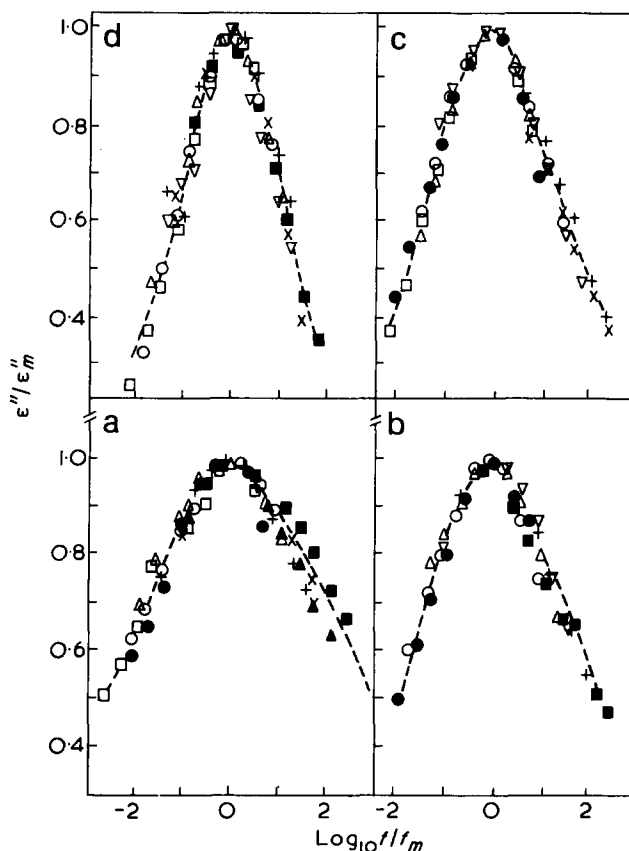
The α relaxation occurred in the temperature region $-10°C$ to $-25°C$ and is clearly due to the large scale segmental motion (manifestation of T_g) in amorphous regions. The shape of the relatively broad α relaxation is shown in detail by the normalized plots of ratio of loss factor ϵ'' to maximum loss factor ϵ''_m against log ratio of frequency f to frequency of maximum loss f_m in Figure 1. As the vinyl acetate content is increased, the plots narrow consistent with a lower crystallinity[7] from a half width of about 5.6


Figure 1 Normalized plots of ϵ''/ϵ''_m against log f/f_m for the α relaxation in samples with varying concentrations of vinyl acetate. decades for the 18—02 sample to 2.8 decades for the 40—50 sample; but an interesting point is that the broader loss curves for samples of lower vinyl acetate content are broader on the high frequency side instead of the low frequency side[7]. The relatively small scatter in the data for each normalized plot is due to the fact that the width of the loss curves varies somewhat with temperature and this scatter is much reduced in the nearly amorphous 40—50 specimen, which has a half width somewhat greater than that for poly(vinyl acetate)[14] (2.0 decades). The position of the loss peak is little affected by the vinyl acetate content and this is illustrated in Figure 2 in the plots of log frequency of maximum loss against $1/T$ on a fairly sensitive scale. Over the frequency and temperature range used the points for the three samples 18—02, 28—05 and 33—25 fall on a roughly common plot corresponding to an activation energy of about 160 kJ/mol as determined from the slopes of lines fitted by the method of least squares to the points for each sample separately. However, the data for the 40—50 sample are slightly shifted to the lower temperature side (at fixed frequency) corresponding to a reproducibly lower activation energy of about 90 kJ/mol as determined from the slope of the line (again) fitted to the corresponding

centration and the linear variation arises because of the increasing number of dipoles per unit volume. The dipole moment, μ for an average repeat unit was calculated from the Onsager[12] formula (MKS system):

$$\mu^2 = \frac{9\epsilon_0 kT(2\epsilon_s + \epsilon_\infty)(\epsilon_s - \epsilon_\infty)}{N\epsilon_s(\epsilon_\infty + 2)^2} \qquad (2)$$

where k is Boltzmann's constant, T the temperature (K) and N is the number of dipolar repeat units per unit volume, equal to $N_A \rho/M$ where N_A is Avogadro's number, ρ is the density and M is the molecular weight of the average repeat unit. In view of the usual inherent errors involved in applying this formula to polymers the values of dipole moment are only estimates. However, the results shown in *Table 1* support the previous suggestion since the dipole moment values are approximately equal for the four samples used. Eidel'nant *et al.*[3] quoted slightly higher values (about 1.7 Debye) probably because they were evaluated for room temperature, suggesting a dependence of dipole moment on temperature. These dipole moment values probably characterize the effective dipole moment of the vinyl acetate unit when surrounded by mainly ethylene units as the values of $\bar{m}$ (in the repeat unit) varied from 14 for the 18–02 sample to about 5 for the 40–50 sample.

The β loss peaks are quite small and the data have been found to be somewhat variable. Generally with 33–25 and 40–50 samples the half width of the loss peaks is 4–5 decades and the size of ϵ''_m is of the order of 0.01. This is about 20 to 30 times smaller than the corresponding peak heights for the α relaxation and an estimate for the magnitude $(\epsilon_s - \epsilon_\infty)_\beta$ for the relaxation using equation (1) is of the order of 0.10. The loss peaks appear in the region of 10 kHz for temperatures in the range -70°C to -85°C, i.e. roughly in the same place as for poly(vinyl acetate)[13,14], with a relaxation magnitude (0.10) of just over half that found in poly(vinyl acetate) (0.14). Thus the β relaxation in these copolymers probably arises from a similar side group motion (in the glassy state) to that in poly(vinyl acetate).

The absence of a higher temperature relaxation equivalent to the α of Eidel'nant *et al.*[3] on the 18–02 sample is not surprising as these authors assigned their α relaxation to crystalline regions. These will contain only ethylene groups and the relaxation magnitude will normally be negligible even when allowing for residual dipole moments, unless accidental impurities or oxidation cause the presence of extraneous carbonyl groups[8,9]. Thus, whilst these may have been present in the samples of lower vinyl acetate content examined by Eidel'nant *et al.*[3] giving his small α relaxation, this relaxation should normally be negligible

Figure 2 Loci plots of log frequency of maximum loss f_m against $1/T$ (K) for the α relaxation in samples with varying concentrations of vinyl acetate. ○, 18–02; △, 28–05; ×, 33–25; □, 40–50

points by the method of least squares. This can be explained by the relatively low crystallinity (4%) of this sample, whereas the lack of variation of activation energy of the other three samples can be explained by the effect of varying crystallinity, (higher crystallinity shifting the loss peaks to higher temperatures at a fixed frequency[8,9] being counteracted by the increased polarity of the chain molecules as the vinyl acetate content is increased. All the copolymers have a lower activation energy than that quoted for poly(vinyl acetate)[14] (250 kJ/mol).

The magnitude of the relaxation was calculated assuming the relationship[10,11]:

$$\epsilon_s - \epsilon_\infty = 1.75\epsilon''_m \Delta \log f \qquad (1)$$

where $\Delta \log f$ is the half width (for $\epsilon'' = \epsilon''_m/2$) and assuming that the plots of ϵ'' vs. $\log f$ can be represented by a Fuoss–Kirkwood relationship. The error involved in this assumption is likely to be small[11]. The calculations were made using average values of ϵ''_m, the $\Delta \log f$ values being taken from the normalized plots, so that the values of $\epsilon_s - \epsilon_\infty$ are averages over the range of temperature used (-10°C to -25°C). Values of ϵ_∞ were obtained by short extrapolations from arc plots. The plots of $\epsilon_s - \epsilon_\infty$ against vinyl acetate content were approximately linear, suggesting that the effective dipole moment for the average repeat unit

$$[-(CH_2 - CH_2)\overline{\overline{m}}CH_2-CHOCOCH_3]$$

is approximately independent of dipolar vinyl acetate con-

Table 1 Parameters of the α relaxation (approximate average values over the range -10°C to -25°C

Copolymer	Crystallinity (%)	Half-width from normalized plots	Peak height, ϵ''_m	Relaxation magnitude, $\epsilon_s - \epsilon_\infty$	Dipole moment estimate (D)*
18–02	37	5.6	0.06	0.6	1.4

* 1 Debye $\equiv 3.33 \times 10^{-30}$ C m

and not usually observable in ethylene–vinyl acetate copolymers over a wide range of concentration of vinyl acetate.

For our α relaxation the lack of variation of dipole moment with vinyl acetate concentration (and a corresponding change in the degree of crystallinity) is attributed to the fact that the vinyl acetate units occur only in amorphous regions[15,16] and not in crystalline regions which contain only ethylene groups. Generally the changes in width of the normalized plots in *Figure 1* are consistent with the corresponding changes in crystallinity except that there seems to be no obvious explanation for the curves for the 18–02 sample being broader on the high frequency side than on the low frequency side. In view of the curved $\log f_m$ against $1/T$ plot found by Eidel'nant *et al.*[3] for a sample with a vinyl acetate content of 11% (as might be expected from the WLF relationship[17]), it is interesting that the data for all our copolymers definitely fit a linear relationship better than a curved one over the frequency and temperature range used. Also, we can separate the locus and lower activation energy for the 40–50 sample from those for the other three samples. Extension of our frequency range by d.c. step response measurements (down to 10^{-4} Hz) might well then show the curved plots typical of WLF behaviour. The much larger relaxation magnitude for the α relaxation $(\epsilon_s - \epsilon_\infty)_\alpha$ as compared with that for the β relaxation $(\epsilon_s - \epsilon_\infty)_\beta$ is explained by the much freer movement of the vinyl acetate group in large scale segmental motion as compared with its small scale side group motion in the glassy state.

Further work (including measurements on samples of higher vinyl acetate content) is required to determine the exact shape of the loci for the α relaxation at lower frequencies in the region of T_g and to determine the causes of variability in the β relaxation and hence evaluate its parameters more accurately.

An improved model for studying the concentration dependence of the configurational behaviour of chain molecules

Theoretical studies of the configurational behaviour of polymer molecules in high concentration solutions have been impeded by the lack of appropriate models. A model considered in the past for Monte Carlo calculations assumes that the chain molecule is confined to an impenetrable 'cell' which simulates the free volume available to the molecule[1]. The concentration varies with the 'cell' size. This model implies an unjustifiable constraint that the maximum length which the molecule can assume will not exceed the dimensions of the 'cell'. Further, the model does not take into account interchain interactions in a valid manner. The purpose of this letter is to put forward an improvement in the model in an attempt to avoid the above shortcomings.

An important consideration in the computer simulation studies is the computational feasibility of the model. Even the most efficient computational machines available at present permit calculations on only single chains of moderate length without incurring unrealistic expenditure. Therefore, an acceptable improvement in the model should incorporate the interchain interactions in such a way that the behaviour of a single chain as the basis of the model is retained, if calculations are not to be limited to short chains. This can be accomplished by postulating that although the positions of chain segments are no longer restricted to the confines of the cell, the system conforms to the periodic boundary conditions such that the number of segments in the 'cell' remains constant. Previously, we have mentioned the use of these conditions in the development of a model for studying the configurational behaviour of adsorbed chains as function of surface coverage[2]. Some other workers also have alluded to such conditions in the context of chain molecular models[3,4].

A two-dimensional pictorial representation of the model with the proposed periodic boundary conditions is given in *Figure 1*. The square ABCD represents the basic 'cell' surrounded by replicas with chain molecular configurations identical to those in the 'cell' itself. In the particular configuration shown the chain molecule leaves the basic 'cell' at b. The parts bc, cd and de exist in the replicas 1, 2 and 3, which are represented in the basic 'cell' by $'b'c$, $'c'd$ and $'d'e$ respectively. Then, in addition to the intramolecular interactions, the interchain interactions between ab, $'b'c$, $'c'd$ and $'d'e$ have to be considered. In three dimensions the number of replicas in the immediate vicinity of the basic 'cell' will be 26.

Assuming the above model we have carried out some preliminary Monte Carlo calculations on 10–, 20–, 30– and 40–bond chains confined to a tetrahedral lattice. The basic 'cell' contained 64 lattice sites. Sufficiently large samples

and not usually observable in ethylene—vinyl acetate copolymers over a wide range of concentration of vinyl acetate.

For our α relaxation the lack of variation of dipole moment with vinyl acetate concentration (and a corresponding change in the degree of crystallinity) is attributed to the fact that the vinyl acetate units occur only in amorphous regions[15,16] and not in crystalline regions which contain only ethylene groups. Generally the changes in width of the normalized plots in *Figure 1* are consistent with the corresponding changes in crystallinity except that there seems to be no obvious explanation for the curves for the 18—02 sample being broader on the high frequency side than on the low frequency side. In view of the curved $\log f_m$ against $1/T$ plot found by Eidel'nant *et al.*[3] for a sample with a vinyl acetate content of 11% (as might be expected from the WLF relationship[17]), it is interesting that the data for all our copolymers definitely fit a linear relationship better than a curved one over the frequency and temperature range used. Also, we can separate the locus and lower activation energy for the 40—50 sample from those for the other three samples. Extension of our frequency range by d.c. step response measurements (down to 10^{-4} Hz) might well then show the curved plots typical of WLF behaviour. The much larger relaxation magnitude for the α relaxation $(\epsilon_s - \epsilon_\infty)_\alpha$ as compared with that for the β relaxation $(\epsilon_s - \epsilon_\infty)_\beta$ is explained by the much freer movement of the vinyl acetate group in large scale segmental motion as compared with its small scale side group motion in the glassy state.

Further work (including measurements on samples of higher vinyl acetate content) is required to determine the exact shape of the loci for the α relaxation at lower frequencies in the region of T_g and to determine the causes of variability in the β relaxation and hence evaluate its parameters more accurately.

Some other workers also have alluded to such conditions in the context of chain molecular models[3,4].

A two-dimensional pictorial representation of the model with the proposed periodic boundary conditions is given in *Figure 1*. The square ABCD represents the basic 'cell' surrounded by replicas with chain molecular configurations identical to those in the 'cell' itself. In the particular configuration shown the chain molecule leaves the basic 'cell' at b. The parts bc, cd and de exist in the replicas 1, 2 and 3, which are represented in the basic 'cell' by 'b'c, 'c'd and 'd'e respectively. Then, in addition to the intramolecular interactions, the interchain interactions between ab, 'b'c, 'c'd and 'd'e have to be considered. In three dimensions the number of replicas in the immediate vicinity of the basic 'cell' will be 26.

Assuming the above model we have carried out some preliminary Monte Carlo calculations on 10—, 20—, 30— and 40—bond chains confined to a tetrahedral lattice. The basic 'cell' contained 64 lattice sites. Sufficiently large samples

Figure 1 A pictorial representation of the periodic boundary conditions

Table 1 Values of the mean square of the end-to-end distance for the chains of various lengths

No. of bonds (N)	ϕ	$\langle\langle R_N^2\rangle\rangle_\phi$	$\langle\langle R_N^2\rangle\rangle_{\phi\to0}$	$\langle\langle R_N^2\rangle\rangle_\theta$
10	0.172	59.2 ± 0.3 (sample size: 40 000 conf.)	60.4[7,8]	55.5
20	0.328	128.8 ± 0.6 (sample size: 100 000 conf.)	140[7,9]	115.5
30	0.484	204 ± 3 (sample size: 100 000 conf.)	228[9,10]	175.5
40	0.640	212 ± 9 (sample size: 200 000 conf.)	321[10]	235.5

of configurations (40 000–200 000 configurations) were generated on a computer following a procedure analogous to the Metropolis sampling technique[5]. Only those configurations were accepted which maintained intramolecular as well as intermolecular excluded volume condition. Mean values of the configurational quantities over the samples thus generated converge to the canonical ensemble averages. The description of the procedure as applied to an isolated chain appeared in a previous publication[6]; details of its extension to the present model will be provided later. Computed values of the mean square of the end-to-end distance, $\langle\langle R_N^2\rangle\rangle_\phi$, for the chains of various lengths (N) are given in *Table 1*. Volume fractions, quoted in the second column, are simply the ratio between the number of segments in the chain ($N + 1$) and the number of lattice sites in the basic 'cell'. For the sake of comparison we have included in *Table 1* the mean values of R_N^2 for systems in the limit of zero concentration (excluded volume isolated chains), $\langle\langle R_N^2\rangle\rangle_{\phi\to0}$, and under the theta condition (chains without excluded volume), $\langle\langle R_N^2\rangle\rangle_\theta$. It is interesting to note that for 10-, 20- and 30-bond chains the values of $\langle\langle R_N^2\rangle\rangle_\phi$ lie

between $\langle\langle R_N^2\rangle\rangle_{\phi\to0}$ and $\langle\langle R_N^2\rangle\rangle_\theta$, but as the chain length increases to 40 bonds $\langle\langle R_N^2\rangle\rangle_\phi$ assumes a value lower than $\langle\langle R_N^2\rangle\rangle_\theta$.

In forthcoming publications we shall consider the effect of concentration on such configurational features as chain molecular shape, chain flexibility and chain/chain entanglements. Also, we shall attempt to evaluate pressure/volume relationships.

The present model, in which there are no interactions other than the excluded volume effect, may be considered to represent athermal solutions. Models representing non-athermal solutions would contain non-zero segment/segment interactions. In future studies we hope to extend the present approach to such models.

Book Reviews

Metals, ceramics and polymers
Oliver H. Wyatt and David Dew-Hughes
Cambridge Univ. Press, London, 1974, 625 pp. £12

This book can be recommended as a reference book to any serious student of materials science. In one volume the authors have combined the atomistic, microscopic and macroscopic approaches to materials and covered metals, ceramics, glasses and high polymers. The properties considered are mechanical, electrical and magnetic. Most of the standard proofs are given, often with an historical basis, which makes for interesting reading. There are many tables containing a great deal of useful, factual information and the diagrams and illustrations are excellent. The authors have chosen a physical, engineering approach to their subject which will be welcomed by physicists and applied scientists, but may be less useful to the polymer chemist who might, with some justification, feel that he has not received his 'fair bite of the cherry'. Although polymers are discussed throughout the book, only 55 pages out of 625 are devoted exclusively to them.

Inevitably there must be omissions in a book which attempts to cover as broad a field as this one. The authors realize this and argue that sensible selection of material is preferable to a wider coverage and superficiality. This is probably true, but it is arguable whether the complete omission of fabrication techniques in the section on polymers can be justified in view of the importance that these techniques have in the choice of polymers in competition with other materials. Also the importance of correct design for plastics is not discussed, and there is nothing on environmental stress cracking. Spherulites are described briefly but there is no mention of the role of impurities in causing constitutional undercooling, although this is a feature which is common to the growth of spherulites in polymers and to cellular growth in impure metals. In the discussions on metals it is surprising that temper brittleness and blue brittleness are dismissed in one sentence.

This is an ambitious book which largely achieves its objectives. It is written with style and humour, and each chapter ends with a selection of novel, often searching, questions.

The price of the hard-back version, £12, is not excessive in these inflationary times; the paper-back version, at just under £5, is excellent value for money.   *J. R. Atkinson*

Polymer materials science
J. M. Schultz
Prentice-Hall, Englewood Cliffs, NJ, 1974, 511 pp.

Not since Geil's 1963 *Polymer Single Crystals* has there been an attempt to embrace the entire field of polymeric physical structure and dependent properties in a single volume. That book, written in the heyday of morphological inquiry, was able to give a comprehensive account of all textural studies then made plus the first rudimentary efforts to relate these to properties. To cover the same, now vastly more extensive, area today is a formidable task, but one which Professor Schultz has set himself in *Polymer Materials Science*. This is a postgraduate text comprising eleven chapters: Introduction dealing with chain conformations; Single crystals; Melt-crystallized polymers; Degree of crystallinity; Polymerization; Methods of measuring molecular weight averages and stereoregularity; Mechanics of amorphous polymers; Time-dependent mechanical behaviour; Crystallization kinetics and mechanism; Electrical and electro-optical behaviour; and Mechanical behaviour of semi-crystalline polymers. The student is helped by needing little background knowledge, by detailed explanations of several investigative techniques and by the separation into appendixes of aspects of diffraction theory. There are also problems, some rather esoteric, attached to the earlier chapters.

The very long second chapter is partly, the author explains, to convince us that 'in many ways the science of polymeric materials is an extension of the science of copper or lithium fluoride or steel.' There is no doubt that Professor Schultz's enthusiasm, which is always evident, knows few bounds whenever he is dealing with such familiar metallurgical topics as dislocations, on which there are 14 pages plus 3 in an appendix. Nowadays one would think that the pendulum of opinion has swung back and that it is appreciated

that with polymers the meaning of 'crystal' has to be extended beyond the usage in simpler solids. It may be partly for this reason that the book seems a little old-fashioned; it is also because the subject matter is strangely out of date. Excepting a slight sprinkling of the author's own papers, there are only nine references to work published after 1970, one on morphology, the rest on mechanical properties. Had work appearing even a few months later been included such erroneous information as e.g. that nitric acid attacks polyethylene in two separate stages (p 72) or that pressure-crystallized polyethylene contains fully-extended molecules (p 182) could have been corrected. Early work on inter- and intra-lamellar deformation was then also available.

The chronological line has, nevertheless, to be drawn somewhere. It is the author's decisions on what to omit from established work which are the more disconcerting. Figure 2.21 is of an energetically vibrating dendrite to illustrate an early idea for the genesis of screw dislocations along re-entrant sector boundaries, but one which can hardly be of general application. Of the more extensive research which established that in non-planar lamellae a deviating sector boundary must lead to the observed overlaps, there is no mention. Nor is there the slightest indication of how morphologically complicated systems other than polyethylene typically are. Most surprising of all, however, is the treatment of spherulites – surely a major point of contact in the relation of properties to structure. Yet the main plank in our understanding of their microstructure, the theory of impurity segregation advanced by Keith and Padden, is referred to only *a propos* dendritic crystallization from solution, a context where mass transport is the dominant diffusion process. In the chapter on melt crystallization the theory is not mentioned. Instead there is a dangerous intermingling of 'dendritic' and 'spherulitic' and Keith and Padden's related work would only have been referred to in passing, as having made measurements on growth rates, had not a whole batch of references on this topic been mistakenly left out of the text.

All things considered, it is undoubtedly useful to have all these topics brought together in a single volume, notwithstanding a certain awkwardness in the sequence of chapters. Indeed any book attempting to fill students' needs in polymer materials science at the present time has to be welcomed. For Professor Schultz's text, however, which in many ways is a disappointment, that welcome must, regrettably, be muted.   *D. C. Bassett*

European Plastics Buyer's Guide 1975

to be published in APRIL

The re-titled *europlastics yearbook* is the ONLY complete guide to the European plastics industry and will be the most extensive yet produced.
The buyer's guide has comprehensive sections on:

- materials and semi-finished products
- plant, ancillary equipment and engineering services
- processing services
- manufactured products and components

There is also an index to products (in English, French, German, Italian and Spanish) and trade names as well as information about more than 12 500 companies.

Price £12 (or £8 to subscribers to *European Plastics News*)

Crosslinked poly [acryloyl *N,N*-bis-(2,2-dimethoxyethyl) amine] and crosslinked poly [acryloylmorpholine/acryloyl *N,N*-bis (2,2-dimethoxyethyl) amine] gel networks and their application to the immobilization of β-D-glucosidase

R. Epton, Barbara L. Hibbert and G. Marr

Department of Physical Sciences, Wolverhampton Polytechnic, Wolverhampton WV1 1LY, UK
(Received 10 October 1974)

The synthesis and homopolymerization of acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine is described. Gel networks were obtained by copolymerization of acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine and *N,N'*-methylenediacrylamide (molar ratio 8:1) and by copolymerization of acryloyl morpholine, acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine and *N,N'*-methylenediacrylamide (molar ratio 8:2:1). Following treatment of the gel networks with tartaric dihydrazide in dilute hydrochloric acid and subsequent activation with nitrous acid, conjugates of β-D-glucosidase were prepared. In both cases the immobilized enzyme was more resistant to heat denaturation than the native enzyme in solution. The nature of the polymer—enzyme linkage is discussed with reference to studies on the model compound phenylacetyl *N,N*-bis(2,2-dimethoxyethyl)amine.

INTRODUCTION

The range of non-ionic, hydrophilic matrices in common use for the immobilization of enzymes is limited to derivatives of polysaccharides, crosslinked polyacrylamide and porous glass[1-3]. There is a need for alternative types of support to provide for enzyme immobilization within micro-environments of differing chemical functionality.

Recently, we have described the synthesis and properties of a new type of support matrix for enzyme immobilization, namely, crosslinked poly(acryloylaminoacetaldehyde dimethylacetal) (Enzacryl® polyacetal)[3]. Controlled acid hydrolysis of this material leads to reactive aldehydrol groups effective in enzyme binding. Immobilization takes place within a novel and intensely hydrophilic micro-environment and in a number of cases the immobilized enzyme exhibits enhanced stability to heat denaturation[4,5].

In view of the efficacy of Enzacryl polyacetal as an enzyme carrier, we have investigated other gel networks of the polyacetal and polyether type. This paper deals with the synthesis of two such materials. The first, crosslinked poly [acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine] is structurally related to Enzacryl polyacetal. The second, a crosslinked copolymer of acryloyl morpholine and acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine, molar ratio 4:1, may be regarded as a functional derivative of crosslinked poly(acryloyl morpholine) (Enzacryl® gel), a hydrophilic matrix introduced recently by us as a packing for gel permeation chromatography. The new gel networks have been evaluated as matrices for the immobilization of the enzyme β-D-glucosidase.

EXPERIMENTAL

Synthesis of N,N-bis(2,2-dimethoxyethyl)amine

Aminoacetaldehyde dimethylacetal (315 g, 3 mol) (Koch-Light Ltd, UK) was added with vigorous mechanical stirring to a slurry of sodium carbonate (212 g, 2 mol) and water (500 cm^3) at 100°C. Bromoacetaldehyde dimethylacetal (355 g, 2 mol) (prepared by the method of Bedoukian[6]) was added slowly over a period of 20 min and the mixture was boiled under reflux for 48 h.

After cooling to 0°C, the organic layer was siphoned off after which the aqueous layer was saturated with sodium chloride and extracted exhaustively with ether. The original organic layer and ether extracts were combined. Evaporation of the ether followed by fractional distillation under reduced pressure gave N,N-*bis(2,2-dimethoxyethyl)amine* (194 g, 39%), b.p. 100–114°C at 5 mmHg, η_D^{25}1.42687, ν_{max} (liquid film) 3325 (amine N–H str.), 1130 and 1080 cm^{-1} (acetal C–O str.), δ (CDCl$_3$; 60 MHz) 1.42 (H, bs, CH$_2$NHCH$_2$), 2.75 (4H, d, $J \sim$ 2 Hz, NHCH_2CH), 3.30 [12H, s, CH(OCH_3)$_2$] and 4.42 ppm [2H, t, $J \sim$ 6 Hz, CH$_2$CH(OCH$_3$)$_2$]. (Found: C, 49.32; H, 10.71; N, 6.92; O, 33.60%. C$_8$H$_{19}$NO$_4$ requires C, 49.73; H, 9.91; N, 7.25; O, 33.12%.) A higher boiling fraction proved to be N,N,N,-*tris(2,2-dimethoxyethyl)amine* (88.1 g, 19%), b.p. 130–

132°C at 5 mmHg, η_D^{25} 1.42886. (Found: C, 50.99; H, 9.73; O, 34.25; N, 5.16%. $C_{12}H_{27}NO_6$ requires C, 51.23; H, 9.68; O, 34.24; N, 4.98%.)

Synthesis of acryloyl N,N-bis(2,2-dimethoxyethyl)amine

Peroxide-free, dry ether was used throughout this experiment. Acryloyl chloride (4.52 g, 0.05 mol) (Koch-Light Ltd, UK) in ether (100 cm³) was maintained at 0°C and a mixture of N,N-bis(2,2-dimethoxyethyl)amine (19.3 g, 0.10 mol) and ether (100 cm³) was added dropwise, with mechanical stirring, over 0.5 h. The reaction mixture was stirred for a further 0.5 h after which the precipitate of N,N-bis(2,2-dimethoxyethyl)amine hydrochloride was removed by filtration and washed with ether (10 cm³). Evaporation of the combined ether solutions gave *acryloyl N,N-bis(2,2-dimethoxyethyl)amine* (11.9 g, 97%) b.p. 120–123°C at 1 mmHg, η_D^{25} 1.46061, ν_{max} (liquid film) 1650 (amide C=O str.), 1130 and 1080 cm⁻¹ (acetal C–O str.), δ (CDCl₃; 60 MHz) 3.45 [16H, CH(OCH₃)₂ and NCH₂CH] 4.48 [2H, m, J ~ 12 Hz, CH₂CH(OCH₃)₂], 5.65 (H, dd, J ~ 8 and 5 Hz, CH₂=CHCO) and 6.45 ppm (2H, m, CH₂=CHCO). (Found: C, 53.25; H, 8.66; N, 5.60; O, 32.47%. $C_{11}H_{21}NO_5$ requires C, 53.49; H, 8.57; N, 5.67; O, 32.39%.)

Preparation of polymers

Poly[acryloyl N,N-bis(2,2-dimethoxyethyl)amine]. The monomer (4.94, 0.02 mol) was mixed with deoxygenated 80% ethanol/water (9 cm³). An aliquot (1 cm³) of a solution of 0.5% w/v ammonium persulphate in the same solvent was added and the mixture was maintained at 40°C for 3 days. The resulting viscous solution was diluted with ethanol, poured into an excess of distilled water and the precipitate was collected by filtration. Removal of excess solvent by lyophilization gave pure *poly[acryloyl N,N-bis(2,2-dimethoxyethyl)amine]* (3.75 g, 75%). (Found: C, 53.47; H, 8.77; O, 32.32; N, 5.53%. $C_{11}H_{21}NO_5$ requires C, 53.49; H, 8.57; O, 32.39; N, 5.67%.) Intrinsic viscosity = 0.57 dl/g at 25°C (CHCl₃), ν_{max} (film) 1645 (amide C=O str.), 1090 and 1130 cm⁻¹ (acetal C–O str.). The homopolymer is soluble in acetone, benzene, carbon tetrachloride, chloroform, ethanol and ether but is insoluble in methanol, light petroleum and water.

Polymerization of acryloyl N,N-bis(2,2-dimethoxyethyl)amine in aqueous solution led to direct precipitation of the homopolymer.

Crosslinked poly[acryloyl-N,N-bis(2,2-dimethoxyethyl)amine] was prepared in gel form in 80% ethanol/water. The technique was similar to that described for the homopolymer, acryloyl-N,N-bis(2,2-dimethoxyethyl)amine (4.9 g, 0.020 mol) and the crosslinker, N,N′-methylenediacrylamide, (0.38 g, 0.0025 mol) being dissolved in a mixture of deoxygenated 80% ethanol/water (13 cm³) and 0.5% w/v ammonium persulphate solution (2 cm³). The block of gel obtained was broken up in a mortar, pressed several times through a wire sieve (75 μm) and stored in suspension in ethanol/water. The weight of the crosslinked poly[acryloyl N,N-bis(2,2-dimethoxyethyl)amine], (copolymer A) was 2.5 g (40%) (estimated by drying out a sample of the hydrated gel).

Crosslinked poly[acryloyl morpholine/acryloyl N,N-bis(2,2-dimenthoxyethyl)amine] molar ratio 4:1, was obtained as gel beads by aqueous suspension polymerization in liquid paraffin. Liquid paraffin (100 cm³) (ρ^{20} 0.85 g/

cm³), η^{20} 3.5–4.0 N sec m⁻²) and a surfactant mixture, HLB[7] 3.0, consisting of sorbitan trioleate (7 cm³) and polyoxyethylene(20)sorbitan trioleate (1 cm³) were placed in a 500 cm³ glass polymerization vessel fitted with a semicircular paddle stirrer. Nitrogen was bubbled through the mixture for 1 h after which a nitrogen atmosphere was maintained in the flask. A saturated solution of potassium persulphate in water (1 cm³) was added rapidly, with stirring to an oxygen-free solution of acryloyl morpholine (2.27 g, 0.016 mol), acryloyl N,N-bis(2,2-dimethoxyethyl)-amine (0.99 g, 0.004 mol) and N,N′-methylenediacrylamide (0.030 g, 0.0002 mol) in distilled water (32 cm³). The solution of monomers was added immediately to the paraffin in the polymerization vessel and the stirring rate was adjusted to give droplets of approximately 10–40 μm. Polymerization was evident within 1 h and was assumed to be complete in 5 h.

After allowing the gel beads to settle overnight, most of the paraffin was decanted and the beads were washed three times with light petroleum ether (b.p. 40–60°C) (500 cm³). three times with acetone (500 cm³) and three times with distilled water (500 cm³). The beads were stored in suspension in distilled water. The weight of the crosslinked copolymer matrix, (copolymer B) within the gel was 3.1 g, (97%) (estimated by drying out a sample of the hydrated gel).

Synthesis of phenylacetyl N,N-bis(2,2-dimethoxyethyl)amine

N,N-bis(2,2-dimethoxyethyl)amine (9.70 g, 0.05 mol) was mixed with dry ether (75 cm³) and maintained at 0°C with magnetic stirring while a solution of phenylacetyl chloride (4.0 g, 0.026 mol) in dry ether (25 cm³) was added. Stirring was continued for 0.5 h after which the reaction mixture was filtered and the precipitate of N,N-bis(2,2-dimethoxyethyl)amine hydrochloride was discarded. On evaporation of the ether solution a yellow oil was obtained which was repeatedly triturated with 2 M aqueous sodium hydroxide solution, washed with distilled water and taken up in light petroleum ether (b.p. 40–60°C). After drying over anhydrous magnesium sulphate the solution was chilled to −78°C to precipitate phenylacetyl N,N-bis(2,2-dimethoxyethyl)amine (8.02 g, 62%) ν_{max} (liquid film) 1650 (amide C=O str.), 1130 and 1080 cm⁻¹ (acetal C–O str.), δ (CCl₄; 60 MHz) 3.30–3.48 [16H, CH(OCH₃)₂ and NCH₂CH], 3.65 (2H, s, C₆H₅CH₂CO), 4.08–4.40 [2H, m, CH₂CH(OCH₃)₂] and 7.15 ppm (5H, s, C₆H₅). (Found: C, 61.68; H, 8.34; N, 5.07%. $C_{16}H_{25}NO_5$ requires C, 61.17; H, 8.42; N, 4.50%.)

Studies on phenylacetyl N,N-bis(2,2-dimethoxyethyl)amine

Acid hydrolysis. This reaction was investigated by dissolving the amine (0.5 cm³) in an aliquot (4.5 cm³) of a solution of 2 M DCl in D₂O/CH₃OD (1:1, v/v) and following the change in the p.m.r. spectrum over 24 h (*Figure 3*). The hydrolysis was repeated using H₂O/CH₃OH over the same period, after which the reaction mixture was neutralized with the minimum amount of Na₂CO₃ and the solvent was removed under high vacuum at 25°C over 24 h to give a clear viscous oil δ (CHCl₃; 60 MHz) 2.65 (4H, d, J ~ 5 Hz, NCH₂CH), 3.55 (2H, s, C₆H₅CH₂CO), 4.30 [2H, t, J ~ 5 Hz, CH₂CH(OH)O], 7.15 (5H, s, C₆H₅CH₂) and 7.95–8.35 (D₂O labile) ppm (2H, b s, CH(OH)O).

Acid mediated reaction with acetyl hydrazide. A solution of amine (0.1 cm³) and acetyl hydrazide (0.1 g) in D_2O/CD_3OD (1:1, v/v) (1 cm³) was prepared and a control p.m.r. spectrum recorded δ (60 MHz) 1.82 (s, $CH_3CONHNH_2$), 3.29 [12H, s, $CH(OCH_3)_2$], 3.48 (4H, d, $J \sim 5Hz$, NCH_2CH), 3.70 (2H, s, $C_6H_5CH_2CO$), 4.35 [2H, m, $CH_2CH(OCH_3)_2$] and 7.16 ppm (5H, s, C_6H_5). A reaction solution consisting of amine (0.1 cm³) and acetyl hydrazide (0.1 g) in 5 M DCl in D_2O/CD_3OD (1 cm³) was prepared and the p.m.r. spectrum recorded after 1 h at 25°C, δ (60 MHz) 1.82 (s, $CH_3CONHNH_2$), 3.25 [2H, s, possibly $CD_2CH(N)O$] and 7.15 ppm (5H, s, C_6H_5).

Activation of copolymer gels and coupling with β-D-gluco-sidase

Samples of the solvated (gel) copolymers A and B were suspended in separate aliquots of a 5% w/v solution of tartaric acid dihydrazide[8] in 1 M HCl. After 18 h at ambient temperature each gel was washed with distilled water until tartaric acid dihydrazide could no longer be detected in the washings on testing with trinitrobenzene sulphonic acid reagent[9].

For enzyme coupling samples of both treated gels (each equivalent to 100 mg of dry copolymer) were equilibrated with 2 M HCl. After centrifuging and discarding the supernatant, each gel was resuspended in an aliquot (5 cm³) of 2 M HCl, cooled to 0°C with magnetic stirring, and an aliquot (4 cm³) of ice-cold 2% sodium nitrite solution was added. Reaction was allowed to proceed for 15 min. The gels were washed four times with aliquots (10 cm³) of 50 mM acetate buffer (pH 5.5). Each washing was of 3 min duration and was carried out with magnetic stirring at 0°C. After discarding the final washings an aliquot (0.5 cm³) of a 1% w/v solution of β-D-glucosidase (ex. sweet almonds, Koch-Light Ltd UK) in 50 mM acetate buffer was added to each gel and coupling allowed to proceed for 18 h at 0–4°C with magnetic stirring. The resulting conjugates were subjected to five washing cycles each consisting of a wash with an aliquot (15 cm³) of 50 mM acetate buffer (pH 5.5) and a wash with an aliquot (15 cm³) of 1 M sucrose in 1 M NaCl solution. The β-D-glucosidase conjugates derived from copolymers A and B, designated conjugate AG and conjugate BG respectively, were each suspended in acetate buffer (10 cm³), and stored at 0–4°C.

Determination of immobilized protein

The amino acids produced on hydrolysis of samples of each conjugate by treatment with 6 M HCl at 110°C for 18 h were separated into groups[10] by paper chromatography and estimated by quantitative ninhydrin determination[11]. A standard graph, obtained on chromatographic assay of a hydrolysate of β-D-glucosidase was used to calculate the amount of bound protein originally present in the conjugates.

Determination of β-D-glucosidase activity

The method due to Agrawal and Bahl[12] was adapted. A solution of the substrate p-nitrophenyl β-D-glucopyranoside (75 mg) in 50 mM sodium acetate buffer (pH 5.5, 10 cm³) was prepared immediately prior to each determination. This solution was stirred magnetically and maintained at 30°C. An aliquot (0.25 cm³) of conjugate suspension was added. At intervals, samples (0.25 cm³) of the reaction mixture were withdrawn, diluted with 200 mM aqueous sodium carbonate solution (0.7 cm³) and centrifuged briefly. The change in extinction (420 nm) recorded was related to p-nitrophenol concentration with the aid of a standard graph. One unit of β-D-glucosidase activity was taken to be that which released one μmol of p-nitrophenol in 1 min.

Stability of immobilized β-D-glucosidase

Heat stability was determined on incubation of samples of the conjugates in suspension in 25 mM acetate buffer (pH 5.5 at 50°C). Enzyme activity was determined at intervals. A control experiment was performed using a solution of the native enzyme in the same buffer.

Storage stability was evaluated by re-determining the activity of each conjugate after 8 weeks in suspension at 0–2°C in 25 mM acetate buffer (pH 5.5).

RESULTS AND DISCUSSION

For an enzyme to retain significant bio-catalytic activity following immobilization it must remain accessible to its substrate in solution. One of the best ways of ensuring this is to effect immobilization by anchorage of the dissolved enzyme molecule to the solvated, three dimensional, space network of polymer chains of a typical xerogel matrix. Coincidentally, high enzyme binding capacities result from this technique. The potential to form an aqueous xerogel is a desirable property in any organic matrix intended for use as an enzyme support.

Crosslinked poly(acryloylaminoacetaldehyde dimethylacetal) (*Figure 1a*) undergoes gelation readily in water and synthesis of the copolymer in this solvent results inevitably in xerogel formation. Since the hydrophilic nature of the copolymer arises as a result of its pendant dimethylacetal groups, it seemed reasonable to expect that crosslinked poly-[acryloyl *N,N*-bis-(2,2-dimethoxyethyl)amine (*Figure 1b*) would also be obtained in gel form if synthesized in water. However, this approach resulted merely in precipitation of the crosslinked polymer from solution.

It was observed that poly[acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine] could be prepared by solution polymerization in 80% ethanol/water. This homopolymer proved to be insoluble in pure water but could be brought into solution on hydrolysis of some of the dimethylacetal groups with dilute acid. Subsequently, successful experiments were conducted in which a xerogel network incorporating crosslinked poly[acryloyl *N,N*-bis-(2,2-dimethoxyethyl)-amine (copolymer A) was prepared by direct copolymerization in 80% ethanol/water and activated for enzyme coupling in an aqueous acid reaction medium. This ensured that the copolymer remained in solution both during the activation process and the concurrent substitution of water as the solvent component of the xerogel.

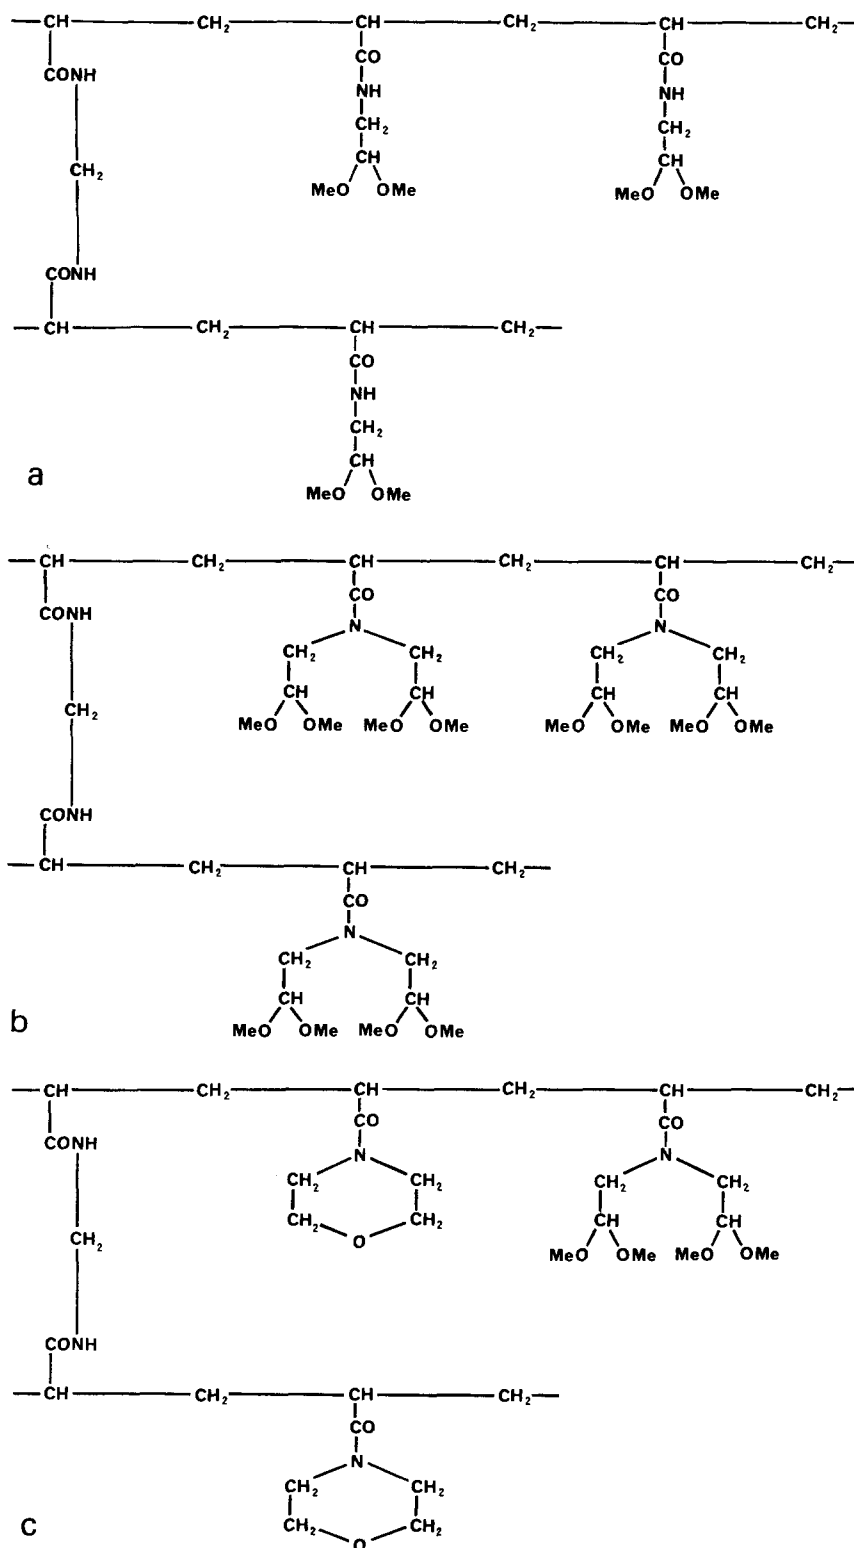
Acryloyl *N*, *N*-bis(2,2-dimethoxyethyl)amine is related structurally to acryloyl morpholine and the two monomers copolymerize readily. Crosslinked poly(acryloyl morpholine) is a relatively cheap copolymer which is known to form xerogel networks readily[13,14]. Recently these have been characterized quite rigorously[15]. Furthermore these networks may be prepared in bead form by aqueous suspension polymerization in liquid paraffin. It was evident that the crosslinked poly(acryloyl morpholine) matrix had considerable potential as an enzyme support provided that a way of introducing the necessary groups functionally active binding could be devised. It was with this in mind that an aqueous xerogel network incorporating the crosslinked poly-


Figure 1 (a) Crosslinked poly(acryloylaminoacetaldehyde dimethylacetal); (b) crosslinked poly[acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine]; (c) crosslinked poly[acryloyl morpholine/acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine]

[acryloyl morpholine/acryloyl *N,N*-bis(2,2-dimethoxyethyl)-amine] matrix (copolymer B) (*Figure 1c*) was synthesized. Copolymer B may be regarded essentially as a substituted poly(acryloyl morpholine) since acryloyl morpholine is used in four fold excess for its preparation.

Controlled acid hydrolysis of homopolymeric poly-[acryloyl *N,N*-bis(2,2-dimethoxyethyl)amine] or its cross-linked analogue, copolymer A, does not lead to the exten-sive generation of aldehydrol groups, as in the related hydro-

lysis of poly(acryloylaminoacetaldehyde dimethylacetal). Consequently, the aldehydrol enzyme binding reaction was impractical in this work and it was necessary to adopt the reaction scheme outlined in *Figure 2*.

It is probable that acid hydrolysis of the *N,N*-bis(2,2-dimethoxyethyl)amine residues lead to pyranose rings of the bis-hemiacetal type which, in the absence of other reactive species, condense spontaneously with their near neighbours to give acetal linkages. Such behaviour has been
Figure 2 Reaction scheme for the immobilization of β-D-glucosidase

observed in the case of polyacraldehyde. With this polymer aldehyde or aldehydrol groups condense spontaneously to give an extended system of fused pyran rings[16].

Evidence for a pyranose bis-hemiacetal structure has been obtained from p.m.r. studies on the DCl catalysed hydrolysis of the model compound phenylacetyl N,N-bis-(2,2-dimethoxyethyl)amine in D_2O/CD_3OD as solvent. It is evident from *Figure 3* that the broad symmetrical signal at δ 4.75 ppm arising from the methine protons of the two $CH_2CH(OCH_3)_2$ groups is replaced, on hydrolysis, by simple triplets, δ 4.73 and 4.94 ppm integrating for 0.6 and 1.4 protons respectively. Non-equivalent integration and chemical shifts might arise if two types of molecule, with methine protons in different chemical environments, are formed. This could be consistent with a mixture of structural units of the type:

Attempts to isolate the products of acid hydrolysis of phenylacetyl N,N-bis(2,2-dimethoxyethyl)amine from larger scale experiments in water resulted in degeneration of the methine proton signal. This suggests possible reversion to a more stable structural unit. It is significant that the p.m.r. spectrum of the aqueous hydrolysis product exhibited a signal, δ 7.95–8.35 ppm, corresponding to two deuterium labile protons. Almost certainly, these are the two hydroxyl groups of the pyranose bis-hemiacetal.

In the activation of copolymers A and B for enzyme coupling, acid hydrolysis was carried out in the presence of tartaric dihydrazide, a water-soluble, bifunctional, reagent. By this device it was possible to exploit the activity of the hemi-acetal and any aldehydrol groups before extensive homocondensation could take place. The exact course of

reaction with tartaric dihydrazide is difficult to study. However, it would seem likely that, as in the reaction of a simple hexose with a single molecule of a substituted hydrazide, the pyranose ring may be preserved[17].

An attempt to obtain direct evidence for the pyranose intermediate by means of a p.m.r. study of the DCl mediated condensation between the model compounds acetyl hydrazide and phenylacetyl N,N-bis(2,2-dimethoxyethyl)amine was made. This was complicated by the relatively high reagent concentrations necessary in order to obtain an acceptable signal to noise ratio. Owing to the high DCl concentration a number of the more active protons in the reacting amine were replaced by deuterium. However, it is significant that no peak between δ 7.8 and 8.0 ppm, characteristic of the non-labile azomethine proton, was recorded.

Enzyme coupling to the two copolymers was effected following conversion of the pendant acyl hydrazide residues to acyl azide groups. Acid azide coupling is well established as an immobilization procedure[18]. The protein bound in the β-D-glucosidase conjugate AG, 12 mg/g and the β-D-glucosidase conjugate BG, 42 mg/g reflects the relative gelation and swelling properties of the respective copolymers, A and B, from which they are derived. The xerogel network derived from crosslinked poly(acryloyl morpholine) (copolymer B) was much the easier to prepare.

In common with most enzymes, the activity of β-D-glucosidase diminished on immobilization. The β-D-glucosidase activities per mg of bound protein in conjugates AG and BG were 2.58 and 0.66 enzyme units respectively while the activity of the native enzyme was 20.50 units per mg. The respective activity retentions of conjugates AG and BG were thus 12.8 and 3.2%. No change in pH–activity profile occurred on immobilization. Rigorous tests for re-solubilized β-D-glucosidase activity in the supernatant solutions derived from centrifuged incubation mixtures involving the two conjugates proved negative.

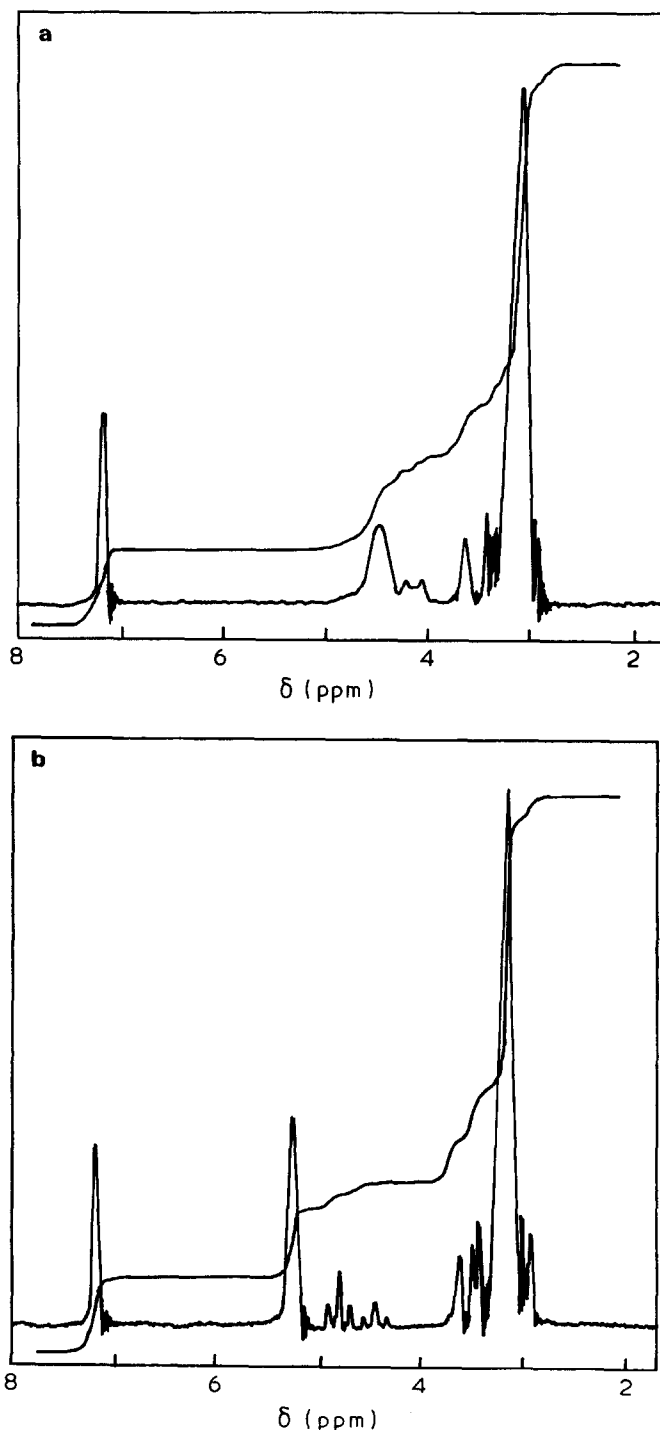
Previous workers have immobilized β-D-glucosidase by covalent coupling to the semi-synthetic carrier, cellulose *trans*-2,3-carbonate[19] and to the totally synthetic carrier, poly(allyl carbonate)[20]. In the case of cellulose *trans*-2,3-carbonate the amount of enzyme bound was too low (<0.2 mg/g of carrier) to estimate accurately. Poly(allyl carbonate) was effective in binding up to 6 mg of β-D-gluco-


Figure 3 Proton magnetic resonance study of the acid catalysed reaction of phenylacetyl *N,N*-bis(2,2-dimethoxyethyl)amine with D$_2$O. (a) Spectrum before addition of DCl: δ 3.30—3.48 [16H, NC*H*$_2$CH and CH(OC*H*$_3$)$_2$], 3.65 (2H, s, C$_6$H$_5$C*H*$_2$CO), 4.08—4.40 [2H, m, CH$_2$C*H*(OCH$_3$)$_2$], 4.49 (*H*OD) and 7.15 ppm (5H, s, C$_6$*H*$_5$). (b) Spectrum after DCl catalysed hydrolysis: δ 3.15—3.45 (NC*H*$_2$CH and C*H*$_3$OD), 3.60 (2H, s, C$_6$H$_5$C*H*$_2$CO), 4.73 [0.6H, t, *J* ~6 Hz, possibly CH$_2$C*H*(OH)OCH or CH$_2$C*H*(OH)$_2$], 4.94 [1.4H, t *J* ~ 6 Hz, possibly CH$_2$C*H*(OH)OCH or CH$_2$C*H*(OH)$_2$], 5.27 (*H*OD) and 7.15 ppm (5H, s, C$_6$*H*$_5$)
Figure 4 Heat denaturation of soluble and immobilized forms of β-D-glucosidase on incubation in acetate buffer at 50°C. ●, β-D-glucosidase conjugate AG; ▲, β-D-glucosidase conjugate BG; □, soluble β-D-glucosidase

sidase per g of carrier although, under reaction conditions most effective for retention of enzyme activity, the binding capacity was lower (2 mg/g of carrier). Probably the much higher binding capacities obtained in the present studies is a result of effecting immobilization by means of a xerogel network rather than a classical solid support.

The retention of enzyme activity per mg of protein immobilized in conjugates AG and BG was inferior to that of the most active β-D-glucosidase—poly(allyl carbonate) derivative (30%). However, it is apparent that the overall activity of conjugate BG was similar to that of the poly-(allyl carbonate) derivative and that of conjugate AG was much better. High overall activity is important for any conjugate in practical applications.

A pleasing feature of the conjugates of this report was the enhanced stability to heat denaturation of the immobilized enzyme as compared to the native enzyme in solution. This property is exhibited by relatively few enzyme—polymer conjugates[1]. It is apparent from *Figure 4* that, whereas the β-D-glucosidase—copoly(acryloyl morpholine) conjugate BG is the more stable initially to heat denaturation, it is less stable, over a longer period, than the conjugate AG derived from poly[acryloyl *N,N*-bis-(2,2-dimethoxyethyl)amine]. This result reflects the activity retentions of conjugate AG (79%) and conjugate BG (28%) on storage in acetate buffer suspension for 2 months at 0–2°C.

These studies demonstrate that xerogel networks derived from crosslinked poly[acryloyl *N,N*-bis(2,2-dimethoxyethyl)-amine] and poly[acryloyl morpholine/acryloyl *N,N*-bis-(2,2-dimethoxyethyl)amine] are viable supports for the immobilization of β-D-glucosidase. As totally synthetic materials they are non susceptible to microbial attack. It is probable that they would be effective for the immobilization of other enzymes. This is of some importance since both provide for enzyme immobilization within a new and distinctive chemical micro-environment.

Study of relationship between network structure of g.p.c. gels and molecular size of permeable substance

Y. Motozato, N. Kusumoto*, C. Hirayama, R. Murakami[†] and H. Isozaki
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860, Japan
(Received 17 April 1974; revised 6 January 1975)

Attempts were made to correlate the average size of the network of crosslinked vinyl acetate–glycidyl methacrylate (GMA) copolymer to the maximum size of permeable molecules when the copolymers were used as g.p.c. packing materials. The root-mean-square of the end-to-end distance $(\overline{r^2})^{1/2}$ and of the hydrodynamic radius $(\overline{s^2})^{1/2}$, which characterizes the maximum extent of the molecules, were calculated. Meanwhile, the average size of the copolymer network, r_c, was estimated from the average molar weight between crosslinkages, this being calculated from the equilibrium rubber elastic modulus, E_r, obtained by dynamic viscoelastic measurements. It was found that the maximum size which can permeate the copolymer decreases as the content of GMA in the copolymer increases. From viscoelastic measurements, E_r was found to increase as the content of GMA in the copolymer increases. Further, linear relationships were obtained among r_c, $(\overline{r^2})^{1/2}$, and $(\overline{s^2})^{1/2}$ covering the wide range of the copolymer composition.

INTRODUCTION

Recently, many studies on synthesis of packing materials for gel permeation chromatography (g.p.c.) and its application have been made. G.p.c. seems to now be accepted as a useful tool for separating high polymers according to molecular size.

For separation of hydrophobic polymers polystyrene gel[1] and poly(vinyl acetate) gel[2,3] and for hydrophilic polymers dextran gel[4], agar gel[5] and polyacrylamide gel[6] have been described. The authors have studied the synthesis of vinyl acetate–glycidyl methacrylate (VAC–GMA)copolymer[7,8]. These gels can be classified into two prototypes: one is a homogeneous gel which separates substances by its network swelled in a solvent; and the other is a heterogeneous gel which separates substances by its so called macroreticular structure.

The size of the network of homogeneous gels is represented by the crosslinking density, which is usually represented by the charge amount of the crosslinking agent. However, the relation between the network size and the size of permeable substances has not yet been described. Therefore, the present work aims to correlate the network size of homogeneous gel of VAC–GMA copolymer to the molecular size of the permeable substance.

EXPERIMENTAL

Preparation of gel plates and beads

Commercial VAC monomer was purified by distillation under atmospheric pressure at its boiling point of 72.5–73.0°C. GMA was distilled at 75–80°C under 4–5 mmHg. The purified VAC and GMA were mixed at the ratios listed in *Table 1*, and then 1 wt % of benzoyl peroxide (BPO) was added as initiator. A polyethylene gasket of 0.4 mm thickness was placed between glass plates (8 x 4 x 0.3 cm). and the gap between the plates was filled with the monomer mixture. The polymerization was carried out at 55°C for 24 h.

To obtain the g.p.c. packing material, suspension polymerization was conducted as follows. A water system was prepared by dissolving 5 g of gelatin in 400 ml of distilled water. A monomer mixture the same as that mentioned above was suspended in the water system and reacted at 60–65°C for 7 h under continuous agitation to form beads of the copolymer; calcium carbonate was used as a stabilizer. Then, the beads were washed with 1 N hydrochloric acid and hot water to remove the calcium carbonate and gelatin.

G.p.c. operation

Substances with different molecular sizes are separated on the basis of the difference in permeability of the substances in the gels. The large molecules which cannot permeate the gel are first eluted at a volume equal to the interstitial volume of the gel beads. Smaller molecules can

E8	PEG	28 300	2

permeate the gel and are delayed. The gel was packed into a glass column with a diameter of 0.75 cm, 120 cm long, and then 0.3 ml of 2% sample was eluted at room temperature with dimethylformamide as eluant at 0.85 ml/min. Ethylene glycol (EG), oligo(ethylene glycol) (OEG) and poly(ethylene glycol) (PEG) with different molecular weights were used, as listed in *Table 2*. Quantitative analysis of the effluent was made using a differential refractometer (Waters Associates, Model 403).

The calibration curves were obtained by plotting the average molecular weights against the peak elution volumes. Further, the straight line at the centre of the calibration curve was extrapolated to the outer volume and the excluded molecular weight, M_{lim}, was obtained.

Viscosity measurements

The viscosity of DMF solution was measured for PEG samples differing in molecular weight using a Ubbelohde viscometer at 30°C, and an experimental viscosity equation was obtained.

Ebrioscopy

The molecular weight of the sample, M_n, was estimated by ebrioscopy using an ebriometer (Takara Kogyo, Model L4). Benzene was used as solvent.

Density measurement

The density of the copolymer at room temperature was measured by the flotation method using a water–$CaCl_2$ system. Further, dilatometry was carried out to obtain the density at higher temperatures by raising the temperature at the rate of 0.5°C/min.

Viscoelastic measurements

Dynamic viscoelastic measurements were carried out for the sheets of the copolymer by using the direct reading dynamic viscoelastometer (Toyo-Bouldwin, Vibron Model DDV-1).

RESULTS AND DISCUSSION

Temperature dependency of viscoelastic properties

Figure 1 shows the variation of the dynamic storage modulus, E' with temperature for the copolymer. In this Figure for GMA copolymer a rapid decrease of E' can be seen around 60°C, after which it becomes constant again at around 140°C. This region, where E' rapidly decreases, corresponds to the glass transition at which micro-Brownian motion of chain segments takes place. The rubbery plateau is at higher temperatures. The lowest curve in the Figure is for the VAC homopolymer, and the curves between those for GMA and PVAC were obtained for the copolymers differing in content of VAC and GMA. The copolymers show

similar viscoelastic behaviour to that of PGMA, but the temperature region where the glass transition occurs shifts to lower temperatures as the content of VAC increases. PVAC shows a somewhat different curve; a more rapid decrease of E' is seen compared with the copolymers.

Change of density with composition of gel

Figure 2 shows plots of the density of the copolymers measured at 20°C and 160°C against composition of the copolymer. The curves at 20°C are similar to those at 160°C, with a rapid change occurring near 50% VAC content.

Average molar weight between crosslinkages

According to the theory of rubber elasticity the rubber elastic modulus E_r is related to the average molecular weight between the crosslinks by the following equation[9]:

$$M_c = 3\rho RT/E_r \tag{1}$$

where ρ is the density of the copolymer, R is the gas content, and T is absolute temperature.

In the present study, the dynamic storage modulus E' in the rubbery plateau in *Figure 1* can be taken as E_r. E_r and ρ at 160°C were taken although E_r shows some tendency to continue to decrease, since this temperature is the maximum achieved in this experiment. For samples F-4 and F-5, E_r at 160°C was obtained by extrapolating the curves to 160°C. E_r of the samples whose VAC content is more than 70% was hard to estimate.

Figure 3 shows plots of M_c calculated from equation (1) against copolymer composition. M_c is found to decrease as the content of GMA increases. This fact indicates that GMA acts as crosslinking agent, and the larger the content of GMA, the larger the crosslinking density becomes. The relation between composition of the copolymer and net-
Figure 1 Plots of E' versus temperature. O, F-1; ▲, F-2; ∇, F-3; □, F-4; ●, F-5; △, F-6; ▼, F-7
Figure 2 Plots of density *versus* composition of copolymer. ○, 20°C; ●, 160°C

that M_{lim} is shifted to higher molecular weights. This is in accordance with the results obtained for the poly(vinyl alcohol) gel in the previous work[7]. A similar result has also been shown by Heitz for PVAC gel[2].

Figure 6 shows the relation between M_{lim} and the molecular composition of the gels. The value of M_{lim} is found to be dependent on the composition of the gels. The larger the content of GMA, which may partially act as a cross-linking agent, the smaller the value of M_{lim}, i.e. it becomes more difficult for molecules with large molecular weight to permeate as the content of GMA increases.

Extent of permeable molecules with maximum size

M_{lim} gives a measure of molecular size in relation to the network of the gels, but the actual extent of the molecules in a solution depends on the eluant used for g.p.c. Therefore, it is desirable to estimate the actual molecular size in

work radius, r_c, is also shown in *Figure 3*. The value of r_c was derived from M_c and the average molar weight of the repeating unit of the copolymer, assuming that the molecules in the network structure are completely extended and the network is a circle. Similar to M_c, r_c decreases as the GMA content increases. The gel swells and the chains between the crosslinks are extended in an eluant. However, r_c calculated assuming that the chains take the completely extended structure may be larger than the actual size in the equilibrium swelling state.

Change of degree of swelling with composition of gel

Figure 4 shows plots of the degree of swelling of the gels in DMF, THF, benzene, and methanol against composition of the gel. The swelling is largest for DMF and becomes smaller in the order of THF, benzene and methanol. In the case of methanol and benzene a maximum is seen for the composition VAC–GMA = 70:30, but is not seen for DMF and THF. In this study, DMF was selected as an eluant, since it shows the maximum swelling, the data obtained will be suitable for discussions related to the network size estimated from the viscoelastic data.

G.p.c.

Figure 5 shows the g.p.c. calibration curves for EG and PEG with different molecular weights using DMF as eluant. It is found that these gel systems have similar line shape, but are different in the elution point where the vertical line crosses the inclined one except for the G-2 gel, indicating

an eluant to discuss the relation between r_c and the molecular size. For this purpose, the root-mean-square end-to-end distance $(\overline{r^2})^{1/2}$ and the root-mean-square hydrodynamic radius $(\overline{s^2})^{1/2}$ were first estimated by the method of Ptitsyn and Eizner[11]:

$$[\eta] = \Phi(\epsilon)(\overline{r^2})^{1/2}/M = \Phi(\epsilon)(\overline{s^2})^{1/2}/\sqrt{6}\,M \qquad (2)$$

$$\Phi(\epsilon) = 2.86 \times 10^{23}(1 - 2.63\epsilon + 2.86\,\epsilon^2) \qquad (3)$$

where $[\eta]$ is the intrinsic viscosity and M is the molecular weight. ϵ is determined by the exponent of the viscosity equation (5) as follows.

$$\alpha = (1 + 3\,\epsilon)/2 \qquad (4)$$

in the range of molecular weight of the all samples except for EG. The viscosity equation obtained is:

$$[\eta] = KM^\alpha \qquad (5)$$

$$K = 6.14 \times 10^{-4}, \quad \alpha = 0.63$$

As to the determination of the value of Φ, it has been pointed out that Φ depends on molecular weight[11]. However, the values of $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$ estimated using the method of Kirkwood and Riseman were not found to differ significantly from those of Ptitsyn and Eizner[10]. According to their theory, the exponent of the viscosity relation varies with molecular weight, but in our case variation of the exponent can be ignored so that the results obtained are reliable in the range of the present work.

Figure 7 shows the logarithmic plot of $(\overline{r^2})^{1/2}$ and

$(\overline{s^2})^{1/2}$ against composition of the gel. It should be noticed that parallel relations are seen among r_c, $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$, covering the wide range of gel composition. The value of r_c lies between those of $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$. It thus seems satisfactory that r_c obtained by viscoelastic measurement is comparable with $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$ obtained by the viscosity equation. From these parallel relations it follows that r_c is proportional to $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$ as follows:
Figure 6 Plot of M_{lim} *versus* composition of copolymer.
Figure 7 Plots of r_c, $(\overline{r^2})^{1/2}$ and $(\overline{s^2})^{1/2}$ *versus* composition of copolymer. ○, r_c; △, $(\overline{r^2})^{1/2}$; □, $(\overline{s^2})^{1/2}$

$$r_c = 0.55 \, (\overline{r^2})^{1/2} = 1.33 \, (\overline{s^2})^{1/2} \tag{6}$$

The discrepancy between r_c and the molecular size $(\overline{r^2})^{1/2}$ may come from the fact that $(\overline{r^2})^{1/2}$ is related to the maximum network size, while r_c is the average size. This discrepancy may be decreased as the homogeneity of the network structure increases.

The value of the exponent of equation (5), 0.63, suggests that the molecular shape in the eluant is almost spherical. As a result, the above relations give us a clear microscopic view that in g.p.c. operations the molecular spheres are passing through the swollen networks whose size is proportional to, or larger than, the sphere.

CONCLUSION

Linear relations were found among the size of the network of the VAC—GMA copolymer gel and the root-mean-square end-to-end distance and the root-mean-square hydrodynamic radius of molecules in DMF eluant when the gels were used as g.p.c. packing materials covering a wide range of copolymer composition.

Stress – strain isotherms and thermoelastic properties of crosslinked amorphous polyoxyethylene in compression

C. U. Yu and J. E. Mark

Department of Chemistry and the Macromolecular Research Center, University of Michigan, Ann Arbor, Michigan 48104, USA
(Received 22 July 1974)

Stress–strain isotherms at a number of temperatures in the range 45–85°C have been determined for a compressed, amorphous polyoxyethylene network swollen with a constant amount of non-volatile diluent. The observed isotherms showed much smaller departures from the form indicated by the molecular theories of rubberlike elasticity than is generally the case for polymer networks in elongation. The thermoelastic behaviour of the network was characterized by the dependence of the stress on temperature at constant deformation. The value of the temperature coefficient of the unperturbed dimensions of polyoxyethylene calculated from these data is in good agreement with values obtained both from thermoelastic measurements on polyoxyethylene networks in elongation, and from viscosity–temperature studies on isolated polyoxyethylene chains in a thermodynamically good solvent.

INTRODUCTION

It has recently been demonstrated that it is quite feasible to use compression measurements to study both stress–strain relationships and stress–temperature coefficients of amorphous polymer networks[1]. In such studies, it is frequently most convenient to determine stress–strain isotherms, at a number of temperatures. One thereby immediately obtains information on the degree to which the observed isotherms differ from the form indicated by the statistical or molecular theories of rubberlike elasticity[2]. In addition, such a series of isotherms directly provides values of the stress as a function of temperature at fixed deformation. As has now been well established, such 'thermoelastic' data may be used to calculate both the fraction f_e/f of the stress which is due to energetic effects, and the temperature coefficient $d \ln \langle r^2 \rangle_0/dT$ of the unperturbed dimensions of the network chains[3].

In the present study, compression measurements were carried out on polyoxyethylene (POE) $[CH_2-CH_2-O-]_x$, a particularly important polymer to be studied in this way because some serious disagreements[4-6] regarding the value of $d \ln \langle r^2 \rangle_0/dT$ for this chain molecule have only recently been resolved[7], and this temperature coefficient plays a crucial role in the understanding of the configuration-dependent properties of polyoxide chains in general[7,8].

EXPERIMENTAL

Preparation of networks

The sample of POE (Polyox WSR-205, Union Carbide) employed had a molecular weight of approximately 600 000 and a melting point of approximately 65°C (in the undiluted, uncrosslinked state). A portion of this material was moulded, under pressure and at approximately 68°C, into a cylindrical pellet having a diameter of 1.76 cm and a length of 3.50 cm. This sample was then crosslinked

under vacuum at room temperature, using approximately 16.4 Mrad of γ-radiation. After the small amount of soluble material present in the sample was extracted, approximately 8% of the antioxidant N-phenyl-2-naphthylamine was incorporated into the network by means of a swelling–deswelling technique[4]. Sufficient m-cresol, a non-volatile diluent, was then incorporated into the network to decrease the volume fraction v_2 of polymer to 0.75, thus further decreasing the melting point of the POE network. The thermal expansion coefficient $\beta = (\partial \ln V/\partial T)_p$ of the swollen network in the vicinity of 65°C was obtained from dilatometric measurements; it was found to be $0.509 \times 10^{-3} K^{-1}$.

Stress–compression measurements

Stress–strain isotherms were obtained for this swollen POE network in compression, at 45, 55, 65, 75, and 85°C, in the manner described in detail elsewhere[1,9]. A slurry of graphite in low molecular weight dimethylsiloxane fluid applied to the Teflon compression plates aided in preventing non-uniform deformation of the network. Values of the relative length or compression $\alpha = L/L_i$ of the sample were in the range 1.00–0.80. The isotherms were found to be reversible and there was no evidence of crystallization under the conditions employed in these measurements.

RESULTS AND DISCUSSION

The experimental data were used to calculate values of the 'reduced force' $[f^*]$ defined by:

$$[f^*] = f v_2^{1/3}/A^*(\alpha - \alpha^{-2}) \tag{1}$$

where f is the elastic force or stress, and A^* is the cross-sectional area of the unswollen, undistorted sample at 45°C. Values of the deformation or compression, α, were
Figure 1 Stress—strain isotherms for polyoxyethylene in compression. The deformation α is defined by $L(T)/L_i(T)$, i.e., the length of the sample at the specified temperature relative to the undeformed length at the same temperature. ●, 45° ; +, 55° ; □, 65° ; △, 75° ; ○, 85°C

calculated relative to the initial length, L_i, at the particular temperature of measurement, and values of the reduced force were expressed in N/mm². (In order to facilitate comparison of these results with others already in the literature, it may be helpful to point out that 1 N/mm² = 1 MN/m² = 10.20 kg/cm².) The values of $[f^*]$ thus calculated were plotted against the reciprocal of the compression, α, as suggested by the semi-empirical Mooney—Rivlin equation[10]:

$$[f^*] = 2C_1 + 2C_2\alpha^{-1} \qquad (2)$$

The results are shown in *Figure 1*; each line, representing a stress—strain isotherm, was located by the method of least squares. The slopes of these lines represent values of the constant $2C_2$, which is a measure of the departure of the observed stress—strain relationship from the theoretical prediction that $[f^*]$ be independent of α^{11}. From these results, $2C_2 = 0.0014(\pm0.0002)$ N/mm², a result very much smaller than the values of this correction generally obtained for networks in elongation[11]. Similarly small values of $2C_2$ have been reported for several other polymers which have been studied in compression[1].

Values of the reduced force at selected values of α in the range 0.95—0.80 were obtained from each stress—strain isotherm by means of interpolation and limited extrapolation. The values of $[f^*]$ thus obtained were found to vary linearly with temperature. Typical results are presented in *Figure 2*, where the lines shown were again located by least-squares analysis. The slopes of these lines were used to calculate[1] values of the coefficient $[\partial \ln ([f^*]/T)/\partial T]_{p,\alpha}$ at the average temperature, 65°C, employed in this study; these results are given in the second column of *Table 1*. The quantities f_e/f and $d \ln \langle r^2 \rangle_0 / dT$ were then calculated from the equations[1,12]:

$$f_e/f = T \, d \ln \langle r^2 \rangle_0 / dT$$

$$= -T[\partial \ln ([f^*]/T)/\partial T]_{p,\alpha} + \beta T/3 \qquad (3)$$

Values of these quantities are given in the last two columns

of the Table. They are seen to vary only slightly with α, and give the average results $f_e/f = 0.06 (\pm 0.01)$ and $d \ln \langle r^2 \rangle_0 / dT = 0.19 (\pm 0.03) \times 10^{-3} \, \mathrm{K}^{-1}$.

The value of $d \ln \langle r^2 \rangle_0 / dT$ for POE which is obtained in the present study is in very good agreement with the value $0.23 (\pm 0.02) \times 10^{-3} \, \mathrm{K}^{-1}$ resulting from a thermoelastic study of a POE network in elongation[4], and with the value $0.2 (\pm 0.2) \times 10^{-3} \, \mathrm{K}^{-1}$ obtained from viscosity—temperature measurements on isolated POE chains in a thermodynamically good solvent[7]. (Other thermoelastic results[5,13] of lower reliability[6,13] are in fair agreement with the results cited above. Values calculated from viscosity—temperature studies on POE chains of low molecular weight[5] have been shown to be unreliable[7], and are therefore not presented here.)

The fact that there is good agreement between values of $d \ln \langle r^2 \rangle_0 / dT$ obtained in compression and elongation has some bearing on the alleged existence of intermolecularly ordered domains[14,15] or 'supermolecular structures'[5] in polymers in the amorphous state. Since any such ordering would reasonably be expected to respond differently to (uniaxial) elongation and compression (mechanically equivalent to biaxial elongation[11]), the absence of any difference between the values of $d \ln \langle r^2 \rangle_0 / dT$ obtained using these two different types of deformation would seem to represent yet another piece of evidence[16] against the existence of ordered regions in amorphous polymers.
Figure 2 Reduced force shown as a function of temperature for selected values of the deformation, α. These results were obtained from *Figure 1*, in which $\alpha = L(T)/L_i(T)$, and thus pertain to constant deformation rather than constant length. ○, $\alpha = 0.80$; +, $\alpha = 0.85$; △, $\alpha = 0.90$; □, $\alpha = 0.95$

Light scattering in an electric field: variations of the H_H (θ) component around $\theta = 90°$

J. C. Ravey and P. Mazeron

Laboratoire de Biophysique, Université de Nancy I, 54037 Nancy Cedex, France
(Received 26 June 1974; revised 13 August 1974)

The studies of the changes ΔH_H of the H_H component of the light scattered by dilute suspensions of particles oriented by an electric field E_0 are shown to be convenient and reliable methods for obtaining simultaneous information on the electrical (μ), geometrical (ω) and optical (δ) anisotropies of the particles. Indeed, when E_0 is applied in three particular directions, which are related to the exterior and interior bisectrices of the observation angle θ, $\Delta H_H (\theta = 90°)$ generally has the same sign as $(-\mu\omega)$, $(+\mu\omega)$ or $(-\mu)$, according to the direction of E_0. Moreover, under the same conditions, the slopes of $\Delta H_H(\theta)$ *versus* θ are shown to be much more informative than those of $\Delta H_H(\theta)/H_H(\theta)$, having the sign of $(-\mu\delta)$, $(+\mu\delta)$ or $(-\mu\delta\omega)$. Experiments on TMV particles illustrate in a very satisfactory manner these theoretical conclusions.

INTRODUCTION

When the Rayleigh–Gans–Debye approximation is used, the light scattering method is a simple and powerful tool for studying the size of diluted particles. Moreover, the measurements of the depolarized components H_v and H_H of the scattered light allow the determination of optical and geometrical parameters which are unattainable by usual light scattering experiments. For example, the *algebraic* value of the optical anisotropy, δ, can be found by measuring the angular position of the minimum of H_H if the shape of the scatterer is known[1]. Likewise it has been shown[2] that the value of $[(H_H - H_v)/H_v]_{\theta=90}$ determines whether the particles are elongated or flattened.

Furthermore if the particles are oriented by means of an electric field $\vec{E}_0$, information concerning optical, geometrical and electrical anisotropies, namely the induced and/or permanent moments of the particles can be obtained[6-9].

Let ω be the anisometry of the scatterer ($\omega = p^2 - 1$, where p is its ellipticity), and $\mu = c + b^2/2$, where b and c are proportional respectively to its electrical-permanent moment and anisotropy (see below).

In the presence of the electric field, the resulting variation ΔV_v of the $V_v(\theta)$ component:

$$\Delta V_v(\theta) = V_v(\theta, E_0) - V_v(\theta, 0)$$

has the same sign as $(\mu\omega)^{3,4,10}$ for a particular (vertical) direction of $\vec{E}_0$, at least for weaker orientation rates. When $b = 0$, $(\mu\omega)$ is always positive, whatever the shape of the spheroidal scatterer. In that case and with such a measurement, the signs of ω and μ cannot be found separately.

Until now, electric light scattering experiments have been only used for obtaining values of the electrical parameters (b and c) of scatterers, the shape and size of which were already known. Moreover, the optical anisotropy δ was generally disregarded. If we wish the algebraic values of δ, ω, μ to be determined with the help of very few measurements, other light scattered components must be studied, as done in the present paper.

On the other hand, studies of H_v and H_H and of their changes are believed to be more fruitful, for they do permit the determination of the *sign* of each quantity of interest, μ, δ, ω; the present work deals with the H_H component which seems most suitable.

DEFINITIONS AND SYMBOLS

Throughout the text, the following functions and symbols are used.

$\beta_1, \beta_2, \beta_3$ are the direction cosines of the $\vec{\xi}$ axis of the scattering spheroid, in the reference frame ($\vec{s}, \vec{s'}, \vec{z}$) built on the exterior $\vec{s}$ and interior $\vec{s'}$ bisector of the observation angle, θ.

$R(\Phi)$ is the normalized interference factor of the scatterer for which $\vec{\xi} \cdot \vec{s} = \beta_1 = \cos\Phi$.

$H_H(\theta)$ and its changes due to an electric orientating field may be expressed in terms of the following integrals introduced by Ravey[3]:

$$I_{pqr} = \frac{1}{4\pi} \int R(\Phi)\beta_1^{2p}\beta_2^{2q}\beta_3^{2r}\,d\Omega$$

the properties of which have been indicated in a previous paper[3]. The full expressions of ΔH_H are rather complicated, and can be found elsewhere[4].

When the particles are oriented by an electric field, their orientation is described by the distribution function $p(\nu)$:

$$p(\nu) = \frac{1}{4\pi U} \exp(b\cos\nu + c\cos^2\nu) \tag{1}$$

where $\cos\nu = \vec{\xi}.\vec{E}_0/ |\vec{E}_0|$, U being a normalization constant. b describes the orientation due to a permanent dipole (along $\vec{\xi}$), and c the one due to induced moment[6-9].

For lower degrees of orientation:

$$4\pi U p(\nu) \simeq 1 + \mu\cos^2\nu$$

where

$$\mu = c + b^2/2 \quad \text{and} \quad U = 1 + \mu/3 + \cdots$$

For time-dependent electric fields, μ must include the rotational diffusion constant of the particles[6-9].

GENERAL THEORETICAL RELATIONS

Any scattered component, I, of the scattered intensity can be expressed by the following integral[3]:

$$I = \frac{1}{4\pi U} \int p(\nu) R(\Phi) f(\theta, \beta, \delta) \, d\Omega \qquad (2)$$

where f is a function of the scattering angle, θ, the two principal optical polarizabilities per unit volume of the spheroid (or cylinder) g_1 and g_2, and of the direction cosines $\beta_1, \beta_2, \beta_3$. The various expressions of f corresponding to the components H_H, H_ν, V_H, V_ν can be found in previous papers[3,11]. In order to avoid complicated expressions, only the cases where $\vec{E}_0$ is directed along the $\vec{s}, \vec{s}', \vec{z}$ direction will be considered here, the resulting changes of H_H being noted respectively by $(\Delta H_H)_s$, $(\Delta H_H)_{s'}$, and $(\Delta H_H)_z$. More general expressions (arbitrary direction of $\vec{E}_0$, any direction of scattering, form- and polarizability ellipsoids not coinciding) may be also deduced[3].

General expressions of $H_H(\theta)$ (within RGD approximation)

Scattered intensity without orientating field. By setting $\theta = \pi/2 + 2\alpha$ in the general expressions giving H_H^0[3], the following expression is obtained:

$$H_H^0(\theta) = \frac{9\delta^2}{4} (I_{200} + I_{002} - 2I_{101}) +$$

$$6\delta(1 - \delta)\alpha(I_{001} - I_{100}) + 9\delta^2\alpha(I_{002} - I_{200}) +$$

$$\sigma(\alpha^2) \qquad (3)$$

whatever the shape and the size of the spheroid (or cylinder) are, and for any value of the optical anisotropy, δ, where

$$\delta = (g_1 - g_2)/(g_1 + 2g_2)$$

The θ-derivatives of the I_{pqr} integrals are always finite, and these functions vary not much around $\theta = 90°$. Moreover, δ^2 is generally negligible compared with δ for most of the anisotropic scatterers. Since the θ-derivative of the first term of equation (3), where α does not explicitly appear, contains the δ^2 factor, the θ-derivative of $H_H^0(\theta)$ will be given to a good approximation by the following term:

$$\left[\frac{d}{d\theta} H_H^0(\theta) \right]_{\theta = 90°} \simeq 3\delta(I_{001} - I_{100})$$

Case of weaker orientation rates. The use of the I_{pqr} formalism allows an immediate obtainment of the results as shown below. From equation (1):

$$4\pi p(\nu) \simeq 1 + \mu \left(\beta_1^2 - \frac{1}{3} \right)$$

when $\vec{E}_0$ is directed along $\vec{s}$ ($\cos \nu \equiv \beta_1$).

Thus the absolute change ΔH_H is simply:

$$\Delta H_H = \mu \left(\Delta' H_H - \frac{1}{3} H_0^0 \right) \qquad (4)$$

where $\Delta' H_H$ is derived from H_H^0 in equation (3) by changing the index p in $p + 1$ in the I_{pqr} functions. Thus we get:

$$\left(\frac{\Delta H_H}{\mu} \right)_s = \frac{9\delta^2}{4} (I_{300} + I_{102} - 2I_{201}) +$$

$$6\delta(1 - \delta)\alpha(I_{101} - I_{200}) +$$

$$9\delta^2\alpha(I_{102} - I_{300}) - \frac{1}{3} H_H^0 + \sigma(\alpha^2) \qquad (5)$$

for any value of δ, and for any shape of the revolution scatterers. As before, the θ-derivative of ΔH_H is approximately given by the factor (2α) which is proportional to δ.

It is clear that $(\Delta H_H)_{s'}$ and $(\Delta H_H)_z$ will be obtained in the same manner from equation (4); $(\Delta' H_H)_s$ and $(\Delta' H_H)_z$ are deduced from H_H^0 by replacing the I_{pqr} functions respectively by $I_{p,q+1,r}$ and $I_{p,q,r+1}$.

Case of higher orientation extent. The various changes of the H_H component have been directly evaluated by numerical integration of equation (2), on a computer. The results will be presented later.

However, for the zero scattering angle, or for very small particles $R(\Phi) \simeq 1$, and the problem has been solved[3,10] by introduction of the so-called generalized Langevin functions[5].

Expression of the I_{pqr} integrals

Calculations have been performed on cylinders, rods, discs and spheroids. Let us recall here some results.

The normalized interference factor of a spheroid, the semi-axes of which are a, a, pa, is:

$$R(x) = \frac{9\pi}{2} \left[\frac{\mathcal{F}_{3/2}(x)}{x^{3/2}} \right]^2$$

where $\mathcal{F}_{3/2}(x)$ is a Bessel function of x, and

$$x = \frac{4\pi a}{\lambda} \sin \frac{\theta}{2} (1 + \omega\beta_1^2)^{1/2} \qquad (6)$$

λ is the wavelength in the medium, $\omega = p^2 - 1$.
The orientation of the spheroid is such that $\vec{\xi} \cdot \vec{s} = \beta_1$.
For quasi-spherical spheroids $(\omega \to 0)$, $R(\beta_1)$ may be expanded in a MacLaurin series of ω, from which it follows:

$$I_{pqr} \simeq G_q^r [J_{q+r}^p P_0 - \omega J_{q+r}^{p+1} P_0' + \sigma(\omega^2)] \qquad (7)$$

where these various functions are given in the Appendix.
The expansion (7) is quite similar to the following one:

$$I_{pqr} = G_q^r [J_{q+r}^p P - \omega J_{q+r}^{p+1} P' + \sigma(\rho^4/\lambda^4)] \qquad (8)$$

$$\left(h = \frac{4\pi}{\lambda} \sin \frac{\theta}{2} \right)$$

which is valid for small particles, the square radius of gyration of which is $\rho^2 \ll \lambda^2$, where $P = 1 - h^2\rho^2/(\omega + 3)$ and

$P' = h^2\rho^2/(\omega + 3)$; small and quasi-spherical particles behave then in the same manner.

For large discs ($\omega \to -1$) and rods ($\omega \to \infty$), the asymptotic behaviour of ΔH_H is deduced from the following properties of the I_{pqr} functions[3].

For large rods, all of the I_{pqr} becomes negligible compared with the I_{oqr}:

$$I_{oqr} \to \frac{2}{H} G_q^r \, \mathrm{Si}(2H)$$

where $H = (2\pi L/\lambda)\sin\theta/2$; L is the length of the rod, and $\mathrm{Si}(x)$ is the function integral sine.

For large discs, all of the I_{pqr} becomes negligible compared with the I_{poo}:

$$I_{poo} \to \frac{2}{H^2} \text{ for any } p$$

where $H = (4\pi R/\lambda)\sin\theta/2$, $2R$ being the diameter of the disc.

THEORETICAL RESULTS AND DISCUSSION

H_H component scattered by small or very large particles

From the above considerations, the following results may be derived (smaller orientation rates).

Case of small ($h^2\rho^2 < 1/5$) *and quasi-spherical particles*
If P and P' are the quantities previously defined, we get:

$$H_H^0 = \frac{3}{5}\delta^2\left(P - \frac{3\omega}{7}P'\right) + \alpha\,\frac{4}{5}\delta\left(1 + \frac{2\delta}{7}\right)\omega P' \quad (9)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_s = \frac{2\delta^2}{35}(P - 2\omega P') - \frac{4}{5}\delta\alpha\left[P\left(1 + \frac{2\delta}{7}\right) - \frac{\omega P'}{21}(11 + 4\delta)\right] \quad (10)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_{s'} = \frac{2\delta^2}{35}(P + \omega P') + \frac{4}{5}\alpha\delta\left(1 + \frac{2\delta}{7}\right)\left(P - \frac{\omega}{3}P'\right) \quad (11)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_z = -\frac{4\delta^2}{35}\left(P - \frac{\omega}{2}P'\right) - \frac{16}{105}\alpha\delta\left(1 + \frac{\delta}{2}\right)\omega P' \quad (12)$$

The behaviour of quasi-spherical spheroids ($\omega \to 0$, any size) is obtained by replacing P and P' by P_0 and P_0' in these relations respectively (see Appendix).

For smaller particles, all the expressions between parentheses or brackets containing both P and P' [e.g.: $(P - (3\omega/7)P')$] are positive.

For quasi-spherical spheroids (of any size) the sign of this quantity depends on the size in a very oscillatory way, due to the presence of the Bessel functions $\mathcal{J}_{3/2}$ and $\mathcal{J}_{5/2}$ in P_0 and P_0'. For this reason, we shall exclude from our

study the values of ellipticity between $p = 2/3$ and $p = 3/2$, for which no general conclusion can be easily drawn if the particle sizes are relatively large ($\rho/\lambda \geqslant 1/3$).

Asymptotic behaviour. The following expressions can be easily obtained for large discs (the $2/H^2$ term has been omitted), from the properties of the I_{pqr} integrals:

$$H_H^0 \to \frac{9\delta^2}{4} - 6\alpha\delta\left(1 + \frac{\delta}{2}\right) \quad (13)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_s \to \frac{3}{2}\delta^2 - 4\alpha\delta\left(1 + \frac{\delta}{2}\right) \quad (14)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_{s'} = \left(\frac{\Delta H_H}{\mu}\right)_z = -\frac{1}{2}\left(\frac{\Delta H_H}{\mu}\right)_s \quad (15)$$

For large rods the factor $2/H\,\mathrm{Si}(2H)$ is omitted also:

$$H_H^0 \to \frac{9\delta^2}{4} \cdot \frac{3}{16} + \frac{3}{2}\alpha\delta\left(1 + \frac{\delta}{8}\right) \quad (16)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_s \to -\frac{1}{3}H_H^0 \quad (17)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_{s'} \to \frac{9\delta^2}{4} \cdot \frac{3}{32} + \frac{5}{8}\alpha\delta\left(1 + \frac{7\delta}{20}\right) \quad (18)$$

$$\left(\frac{\Delta H_H}{\mu}\right)_z \to -\frac{9\delta^2}{4} \cdot \frac{1}{32} - \frac{\alpha\delta}{8}\left(1 + \frac{5}{4}\delta\right) \quad (19)$$

Study of $[\Delta H_H/H_H^0]_{\theta=90}$

We shall now study how the expressions change when p increases from zero (discs) to infinity (rods), for various values of the radius of gyration, ρ.

Case of weaker orientation rates. The results derived from the above equations are summarized in *Table 1*.

It can be seen that the sum of the variations corresponding to $\vec{E}_0$ directed along $\vec{s}$, $\vec{s'}$, $\vec{z}$ is zero as it must be[4,11].

Numerical computations of $(\Delta H_H/H_H^0)_{\theta=90}$ for other values of ω have allowed the curves of *Figure 1* to be drawn in a logarithmic scale for p. These computations have been made by using two particle shapes: the spheroid and the cylinder. The results are generally very close to each others for these two models. For simplicity, only the spheroid-like particles will be considered in the present paper. The curves illustrate the following conclusions: let $w = 4\pi\rho/\lambda$.

If $w < 1$ (smaller particles), the relative change $[\Delta H_H/H_H^0]_{\theta=90}$ is about $(2/21)\mu$ for $\vec{E}_0$ directed along $\vec{s}$ or $\vec{s'}$,

Table 1 Theoretical values of $(1/\mu)[(\Delta H_H)/H_H^0]_{\theta=90}$ for the three particular directions of $\vec{E}_0$, obtained for smaller or quasi-spherical particles, large discs and large rods

$\vec{E}_0$ directed along	$\omega \to 0$ (spheres of any size) small particles	$\omega \to -1$ (large discs)	$\omega \to \infty$ (large rods)
$\vec{s}$	2/21	2/3	-1/3
$\vec{s'}$	2/21	-1/3	1/2
$\vec{z}$	-4/21	-1/3	-1/6
Figure 1 The ratio $(1/\mu)[(\Delta H_H/H_H^0)]$ 90° for smaller orientation rates as a function of the ellipticity p of the particles for various values of the size (w) and for $\vec{E}_0$ oriented along $\vec{s}$, (——), $\vec{s'}$ (– – –) or $\vec{z}$ (–·–·–). A decimal logarithmic scale is used for p. The common value of the curves for spheres is 2/21 (s and s') and —4/21 (z). The horizontal arrows represent the asymptotical values given in Table 1

and about $(-4/21\ \mu)$ for $\vec{E}_0$ along $\vec{z}$, for any values of δ and ω.

For $1.5 < w < 6$ (values of w greater than 6 are generally out of the scope of the Rayleigh–Gans–Debye approximation), we recall that we exclude here the values of p between 2/3 and 3/2. Whatever δ and ω are:

$(\Delta H_H/H_H^0)_{90}$ has the sign of $(-\mu\omega)$,
   for $\vec{E}_0$ directed along $\vec{s}$

$(\Delta H_H/H_H^0)_{90}$ has the sign of $(+\mu\omega)$,
   for $\vec{E}_0$ directed along $\vec{s'}$

$(\Delta H_H/H_H^0)_{90}$ has the sign of $(-\mu)$,
   for E_0 directed along $\vec{z}$

$(\Delta H_H)_{90,z}$ has thus always the sign of $(-\mu)$ for any δ, ω and w. Such a measurement supplies then the sign of the electric parameter μ, independently of the values of ω and δ.

Higher orientating field strength: the effect of the saturation. How are the previous results modified with increasing orientating field strength, E_0? The effect depends on the direction of $\vec{E}_0$, the size of the particle and on its ellipticity. The curves of related figures are drawn for an orientation due to the induced moment only ($b = 0$), so that $\mu \equiv c$.

$\vec{E}_0$ directed along $\vec{z}$. In this case, $(1/\mu)[(\Delta H_H)/(H_H^0)]$ 90,z slightly increases, but remains negative when E_0 increases, whatever the shape and the size of the scatterers are, a very useful result.

$\vec{E}_0$ directed along $\vec{s'}$. Let us consider elongated particles ($p > 1$). It can be seen from *Figure 2* ($w = 2$) that for increasing values of c the effect is becoming first larger and

then less important, but the *sign* of the ratio $(1/\mu)[(\Delta H_H)/(H_H^0)]$ 90,s' does not change. This conclusion is still true for other values of w: increasing values of w only shifts the curves towards higher values (*Figure 3*). For flattened particles, the ratio $(1/\mu)[(\Delta H_H)/(H_H^0)]$90,s' is generally negative, and becomes more and more negative with increasing values of w. But for quasi-spherical or smaller particles, its sign may be reversed (*Figure 2*).

$\vec{E}_0$ directed along $\vec{s}$. As shown in *Figure 4*, the value of $(1/\mu)[(\Delta H_H)/(H_H^0)]$90,s generally decreases with μ. Its sign does not change, except for smaller particles (*Figures 3* and *4*) or for small values of ω (*Figure 4*). When w increases, the curves are shifted 'downward' for elongated particles, and 'upward' for flattened ones.

As a conclusion, the previous theoretical results concerning the sign of $(\Delta H)_{90}$ are generally not changed under electrical saturation effects: a change of sign may occur only in the case of smaller or quasi-spherical particles.

Study of the slope of $[\Delta H_H(\theta)]_{\theta=90}$

The absolute slope of $[\Delta H_H(\theta)]_{\theta=90}$ have been divided by $H_H^0(90)$, and denoted by m_a:

$$m_a = \left[\frac{d}{d\theta}\ \Delta H_H(\theta)\right]_{\theta=90} \Big/ H_H^0(90)$$
Figure 2 $(1/\mu)[(\Delta H_H/H_H^0]$ 90°,s' as a function of the electrical parameter μ for various values of the ellipticity of the particles for which $w = 2$. The orientation is assumed to be due to the induced electric moment only, so that μ has the same sign as $(p - 1)$. The upper and lower curves do not correspond to ellipsoids but to cylinders of length L and diameter $2R(L/2R = 10$ or 0.1). p: A, 0.1; B, 0.25; C, 0.33; D, 0.5; E, 0.66; F, 0.8; G, 1.25; H, 2.0; I, 3.0; J, 4.0; K, $L/2R = 10$
Figure 3 $(1/\mu)[(\Delta H_H/H_H^0)]_{90^\circ}$ as a function of μ for various small anisotropic elongated $(p = 10)$ particles. w: A, A', 1.5; B, B', 1.0; C, C', 0.5. It should be noted that for the lower curve (A) the sign of the above ratio is changed
Figure 4 $(1/\mu)[(\Delta H_H/H_H^0)]_{90^\circ,s}$ as a function of μ for anisotropic ellipsoids or cylinders of various ellipticities p $(p = L/2R$ for cylinders). X, $L/2R = 0.1$. p: A, 0.25; B, 0.5; C, 0.66; D, 0.8; E, 1.25; F, 2.0; G, 3.0; H, 4.0; I, 10.0

Case of lower orientation rates. As stated above the various absolute slopes (or θ-derivatives) are approximately given in expressions (9)–(19), as half of the factor of α: it is seen that they are nearly proportional to the optical anisotropy, δ; they depend on ω chiefly when $\vec{E}_0$ is directed along $\vec{z}$. Let us give the following approximate asymptotic

expressions, where the slopes are expressed as variations per unit radian (they are approximate in the sense that only the term proportional to δ is kept).

$$\text{smaller particles} \begin{cases} (m_a)_s = -\dfrac{2\mu}{3\delta}\left(1 + \dfrac{2\delta}{7}\right) \\[2ex] (m_a)_{s'} = -(m_a)_s \\[2ex] (m_a)_z = 0 \end{cases}$$

$$\text{large discs} \begin{cases} (m_a)_s \simeq -\dfrac{8\mu}{9\delta} \\[2ex] (m_a)_{s'} = -\dfrac{1}{2}(m_a)_s = (m_a)_z \end{cases}$$

$$\text{large rods} \begin{cases} (m_a)_s \simeq -\dfrac{16}{27}\dfrac{\mu}{\delta} \\[2ex] (m_a)_{s'} \simeq +\dfrac{20}{27}\dfrac{\mu}{\delta} \\[2ex] (m_a)_z = -(m_a)_s - (m_a)_{s'} \end{cases}$$

These values should be multiplied by $\pi/180$ before being marked on *Figure 5*, where θ is expressed in degrees rather than in radians.
Figure 5 Absolute slope $(m_a)_{90^\circ}$ for smaller orientation rates as a function of the ellipticity p (decimal logarithmic scale) of anisotropic $(\delta = 0.1)$ spheroids and for various values of the size. —, $\vec{E}_0$ along $\vec{s}'$; ---, $\vec{E}_0$ along $\vec{z}$; -·-·-, $\vec{E}_0$ along $\vec{s}$. Arrows represent the asymptotic values for larger particles, discs and rods. Identical curves can be obtained for cylinders (except for $2/3 < p < 3/2$) For $\delta = -0.1$, one has roughly the general shape of the corresponding curves by multiplying the above ones by -1
Figure 6 Absolute change $(1/\mu)(\Delta H_H)_s$ versus θ for a spheroid ($w = 2$, $\delta = 0.1$) and for lower orientation rates. When p increases from 0.1 to 10, the curvature of the curve changes but the slope at $\theta = 90°$ has always the same sign. For $\delta < 0$, this sign is changed. —, $\delta = -0.1$; ---, $\delta = +0.1$. p: A, A', 0.1; B, 0.8; C, 2.0; D, D', 10.0

For the general case, the slopes have been numerically calculated on a computer, by using the Richardson and Romberg extrapolation method[12]. These exact theoretical results are represented on the curves of *Figure 5* (where the slopes are expressed as variations per degree); the following conclusions, valid for $w < 6$ except for $\omega \simeq 1$, can be drawn:

$(m_a)_s$ has the sign of $(-\mu\delta)$, for any ω

$(m_a)_{s'}$ has the sign of $(+\mu\delta)$, for any ω

$(m_a)_z$ has the sign of $(-\mu\delta\omega)$

As it must be, the absolute slope for small particles is nearly independent of p.

By measuring the experimental variations of H_H due to E_0 in the vicinity of $\theta = 90$, it is thus easy to determine the sign of μ, δ and ω.

All of these conclusions [both for the absolute slope and for the values of $(\Delta H_H/H_H^0)_{90}$] may be ascertained by considering the curves in *Figures 6–8*.

Effects of the saturation. The numerical computations show that the above results remain unchanged for higher electrical field strength, E_0 (until $\mu = 12$). *Figure 8* indicates how the various curves are modified when $|\mu|$ increases from 1 to 10.

Study of the relative change $\Delta H_H(\theta)/H_H^0(\theta)$

A priori it would have seemed more natural to study the relative changes of $H_H(\theta)$ as far as experiments are concerned. The present question is to know whether such a study supplies more information and is more fruitful or not than the previous one.

Slope, m_r, *of the relative change*. Let $m_r = \{(d/d\theta)[\Delta H_H(\theta)/H_H^0(\theta)]\}_{\theta=90}$ be the relative slope.

For smallest particles $(w < 1)$ m_r and m_a are of the same order of magnitude. The conclusions deduced from m_a are also valid for m_r.

For increasing w, m_r rapidly decreases, and tends to zero for disc-like particles.

For rod-like scatterers, we get·

$$(m_r)_{s'} \rightarrow -\frac{4}{27}\frac{\mu}{\delta} = -(m_r)_z$$

$$(m_r)_s \rightarrow 0$$

It is then clear that the study of m_r is much less fruitful than the study of m_a, as shown by comparison of *Figure 5* and *Figure 9*.
Figure 7 Absolute change $(1/\mu)(\Delta H_H)_z$ versus θ for spheroids ($w = 2$) and for lower orientation rates. —, $\delta = +0.1$; ---, $\delta = -0.1$. When p increases, both the curvature and the slope at $\theta = \pi/2$ change their sign. This conclusion is still valid for δ negative. p = A, A', 0.1; B, 0.5; C, 2.0; D, 3; E, E', 7
Figure 8 Influence of the electrical saturation on $(1/\mu)(\Delta H_H)_z$ for spheroids [$p = 4$ (---) and 0.1 (——), $w = 4$, $\delta = 0.1$]. The absolute slope keeps always the same sign as μ increases: A, −10; B, −0.1; C, 0.1; D, 10
Figure 9 Relative slope $(m_r)_{90°}$ for smaller orientation rates as a function of the ellipticity p (decimal logarithmic scale) of anisotropic (δ = 0.1) spheroids and for various values of their size. —, $\vec{E}_0$ along $\vec{s}'$, —·—·—, $\vec{E}_0$ along $\vec{s}$; ———, $\vec{E}_0$ along $\vec{z}$. Horizontal arrows represent the asymptotic values for larger particles, discs and rods. $(m_r)_{90°}$ rapidly decreases with p or increasing values of w

General shape of the relative curves. In order to avoid tedious descriptions of curves, only some typical results will be presented.

The relative curves $\Delta H_H(\theta)/H_H^0(\theta)$ generally present very pronounced effects around θ = 90: a maximum (M) and/or a minimum (m) occur near θ = 90 as shown on the curves of *Figure 10*. It should be noted that for small disc-like particles without permanent moment ($\mu \equiv c < 0$), the related shapes of relative curves $(1/\mu)$ $(\Delta H_H/H_H^0)$ are quite similar to those shown in *Figure 10*.

Let θ_M and θ_m be the respective angular positions of the maximum M and the minimum m which occur near θ = 90.

$\vec{E}_0$ directed along $\vec{s}$. Whatever ω and w, we have $\theta_M < \theta_m$ if $(\mu\delta)$ is positive, and *vice versa* as shown in *Figures 11* and *12*, corresponding to various values of the particle sizes. Moreover, the electrical saturation has little effect on the general shape of these curves.

$\vec{E}_0$ directed along $\vec{s}'$. We get a similar conclusion, but for $\mu\delta > 0$, $\theta_m < \theta_M$.

$\vec{E}_0$ directed along $\vec{z}$. The quantity $(m_r)_z$ very rapidly vanishes (*Figure 9*) so that in most cases an extremum should be observed for $(\Delta H_H/H_H^0)_z$ very close to θ = 90. For any value of δ, this extremum is a maximum if $\mu < 0$, and *vice versa*; in other words, the curves $(1/\mu)[(\Delta H_H/H_H^0)]_z$ always present a minimum near θ = 90. For increasing particle size these last curves are modified as follows:

a maximum rises for $\theta_M < 90$, if $(\delta\omega)$ is positive

it rises for $\theta_M > 90$, if $(\delta\omega)$ is negative (*Figure 13*)

Electrical saturation has little effect on the general shape of these curves.

Figure 10 General shape of the relative change $(1/\mu)(\Delta H_H/H_H^0)$ versus θ for small orientation rates. These curves correspond to anisotropic (δ = 0.1) small rods of length L such that $2\pi(L/\lambda) = 2$, and to the three principal directions of the electric field, $\vec{E}_0$: $\vec{s}, \vec{s}', \vec{z}$
Figure 11 Relative change $(1/\mu)[(\Delta H_H/H_H^0)]_s$ versus θ for a rod of length L such that $2\pi(L/\lambda) = 2$, for two values of δ and two values of μ: ———, 0.1; ———, 10
Figure 12 Relative change $(1/\mu)[(\Delta H_H/H_H^0)]_s$ *versus* θ for a rod such that $2\pi(L/\lambda) = 6$, as a function of μ and δ. (Compare with *Figure 11* for the influence of the size.)
Figure 13 Relative change $(1/\mu)[(\Delta H_H/H_H^0)]_z$ *versus* θ for two spheroids of different size $w = 2$ (——) and 5 (----). (Small orientation rates). $p = 2$; $\delta = 0.1$

EXPERIMENTAL AND CONCLUSION

As previously stated, the study of the depolarized components of the light scattered by particles, although experimentally difficult because of the weakness of the intensities to be measured, seems to be very suitable for obtaining reliable information concerning geometrical, optical and electrical parameters of the scatterers.

In the present work, it is shown that the study of the

changes of $H_H(\theta)$ under an electric field is a fruitful method: of particular interest is the study of $(\Delta H_H)_{z,90}$, the sign of which is the same as $(-\mu)$, for any δ, ω, w, and is not modified by electrical saturation. Likewise studying the absolute slope m_a is a very sure way to ascertain the sign of δ, ω and μ.

An application of this method is given in *Figure 14*, which represents the absolute change $\Delta H_H(\theta)$ occurring when tobacco mosaic virus (TMV) (rod-like particle) solutions are subjected to an electric field directed along $\vec{s}$ or $\vec{s}'$. The slopes of the s and s' graphs are consistent, as they should be, with positive values of $\mu\delta$; the values of $[\Delta H(90)]_{s \text{ and } s'}$ are consistent with positive values of $(\mu\omega)$, i.e. positive values of μ, since $\omega > 0$ (as expected, and previously shown[1]; as a result, δ has a positive value[2].

As far as relative values of $\Delta H_H/H_H^0$ are concerned, the following comments can be made (TMV suspensions) (*Figures 15* and *16*).

$\vec{E}_0$ directed along $\vec{s}$. *Figures 12, 15* and *17* have the same appearance: ΔH_H is negative between $\theta = 60°$ and $\theta = 120°$; and the angular position of the maximum θ_M is about $86°$, the minimum occurring for $\theta_m > 90°$.

$\vec{E}_0$ directed along $\vec{s}'$. *Figures 10, 16* and *17* are to be compared (although *Figure 10* is related to small particles). Here we have $\theta_M \simeq 100° > \theta_m \simeq 86°$ which is also consistent with $\mu\delta > 0$.

$\vec{E}_0$ directed along $\vec{z}$. ΔH_H is probably negative, (i.e. $\mu > 0$) at its minimum. A flat maximum occurs at $\theta_M \simeq 80° < 90°$, which proves that $\mu\delta\omega$ is positive.

Such results are then compatible with positive values of
Figure 14 Experimental variation of $(\Delta H_H)_s$ (+) and $(\Delta H_H)_{s'}$ (O) as a function of θ for tobacco mosaic virus solutions. Electric field strength = 300 V/cm. Frequency = 1000 Hz. k = arbitrary scale factor
Figure 15 Experimental relative variation of H_H obtained for TMV when the electric field direction is along s, *versus* θ; electric field strength = 300 V/cm; frequency = 1000 Hz
Figure 16 Experimental variation of $(\Delta H_H/H_H^0)_{s'}$ (●), and $(\Delta H_H/H_H^0)_z$ (○) as a function of θ for TMV. Electric field strength = 300 V/cm; frequency = 1000 Hz

μ, δ, ω and illustrate in a very satisfactory manner the theoretical relations of the present paper.

Other experiments have been carried out on carbon black suspensions; the results are also consistent with the theory and will be presented elsewhere.

APPENDIX

The following functions are used in relation (7):

$$J_k^p = \frac{(2p)!k!(k+p)!2^{2k+1}}{p!(2p+2k+1)!}$$

$$G_k^p = \frac{(2p)!(2k)!}{2^{2p+2k+1}p!k!(p+k)!}$$

P_0 is the interference factor of a sphere of radius, a:

$$P_0 = \frac{9\pi}{2}\left[\frac{\mathscr{F}_{3/2}(ha)}{(ha)^{3/2}}\right]^2$$

$$P_0' = \frac{9\pi}{2}\frac{\mathscr{F}_{3/2}(ha)\,\mathscr{F}_{5/2}(ha)}{(ha)^2}$$

where $\mathscr{F}_{3/2}$ and $\mathscr{F}_{5/2}$ are Bessel functions and $h = (4\pi/\lambda)\sin\theta/2$.

N.m.r. studies of butadiene – styrene copolymers

A. L. Segre, M. Delfini and F. Conti
Istituto Chimico dell'Università di Roma, 00185 Roma, Italy

and A. Boicelli
Laboratorio CNR, Ozzano Emilia, Bologna, Italy
(Received 29 April 1974)

An analysis of the ^{13}C nuclear magnetic resonance spectra of copolymers of butadiene—styrene, both block or random type, shows the possibility of observing the microstructure of the copolymers themselves. The microstructure of the copolymers was analysed in terms of triads of monomeric sequences. The units present in the copolymers are of the type: *trans*-1,4-butadiene, *cis*-1,4-butadiene, 1,2-butadiene and styrene. An assignment for all the experimental bands observed is proposed on the basis of correlation with homopolymers as well as on the basis of the frequencies for the single triads, calculated by additivity rules.

INTRODUCTION

In the sphere of characterization of butadiene—styrene copolymers, until now no exhaustive analysis of the microstructure of the polymeric chains in terms of the distribution of monomeric sequences has been carried out. In the case of SB or SBS copolymers, a differentiation was made on the basis of different ways of preparation[1]. Only scant knowledge of the microstructure of the block or random copolymers has been obtained, even with the help of proton nuclear magnetic resonance (n.m.r.) spectroscopy[2], for other types of comonomer, ^{1}H n.m.r. gave definite information regarding the polymeric chain microstructure[3]. We have studied certain types of butadiene—styrene copolymers using ^{13}C n.m.r. and the results obtained are given here.

Mechanism of copolymerization

The addition of a butadiene monomeric unit to a polymeric chain in growth can occur in the 1,4-position or across the double bond (1,2-).

In the case of the 1,4- addition the butadiene unit can be in a *cis* or *trans* configuration. In the case where the polymeric chain in growth ends with a 1,4- unit the addition of a 1,2-unit can result in two ways:

$$-CH_2-CH=CH-CH_2-CH_2-CH-$$
$$|$$
$$CH$$
$$\|$$
$$CH_2$$

or

$$-CH_2-CH=CH-CH_2-CH-CH_2-$$
$$|$$
$$CH$$
$$\|$$
$$CH_2$$
while if the chain in growth ends with a 1,2-unit the addition of another 1,2-unit takes place regularly.

With regard to the butadiene units which can be *cis*-1,4-, *trans*-1,4 or 1,2-, the styrene residues can attach themselves either by the head ($-CH_2-C(\phi)H-$) or by the tail ($\phi-CH-CH_2-$), resulting in different sequences; i.e. with respect to the last growing unit the entering styrene monomeric unit can present itself either with its head or its tail.

The great sequential multiplicity which can result from the different possible combinations is therefore evident.

To simplify the notation and to keep in mind all the combinations we mark differently the units which can present themselves by the head and by the tail, i.e.:

$$\overrightarrow{v} = -CH-CH_2- \qquad \overleftarrow{v} = -CH_2-CH-$$
$$| \qquad\qquad\qquad |$$
$$CH \qquad\qquad\qquad CH$$
$$\| \qquad\qquad\qquad \|$$
$$CH_2 \qquad\qquad\qquad CH_2$$

$$\overrightarrow{\phi} = -CH-CH_2- \qquad \overleftarrow{\phi} = -CH_2-CH-$$
$$| \qquad\qquad\qquad |$$
$$\phi \qquad\qquad\qquad \phi$$
and with c and t respectively the 1,4-units in a *cis* or *trans* configuration.

The number of possible triads is $6^3 = 216$, each of which will give rise to two resonances, which might or might not be different as far as the backbone carbon atoms are concerned.

As a matter of fact, considering that due to the steric hindrance, $\overleftrightarrow{\phi v}$ additions do not seem very likely and, as will be seen, have not been observed, and considering that the $\overrightarrow{v}\overleftarrow{v}$ and $\overrightarrow{\phi}\overleftarrow{\phi}$ additions are not present in the homopolymers[4,5] the number of possible triads is reduced to 152, each of which must be considered twice, owing to the fact that in the backbone, whichever monomeric unit is considered, this has two saturated carbon atoms.

Calculation of the backbone ^{13}C chemical shifts

All the central units of possible triads give rise to two n.m.r. signals, corresponding to the saturated carbon atoms of the backbone. However, the two signals in certain cases can be coincidental by symmetry.

The assignment of different resonance signals to the possible sequences has been done either by direct comparison with corresponding homopolymers expressly prepared, or by calculating the chemical shifts relative to various groups according to additivity rules[6], i.e. adding the contributions relative to α, β and γ positions. Contributions relative to the δ position and those that follow have been neglected. Obviously no steric effect can be kept in consideration with this type of approach.

By using the data relative to homopolymers, considered as model compounds, it has been possible to evaluate the contributions relative to α, β and γ positions of various groups.

In fact, if model compounds, such as octene, heptene etc. for the vinyl contribution, and ethyl benzene, butyl benzene etc., for the phenyl contribution, are used, the calculated values for the spectra relative to homopolymers show a very poor fit.

On the contrary, values for α, β and γ contribution for *cis* and *trans* double bond in the backbone, are consistent with the values obtained by Roberts *et al.*[7].

In order to obtain the vinyl group contribution we carefully studied various polymers of butadiene (with different content of 1,2-, *cis*-1,4- and *trans*-1,4-units, so that the vinyl contributions on the polymeric chain were obtained*.

A study of the same type has been done on polystyrene, in order to ascertain the phenyl contribution on the backbone carbon atoms. Finally, branching corrections as indicated by Grant and Paul[8] were added.

The polyethylene chemical shift, 29.9 ppm from tetramethylsilane (TMS), was chosen as starting point, in which all CH_2 contributions must be considered nil.

The values for the contributions are:

Starting chemical shift	29.9 ppm
Corrections for $CH_2 (\alpha = \beta = \gamma$ etc. $= 0)$	
Corrections for CH tertiary saturated	$\alpha = -2.5$
	$\beta = 0$
	$\gamma = 0$
Contribution for a *cis* double bond	$\alpha = -2.5$
	$\beta = 0$
	$\gamma = -0.5$
Contribution for a *trans* double bond	$\alpha = +3.0$
	$\beta = 0$
	$\gamma = -0.5$
Contribution for a vinyl group	$\alpha = 13.5$
	$\beta = 8.4$
	$\gamma = -2.4$
Contribution for a phenyl group	$\alpha = 18.9$
	$\beta = 7.9$
	$\gamma = -2.2$

Thus it is possible to calculate the values of chemical shifts relative to different C atoms in the different triads, and these values can be compared with the observed peaks experimentally.

Calculation of the intensities (random copolymers)

Let us consider now the case of a random copolymer. If p_i = probability of the ith monomer and n_i = percentage of the ith monomer, $\delta_{ij} = 1$ or 0, where δ_{ij} is zero only if $\overleftrightarrow{i\,j}$, $\overrightarrow{i}\overleftarrow{i}$ or $\overleftarrow{i}\overrightarrow{i}$, otherwise it is 1. Then with this notation, the probability Φ_{ij} of a diad ij is:

$$\Phi_{ij} = \frac{p_i p_j \delta_{ij}}{\Sigma p_i p_j \delta_{ij}}$$

Thus, in the case of random copolymers, knowing the different percentages n_i, it is possible to compare the experimental and calculated intensities.

The latter are coincidental with the triad probabilities themselves:

$$\Phi_{\text{triad } ijk} = \frac{n_i n_j n_k \delta_{ij} \delta_{jk}}{\Sigma_{i,j,k} n_i n_j n_k \delta_{ij} \delta_{jk}} \tag{1}$$

and clearly: $n_{\overrightarrow{\phi}} = n_{\overleftarrow{\phi}} = 1/2 n_\phi$ and $n_{\overrightarrow{v}} = n_{\overleftarrow{v}} = 1/2 n_v$. The quantitative determination of n_ϕ, n_v, n_c and n_t is possible by running both the ^1H and ^{13}C n.m.r. spectra. In the proton spectrum three groups of resonances are present, with chemical shift values of ~ 7, ~ 5.5 and ~ 1.5 ppm from TMS, respectively, from aromatic groups, vinyl and vinylenic groups, and aliphatic groups. If A = percentage of styrene units, B = percentage of 1,4-polybutadiene units $(c + t)$, C = percentage of 1,2-polybutadiene units, then peak at 7 ppm = 5A, peak at 5.5 ppm = 2B + 3C, and peak at 1.5 ppm = 4B + 3C + 3A from which it is easy to obtain A, B and C[9]. In order to obtain n_c and n_t, these can easily be obtained from the ^{13}C spectrum, by considering the peaks at 130.75 and 130.25 ppm from TMS, respectively due to *trans* and *cis* double bonds[10]. The use of the peaks at 27.4 and 32.7 ppm, relative to ethylene groups adjacent to a *cis* or *trans* double bond (see ref 10 and references quoted therein), is not a good choice, because, in that range of the spectrum, in the copolymers, there is a very large number of peaks, which partially overlap.

Finally, by considering that $\overrightarrow{v}$ and $\overleftarrow{v}$ are equally populated, as well as $\overrightarrow{\phi}$ and $\overleftarrow{\phi}$, it is possible to obtain the following resolution:

$$\left\{ \begin{array}{l} n_{\overrightarrow{\phi}} = n_{\overleftarrow{\phi}} \quad = A/2 \\ \\ n_{\overrightarrow{v}} = n_{\overleftarrow{v}} \quad = C/2 \\ \\ n_{cis} + n_{trans} = B \\ \\ n_{cis}/n_{trans} = \dfrac{\text{peak at } 130.25}{\text{peak at } 130.75} \end{array} \right\} \begin{array}{l} {}^1H \text{ spectrum} \\ \\ \\ {}^{13}C \text{ spectrum} \end{array}$$

from which it is possible to get the values of equation (1) giving Φ_{ijk}.

Thus it is possible to compare experimental and calculated intensities for a random copolymer.

EXPERIMENTAL

We studied four copolymers whose preparation was as follows.

Sample A: block copolymer SB type. Catalyst, n-butyl-Li. Adiabatic reaction between 50°C and 115°C.

Sample B: random copolymer. Catalyst, n-butyl-Li/

tetrahydrofuran. Adiabatic reaction between 50°C and 110°C.

Sample C: block copolymer SB type. Catalyst, n-butyl-Li/tetrahydrofuran. Adiabatic reaction between 50°C and 95°C.

Sample D: same as C but different composition.

The analysis in terms of percentages of composition of units in the copolymer (by ^{1}H and [13]C n.m.r. spectra) is given below. A: styrene, 16.0; 1,2-butadiene, 11.2; *cis*-1,4-butadiene, 30.5; *trans*-1,4-butadiene, 42.3. B: styrene, 16.0; 1,2-butadiene, 26.0; *cis*-1,4-butadiene, 19.0; *trans*-1,4-butadiene, 39.0. C: styrene, 28.2; butadiene, 9.0; *cis*-1,4-butadiene, 24.9; *trans*-1,4-butadiene, 37.9. D: sty-

rene, 20.9; 1,2-butadiene, 8.0; *cis*-1,4-butadiene, 28.8; *trans*-1,4-butadiene, 42.3.

The butadiene—styrene ratio has been verified by elemental analysis.

[13]C n.m.r. spectra have been run on 10% (by wt) solution in CDCl₃, with TMS as an internal reference and under the following conditions: pulse width, 9 μsec; repetition, 1.1 sec; data points, 8 K; frequency range, 4 K. The spectrometer was a Jeol PFT 100.

RESULTS AND DISCUSSION

Spectra relative to different samples of styrene—butadiene copolymers are reported in *Figures 1* and *2*.

The chemical shift values, relative to the observed resonances in different samples of copolymers as well as homopolymers, are reported in *Tables 1* and *2* together with the relative normalized intensities. Finally in *Table 3* the calculated values are reported together with different assign-

ments in term of triads relative to all observed resonance peaks.

Interesting considerations of the different spectral assignments, follow from an analytical inspection of all resonance lines.

1. Peak at 25.07 ppm. Present in all copolymer samples. Present also in homopolymers of butadiene containing 1,2-units and cis-1,4-units. It is due to the γ effect of a vinyl group on a cis-1,4-unit.

2. Peak at 25.40 ppm. Present in samples A and B. By analogy with the attribution of peak 1, this peak is attribut-ed to the γ effect of a phenyl group on cis-1,4-units. This attribution is supported by the lack of this peak in block samples C and D, where these sequences ought to be ex-tremely low.

3. Peak at 27.55 ppm. Present in all copolymer samples, it has also been observed by Grant[11] in homopolymers of butadiene in a cis-1,4-configuration. All sequences. having a central cis-1,4-unit and to which the neighbouring con-tribution has no effect, should give rise to this signal.

4. Peak at 30.16 ppm. Present in all copolymer samples. Present also in homopolymers of butadiene containing

not assigned any peak to the sequences cφ̄v*, tφ̄v*, v̄φ̄t*, v̄φ̄c*, calculated at 48.8

trans-1,4- and 1,2-units. Absent in a polybutadiene sample containing cis-1,4- and 1,2-units. It is due to the γ effect of a vinyl group on a trans-1,4-unit.

5. Peak at 30.51 ppm. Present only in samples A and B. It is attributed to the γ effect of a phenyl group on a trans-1,4- butadiene unit.

6. Peak at 32.33 ppm. It has been observed only in the random copolymer. It is tentatively assigned to sequences of the type φ⃗v, in which there is a γ effect of a vinyl on the methylene carbon atom of a styrene unit. An alternative interpretation is that it might be due to the effect of a phenyl on a cis-1,4-unit. The assignment is uncertain and, on the basis of intensities, these last units should instead contribute to peak 7.

7. Peak at 32.74 ppm. Present in all copolymer samples. Present in homopolymers of butadiene in the trans-1,4-configuration[11]. All sequences, having a central unit of the type trans-1,4-, and to which the neighbouring contribution has no effect should give rise to this signal. Moreover, a portion of this peak is due to cis-1,4-units with a vinyl in β position, as observed on homopolymers of cis-1,4-polybutadiene containing 1,2-units.

8. Peak at 33.65 ppm. Present only in the random co-

polymer. Owing to the weak intensity of this peak, the assignment is uncertain. However, from the fact that no other calculated peak is near this position, the peak is attributed to units of the type R--v⃗ φ, with R = c, t, or v⃗ or φ⃗.

9. Peak at 34.25 ppm. Present in all copolymers. Present in samples of 1,4-butadiene (cis or trans) containing 1,2-units. It is due to methylenes of 1,2-units, interspersed between 1,4-units. The assignment has been verified by off resonance experiments.

10. Peak at 34.56 ppm. It is present only in the random copolymer (at high vinyl content); it has also been observed in a homopolymer of 1,2-butadiene containing a small percentage of 1,4-units (both cis and trans). As a consequence it is attributed to methylenes of sequences of the type (1,4-)/(1,2-)/(1,2-). The assignment has been verified by off resonance experiments. Moreover, other sequences (see Table 3) might contribute to this peak; in fact, some sequences attributed to peak 11 might stay in peak 10 and vice versa.

11. Peak at 35.88 ppm. Present in copolymers A and B presumably due to styrene units interspersed between 1,4-butadiene units.

12. Peak at 37.72 ppm. Present only in the random co-

polymer and tentatively assigned to sequences with a central vinyl surrounded by a vinyl and a neighbouring styrene.

13. Peak at 37.88 ppm. Present only in the random copolymer. Attributed to the β effect of a phenyl group on *trans*-1,4-units. The assignment of peaks 12 and 13 can be switched.

14. Peak at 38.17 ppm. Present in all copolymer samples, as well as in a homopolymer of 1,2-polybutadiene containing *trans*-1,4-units. It is attributed to ethylenes of *trans*-1,4-units with a vinyl group in β position.

15. Peak at 38.89 ppm. Tentatively assigned to methines of vinyl units interspersed between neighbouring styrene units. It has been observed only in the random copolymer.

16. Peak at 39.05 ppm. Present only in the random copolymer; tentatively assigned to methines in $\overrightarrow{v}\,\overleftarrow{v}\,\overrightarrow{\phi}$ sequences.

17. Peak at 39.60 ppm. Present only in the random copolymer; the assignment again is only a tentative one, owing to the fact that this peak is very near and has the same intensity of peak 18. Assignments of peaks 17 and 18 can be interchanged. It is tentatively attributed to the CH_2 group between two neighbouring styrenes adjacent to 1,4-units. May also be due to the CH of two 1,2-units adjacent to 1,4-units.

18. Peak at 39.83 ppm. Present only in the random copolymer. Tentatively assigned to a CH_2 group between two neighbouring styrenes adjacent to a 1,2-unit. Plus probably the CH groups of sequences of the type (1,4-)/(1,2-)/ (styrene) (see *Table 3*).

19. Peak at 40.09 ppm. Present only in the random copolymer. It might be due to sequences of the type (1,4-)/(1,2-)/(styrene). The assignment is mainly due to the calculated and experimental intensities of this peak.

20. Peak at 40.73 ppm. Present in all the copolymers and due to the CH_2 groups of styrene blocks. It is also present in polystyrene (see *Table 1* and *Figure 3*).

21. Peak at 41.14 ppm. Present in the random copolymer (at high vinyl content) and also in a 1,2-polybutadiene sample containing 1,4-type units (*cis* and *trans*). From off

Figure 3 Spectrum of an atactic high molecular weight polystyrene sample, upper field range; shift values are given in *Table 1*

resonance experiments this peak is mainly due to CH_2 groups. It is attributed to two 1,2-units, neighbouring 1,4-units. It might also be due to mixed sequences of CH groups of 1,2-units having in the γ position either a vinyl group or a phenyl group (see *Table 3*). Assignment among bands 21 and 22 which might be and probably are, mixed together.

22. Peak at 41.51 ppm. Present only in the random copolymer. It must be observed that many calculated sequences lie between 41.2 and 41.7 ppm (see *Tables 1* and *3*). All these sequences should give rise to peaks 21 and 22. The attribution of these two bands is quite reliable as a whole, but we do not know which sequences contribute to peak 21 and which ones to peak 22. The total assignment of the sum of peaks 21 and 22 as shown in *Table 3* is in satisfactory agreement with the experimental data.

23. Peak at 42.15 ppm. Present only in sample C (block copolymer with high styrene content). It is present in the spectrum of atactic polystyrene as one of the peaks in which the CH signal is split due to configurational effect. It is attributed to polystyrene blocks (see *Figure 3*).

24. Peak at 42.62 ppm. Present only in the random copolymer. Its intensity is very weak. Tentatively it is assigned to 1,2-units interspersed between styrene units. As another tentative assignment it might be due to the methines of $\overrightarrow{\phi}\,\overleftarrow{v}$ sequences. This last assignment must be considered solely a tentative one.

25. Peak at 42.98 ppm. Present in copolymers B, C and D and in the spectrum of atactic polystyrene. It is attributed to polystyrene blocks. It might also be due (low probability) to styrene adjacent to 1,2-units.

26. Peak at 43.52 ppm. Present in all copolymer samples. Present in 1,4-polybutadiene containing low percentages of 1,2-units, in which off resonance experiments demonstrate that it is due to the superimposition of CH and CH_2 resonances. It is attributed to the CH of 1,2-units interspersed between 1,4-units and also to the CH_2 groups of units of the type 1,4-, 1,2-.

27. Peak at 44.26 ppm. Present in copolymers B, C and D and in atactic polystyrene. Attributed to CH of polystyrene blocks (see *Figure 3*).

28. Peak at 45.82 ppm. Present only in the random copolymer. By comparison of the intensities it might be due to a set of mixed sequences as shown in *Table 3*. This assignment is only a tentative one.

29. Peak at 45.95 ppm. Present in all copolymer samples. Present also in the atactic polystyrene. It is due to polystyrene blocks. Moreover, it might be due to other sequences (see *Table 3*), which present a calculated chemical shift in reasonable agreement.

30. Peak at 46.22 ppm. Present only in samples C and D. Present in atactic polystyrene. Attributed to polystyrene blocks (see *Figure 3*).

No peak has been assigned to the CH groups relative to sequences of the type $c\overleftarrow{\phi v}\,{}^*,\ t\overrightarrow{\phi v}\,{}^*;\,\overleftarrow{v\phi t}{}^*,\,\overleftarrow{v\phi c}{}^*$ (calculated at 48.8) because any assignment would have been absolutely hypothetical. Sequences $\overrightarrow{v\,v\,v}$ and $\overleftarrow{v\,v\,v}$, of which the chemical shift values, both for CH and CH_2, were known, were not found.

It must be remarked that sequences $\overleftarrow{\phi}\,\overrightarrow{\phi}$ or $\overleftarrow{\phi v}$ not considered in this analysis, have calculated values higher than 60 ppm; no peak higher than 46 ppm has been observed. The use of additivity rules has no meaning in the spectral range between 110 and 150 ppm. In this range, assignments have been made only on direct comparison with homopolymers. Assignments as well as experimental values are reported in *Table 2*.
Bands A, B, C, P and R have been assigned on the basis of the results obtained on polystyrene: A, B, C, aromatic quaternary carbon atom; P, *meta* and *ortho*; R, *para*.

It must be observed that the P peak is a very broad one, as observed in samples B, C and D and in high molecular weight atactic polystyrene; while it is split in sample A. In this sample the O peak is assigned to C atoms in an *ortho* position, while the P peak is assigned to the *meta* positions; the N peak is probably due to styrene, but is probably dependent on the sequences.

Peaks I, L and M belong to sequences due to 1,4-butadiene.

Peaks D, E, S, T and V are also present in the spectrum of 1,2-polybutadiene and in samples of 1,4-polybutadiene containing small percentages of 1,2-units; these peaks can be assigned to vinyl groups. In the random sample these peaks are partly split probably due to the presence of different sequences. Peak G, present in all copolymers, is due to vinylic groups of 1,4-units adjacent to 1,2-units.

Peaks F and H might be due (tentative) to vinylic carbon atoms of 1,4-units adjacent to styrene units.

CONCLUSION

From the reported results the possibility of obtaining information on the distribution of comonomers in chains of copolymers of the SB type is evident. These data, even if not strictly quantitative, give us a knowledge of the microstructure of polymer chains, that can be considered a base for a more rational correlation with technological properties of this important class of copolymers.

With regards to this, we are studying polymers of the SBS type, polymers at very different content of comonomers and polymers prepared with different catalysts.

Conformational studies of N-acetyl-N-methyl-L-alanine dimethylamide-d_6 by n.m.r. spectroscopy*

Yukio Imanishi, Kazuya Kugimiya and Toshinobu Higashimura
Department of Polymer Chemistry, Kyoto University, Kyoto, Japan
(Received 14 June 1974)

Nuclear magnetic resonance of N-acetyl-N-methyl-L-alanine dimethylamide-d_6 in methylene chloride-d_2/dichloroacetic acid was investigated. In methylene chloride-d_2 the amide assumed nearly all-*trans* conformation. Small signals corresponding to trace amounts of *cis* conformation were observed. Dichloroacetic acid induced the shift of the resonance signals immediately after the addition. On leaving the solution containing dichloroacetic acid, the amide nitrogen was protonated and the isomerization around the amide bond took place. After a sufficient time lapse a complex spectrum resulted, which corresponded to at least five different conformations. On heating the solution several signals disappeared without coalescence and the resonance signals corresponding to three different conformations remained at 120°C. These conformations should include non-planar conformations as well as planar *cis* and *trans* conformations.

INTRODUCTION

Simple amides have been useful models for polypeptides in respect to their conformational properties. In fact the conformational changes of simple amides under suitable conditions have been a basis for considering the conformational behaviour of polypeptides. A particular interest has been paid to the presence of a *cis* amide bond in poly(imino acids). The *cis–trans* isomerism of simple substituted amides has long been known[1]. With poly(L-proline)[2] and polysarcosine[3,4] the presence of a *cis* amide bond was observed mainly by nuclear magnetic resonance (n.m.r.) spectroscopy, and the conformational behaviour of these poly(imino acids) was discussed in comparison with the corresponding monomeric amides. With poly(N-methyl-L-alanine)[5,6], the open chain analogue of poly(L-proline), the presence of a *cis* amide bond was suggested by the calculation of potential energies and was observed by n.m.r. spectroscopy, and the conformational transition was discussed in terms of the *cis–trans* isomerism of the amide bonds. However, no such investigation has been carried out with the monomeric amide. Recently Goodman *et al.*[7] reported the n.m.r. investigation of N-acetyl-N-methyl-L-alanine methyl ester. They investigated the *cis–trans* isomerism (thermodynamics and kinetics) of the ester only in the so-called helix-supporting solvents.

In our study of enzyme-model reactions[8] using various polypeptides, we became interested in the conformational behaviour of poly(N-methyl-L-alanine). So we investigated at first N-acetyl-N-methyl-L-alanine dimethylamide in methylene chloride-d_2 (CD$_2$Cl$_2$)/dichloroacetic acid (DCA) mixed solvent. We believe that the amide is a better model for poly(N-methyl-L-alanine) than the ester. Furthermore, the conformational studies in strongly solvating DCA are directly related to the conformational transition of poly(N-methyl-L-alanine) in so-called helix-breaking solvents. In the present paper we will describe the n.m.r. studies of N-acetyl-N-methyl-L-alanine dimethylamide. The observations with poly(N-methyl-L-alanine) will be described in the following paper[9].

EXPERIMENTAL

N-Methyl-L-alanine N-carboxyanhydride (NCA) was synthesized from commercial L-alanine as reported previously[10,11]. The NCA was added in portions to a large excess of dimethylamine cooled by Dry Ice and allowed to react for 15 min. After the excess dimethylamine was evaporated, the residual oil, N-methyl-L-alanine dimethylamide was acetylated with acetic anhydride/pyridine. N-Acetyl-N-methyl-L-alanine dimethylamide was purified by distillation. When N-acetyl-N-methyl-L-alanine dimethylamide-d_6 was synthesized, dimethylamine-d_6 was used (b.p. 89–92°C at 4 mmHg).

100 and 220 MHz n.m.r. spectra were recorded with Varian HA-100 and HA-220 spectrometers, respectively. Tetramethylsilane was used as an internal standard. CD$_2$Cl$_2$ (Merck, 99%) was used without further purification. DCA was purified by vacuum distillation.

RESULTS

N-Acetyl-N-methyl-L-alanine dimethylamide can be represented in either *cis* or *trans* form:

trans   *cis*
The 100 MHz n.m.r. spectrum of N-acetyl-N-methyl-L-alanine dimethylamide dissolved in CD$_2$Cl$_2$ is shown in *Figure 1*. For the peak assignment the n.m.r. spectra of N-acetyl-N-methyl-L-alanine methyl ester[7] and N-acetyl sarcosine dimethylamide[4] were referred to: C_α–H resonance appeared as a quartet (4.52τ, $J = 6.67$ cycles/sec), C_α–CH$_3$ resonance appeared as a doublet (8.82τ, $J = 6.67$ cycles/sec), and acetyl-CH$_3$ (7.95τ) and N–CH$_3$ (7.15τ) resonances appeared as a singlet. There are two signals for the terminal amide-CH$_3$ (7.06τ, 7.11τ), which correspond to *cis* and *trans* CH$_3$.
Figure 1   100 MHz n.m.r. spectrum of N-acetyl-N-methyl-L-alanine dimethylamide in CD_2Cl_2 at 31.5°C; concentration 5% w/v

However, in CD_2Cl_2 a small doublet for C_α–CH_3 and a small singlet for N–CH_3 appeared in addition to the main signals. Goodman et al.[7] assigned these resonances to the presence of cis form. The experimental results which appear subsequently confirmed Goodman's proposal. These small resonance signals were not observed in CCl_4. These results indicate that N-acetyl-N-methyl-L-alanine dimethylamide exists in CCl_4 as completely trans form and in CD_2Cl_2 as nearly all trans form.

DCA promotes the transition of an ordered structure of polypeptide to a randomly coiled structure owing to its strongly solvating ability. DCA would induce more drastic isomerization of amide bond of N-acetyl-N-methyl-L-alanine dimethylamide than CD_2Cl_2. So, we examined the effect on the n.m.r. spectrum of increasing amount of DCA added to the CD_2Cl_2 solution of N-acetyl-N-methyl-L-alanine dimethylamide-d_6. Hereafter the deuterated amide was used to eliminate the complication due to the terminal methyl signals. Figure 2 shows the effect of DCA. The spectra were recorded immediately after the addition of DCA. The addition of small amount of DCA (2–13% v/v) caused a peak shift towards lower magnetic field. The effect was most marked with N–CH_3 and C_α–CH_3 resonances, and least marked with C_α–H resonance. It should be noted here that on adding DCA only the peak shift was observed, and that neither the peak-splitting nor the appearance of new signals was observed. This peak shift induced by DCA is a fast process.

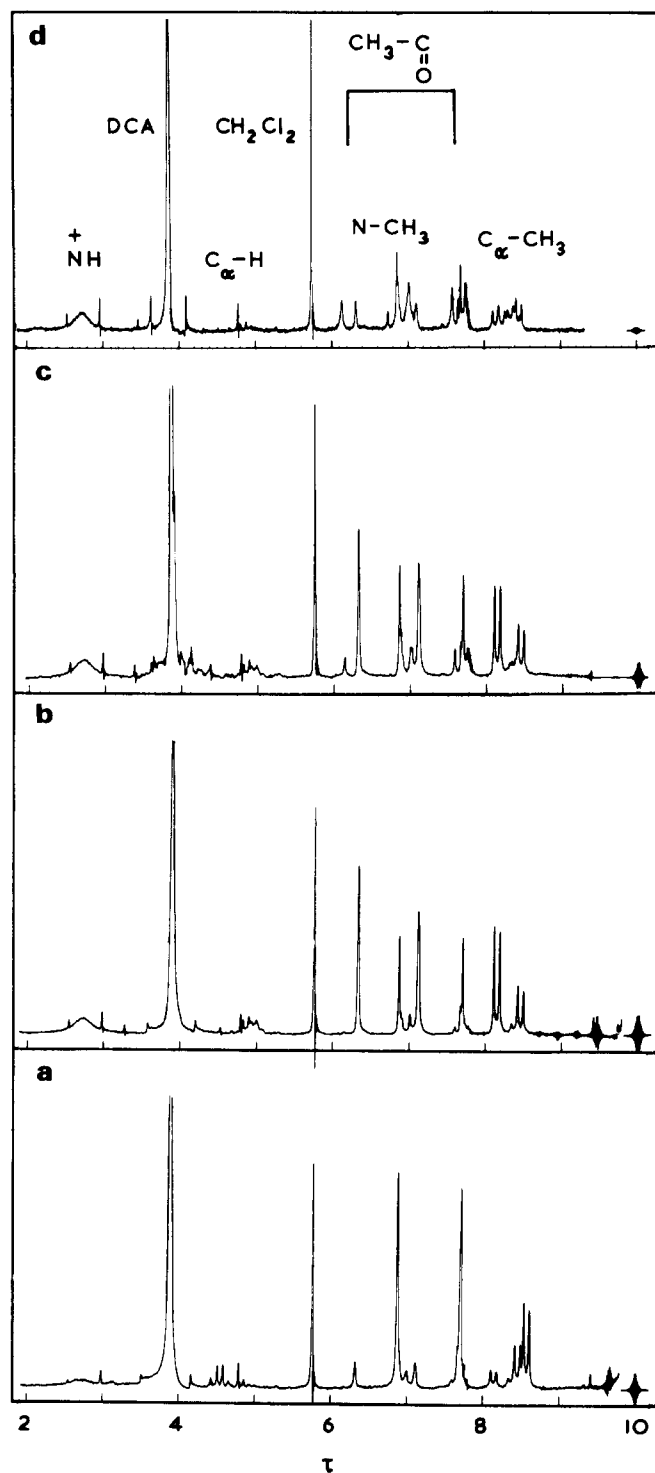
It was found that the n.m.r. spectrum of N-acetyl-N-methyl-L-alanine dimethylamide-d_6 in CD_2Cl_2/DCA mixed solvent was time-dependent. In Figure 3 the change with time of the n.m.r. spectrum of the amide-d_6 dissolved in DCA/CD_2Cl_2 (9:1 v/v) mixed solvent is shown. Immediately after DCA was added to the CD_2Cl_2 solution (Figure 3a), the signals are seen to have shifted to a lower magnetic field as compared with Figure 2a. At this stage new signals appeared only to a minor extent. When the solution was kept for several days at room temperature, the peak shift was no longer observed, but the peak intensity changed drastically and consequently a number of new signals were observable. After 27 days the n.m.r. spectrum became very complicated (Figure 3d), and C_α–H resonance which originally centred at 4.53τ became very obscured because of the peak broadening and the spin side band of DCA. The assignment of other resonance signals was made on the basis of the chemical shift and the peak area. Roughly five resonance signals are observed for each of C_α–CH_3, N–CH_3 and
Figure 2   100 MHz n.m.r. spectra of N-acetyl-N-methyl-L-alanine dimethylamide-d_6 in CD_2Cl_2 at 31.5°C; concentration 25.76% w/v; (a)0; (b) 1.96; (c) 3.85; (d) 13% v/v DCA


Figure 3 100 MHz n.m.r. spectra of *N*-acetyl-*N*-methyl-L-alanine dimethylamide-*d₆* in CD₂Cl₂/DCA (1:9 v/v) mixed solvent at 31.5°C; concentration 13% w/v. Measured after the preparation of solution: (a) immediately; (b) 24 h; (c) 6 days; (d) 27 days

dissolved in DCA/CD₂Cl₂ (9:1 v/v) mixed solvent and stored at room temperature for 27 days was measured at varying temperatures. *Figure 4* represents the effect of temperature on the methyl resonance region of the n.m.r. spectrum. At 36°C at least five signals are observable for each of C_α–CH₃, CH₃–CO, and *N*–CH₃ protons (*Figure 4a*). At 120°C three of the five remain (*Figure 4e*). On cooling the solution, the original spectrum appeared again so that this change is reversible. It should be noted that the disappearance of the peaks with increasing temperature did not take place through coalescence but through the decrease of the intensity. It should also be noted that three different conformations still existed at 120°C.

DISCUSSION

N-Acetyl-*N*-methyl-L-alanine dimethylamide was found to assume all-*trans* conformation in CCl₄ at room temperature. A small amount of *cis* conformation was observed in CD₂Cl₂.

acetyl-CH₃, *N*–CH₃ so that the amide should exist as a mixture of at least five different conformers (see also *Figure 4a*). It was interesting to note that the peak splittings were accompanied by the appearance of a new broad singlet centred at 2.7τ. The latter could be assigned to *N*–H resonance signal which was formed by the protonation of amide nitrogen (see later discussion). Both the splittings of signals and the protonation of amide nitrogen are a slow process.

To investigate further the peak splittings, the n.m.r. spectrum of *N*-acetyl-*N*-methyl-L-alanine dimethylamide-*d₆*

Figure 4 220 MHz n.m.r. spectra of *N*-acetyl-*N*-methyl-L-alanine dimethylamide-*d₆* in CD₂Cl₂/DCA (1:9 v/v) mixed solvent 27 days after the preparation; concentration 13% w/v. Measured at: (a) 36°; (b) 60°; (c) 70°; (d) 100°; (e) 120°C

Weakly hydrogen bonding CD_2Cl_2 may have caused the difference.

Addition of DCA to the CD_2Cl_2 solution caused a fast change and a slow change of the n.m.r. spectrum. The fast change is a shift of signals towards a lower magnetic field. The same effect has been reported in many papers[12,13] in which the effects of a strong acid on the chemical shift of simple amides are investigated. A stronger hydrogen bonding by DCA than CD_2Cl_2 would have caused the shift. On the other hand, the slow change is peak-splitting accompanied by N-protonation. This change is of similar type as that observed with the change of solvent from CCl_4 to CD_2Cl_2. Hence the spectral change is associated with the conformational change. We shall explain this in terms of an isomerization around the amide bond induced by the protonation of amide nitrogen.

Relatively strong acids, such as DCA and trifluoroacetic acid, induce a helix—coil transition of polypeptides. It has been a subject of controversy whether polypeptides are protonated or hydrogen bonded by acids at the transition. For some instances, simple amides are protonated more easily than polypeptides[12,14]. With regard to the mechanism of amide protonation, O-protonation and N-protonation have been considered. Although the fact that amides protonate predominantly on oxygen in strongly acidic media has been established for some time[15], predominant protonation is on nitrogen in dilute acid[14,16-18]. The present authors took N-protonation because a new peak appeared at 2.72τ on adding DCA. Allowing for the chemical shift and the shape this signal is reasonably assigned to $\equiv\overset{+}{N}$—H resonance[19]. >C=O—H resonance signal has been reported to appear at about 0τ only at low temperatures[20]. Intermediately fast exchanging $\equiv\overset{+}{N}$—H would appear as a broad singlet and its coupling with *vicinal* protons would be negligible. Amide nitrogen having electron-releasing substituents seems to be easily protonated. As is seen in *Figure 3*, the appearance of a signal at 2.72τ was accompanied by the conformational change. This gives further support to N-protonation. The N-protonation decreases the double bond character of the amide bond, making the isomerization easier, whereas O-protonation increases the double bond character, according to the mechanism shown for the protonation of N, N-dimethylacetamide below:
In *Figure 3d* five signals ascribable to different conformations are observed for each methyl proton. This complicated spectrum cannot be explained in terms of *cis—trans* diad of the amide bond, because N-acetyl-N-methyl-L-alanine dimethylamide possesses only one isomerizable amide bond. A restricted rotation around C_α bonds[5] could result in different stable conformations. However, the spectral change shown in *Figure 3* does not seem to be explained on this basis. One day after the addition of DCA (*Figure 3b*), *trans*-C_α—CH_3 resonance (doublet 8.58τ, $J = 6.67$ cycles/sec) disappeared and a new doublet at 8.14τ became predominant. At the same time a new CH_3—CO resonance at 6.34τ, and a

new N—CH_3 resonance at 7.13τ increased their intensities. These changes and in particular the large shift observed with CH_3—CO resonance can hardly be explained by the isomerization around C_α bonds. Although on a quite different ground, Goodman *et al.*[7] also considered that the isomerization of N-acetyl-N-methyl-L-alanine methyl ester is associated with the amide bond (not with the C_α bonds).

The new signal at 6.34τ was assigned to CH_3—CO resonance on the basis of peak area and the fact that this signal was not observed with poly(N-methyl-L-alanine)[9]. The chemical shift difference of CH_3—CO resonance between the original peak at 7.94τ and the new one at 6.34τ is very large. Such a large shift must have arisen from a twisted acetyl group adjacent to nitrogen carrying a positive charge. To explain such a complex spectrum as *Figure 3d* in terms of the isomerization around a single amide bond, non-planar amide conformations should be taken into account in addition to planar *cis* and *trans* conformations. Non-planar amide conformations have been considered to be unfavourable, because the conjugation $\overset{\frown}{N}$-C=O is lost. However, in the present case nitrogen is protonated to use up its lone-pair electrons. Thus the amide bond became a pure single bond, the rotation around which became less hindered. In this connection it should be remembered that the large splitting of CH_3—CO resonance as well as the moderate splitting of other methyl protons commenced when the amide nitrogen was protonated. Furthermore, the peak splittings progressed with increasing peak intensity at 2.72τ.

A strong support for the isomerization around the peptide bond is obtained from the temperature effect. Three different conformations still remains at as high a temperature as $120°C$ (*Figure 4e*). Restricted rotations around C_α bonds at $120°C$ are hardly acceptable[21]. On cooling the solution the spectrum *Figure 4a* was restored. It is most plausible that there are planar and non-planar conformations of the amide bond, and that some of them are relatively unstable at higher temperatures. The long-lived (on n.m.r. time scale) non-planar amide conformers are unique, but they are acceptable if one takes into account the steric interactions among methyl groups in the acetylated imino acid amide. Recently, the n.m.r. chemical shift of oligopeptides containing proline residue was explained by the proline stereoisomerism due to a slow nitrogen inversion[22]. This idea would involve steric interactions among substituents and non-planar amide links.

It is not known whether the deprotonation of the protonated amide took place during the temperature rise, because at higher temperatures only the regions of N—CH_3 and C_α—CH_3 resonance signals were examined.

Conformational studies of poly(*N*-methyl-L-alanine) by n.m.r. spectroscopy*

Yukio Imanishi, Kazuya Kugimiya and Toshinobu Higashimura
Department of Polymer Chemistry, Kyoto University, Kyoto, Japan
(Received 14 June 1974)

Nuclear magnetic resonance (n.m.r.) and circular dichroism of poly(*N*-methyl-L-alanine) in methylene chloride-*d₂*/dichloroacetic acid were investigated. In methylene chloride-d_2 poly(*N*-methyl-L-alanine) was found to consist of nearly all-*trans* amide bonds and assume a stable secondary structure. Trace amounts of *cis* amide bonds were also present. The addition of dichloroacetic acid destroyed the secondary structure and induced a drastic change of the n.m.r. spectrum, which was similar to that observed with the monomeric amide, *N*-acetyl-*N*-methyl-L-alanine dimethylamide. In comparison of the polymer with the monomeric amide, it was concluded that the transition of poly(*N*-methyl-L-alanine) was caused by the isomerization of amide bonds. The complex n.m.r. spectrum was interpreted in terms of the distribution along the polymer chain of various non-planar amide links as well as planar *cis* and *trans* amide links. The difference of the mechanism of conformational transition between poly(amino acid) and poly(imino acid) is also discussed.

INTRODUCTION

Synthetic polypeptides have been used as simplified model systems to investigate enzymic reactions[1]. In our laboratories poly(*N*-methyl-L-alanine) was used as a catalyst to initiate the polymerization of α-amino acid *N*-carboxyanhydride[2,3]. Poly(*N*-methyl-L-alanine) showed an interesting stereoselectivity in the polymerization, and the selectivity seemed to be related to a unique conformation of poly(*N*-methyl-L-alanine) in solution.

There have been a few papers published on the conformation of poly(*N*-methyl-L-alanine). Pioneering work by Goodman *et al.*[4] showed that this polymer consisted of all-*trans* amide bonds and assumed an ordered structure in methylene chloride. Later, the calculations made by Goodman *et al.*[5] and Liquori *et al.*[6] suggested the possibilities for stable secondary structures of poly(*N*-methyl-L-alanine).

The present authors were interested in the conformation of poly(*N*-methyl-L-alanine) in strongly acidic media as well as in non-polar media. Soon after the present authors started the investigation on the effect of dichloroacetic acid, Conti *et al.*[7] published a paper concerning the effect of trifluoroacetic acid. They observed a complex multiplet for each proton resonance in nuclear magnetic resonance (n.m.r.) spectrum in trifluoroacetic acid and explained the spectrum in terms of multiple energy minima in the rotation around C_α bond in combination with *cis* and *trans* amide bonds. However, their conclusion came mainly from calculation and little experimental work was made with n.m.r. spectroscopy. More recently Goodman *et al.*[8] made a more detailed study on the same problem and suggested that the addition of trifluoroacetic acid to the methylene chloride solution of poly(*N*-methyl-L-alanine) induced the *trans* → *cis* isomerization of amide bonds. Thus, *cis* and *trans* amide bonds

became randomly distributed along the polymer chain, and the secondary structure was destroyed in trifluoroacetic acid. However, their n.m.r. work was not detailed enough to give a complete explanation to the nature of the isomerization around amide bond. They investigated only the effect of trifluoroacetic acid concentration on the n.m.r. spectrum.

The present authors investigated the effect of dichloroacetic acid on the n.m.r. spectrum of poly(*N*-methyl-L-alanine) in more detail and found a number of interesting features which were observed neither by Conti *et al.* nor by Goodman *et al.* These aspects are described and discussed here in comparison with the effect of dichloroacetic acid on *N*-acetyl-*N*-methyl-L-alanine dimethylamide, the monomeric analogue of poly(*N*-methyl-L-alanine)[9]. Part of the experimental results have been reported in a previous paper[2], together with the properties of poly(*N*-methyl-L-alanine) as an initiator for the polymerization of phenylalanine *N*-carboxyanhydride.

EXPERIMENTAL

Poly(*N*-methyl-L-alanine) was synthesized by the polymerization of *N*-methyl-L-alanine *N*-carboxyanhydride with *N*-methyl-L-alanine diethylamide as an initiator in methylene chloride. Details of the synthesis and the control of the degree of polymerization have been described in a previous paper[2]. The degree of polymerization of poly(*N*-methyl-L-alanine) used for the present investigation was 15 or 30. Poly(*N*-methyl-DL-alanine) having a degree of polymerization of 30 was synthesized for comparison as reported previously[10].

N.m.r. spectra of the polypeptides were measured as described in the preceding paper[9]. Methylene chloride-*d₂* (CD_2Cl_2) (Merck, 99%) was used without further purification and dichloroacetic acid (DCA) was purified by distillation.
Figure 1 100 MHz n.m.r. spectrum of poly(N-methyl-L-alanine) (DP = 30) in CD$_2$Cl$_2$ at 31.5°C; concentration 5% w/v

RESULTS

Poly(N-methyl-L-alanine) can be represented in either *cis* or *trans* form as:
100 MHz n.m.r. spectrum of poly(N-methyl-L-alanine) having a degree of polymerization of 30 in CD$_2$Cl$_2$ is shown in *Figure 1*. The spectrum is identical with that reported by Goodman *et al.*[4,8]. N—CH$_3$ resonance signal appeared as a singlet at 7.2 τ and C$_\alpha$—CH$_3$ resonance signal appeared as a doublet at 8.75 τ (J = 6.7 cycles/sec). C$_\alpha$—H resonance signal appeared as a quartet at 4.58 τ (J = 6.3 cycles/sec), which was obscured by the resonance signal of methylene chloride. According to the peak assignment proposed by Goodman *et al.*[4,8] poly(N-methyl-L-alanine) in CD$_2$Cl$_2$ possesses nearly all-*trans* amide bonds. A small doublet at a lower magnetic field than the main C$_\alpha$—CH$_3$ doublet, and a small singlet at a higher magnetic field than the main N—CH$_3$ singlet are ascribed to the presence of a small amount of *cis* amide bond. Under this condition poly(N-methyl-L-alanine) assumes an ordered structure which is evident from the circular dichroism spectra reported in a previous paper[2].

100 MHz n.m.r. spectra of poly(N-methyl-L-alanine) were recorded soon after the addition of a small amount of DCA to the CD$_2$Cl$_2$ solution (*Figure 2*). The C$_\alpha$—CH$_3$ and the N—CH$_3$ signals shifted slightly towards a lower magnetic field and the C$_\alpha$—H signal shifted a little towards a higher magnetic field. New signals for C$_\alpha$—CH$_3$ and N—CH$_3$ resonances began to appear only to a minor extent. This change is similar to that observed with N-acetyl-N-methyl-L-alanine dimethylamide[9]. It is interesting to note that a broad singlet appeared at 4.35 τ (DCA 0.60 % v/v) or at 3.40 τ (DCA 1.18 % v/v). The chemical shift of the signal was dependent on the concentration of DCA. Thus the signal appeared at 2.07 τ, when the solution contained 90 % v/v DCA.

When the solution of poly(N-methyl-L-alanine) containing DCA was left for standing, the chemical shifts of the proton

resonances no longer changed, but the intensities of the original signals decreased and new signals appeared. *Figure 3* shows the effect of standing for 24 h on the methyl resonance region of the 100 MHz n.m.r. spectra. The time-dependent n.m.r. spectra and the mode of peak splittings are very similar to those observed with N-acetyl-N-methyl-L-alanine dimethylamide[9]. However, the n.m.r. spectra of the polymer in DCA-containing solvent after standing for 24 h were more complex than those of the simple amide. Under this condition poly(N-methyl-L-alanine) is in a random-coil form, which has been evidenced by optical rotatory dispersion as reported in a previous paper[2]. This change was found to be reversible; i.e. after the recovery of the polymer from the solution, it was redissolved in CD$_2$Cl$_2$ to give a n.m.r. spectrum very similar to *Figure 1*.

Figure 4 shows the n.m.r. spectra of poly(N-methyl-DL-alanine) in CD$_2$Cl$_2$ and in DCA/CD$_2$Cl$_2$ (9:1 v/v) mixed solvent. 100 MHz n.m.r. spectrum of poly(N-methyl-DL-alanine) in CD$_2$Cl$_2$ is very similar to that of poly(N-methyl-L-alanine). The N—CH$_3$ signal split into two sharp peaks. The peak splitting was maintained at higher temperatures, so it may be related with the configurational (L or D) diad. However, it is not known why the configuration of C$_\alpha$ affects only the N—CH$_3$ resonance signal. The addition of DCA gave a complex spectrum, which is very similar to the spectrum of poly(N-methyl-L-alanine) in a solvent containing DCA.

Poly(N-methyl-L-alanine) was dissolved in DCA/CD$_2$Cl$_2$ (9:1 v/v) mixed solvent and left at room temperature for 14 days. The solution was then heated up to 130°C and the change of n.m.r. spectra (C$_\alpha$—CH$_3$ and N—CH$_3$ regions only) was followed (*Figure 5*). At 31.5°C the signals were overlapped and broad, but at least six singlets for N—CH$_3$
Figure 2 100 MHz n.m.r. spectra of poly(N-methyl-L-alanine) (DP = 15) in CD$_2$Cl$_2$ at 31.5°C. (a) 0.60; (b) 1.18% v/v DCA
Figure 3 100 MHz n.m.r. spectra of poly(*N*-methyl-L-alanine) (*DP* = 15) at 31.5°C. (a) CD$_2$Cl$_2$/DCA 9:1 v/v soon after preparation; (b) CD$_2$Cl$_2$/DCA 9:1 v/v 4 days after preparation; (c) CD$_2$Cl$_2$/DCA 7:3 v/v soon after preparation; (d) CD$_2$Cl$_2$/DCA 7:3 v/v 24 h after preparation; (e) CD$_2$Cl$_2$/DCA 5:5 v/v soon after preparation; (f) CD$_2$Cl$_2$/DCA 5:5 v/v 24 h after preparation; (g) CD$_2$Cl$_2$/DCA 3:7 v/v soon after preparation; (h) CD$_2$Cl$_2$/DCA 3:7 v/v 24 h after preparation; (i) CD$_2$Cl$_2$/1:9 v/v soon after preparation; (j) CD$_2$Cl$_2$/DCA 1:9 v/v 24 h after preparation

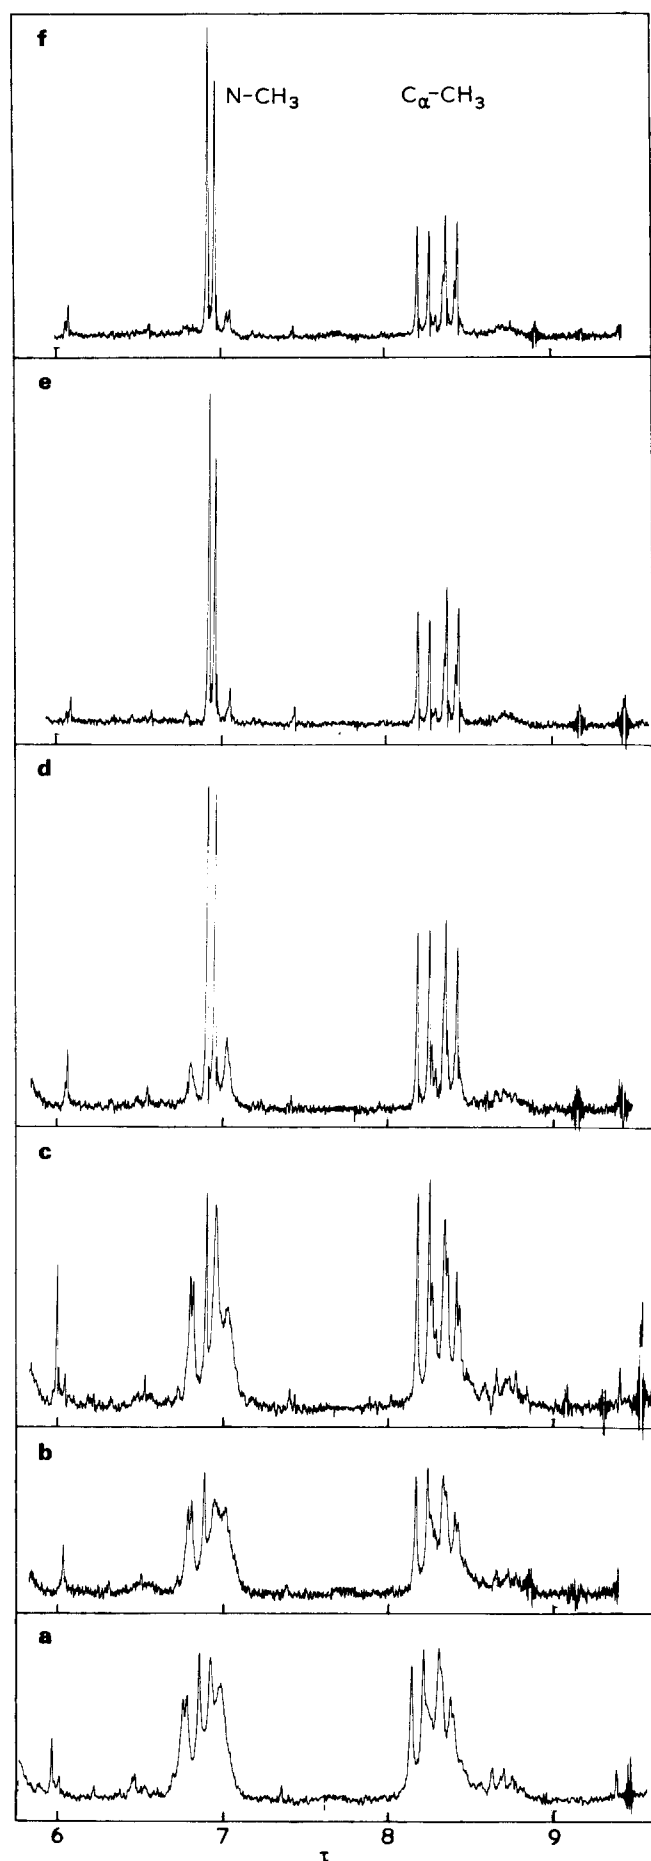
resonance signals and six doublets for C_α—CH$_3$ resonance signal were observed. On heating, the signals shifted slightly towards a higher magnetic field and were sharpened. A sudden change of the relative peak intensities occurred at a temperature rise from 70°C to 90°C. At 130°C, two main resonance signals and one minor resonance signal were observed for either *N*—CH$_3$ or C_α—CH$_3$ proton. During this procedure, the chemical shift difference for the *N*—CH$_3$ signals decreased a little, but that for the C_α—CH$_3$ signals did not change significantly. The coupling constant of the C_α—CH$_3$ doublet was little affected by the temperature.

DISCUSSION

Poly(*N*-methyl-L-alanine) was found to consist of all-*trans* amide bonds and assume an ordered conformation in CD$_2$Cl$_2$. The preponderence of *trans* amide bonds in CDCl$_2$ have also been observed with the monomeric amide, *N*-acetyl-*N*-methyl-L-alanine dimethylamide. The same observations have been made by Goodman *et al.*[4,8].

The addition of DCA induced a shift of the resonance peaks. This change took place immediately after the addition of DCA, so that it may have been caused by the solvation, hydrogen bonding with added DCA being involved. The same phenomenon has been observed with the monomeric amide[9].

On adding 0.60% v/v DCA a broad singlet appeared at 4.35 τ. The chemical shift of this resonance peak was dependent on the concentration of DCA, and finally moved to 2.07 τ at the DCA concentration of 90% v/v. The protonated amide nitrogen was considered to be the origin of this new signal. This consideration came from the comparison with the n.m.r. spectrum of the monomeric amide in DCA-containing solvent[9]. The chemical shift value (2.07 τ) is reasonable for $\equiv\overset{+}{N}$—H resonance[11]. The signal was broad because of quadrupole moment of nitrogen, but less broad than that of monomeric amide because of a slower molecular motion of the polypeptide[12,13].

It has been the subject of controversy whether polypeptides are protonated or not at the conformational transition in strong acids. Some papers[14,15] have been published in favour of protonation, and others[16,17] against it. $\equiv\overset{+}{N}$—H resonance signal observed in the present investigation unam-
Figure 4 100 MHz n.m.r. spectra of poly(*N*-methyl-DL-alanine) (*DP* = 30) at room temperature; concentration 5% w/v; (a) in CD$_2$Cl$_2$; (b) in CD$_2$Cl$_2$/DCA 1:9 v/v mixed solvent 8 days after preparation


biguously indicates the occurrence of protonation at least in case of poly(*N*-methyl-L-alanine).

The resonance peak at 2.07 τ increased the intensity without changing the chemical shift on standing at room temperature. Together with this, the resonance peaks for C_α—CH_3 and N—CH_3 protons began to change. This mode of change is very similar to that observed with the monomeric amide. So we considered that the amide nitrogen of the polypeptide was slowly protonated by DCA and the increased single bond character made the amide bonds take various rotational states. The restricted rotation around the single bond could have resulted from the strict steric interaction among substituents, which is characteristic of poly-(imino acids).

Comparison can be made between poly(*N*-methyl-L-alanine) and poly(*N*-methyl-DL-alanine) for the n.m.r. spectra in CD_2Cl_2 (*Figure 1* and *Figure 4a*) and in DCA/CD_2Cl_2 (9:1 v/v) mixed solvent (*Figure 3j* and *Figure 4b*). In either solvent, two polymers gave similar spectra; that is, the configuration of C_α affects little the pattern of n.m.r. spectrum. A complex spectrum observed in DCA-containing solvent is no doubt a result of the isomerization around amide bond.

Goodman *et al.*[8] observed the similar effect of trifluoro-acetic acid on the n.m.r. spectrum of poly(*N*-methyl-L-alanine), and proposed that the multiplets stem from the sensitivity of the n.m.r. spectrum to triads of adjacent *N*-methyl-L-alanine residues along the polymer chain. Their conclusion was drawn mainly from the fact that two sets of *N*-methyl multiplets were observed. However, their idea was not tested further. A similarity shown up between poly(*N*-methyl-L-alanine) and the monomeric amide, in the latter the *cis—trans* triad being impossible, strongly suggests that the multiplets reflect the multiple energy minima involved in the restricted rotation around the protonated amide bond.

A further support for the above conclusion is obtained from the n.m.r. spectra at higher temperatures. A complex spectrum in DCA-containing solvent became simple at higher temperatures. In that event, the coalescence was never observed, but the relative intensities of the resonance signals changed. This excludes the possibility for the *cis—trans* triad and supports the multiple energy minima around amide bond. It is not clear whether amide nitrogens still protonate at higher temperatures. Deprotonation might have bearing on a sudden change of the n.m.r. spectrum observed at the temperature rise from 70°C to 90°C. Two main signals survived at 130°C could be assigned to planar *cis* and *trans* amide conformers. One small resonance observed at 130°C should be ascribed to a minor non-planar conformation of amide bond.

With poly(*N*-methyl-L-alanine) and its monomeric amide the effects of DCA and temperature on the n.m.r. spectrum were very similar but not completely the same. Some difference of the steric interactions among substituents and hence the different behaviour of n.m.r. spectra have been noted between poly(*N*-alkylglycines) and their monomeric amides, too[18].

It is conceivable that the nature of the denaturation of poly(imino acid) is different from poly(amino acid). Poly-(amino acids) consist of *trans* amide bonds and a uniform conformation around C_α is essential to assume a secondary structure. Intra- or inter-molecular hydrogen bond stabilizes the uniform conformation. Strong acids destroy these hydrogen bonds and thereby the secondary structure. With poly(imino acids) severe steric interactions among substitu-

ents confine the conformation of C_α into a unique one without the help of hydrogen bonding. A uniform (*cis* or *trans*) conformation of amide bond is necessary for the poly-peptide to assume a secondary structure. Strong acids enhance the isomerization of amide bonds and hence destroy the secondary structure.

On the theory of the Ising model of the macromolecular solution

L. Georgescu

Faculty of Physics, University of Bucharest, Măgurele, Bucharest, Romania
(Received 25 June 1974; revised 13 September 1974)

The partition function of a macromolecular binary solution is transposed in the partition function in Ising's model. On the basis of this model the macrocanonical function is explained by the presence of the interaction forces, in the one-dimensional as well as in the two-dimensional cases. The chemical potential of the macromolecular solution is calculated in both cases and compared with the results obtained by Flory and Huggins.

INTRODUCTION

The chemical potential of the athermal macromolecular solution has been calculated by Flory[1] and Huggins[2], the flexible macromolecular chain being introduced in a pseudoreticular lattice (model lattice proposed by Bethe[3]). The entropy of mixing was calculated by a combination method.

Later, the calculations were improved by Miller[4] and Guggenheim[5]. Interaction forces between the macromolecules and solvent molecules were taken into account by Orr[6] and Guggenheim[7] who studied the irregular solution, starting from the above described quasichemical approximation.

The historical evolution with regard to the calculation of the chemical potential of the macromolecular solutions as well as other papers in this field may be found in Tompa's and Petrea's[8] monographs.

In this paper the same problem is discussed again, i.e. the calculation of the chemical potential of a macromolecular solution on the Ising model base is adopted for a binary solution[9]. The lattice model is maintained and in each cell of the lattice it is possible to introduce either a solvent molecule or a monomer unit of the macromolecule. In the language of Ising's model we may say that a state j of the lattice can be represented by a quantity σ_j that can take two values only, ± 1. In the event when $\sigma_j = 1$, the lattice j is occupied by a particle of type 1 (a solvent molecule) and when $\sigma_j = -1$ the lattice j is occupied by a particle of type 2 (a monomer unit of the macromolecule).

The quantity $(1 + \sigma_j)/2$ that also takes the value 1, may be defined if the lattice cell j is occupied by the particle of type 1, and the quantity $(1 - \sigma_j)/2$ that also takes the value 1 if the particle of type 2 is present in the j cell. In this manner the number of particles of type 1 and 2 is:

$$N_1 = \frac{1}{2} \sum_{j=1}^{N} (1 + \sigma_j) \tag{1}$$

$$N_2 = \frac{1}{2} \sum_{j=1}^{N} (1 - \sigma_j) \tag{2}$$

with $N_1 + N_2 = N$.

Macrocanonical partition function of the binary solution is transformed into the equivalent form of Ising's model. On this basis, the chemical potential is calculated in Ising's one-dimensional model, either when the interaction forces are neglected or in the presence of the interaction forces between the neighbouring particles to the lattice of $1-1$, $2-2$ and $1-2$ types.

Later the chemical potential in Ising's two-dimensional model is calculated again in the presence of the interaction forces. In fact, one can calculate the free energy of mixing where by derivation, the chemical potential of the solvent or macromolecule may be obtained.

GENERAL FORMULATION OF THE THEORY

We consider a binary solution which consists of solvent molecules (1) and of macromolecules (2), each particle being introduced in a lattice cell only. The flexible macromolecular chain is supposed to be homogeneous with the degree of polymerization σ. We choose the macrocanonical partition function of the binary solution in the following form:

$$Z = \sum_{N} \sum_{m} \exp \left(N_1 \ln \phi_1 + N_2 \ln \phi_2 - \frac{E_m}{kT} \right) \tag{3}$$

where

$$\phi_1 = \frac{n_1}{n_1 + \sigma n_2} \quad \text{and} \quad \phi_2 = \frac{\sigma n_2}{n_1 + \sigma n_2}$$

are the respective concentrations, with $N_i = n_i N_A$ (N_A is the Avogadro number), and E_m the system energy in the state m. This energy may be expressed in the form:

$$E_m = \sum_{i,j=1}^{N} \frac{1}{2} a_{ij} A(\sigma_i, \sigma_j) \tag{4}$$

where

$$A(\sigma_i, \sigma_j) = \frac{1}{4} E_{11}(1 + \sigma_j)(1 + \sigma_j) +$$

$$\frac{1}{4} E_{22}(1 - \sigma_i)(1 - \sigma_j) +$$

$$\frac{1}{2} E_{12}(1 - \sigma_i \sigma_j) \tag{5}$$

represents the energy between the pairs j and i and a_{ij} can take only the values 1 and 0.1 if j is a near neighbour of i and zero in the any other case. When we have mentioned relation (5), relations (1) and (2) were taken into account, as well as the fact that two neighbouring cells of the lattice can be occupied only by 1–1, 2–2, 1–2 pairs type with the corresponding energies E_{11}, E_{22} and E_{12}.

Considering equations (4) and (5), relation (3) can also be expressed as:

$$Z = \sum_{\sigma_1 = \pm 1} \cdots \sum_{\sigma_N = \pm 1} \exp\left\{ \frac{N}{2}\left[\ln\phi_1 + \ln\phi_2 - \frac{z}{4kT}(E_{11} + E_{22} + 2E_{12}) \right] + \frac{1}{4}\left[2\ln\phi_1 - 2\ln\phi_2 - \frac{z}{kT}(E_{11} - E_{22}) \right]\sum_j \sigma_j - \frac{1}{8kT}(E_{11} + E_{22} - 2E_{12})\sum_{i,j} a_{ij}\sigma_i\sigma_j \right\} \tag{6}$$

where

$$z = \sum_{j=1}^{N} a_{ij}$$

is the number of the nearest neighbours.

If we introduce the relations:

$$\alpha = \frac{1}{2}\left[\ln\phi_1 + \ln\phi_2 - \frac{z}{4kT}(E_{11} + E_{22} + 2E_{12}) \right] \tag{7}$$

$$J = -\frac{1}{8kT}(E_{11} + E_{22} - 2E_{12}) \tag{8}$$

$$B = \frac{1}{4}\left[2\ln\phi_1 - 2\ln\phi_2 - \frac{z}{kT}(E_{11} - E_{22}) \right] \tag{9}$$

relation (6) can be condensed as:

$$Z = e^{N\alpha} \sum_{\sigma_1 = \pm 1} \cdots \sum_{\sigma_N = \pm 1} \exp\left[J\sum_{i,j} a_{ij}\sigma_i\sigma_j + B\sum_j \sigma_j \right] \tag{10}$$

or

$$Z = e^{N\alpha}Z_I \tag{11}$$

where Z_I is the partition function in Ising's model. This

partition function can be expressed either in the one-dimensional model, or in the two-dimensional one in the form:

$$Z_I = \lambda^N \tag{12}$$

where λ is the maximum eigenvalue of matrix P, that is connected to the partition function through the relation $Z_I = SpP^N$ [10]. The maximum eigenvalue λ can be explained as a function of the adopted model, which may be one- or two-dimensional.

CHEMICAL POTENTIAL OF A MACROMOLECULAR SOLUTION IN ISING'S ONE-DIMENSIONAL MODEL

In the case of Ising's one-dimensional model, the maximum eigenvalue has the form:

$$\lambda = e^J[chB + (ch^2B - 2e^{-2J}sh^2 2J)^{1/2}] \tag{13}$$

and the macromolecular partition function, according to equation (12), will be:

$$Z = e^{N\alpha}e^{JN}[chB + (ch^2B - 2e^{-2J}sh^2 2J)^{1/2}]^N \tag{14}$$

the quantities α, J and B being given by relations (7)–(9). If the interaction forces are not considered ($E_{11} = E_{22} = E_{12} = 0$), then relations (7)–(9) can be written in the form:

$$\alpha = \frac{1}{2}[\ln\phi_1 + \ln\phi_2]$$

$$J = 0 \tag{15}$$

$$B = \frac{1}{2}[\ln\phi_1 - \ln\phi_2]$$

In this case, relation (14) takes the simplified form:

$$Z = e^{N\alpha}[e^B + e^{-B}]^N \tag{16}$$

For the very diluted solutions $[2chB]^N \approx e^{B(2N_1 - N)}$ because of the relation

$$\sum_j \sigma_j = 2N_1 - N$$

Then relation (16) becomes:

$$Z = \exp(N_1\ln\phi_1 + N_2\ln\phi_2) \tag{17}$$

which is analogous to that obtained by Flory[1] and Huggins[2], because, if we pass to the chemical potential of the solvent, the well known relation:

$$\Delta\mu_1 = RT\left[\ln(1 - \phi_2) + \phi_2\left(1 - \frac{1}{\sigma}\right) \right]$$

is obtained. If $N \gg N_1$ with $N \to \infty$, e^{-B} may be always neglected with respect to e^B. Here the macrocanonical partition function (16) takes the form:

$$Z = e^{(N_1 + N_2)\ln\phi_1} \tag{18}$$

and the solvent chemical potential:

$$\Delta\mu_1 = \frac{\partial \Delta F_m}{\partial n_1} = RT\left[\ln(1 - \phi_2) + \phi_2\left(1 + \frac{\phi_2}{\sigma\phi_1}\right)\right] \quad (19)$$

for the reason of the case of the macrocanonical distribution $\Delta F_m = kT\ln Z$.

When the chemical potential of the solvent is calculated from relation (16), without any approximation, we obtain the following relation:

$$\Delta\mu_1 = RT\left\{\frac{1}{2}(\ln\phi_1 + \ln\phi_2) + \ln\left[\exp\frac{1}{2}(\ln\phi_1 - \ln\phi_2) + \exp\left(-\frac{1}{2}(\ln\phi_1 - \ln\phi_2)\right)\right] + \phi_2\left(1 + \frac{\phi_2}{\sigma\phi_1}\right)\right\}(20)$$

When in relation (20) e^{-B} is neglected again with respect to e^B we find a new relation (19).

If the interaction forces are taken into account and we introduce the notations:

$$\frac{E_{11}}{kT} = \epsilon_{11}, \quad \frac{E_{22}}{kT} = \epsilon_{22}, \quad \frac{E_{12}}{kT} = \epsilon \quad (21)$$

the relations (7)–(9) become:

$$\alpha = \frac{1}{2}\left[\ln\phi_1 + \ln\phi_2 - \frac{z}{4}(\epsilon_{11} + \epsilon_{22} + 2\epsilon)\right] \quad (22)$$

$$J = -\frac{1}{8}(\epsilon_{11} + \epsilon_{22} - 2\epsilon) \quad (23)$$

$$B = \frac{1}{2}[2\ln\phi_1 - 2\ln\phi_2 - z(\epsilon_{11} - \epsilon_{22})] \quad (24)$$

and the maximum eigenvalue can be also expressed as:

$$\lambda = e^J chB + (e^{2J}sh^2B + e^{-2J})^{1/2} \quad (25)$$

If we consider e^{-2J} negligible with respect to $e^{2J}sh^2B$, then relation (25) becomes:

$$\lambda = e^{J+B} \quad (26)$$

and the macrocanonical partition function will be:

$$Z = e^{N\alpha}\lambda^N =$$

$$\exp\frac{N}{2}\left[\ln\phi_1 + \ln\phi_2 - \frac{z}{4}(\epsilon_{11} + \epsilon_{22} + 2\epsilon)\right] \times$$

$$\left\{\exp\left[-\frac{1}{8}(\epsilon_{11} + \epsilon_{22} - 2\epsilon)\right] \times\right.$$

$$\left.\exp\frac{1}{4}[2\ln\phi_1 - 2\ln\phi_2 - z(\epsilon_{11} - \epsilon_{22})]\right\}^N \quad (27)$$

Now the chemical potential of the solvent may be calculated for the binary solution when we consider also the interaction between the neighbouring pairs without any

approximation as follows:

$$\Delta\mu_1 = RT\left[\ln(1 - \phi_2) + \phi_2\left(1 - \frac{1}{\sigma}\right) - \right.$$

$$\left.\phi_2^2\left\{\frac{1}{8}\epsilon_{11}(1 + 3z) + (z - 1)\frac{\epsilon_{22}}{8} - \frac{\epsilon}{4}(z - 1)\right\}\right] \quad (28)$$

CHEMICAL POTENTIAL OF A MACROMOLECULAR SOLUTION IN ISING'S TWO-DIMENSIONAL MODEL

In the framework of the two-dimensional model in the absence of external fields, the eigenvalue λ has the form[10]:

$$\lambda = \frac{1}{2}\ln[2sh(2J)] + \frac{1}{2}\ln\frac{2ch^22J}{sh^2J} + \mathscr{I} \quad (29)$$

where

$$\mathscr{I} = \frac{1}{2\pi}\int_0^\pi d\varphi\ln\frac{1}{2}[1 + (1 - \kappa^2\sin^2\varphi)^{1/2}] \quad (30)$$

with

$$\kappa = \frac{1}{ch2Jcth2J}$$

The free energy per particle may be expressed as:

$$\beta F = \alpha - \ln(ch2J) - \mathscr{I} \quad (31)$$

or as

$$\beta F = \alpha + \frac{1}{2}\ln(2sh2J) + \frac{1}{2}\ln\frac{2ch^2J}{sh2J} + \mathscr{I} \quad (32)$$

with $\beta = 1/kT$.

If neither interaction forces nor the external field are taken into consideration, then $J \to 0$. In this case, taking into account the compound of the field of the matrix

$$V_3 = \exp\left(B\sum_j \sigma_j\right)$$

we have:

$$\beta F = N\alpha + B\sum_j \sigma_j = N_1\ln\phi_1 + N_2\ln\phi_2$$

and we have found again at the limit, Flory's results.

In the event when the interaction forces are considered, such as:

$$\beta F = N(\alpha + \ln\lambda) + B\sum_j \sigma_j \quad (33)$$

the free energy of mixing can be expressed in the form:

$$\Delta F_m = RT[n_1 \ln \phi_1 + n_2 \ln \phi_2 -$$

$$\frac{nz}{8}(\epsilon_{11} + \epsilon_{22} + 2\epsilon) - n \ln(2ch2J) -$$

$$n\mathscr{J} - \frac{2n_1 - n}{4} z(\epsilon_{11} - \epsilon_{22})] \tag{34}$$

On the basis of relation (34) the chemical potential of the solution may be calculated:

$$\Delta\mu_1 = RT\left[\ln \phi_1 + \phi_2 \left(1 - \frac{1}{\sigma}\right) - \right.$$

$$\left. \phi_2^2 \left\{\frac{z}{8}(3\epsilon_{11} - \epsilon_{22} + 2\epsilon) - \ln(2ch2J) - \mathscr{J}\right\}\right] \tag{35}$$

the elliptical integral $\mathscr{J}$ might be evaluated from tables[11].

If $\exp(-2J)$ is neglected with respect to $\exp(2J)$, relation (35) takes the final simplified form:

$$\Delta\mu_1 = RT\left[\ln \phi_1 + \phi_2 \left(1 - \frac{1}{\sigma}\right) - \left\{\frac{\epsilon_{11}}{8}(3z - 1) + \right.\right.$$

$$\left.\left. \frac{\epsilon_{22}}{4}\left(1 + \frac{z}{2}\right) - \frac{\epsilon}{2}\left(1 + \frac{z}{2}\right) - \mathscr{J}\right\}\phi_2^2\right] \tag{36}$$

Analogously, the chemical potential of the solute may be calculated by deriving the free energy of mixing, relation (34), with respect to the variable n_2.

The expression of the solvent chemical potential for a binary macromolecular solution, expression (34), at the limit, coincides with the expression given by Flory for the athermal solutions which is in accordance with Ising's two-dimensional lattice. Different results appear in the presence of the interaction forces, and the chemical potential is different depending on the forces of types ϵ_{11}, ϵ_{22} and ϵ as well as on the nearest neighbour number z.

In the one-dimensional model, the chemical potential expression is given by Flory, but it must not be forgotten that Ising's one-dimensional model no longer corresponds to a two-dimensional lattice from Flory's model.

At the limit only, in the case of very dilute solutions and in the absence of interaction forces, the results are analogous. The chemical potential also differs depending upon the interaction forces in the two models, see relations (28) and (34). The dependency on z is different too, stressing still more the essential differences between the one-dimensional model and the two-dimensional one, the latter being nearer to a flexible macromolecular chain.

Flow birefringence studies of polymer conformation: cellulose tricarbanilate in two characteristic solvents *

J. W. M. Noordermeer, R. Daryanani and H. Janeschitz-Kriegl

Laboratory of Physical Chemistry, Delft University of Technology, Delft 8, The Netherlands
(Received 12 July 1974)

Flow birefringence measurements are reported on ten samples of cellulose tricarbanilate ($14.1 \times 10^3 < M < 2180 \times 10^3$). Phenyl benzoate, dioxane and mixtures of both were used as solvents. The ratio of Maxwell constant to intrinsic viscosity $[n]/[\eta]$ strongly depends on temperature and kind of solvent. In ether solvents this polymer has a stiffer conformation than in an ester or a ketone. With the aid of the theory of Gotlib and Svetlov quantitative conclusions about chain stiffness can be drawn from the observed molecular weight dependence of $[n]/[\eta]$. A number of 50 monomer units per random link were obtained in dioxane at $25°C$. This agrees quite well with light scattering and intrinsic viscosity data. According to Burchard an interpretation of the great chain stiffness of this polymer in ether solvents can be given in terms of the formation of intramolecular hydrogen bonds. The tremendous influence of a change in stiffness on $[n]/[\eta]$ must be ascribed to the varying sterical hindrance of rotation of the phenyl rings in the side groups of the chain. Unfortunately, no valuable information with respect to chain stiffening can be deduced from extinction angle data. Relatively small effects, as expected from theory, are almost completely masked by the influence of the polydispersity of the samples.

INTRODUCTION

It is well known that, under certain conditions, biopolymers and their synthetic analogues can retain well ordered conformations after dissolution. These ordered conformations are usually stabilized by intramolecular hydrogen bonds and are extremely stable in the sense, that breaking of a single hydrogen bond is not advantageous. Only with the simultaneous breakage of a large number of adjacent hydrogen bonds does the ordered conformation collapse[1].

At the present time conformational transitions in biological as well as synthetical macromolecules, are the subject of very intensive experimental and theoretical studies. Surprisingly, the technique of flow birefringence has been applied to the study of conformational transitions only in a few cases. As an example, Tsvetkov et al.[2,3] carried out experiments on the helix-coil transition of poly(γ-benzyl-L-glutamate) in mixtures of dichloroethane and dichloroacetic acid. In the rather apolar solvent dichloroethane this macromolecule occurs as an α-helix. In the strongly polar solvent dichloroacetic acid, however, the molecule assumes a randomly coiled conformation. At this transition the reduced viscosity η_{sp}/c of the polymer solution changes by a moderate factor of 2.5. In contrast, the intrinsic optical anisotropy of the molecules, which can be determined with the aid of flow birefringence, appears to decrease by a factor of about 50. This example clearly indicates the importance of flow birefringence as a technique for the study of conformational transitions in polymers.

In a recent paper[4] we have shown for a polyelectrolyte that valuable information concerning coil expansion can be

derived from flow birefringence data. In the present work we extend our flow birefringence studies to cellulose tricarbanilate in a series of solvents. Previously, flow birefringence of cellulose tricarbanilate has been measured by Janeschitz-Kriegl and Burchard[5] only in a single solvent but for a number of sharp fractions of various molecular weights. As a solvent benzophenone was used. Meanwhile new information has been gathered concerning this polymer. This information gives rise to the supposition that the formation of intramolecular hydrogen bonds between CO- and NH- groups of neighbouring carbamate groups, as already proposed by one of the mentioned authors[6], would be more pronounced in ethers rather than in esters or ketones[7]. In fact, when the mentioned hydrogen bonds are formed, cellulose tricarbanilate assumes a kind of ladder conformation which has a greater chain stiffness than the conformation occurring in the absence of these hydrogen bonds.

The aim of the present investigation was to produce an independent check of the reported sensitivity of flow birefringence to changes of chain stiffness, as caused by changes in solvent composition.

Because of the considerable chain stiffness which is a property of all cellulose derivatives, and owing to the additional effect of the phenyl rings in the carbamate side-groups, cellulose tricarbanilate has an extraordinarily high intrinsic optical anisotropy. As under these circumstances form birefringence will hardly influence the measurements, the choice of solvent is greatly simplified; one can admit rather high refractive index increments without taking the risk of a disturbing influence of form birefringence. As is well known, this birefringence becomes considerable if a large difference exists between the refractive indices of polymer and solvent. In such a case the macromolecule as a whole contrasts with the solvent.

In the following measurements are reported on several samples of cellulose tricarbanilate covering a molecular

---

weight range from 14×10^3 to 2180×10^3. As an ester solvent we have chosen phenyl benzoate. Its refractive index is very close to that of the polymer. As an ether solvent we have chosen dioxane. Admittedly, the refractive index of the latter solvent differs quite considerably from that of the polymer. However, as will be shown below, the influence of form birefringence lies within the accuracy of the measurements. A considerable temperature range, viz. from 25°C to 100°C, has been covered by the reported experiments.

THEORY

Flow birefringence is characterized by two quantities which can be measured separately, viz. the extinction angle and the birefringence, both as functions of shear rate. In addition the viscosities of the solution and of the solvent are needed for a proper interpretation of the results. For the theoretical background of flow birefringence reference can be made to the literature[8]. However, for the present purpose some additional remarks must be made.

A description of the hydrodynamic behaviour of a macromolecule in dilute solution was worked out in its most general form by Kramers[9], Kirkwood and Fuoss[10-12]. These authors derived a general diffusion equation, which was the starting point for nearly all theoretical work on specialized model chains, as for example on the well known bead-spring model of Rouse[13], Bueche[14] and Zimm[15]. It should be emphasized, however, that from such a diffusion equation only a linear elasticoviscous behaviour can be derived, in principle. A diffusion equation in the above sense is not consistent with non-linear constitutive equations which have often been used to describe non-Newtonian viscosity and non-linear flow birefringence behaviour of polymer fluids. In this connection we should refer to an early discussion between Saito and Prigogine[16] and to a recent report published by Merk[17]. According to Kirkwood[11] the generalized diffusion equation only holds for 'systems departing from equilibrium'. As a matter of fact, without rather arbitrary modifications introduced into this diffusion equation only linear results can be obtained. In particular, only Newtonian viscosities can be derived for polymer solutions.

As a consequence of the limitation of the linear theory to only small disturbances of the equilibrium situation we have to carry out proper extrapolations of our experimental results to zero shear rate in order to enable a correct interpretation. Notwithstanding the fact that cellulose tricarbanilate solutions show considerably non-linear behaviour, an unambiguous extrapolation into the range of linear behaviour appeared to be possible in all cases which are of interest for the present investigation. An attempt to describe the non-linear behaviour of cellulose tricarbanilate solutions is postponed to a later paper.

As is well-known, cellulose derivatives usually have a too low degree of polymerization for the formation of a Gaussian distribution of the end-to-end distances of the molecular coils. It has become customary to describe the flow birefringence of such non-Gaussian polymers with the aid of a molecular weight dependent coefficient $[n]/[\eta]$ defined by:

$$\Lambda = [n]/[\eta] = (\Delta n \sin 2\chi - \Delta n_s)/q(\eta - \eta_s) \qquad (1)$$

where Δn is the flow birefringence, χ the extinction angle, η the viscosity of the solution and Δn_s the flow birefrin-

gence of the pure solvent, all these quantities being measured at the same shear rate, q. The solvent viscosity, η_s, usually does not depend on the shear rate. Notwithstanding the fact that the Maxwell constant $[n]$ and the intrinsic viscosity $[\eta]$ are separately defined only for the limiting cases of zero shear rate, q and concentration, c, i.e.:

$$[n] = \lim_{\substack{c=0 \\ q=0}} (\Delta n - \Delta n_s)/cq\eta_s; \quad [\eta] = \lim_{\substack{c=0 \\ q=0}} (\eta - \eta_s)/c\eta_s \qquad (2)$$

the right hand side of equation (1) is independent of concentration, if the form birefringence effect is absent[18,19], and also independent of shear rate, if the molecular weight of the polymer is sufficiently high. For such a solution of Gaussian chain molecules Λ has reached an upper limiting value Λ_∞, no longer dependent on the molecular weight (the suffix stands for 'infinite' molecular weight). This means that a restriction of the definition of Λ_∞ to the limiting cases of zero shear rate and zero concentration becomes irrelevant. However, for non-Gaussian polymers, an extrapolation to zero shear rate has to be carried out anyway.

The quantity Λ_∞ is related to the structure of the macromolecular chain in the following way:

$$\Lambda_\infty = (4\pi/45)[(n^2 + 2)^2/n](\alpha_1 - \alpha_2)/kT \qquad (3)$$

where n is the refractive index of the solution, kT has its usual meaning and $(\alpha_1 - \alpha_2)$ is the anisotropy of polarizability of the statistical random link with respect to directions parallel and perpendicular to its extension. Equation (3), which does not contain molecular weight, concentration and shear rate as parameters, can be obtained from all variants of the linear theory for Gaussian chains. In particular, Λ_∞ is also independent of the degree of hydrodynamic interaction ('free draining' or 'non-draining'). However, this is strictly valid only if the refractive index of the solvent is equal to that of the polymer ('matching solvent'). Otherwise the form birefringence gives a complicated contribution. The Λ_∞ value, undisturbed by form birefringence, as given by equation (3), depends roughly on two quantities: the temperature and the anisotropy $(\alpha_1 - \alpha_2)$, where the latter quantity should again be considered as a function of temperature. As to the temperature dependence of Λ_∞ very little is known. For the very flexible polymers polystyrene and polyethylene, for instance, nearly no influence of temperature on Λ_∞ could be observed in the accessible temperature range[8]. On the contrary, a strong temperature dependence of Λ_∞ was found for cellulose tricarbanilate in benzophenone[5] and for undiluted polydimethylsiloxanes[20]. The temperature dependence of Λ_∞ for cellulose tricarbanilate in some other solvents will be discussed in the experimental part of this work.

The anisotropy $(\alpha_1 - \alpha_2)$ has formally been related separately to the length of the random link, the chemical structure of the chain[18,21] and to the degree and kind of solvatation of the chain[22]. A change of one of these properties will lead to a change of the anisotropy which, on its part, can be observed as a change of the value of Λ_∞. The conformation of the macromolecule is strongly related to the first two properties. Consequently, it must be expected that valuable information concerning conformational transitions of polymers can be deduced from the experimental values of Λ_∞. However, if a change of solvent or solvent composition is involved in such a conformational transition, solvatation effects may have a disturbing influence. Investi-

gations with atactic polystyrene, for instance, have shown that the solvent influence on the value of Λ_{∞} can amount to 30% of its value for the polymer melt[8]. Unfortunately, correction methods or ways to exclude this influence are not known, so that solvatation influences will cause some uncertainty in the interpretation of the experimental results. One can only hope that the extraordinarily high intrinsic optical anisotropy of the chain of cellulose tricarbanilate will be predominant under all circumstances.

Whereas Λ_{∞} is independent of molecular weight in the range of sufficiently high molecular weights, it appears that Λ decreases with decreasing molecular weight for non-Gaussian polymers. Gotlib and Svetlov[23] have made a successful approach to a calculation of the molecular weight dependence of Λ. For their calculations they used the model of a wormlike chain as described by Kratky and Porod[24]. For the calculation of the Maxwell constant, in principle, a detailed distribution function of chain coordinates is required, while for the calculation of the intrinsic viscosity only average chain dimensions are needed[8]. Gotlib and Svetlov calculated these quantities separately for the free draining case. They considered an assembly of 'frozen' random conformations of the wormlike chain. Brownian motion was taken into account only as far as rotary diffusion of the random conformations was concerned. In such a case only the average orientations of 'frozen' macromolecules determine their contributions to the flow birefringence of the streaming solution. In this way a first order distribution function with respect to shear rate is obtained, which holds for the limit of zero shear rate. Since Λ_{∞} is independent of the degree of hydrodynamic interaction, the same is assumed for Λ. This justifies the use of the free draining approximation. Gotlib and Svetlov have derived the following relation for the dependence of Λ on chain length L and Λ_{∞}:

$$\Lambda = (3/10)[x\phi_1(x)/\phi_2(x)]\,\Lambda_{\infty} \tag{4}$$

where $x = L/a$ and a is the persistence length[24] of the wormlike chain. As is well known, this length is half the length of the statistical random link as introduced by Kuhn. The functions $\phi_1(x)$ and $\phi_2(x)$ depend in a complicated manner on x. They are explicitly given by Gotlib and Svetlov. This theory predicts Λ values which increase continuously with molecular weight and level off at Λ_{∞}.

Equation (4) has been shown to give a good description of the molecular weight dependence of Λ for many polymer systems[8]. In particular, Janeschitz-Kriegl and Burchard[5] have shown its validity for cellulose tricarbanilate fractions in benzophenone. Some further examples will be given in the experimental part of this paper.

Another point of interest is the behaviour of the extinction angle. It has become quite customary to interpret the optically measured extinction angles in terms of the hydrodynamic theory of the bead-spring model of Rouse[13] and Zimm[15]. For a solution of Gaussian chain molecules this is a permitted procedure, since in this case the contributions of the polymer molecules to the deviatoric components of the stress tensor and the refractive index tensor of the streaming solution are proportional. This means that the tensor ellipsoids are coaxial[19]. With this coaxiality taken for granted, the Rouse–Zimm theory yields the following result for Gaussian coils:

$$\cot 2\chi_c = \cot 2\chi' = J_{eR}\beta_N \tag{5}$$

where χ_c is the extinction angle, as corrected for the solvent contribution to the flow birefringence of the solution, and χ' is the orientation angle of the stress ellipsoid*. The appropriate correction formula for the extinction angle χ_c reads:

$$\cot 2\chi_c = \cos 2\chi/(\sin 2\chi - \Delta n_s/\Delta n) \tag{6}$$

For the symbols used see equation (1).

In equation (5) J_{eR} is the reduced steady-state shear compliance[25] and β_N is the reduced shear rate[26] defined by:

$$\beta_N = \frac{Mq(\eta_N - \eta_s)}{cRT} \tag{7}$$

where M is the molecular weight of the polymer and R the gas constant. The suffix N is used to indicate that the zero shear viscosity of the solution η_N is inserted. The use of the parameter β_N should result in a reduction of experimental data with respect to temperature, molecular weight and concentration. Owing to the linear character of the Rouse–Zimm theory the value of J_{eR} should be independent of shear rate. The numerical range quoted for Gaussian coils reads[15]:

$$\text{Gaussian coils} \begin{cases} \text{'free draining'} & J_{eR} = 0.4 \\ \\ \text{'non draining'} & J_{eR} = 0.205 \end{cases} \tag{8}$$

As the validity of this theory is restricted to very small shear rates, it can be expected that equation (5) is valid only for sufficiently small values of β_N.

In dealing with stiff, non-Gaussian chain molecules several difficulties arise. Primarily, the coaxiality condition, equation (5), does not hold for these cases. Secondly, recent work[27–29] on the bead-spring model has shown that the introduction of a certain kind of chain stiffness into this model causes a rise of the numerical value of J_{eR}.

For a demonstration of these facts we can look at the model of a rigid rodlike pearl necklace, which can be considered as the best approximation for a really rigid rodlike macromolecule. If the influence of hydrodynamic interaction is disregarded, the relations between the respective angles χ' and χ_c and the reduced shear rate β_N read[30,31]

$$\text{Rigid rodlike pearl necklace} \begin{cases} J_{eR} = \cot 2\chi'/\beta_N = 0.6 \\ \\ \cot 2\chi_c/\beta_N = 1.0 \end{cases} \tag{9}$$

For this model clearly no coaxiality exists. However, one can also conclude that the effects of varying chain stiffness on the value of J_{eR} and even on the value of the ratio cot $2\chi_c/\beta_N$ are moderate. In this connection one has to keep in mind that a broad molecular weight distribution can produce changes of at least the same order of magnitude. In fact, it can be deduced that for a polydisperse system of Gaussian chain molecules equation (5) must read:

$$\cot 2\chi_c = pJ_{eR}\langle\beta_N\rangle_n \tag{10}$$

---

* The reader may observe that the direction of each ellipsoid can be described by a single angle. Because of symmetry, one axis of the ellipsoid is perpendicular to the flow direction and lies in the shearing plane. The other two axes lie in a plane perpendicular to the shearing plane. The smallest angle between the shearing plane and one of the latter axes is chosen for convenience.

where p is a polydispersity factor and the angular brackets $\langle \rangle_n$ mean that the number average molecular weight $\langle M \rangle_n$ of the polymer is inserted in equation (7). For a description of the calculation of p, which can become rather large and dependent on solvent power, reference is made to the literature[32-34].

Finally, the result should be quoted of a theory which describes the molecular weight dependence of the intrinsic viscosity of stiff polymers. Eizner and Ptitsyn[35] derived the following equation for the intrinsic viscosity of wormlike chains:

$$[\eta] = \frac{2^{3/2}(b/M_0)\Phi_0 N \chi(N/\lambda)}{[45(2\pi/3)^{1/2}/32(3 - 2^{1/2})](b/\lambda r_0) + (1/\lambda^{3/2})\phi(\lambda, N)N^{1/2}}$$

(11)

where Φ_0 is the Flory–Fox constant[36] equal to 2.86×10^{23} mol^{-1}; N is the degree of polymerization; r_0 is the hydrodynamic radius of the monomer unit; M_0 is the molecular weight of this unit; and λ is the ratio of the persistence length a to the length b of the monomer unit, i.e. $\lambda = a/b$. The ratio N/λ equals the parameter $x = L/a$, used in equation (4). The function $\chi(N/\lambda)$ describes the ratio of the real mean square radius of gyration of the considered wormlike chain to the quantity $aL/3$. It is separately calculated by Eizner and Ptitsyn. The function $\phi(\lambda, N)$ describes the intramolecular hydrodynamic interaction as a function of λ and N. It was tabulated by Kurath et al.[37].

It should be emphasized that, from a physical point of view, equation (11) is valid only for an infinitively thin (persistent) thread. The hydrodynamic radius r_0 is only a kind of friction factor for relative translational movements between chain units and solvent. In a double logarithmic plot equation (11) yields a continuously curved line which has a slope two at low molecular weights and a slope of one half at high molecular weights (non-draining limit).

The theories reviewed here are all valid only for theta solvents in which the excluded volume of the polymer chain is taken to be zero. For short or stiff chains in reasonably good solvents this may be a much less serious restriction than for long and intensively coiled molecules.

EXPERIMENTAL

The investigations were done on ten samples of cellulose tricarbanilate. Data on these samples are gathered in *Table 1*. The low molecular weight samples of the series CCI and CC II were prepared by partial precipitation from solutions in acetone with the aid of water. CC III was prepared from saponified cellulose 2½-acetate (Lonza). CC IV originates from bleached Linters cotton. The chemical origin of the sample CC V was not traced back*.

Weight average molecular weights $\langle M \rangle_w$ were determined by light scattering from solutions in dioxane[7]. No details about the heterogeneity of the low molecular weight fractions are known. *Table 1* also contains the intrinsic viscosities of the samples, as determined in dioxane at 20°C.

The solvents were prepared in the following ways: 1, 4-dioxane (UCB) was dried over $MgSO_4$ and distilled after-

wards. Phenyl benzoate (Fluka AG) was recrystallized from ethanol and thoroughly dried in vacuum.

Solutions were prepared by weighing dried polymer samples and freshly prepared solvent. In dioxane the samples dissolved within 1 or 2 days at room temperature. The phenyl benzoate solutions were prepared by shaking at 75°C for a few hours in a nitrogen atmosphere. Solutions in mixtures of both solvents were prepared by dissolving a certain amount of the sample in the calculated quantity of dioxane at room temperature and adding afterwards the required amount of phenyl benzoate. The compositions of the mixed solvents will be expressed in weight percentages.

Data of the pure solvents are given in *Table 2* for the temperatures at which measurements were carried out. Pure phenyl benzoate shows a measurable flow birefringence. This means that all measurements carried out in this solvent and in mixtures with dioxane, have to be corrected for the solvent contribution to the flow birefringence of the solutions [cf. equations (1) and (6)]. Since, for low molecular weight fluids, a plot of flow birefringence against shear rate is always linear, *Table 2* only contains the slopes of these plots. Data for the mixed solvents had to be determined separately, but are not quoted. Phenyl benzoate can be considered as a matching solvent, i.e. the refractive index increment dn/dc of cellulose tricarbanilate is almost zero in this solvent. In dioxane, however, this quantity amounts to a measurable value of $dn/dc = 0.156$ cm^3/g at 20°C[6]. Normally such a high value results in a relatively large contribution of form birefringence to the measured value of Λ. This contribution Λ_f can be calculated for Gaussian coils [equation (5.3) of Janeschitz-Kriegl[8]]. Using the above given value of dn/dc one obtains for the high molecular weight sample CC IV in dioxane:

$$(\Lambda_f/\Lambda_\infty) = 2.3 \times 10^{-2}$$

(12)

where the value of Λ_∞ is taken from the measurements at 25°C to be described below. In this comparison the

influence of a difference of 5°C between the temperatures of measurements of dn/dc and Λ_∞ is disregarded. It appears that the relative contributions of Λ_f for this high molecular weight sample is small enough to lie completely within the accuracy limits of the flow birefringence technique. If one keeps in mind that, from a theoretical point of view[18], the form birefringence of the molecular coils should decrease with decreasing molecular weight, one arrives at the conclusion that this effect can be disregarded throughout the present investigation.

Flow birefringence measurements were carried out in the equipment previously described[8,38]. Viscosity measurements were done with the aid of ordinary Ubbelohde viscometers. A check with a special viscometer for non-Newtonian viscosities[39] showed that, except for the sample CC V, Ubbelohde measurements were always in fair agreement with the Newtonian viscosities at small shear rates. A few examples are given in *Figure 1* for a series of solutions of CC IV in phenyl benzoate at 75°C. To remove dust all solutions were filtered through glass filters.

RESULTS

Figure 2 gives extinction angle curves for a series of solutions of various concentrations of sample CC IV in dioxane at 25°C. The corresponding measurements of the birefringence Δn are given in *Figure 3*. For the lowest concentra-

tion the dependence of flow birefringence on shear rate appears to be linear. For higher concentrations some downward deviation can be noticed with increasing shear rate. With decreasing molecular weight the deviation of the extinction angle from 45° decreases rapidly, as can be seen in *Figure 4*. In this Figure extinction angles are given for a 1.32% (w/v) solution of sample CC III in pure phenyl benzoate at 75° and 90°C. In this connection it is important that the viscosities of dioxane and of phenyl benzoate are of the same order of magnitude at the respective temperatures of the measurements. This means that solvent viscosities cannot account for the differences between *Figures 2* and *4*. For the lowest molecular weight samples the deviations from 45° angle were so small that no reliable measurements could be done.

With the aid of equation (1) the experimental values of Λ can be calculated from these measurements. In *Figure 5* Λ values, as extrapolated to zero shear rate, are plotted for the sample CC IV in pure dioxane, respectively in pure phenyl benzoate, against concentration and with temperature as a parameter. In both solvents no significant influence of concentration on the results is observed. A relative scatter of about 10% is quite normal for these types of results, as they are calculated from three separate measurements of limited accuracy. The independence of Λ of concentration was found for all CC samples in all kinds of solvents. The importance of this fact for the interpretation will be discussed in the next paragraph.

On the other hand, Λ strongly depends on temperature in both solvents. This is quite a striking result, because

about 70°C. Consequently, on the ester side no measurements could be carried out at low temperatures. In *Figure 6* a clear transition can be observed, which almost entirely takes place in the range of high phenyl benzoate contents of the solvent.

A similar transition can also be observed in the intrinsic viscosity of CC IV as measured with changing composition of the solvent mixture at the same temperatures at which also flow birefringence measurements were carried out. This is shown in *Figure 7*. A comparison with *Figure 6* shows that both transitions occur at about the same solvent composition. However, the total effect, as observed on the intrinsic viscosity, appears to be much smaller than that observed on the value of Λ, although the transition in the intrinsic viscosity is much sharper.

To understand the observed transitions more quantitatively, the dependence of Λ on molecular weight has been determined. For these measurements also the other CC samples, mentioned in *Table 1*, were used. In *Figure 8* Λ values, as obtained in pure phenyl benzoate and in pure

until now no other polymer is known to have a Λ, which is so strongly temperature dependent. Moreover, Λ appears to be considerably larger for CC IV in dioxane than in phenyl benzoate at corresponding temperatures. To investigate this difference in more detail we have measured the value of Λ for CC IV in a series of mixtures of both solvents. The results, given in *Figure 6*, are averages of the values obtained on at least two concentrations. Phenyl benzoate melts at

Figure 9 An example for the poor reducibility of extinction angle curves with respect to concentration. The indicated points are obtained with CC IV in dioxane at 25°C. dioxane, are given as functions of the estimated number average molecular weights of the samples for the temperatures indicated. For the samples with weight average molecular weights between 3000 and 15 000 no number average molecular weights could be estimated. As a consequence, for these samples the Λ values are plotted against the weight average molecular weights. Most Λ values are averages of measurements on at least two concentrations. Of the high molecular weight sample CC V only a small amount was available, so that measurements could be carried out at only one concentration. The non-Newtonian behaviour of the viscosity of this solution, which was expected to be more pronounced than for the other samples, could not be measured either. As for CC V Ubbelohde measurements will lie in the non-Newtonian region of shear rates, no exact values of Λ can be determined. Shear rates at the capillary wall in the Ubbelohde viscometers were estimated on the approximate assumption of a parabolic flow profile. Values of Λ, however, as calculated according to equation (1) for those finite shear rates, can only be lower than the 'true' Λ for zero shear rate. This is a general experience for non-Gaussian polymers. For cellulose tricarbanilate it is supported by Figure 10 of ref 5. On the other hand, flow birefringence data, which are first extrapolated to zero shear rate and then combined with the mentioned Ubbelohde viscosities, must give too high values of Λ. Both limits are given in *Figure 8* by the endpoints of the vertical lines. As the best approximations for the true zero shear values of Λ the averages of both limits have been taken, as indicated by the symbols.

In *Figure 9* an example is given for a plot of extinction angle curves against reduced shear rate $\langle \beta_N \rangle_n$. The points correspond to the measurements reproduced in *Figure 2*. The curves show an upwards shift with increasing concentration. This means that the reduction of the extinction curves with respect to concentration is not successful, as was found also for anionic polystyrenes by Daum[40] and Janeschitz-Kriegl[8]. Furthermore, a clear curvature can be observed for all concentrations at sufficiently high values of $\langle \beta_N \rangle_n$. Only for the lowest $\langle \beta_N \rangle_n$ values a linear relationship between cot $2\chi_c$ and β_N, as predicted by the linear theory, seems approximately valid. For CC IV in phenyl benzoate no measurements could be done at shear rates, low enough

to reach the linear region. In this connection it should be admitted that, with decreasing shear rate, the inaccuracy in the measurement of extinction angles becomes considerable. From *Figure 9* it can be concluded that the results on the high molecular weight sample CC IV are not very useful for a determination of the zero shear values of the ratio of cot $2\chi_c$ and $\langle \beta_N \rangle_n$.

In fact, the determination of this ratio is equivalent with a direct determination of the initial slope of the extinction angle curve. The accuracy of this determination mainly depends on the number of reliable extinction angle measurements carried out in the vicinity of the 45° angle. In this respect the measurements on sample CC III, which has a much lower molecular weight, look more promising as is seen from *Figure 4*. For this sample the initial slopes can be determined directly and with great accuracy.

The values of the ratio of cot $2\chi_c$ and $\langle \beta_N \rangle_n$, as obtained for sample CC III according to this more direct method, are given in *Figure 10*. In the upper part of this Figure one finds the results for dioxane, in the lower part those for phenyl benzoate. The temperatures are indicated near the respective experimental curves. For solutions in dioxane at 90°C the extinction angles deviate so little from 45° that a reasonable estimate of cot $2\chi_c/\langle \beta_N \rangle_n$ becomes impossible. From *Figure 10* it may be concluded that the ratios of $\cot 2\chi_c$ and $\langle \beta_N \rangle_n$, as extrapolated to zero shear rate do not only depend on concentration but also on temperature, at least for the solutions in dioxane. However, the temperature influence diminishes when the concentration is lowered. In other words, the reduction with respect to temperature may hold for infinite dilution. For finite concentrations it does not hold for CC III in dioxane. In the phenyl benzoate part of this Figure, however, the temperature difference between both series of measurements seems too small to show up in the results. A comparison of the results in both solvents shows that the values of $\cot 2\chi_c/\langle \beta_N \rangle_n$ for the solutions in phenyl benzoate seem to lie below those for the dioxane solutions. The same trend was also observed for the solutions of CC IV. An extrapolation of the results in *Figure 10* to zero concentration can be made with reasonable accuracy. Strictly speaking, however, the differences between the obtained results are so small that they nearly lie within the accuracy limits of the extrapolations. So it must be concluded that, if the transitions in Λ and in intrinsic viscosity

of cellulose tricarbanilate are accompanied by a change of the value of $\cot 2\chi_c/\langle\beta_N\rangle_n$, this change must be a very small one.

DISCUSSION

The experimental results clearly demonstrate that cellulose tricarbanilate undergoes a kind of conformational transition when the solvent composition is changed from ester to ether. The simultaneous growths of Λ and of the intrinsic viscosity (*Figures 6* and *7*) probably point to a stiffening of the chain. The most direct proof for the character of the transition can be derived from *Figure 8*. The measurements represented in this Figure can be interpreted straight-forwardly by the theory of Gotlib and Svetlov[23]. In fact, the full lines connecting these points are theoretical curves with the following parameters.

> Dioxane: 25°C $\Lambda_\infty = -17.52 \times 10^{-9}$ cm^2/dyne, $S = 50.0$
> 50°C $\Lambda_\infty = -12.34 \times 10^{-9}$ cm^2/dyne, $S = 42.5$
> 75°C $\Lambda_\infty = -9.10 \times 10^{-9}$ cm^2/dyne, $S = 42.5$
> 90°C $\Lambda_\infty = -7.40 \times 10^{-9}$ cm^2/dyne, $S = 38.6$
>

> benzoate: 75°C $\Lambda_\infty = -4.12 \times 10^{-9}$ cm^2/dyne, $S = 30.0$

where S is the number of monomer units per statistical random link (i.e. twice the number of units per length of persistence).

The lowest molecular weight samples usually give too low values when compared with theory. In the first place, this may be caused by the fact that for these samples the experimental values of Λ are plotted against the weight average instead of the number average molecular weight. This means that the points are probably shifted to the right. In the second place, for these low molecular weights, the chain can no longer be considered as an 'infinitely thin' persistent thread. Consequently, the theory of Gotlib and Svetlov cannot hold exactly for these samples. In the third place, Tsvetkov[41] has shown that, at sufficiently low degrees of polymerization, the anisotropy of the side-groups can take over the function of the anisotropy of the main chain which, for cellulose tricarbanilate, can result in an extraordinary descent of the absolute value of Λ with decreasing molecular weight and, in the worst case, even in a change of sign of the birefringence. Finally, it should be noticed that a loga-rithmic molecular weight scale is used in *Figure 8*. This overemphasizes the importance of the experimental points at low molecular weights.

Special attention should be paid to the high value of $S = 50.0$ for cellulose tricarbanilate in dioxane at 25°C. From light-scattering measurements in a mixture of dioxane and

methanol of 56.5:43.5 (vol %), which is a θ-solvent at 20°C, Burchard[6,42] calculated a length of the statistical random link of 282 Å. He assumed a symmetric rotational poten-tial around β-glycosidic bonds with respect to a straight zig-zag conformation of the chain. The best fit of experimental results was obtained when an average monomer length of 5.50 Å was assumed. Using these values one obtains $S = 51.3$, which is close to the value given above for the dioxane solutions at 25°C.

From the above given values of S it can be concluded that the stiffness of cellulose tricarbanilate increases with a decrease of temperature. Moreover, it appears that also the transition, as observed with a change of solvent composition, must be ascribed to a changing stiffness of the chain; in the ester phenyl benzoate the chain is less stiff than in the ether dioxane at comparable temperatures.

In *Table 3* a survey is given of the results obtained on sample CC IV in both pure solvents. In addition, results are mentioned which were obtained on the sharp fraction CC IX 4 of comparable molecular weight in benzophenone[5]. Before drawing conclusions from the values of Λ or Λ_∞, one should realize that Λ_∞ is influenced by the refractive index of the solution and also explicitly by temperature. This means that it will be more adequate to use the values of the anisotropy $(\alpha_1 - \alpha_2)$ as calculated from Λ_∞ with the aid of equation (3). In the case of phenyl benzoate at 100°C the value of Λ_∞ is not known, as only one sample, i.e. CC IV, was investigated at that temperature. However, a look at *Figure 8*, where results for phenyl benzoate are given for 75°C, leads us to the conclusion that the molecu-lar weight of CC IV is sufficiently high to yield a value of Λ which is practically equal to Λ_∞. The calculated values of $(\alpha_1 - \alpha_2)$ are given in *Table 3*. The influences of tempera-ture on the intrinsic viscosity and on the anisotropy of these polymer samples in the different solvents can be compared if the temperature coefficients of both quantities are cal-culated from the data in *Table 3* (the results are given in columns 9 and 10).

Two groups of solvents can easily be discerned: on the one hand, the ether dioxane, in which cellulose tricarbani-late has a relatively high stiffness, on the other the ester phenyl benzoate and the ketone benzophenone, in which this polymer is more flexible. Also the high temperature coefficients of the intrinsic viscosity and of the anisotropy in dioxane must be noticed, compared with those for both other solvents. It further strikes that both coefficients are nearly equal in the same solvent. The temperature coeffi-cients of the viscosity in phenyl benzoate and in benzophe-none are of the same order of magnitude as those found for other cellulose derivatives[43]. The value found in dioxane is higher than the just mentioned ones. An interpretation of these facts in terms of the formation of a certain number
Figure 11 Anisotropy $(\alpha_1 - \alpha_2)$ of the statistical random link against the number S of monomer units per random link for CC in three solvents and at several temperatures. $\circ$, Dioxane; +, benzophenone; $\square$, phenyl benzoate

of intramolecular hydrogen bonds for cellulose tricarbanilate in ethers[7] seems quite obvious.

In *Figure 11* the results given in *Table 3* are plotted graphically to illustrate the tremendous influence of S on the anisotropy $(\alpha_1 - \alpha_2)$; the latter quantity increases much more than proportional to the length of the statistical random link. Consequently, besides chain stiffening, which would lead to a linear relation between $(\alpha_1 - \alpha_2)$ and S, also other effects must play a role in the change of the anisotropy $(\alpha_1 - \alpha_2)$. Changes of the following effects can be responsible: (1) form birefringence; (2) polymer—solvent interaction resulting in variations of solvatation as well as excluded volume; (3) stereochemical structure and conformation of the molecular chain. This classification is certainly quite arbitrary, as the different effects are usually interrelated. There are reasons, however, to expect a simpler situation with cellulose tricarbanilate.

As to the effect of form birefringence, it has already been argued that this effect should be negligible even in dioxane. In fact, if form birefringence is of importance, Λ shows a systematic concentration dependence[44]. With a negative intrinsic anisotropy, as in the case of cellulose tricarbanilate, an increase of the absolute value of Λ should be expected with increasing concentration. This was never found, which confirms that this effect can be neglected.

With a value of $S = 50.0$ in dioxane at $25°C$ one molecule of the sample CC IV comprises only 17 random links. With such a small number of random links the molecule will only approximately form a Gaussian coil. In such a case, however, excluded volume cannot play a role of importance. On the other hand, in the transition of the anisotropy $(\alpha_1 - \alpha_2)$, as observed with a change of solvent composition, a change of solvatation is certainly involved to some extent.

Undoubtedly, however, the strong change of the anisotropy with temperature and also with solvent composition, is mainly due to a change of the stereochemical structure of the chain. The fact that the anisotropy of the cellulose tricarbanilate is negative, is caused by the presence of the phenyl rings in the side-groups. The polarizability of the phenyl groups, probably enhanced by the -CONH- links with the main chain, is certainly greater in the plane of the ring than in a direction perpendicular to the ring. The

extent to which these groups influence the anisotropy of the chain can be expected to depend on the average orientation of the rings with respect to the direction of the chain. A similar hypothesis has been put forward and evaluated quantitatively for the comparison of atactic and isotactic polystyrene[21,45]. When cellulose tricarbanilate gets a stiffer structure by the formation of intramolecular hydrogen bonds, the phenyl groups become more closely packed. This can be seen with the help of a molecular model. The angle of rotation of the phenyl rings becomes nearly zero. A greater flexibility of the chain is accompanied by a greater freedom for rotation of the phenyl rings, which certainly explains a decrease of the negative anisotropy $(\alpha_1 - \alpha_2)$.

Another point of discussion is the interpretation of the transition found with the measurements of intrinsic viscosity (*Figure 7*). Before starting this discussion, however, the molecular weight dependence of the intrinsic viscosity in pure solvents should be interpreted.

In this context it is of importance that Burchard *et al.*[46] had already measured the molecular weight dependence of the intrinsic viscosity of cellulose tricarbanilate in dioxane at $20°C$. For these measurements a great number of samples with narrow molecular weight distribution $(\langle M \rangle_w / \langle M \rangle_n < 1.1)$ was used. The respective results are given in *Figure 12*. This Figure also contains measurements on a series of sharp fractions in benzophenone at $55°C$[5] and on the samples CC I5, CC I12, CC III and CC IV in phenyl benzoate at $75°C$.

With the aid of the Eizner—Ptitsyn theory[35] we have calculated the molecular weight dependence of the intrinsic viscosity of cellulose tricarbanilate in dioxane at $20°C$. The molecular weight of the monomer unit M_0 is 519. For the length b of the monomer unit a value of 5.15 Å was taken, as obtained from X-ray diffraction data on cellulose[47]. For the number of monomer units per random link $S = 2\lambda$ we used the value of 50.0, in accordance with our flow birefringence data, as obtained on solutions in dioxane at $25°C$. The difference of $5°C$ between the temperatures of the flow birefringence and viscosity measurements seem to us of minor importance. For the hydrodynamic radius r_0 of the monomer unit a value of 9.2 Å was chosen, which agrees
Figure 12 Intrinsic viscosity of cellulose tricarbanilate fractions against molecular weight in various solvents: $\circ$, dioxane at $20°C$ according to ref 46; x, benzophenone at $55°C$ according to ref 5; $\square$, phenyl benzoate. - - - -, theory of Eizner and Ptitsyn for the parameters indicated; *, theoretical point for a rigid prolate ellipsoid of one persistence length and appropriate thickness. $b = 5.15$ Å; $r_0 = 9.2$ Å; $S = 50$

with the one used by Janeschitz-Kriegl and Burchard[5]. The results of this calculation are given by the broken line in *Figure 12*. Except for the lowest and highest molecular weights the experimental and theoretical lines completely coincide, which means that the flow birefringence and viscosity measurements on cellulose tricarbanilate in dioxane at 20° and 25°C respectively are in excellent agreement.

For the low molecular weight samples the model of an infinitely thin wormlike chain, as used by Eizner and Ptitsyn, cannot be realistic. For these samples the finite thickness of the chain will have a pronounced influence on the intrinsic viscosity. As has been pointed out by Janeschitz-Kriegl and Burchard[5], short wormlike chains of finite thickness can better be approximated by prolate ellipsoids. For these ellipsoids the well known theory of Simha[48] can be used to calculate the intrinsic viscosity. Following this idea we calculated the intrinsic viscosity for a particle of a length equal to one persistence length a ($= bS/2$). As such a particle contains about 25 monomer units in dioxane at 20°C, its molecular weight is 13×10^3. In fact, some mistake was made in ref 5 in the calculation of the volumes of the equivalent ellipsoids. This mistake resulted in too low values of the intrinsic viscosity for these ellipsoids, when no effective increase of thickness was assumed as a consequence of solvatation. The value obtained by the present authors on assuming a value of 5.15 Å for the monomer length and a value of 9.2 Å for the mean radius of the cross-section of the chain, is indicated in *Figure 12* by an asterisk. This value agrees quite well with the experimental results for dioxane.

The character of the curves drawn through the experimental points for benzophenone and phenyl benzoate, however, is quite different from the theoretically predicted curve. In fact, contrary to the theoretical prediction these curves show an upwards curvature in the whole range of molecular weights. The minor differences between the experimental curves in benzophenone and phenyl benzoate are probably due to the fact that the samples measured in the latter solvent are polydisperse. The curves obtained for benzophenone and phenyl benzoate are below the one for dioxane. According to the Eizner–Ptitsyn theory this would correspond to a lower value of S, in accordance with flow birefringence data. As already suggested[5] the opposite curvature of these experimental curves must be ascribed to the influence of the excluded volume effect which can be expected to show up at a lower molecular weight for a more flexible chain. As a matter of fact, for the stiff chains in dioxane one can see a slight deviation from the theoretical line due to excluded volume only at the highest molecular weights. Finally, it can be observed in *Figure 12* that all experimental curves seem to converge at small molecular weights, where the influences of chain stiffness as well as excluded volume vanish.

At this point it is no longer difficult to interpret the transition of intrinsic viscosity, as observed in *Figure 7* for sample CC IV, when dissolved in various mixtures of dioxane and phenyl benzoate. From an inspection of *Figure 12* one can learn that, for a molecular weight of about 500 000, the transition occurs from a $[\eta]$ value in pure dioxane, which is practically uninfluenced by excluded volume, to a lower $[\eta]$ value in phenyl benzoate, which is due to an increased flexibility. This $[\eta]$ value would be even lower, if there would be no influence of excluded volume. In connection with this last statement it is convenient to know that the concave experimental curve for phenyl benzoate and a convex theoretical curve according to equation (11) with $S = 2\lambda = 30$ just touch each other at a molecular weight some-

what higher than 10^5. The same has been shown for benzophenone[5].

As a final point of discussion we now choose the behaviour of the extinction angle. For this purpose *Figures 9* and *10* are considered. For a comparison of these measurements with the results of Zimm's[15] treatment of the bead-spring model, two theoretical lines are also drawn in *Figure 9*. The upper line, denoted by F, stands for the free-draining approximation of a Gaussian coil molecule, the lower one, designated by N, for the non-draining case (see equation 8). Apart from a considerable upwards shift with respect to the theoretical lines, which is due to the polydispersity of the sample CC IV, this Figure clearly shows the non-linear behaviour of the extinction angle curves of this sample. The low molecular weight CC III, does not show a non-linear behaviour. By this fact an extrapolation to zero shear rate becomes possible. But even then it is rather difficult to draw conclusions from the observed changes of $\cot 2\chi_c / \langle \beta_N \rangle_n$, as shown in *Figure 10*. However, a general trend can be deduced from this Figure: the value of $\cot 2\chi_c / \langle \beta_N \rangle_n$ shows a tendency to grow with increasing stiffness of the chain. The temperature and the solvent influence on the chain stiffness can be recognized in a change of $\cot 2\chi_c / \langle \beta_N \rangle_n$. If one assumes that the behaviour of $\cot 2\chi_c / \langle \beta_N \rangle_n$ reflects that of the quantity pJ_{eR}, one can conclude that the prediction put forward in the theoretical part of this paper, viz. that J_{eR} increases with growing stiffness is confirmed by these experiments. However, in view of the limited accuracy of the extrapolation procedures the question remains in how far the observed changes can be considered as significant. Moreover, also a possible influence of chain stiffness on the value of the polydispersity factor p can be responsible for the observed effects.

To get an idea of the values of J_{eR} for a monodisperse sample, certain assumptions can be made. If we assume that the molecular weight distribution of sample CC III is of the Schulz–Zimm type, we can calculate a value of p according to Peterlin[32,34] and Daum[33]. For this purpose we need the polydispersity index of this sample, as given in *Table 1*, and the exponent α in the Mark–Houwink equation. As is well known, this equation reads $[\eta] = KM^\alpha$. However, the value of α is not a constant for cellulose tricarbanilate in all solvents and at all temperatures used (see the curved lines in *Figure 12*). But from *Figure 12* a smoothed exponent α of about 1.0 can be deduced for CC III in dioxane at 20°C. On using this value we obtain a polydispersity factor:

$$p = 3.80 \qquad (13)$$

If we further assume that this value will approximately hold in dioxane at the slightly different temperature of 25°C, it can be used for a correction of $\cot 2\chi_c / \langle \beta_N \rangle_n$, as extrapolated in *Figure 10* to infinite dilution. One obtains in this way: $J_{eR} \sim 0.57$. This value lies only slightly above the range quoted for Gaussian coils (see equation 8). As a matter of fact, this is surprising, as sample CC III comprises in dioxane at 25°C only about 4 random links.

The conclusion can be drawn that the influence of chain stiffness on the behaviour of the extinction angle is very small; it nearly lies within the limits of experimental error. Moreover, the influence of polydispersity masks the effects to such an extent that no quantitative conclusion can be drawn. It appears that the behaviour of the extinction angle hardly gives any valuable information concerning the observed stiffening of cellulose tricarbanilate.

Polymers from acrylonitrile polymerized in the presence of vinylsulphone dyes

N. S. Batty and J. T. Guthrie
Department of Colour Chemistry and Dyeing, University of Leeds, Leeds LS2 9JT, UK
(Received 24 July 1974)

The properties of a series of 'copolymers' of acrylonitrile and various vinylsulphone dyes are discussed. Information relating to molecular size, the nature of the linkage between the chromophore and the backbone and the reactivity ratios of the two 'monomers' is given. These reactivity ratios are calculated from extinction coefficients on the assumption that there is no appreciable breakdown of the chromophore during polymerization. Factors governing the role of the dye in the polymerization process are considered in some detail. Thermal analysis techniques have been used to investigate the thermal stability of the products of polymerization. The thermograms have been used to assess the potential of these materials as pigments and to study the nature of their decomposition.

INTRODUCTION

In a previous paper[1] we outlined a method for making coloured polymers by copolymerizing a dye with vinyl monomers. The kinetics of the reaction of acrylonitrile with three vinylsulphone dyes were investigated. This paper deals with the properties of the polymers so produced, attempts at their characterization and some of their uses. Work of this type falls within the concept of intrinsically coloured polymers, a topic which has been neglected somewhat in the past, especially outside industrial circles. However, there are notable exceptions[2]. We are mainly interested in the potential of such materials as pigments, though other avenues are not forgotten.

The properties desirable in a pigment depend on its end use. Fastness to migration and to light are generally required but may not be essential in particular applications. Good thermal stability is often necessary, especially in the pigmentation of moulded plastics. The cost of the pigment is important and may be an overriding factor. Problems of migration which are commonplace in many pigment applications should be overcome by using polymeric pigments, as the higher molecular weight will inhibit any tendency to migration.

It is well known that the light fastness of many dyes on polyacrylonitrile fibres is increased out of all proportion to the values obtained on wool or other fibres[3]. We hoped to take advantage of this fact by placing the chromophore in a compact environment of polyacrylonitrile through copolymerization. In this way we hoped to make polymeric pigments having improved light fastness over the unmodified chromophore.

A grinding operation is required to produce the full tinctorial value from all conventional pigments. In some cases the intensity of colour changes quite sharply with particle size[4]. Grinding is a long and expensive process, usually accounting for a large proportion of the cost of manufacturing the pigment. Using polymeric pigments this operation could become redundant.

The thermal stability of polyacrylonitrile and its copolymers has been extensively studied by Grassie and his co-workers[5]. On heating the polymer above 200°C, it becomes coloured, yellow then red and ultimately black. The same sequence of coloration can be produced by the action of a basic catalyst on a solution of polyacrylonitrile[6]. There are some differences but the coloration in each case has been attributed to the formation of a conjugated —C=N— system; for example, by cyclization of the nitrile groups, thus:
The mechanism of this conjugation has been considered in detail by Gachkovskii[7]. The colour intensifies as the number of rings in sequence increases and the reaction is exothermic in character[8].

EXPERIMENTAL

In view of some of the problems encountered, the experimental procedure is given in considerable detail. The preparation of the copolymers of acrylonitrile and vinylsulphone dyes has already been described[1].

Osmometry

A Hewlett—Packard Series 500 high-speed osmometer was used for number-average molecular weight determinations. Each sample of polymer was dissolved in freshly distilled N,N-dimethylformamide (DMF) to give solutions of known concentration. The osmotic pressure between each polymer solution and the pure solvent at 37°C was measured. Initially the 'solvent-resistant' membranes (type 0-8) recommended by the manufacturer of the instrument were used. At best these membranes lasted only two days in the solvent before they began to disintegrate. Small pieces of debris from the membrane then obstructed the smooth flow of solvent through the capillary and its connecting tubes. The results became erratic and irreproducible.
Figure 1 Plot of π/c (cm l g^{-1}) against c(g/l) for sample of yellow 'copolymer' in DMF. Total dose: $\bigcirc$, 6.3 x 10^4; $\bullet$, 1.4 x 10^5 rad

This problem was overcome using modified hydroxyethyl cellulose membranes, whose preparation we have already disclosed[9]. Results obtained with these membranes were more reproducible and the useful lifetime of the membrane was far greater than that of the type 0-8 membrane. Indeed, membranes are still in service after six months in contact with DMF.

Spectroscopy

Infra-red spectra were recorded on a Perkin—Elmer recording spectrophotometer, model 157G, using the pressed disc technique and a constant polymeric pigment: potassium bromide ratio. Visible and ultra-violet spectra, recorded on a Unicam SP800 recording spectrophotometer, were obtained for samples in solution in DMF.

Thermal analysis

Samples were examined by differential thermal analysis (d.t.a.). Approximately 5 mg of sample were sealed in an aluminium pan and heated at 10°C/min from 30° to 350°C using a DuPont Model 900 Thermal Analyzer. An empty pan was used as the reference and the chamber purged with nitrogen during heating. One sample of each of the polymers made with yellow, red or blue dye was examined and compared with both the pure vinylsulphone dyes and poly-acrylonitrile homopolymer.

Light fastness

Simple paints were made using the coloured polymers as pigments, drawn into even films on paper and dried at 40°C. The pigment was used both in full strength and reduced with titanium dioxide. Strips of the printed paper, 2.5 cm x 1.0 cm, were cut out and stapled across a 2.5 cm x 8.0 cm card. A similar card was prepared with dyed wool light fastness standards, supplied by the British Standards Institution. The cards were mounted in frames so that half of each sample was masked, than placed in a Xenotest (Quarzlampen GmbH, Hanau, Germany) 150 xenon arc fading lamp at 33° ± 2°C and 63% ± 2% relative humidity. Samples and standards were examined periodically until the contrast between the protected and exposed parts was judged to be equivalent to grade 3 of the Grey Scale for assessing change in colour[10]. The light fastness was then the number of the standard which had faded to the same extent.

Fibre-forming characteristics

Fibres were spun using 25% of the yellow 'copolymer' with 75% of commercial polyacrylonitrile. The respective amounts of polymer were dissolved in DMF to give a 30%

w/v solution. This solution, under a nitrogen atmosphere, was forced at 110°C through a spinneret and dried in a stream of air at 190°C. The fibres were collected as 8 filaments each of approximately 10 dtex. Their light fastness was assessed in the same way as the paint films.

Sulphur analysis

As a further check of the composition of the 'copolymers', quantitative sulphur analyses of a number of samples were carried out by the Microanalytical Section of the School of Chemistry, University of Leeds. The results were then compared with those obtained from spectroscopic analysis. From these results, values of the reactivity ratio, r_{AN} were derived, where r_{AN} denotes the reactivity ratio of the acrylonitrile monomer.

RESULTS

Osmometry

DMF was used throughout as a solvent for the polymers. It is not an ideal solvent for osmometry because it rapidly attacks conventional membranes and has a strong affinity for water. Hence, moisture is constantly absorbed from the atmosphere and markedly reduces the efficiency of the solvent for polyacrylonitrile. In addition there is a tendency for small bubbles to form on and around the membrane during measurements.

The results of measurements on the coloured polymers are shown in *Figures 1* to *4*. *Figures 1a* and *1b* relate to two yellow copolymers, (acrylonitrile with Remazol Golden Yellow G), made by exposing the mixed monomer solutions *in vacuo* to 6.3 x 10^4 (a) and 1.4 x 10^5 (b) rad of γ radiation. Although there is some scatter in the plots of π/c against concentration, values for $\overline{M}_n$ of 21 900 ± 1000 and 23 000 ± 1000 g/mol were obtained for the two polymers respectively.

Plots of some of the other yellow samples, (identical monomers but various total doses of high energy radiation), are given in *Figure 2*. These indicate a decrease in the molecular weight with increasing total dose (*Figure 3*). This observation must be treated with reservation owing to the limited number of points available for each sample. In fact in several examples there was only sufficient sample for one concentration to be used. Here we have assumed the nature of polymer—solvent interactions to be identical to those
Figure 2 Plot of π/c (cm l g^{-1}) against c(g/l) for a series of yellow copolymers for various total doses. Solid symbols indicate only one measurement carried out through lack of sample (see text). ————, *in vacuo*; - - - - -, in air. $\bigcirc$, 0.36 x 10^5; $\bullet$, 0.76 x 10^5; $\triangle$, 1.2 x 10^5; $\blacksquare$, 1.4 x 10^5; $\square$, 1.8 x 10^5; $\blacktriangle$, 2.4 x 10^5 rad
Figure 3 Variation in $\bar{M}_n$ with increasing dose (rad); yellow 'copolymer'. □, In air; ○, *in vacuo*

observed with the yellow copolymers in DMF. With caution, certain observations can be made but these will require subsequent confirmation.

The data for 'red' and blue copolymers are shown in *Figure 4*. They are more erratic than the results from the yellow polymers. The values of π/c at equivalent concentrations are significantly higher.

Membrane osmometry is not normally suitable for measuring molecular weights of unfractionated polymers with number-average molecular weights below about 20 000 g/mol[11]. Significant amounts of smaller molecular species diffuse through the membrane and do not contribute to the osmotic pressure. The derived value of $\bar{M}_n$ then becomes too high. Values obtained for the coloured 'copolymers' cannot be considered to be accurate, particularly in the case of the blue and 'red' copolymers, but they give a useful indication of the probable range and of relative values.

Visible spectroscopy

Measurements of the absorption peaks were made on the three free Remazol dyes at a series of dilutions in DMF and were found to obey the Beer—Lambert law. The extinction coefficient, E, was calculated for each dye and was used to calculate the concentration of the chromophore in solutions of the coloured polymers. This approach was suitable for polymers made with the yellow and blue dyes but not the red. The red copolymers presented problems which will be discussed later.

The absorption peaks of the free yellow, red and blue dyes in DMF were at 433, 512 and 584 nm respectively, with corresponding extinction coefficients of 3.18, 3.97 and 2.32 m^2/g.

The spectra of the solutions of the yellow and blue polymers were identical in shape to those of the parent dyes, with the absorption maxima at the same wavelengths. In these instances it can be assumed that there has been no change in the chromophore on polymerization and, therefore, that the extinction coefficient has not been altered. The extinction coefficient of the polymer in comparison with that of the free dye then gives a direct measure of the chromophore content of the 'copolymer'. It is useful to consider one example in detail. A sample of the yellow copolymer had an extinction coefficient of 8.16×10^{-2} m^2/g. The chromophore content of the copolymer is found by dividing the extinction coefficient of the pure dye (3.18 m^2/g) by that of the copolymer, thus $3.18/8.16 \times 10^2 = 39.0$. This means that 39 g of coloured copolymer

contains 1 g of dye and therefore 38 g of polyacrylonitrile residues. Thus the composition of the coloured copolymer is 1 mol of dye: 380 mol of acrylonitrile. (The monomer molecular weights are 530 and 53 respectively.)

Such composition data can be used to derive the reactivity ratio, r, of the two monomer types. The Mayo and Lewis[12] integrated copolymer equation can be simplified if it is assumed that the large bulk of the dye molecules prevents two of them adding consecutively to the chain, that is, $r_{dye} = 0$. This is a reasonable assumption when one considers the structures of the three dyes used[1]. The modified equation is then:

$$\log\left(\frac{[dye]_0}{[dye]}\right) = \left\{\frac{1}{(1-r_{AN})}\right\} \log\left\{\frac{(r_{AN}-1)\left(\frac{[AN]}{[dye]}\right)+1}{(r_{AN}-1)\left(\frac{[AN]_0}{[dye]_0}\right)+1}\right\}$$

The calculated values of r_{AN} are shown in *Table 1*. These were calculated on the assumption that the reactivity ratios are constant for each system. For polymerizations with the yellow dye *in vacuo*, consistent values (2.5 ± 0.3) were
Figure 4 Plot of π/c (cm l g^{-1}) against concentration for red (○, X) and blue (□, ●) 'copolymers', obtained after irradiation *in vacuo* for the specified dose: □, 0.7×10^5; ○, 1.9×10^5; X, 2.7×10^5; ●, 12.6×10^5 rad

4.1	vac	20:1	74	9.02	1.45
2.9	air	20:1	22	8.87	1.50

obtained. Considerably greater deviation in r_{AN} was observed for reactions carried out in air. For the blue dye systems, the value of r_{AN} was found to be about 1.5, both in air and *in vacuo*.

The visible spectra of solutions of samples of 'copolymer' made with the red dye were recorded similarly in DMF. The wavelength of maximum absorption moved from 512 nm in the free red dye to 440 nm in the coloured 'copolymer'. The polymers and their solutions were yellow instead of the expected deep red. During polymerization, the chromophore must have been modified, so the extinction coefficient found for the free dye cannot be applied. There is a large spread in the extinction coefficients of the 'red copolymers' made in air with no clear trend, as shown in *Table 2*.

One useful aspect of the change in peak absorption is that any free dye remaining in the polymer sample is detected through its absorption at 512 nm. Thus, less than 0.1% by weight of free dye in the copolymer should be apparent. This is important since it enables an efficient purification system to be devised for the 'copolymer'. It can be extended to systems which do not undergo changes in the structure of the chromophore. No peaks at 512 nm were found which indicates that the extraction and washing procedures, given in detail in ref 1, are effective in removing free dye. This removal of free dye will become an essential feature of the envisaged use of this type of polymeric pigment, since the presence of free dye will introduce problems of migration.

The structure of the red dye has previously been quoted as[1]:
However, this type of phenylazo-1-naphthol derivative exists in two tautomeric forms, the hydroxyazo and the hydrazone[13]. In this case the hydrozone form has the structure:
Usually, the forms of a dyestuff are markedly different in colour, the hydroxyazo being yellow and the hydrazone being red. The equilibrium between the two forms may also be affected by the solvent. The red dye in DMF solution must be almost exclusively in the hydrazone form as there is no evidence of the hydroxyazo form in the spectrum (400—500 nm region).

The hypsochromic shift (from a deeper to a lighter colour) on polymerization probably arises through conversion to the hydroxyazo form. One possible cause of this change could be the different environment of the chromophore. In the polymer it will be surrounded by polar nitrile groups. It should be possible to make a metal complex of the dye after it has been incorporated into the polymer. Such complexing would deepen the colour again.

20% of pyridine was added to a solution of the polymer in DMF. A solution of nickel acetate in pyridine was added, the mixture shaken, allowed to stand for several minutes

and then warmed gently to its boiling point. There was no colour change at any stage of this sequence, so no nickel complex was formed. It is possible that the polymer molecules were so tightly coiled in the poor solvent that the nickel ions could not reach the chromophore. This seems unlikely, however, especially as heating had no effect whatever.

A more probable explanation is that the chromophore is altered during polymerization, changing into the hydroxyazo form and so preventing the possibility of complexing with nickel ions. This could occur if the polymerizing radical became attached to the chromophore through the hydroxyl oxygen atom instead of through the vinyl group:
Preliminary work has been undertaken using mixtures of acrylonitrile and Remazol Red 3B, whose structure is given as:
Here, conversion from the hydrazone to hydroxyazo form of the dye cannot take place because of the presence of the metal atom. 'Copolymers' made using this system are red, with the same wavelength of maximum absorption as the parent dye. We may assume that the above mechanism for conversion from the hydrazone to hydroxyazo form is valid.

These observations may have important consequences for polymeric pigments. Inexpensive dyes, able to exist in such tautomeric forms could take part in termination in the manner described, thus providing useful pigments with relative ease.

Table 2 Extinction coefficients of red copolymers with change in total dose

Total dose $\times 10^{-5}$ (rad)	Environment	Extinction coefficient, E, at 440 nm (m^2/g)
1.9	vac	10.55

Infra-red spectroscopy

The coloured 'copolymers' were examined by infra-red spectroscopy. This proved that the colour was derived from the chromophores of the dyes and not from degradation of the acrylonitrile. Such degradation is thought to involve the formation of a —C=N— conjugated system and can arise from the action of heat or a base on polyacrylonitrile. During this process the sharp nitrile peak at 2240 cm⁻¹ decreases in intensity while new peaks appear at 1627 cm⁻¹ and 1772 cm⁻¹[14].

In the spectrum of pure polyacrylonitrile, prepared in the same manner as the coloured polymers, there were small peaks at 1627 cm⁻¹ and 1722 cm⁻¹, showing the presence of some —C=N— groups, although no colour was apparent in the sample. The spectra of the coloured 'copolymers' show additional peaks, nearly all of which correspond to absorption peaks in the dye. Composite spectra can be built up almost completely by addition of a suitable proportion of the spectra of the pure dyes to the spectrum of pure polyacrylonitrile. The peaks at 1627 cm⁻¹ and 1722 cm⁻¹ are very weak in all the samples. Clearly, colour is due to incorporation of the chromophore and not to the formation of a conjugated —C=N— system.

A small peak occurred at 1580 cm⁻¹ in several 'copolymer' samples. This peak cannot be attributed to either the dye or polyacrylonitrile. A peak in this position is indicative of the carboxylate anion[15]. This is probably due to a small amount of hydrolysis of the nitrile groups. It seems unlikely that any potassium acetate could remain in the polymer from the original precipitation stage[1]. The washing process was effective in removing all the free dye from the polymer (shown by the absence of a 512 nm peak in the visible spectra of the copolymers of the red dye) and potassium acetate is far more soluble in methanol. Thorough washing of a finely ground sample with methanol gave no reduction in the peak at 1580 cm⁻¹.

The infra-red spectra confirm that the chromophore is an integral part of each copolymer. Further, the heights of the absorption peaks change with the dye content in the polymers made from 40:1, 20:1 and 10:1 (w/w), acrylonitrile/dye starting mixtures. The extinction coefficients of solutions of the copolymers increase in regular fashion with each increase in the above dye/acrylonitrile ratio (*Table 1*).

Sulphur analysis

Each dye chromophore contains two atoms of sulphur. Since there is no other sulphur in the system, it should be possible to calculate the proportions of dye and acrylonitrile in the 'copolymers' from the sulphur content. The reactivity ratios calculated from the analysis figures are shown in *Table 3*, together with the sulphur contents. The agreement of the reactivity ratios with values calculated from spectroscopic data is poor. This implies that degradation of the chromophore is occurring to some extent, presumably during irradiation, which lowers the visible absorption. In this way some sulphur-containing fragments may be incorporated into the polymer, increasing the sulphur content but not the extinction coefficient.

Differential thermal analysis

D.t.a. was carried out on one sample of each of the 'copolymers' containing yellow, red and blue dye, the free vinylsulphone dyes and pure polyacrylonitrile. The results are shown in *Figures 5* to *7*. The thermogram of polyacry-

	1:2.6	1/20	6—7
	1:32	1/200	6—7

lonitrile is shown, for comparison, in all three Figures. Poly-acrylonitrile provides a steady thermogram with no deviations up to $278 \pm 2°C$ when a sharp exotherm occurs, corresponding to decomposition. The 'copolymer' containing the yellow dye showed an exotherm, beginning at $110°C$ and gradually increasing up to the decomposition temperature of $259°C$, about $20°C$ lower than for polyacrylonitrile. The red and blue 'copolymers' both give gradually increasing exotherms from $140°$ or $150°C$ up to $278° \pm 2°C$. With the blue 'copolymer' a slight exotherm at $180°C$ is in evidence. The decomposition temperature is only slightly affected by incorporation of the red and blue dyes into polyacrylonitrile, but is lowered significantly by the yellow dye.

The thermograms of the pure yellow and red vinylsulphone dyestuffs show gradual decomposition, roughly parallel to the exotherms of the polymers. The blue dye is much more thermally stable than the other two, showing no strong exotherm below $350°C$. The blue copolymer is also thermally stable. The exotherms seen with all the 'copolymers' may arise from decomposition of the chromophore only, the environment having no significant effect. Alternatively, the exotherms could be due to the occurrence of conjugation already mentioned. In polyacrylonitrile this reaction can start at as low a temperature as $175°C^{16}$ and increases with increase in temperature. It is accelerated by nucleophilic agents such as acids and phenols. The extended isotherms observed with the yellow and red 'copolymers' could well be due to this reaction, catalysed by the dye residues. The heat stability of this type of product may well be improved by using more suitable vinylsulphone dyes.

Light fastness

The light fastnesses of the three types of 'copolymers' red, yellow and blue were assessed in simple paint films. The light fastness of a pigment usually falls as the proportion of white pigment, incorporated in the mix, is increased. The results, shown in *Table 4*, show that the above observation is substantiated by the yellow and red polymeric pigments but that the fastness of the blue paint actually increases on reduction. Explanations of such differences are beyond the scope of this paper and are the subject of further work.

Fibre and film-forming character

Fibres spun from a mixture of 25% of the yellow 'co-polymer' and 75% Courtelle (polyacrylonitrile fibre) have physical properties which compare well with a sample of Courtelle spun in the same way. The fibres have a very attractive appearance and are highly coloured. However, the fastness of the yellow polymer is much better in the

paint than in the fibre form. The reason for this is not clear. Possibly it arises from degradation which occurs in the spinning process. It has been shown that some degradation can occur at temperatures as low as $130°C$ and this is well below the tower temperature used in drying the fibre.

The 'copolymers' could also be made into films by spreading their solutions in DMF and either immersing them in water or methanol or allowing a combination of moisture adsorption and solvent evaporation to precipitate the polymer. The films, although tough and flexible initially, become very brittle over extended periods as the last traces of solvent evaporate. However, such films facilitate investigation by infra-red spectroscopy provided allowance is made for residual solvents.

CONCLUSIONS

The polymers described in this paper represent a potentially useful class of pigment. The high molecular weight should prevent migration. A further advantage lies in the insolubility of polymers with a high acrylonitrile content in virtually all common solvents. This type of pigment is admirably suited to the manufacture of water-based paints. The emulsion form in which they are produced is quite stable and, unless they have been allowed to dry out, the polymers emulsify spontaneously in water without the need of additives. In principle, it should be possible to form a paint by adding a water-soluble film-forming agent to such an emulsion. By selection of the vinyl monomer, polymeric pigments can be visualized which will form stable emulsions and act as their own film former. Such materials would represent a considerable advance in pigment technology.

The system is by no means limited to the three vinylsulphone dyes that have been described. There is a large number of commercially available dyes of the vinylsulphone and related acrylamide types. More convenient initiator systems could also be used. Benzoyl peroxide, potassium persulphate and azobisisobutyronitrile have all been used successfully in preliminary experiments using the three acrylonitrile/dye systems already described. Various vinyl monomers are also being investigated in this context to assess the factors involved in 'copolymer' formation and to evaluate their physical properties.

On the whole the strength of colour in the polymers is rather weak. It must always, of course, be much weaker than that of the parent dye. Some increase should be obtainable by use of higher initiation rates and dye concentrations, but this would be at the expense of the molecular weight. It appears that the polymer—dye system is not 'copolymeric' in the accepted sense. Rather, it would seem that the dye is involved in reaction termination though this position is by no means clear.

The concept of intrinsically coloured polymers could be extended into other areas. These include polymers which are stable to light and oxidative degradation, intrinsically fluorescing polymers and so on.

Network properties: 2. A broadline n.m.r. study of molecular motions in some multicomponent crosslinked polymers

C. H. Bamford, G. C. Eastmond and D. Whittle*

Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK
(Received 3 October 1974)

A series of multicomponent polymers of known structure and consisting of poly(vinyl trichloroacetate) crosslinked with poly(methyl methacrylate) (PMMA) have been examined by broadline n.m.r. Both enhanced and retarded rotation of the α-methyl groups on the PMMA chains, compared with those in PMMA homopolymer, have been observed. A previous assessment of the morphologies of the same polymers, based on the results of dilatometric studies, has been extended. The modifications to the rotations of the α-methyl groups have been correlated with the morphologies of the multicomponent polymers and it is proposed that both effects arise as a result of changes in the distribution of conformations adopted by the PMMA chains in the multicomponent polymers compared with that in the pure homopolymer.

INTRODUCTION

A previous series of publications described a general method for preparing multicomponent crosslinked polymers of known structure[1-4]. These materials, which we refer to as ABCPs, consist of chains of a polymer A crosslinked with chains of a chemically different polymer B. The ABCPs are prepared by reacting a preformed polymer A, containing reactive chlorine or bromine atoms in side groups, with a suitable metal derivative in the presence of a free-radically polymerizable monomer. The metal derivative specifically removes a halogen atom from a side group of the A polymer to generate a polymeric radical species. This radical then initiates the graft polymerization of the monomer to form propagating B-chains attached to the A-chains. Combination termination of the propagating radicals produces a cross-linked species consisting of two A-chains linked by a B-chain; i.e. an H-shaped species in which the A-chains form the limbs of the H, as represented in structure I. Disproportionation termination of the propagating radicals gives rise to branched structures. As reaction proceeds more multicomponent species are produced and, by using additional side groups on previously reacted A-chains, structures of greater complexity are produced, e.g. structure II.

(I)

(II)
All propagating radicals we have examined undergo combination termination at least to some extent[4] and ultimately

the reaction mixture gels with the formation of infinite network structures. Continued reaction beyond the gel point increases the crosslink density and incorporates more A- and B-chains into the infinite networks. The major structural parameters of the ABCPs, including crosslink length and density, are calculable on a statistical basis from the reaction kinetics. The branch/crosslink ratio is determined by the relative rates of the two termination reactions.

In the preceding paper of this series[5] we described the preparation of a series of ABCPs, in which poly(vinyl tri-chloroacetate) (PVTCA) was used as the A-component and poly(methyl methacrylate) (PMMA) was the B-component, and we discussed the results of a dilatometric study of the solid PVTCA/PMMA ABCPs. The major structural parameters of these polymers are given in Table 1. The dilatometric data showed the existence of multiple glass-transition temperatures, indicating microphase separation of the incompatible component polymers, even at high crosslink densities. From the values of the glass-transition temperatures and coefficients of expansion of the ABCPs it was concluded that microphase separation was incomplete and that mixed phases, containing both A- and B-chains were present in the polymers; the compositions of the mixed phases were estimated.

The present paper describes the results of a broadline n.m.r. study of the materials referred to in Table 1 and a more detailed analysis of the previous dilatometric data. Effects on the rotation of the α-methyl groups in the PMMA chains are discussed in terms of polymer morphology.

Table 1 Structural parameters of PVTCA/PMMA ABCPs

Sample	PVTCA in network (% w/w)	$\bar{P}_n$ of PMMA crosslinks	Branches: crosslinks	γ_r
I	21.4	4560–4740	4	3

Figure 1 Variation in second moment (ΔH_2^2) of n.m.r. absorption line of poly(methyl methacrylate) with temperature

EXPERIMENTAL

The reaction conditions used to prepare the ABCPs referred to in *Table 1* were presented in a previous paper[5]. The PVTCA was a copolymer of poly(vinyl trichloroacetate) and poly(vinyl alcohol) prepared by trichloroacetylation of poly(vinyl alcohol) to 60.4% conversion; the polymer had a glass-transition temperature of 59°C. $\bar{P}_w$ of the trichloroacetate residues in the PVTCA was 2600. Crosslink densities of the ABCPs are described by values of the relative crosslinking index γ_r which is the crosslinking index relative to that at the gel point and is equal to the reaction time divided by the gel time; where appropriate, corrections have been applied for initiator consumption and a small amount of transfer to monomer.

Solid polymers were isolated from solutions or gels swollen in methyl methacrylate by evaporation of the solvent and heating under vacuum at 100°C.

N.m.r. spectra were recorded using a Varian DP60 spectrometer. Second moments of the absorption spectra were calculated from the derivative spectra[6] and corrected for modulation broadening[7].

In samples I and IV over 80% of the protons, and in the other samples investigated in this study over 90% of the protons, are contained in the PMMA chains so that the n.m.r. signals arise predominantly from the PMMA.

RESULTS AND DISCUSSION

N.m.r. observations

Figure 1 shows the variation in second moment (ΔH_2^2) of the n.m.r. absorption line with temperature for a sample of PMMA homopolymer prepared under the same conditions as the PMMA chains in the ABCPs, except that the PVTCA component of the initiating system was replated by ethyl trichloroacetate. The shape of the curve in *Figure 1* is virtually identical with that obtained by previous workers[8,9]. Absolute values of ΔH_2^2 at −196° and 0°C obtained in this study were 24.0 and 12.0 G² respectively, compared with corresponding values of 18.6 and 10.5 G² reported by Sinnott[8] and 19−20.5 and 11.5−12.5 G² found by Odajima *et al.*[9] for various samples of PMMA. The differences in values of ΔH_2^2 reported by various workers possibly reflect differences in sample preparation; we therefore compare

the n.m.r. data from the ABCPs with the data in *Figure 1*. Slichter and Mandell[10] have confirmed that the reduction in ΔH_2^2 when samples were warmed from −196° to −75°C is due to the establishment of α-methyl group rotation; the ester methyl groups are rotating at all temperatures above −200°C. The decrease in ΔH_2^2 at about 100°C is due to the development of segmental motion associated with the glass transition.

A blend of PVTCA and PMMA containing 22% (w/w) PVTCA, a higher PVTCA content than in any of the PVTCA/PMMA ABCPs, gave values of ΔH_2^2 indistinguishable from those for PMMA. This result is consistent with previous dilatometric data which indicated complete microphase separation of the component polymers, and also confirms that the n.m.r. signals from the ABCPs can be effectively attributed to the PMMA component.

Variation of ΔH_2^2 with temperature for the PVTCA/PMMA ABCPs I−VI are given in *Figures 2, 3* and *4*. Significant differences exist between the data for the ABCPs and those for PMMA homopolymer (shown as a dotted line without experimental points on each graph for comparative purposes). Absolute values of ΔH_2^2 at −196°C and in the plateau region between the establishment of α-methyl group rotation and the onset of segmental motion are generally higher for the ABCPs than for PMMA. Comparing these data with the parameters in *Table 1* we see that samples I and IV, which have the highest PVTCA content and lowest crosslinking index, have the highest values of ΔH_2^2. As γ_r and the PMMA content increase, values of ΔH_2^2 approach those for PMMA.

Other major differences between the broadline data for the ABCPs and for PMMA are associated with the transition region corresponding to the development of α-methyl group rotation. For samples II and III (*Figure 2*) ΔH_2^2 decreases, and methyl group rotation develops more slowly than for PMMA, the transition region covering a comparatively large temperature range. For PMMA all α-methyl groups are rotating at temperatures above −40°C but in samples II and III rotation of the methyl groups is not fully developed until temperatures in excess of 0°C are attained. By contrast, with samples I, IV and V (*Figures 3* and *4*) α-methyl group rotation both sets in and is fully established at temperatures lower than for PMMA. There appears to be no direct correlation between these data and the structural parameters and overall compositions in *Table 1*. These

effects will be discussed later in terms of polymer morphology.

Sample VI which contains 97% (w/w) PMMA exhibited only one T_g at about 100°C and produced n.m.r. data almost identical with those of pure PMMA; data for this sample are not discussed further.

Decreases in ΔH_2^2 associated with the development of segmental motions appear to be similar for the ABCPs and for PMMA homopolymer, within the limited temperature range investigated. Possibly sample II (*Figure 2*) shows significantly different behaviour. So far we have been unable to identify any trends in behaviour in this temperature range which can be interpreted in terms of structure and morphologies of the polymers. Pulsed n.m.r. studies of segmental motions appear to be more informative[11] than broadline studies and these will be discussed in a subsequent publication.

Re-assessment of dilatometric data

In our previous publication[5] we reported volume–temperature data for PVTCA/PMMA ABCPs I to VI. We

analysed the data quite simply in terms of two glass-transition temperatures, drawing three straight lines through the dilatometer plots. For PVTCA/PMMA blends the two glass-transition temperatures identified correspond to those of the component homopolymers (*Table 2*). The lower glass-transition temperatures T_{g1} for the PVTCA/PMMA ABCPs were 10–15°C higher than T_g for PVTCA, while the higher glass-transition temperatures T_{g2} appeared to correspond to that of PMMA; values of T_{g1} and T_{g2} identified in this way are given in *Table 2*. Sample VI contained only 3% PVTCA and did not exhibit a lower glass-transition temperature.

While the appearance of two glass-transition temperatures indicates microphase separation of the incompatible constituent polymers, the elevated values of T_{g1} for the ABCPs were taken to indicate that microphase separation was incomplete. The results were interpreted in terms of formation of a mixed phase containing PVTCA and PMMA and a phase of pure PMMA. On the basis of volume additivity and normal coefficients of expansion for the liquid polymers in the mixed phase above T_{g1}, the compositions of the mixed phases were calculated from the coefficients of expansion. The compositions of the mixed phases calculated in this way are given in *Table 2*; W is the weight of PMMA associated with unit weight of PVTCA in the mixed phase. From the values of W and the overall compositions of the polymers the distribution of the PMMA between the mixed and pure PMMA phases can be calculated; the percentages of PMMA in each phase is given in *Table 2*. This simple analysis requires some elaboration.

Glass-transition temperatures for mixtures of amorphous materials, for which simple additivity of free volume applies, can be calculated from the coefficients of expansion of the glassy and liquid materials and their volume fractions and glass-transition temperatures by use of the Kelley–Bueche equation[12]. This equation has been successfully applied to polymer–diluent systems[12], compatible mixtures of PMMA and poly(ethyl methacrylate)[13] and certain PVTCA/polystyrene ABCPs which show a single glass transition[14]. Assuming simple additivity of volumes applies to mixtures of PVTCA and PMMA in the mixed phase we can calculate the T_g of the mixed phase from the values of W given in *Table 2*. Values of T_{g1} calculated in this way are given in *Table 2*, and are seen to be consistently higher than the observed values of T_{g1}. The calculated values of T_{g1} also vary monotonically with composition of the mixed phase whereas observed values do not. Validity of the Kelley–Bueche equation to mixtures of PVTCA and PMMA can only be checked by producing homogeneous mixtures of the polymers of known composition. This has not yet been achieved.

Table 2 Glass transitions and compositions of phases in PVTCA/PMMA ABCPs

Sample	T_{g1} (obs)	T_{g2}	W	% (w/w) of PMMA in mixed phase	% (w/w) of PMMA in pure PMMA phase	T_{g1} (calc.)
I	74	97.5	1.2	32.6	67.4	82.6

Figure 5 Dilatometric data for PVTCA/PMMA ABCPs. ○, Sample I; □, sample IV; ×, sample V

In the absence of information to the contrary we shall continue to assume that the Kelley–Bueche equation is applicable to mixed phases in PVTCA/PMMA ABCPs and look elsewhere for an explanation of the discrepancy between the observed and calculated values of T_{g1}

Further examination of the dilatometer plots reveals that the data are not accurately represented by three straight lines; in general the dilatometer plots above T_{g1} are curved as is clearly seen in *Figure 5* in which the original dilatometric data for samples I, IV and V are redrawn. *Figure 6* shows data for samples II and III which also exhibit multiple transitions with a well defined upper glass-transition. The curvature in the dilatometer plots indicates that the PVTCA/PMMA ABCPs do not undergo microphase separation into a mixed phase of well defined composition (with a unique T_g) and a pure PMMA phase, rather the mixed phase can have a continuous variation of composition. Thus, if each portion of the mixed phase exhibits a T_g according to its composition the sample will effectively exhibit a broad glass-transition region. The range of compositions of the mixed phase may reflect domains of different composition through that phase. The values of W calculated on the basis of the original analysis will represent average compositions of the mixed phase and the lower glass-transition temperatures (which are usually well defined) will arise from those regions of the mixed phases richest in PVTCA.

For samples I, IV and V (*Figure 5*) the dilatometer plots are smooth curves through T_g of PMMA. There is no sharp transition corresponding to pure PMMA and it must be concluded that essentially all the PMMA is incorporated in the mixed phase; i.e. the distribution of the PMMA between the phases given in *Table 2* and based on the simple analysis for samples I, IV and V, is incorrect. In contrast, samples II and III exhibit well defined transitions at about 100°C so that, in addition to the mixed phase, these materials contain an essentially pure PMMA phase. From the coefficients of expansion it can be estimated that the fractions of the PMMA existing in the pure PMMA phase in samples II and III are 0.85 and 0.93, respectively.

Correlation of broadline n.m.r. data with morphology

Comparison of the n.m.r. and dilatometric data brings to light a definite correlation between polymer morphology and the onset of α-methyl group rotation in the PMMA

chains. In samples I, IV and V the α-methyl group rotation starts, and is fully established, at lower temperatures than in pure PMMA, and dilatometry leads to the conclusion that for these samples essentially the whole of the PMMA is in the mixed phase. For samples II and III the α-methyl group rotation develops more slowly, with increasing temperature than, for pure PMMA and dilatometry suggests that in these samples most of the PMMA is in a pure PMMA phase. Thus, enhancement of the methyl-group rotation arises in the mixed phase and retardation of the rotation in the PMMA phase.

The temperature range over which the α-methyl group rotation in pure PMMA develops, as observed by n.m.r. must reflect the energy barriers to rotation of the methyl groups and hence the conformations of the PMMA chains which control the local environments of those groups. Thus, the breadth of the transition will be influenced by the variety of local environments which are present in the amorphous polymer. Modifications to the development of α-methyl group rotations, as observed in the ABCPs, must result from changes in the environment of the methyl groups. Recent neutron scattering studies[15] have demonstrated that torsional vibration frequencies of the α-methyl groups in isotactic and syndiotactic PMMA are different, the differences arising from changes in chain conformation in consequence of the different chain configurations. Modifications to α-methyl group rotations in the ABCPs, however, cannot arise from differences in tacticity since all the PMMA chains are predominately syndiotactic and samples I (enhanced rotation) and II (retarded rotation) were prepared under identical conditions (PMMA polymerization at 80°C) and should have the same tacticity.

To explain the modifications to α-methyl group rotation observed in this work it is necessary to consider the PMMA chain conformations in the mixed phase and in the pure PMMA phase in the ABCPs. It is not known whether the PMMA and PVTCA chains in the mixed phase are intimately mixed on a segmental level or if some very small-scale microphase separation exists. In either case it must be presumed that in order to pack efficiently in the solid state the PMMA chains must adopt a distribution of conformations different from those adopted by PMMA chains in PMMA homopolymer. We believe that in this situation the conformations adopted are such that on average steric restrictions to α-methyl group rotation are reduced, so that
Figure 6 Dilatometric data for PVTCA/PMMA ABCPs. ○, Sample II; □, sample III

methyl group rotation in samples I, IV and V is observed at a lower temperature than in PMMA homopolymer.

The essential difference between PMMA chains in the homopolymer and in the essentially pure PMMA phase in the ABCPs is the presence of a domain—matrix interface in the latter. In the ABCPs all the PMMA chains are attached to PVTCA chains, consequently the interdomain separation (assuming the PMMA forms the matrix) must be comparable with the PMMA chain dimensions and a large proportion of each PMMA chain must be in close proximity to the interface. A PMMA chain emerging from a PVTCA domain will necessarily adopt conformations which provide good space filling on the surface of the domain. We believe that this can only be achieved if the PMMA chains adopt conformations different from those adopted by a 'free' PMMA chain in the homopolymer, and that the retardation of the methyl group rotation arises as a result of the enhanced barrier to methyl group rotation in the vicinity of the interface. At the present time it is impossible to determine how far the influence of the interface is transmitted into the PMMA phase.

Davis and Slichter[16] have recently observed that when tetraethylene glycol dimethacrylate is polymerized and crosslinked within a poly(vinyl chloride) matrix molecular motions, including rotation of the α-methyl groups, are impeded.

Absolute values of ΔH_2^2 are determined by the inter-proton distances and the motions of the protons together with a contribution from the other nuclei with non-zero spin. No satisfactory quantitative interpretation of the absolute values of ΔH_2^2 observed for the ABCPs in this work

has been obtained so far. However, the relatively high values of ΔH_2^2 obtained for the ABCPs may arise from the unusual conformations adopted by the PMMA chains which must influence the inter-proton distances and modify both the intra- and inter-molecular contributions to ΔH_2^2.

INTRODUCTION

Two topics of interest in recent years have been the study of the solvent effects on the physico-chemical properties of bio-polymers[1-6] and the conformational analysis of sequential polypeptides[7-10]. Research on these subjects may throw light both on the role that the hydrophobic interactions play in proteins, displaying the contribution of the water molecules in such biological systems, and on the influence of different sequences of peptide residues in connection with the macromolecular geometry.

The copolymers poly(L-leucyl-L-leucyl-L-aspartic acid)[11,12] (PLLAA) and poly(L-leucyl-L-leucyl-L-lysine)[13,14] (PLLL) were synthesized and hence investigated in aqueous solution by potentiometric and spectral measurements. The experimental results were in agreement with the presence of α-helical segments stabilized by hydrophobic interactions both in PLLAA and PLLL. Moreover the ΔH^0 values seem to point to the existence of a more compact hydrophobic state in PLLAA than in PLLL (6173 and 2784 cal/repetitive unit respectively).

As a development of the research programme concerning PLLAA and PLLL circular dichroism (c.d.) spectra in mixed solvents were recorded in order to obtain some information about the influence of the medium dielectric constant and of the electric dipole moment of the solvent molecules on the PLLAA and PLLL conformation.

EXPERIMENTAL

Stock solutions of PLLAA[12] and PLLL · HCl[14] were prepared by dissolving the polymer in double-distilled water (conductivity less than 2.5×10^{-6} ohm^{-1} cm^{-1} at 20°C) and then adding the appropriate amount of spectroscopic grade solvents (Merck). PLLAA was dissolved in water by adding a small amount of 0.1 N NaOH.

The concentrations of the polymer stock solutions were obtained by a Beckman 120 C amino acid analyser after complete hydrolysis in 6 N HCl at 106–110°C in sealed tubes under vacuum. The concentration range was 1×10^{-4} to 2×10^{-4} M (referred to the mass weight of one third of the repetitive unit).

pH was measured on a Radiometer pH meter 26 which was standardized at several pH values with buffers in aqueous media. Thus we report the apparent pH for mixed solvent solutions.

*To whom enquiries should be addressed

The c.d. spectra were recorded on a Cary 61 and a Cary 60 spectropolarimeter with c.d. attachment. No time effect was detected in the spectral patterns of the polymers in the charged state. The spectra within the pH range corresponding to the region near to the uncharged state were collected by making sure that no precipitation occurred in solution as well as that the pH had reached a constant value. This was done in order to handle data describing equilibrium states.

RESULTS AND DISCUSSION

Two series of c.d. measurements were accomplished for PLLAA and PLLL in methanol–water solvent mixtures and some spectra are displayed in Figures 1 and 2 for PLLAA (pH $\simeq$ 10.9) and PLLL (pH $\simeq$ 5.5) in the charged state. In addition the molar ellipticity $[\theta]$ of the two polymers at 205 and 220 nm is reported in Figure 3 as a function of the methanol concentration. From inspection of this Figure it is clear that both the polypeptides show a rather constant $[\theta]$ value within almost wide range of the methanol percentage. However, the plateau's start at a very different solvent composition and the slope in the first part of the curves is greater for PLLL than for PLLAA.

PLLL exhibits a higher α-helical content in water than PLLAA. The helicity increases more rapidly by adding less methanol for PLLL than for PLLAA and at 90:10% (v/v) methanol–water PLLL is nearly completely α-helical. The
Figure 1   C.d. curves of PLLAA as a function of methanol concentration at 27°C. A, 0; B, 20; C, 50; D, 80% methanol

chains, as those of the leucine and lysine, suitably interact with the apolar parts of the solvent molecules. These molecules produce a short-range ordered structure around the protruding side chains in such a way as to support the α-helix. For this reason the smaller α-helical content of PLLAA may be explained as due to the low solvation ability of the aspartyl side chain residue, which is very near to the backbone chain.

It should be mentioned that the α-helical conformation is just as stable when higher alcohols are used[2,4], because the hydrophobic part of the solvent molecule is increased. A similar effect is found in water and in methanol—water mixtures for a series of polymers of the N^5-(ω-hydroxyalkyl)-L-glutamines[1] and for poly(diaminobutyric acid), polyornithine and polylysine[5] as a direct function of the number of methylene groups within the side chain.

C.d. spectra were performed for PLLL in the charged state in order to evaluate the influence of solvents with various dielectric constants on the conformation of the polypeptides. Solvent mixtures containing 80% of methanol, acetonitrile or dioxane and 20% of water were employed. No remarkable change of [θ] was detected (see *Figure 4*) although the dielectric constants of methanol and acetonitrile, which are nearly equal, differ from that of dioxane[15]. On the other hand the electric dipole moments, increasing from dioxane to acetronitrile, seem to be ineffective in stabilizing the α-helix.

The ellipticity of PLLAA in methanol—water (80:20 % v/v) was measured at various pH values. Only three illustrative curves are reported in *Figure 5*. A similar plot is given in *Figure 6*, where the charge effect is studied in the aceto-

Figure 2   C.d. curves of PLLL as a function of methanol concentration at 27°C. A, 18; B, 36; C, 54; D, 72% methanol. The C and D profiles coincide

Figure 3   Molar ellipticity vs. methanol concentrations at 27°C. PLLAA: ○, λ = 205 nm; △, λ = 220 nm. PLLL: ●, λ = 205 nm; ▲, λ = 220 nm. The [θ] values of PLLL at 0 and 90% of methanol are taken from spectra reported in ref 14

curves of PLLL seem to indicate that the increase in helicity occurs in two distinct stages, the second of which causes only a small change in [θ]. Thus methanol might give rise to a double-step process characterized by two different types of interaction states. In this connection it may be reasonable to suppose that bulky and hydrophobic side

nitrile—water mixture. $[\theta]$ decreases slightly more for methanol than for acetonitrile by lowering the pH in the charged state region. However, a fast decrease of the absolute magnitude of $[\theta]$ appears for the uncharged polymer (curve A of Figures 5 and 6). This peculiar behaviour seems to denote the existence of inter- or intra-molecular aggregation.

Clearly the lack of repulsive Coulombic interactions in the uncharged state and the very hydrophobic side chains of PLLAA and PLLL may strongly favour aggregation states.

Active centre determination in donor-modified Ziegler—Natta polymerization

D. R. Burfield
Department of Chemistry, University of Malaya, Kuala Lumpur 22—11, Malaysia
(Received 20 October 1974; revised 30 December 1974)

INTRODUCTION

Recently a detailed kinetic study of the effect of addition of triethylamine to the catalyst system $VCl_3/Al(iBu)_3$ for the polymerization of 4-methylpentene-1, has been reported[1]. It was conjectured that differing rates encountered, when using various orders of addition of polymerization components, could be ascribed to variation in the number of active centres. This proposal has been tested by further tritium quench experiments which are now described.

EXPERIMENTAL

Details of catalysts, solvents and procedure have already been published[1-3].

RESULTS AND DISCUSSION

Kinetic isotope effect

The correction factor, K, for the kinetic isotope effect arising from difference in reactivity between the oxygen—hydrogen and oxygen—tritium bonds in the quench methanol, was determined as described previously[3]. A value of 1.7 ± 0.2 was obtained in the donor-modified system, this being the mean of three determinations. This is within the range of values of 1—3.7 obtained by other workers[4-8], but is significantly lower than that of 3.20 ± 0.15 found previously for the same system in the absence of donor[3]. This observation clearly demonstrates the necessity of determination of the correction factor for meaningful comparison of

(Received 20 October 1974; revised 30 December 1974)

INTRODUCTION

Recently a detailed kinetic study of the effect of addition of triethylamine to the catalyst system $VCl_3/Al(iBu)_3$ for the polymerization of 4-methylpentene-1, has been reported[1]. It was conjectured that differing rates encountered, when using various orders of addition of polymerization components, could be ascribed to variation in the number of active centres. This proposal has been tested by further tritium quench experiments which are now described.

EXPERIMENTAL

Details of catalysts, solvents and procedure have already been published[1-3].

RESULTS AND DISCUSSION

Kinetic isotope effect

The correction factor, K, for the kinetic isotope effect arising from difference in reactivity between the oxygen—hydrogen and oxygen—tritium bonds in the quench methanol, was determined as described previously[3]. A value of 1.7 ± 0.2 was obtained in the donor-modified system, this being the mean of three determinations. This is within the range of values of 1—3.7 obtained by other workers[4-8], but is significantly lower than that of 3.20 ± 0.15 found previously for the same system in the absence of donor[3]. This observation clearly demonstrates the necessity of determination of the correction factor for meaningful comparison of

results obtained in donor-modified and conventional Ziegler systems. The lower kinetic isotope effect in the presence of triethylamine may possibly reflect the increased reactivity of the donor-complexed polymeric alkyl in the quench reaction.

In addition, it was noticed that at very high conversions (>80%), when the reaction mixture had become extremely viscous, the rate of the quench reaction (as judged by the colour change[3]) became much slower, requiring up to 30 min for complete catalyst penetration compared to about 1–3 min under normal conditions. At the same time, the value of the correction factor for the kinetic isotope effect was found to approach unity, which is to be expected if the quench reaction had become diffusion controlled. This observation introduces a further complication in the tritium quench method of active centre determination since the isotope effect may be dependent on the viscosity of the reaction medium under extreme conditions. However, all values used in this study were obtained outside the viscosity dependent region.

Active centre measurements

The number of active centres was determined as previously described[3] by following the variation of the concentration of metal–polymer bonds (MPB) during polymerization. The active centre concentration (C_0) is taken as the intercept, at zero conversion, of a plot of [MPB] *versus* $\log_{10}(100 - \%$ conversion)^3. C_0 was determined in the absence of Et_3N (control experiment) and in the presence of Et_3N: (i) where the donor is added prior to the monomer (order A); and (ii) where the donor is added subsequent to monomer addition (order B). The C_0 values together with the rates of polymerization and experimental conditions are summarized in *Table 1*.

The results show that the number of active centres in the donor modified system is dependent on the order of addition of triethylamine to the catalyst (VCl_3), in particular whether the donor is added before or after the addition of monomer. Prior addition of triethylamine to the catalyst leads to a significant drop in the number of active centres as has been previously suggested[1]. That the rate of polymerization, in this case, remains almost unchanged is probably due to the simultaneous increase in the value of the concentration of adsorbed monomer, θ_M, since the rate of polymerization has been shown to be governed by the equation:

$$R_p = k_p \theta_M C_0 \tag{1}$$

The increase in θ_M arises through the removal of adsorbed aluminium alkyl species, from the catalyst surface, by complexation with donor.

Where triethylamine is added after monomer addition C_0 is only marginally higher and is in fact within experimental error of the control value. The large increase in rate of polymerization, in this case, is seen to be mainly due to an increase in θ_M rather than in the number of active centres.

These results confirm the importance of the initial monomer/catalyst interaction, and are suggestive of some intermediate species necessary for active centre formation.

Chain transfer with metal alkyl

Besides the effect of donor on the number of active centres it is also possible to determine its influence on the rate of transfer with metal alkyl (R_{ta}). The rate of transfer with metal alkyl is found[3] directly from the gradient of a plot of [MPB] *versus t*. The results for the control and donor-modified polymerization are summarized in *Table 1*.

It is apparent that the donor may either increase or decrease the rate of transfer with metal alkyl dependent upon the order of addition and concentration. This partly reflects the observed[9] dependence of R_{ta} upon C_0 of:

$$R_{ta} = k_a \theta_A C_0 \tag{2}$$

Thus the rate of transfer decreases in order A, where C_0 is decreased and increases in order B where C_0 is increased, relative to the control.

The effect of donor on the rate of chain transfer is not, however, totally expected since the polymerization activation has been explained[1] in terms of complexation of metal alkyl, which should also reduce the value of θ_A, and hence the ratio R_{ta}/C_0 (*Table 1*). This apparent discrepancy may well arise if the denominator of θ_A contains additional terms, i.e. θ_A is given by the modified equation:

$$\theta_A = \frac{K_A[A]}{1 + K_M[M] + K_A[A] + K_{A'}[A']} \tag{3}$$

where the additional term $K_{A'}[A']$ represents the adsorption of aluminium chloroalkyl species. Such modification is consistent with earlier results[1]. If the aluminium chloroalkyl species are strongly adsorbed, as seems likely, and are preferentially complexed by donor then θ_A could remain virtually unchanged or even somewhat increased on addition of triethylamine.

What, however, is more significant is the fact that the ratio of R_p/R_{ta} increases in the presence of donor by a factor of about 2. As it has been shown[10] that in this system transfer with metal alkyl is a major molecular weight limiting reaction, this would be expected to lead to a significant increase in the molecular weight. Such molecular weight increases have been generally observed on donor modification of conventional catalyst systems[11–19]. Thus it may be speculated that the increase in molecular weight in the presence of electron donors is largely due to the reduction in rate of chain transfer with metal alkyl relative to the rate of polymerization.

Table 1   Comparison of active centre concentration and rate of chain transfer with aluminium alkyl in control and donor modified polymerization

	R_p (mol l^{-1} min^{-1} VCl_3^{-1})	$C_0 \times 10^4$ (mol/mol VCl_3)	$R_{ta} \times 10^6$ (mol l^{-1} min^{-1} VCl_3^{-1})	R_p/R_{ta} $\times 10^{-5}$	$R_{ta}/C_0 \times 10^2$ (min^{-1})
Control	0.270	3.8 ± 0.4	3.2	0.83	0.85

Properties of poly(p-biphenyl methacrylate) in dilute solution

J. B. Alexopoulos, N. Hadjichristidis and A. Vassiliadis

Department of Industrial Chemistry, University of Athens, 13A Navarinou Street, Athens 144, Greece

(Received 2 December 1974)

As part of a research programme for the investigation of solution properties of polymethacrylate esters as a function of the chemical structure of the side groups, we present here the results for poly(p-biphenyl methacrylate).

The p-biphenyl methacrylate[1] was polymerized at 50°C in benzene solution under vacuum with azobisisobutyronitrile as initiator. Fractions of the polymer were obtained by stepwise precipitation from benzene solutions using methanol as precipitant. The fractions were analysed by gel permeation chromatography (g.p.c.). Finally six fractions (B1 to B6) were chosen among those obtained from five polymerizations.

Viscosity, light scattering, osmotic pressure sedimentation and g.p.c. results are given in *Table 1*. The methods used have been described elsewhere[2–4].

RESULTS AND DISCUSSION

The experimental values of the constants for the relations:

$$[\eta] = K_a \bar{M}_w^a \qquad (S_0) = K_c \bar{M}_w^c \qquad A_2^* = K_d \bar{M}_w^d$$

$$A_2 = K_e \bar{M}_n^e \qquad (\bar{r}_z^2)^{1/2} = K_f \bar{M}_w^f$$

are given in *Table 2*. The values of the constants c and f cal-

culated from the Mark–Houwink constant $a (c = (2 - a)/3,$ $f = (a + 1)/3)$ are 0.475 and 0.57 in excellent agreement with the experimental values.

The value of $k = k_s/[\eta]$ varies from 1.4 to 1.6 in good agreement with theory[5]. The average value of $\Phi^{1/3}P^{-1}$ of the Mandelkern–Flory equation[6] is 2.3 x 10^6.

The value of K_θ leading to the unperturbed dimension $(\bar{r}_0^2)^{1/2}$:

$$K_\theta = \Phi \left(\frac{\bar{r}_0^2}{M} \right)^{3/2}$$

has been calculated by the well known relations of Stockmayer–Fixman[7] and Kamide–Moore[8]. The values of K_θ obtained by these relations are: 43 x 10^{-5} dl/g (S–F) and 45 x 10^{-5} dl/g (K–M) (*Figures 1* and *2*).

Adopting the value of 44 x 10^{-5} dl/g for K_θ, the relation between $(\bar{r}_0^2)^{1/2}$ and molecular weight is:

$$(\bar{r}_0^2)^{1/2} = 0.60 M^{1/2} \ (\text{Å})$$

taking the value of 2.0 x 10^{21} for Φ.

The root-mean-square end-to-end distance, assuming completely free rotation around the bonds or $(\bar{r}_{of}^2)^{1/2}$,

Properties of poly(*p*-biphenyl methacrylate) in dilute solution

J. B. Alexopoulos, N. Hadjichristidis and A. Vassiliadis
Department of Industrial Chemistry, University of Athens, 13A Navarinou Street, Athens 144, Greece
(Received 2 December 1974)

As part of a research programme for the investigation of solution properties of polymethacrylate esters as a function of the chemical structure of the side groups, we present here the results for poly(*p*-biphenyl methacrylate).

The *p*-biphenyl methacrylate[1] was polymerized at 50°C in benzene solution under vacuum with azobisisobutyronitrile as initiator. Fractions of the polymer were obtained by stepwise precipitation from benzene solutions using methanol as precipitant. The fractions were analysed by gel permeation chromatography (g.p.c.). Finally six fractions (B1 to BG) were chosen among those obtained from five polymerizations.

Viscosity, light scattering, osmotic pressure sedimentation and g.p.c. results are given in *Table 1*. The methods used have been described elsewhere[2-4].

RESULTS AND DISCUSSION

The experimental values of the constants for the relations:

$$[\eta] = K_a \bar{M}_w^a \qquad (S_0) = K_c \bar{M}_w^c \qquad A_2^* = K_d \bar{M}_w^d$$

$$A_2 = K_e \bar{M}_n^e \qquad (\bar{r}_z^2)^{1/2} = K_f \bar{M}_w^f$$

are given in *Table 2*. The values of the constants c and f cal-

culated from the Mark—Houwink constant $a (c = (2 - a)/3, f = (a + 1)/3)$ are 0.475 and 0.57 in excellent agreement with the experimental values.

The value of $k = k_s/[\eta]$ varies from 1.4 to 1.6 in good agreement with theory[5]. The average value of $\Phi^{1/3}P^{-1}$ of the Mandelkern—Flory equation[6] is 2.3 x 10^6.

The value of K_θ leading to the unperturbed dimension $(\bar{r}_0^2)^{1/2}$:

$$K_\theta = \Phi \left(\frac{\bar{r}_0^2}{M} \right)^{3/2}$$

has been calculated by the well known relations of Stockmayer—Fixman[7] and Kamide—Moore[8]. The values of K_θ obtained by these relations are: 43 x 10^{-5} dl/g (S—F) and 45 x 10^{-5} dl/g (K—M) (*Figures 1* and *2*).

Adopting the value of 44 x 10^{-5} dl/g for K_θ, the relation between $(\bar{r}_0^2)^{1/2}$ and molecular weight is:

$$(\bar{r}_0^2)^{1/2} = 0.60 M^{1/2} \text{ (Å)}$$

taking the value of 2.0 x 10^{21} for Φ.

The root-mean-square end-to-end distance, assuming completely free rotation around the bonds or $(\bar{r}_{of}^2)^{1/2}$,

Figure 1 Stockmayer—Fixman plot for poly(p-biphenyl methacrylate) in different solvents at 25°C. ●, CHCl₃; ○, THF; ■, dioxane; □, benzene

is given by the relation:

$$(\overline{r}_{of}^2)^{1/2} = 0.20 M^{1/2} \text{ (Å)}$$

The value $(\overline{r}_o^2)^{1/2}/(\overline{r}_{of}^2)^{1/2}$ or σ, representing the effect of steric hindrance on the flexibility of the chain, is consequently equal to 3.0.

In conclusion, poly(p-biphenyl methacrylate), as with other aromatic polymethacrylates[2,3], has a high rigidity probably because of the specific interactions between the aromatic rings.

Solvent sorption of heat treated vinyl chloride polymers

Introduction

The results reported here are part of an investigation into the effect of heat treatment on structural order in vinyl chloride polymers. The solvent sorption technique described is based on that used by Blackadder and Vincent[1] for following small morphological changes in polypropylene and poly(ethylene terephthalate). Changes in the solvent sorption behaviour of heat treated suspension polymerized poly(vinyl chloride) have been reported by Illers[2], but long annealing times (100 h at 65°C, 94 h at 90°C) were used. In the present work the effect of much shorter heat treatments

on solvent sorption is examined for three vinyl chloride polymers. The shorter heat treatments are used in an attempt to find out whether structural changes are likely to occur during the processing of PVC.

Experimental

Materials. The three polymers were as follows: (1) PVC 2 (a BP suspension homopolymer supplied by RAPRA Polymer Supply and Characterisation Centre); (2) Breon AS 60/41 X15 (a BP suspension polymer containing 15% vinyl acetate); (3) a PVC homopolymer polymerized at −30°C (Montecatini Edison).

Glass transition temperatures of the polymers, measured by a du Pont thermomechanical analyzer, are listed below.

Solvent sorption of heat treated vinyl chloride polymers

Introduction

The results reported here are part of an investigation into the effect of heat treatment on structural order in vinyl chloride polymers. The solvent sorption technique described is based on that used by Blackadder and Vincent[1] for following small morphological changes in polypropylene and poly(ethylene terephthalate). Changes in the solvent sorption behaviour of heat treated suspension polymerized poly(vinyl chloride) have been reported by Illers[2], but long annealing times (100 h at 65°C, 94 h at 90°C) were used. In the present work the effect of much shorter heat treatments

on solvent sorption is examined for three vinyl chloride polymers. The shorter heat treatments are used in an attempt to find out whether structural changes are likely to occur during the processing of PVC.

Experimental

Materials. The three polymers were as follows: (1) PVC 2 (a BP suspension homopolymer supplied by RAPRA Polymer Supply and Characterisation Centre); (2) Breon AS 60/41 X15 (a BP suspension polymer containing 15% vinyl acetate); (3) a PVC homopolymer polymerized at −30°C (Montecatini Edison).

Glass transition temperatures of the polymers, measured by a du Pont thermomechanical analyzer, are listed below.

	T_g(°C)
PVC 2	82
Breon AS 60/41 X15	75
Low temperature polymerized PVC	91

The polymers were selected to represent a typical commercial suspension polymer, a copolymer in which structural order would be disrupted by bulky acetate groups, and a low temperature polymerized PVC which is known to have a higher syndiotacticity, hence a higher crystallinity than a typical commercial PVC homopolymer[3].
After dry blending with 4 parts per hundred (by weight, of dibasic lead stearate each polymer was milled, then compression moulded to form sheet approximately 0.5 mm thick.

Heat treatment. In an attempt to destroy existing order and to ensure a uniform heat history all samples were first heated under nitrogen for 3 min and then quenched in an ice/water mixture. The pre-treatment temperatures used were: PVC 2, 200°C; PVC/PVAC copolymer, 175°C; low temperature polymerized PVC, 220°C.

Selected samples were further heat treated at 70°C and 110°C, i.e. above and below their glass transition temperature.

Solvent sorption. The heat treated sheet was cut into strips 13 mm x 40 mm for the solvent sorption measurements. The weight and average thickness of each strip were measured, and the samples were immersed in toluene in stoppered jars which were placed in a water bath thermostated at 30 ± 0.1°C. Samples were removed after selected intervals of time. Each sample was quickly dabbed with a tissue to remove excess toluene, and a plot of its weight against time was used to find the sample weight at the time of its removal from toluene.

Results and Discussion

In *Figures 1a–1c* the % weight gain due to solvent sorption for the three polymers are plotted against $t^{1/2}/l$ where t is the immersion time of the strip in toluene, and l its average thickness in mm. The term $t^{1/2}/l$ is used to correct for any slight thickness differences of the samples. Results for the three polymers, heat treated for 8 h at 110°C are compared in *Figure 2*.

The PVC/PVAC copolymer absorbed over 90% of its own weight of toluene in 1 h. During the same time PVC 2 and the low temperature polymerized PVC absorbed less than 1% of toluene. After longer immersion times the two homopolymers exhibited different behaviour. For PVC 2 the rate of solvent sorption increased, then the weight gain reached an equilibrium value of 50–60% after about 24 h. For the low temperature polymerized PVC the rate of solvent sorption increased more slowly and an equilibrium value had not been reached after 4 days. For the copolymer it is clear that the equilibrium weight gain must be higher than for PVC 2.

Figure 1 Sorption curves for (a) PVC 2 (b) PVC/PVAC copolymer and (c) low temperature polymerized PVC. ○, pre-treated and quenched; △, pre-treated, quenched and heated 8 h at 70°C; X, pre-treated, quenched and heated 8 h at 110°C
Figure 2 Sorption curves for three vinyl chloride polymers heat treated 8 h at 110°C. X, PVC 2; ○, PVC/PVAC copolymer; △, low temperature polymerized PVC

The different solvent sorption behaviour of the three polymers may be due to several factors. Some X-ray diffraction work currently in progress has shown that, as expected, the PVC/PVAC copolymer appears to be virtually amorphous while the low temperature polymerized PVC has the highest crystallinity. Crystallinity is expected to have a significant effect on solvent sorption since the polymer chains are packed more closely in crystalline regions thus restricting solvent penetration. The results obtained for the two PVC homopolymers may be explained on this basis. In the copolymer chain packing is also reduced by the bulky acetate groups present and the decrease in polar forces between chains caused by the replacement of chlorine atoms by these groups.

Heat treatment changed the solvent sorption behaviour of the two homopolymers (*Figures 1a* and *1c*) but had no significant effect on the solvent sorption of the copolymer (*Figure 1b*). For PVC 2 (*Figure 1a*), the quenched sample, in which order would be expected to be lowest, absorbs solvent most rapidly. The sample heat treated at 70°C (i.e. below the glass transition temperature of the polymer) absorbs solvent slightly more slowly, but the weight gain reaches the same equilibrium value. The sample heat treated at 110°C (i.e. above the glass transition temperature) absorbs solvent more slowly and reaches a lower equilibrium value. Also the solvent sorption curve is S-shaped in the latter case, while for the quenched sample and the sample heat treated at 70°C the initial part of the plot of weight gain *versus* $t^{1/2}/l$ appears linear before the equilibrium value is reached.

The effect of heat treatment on the solvent sorption behaviour of the low temperature polymerized PVC appears

Figure 3 Solvent uptake for PVC 2 immersed 4 h in toluene as a function of heat treatment time at 110°C

Figure 4 Solvent uptake for low temperature polymerized PVC immersed 72 h in toluene as a function of heat treatment time at 110°C

to be similar to that of PVC 2, but the rates of solvent sorption were much slower and none of the experiments were continued to equilibrium.

The above results can be explained tentatively as follows. Heat treatment is considered to have no effect on solvent sorption behaviour of the copolymer either because the rapid uptake of solvent is governed only by the presence of acetate groups, or because the polymer structure is too irregular for crystallization to occur.

For the two homopolymers results were similar to those reported by Illers[2]. Quenching would be expected to remove order, and actually resulted in more rapid solvent sorption in each case. The different solvent sorption behaviour for samples heat treated above and below T_g has been attributed to changes in crystallinity and free volume respectively[2]; further evidence (from density measurements, thermal analysis and X-ray diffraction) will be presented later.

Figures 3 and *4* illustrate the effect of time of heat treatment at 110°C on solvent sorption and provide some information about the rate of the crystallization or ordering process occurring. These results suggest that structural changes occur within quite short times. However, it is necessary to examine the effects of short term heat treatment in more detail.

Evaluation of relative reactivities of vinyl monomers towards t-butoxy radical by means of spin trapping technique

Szwarc[1] developed a concept of 'methyl affinity', i.e. a measure of relative reactivities of various compounds, including vinyl monomers, towards the methyl radical produced by the thermal decomposition of diacetyl peroxide in iso-octane. To determine the relative reactivities, the following competitive reactions were used:

$$CH_3\cdot + C_8H_{18} \xrightarrow{k_1} CH_4 + \cdot C_8H_{17} \tag{1}$$

$$CH_3\cdot + M \xrightarrow{k_2} CH_3\text{-}M\cdot \tag{2}$$

where M represents a vinyl monomer. It has also been

The different solvent sorption behaviour of the three polymers may be due to several factors. Some X-ray diffraction work currently in progress has shown that, as expected, the PVC/PVAC copolymer appears to be virtually amorphous while the low temperature polymerized PVC has the highest crystallinity. Crystallinity is expected to have a significant effect on solvent sorption since the polymer chains are packed more closely in crystalline regions thus restricting solvent penetration. The results obtained for the two PVC homopolymers may be explained on this basis. In the copolymer chain packing is also reduced by the bulky acetate groups present and the decrease in polar forces between chains caused by the replacement of chlorine atoms by these groups.

Heat treatment changed the solvent sorption behaviour of the two homopolymers (*Figures 1a* and *1c*) but had no significant effect on the solvent sorption of the copolymer (*Figure 1b*). For PVC 2 (*Figure 1a*), the quenched sample, in which order would be expected to be lowest, absorbs solvent most rapidly. The sample heat treated at 70°C (i.e. below the glass transition temperature of the polymer) absorbs solvent slightly more slowly, but the weight gain reaches the same equilibrium value. The sample heat treated at 110°C (i.e. above the glass transition temperature) absorbs solvent more slowly and reaches a lower equilibrium value. Also the solvent sorption curve is S-shaped in the latter case, while for the quenched sample and the sample heat treated at 70°C the initial part of the plot of weight gain versus $t^{1/2}/l$ appears linear before the equilibrium value is reached.

The effect of heat treatment on the solvent sorption behaviour of the low temperature polymerized PVC appears

Figure 3 Solvent uptake for PVC 2 immersed 4 h in toluene as a function of heat treatment time at 110°C

Figure 4 Solvent uptake for low temperature polymerized PVC immersed 72 h in toluene as a function of heat treatment time at 110°C

to be similar to that of PVC 2, but the rates of solvent sorption were much slower and none of the experiments were continued to equilibrium.

The above results can be explained tentatively as follows. Heat treatment is considered to have no effect on solvent sorption behaviour of the copolymer either because the rapid uptake of solvent is governed only by the presence of acetate groups, or because the polymer structure is too irregular for crystallization to occur.

For the two homopolymers results were similar to those reported by Illers[2]. Quenching would be expected to remove order, and actually resulted in more rapid solvent sorption in each case. The different solvent sorption behaviour for samples heat treated above and below T_g has been attributed to changes in crystallinity and free volume respectively[2]; further evidence (from density measurements, thermal analysis and X-ray diffraction) will be presented later.

Figures 3 and *4* illustrate the effect of time of heat treatment at 110°C on solvent sorption and provide some information about the rate of the crystallization or ordering process occurring. These results suggest that structural changes occur within quite short times. However, it is necessary to examine the effects of short term heat treatment in more detail.

$$CH_3\cdot + M \xrightarrow{k_2} CH_3\text{-}M\cdot \qquad (2)$$

where M represents a vinyl monomer. It has also been

pointed out that the observed relative reactivities (k_2/k_1) of vinyl monomers towards the methyl radical correlated well with those towards a polystyryl radical[2].

Subsequently Bevington and his coworkers[3,4] attempted to evaluate the reactivity (k_3/k_4) of the benzoyloxy radical towards vinyl monomers by using ^{14}C-labelled benzoyl peroxide. In this case, the reactivities were determined by the ^{14}C-labelled end group analysis of the polymers obtained as the result of the following competitive reactions:

$$C_6H_5COO \cdot \xrightarrow{k_3} C_6H_5 \cdot + CO_2 \qquad (3)$$

$$C_6H_5COO \cdot + M \xrightarrow{k_4} C_6H_5COO-M \cdot \qquad (4)$$

$$C_6H_5 \cdot + M \xrightarrow{k_5} C_6H_5-M \cdot \qquad (5)$$
They also emphasized that polar effects were more important in the reaction of the benzoyloxy radical than that of methyl radical with the monomers[4].

Although order of reactivity to the methyl radical towards vinyl monomers was confirmed to be similar to that of ethyl[5], n-propyl[5] and phenyl radicals[6,7], no data with respect to the reactivity of the oxy radicals except benzoyloxy radical towards vinyl monomers were found.

Recently, we have succeeded to trap with 2-methyl-2-nitrosopropane (BNO) as a spin trapping agent, the intermediate radical species (I and II) produced from the reactions of a number of vinyl and α-methyl-vinyl monomers having X substituents with the t-butoxy radical produced by the thermal decomposition of di-t-butyl peroxalate[8]:

$$t\text{-}C_4H_9O-CH_2-\overset{\cdot}{\underset{X}{C}}-Y \qquad CH_2=\overset{}{\underset{X}{C}}-\overset{\cdot}{C}H_2$$
$$(I; Y=H, CH_3) \qquad\qquad (II)$$

When decomposition is carried out in p-xylene in the presence of a monomer, the t-butoxy radical produced participates in competitive reactions:

$$t\text{-}C_4H_9O \cdot + M \xrightarrow{k_6} t\text{-}C_4H_9O-M \cdot \qquad (6)$$

$$t\text{-}C_4H_9O \cdot + M \xrightarrow{k_7} t\text{-}C_4H_9OH + M' \cdot \qquad (7)$$
$$\qquad\qquad\qquad\qquad\qquad (II)$$

$$t\text{-}C_4H_9O \cdot + CH_3-\phi-CH_3 \xrightarrow{k_8} t\text{-}C_4H_9OH + CH_3-\phi-\overset{\cdot}{C}H_2 \qquad (8)$$
$$\qquad\qquad\qquad\qquad\qquad (III)$$
If this reaction is performed in the presence of BNO, the radicals (I, II and III) produced react readily with BNO to give the respective nitroxides:

$$t\text{-}C_4H_9O-CH_2-\underset{\underset{X}{|}}{C}Y-\underset{\underset{O\cdot}{|}}{N}-C_4H_9\text{-}t$$

(IV)

$$CH_2=\underset{\underset{X}{|}}{C}-CH_2-\underset{\underset{O\cdot}{|}}{N}-C_4H_9\text{-}t$$

(V)

$$CH_3-\phi-CH_2-\underset{\underset{O\cdot}{|}}{N}-CH_4H_9\text{-}t$$
(VI)

Figures 1 and *2*, for example, show the e.s.r. spectra of the reaction mixtures of styrene and methyl methacrylate, respectively, with di-t-butyl peroxalate in the presence of BNO without p-xylene at 25°C.

From the e.s.r. spectrum of *Figure 1*, it is seen that only a nitroxide was produced and assigned as IV(A_N = 14.2 G, A_H^β = 2.3 G and A_H^γ (2H) = 0.6 G) in which X and Y are C_6H_5 and H, respectively. However, *Figure 2* appears to be the combined spectra of the nitroxides IV (X=COOCH$_3$, Y=CH$_3$; A_N = 14.9 G) and V(X=COOCH$_3$; A_N = 14.8 G, A_H^β (2H) = 9.8 G). When reactions are carried out in p-xylene, of course, the e.s.r. spectrum due to the nitroxide VI (A_N = 15.0 G, A_H^β (2H) = 7.5 G) is superimposed on the respective spectra of *Figures 1* and *2*.

Therefore, if the relative concentrations of the nitroxides ([IV], [V] and [VI]) produced are determined from the areas of the peaks due to the respective nitroxides in the absorption spectra obtained from integration of the observed first derivative e.s.r. spectra, the relative reactivities $(k_6/k_8$ and $k_7/k_8)$ of the t-butoxy radical towards the monomers can be evaluated by using the following equations

$$\frac{[IV]}{[VI]} = \frac{k_6}{k_8} \frac{[M]}{[CH_3-\phi-CH_3]} \qquad (9)$$

$$\frac{[V]}{[VI]} = \frac{k_7}{k_8} \frac{[M]}{[CH_3-\phi-CH_3]} \qquad (10)$$
Figure 1 E.s.r. spectrum of the reaction mixture of styrene and di-t-butyl peroxalate in the presence of BNO
Figure 2 E.s.r. spectrum of the reaction mixture of methyl methacrylate and di-t-butyl peroxalate in the presence of BNO; the peaks A are due to t-butyl-t-butoxynitroxide which is obtained from the reaction of BNO with t-butoxy radical

Table 1 Relative reactivities of vinyl monomers towards t-butoxy radical at 25°C: comparison with those towards benzoyloxy, methyl and phenyl radicals

Monomer	e	Q	t-C$_4$H$_9$O· k_6/k_8	t-C$_4$H$_9$O· k_7/k_8	C$_6$H$_5$COO·[a] k_4 (rel. value)	CH$_3$·[b] k_2/k_1	C$_6$H$_5$·[c] k_5 (rel. value)
Isobutyl vinyl ether	−1.77	0.023	9.06	−	−	−	−
α-Methylstyrene	−1.27	0.98	6.90	<0.05	−	926	1.24
t-Butyl vinyl sulphide	−1.1	0.32	7.43	−	−	−	−
Styrene	−0.8	1.0	29.8	−	1.0	792	1.0 (1.0)
Vinyl acetate	−0.22	0.026	0.28	−	0.36	31	0.23 (≥0.08)

[a] Data of Bevington *et al.*[3,4] at 60°C
[b] Data of Szwarc[1] at 65°C
[c] Data of Pryor *et al.*[7], who determined these values through tritium abstraction reaction of a phenyl radical, produced by phenyl azotriphenyl-methane, with tritiated pentanethiol at 60°C, as the standard. The values in parentheses indicate the data of Bevington *et al.*[6] who used hydrogen abstraction reaction from dimethylformamide by a phenyl radical, produced by decarboxylation of benzoyloxy radical, as the standard
Figure 3 Plots of [IV]/[VI] with [M]/[CH$_3$−φ−CH$_3$]: △, Methyl acrylate, □, styrene; ○, acrylonitrile

where [M] and [CH$_3$−φ−CH$_3$] are initial concentrations of monomer and *p*-xylene, respectively.

Figure 3 shows the plots of [IV]/[VI] with [M]/[CH$_3$−φ−CH$_3$] for the reactions of di-t-butyl peroxalate with styrene, methyl acrylate and acrylonitrile in *p*-xylene in the presence of BNO at 25°C. As can be seen from this Figure, linear relationships are obtained, and the relative reactivities of these monomers towards the t-butoxy radical are determined from their slopes.

The results are summarized in *Table 1*, in which the relative reactivities of vinyl monomers towards methyl, phenyl and benzoyloxy radicals are also indicated.

It is of interest that the relative reactivities (k_6/k_8) of the monomers towards addition of the t-butoxy radical are related more with their e values than their Q values, indicating that the polar effect is more important than resonance effect, similar to the case of the benzoyloxy radical[4]. In connection with these results, it is also noted that the t-butoxy radical can easily abstract the allylic hydrogen of α-methyl-vinyl monomers such as methyl methacrylate and

methacrylonitrile. This observation seems to be related to that found for the benzoyloxy radical[4], and to provide important information on the initiation mechanism of radical polymerization of vinyl monomers with the oxy radical.

Conference Announcement

Polymer Physics

Shrivenham, Wilts, 24—26 September 1975

The Polymer Physics Group will be holding its biennial meeting at the Royal Military College of Science, Shrivenham, Wiltshire from 24 to 26 September 1975. Contributed papers (20 minutes) are invited. The subject matter of this meeting is deliberately wide and is meant to include all aspects of the physics of polymers and macromolecules, including the morphology, mechanical, electrical and optical properties of solids, melts and solutions. Intending contributors are asked to send a title and short abstract (250 words) to Mrs H. Higdon, Department of Physics, Brunel University, Uxbridge, Middlesex UB8 3PH, UK by *31 May 1975*. Further details and application forms will be available in June from the Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK.

Book Reviews

Particle size analysis
Z. K. Jelinek
John Wiley, New York (for Ellis Horwood) 1974,
178 pp. £5

This book, which is a translation of a Czechoslovak text is a welcome
addition to the few books on this subject already available. The
others I have seen relate primarily to powders. This book also
includes critical accounts of the determination of the size or mole-
cular weight distributions in colloid systems, mostly of polymers,
besides chapters on surface area and pore size measurement.

The depth of the criticism of the interpretation of experimental
results and of the theoretical basis of the methods should appeal to
the research specialist in disperse system analysis. I agree with the
publisher's claim that this book should also interest any chemist or
chemical engineer who desires a rapid insight into the practical
application of dispersoid analysis. This could best be achieved by
reading the excellent practical examples of the applications, extract-
ed from the literature, which accompany the description of each
method of size analysis. Polymer chemists will appreciate the fact
that twelve out of the seventeen applications described refer to
polymer systems.

Well written practical instructions in most of the methods of size
analysis are given. I would, however, have preferred a longer more
detailed description of representative sampling.

The book includes all the normal methods of size analysis namely
by optical, ultra and electron microscopy, X-ray analysis, sieve
analysis, ultrafiltration, gel permeation, sedimentation, centrifuga-
tion, diffusion, osmometry, viscometry and permeametric methods.

The book is well produced and worth the price of £5.

Fluorine chemistry reviews: Vol 7
Edited by Paul Tarrant
Marcel Dekker, New York, 1974, $24.50

This series of reviews sets out to provide articles which cover the
international literature comprehensively and are aimed mainly at
research workers in the field of fluorine chemistry but also provide
a means for others outside the field to keep abreast of developments.

This volume contains two articles, the first on Nucleophilic
substitution in polyfluoroaromatic compounds by L. S. Kobrina,

---

and the second on the Preparation and reactions of polyfluorinated
aromatic heterocyclic compounds by G. G. Yakobson, T. D. Petrova
and L. S. Kobrina. They originally covered the literature to the end
of 1970 but, owing to delays in printing, the authors have added, in
the first case, a list of pertinent papers up to the end of 1972 and,
in the second case, a short commentary and list of papers which take
us into early 1973. Both reviews are excellent, they cover their
fields very thoroughly indeed and are particularly useful in putting
work in Russia in perspective with work in the western world. Since
it is eighteen months to two years from the time of their submis-
sion before English translations of Russian papers (and then not all
papers) are available, and presumably there is a similar delay in
reverse, there has tended to be some duplication of effort.

Points worth special mention are that both articles bring out the
importance of solvent polarity in controlling the nature of reaction
products (an area where there has been considerable Russian work);
and they clearly indicate the need for more kinetic measurements
to help rationalize reaction mechanisms with complete confidence.

Apart from a few awkward grammatical word formations and
some typing errors, the latter particularly in the list of references,
the articles are well written and easy to read. The errors are, in the
main, easily resolved and one must pay tribute both to the authors'
command of English and to the efforts of the editor. Presumably
these efforts, together with postal delays, caused the original delay
in publication. This delay, while disappointing for the authors
when the field is so active, does not detract from the quality and
usefulness of the articles as sources of reference to research workers
and also to those teaching undergraduate courses in this field.

At $24.50 (£10—£11) the price is fairly high but the book is
well worth the money.

W. K. R. Musgrave

Polymer synthesis: Vol 1
Stanley R. Sandler and Wolf Karo
Academic Press, New York, 1974, 572 pp. £18.95

The title indicates coverage of an enormous topic. The authors have
reduced this to this one volume by selecting only the preparation
of uncomplicated 'linear' polymers for review by functional group
classes. They deviate, for no adequate reason, from this format in
chapters entitled 'Thermally stable polymers' and 'Organo-
phosphorus polymers' and incorporate two chapters comprising
sixty-five pages on peroxidic initiators which seem to me to be an
unnecessary inclusion. The various chapters discuss a number of
classes of addition and condensation polymers and each chapter
comprises a general introduction, a set of experimental methods
and a list of titles for miscellaneous preparations with copious
references. The more complicated polymers such as blocks, grafts,
gels or more commercially interesting systems such as alkyds, urea—
formaldehyde and melamine—formaldehyde resins are omitted.

A more serious criticism of this book is that it presents an
inadequate and often incorrect view of polymer science to the
intended audience—industrial research workers, graduate and
advanced undergraduate students in polymer, organic or medicinal
chemistry. The book uses extracts from older references without
updating the terminology and, annoyingly, mixes and confuses
crystalline melting temperature and softening point. The introduc-
tions to the chapters contain too many errors of fact. For example
'ethylene can be initiated by all except the anionic type' (page 2)
and 'cationic polymerizations such as the $BF_3.H_2O$ complex-
catalysed polymerization of isobutylene is considered a "living"
type polymer', this latter statement having been taken from a
1950 literature reference.

My assessment of this book is that it is a useful factual reference
work for libraries, more useful for the critical experienced polymer
chemist and industrial research chemist than undergraduate or
graduate students. The price is high and I would not recommend it
for purchase by individuals.

As this is volume 1, further volumes can be anticipated. I hope
that they will not contain similar flaws as this could be a quite
useful series.

N. B. Graham

Polymer engineering

Over the years there has been a suggestion that more research and basic training are essential for satisfactory progress in the polymers industry. Here is a field of industrial enterprise where it is said that scientific and technical innovation in the provision of polymeric materials, their use in many forms and applications, and fabrication by a variety of processing methods have often been made in advance of sound understanding of the basic principles. One may argue that this is far from the true picture since study of polymeric materials has long been a discipline in its own right, especially with regard to synthesis, structure and physical properties. However, this is polymer science and it is clear that polymer engineering, i.e., the operations concerned with design, fabrication, and properties of the final products, has been less well studied. A glance at the contents of most journals devoted to polymer research and development may give support to this; papers on polymer science are far more numerous than those on polymer engineering.

In two decades manufacture and usage of polymers have become a major industry in developed countries and call for much effort in training, research, development and production. Low levels of such effort cause short term concern and can have more serious consequences in the long run. The need to encourage research and advanced training to meet growing requirements in the UK was recognized in 1969 when the Science Research Council formed the Polymer Science Committee, which body selected polymer engineering as one area for preferential support and approached academic institutions for research proposals. Again, in 1972, the Chemicals EDC Plastics Working Party of NEDO stressed that industry should upgrade its technology through improved knowledge of plastics materials and development of processes and machinery.

However, polymer engineering still appeared to be taking second place to polymer science. Although the SRC Polymer Science Committee received requests for research support in all branches of polymers, it was significant that there were far fewer applications for investigations in polymer engineering compared with those for polymer science. Last year the SRC set up a working party under the chairmanship of Professor G. Allen to examine the national needs for effective research and development and for suitably trained manpower. Their findings have recently been issued* and give new impetus to encouragement of work in this field. The report outlines a number of proposals by which positive progress should be possible, following a study of the current industrial background and requirements.

In personnel, the industry requires graduate engineers and technicians trained specially for production activities while on the research front it stresses that there is much scope for technological improvement in processes and applications, i.e., in processing machinery and knowledge of physical and mechanical properties associated with product design and fabrication methods. These are areas which call for large-scale equipment and the capital costs and provision of facilities for such research have often proved prohibitive to other than a few university departments. The report stresses that there are too few research students in polymer engineering. One might add that also there are probably too few lecturers and experienced research workers in this same subject. The advanced courses in polymers supported by the SRC are more closely related to science than engineering and this may in part be due to the scarcity of expert staff. In the past when efforts have been made to recruit teaching staff specifically for polymer engineering the number of suitably qualified applicants has generally been small.

In setting out a sound course of action, the SRC paper puts forward a number of possibilities but wisely decides against single, narrow, and often fragmented, research proposals or even on relying implicitly on those centres of polymer

---

* Polymer Engineering: The Report of an SRC Working Party, Science Research Council, London, 1975.

research established through major SRC funding over the last five years. It indicates that while there is no single remedy to promote adequate polymer engineering and training, one needs fully to exploit existing facilities but in a coordinated manner. There is recommended, then, the establishment of a Polymer Engineering Directorate as a primary move in a two-phase activity; this could be followed, as necessary, by formation of an Engineering Institute which would provide (in association with other organizations where convenient) a facility for experimental work and training in areas not now fully catered for by industry or university.

The Directorate, comprising a Director and appropriate supporting staff and working in collaboration with a small task force or management committee appointed by SRC, is thus to establish a group of coordinated centres in university and polytechnic engineering departments so as to form a coherent training and research programme. Such a programme would be drawn up in consultation with representative bodies of the polymer-making and -using industries and, when accepted, be funded by SRC. The cost of the Directorate is estimated at £60 000 per year for a five year period, together with up to £2M to meet the costs of the researches proposed.

These recommendations are full of interest and have the merit of ensuring, when implemented, that live engineering centres for polymer research and training are brought into being and receive both adequate recognition and adequate finance. Science, technology and commerce would profit by such a move and one looks forward to the introduction of research and teaching which is not subject to any fragmentation as was sometimes experienced in past endeavours. The immediate concerns will be to appoint an active Director who is knowledgeable in polymer engineering and appreciates fully the needs in training and research and to formulate practical programmes which will lead to positive action and findings of rapid benefit to the industry. One hopes to see, in due course, papers in POLYMER which arise from research contained in the Directorate programme.

The Science Research Council will welcome comments on and offers of assistance in implementing the proposals.

R. J. W. Reynolds

Readers of POLYMER may also be interested to learn that Dr J. G. Williams, one of our UK Editorial Board members since July 1973, has recently had conferred on him the title of Professor of Polymer Engineering in the Department of Mechanical Engineering at Imperial College, London, Hopefully, this should encourage both technical and graduate staff to enter the relatively new discipline of polymer engineering.

Helix – coil transition of poly-(ε-carbobenzyloxy-L-lysine) in *m*-cresol

Toshio Hayashi, Shingo Emi and Akio Nakajima
Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto, Japan
(Received 6 August 1974; revised 25 September 1974)

The thermodynamic parameters for the helix—coil transition of poly(ε-carbobenzyloxy-L-lysine) (PCBL) in *m*-cresol have been determined calorimetrically by determining the heat capacity of the solution in the transition region, and spectropolarimetrically by measuring the helix content of the polypeptide as functions of temperature. From the former measurements, the enthalpy of transition, ΔH_0, was calculated directly. The values of ΔH_0 in *m*-cresol determined from the polarimetric measurements, using experimental data of PCBL samples with rather high molecular weights, are found to be larger than the published data but agree fairly well with the calorimetric values presented in this paper. Further, the transition curves are independent of the concentration of the polymer over the concentration range studied. The values of ΔH_0 in *m*-cresol determined from the calorimetric measurements may be considered to be independent of the molecular weights of PCBL.

INTRODUCTION

A number of papers have reported in the past few years on the helix—coil transitions of un-ionized polypeptides using solvents that destroy the helix such as dichloroacetic acid (DCA) and trifluoroacetic acid (TFA)[1,2]. It was found that poly(ε-carbobenzyloxy-L-lysine)(PCBL) underwent thermal transition of an inverse type in DCA containing a proper amount of 1,2-dichloroethane (DCE) or chloroform, and efforts were made to determine the thermodynamic parameters of the helix—coil transitions from polarimetric measurements[3,4] or from calorimetric measurements[5,6]. However, the results were divergent with respect to both the transition enthalpy, ΔH_0, and the cooperativity parameter, σ. For a number of reasons, the transition always occurred in a finite temperature range, depending on the kinds of solute and solvent and on the molecular weight of the polypeptide. It is therefore useful to define an apparent heat of transition, ΔH, which is obtained from the van't Hoff equation. In the formulation of Zimm—Bragg[7] and Applequist[8], ΔH is related to the transition enthalpy, ΔH_0, by the equation $\Delta H = \Delta H_0/\sigma^{1/2}$. The parameter σ may be related to the statistical length of a helical section of polypeptide at the middle point, T_c, of the transition. We found *m*-cresol to be an exceptional single solvent in which PCBL exhibits an extremely sharp thermal transition of the inverse type[9]. Recently, Matsuoka *et al.*[4] reported a similar sharp transition of PCBL in *m*-cresol. They investigated helix—coil transitions of PCBL in *m*-cresol by optical rotation measurements. On the other hand, no calorimetric measurements to obtain the transition enthalpy ΔH_0 have been carried out for PCBL in *m*-cresol. We therefore attempted a detailed study of the thermal transitions in *m*-cresol by calorimetric as well as polarimetric measurements.

EXPERIMENTAL

Materials

The monomer, CBL—NCA, was prepared by the method proposed by Blout and Karlson[10], and purified by repeated recrystallizations from an ethyl acetate solution with the addition of petroleum ether. Polymerization of the CBL—NCA was carried out at 25°C in a 1:1(v/v) mixture of dioxane and methylene dichloride in the presence of triethylamine (TEA) as an initiator. The solvents and the initiator were purified by the usual means described in the literature and finally distilled by the use of a long column. The fractionation of the PCBL samples was done by fractional precipitation of the polymer from a solution in *N,N'*-dimethylformamide (DMF), using ethanol as the precipitant. The resulting fractions were dissolved in dioxane and filtered through a sintered glass plate, freeze dried, and stored in a refrigerator.

The number-average molecular weights, M_n, of the fractions were determined by osmotic pressure measurements. An Electronic Membrane Osmometer (Knauer Co.) equipped with a variable temperature controller was employed. Regenerated cellulose membrane SD (Sartorius-Membran-Filter GmbH) for organic solvents was used. The solvent used for the measurements was DMF and the temperature was fixed at 30°C. *Table 1* gives the value of M_n of the seven PCBL fractions used in the optical rotatory dispersion (o.r.d.) and calorimetric experiments.

Measurements

The calorimeter employed was a Calvet differential twin-type microcalorimeter manufactured by Setaram of Lyon. A general description of this precision apparatus is given elsewhere[11]. The principle for the measurement of the spe-

Table 1 Molecular weights of PCBL fractions used for experiments

Fractions	M_n	N_n
PCBL-1	400 000	1525
PCBL-2	320 000	1220
PCBL-3	300 000	1145
PCBL-4	238 000	905
PCBL-5	202 000	770
PCBL-6	170 000	650
PCBL-7	140 000	570
Figure 1 Schematic ΔT vs. time curves with (a) an empty cell, (b) a cell containing pure water, and (c) a cell containing the sample at the constant temperature of 22.4°C

cific heat consists of: (1) making the system containing the cell an equilibrium constant temperature; (2) changing the temperature of the cell by a definite increment using the Peltier effect[11]; (3) maintaining the calorimetric unit at a constant temperature; and (4) measuring the energy evolved to return to the original equilibrium temperature (i.e., the temperature of the cell is identical to the temperature of the calorimetric unit). The evolved energy, which can be measured by the flow-meter immediately after cutting off the Peltier current by automatic commutation, is proportional to the total heat capacity of the cell. Three successive operations, with an empty cell, a cell with calibrated medium and a cell with sample, make it possible to measure the specific heat of the sample at each temperature. *Figure 1* illustrates a typical scheme of the chart for these three operations. Integration of the recorder trace was obtained by the area of the chart. If S_0, S_1, and S_2 are the areas corresponding to the three successive experiments, i.e., with the empty cell, cell containing a specimen of known heat capacity (C_1) (in this case, we use a pure water as standard specimen), and cell containing the sample (C_2), the heat capacity, C_2, is determined by the relation:

$$C_2 = C_1 \cdot \frac{S_2 - S_0}{S_1 - S_0} \cdot \frac{M_2}{M_1} \tag{1}$$

where M_1 and M_2 are the weight of pure water and sample solution in the cells, respectively. A glass vessel stopped with Teflon stoppers and covered with a stainless-steel jacket for measuring the heat capacity was designed by the authors, and had an internal volume of about 15 ml. The polymer concentration was in all cases about 2 wt %. A measurement of the heat capacity of solution over a temperature range of 20°C can be made with a precision of ±3%. The heat of mixing of benzene and carbon tetrachloride was measured as a test of the accuracy of the calorimeter and of the cell. The average of several replicate experiments led to a value of 22.3 cal/mol for the heat of mixing, which agreed within 1.2% with the published value of 22.0 cal/mol[12].

O.r.d. in a temperature range from 5° to 50°C was measured with a Yanagimoto OR-100 type spectropolarimeter using a tungsten lamp as light source. The wavelengths used

ranged from 325 to 610 nm. The concentration of polymer solutions was about 1.0 g/dl throughout these measurements. The o.r.d. data were fitted to the Moffitt—Yang equation[13] to obtain values of the helix parameter b_0 for PCBL in m-cresol. A value of 212 nm was used for the constant λ_0 of the Moffitt—Yang equation. In addition, correction was also made for the change in concentration of the polymer due to the change in volume of the solvent mixture at different temperatures from experimental data by the density measurements for sample solution at each temperature. The average error in the determination of b_0 from the slope of the least-squares Moffitt—Yang plot was estimated to be ±3 units in b_0 throughout the range of values of b_0.

RESULTS AND DISCUSSION

Polarimetric measurements

The thermally induced conformational transition of PCBL from the coil conformation at low temperatures to the helix conformation at high temperatures was studied in m-cresol by o.r.d., using the fractionated PCBL samples listed in *Table 1*. The course of the transition was followed by the change in the value of b_0 of the polypeptide solution with temperature (see *Figure 2*). The transition was found to be completely reversible, as was first observed by Doty and Yang[14]. The transition temperature T_c of PCBL in m-cresol is about 25°C, and the decrease in molecular weight of PCBL broadens and shifts the transition curve towards higher temperature. Furthermore, it is shown that the value of b_0 at the lower temperature side gives a positive value of about +150; this value is larger than that $(b_{0,c} = 0)$[15,16] found for coil conformation in DCA—DCE mixture. While at the higher temperature side the value of b_0 is in a range of −350 to −400; these values of b_0 are largely remote from the value of −550 for helix conformation obtained in DMF or chloroform[4,16]. Matsuoka *et al.*[4] reported a similar result for the thermal transition of PCBL in m-cresol.

Figure 3 shows the relation between two coefficients relating to the helix content in the modified two-term Drude equation[17]: $[M'] = A_{193}\lambda_{193}^2/(\lambda^2 - \lambda_{193}^2) + A_{225}\lambda_{225}^2/(\lambda^2 - \lambda_{225}^2)$, where A_{225} is plotted against A_{193} for PCBL in m-cresol. Since A_{193} and A_{225} are directly related to the
Figure 2 Temperature dependence of Moffitt—Yang parameter b_0 of PCBL in m-cresol. 1, PCBL-1, $N_n = 1525$; 2, PCBL-2, $N_n = 1220$; 3, PCBL-3, $N_n = 1145$; 4, PCBL-4, $N_n = 905$; 5, PCBL-5, $N_n = 770$; 6, PCBL-6, $N_n = 650$; 7, PCBL-7, $N_n = 570$
Figure 3 Plot of A_{193} against A_{225} for PCBL in *m*-cresol. Solid straight line denotes the relation; $A_{225} = -0.55\ A_{193} - 280$ given by Schechter and Blout[17]

rotational strength of the Cotton effects due to the α-helix and random coil conformations, respectively, a definite linear relation should be found between A_{193} and A_{225} for mixtures of α-helix and random coil conformations. A failure to fit the relation is taken as an indicator of the presence of another structure such as β-conformation[17]. The straight line in *Figure 3* represents the relation $A_{225} = -0.55\ A_{193} - 280$ obtained by Shechter and Blout[17] by assuming that polypeptides exist either in α-helix or random coil conformation, and not contain other conformations. As is shown in *Figure 3*, all the points fall on the straight line; therefore, it should be concluded that PCBL does not include structures other than α-helix and random coil in *m*-cresol.

Calorimetric measurements

A linear dependence of the measured heat capacity on temperature is obtained for pure solvent without polymer. The heat capacity of the PCBL in *m*-cresol was measured as a function of temperature over a 20°C range centred about T_c. The maxima in the heat capacity curves appeared at 24.5°C and 25.2°C with PCBL-1 and PCBL-7, respectively, in excellent agreement with the o.r.d. data. Heat capacity curves, referred to a smoothed baseline, are shown as a function of temperature in *Figures 4a* and *4b*, with PCBL-1 and PCBL-7, respectively. The area surrounded by the curve and the baseline is directly proportional to ΔH_0. Our results yield a value of +1200 cal/mol with PCBL-1 and of +1150 cal/mol with PCBL-7. The effect on the molecular weight on the transition behaviour is shown in *Figure 4* for two samples of nearly equal PCBL concentration. For the sample of lower molecular weight (PCBL-7), the transition region locates at a higher temperature and the transition temperature T_c is a higher value, while the area surrounded by the curve and the baseline is approximately equal to that obtained for the sample of higher molecular weight (PCBL-1). Thus, the values of ΔH_0 in *m*-cresol determined from the calorimetric measurements may be considered to be independent of the molecular weight of PCBL.

Thermodynamic parameter for thermally induced coil-to-helix transition

The experimental data of o.r.d. measurements relating to the thermally induced conformational transition have been analysed in terms of the Zimm—Bragg theory[7]. The helix content f_H was obtained as a function of temperature at a fixed solvent composition; hence the value of ΔH, van't Hoff heat of transition, is readily determined experimentally from the slope of the b_0 against temperature plot using the equation[18]:

$$\left(\frac{df_H}{dT}\right)_{T_c} = \frac{1}{b_{0,h} - b_{0,c}}\left(\frac{db_0}{dT}\right)_{T_c} = \frac{\Delta H}{4RT_c^2} \qquad (2)$$

The values of $b_{0,h}$ and $b_{0,c}$ for the complete helix and complete coil, respectively, required for the computation of the fractional helix content from b_0, were obtained as follows. The value of $b_{0,c}$ was assumed to be +150 from measurements, judging that PCBL seems to be completely random coil conformation below 22°C. While $b_{0,h}$ was assumed to be −480, considering that a relation $b_{0,c} - b_{0,h} = 630$ obtained for PBLG in DCA—DCE mixture[16] may be expected to hold even for PCBL in *m*-cresol. f_H was then calculated from $f_H = -(b_0 - 150)/630$. The error involved in computing f_H should include not only the error in b_0 mentioned earlier but also the possible error in the limiting values of $b_{0,h}$ and $b_{0,c}$.

The ΔH values calculated for PCBL in *m*-cresol with various molecular weights are illustrated in *Figure 5* as a function of the reciprocal of degree of polymerization, $1/N_n$. It should be pointed out that the ΔH value decreases with decreasing molecular weight. A similar curve was obtained with PCBL in DCA—DCE mixture[16] (see the broken line in *Figure 5*).

Although the value of ΔH_0 should directly be measured by the calorimetric method as described above, it also can be estimated from the o.r.d. data. In the present work, experimental data obtained with PCBL in *m*-cresol (see *Figure 2*) are analysed by the method proposed by Okit et al.[19]. They proposed a new procedure to estimate the parameters ΔH_0 and σ independently from the o.r.d. measurements by using Nagai's theory[20] for the helix—coil transition in polypeptide. It has been shown that the helix content f_H of a polypeptide having N_n degrees of polymerization is represented to a good approximation by[19]:

$$f_H = f_H^0 = \frac{2f_H^{0\ 3/2}(1 - f_H^0)^{1/2}}{N_n \sigma^{1/2}} \qquad (3)$$
Figure 4 Heat capacity as a function of temperature of PCBL solution: (a) PCBL-1 (N_n = 1525) at 0.0179 g PCBL/g of solution; (b) PCBL-7 (N_n = 570) at 0.0188 g PCBL/g of solution. ● data for *m*-cresol

Figure 6 Plots of f_H vs. $1/N_n$ for PCBL in *m*-cresol at temperatures: $\bigcirc$, 23.3°; $\bullet$, 24.1°; $\triangle$, 24.3°; $\square$, 24.7°; +, 26.2°; $\blacktriangle$, 29.3°C

provided that $\sigma^{1/2} \ll 1$, $N_n \gg 1$ and $N_n\sigma^{1/2} \gg 2$. Here, f_H^0 denotes the value of f_H for infinitely large N_n and is related to σ. *Figure 6* illustrates plots of the helix content f_H against the reciprocal $1/N_n$ of number-average degrees of polymerization from data in *Figure 2*. In *Figure 6*, the solid lines represent the theoretical curves calculated by using equation (3) with sets of proper values of f_H^0 and σ

to fit the experimental data at each temperature. The sets of values of f_H^0 and $\sigma^{1/2}$ used are 0.60 and 0.35 x 10^{-2} at 24.3°C, and 0.74 and 0.40 x 10^{-2} for at 24.7°C. Thus, the average value 0.38 x 10^{-2} is given for $\sigma^{1/2}$ in the transition region for PCBL in *m*-cresol. Similar sets of f_H^0 and $\sigma^{1/2}$ were applied to the data at other temperatures. The results for f_H^0 and $\sigma^{1/2}$ as functions of temperature are summarized in *Table 2*. *Table 3* lists the estimated values of thermodynamic parameters from the o.r.d. data as well as values of ΔH_0 obtained by the calorimetric measurement.

The thermal transition curves of PCBL-1 in *m*-cresol were also obtained by o.r.d. measurements at various PCBL concentrations from 0.5 to 3.0 % w/v (see *Figure 7*). The values of ΔH estimated from these curves agreed with each other within experimental error, while the values of T_c slightly decreased with increasing concentrations of PCBL. Therefore, it may be concluded that the values of ΔH are independent of the polypeptide concentration over the concentration range studied. Ananthanarayanan *et al.*[21,22] investigated the helix—coil transition of PBLG in DCA—DCE mixtures from both polarimetric and calorimetric measurements and concluded that ΔH_0 is independent of the concentration of the polypeptide from 0.35 to 2.5 % w/v. Therefore, for a comparison of the polarimetric with the calorimetric data, the difference of less than 1% in polymer concentration between them was neglected. The values of ΔH_0, estimated from the o.r.d. data using $\sigma^{1/2} = 0.38$ x 10^{-2} derived from the o.r.d. data of PCBL samples having a

degree of polymerization greater than 1000, are in fair agreement with those obtained by calorimetric measurements. If we use the values of 0.38×10^{-2} for $\sigma^{1/2}$ to estimate the value of ΔH_0 for PCBL samples having rather low degrees of polymerization, such as PCBL-7, the value of ΔH_0 calculated by $\Delta H = \Delta H_0 / \sigma^{1/2}$ from the experimental values of ΔH (see *Figure 5*) is +650 cal/mol. This value of ΔH_0 is much smaller than that obtained by our calorimetric measurement (see *Table 3*). This fact suggests that the dependence of thermodynamic parameters, σ and ΔH, for helix—coil transition, on N_n is quite remarkable for PCBL in m-cresol. Thus, it should be noted that the estimation of these parameters from the o.r.d. data is valuable only for samples with a considerably high degree of polymerization ($N_n > 1000$) for PCBL in m-cresol. In conclusion, in any event, the sharp transition of PCBL in m-cresol is mainly attributed to an unusually large value of ΔH_0, and to a small value of σ.

Preferential and absolute adsorption on poly (L-glutamic acid) in water – dioxane mixtures

Michel Morcellet and Claude Loucheux

Laboratoire de Chimie Macromoléculaire, Université des Sciences et Techniques de Lille, BP 36, 59650 Villeneuve d'Ascq, France
(Received 25 July 1974; revised 14 October 1974)

The preferential adsorption exhibited by poly(L-glutamic acid) (PLGA) in water—dioxane mixtures has been determined by measuring the specific refractive index increments at constant concentration and at constant chemical potential. These measurements have been carried out at two values of pH (12 and 4.5) and in the presence or in absence of a strong electrolyte (NaCl). At pH 12, in the absence of dioxane, the conformation of the PLGA macromolecule is an ionized chain. When adding low concentrations of dioxane (whether NaCl is present or not) a preferential adsorption of dioxane takes place. While increasing the dioxane concentration the preferential adsorption of dioxane increases and then after passing through a maximum, it decreases and an inversion of the preferential adsorption is observed at higher concentrations of dioxane, water being now preferentially adsorbed. The conformation of PLGA is α-helical, showing that a transition takes place from a disordered ionized state to an ordered one by the addition of dioxane. At pH 4.5, in the absence of dioxane, the conformation of PLGA is α-helical. When adding dioxane in the presence of NaCl, a preferential adsorption of dioxane occurs. While increasing the dioxane concentration no change of the preferential adsorption is observed.

INTRODUCTION

A conformational transition is usually induced in water-soluble polypeptides from a disordered conformation to an ordered one (α-helical for instance), by changing the pH of the solution[1-5]. However, at pH 7.0, the transition from the ionized disordered chain to an α-helical conformation has been obtained by Tiffany and Krimm[5] by adding methanol to poly(L-glutamic acid) (PLGA) solutions. The same transition has been observed by Giancotti et al.[6] by adding pyridine and by Iizuka and Yang[7] by adding dioxane to PLGA solutions.

To date the variation of the preferential adsorption on PLGA when adding increasing quantities of an organic solvent at a constant value of the pH has never been determined.

The aim of this work is to study the preferential adsorption on PLGA in water –dioxane mixtures at two values of pH (when the macromolecule is ionized and when it is not) and eventually in the presence of a strong electrolyte. Such studies have been made by Inoue and Timasheff[8] on the β-lactoglobulin/water/2-chloroethanol system. They have pointed out that for low 2-chloroethanol concentrations a preferential adsorption of this alcohol takes place. However, for higher 2-chloroethanol concentrations, an inversion of the preferential adsorption occurs and water is then preferentially adsorbed. The addition of increasing quantities of 2-chloroethanol induces a transition from the native α-helix poor state of the protein to an α-helix rich one. as shown by the study of the dichroic spectra. This inversion of the preferential adsorption has been interpreted[9] in terms of water polar group interactions and organic solvent hydrophobic zone interactions. In the case of PLGA the side chains of the macromolecule are always polar ones and it is interesting to see whether such an inversion of preferential adsorp-

tion exists and to seek a correlation with the disordered conformation $\leftrightharpoons$ α-helix transition.

THEORY

The notation used here is that of Scatchard[10] and Stockmayer[11] for three component systems, in which the polymer is referred to as component 2, water as component 1 and the organic solvent as component 3. In the case where a strong soluble electrolyte is added the system may be considered as a pseudo-3 component system in which component 1 becomes water + electrolyte.

The measurement of the specific refractive index increment, $\partial n/\partial C_2$ can be made in two experimental conditions, either at constant concentration m_3 or at constant chemical potential μ_3 of the organic solvent. These two values $(\partial n/\partial C_2)_{m_3}$ and $(\partial n/\partial C_2)_{\mu_3}$ are obtained by measuring the specific refractive index increment respectively before and after a dialysis against the water–organic solvent mixture which has been used to dissolve the polymer. The following relationship can be written[9]:

$$\left(\frac{\partial g_3}{\partial g_2}\right)_{\mu_1,\mu_3} = \frac{(1 - V_3 C_3)\left[\left(\frac{\partial n}{\partial C_2}\right)_{\mu_3} - \left(\frac{\partial n}{\partial C_2}\right)_{m_3}\right]}{\left(\frac{\partial n_0}{\partial C_3}\right)_{m_2}} \qquad (1)$$

g is the concentration (in g/g of component 1), C is the concentration (in g/ml of solution), V is the partial specific volume. $(\partial n_0/\partial C_3)_{m_2}$ is the refractive index increment of the mixed solvent as a function of the concentration of

Table 1 Preferential adsorption data as a function of the dioxane content (% v/v) at pH 12.5 in the absence (A) and in the presence (B) of NaCl

Dioxane (% v/v)	$\bar{v}_3$ (ml/g)	$\left(\dfrac{\partial n_0}{\partial C_3}\right)_{m_2}$ (ml/g)	$\left(\dfrac{\partial g_3}{\partial g_2}\right)_{\mu_1,\mu_3}$ (g/g) A	B
0		0.098		
10	0.911	0.100	0.19	0.21
20	0.917	0.099	0.07	0.08

component 3 (organic solvent), and $\partial g_3/\partial g_2{}_{\mu_1,\mu_3}$ is the preferential adsorption coefficient of component 3 on component 2 (the macromolecule). If this coefficient is positive, there is a preferential adsorption of the organic solvent; if it is negative there is a preferential adsorption of water which can be measured by the coefficient $(\partial g_1/\partial g_2)_{\mu_1,\mu_3}$. We have the following relation between these two coefficients:

$$\left(\frac{\partial g_1}{\partial g_2}\right)_{\mu_1,\,\mu_3} = -\frac{g_1}{g_3}\left(\frac{\partial g_3}{\partial g_2}\right)_{\mu_1,\mu_3} \tag{2}$$

EXPERIMENTAL

PLGA sample

The PLGA sample has been prepared in the laboratory by debenzylation of a poly(γ-benzyl-L-glutamate) according to the method of Idelson and Blout[12]. Its intrinsic viscosity, measured at 25°C, pH 7.3, in a 0.2 M NaCl solution, is 60.4 ml/g corresponding to a weight-average molecular weight $M_w = 26\ 000$, if using a calibration given by Wada[13].

Preparation of solutions

Undialysed solutions. The water–dioxane mixtures used were prepared by adding a given volume of dioxane to an aqueous solution of 0.125 N NaOH (or 0.125 N NaOH + 0.2 M NaCl for experiments in the presence of NaCl). The basic solutions were obtained by dissolving directly a weighed quantity of PLGA to the mixed solvent. The value of the pH was 12.5 ± 0.15. These solutions were used directly to measure the values of $(\partial n/\partial C_2)_{m_3}$ at constant concentration at higher pH.

The acidic solutions of PLGA cannot be obtained directly by dissolution of PLGA in a water—dioxane mixture at a convenient pH. A solution was prepared as mentioned above at pH 12.5 and then the pH was adjusted to 4.5 The mixed water—dioxane solvent was adjusted separately at the same pH. In these conditions the values of $(\partial n/\partial C_2)_{m_3}$ at constant concentration for lower values of pH can be determined.

In both cases the concentration of the starting solution was approximately 6 x 10^{-3} g/ml. In order to extrapolate the specific refractive index increment measurements at zero the solution of a given composition was diluted with the corresponding water—dioxane mixture. In all cases it has been verified that the variation of pH by dilution was negligible (within ±0.1 pH unit).

Dialysed solutions. The dialysis was carried out in the same way whether the solutions were acidic or basic. The

solution in the mixed solvent was introduced in a dialysis bag (Union Carbide Co.) which was brought into equilibrium with the solvent. In order to prevent the evaporation of the solvent, the dialysis was performed in a vessel sealed with Parafilm wax (Marathon Division, American Can Co.) and a rubber band until a few moments before filling the refractometer cells. As mentioned by Tuzar and Kratochvil[14] the time needed to reach the equilibrium depends on the experimental conditions. Preliminary measurements have shown that for our experiments the equilibrium is always reached within 12 h of dialysis. Under these conditions the measurements of refractive index increments were made at constant chemical potential.

Specific refractive index increment measurements

They were performed using a Brice—Phoenix BP 2000 differential refractometer (15) at 20°C. The value of the increment $(\partial n/\partial C_3)_{m_2}$ was also determined by using the differential refractometer.

Circular dichroism

Circular dichroism spectra were recorded in order to ascertain the conformation of PLGA under different experimental conditions. A Roussel—Jouan dichrograph model II equipped with a xenon source was used with 0.1 mm cells under a dried oxygen-free nitrogen flow. The concentrations used were ~5 x 10^{-4} g/cm^3.

RESULTS AND DISCUSSION

Study of PLGA at pH 12.5

The measurements of the specific refractive index increment have been made in the presence and in the absence of NaCl, varying the dioxane from 0 to 45% in the absence of NaCl and from 0 to 33% in the presence of NaCl, the precipitation of PLGA taking place beyond this percentage of dioxane. This precipitation phenomenon has been mentioned by Iizuka and Yang[7].

Table 1 gives the values of the preferential adsorption coefficient $(\partial g_3/\partial g_2)_{\mu_1,\mu_3}$ as a function of the percentage of dioxane in the mixed solvent, in the absence or in the presence of NaCl respectively. This coefficient has been calculated from equation (1) using the values of $\partial n/\partial C_2$ plotted in *Figure 1*. The values of the partial specific volume $\bar{v}_3$ of dioxane in the mixed solvent have been found in the literature[16] and are also reported in *Table 1*.

Figures 1a and *1b* show the values of $(\partial n/\partial C_2)$ before
Figure 1 Variation of the specific refractive index increments in basic solutions of PLGA *versus* the dioxane composition (% v/v) before (O) and after (X) dialysis. (a) In the absence of NaCl; (b) in the presence of 0.2 M NaCl
Figure 2 Variation of the preferential adsorption coefficient in basic solutions of PLGA *versus* the dioxane composition (% v/v). (a) In the absence of NaCl; (b) in the presence of 0.2 M NaCl
Figure 3 Variation of the ellipticity [θ] $_{222}$ at 222 nm as a function of the dioxane composition, in basic solutions of PLGA, in the absence of NaCl

and after dialysis, in the absence and in the presence of NaCl respectively *versus* the percentage of dioxane. In each case one observes an intersection which corresponds to an inversion of preferential adsorption. This inversion occurs at 22% of dioxane in the absence of NaCl and approximately 30% of dioxane in the presence of NaCl. The vicinity of the precipitation point of the solutions in the last case makes the determination of this inversion point less sure. *Figures 2a* and *2b* give the variation of the preferential adsorption coefficient as a function of the percentage of dioxane, in the absence and in the presence of NaCl respectively. In both cases, while increasing the percentage of dioxane, the preferential adsorption coefficient increases, then passes through a maximum, decreases and becomes zero and even negative in the absence of NaCl. This kind of variation means that dioxane is first preferentially adsorbed, then this preferential adsorption decreases, and is replaced by a preferential adsorption of water when the coefficient becomes negative. The maximum of preferential dioxane adsorption lies in both cases at ~10% dioxane.

It is important to determine the conformation adopted by the PLGA macromolecule before and after this inversion of preferential adsorption. The measurement of the ellipticity at 222 nm [θ] $_{222}$ on the dichroic spectra can be an estimation of the helix content of the polypeptide. This

value is reported in *Figure 3* as a function of the percentage of dioxane for PLGA solutions in the absence of NaCl. This curve exhibits a broad transition range between 30 and 50% of dioxane, much broader than the transition obtained when varying the pH. The dichroic spectra for lower (30%) and higher (50%) dioxane concentrations are given in *Figure 4*. The former corresponds to a disordered conformation and the latter to an α-helix. It is difficult to find any correlation between the variation of the preferential adsorption coefficient (*Figure 2a*) and the variation of the ellipticity during the transition, when adding dioxane. It is important to point out that the preferential adsorption coefficient represents a comparison of the solvent compositions in bulk and in the immediate domain of the polymer. In order to determine the absolute adsorption of the organic solvent onto the polymer, Inoue and Timasheff[17,18] suggest splitting the preferential adsorption ceofficient into two terms:

$$\left(\frac{\partial g_3}{\partial g_2}\right)_{\mu_1, \mu_3} = A_3 - A_1 g_3 \tag{3}$$

A_1 and A_3 are respectively the number of grammes of water and of dioxane bound to one gramme of polymer. In equation (3) A_1 and A_3 are unknown. If one makes an assumption for the number of water molecules bound to a carboxylic group, A_3 can be calculated. Timasheff and Inoue[9] think that a hydrophilic site of a globular protein retains six to eight water molecules. We have considered that the number of water molecules bound to a carboxylic group in PLGA does not change when dioxane is added. This assumption is probably an oversimplification of the problem because this number changes very likely when the transition: disordered conformation ⇌ α-helix occurs. However,
Figure 4 Dichroic spectra of basic solutions of PLGA in the absence of NaCl, for different values of the dioxane content: ●, 30% v/v; ○, 50% v/v
Figure 5 Variation of the absolute adsorption of dioxane as a function of the solvent composition (% v/v of dioxane) assuming (a) 6, (b) 7, (c) 8 and (d) 9 water molecules adsorbed on each residue of PLGA

under these conditions, fixing successively this number, n, of water molecules adsorbed on a carboxylic group at 6, 7, 8 and 9, we have obtained 4 corresponding variations of the absolute coefficient A_3 which describes the absolute fixation of dioxane onto the PLGA molecule, as a function of the percentage of dioxane added in the solution (*Figures 5a, 5b, 5c* and *5d*). The common feature of these four graphs is that the A_3 coefficient undergoes a change of behaviour at a value of approximately 15% dioxane. Then the value of A_3 levels off in the case of 8 or 9 water molecules bound to a carboxylic group. In all cases the absolute amount of dioxane adsorbed on the macromolecule increases again, when reaching about 30% dioxane in the mixed solvent.

The value of the helix content F_H has been calculated using the relation:

$$F_H = \frac{4000 - [\theta]_{222}}{41\,000} \qquad (4)$$

The variation of F_H *versus* the percentage of dioxane is also plotted in *Figures 5c* and *5d* (broken lines). It can be seen that the macromolecule is almost entirely disordered until 30% of dioxane. Then the transition occurs and F_H increases, paralleling the increase of A_3. Thus, the plateau observed between 15 and 30% of dioxane refers to the adsorption of dioxane on the disordered conformation. A second plateau in the A_3 variation should be obtained after the end of the transition, but measurements in this domain are not possible because of the limit of solubility. On the contrary, dichroic spectra can be recorded up to 60% dioxane, probably owing to the fact that the concentration needed is smaller — of an order of magnitude in this case. Assuming successively 6, 7, 8 and 9 water molecules bound to a carboxylic group, the absolute number of dioxane molecules adsorbed on a residue has been calculated. For 20% of dioxane these numbers are respectively 0.43, 0.48, 0.53 and 0.58 mol/residue. For 45% dioxane, at the end of the conformational transition, these numbers are respectively 0.43, 0.63, 0.77, 0.86 mol/residue. Assuming 8 or 9 water molecules bound to a residue in the α-helical conformation should be about 1.0 when the transition is achieved. The curves of

Figures 5c or *5d* seem to be more reliable in describing the adsorption phenomenon. Inoue and Timasheff[17] have calculated the mean number of organic solvent molecules bound to a non-polar residue for β-lactoglobulin as between 2 and 3. In the case of PLGA the residue is a polar one and the mean number of organic solvent molecules bound to each residue is much lower, ~1.0, but this type of adsorption does exist and hence the maximum of preferential adsorption is reached more easily.

Influence of NaCl

In the presence of NaCl, such calculations are more hazardous owing to the proximity of the precipitation range for the solutions. The presence of NaCl is known to stabilize the disordered structure and the addition of 0.2 M NaCl to a water/dioxane mixture (2:1 v/v) shifts the transition of one pH unit towards the lower pH valve. A similar behaviour has been observed in our preferential adsorption experiments: the addition of NaCl shifts the zero value of the $(\partial g_3/\partial g_2)_{\mu_1,\mu_3}$ coefficient from 22 to 33% of dioxane. Such similar effects may suggest a correlation between the conformational transition and the inversion of the preferential adsorption.

Study of PLGA at pH 4.5

The measurements of the specific refractive index increment have been made with mixed solvent in the presence of 0.2 M NaCl, varying the dioxane content from 0 to 33%. (Beyond this value precipitation of PLGA occurs.) The preferential adsorption coefficient $(\partial g_3/\partial g_2)_{\mu_1,\mu_3}$ has been calculated as above, using equation (1). Between 10 and 30% of dioxane, the values of $(\partial n/\partial C_2)_{m_3}$ and $(\partial n/\partial C_2)_{\mu_3}$ are almost constant (about 0.110 and 0.135 ml/g respectively). Thus, the value of the preferential adsorption coefficient is positive and practically constant in this range of solvent composition and dioxane is preferentially adsorbed on PLGA.

Whatever the percentage of dioxane, the conformation of PLGA in the mixed solvent at pH 4.5 is always α-helical.

The shape of the dichroic spectra and the values of the ellipticities at 222 nm indicate an α-helical structure without ambiguity (in good agreement with the results of Holzwarth and Doty[3]).

Measurements have been made in a solvent containing 33% of dioxane with the pH varying between 4.5 and 5.15. The results obtained show that pH has little effect on the extent of the preferential adsorption on the α-helical conformation (*Table 2*).

CONCLUSION

The results obtained show that, in acidic solutions, the preferential adsorption on PLGA is essentially a preferential

Table 2 Preferential adsorption data in a mixture of 0.2 M NaCl/dioxane (67:33 % v/v) for different pH values

pH	$\left(\dfrac{\partial n}{\partial C_2}\right)_{m_3}$ (ml/g)	$\left(\dfrac{\partial n}{\partial C_2}\right)_{\mu_3}$ (ml/g)	$\left(\dfrac{\partial g_3}{\partial g_2}\right)_{\mu_1,\mu_3}$[a] (g/g)
4.5	0.085	0.129	0.664
4.8	0.089	0.140	0.770
5.15	0.089	0.120	0.468

[a] Calculated by using $\bar{v}_3 = 0.927$ ml/g and $(\partial n_0/\partial C_3)_{m_2} = 0.097$ ml/g

adsorption of dioxane, in the whole range of composition studied. At the same time, the dichroic spectra indicate no conformational change in the macromolecule. In basic solutions, an inversion in the preferential adsorption is observed and the dichroic spectra show a transition between a disordered and an α-helical conformation. This transition is closely related to the variation of the absolute adsorption of dioxane. Unfortunately, in the case of the system PLGA/water/dioxane, the experimental conditions make the desscription of the whole transition by a preferential adsorption study difficult. This system had been chosen because it was the first used to define the disordered conformation ⇌ α-helix transition for PLGA, by Doty and coworkers[2]. Other systems with a broader range of solubility for the PLGA would be more convenient for preferential adsorption studies. Moreover, studies in the absence of salt should be more interesting because of the larger range of solubility of the polymer.

Effect of oligo-amine (or polyamine) on the vinyl chloride polymerization by alkyl aluminium compounds

Akira Akimoto

Central Research Laboratory, Toyo Soda Manufacturing Co. Ltd., Yamaguchi-ken, Japan
(Received 17 May 1974; revised 21 October 1974)

Polymerization of vinyl chloride was investigated in the presence of AlR_3, oligo-amine (or polyamine) as a multidentate ligand, and CCl_4. Among oligo-amines and polyamines, diethylenetriamine gives the best yield. The yield of polymer decreased with increase of n in compounds of the type (n)ethylene $(n + 1)$amine. The addition of monodentate amine such as ethylamine and n-butylamine markedly reduced the rate of polymerization. It is suggested that the formation of the hexa-coordinated complex between AlR_3 with oligo-amine is important in the initiation process.

INTRODUCTION

In a previous paper[1], the author showed that the catalyst system $AlEt_3$/Lewis base/CCl_4 can initiate vinyl chloride (VC) polymerization, particularly in the presence of diethylenetriamine (DETA). A kinetic study showed that the polymerization occurred by a free radical mechanism, and the formation of the complex between $AlEt_3$ and DETA greatly contributes to the initiation reaction[2].

The present paper deals with a detailed study of the catalytic behaviour of oligo-amine as a multidentate ligand.

The polymerization was carried out in the presence of AlR_3, oligo-amine (or polyamine) and CCl_4, in order to clarify the relationship between the structural character of the AlR_3–amine complex and its activity for initiating polymerization.

EXPERIMENTAL

VC was dried and purified by passing it through columns containing calcium chloride and phosphorus pentoxide. Vinyl monomers, i.e. methyl methacrylate (MMA), styrene (S) and vinyl acetate (VAC) were purified in the usual manner.

Organo-aluminium compounds, i.e. $AlEt_3$ and $Al(iBu)_3$, were distilled in the presence of nitrogen under reduced pressure and preserved under nitrogen atmosphere.

Commercial ethylenediamine (EDA), tetramethylethylenediamine (TMEDA), DETA, triethylenetetramine (TETA), and tetraethylenepentamine (TEPA) were used as the multidentate ligands. Polyethyleneimine (PEI) was obtained by cationic polymerization of ethyleneimine with p-toluenesulphonic acid ($[\eta]$ = 0.18, 0.08 and 0.03, respectively, in water at 30°C). These amines except polyethyleneimine were purified by distillation before use.

CCl_4 was washed with concentrated sulphuric acid, then with water, and distilled before use.

Polymerization was carried out in a sealed tube at 40°C, as reported earlier[1].

The intrinsic viscosity of the polymers was measured in nitrobenzene solution at 30°C.

The n.m.r. spectra of a mixture of $AlEt_3$ and amine in benzene were measured at room temperature on a 100 MHz n.m.r. spectrometer with benzene as the internal standard.

RESULTS AND DISCUSSION

As previously reported, $AlEt_3$/CCl_4 was found to be an effective initiating catalyst system for the polymerization of VC in the presence of DETA[1]. It was assumed that the reaction between the $AlEt_3$ · DETA complex and CCl_4 might be involved in the initiation process:

$$AlEt_3 + DETA \rightleftharpoons AlEt_3 \cdot DETA \text{ complex}$$

$$AlEt_3 \cdot DETA \text{ complex} + CCl_4 \rightleftharpoons Et_2AlCl \cdot DETA + Et \cdot + CCl_3$$

$$Et \cdot \text{ or } CCl_3 \cdot + VC \longrightarrow \text{polymer}$$
From these considerations, it seems probable that other oligo-amines and polyamines may also be effective for initiation. Therefore, the polymerization of VC was investigated by the AlR_3/oligo-amine (or polyamine)/CCl_4 catalyst system.

Table 1 lists the effect of varying the structure of amine complexed with $Al(iBu)_3$ on the polymerization in the presence of CCl_4. Good activity was also observed with compounds of the type $oligo(n)$ethylene$(n + 1)$amine, which have multidentate ligands, in the case of $Al(iBu)_3$ as well as $AlEt_3$[1]. However, alkylamines having a monodentate ligand showed low catalytic activities and as expected from Breslow's data[3] their basicity did not influence the activity of the catalyst. Although Breslow reports that tertiary amines give fairly active catalysts, the catalysts containing triethyl-

amine did not show the activity under the experimental conditions used in this work.

Figure 1 shows a typical plot of percentage yield against time for the catalyst system Al(iBu)$_3$/CCl$_4$ in the presence of oligo-amine. It can be seen that there is a moderate fall off in rate, which is a characteristic of the VC polymerization. With oligo-amines, the order of the catalyst activity was found to be: DETA > TETA > TEPA ≫ EDA, in the initial period of polymerization.

Figure 2 presents the results obtained in the presence of PEI (concentration expressed in base mol/l of ethyleneimine) for the Al(iBu)$_3$/CCl$_4$ catalyst system. The concentrations of monomer, CCl$_4$ and Al(iBu)$_3$ remained constant, whilst molar ratio of PEI to Al(iBu)$_3$ was varied from 0.25:1.0 to 3.0:1.0.

PEI is representative of a polymeric ligand, and 'polymer effect' as a catalyst[4] has been noticed by many authors. Although the polymerization starts immediately in the presence of suspended PEI, it can be seen that with PEI having various values of [η] the rate of polymerization increases as the molar ratio of PEI to Al(iBu)$_3$ is increased, and then flattens out as the ratio is equal to or greater than one, similar to DETA[2]. However, the yield of polymer was lower in the presence of PEI than of oligo-amine, and decreased with increase of the degree of polymerization. This seems to be due to the insolubility of PEI and the existence of non-coordinated amine in the polymer. The approach of Al(iBu)$_3$ to the surface of polymer is likely to be hindered and apparently the polymerization occurs from the surface of the PEI.

Although the excessive amounts of free amines do not influence the polymerization in the case of oligo-amine and

polyamine, excessive amounts of monodentate alkylamine such as ethylamine and n-butylamine leads to the retardation of the polymerization. As shown in *Table 2*, the mixtures of DETA and ethylamine, and of TETA and n-butylamine have the lower catalytic activity.

Table 3 presents the results with AlEt$_3$/DETA/CCl$_4$ catalyst system in various diluents. Expected yields of polymer were obtained in n-hexane, while tetrahydrofuran, dioxane and ethyl acetate were poor diluents. In acetone and in hexamethyl phosphoric acid triamide the polymerization was inhibited.

All the experimental results point out the effectiveness of oligo-amines except EDA and this may be ascribed to the chemical activity of the complex between AlR$_3$ with oligo-amine. The change of the catalytic activity of organoaluminium compounds, when combined with a Lewis base, has been reported in the MMA polymerization, and it was interpreted on the basis of the change of electronegativity of a central aluminium ion[5]. This is not so in the present work. In *Table 4* the internal chemical shifts are presented for free AlEt$_3$ and for AlEt$_3$ with some amines (1:1 molar ratio)[6]. The shifts, i.e. the electronegativity, show little relationships with the catalytic activity given in *Table 1*.

Figure 3 presents the n.m.r. spectrum of the mixture of DETA with AlEt$_3$ (1:1 molar ratio). The A, B, C and D

peaks are assigned to the $-NH-CH_2-CH_2-$, $C-CH_3$, $-NH_2$ and the CH_2 hydrogens, respectively.

Extensive work has been carried out on the study of the structure of AlR_3 and amine having multidentate ligands. According to Fetter[7,8], $AlMe_3$ reacts with $Me_2N(CH_2)_2NMe_2$ and $Me_2N(CH_2)_3NMe_2$ to give complexes with two molecules of $AlMe_3$ per amine, the structures being a penta-coordinated aluminium atom with a linear $N \rightarrow Al \leftarrow N$ covalent bond. According to Thiele[9,10], however, $AlMe_3$ and $AlEt_3$ yield 2:1 complexes with TMEDA and the aluminium atom has in these compounds the coordination number of 4. In the n.m.r. spectrum of *Figure 3* there is a single NH_2 peak, indicating that both of the amine groups are equivalent, as mentioned in a previous paper[2]. If the aluminium was bonded to only one of the nitrogens, the NH_2 groups would be expected to show two peaks in the spectrum because the environment of the NH_2 group attached to the quadruple bonded nitrogen should differ from that of the NH_2 group attached to triple bonded nitrogen. The change of the chemical shifts of the $-NHCH_2CH_2-$ of DETA in the presence of $AlEt_3$ means that the $-NHCH_2CH_2-$ group of DETA interacts with $AlEt_3$. One possible complication in the interpretation of the spectrum is that the state of aggregation is not known. However, in benzene solution of $DETA/AlEt_3$ molecular weight determination indicates the presence of a monomeric species.

These results indicate that $AlEt_3$ · DETA may be a species involving a hexa-coordinated aluminium atom:

```
        Et
      N-|-Et
     /  Al /
    /     /
   N------Et
      |
      N
```
Such a scheme is a better rationalization of both n.m.r. and molecular weight data, than the penta-coordinated structure proposed earlier[1,2].

The high catalytic activity with DETA may be ascribed to the presence of this type of complex whereas the low catalytic activity with EDA and TMEDA may be attributed to the impossibility of the formation of this type of complex. Furthermore, the difficulty of formation of the complex with long chain molecules causes the retardation of polymerization with PEI. The fact that the catalytic activity with DETA is highest is important. $AlR_3/CCl_4/TETA$ and TEPA catalyst systems showed less activity, probably because of the existence of a residual free amino group in the tetradentate and pentadentate ligands. Free amino groups may retard the polymerization as seen with monodentate alkylamine.

As mentioned before, the rate of polymerization was

reduced by addition of the alkylamine on the $Al(iBu)_3/$ amine (having a multidentate ligand)/CCl_4 catalyst system or by polymerizing in a polar solvent. These results can be interpreted in terms of a competitive solvation or coordination of amine to the catalyst site so as to hinder the formation of this type of complex.

The copolymerization of VC and VAC was retarded even in the presence of small amounts of the latter monomer (*Table 5*), because VAC coordinates the catalyst active site. However, copolymerization of MMA with S was successful with the $AlEt_3/DETA/CCl_4$ catalyst system. The monomer-copolymer composition curve is shown in *Figure 4*. For each experiment monomer mixtures were polymerized in the range 5–10% by weight. The results show the free radical character of the polymerization.

Biomedical applications of polymeric materials and their interactions with blood components: a critical review of current developments*

Stephen D. Bruck

National Heart and Lung Institute, National Institutes of Health, Bethesda, Maryland 20014, USA
(Received 8 August 1974)

A critical review is presented of some of the current developments in the biomedical applications of polymeric materials, with emphasis on naturally occurring macromolecules present in blood vessel walls, synthesis and surface modifications, mechanical properties, and interactions between surfaces and blood components.

INTRODUCTION

Polymeric materials in prosthetic devices have attracted considerable attention, and several aspects of this complex problem have been discussed by Bruck[1-4], Salzman[5], Berger and Salzman[6], Mason[7], and Leininger[8]. In previous publications some of the biological test methods[9], problems of sterilization[10,11], hydrogels[12], and specially prepared segmented polyether-urethanes[13] have been discussed by the present author.

It is the purpose of this paper to review critically some of the latest developments in blood compatible polymeric materials and in the interactions of blood components with surfaces. In order to present the subject matter in a logical manner, attention is focused on the following areas: (1) naturally occurring macromolecules present in the cardiovascular wall, (2) some newer synthetic polymers and surface modifications, (3) mechanical properties, and (4) interactions between blood components and surfaces.

As indicated previously[1-4], materials that are to be useful for prostheses in blood should not cause: (a) thrombosis, (b) destruction of the cellular elements of the blood, (c) alteration of the plasma proteins, (d) destruction of enzymes, (e) depletion of electrolytes, (f) adverse immune responses, (g) damage to adjacent tissue, (h) cancer, and (i) toxic and allergic reactions; furthermore, the biomaterials should not deteriorate in the biological environment (if used for prostheses which must perform appropriate mechanical functions), or during sterilization with resultant changes in their physical, chemical, and surface characteristics. Usually, polymers that are blood compatible are also tissue compatible, but the reverse is not always true. It is most important that all biomaterials be free of leachable impurities or additives of unknown composition which could adversely affect the physiological environment.

Figure 1 illustrates some of the major areas involved in biomaterials research and development. Investigations include both basic and more applied areas, since without an adequate understanding of basic phenomena, applied research and development efforts would remain empirical.

These studies involve work in the areas of: (a) natural macromolecules present in the cardiovascular wall and their chemical modifications, (b) synthetic macromolecules, (c) microfibre tissue culture approaches, (d) technological problems, (e) biological properties, (f) physico-chemical properties, and (g) biological testing according to a carefully devised protocol. It is very important that the biological testing of candidate biomaterials be done in such a way that statistically significant data may be derived from it. This involves a relatively large number of various tests, including *in vitro, in vivo* and *ex vivo*, with the same materials, prepared, fabricated, sterilized, and handled in an identical manner. All too often, residual solvents, degradation products due to careless fabrication processes, impurities due to improper handling, and unsuitable sterilization techniques can affect the biological performance of even the best materials. Biomedical materials should be handled in a clean room environment throughout the various operations.

MACROMOLECULAR COMPONENTS OF THE VASCULAR WALL: THE BIOLOGICAL INTERFACE WITH BLOOD

The eventual development of blood compatible synthetic materials depends on a better understanding of the physico-chemical and biological characteristics of components of the vascular wall and their interactions with blood. The components of the vascular wall are proteins which differ in their complexity from synthetic polymers. Nevertheless, the study of the former are especially important for the development of synthetic blood compatible polymeric materials as nature provides the best guidance in this area. Consequently, brief descriptions are given below of the vascular wall components.

Endothelium

The inside of the vascular wall is lined with endothelial cells and this lining is characteristic of blood vessels as well as lymph capillaries. It is the healthy and intact endothelium on the innermost surface of blood vessels that prevents thrombosis.

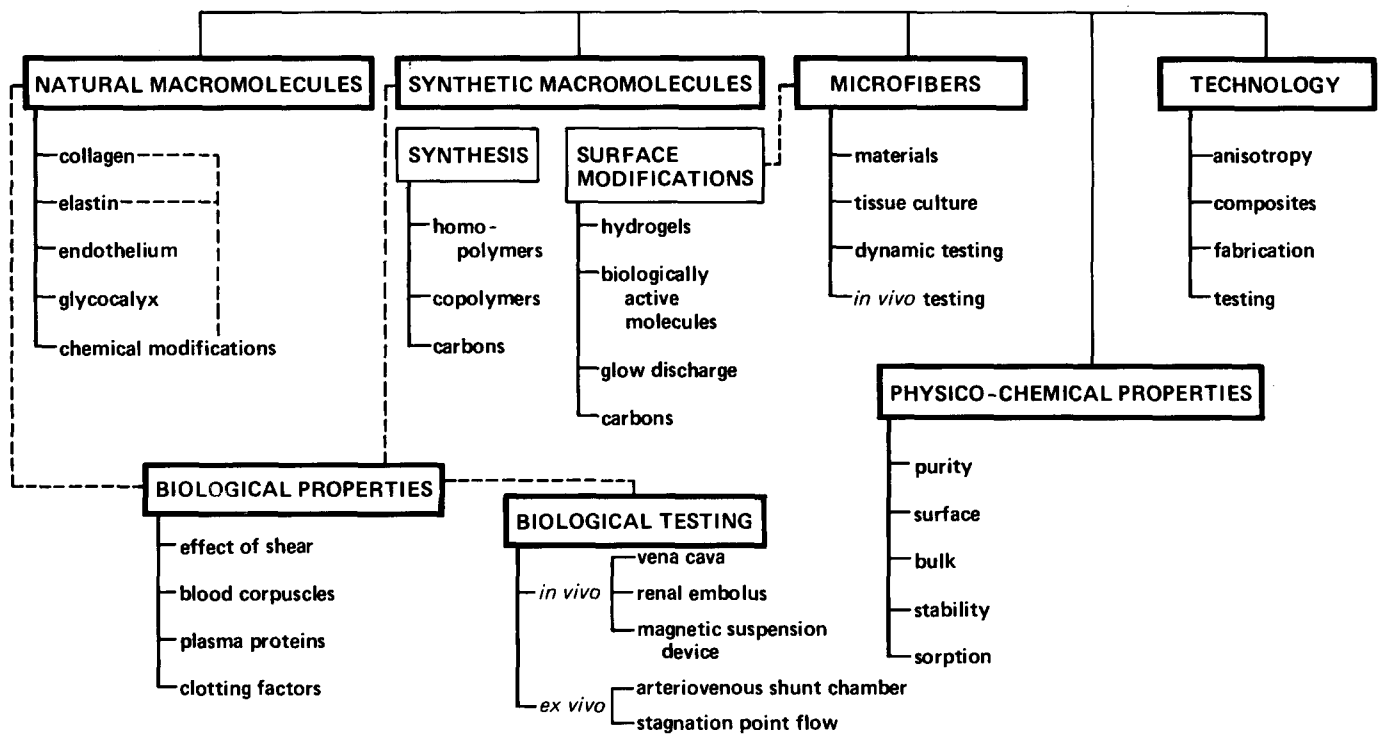
BIOMATERIALS R&D


Figure 1   Biomaterials R & D

The thrombotic events may be subdivided into the intrinsic and extrinsic pathways, both of which involve a series of complex reactions of blood factors (including calcium ions), and phospholipids[4,14,15]. The intrinsic pathway can be initiated by a variety of stimuli, including the contact of blood with glass, many artificial materials, native collagen, and may be influenced by disturbances in blood flow[16], as well as by the abnormal functioning of the clotting factors arising from hereditary disorders[17]. The extrinsic pathway is triggered when blood contacts an injured blood vessel, thus exposing the underlying surface to which platelets and other blood elements can adhere. When platelets do adhere to this surface, they can release their granules and liberate adenosine diphosphate (ADP), serotonin and other substances. Alternately, the red cells also can release ADP as the result of haemolysis[18], caused by stimuli such as alteration of blood flow patterns and by plaques that may be present as a result of previous injury to the endothelial lining. The release of ADP in turn attracts more platelets with the alteration in the shape of the platelets by the formation of so-called pseudopods[19]. Eventually, the blood vessel might become completely occluded with the formation of a temporary haemostatic plug. This is converted into a mechanically stable thrombus by the activation of the blood coagulation mechanism, mentioned above.

The surface coating (glycocalyx) of the endothelium is approximately 500–1000 Å thick and appears to be a mucopolysaccharide[20]. The endothelial cells and the surface coating can stretch and contract with the dilation and contraction of the blood vessels. The endothelial cells exhibit a low turnover rate[21] but this varies depending on their location in the organism. The endothelial cells of veins and pulmonary arteries are likely involved in fibrinolysis[22,23] (dissolution of fibrin strands) and appear to have an antigenic site[14]. Recently, Jaffe *et al.*[24] have been able to culture endothelial cells *in vitro*, thus enabling their more detailed study.

Subendothelium and basement menbrane

Immediately below the endothelium is the subendothelium which in larger blood vessels is approximately 1000 Å wide. In capillaries, the subendothelium consists of a well-defined morphological structure called the basement membrane, which seems to have a trilaminar structure[25]. Adjacent to the outermost region of the basement membrane are collagen fibres[25]. These fibres are not in contact with the blood elements, unless the endothelium and the basement membrane are injured. In such an event, collagen will initiate thrombosis by adversely interacting with platelets and the coagulation factors.

The basement membrane has some chemical similarity to collagen fibres, although there is considerable controversy on its exact structure. For example, Lazarow and Speidel[26] have shown that the basement membrane of isolated glomeruli can be digested by colleganase and trypsin, and appeared to be a complex glycoprotein. Dische[27] showed that the lens capsule of the eye seems to be composed largely of a protein similar to collagen.

The subendothelium is associated with the internal elastic lamina[28], and in the arteries of rabbits consists of elastin, microfibrils of elastin, and vestiges of the basement membrane[28]. In man, the space between the endothelium and the internal elastic lamina is characterized by the presence of cells and connective tissue. Elastin does not come in direct contact with the endothelium unless both the basement membrane and the microfibrils covering the elastin are lost.

Collagen

Once the endothelium and the subendothelial lining are damaged, collagen may become exposed than can initiate the thrombotic process by causing platelet adhesion, aggregation, release of the platelet constituents, and by activating some of the coagulation factors[28,29].

The fundamental structural unit of collagen appears to be the tropocollagen molecule having a diameter of 15 Å, length of 2800 Å, and molecular weight of about 300 000. The tropcollagen molecules are organized into approximately 5000 Å long fibrils in such a way that they overlap by a quarter of their length[30]. The tropocollagen molecule forms a triple helix, the structure of which was established by Rich and Crick[31] and by Ramachandran[32]. The individual chains are nearly extended so that only intermolecular hydrogen bonding is possible between them. One-third of collagen is glycine, and an additional quarter is composed of proline and hydroxyproline. According to Ramachandran and Chandrasekharan[33], collagen contains one intermolecular hydrogen bond via the N—H---O=C group, plus one intermolecular hydrogen bond via a water molecule per three residues. This is in contrast to other proteins, the architecture of which permits a greater amount of hydrogen bonding to occur. Chang and Chien[34] have shown that a variety of electrolytes can affect the stabilization and destabilization of the rod-like superstructure of reconstituted collagen. Apparently, ions influence the structural order of reconstituted collagen both at the micron level (association—disassociation of tropocollagen—supermolecular rods of collagen) and at the molecular level (helix—coil transition). Concerning the water structure in collagen, Dehl[35] has concluded that most of the water in collagen is 'bound' rather than 'free'. In other words, the bound water molecules are oriented by the polar groups of collagen and do not have the freedom of motion characteristic of liquid water. It should be pointed out that 'oriented' or 'bound' water should not be equated with 'structured' water[35].

The triple-stranded helical structure of collagen is formed by intracellular processes involving the three α-polypeptide chains which constitute the collagen sub-units. A precursor, called procollagen, is involved in the biosynthesis of collagen and consists of polypeptide chains with molecular weight in the range of 120 000 to 125 000. Cysteine residues in procollagen give rise to disulphide crosslinks between the α-polypeptide chains. These crosslinks seem to have a stabilizing effect for the formation of the triple-stranded helix which has a molecular weight of ~360 000[36]. The stabilizing effect of disulphide crosslinks was also suggested by Grant *et al.*[37]. These investigators found that procollagen secreted by chick embryonic lens cells was in the triple-helical conformation, while the intracellular lens collagen contained no disulphide bonds and was in a random coil conformation. Further evidence for the role of the disulphide crosslinks in the formation of the triple-helical conformation was provided by Schofield *et al.*[38] and by Uitto and Prockop[39]. These latter studies suggested that the α-polypeptide chains of procollagen must be linked by disulphide crosslinks prior to the formation of the triple helix. In other words, it appears that without such crosslinks, the production of a triple-helical structure would not be possible. The triple-helical conformation of procollagen polypeptides is apparently stabilized by the presence of hydroxyproline in the molecule and contributes to the thermal stability of the collagen molecule[40].

Elastin

The components of the subendothelium also contain elastin that accounts for the elastic properties of arteries, lung tissue and skin, and apparently is a gel consisting of randomly coiled, crosslinked peptide chains[41,42]. The crosslinks arise from oxidized lysine groups[43], and are responsible for the insolubility of mature elastin. In the absence of crosslinks, elastin remains soluble and the isolated product has a molecular weight of 70 000[44,45]. Two basic types of regions have been reported in elastin: one which is apparently involved with the formation of the crosslinks and the other which influences extensibility[42] of the molecule. The crosslinking regions could favour an α-helical conformation[42]. The helical content of hydrated elastin is estimated to vary from 10 to 25%, with the crosslinking areas contributing 15 to 20% of the α-helical content[42].

As will be discussed later, elastin apparently does not directly cause platelet aggregation.

SYNTHETIC POLYMERS

Perfluorinated ethylcellulose

There is considerable interest in extracorporeal circulatory assistance devices, such as blood oxygenators, for which polymeric membranes are needed having both good blood compatibility and high gas transmission rates towards oxygen and carbon dioxide. Among such polymers are the perfluoroacyl derivatives of ethylcellulose[46]:
These polymers are amorphous materials exhibiting neither glass transition nor melting temperatures, have good tensile properties, and dissolve readily in a number of organic solvents. Based on the vena cava and renal embolus tests, the perfluorobutyryl ethylcellulose shows very promising thromboresistance in dogs. These properties compare favourably to low temperature isotropic (*LTI*) carbons (developed at Gulf Oil Corporation) and are widely used in artificial heart valve prostheses[2,9]. Although the gas-to-gas *permeabilities* towards oxygen and carbon dioxide are low in comparison to polydimethylsiloxane (*Table 2*), ultra-thin membranes in the range of 1–3 μm can be prepared and laminated to porous polyolefin paper (Tyvek 1073) to give the membrane adequate physical support. Such ultra-thin membranes exhibit approximately a four-fold increase in the gas-to-gas *transmission rates* towards oxygen and carbon dioxide in comparison to polydimethylsiloxane (*Table 1*). The gas-to-blood permeabilities and gas-to-blood transfer rates towards oxygen are at least as high as those exhibited by

Table 1 Gas-to-gas transmission rates of ultra-thin membranes of perfluorobutyryl ethylcellulose[46]

Membrane	Gas transmission rate (cm^3/min m^2 atm)	
	O_2	CO_2
Perfluorobutyryl ethylcellulose*	880 ± 160	4680 ± 580
Polydimethylsiloxane†	195 ± 25	1090 ± 150

* 2 to 3 μm membrane coated onto Tyvek 1073 with 1.5 to 2 μm layer of Dow Corning No.282 Silicone adhesive
† 127 μm (5 mil) fabric-reinforced Dow Corning Silastic

polydimethylsiloxane under typical clinical flow conditions[46]. The combination of the promising biological properties and high gas transfer rates towards oxygen and carbon dioxide make the perfluorobutyryl ethylcellulose membranes potentially useful candidates for blood oxygenators and for blood compatible surface coatings. This could eliminate the need to use heparinized materials in oxygenator applications, such as heparinized polydimethylsiloxanes, to prevent thrombosis. While specially purified polydimethylsiloxane has many desirable attributes (such as flexibility, relative inertness to body fluids, non-toxicity, and sterilizability by steam autoclaving), its overall blood compatibility is relatively poor[4,9].

Poly(alkyl sulphones)

Other polymers with possible applications for membrane oxygenators and surface coatings are the poly(alkyl sulphones)[47,48]. Polymers and copolymers of poly(alkyl sulphones) can be prepared from the C_{16} and C_{18} straight chain α-olefins and sulphur dioxide yielding the general structure illustrated below:
Although gas-to-gas permeabilities towards oxygen and carbon dioxide are about one-tenth of those of polydimethylsiloxane (*Table 2*), ultra-thin (2.5 μm) membranes can be made and coated onto a microporous polypropylene (Celgard® of Celanese Corporation). This composite membrane exhibits gas-to-gas *transfer rates* towards oxygen which are approximately double of those typical of polydimethylsiloxane[48]. The gas-to-blood transfer rates (measured with a large spiral channel membrane cell) are ~20% higher with oxygen and approximately three times higher with carbon dioxide in comparison to polydimethylsiloxane[48].

Poly(alkyl sulphones) have molecular weights over one million and M_w/M_n ratios between 5 and 7. Thermal decomposition begins at approximately 200°C and the polymer starts to soften between 75° and 90°C. Owing to these properties, steam autoclaving cannot be used. However, ethylene oxide gas gives a satisfactory means for sterilization, provided that a careful outgassing procedure is followed[10,11]. The biological properties of the poly(alkyl sulphones) based on the vena cava test in dogs appear promising and additional evaluations are in progress.

Table 2 Gas-to-gas permeabilities of various membranes[46,48]

Membrane	'Barrier' permeability $\times 10^{10}$ (cm^3 (STP) cm/cm^2 sec cmHg)	
	O_2	CO_2
Ethylcellulose	7–15	42–90
Perfluorobutyryl ethylcellulose	40–50	200–250
Poly(alkyl sulphone)*	60	260
Poly(dimethylsiloxane-*co*-carbonate)	140–160	790–970
Polydimethylsiloxane (Dacron-reinforced)	500–640	2530–2800

* 50:50 wt % copolymer of C_{16} and C_{18} straight chain α-olefins

Sulphonated polystyrenes

Other polymers which may be useful as blood compatible surface coatings are the sulphonated polystyrenes[49]:
The biological properties of these polymers may be associated with the sulphate groups[50,51] and with the rigid spacing of these anionic groups[52,53]. Optimum blood thromboresistance (based on the vena cava and renal embolus test systems) is exhibited by the styrene–sulphonate copolymers having sulphonate contents in the range of 8.3 to 14.5%. The adhesion of these polymers to specially prepared segmented polyether-urethanes is good.

Surface modifications of polymers

One approach to the preparation of blood compatible surfaces involves hydrogels. These are coherent three-dimensional polymeric networks that can imbibe large quantities of water without dissolution of the polymeric network[54]. Wichterle and Lim[55] in 1960 were the first to call attention to the potential biological use of hydrogels based on 2-hydroxymethylmethacrylate (HEMA) in soft contact lenses. Until recently, a major problem with hydrogels was their lack of good mechanical strength. In 1971, a microwave discharge grafting technique was developed by Kronick[56]. Also in 1971, Halpern and colleagues[57], using chemical means, successfully grafted polyacrylamide hydrogels onto polyurethanes and other polymers. On the author's recommendation, the grafting technique was applied to prosthetic devices which extended the usefulness of hydrogels by combining mechanical strength with blood compatibility. Following these developments, other investigators using high energy irradiation have grafted hydrogels onto polymeric substrates[58].

Bruck has recently reviewed the physical and biological aspects of hydrogels for biomedical applications[12]. The evidence strongly suggests that the presence of negatively charged ionic groups on certain synthetic hydrogels is not essential for blood compatibility[2,4,12]. The biological performance of hydrogels apparently depends on a critical level of water uptake, chemical composition, purity, crosslinking density, porosity, the possible existence of a quasi-organized water structure, and on the thermodynamic interaction parameters between the components of the biological environment and the gel[2,4,12]. The possible existence of a quasi-organized water structure in certain hydrogels was subsequently also proposed by others[59]. However, solid experimental evidence is lacking in support of this. Small amounts of impurities can influence the blood compatibility of the hydrogel. Hydrogels based on acrylamide have been also grafted onto several substrate polymers[57]. Optimum blood compatibility was achieved only with highly purified monomers and small quantities of crosslinking agent. It should be stressed that not all hydrogels perform well and therefore each of these materials must be identified and treated individually. This is especially important since it is likely that blood components (especially proteins) interact

differently with the various types of hydrogel surfaces.

Recent evidence suggests that there is practically no penetration by plasma proteins into the covalently grafted hydrogels based on polyacrylamide or PHEMA. Smaller molecules, ions, and oxygen and carbon dioxide can penetrate into the network. These properties of covalently grafted hydrogels permit their use in oxygenators where high gas transfer rates and good blood compatibility are essential. Also under development are hydrogels based on poly(vinyl acetate-co-crotonic acid) grafted onto polymeric surfaces by high energy irradiation from a ^{60}Co source[60]. These hydrogels, which carry anionic groups, are being evaluated for their blood compatibility.

Certain hydrogels have been also studied as coatings for copper intrauterine devices in rabbits[61]. Other applications involve the encapsulation of activated charcoal particles with hydrogels for extracorporeal blood perfusion to impart blood compatibility to them[62,63]. Materials other than hydrogels for the microencapsulation of charcoal have been reported earlier by Chang[64-66]. Recently, Castino and colleagues encapsulated charcoal particles with hydrophilic cellulose triacetate for artificial kidney applications[67].

In addition to the covalent grafting of hydrogels onto polymeric substrates, microwave discharge techniques can also be used to treat polymer surfaces with or without the deposition of polymer coatings[68-70]. The technique permits the preparation of very low as well as very high surface energy polymeric surfaces, and some of these exhibit interesting biological performance in preliminary tests[70].

Still another approach to the surface modification of polymers involves the ionic and covalent bonding of biologically active molecules. The use of heparin has been adequately described by several authors[71-78]. Ionically bonded heparin surfaces have been used successfully in short-term clinical applications. Although heparin has been covalently bonded to hydrogels and other polymers, the biological activity of these is diminished in comparison to ionically bonded heparin surfaces[58].

Work is currently underway to attach covalently platelet protective agents to polymeric surfaces, including prostaglandin E_1 and others[79]. The covalent attachment of fibrinolytic enzymes has also been reported[80].

In order to extend the usefulness of *LTI* carbons with their excellent biological properties, investigations are being conducted to deposit carbons onto appropriate polymeric and non-polymeric substrates by vacuum-vapour and ion-plating techniques[81], and by ion-beam processes[82]. Studies showed that both the vacuum-vapour and ion-plating techniques yield carbon surfaces on polymeric substrates which are nearly impermeable to gases at a thickness of 0.1 μm. The coatings adhere well to a number of polymers, including polyimides, cellulose acetate, and segmented polyetherurethanes[81]. The biological evaluation of these composite carbon structures are under investigation[81,82].

MICROFIBRES

Although woven fabrics, velours, and flocked surfaces have been used in clinical practice (especially in large blood vessel replacements), the blood compatibility of these materials depends on the formation of a fibrin layer and subsequent vascularization[83]. In prosthetic devices that undergo repeated flexing and stretching, such an approach is not entirely satisfactory. Furthermore, in comparison to many animals, the regeneration of a pseudo-intimal lining in man is slow.

An important alternate approach is the use of microfibres as scaffold structures for the anchoring of viable cells and for the production of a vascular intima[84,85]. Such cellular linings must be able to survive the shearing forces of blood and the pressure differentials between cardiac contraction and relaxation. To date, the best results were obtained with diploid WI-38 cells from embryonic human lung tissue which were uniformly seeded onto non-woven microfibres[85], including those made from specially prepared poly(tetramethylene terephthalate) and parylene-C coated polypropylene[85]. In order to use the microfibre-scaffold cellular linings for prosthetic applications in humans, autologously derived cells must be available for the seeding of devices. Work is currently underway to accomplish this objective[85].

MECHANICAL PROPERTIES

The components of the cardiovascular system, such as the arteries, veins, and heart valves, are composite materials, the stress–strain properties of which vary in the transverse and longitudinal directions. This stiffness *anisotropy* is important in the performance of physiological functions as it prevents buckling of the blood vessels and provides for the accommodation of the vessels to systolic and diastolic blood pressure changes. This anisotropy also plays an important role in the operation of natural heart valves. Several authors have called attention to the role of the anisotropic property of natural tissues[4,86-88].

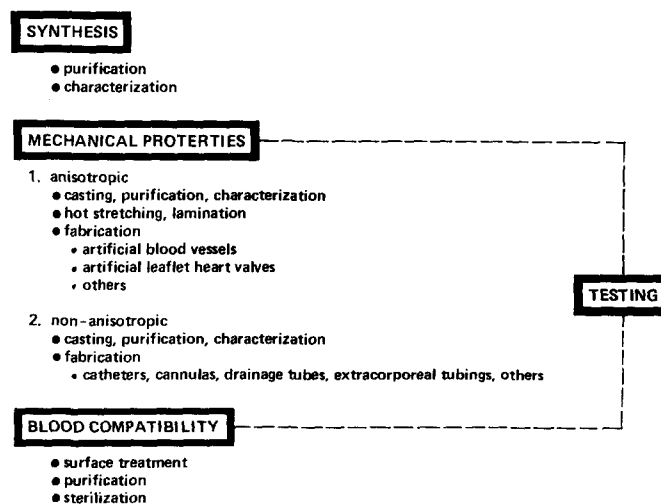
To imitate some of the mechanical properties of the components of the cardiovascular system, investigations are underway with specially prepared segmented polyetherurethanes[89]. It should be stressed that the aim is to provide the required mechanical properties rather than blood compatibility. Although these polyether-urethanes have shown fairly good blood compatibility especially in short range applications[9,13], their overall biological performance for longer use can be enhanced further by various surface modifications (*Figure 2*). To impart anisotropy specially synthesized segmented polyether-urethanes[13] are used which are cast in 6 mil thick films (plies) with the careful removal of residual solvent (dimethylformamide). These individual plies are then stretch-oriented to produce the desired stiffness anisotropy. After quenching, the individual stretched plies are stacked at $0°, 90°, 90°$ and $0°$ and compression moulded at a moderate temperature to form composite


Figure 2 Blood compatible composite materials

laminates with a thickness of 24 mil. Exposure of the plies to whole blood for 32 days showed no significant change in the anisotropy, although some relaxation occurred. Cyclic biaxial straining experiments indicated some irreversible creep for the polymer and investigations are underway to minimize this property[89,90].

Another approach involves the so-called 'springy' polypropylenes[91]. These are strong, tough, resilient, and dynamic materials and have the ability to recover immediately from extensions of 100 to 1000% in excess of the 'yield point'. The polymers can be steam autoclaved and no changes in the mechanical properties have been noted after prolonged immersion in isotonic saline solution. They are also non-toxic and can be surface-treated to impart blood compatibility to them. Although these polymers are not anisotropic, their mechanical properties (including high resistance to fatigue and abrasion) indicate a potential utility in prosthetic applications.

INTERACTIONS OF BLOOD COMPONENTS WITH MATERIALS

When synthetic surfaces come in contact with blood, the available evidence indicates that most, if not all of them, become coated with plasma proteins within a very short time. This rapid adsorption process most likely influences the activation of factor XII (Hageman factor) and possibly other coagulation factors as well, and affects the adhesion of platelets. Depending on these initial events, thrombosis may or may not take place. The adsorption phenomenon is influenced by a combination of factors, including surface smoothness, ionic and electronic charge, wettability by blood components, chemical structure, and haemodynamic parameters. However, no single factor alone can explain the relative blood compatibility of some materials in comparison to others[4].

The situation is even more complex in the case of natural surfaces. It is well known that platelets adhere to the sites of injured blood vessels as the result of exposure of the subendothelial tissue and native collagen[92]. As a result of this interaction, the platelets release ADP, which causes platelet aggregation. Also, when platelets aggregate they release phospholipids which are essential for the coagulation process. Several blood coagulation factors may be adsorbed on them, thus accelerating the coagulation.

Recently, Ganguly[93] presented evidence that while human platelets bind thrombin, this by itself is insufficient to cause platelet aggregation and that other reactions seem to be also involved. He suggested that the receptor of thrombin on platelets may be a protein having a molecular weight in excess of 200 000. The property of collagen to activate and aggregate the platelets appears to be related to its native, higher-ordered structure because denatured (random coil) collagen neither promotes the aggregation of platelets nor initiates the clotting process. It has been shown also that the activation of the Hageman factor may be related to the free carboxyl groups of collagen because esterification of these groups prevents the activation process[94]. The aggregation of platelets is drastically reduced when the positively charged free amino groups of collagen are replaced by neutral groups, suggesting that rigidly spaced polar groups in the molecule may be required for platelet aggregation[94]. Furthermore, the ability of native collagen to aggregate the platelets may be related also to the particular architecture of the collagen molecule because

monodisperse *tropocollagen* with its triple helix is apparently insufficient for platelet aggregation[95]. However, this does not necessarily rule out the possibility that the more complex triple helical structure of multimeric tropocollagen or collagen fibrils is not involved in the observed platelet aggregation.

Vertebrate collagens contain small quantities of carbohydrate that constitutes less than 2% by wt of the molecule[96]. Studies with soluble collagen from guinea pig skin have shown that glucose and galactose are linked to the hydroxyl groups of hydroxylysine in the peptide chain[97]. Suggestions were also made that an enzyme (platelet-bound glycosyl transferase) may be needed for the adhesion of platelets to native collagen as the primary step in haemostasis when the blood vessels are injured[98,99].

Recently, Bruck has called attention to the fact that the known electrical conduction properties of collagen may have a role in blood compatibility[100,101]. At low water adsorption levels, the conductivity is electronic, but when the water uptake exceeds approximately 10%, the conduction appears to become protonic[102]. Any disturbance to the native structure of this protein (such as increased salt concentration and dehydration) would be expected to affect its fibrillar structure and partly disrupt the supermolecular architecture. This in turn should be reflected in increased ion binding and changes in the electrical conduction of the molecule. As a speculative argument, it was proposed[100] that a sufficient alteration in the water structure and hence in the electrical conductivity of the molecule may be brought about also as a result of injury to the endothelium of blood vessels by exposing the underlying subendothelial components and collagen to the inorganic ions and organic polyelectrolytes of blood. The adsorption of these could subsequently affect both the platelets, which normally carry a net negative charge density, and also the coagulation factors. In other words, fundamental changes may occur in the native collagen molecule when it changes from the milieu that prevails underneath the normal endothelium to the one that may become operative when collagen is exposed to blood constituents as the result of injuries to the endothelial lining of the blood vessels. These changes are by themselves apparently insufficient to cause the denaturation of collagen, but sufficient to initiate the complex biochemical events that lead to platelet adhesion, aggregation, and the release of platelet constituents. The question may be raised in what way does electrical conduction influence the nature of the adsorption of plasma proteins and the activation of the blood clotting factors and the platelets, leading to thrombosis[100]?

In the absence of severe vascular injury and hence the exposure of collagen fibres, other subendothelial components, such as basement membranes and microfibrils, may be involved in the thrombogenic process. Work by Stemerman and his colleagues[103] suggests that microfibrils exhibit affinity for platelets. The basement membranes of the blood vessels have also been implicated in platelet adhesion[104]. On the other hand, elastin does not seem to cause platelet adhesion and aggregation[105].

Red cells contain a factor that can cause platelet adhesion and aggregation[106], which was subsequently identified as ADP[107]. The red cells also contain a clot-promoting factor called erythrocytin, which can be released on haemolysis[108,109]. Based on these and other observations, Stormorken[110] suggested including haemolysis in the theory of thrombogenesis.

Damage to the red cells can result from rheological

stresses and from the interaction with surfaces[111,112]. Shear-induced haemolysis is a common occurrence in various prosthetic devices[113]. A good correlation was demonstrated between critical surface free energy and haemolysis in a rotating shearing device for various polymeric surfaces[113]. Other investigators[114] reported that the adhesion of red cells to glass, siliconized glass, polyethylene and Teflon is governed by shear stresses which must exceed a minimum critical value before the cells will detach and that the minimum critical shear stress for detachment from clean surfaces correlates with the critical surface tension of the materials. This is in agreement with the finding of other investigators[113]. Exposure of blood to foreign surfaces also results in damage to the white cells, causing morphological changes, altered oxygen utilization, and impairment of their phagocytic activity[115].

As it was mentioned earlier, the exposure of synthetic surfaces to whole blood results, in most cases, in protein adsorption in a very short time, preceding the arrival of the formed elements, such as the platelets, red cells, and white cells. As pointed out elsewhere[4], several questions remain to be answered. Is there protein adsorption in every case (for example with hydrogels), and if so, what is the nature of the *first* layer of protein that is adsorbed during the initial contact? What conformational changes occur in this initially adsorbed protein? Is this protein denatured as the result of sufficiently large changes in its molecular architecture? What is the nature of the proteins that are adsorbed *by* this initially adsorbed protein layer? How do these adsorbed proteins trigger the blood clotting process and the adsorption and activation of platelets?

One way to study the adsorption of protein films on surfaces is by ellipsometry. Rothen[116] in 1945 designed the first ellipsometer (and coined its name) that can measure the thickness of thin transparent films up to several thousand Ångstroms adsorbed on solid surfaces. The ellipsometer determines the change in the elliptical polarization of a beam of light which is reflected from a surface coated with a thin film[117]. Vroman and Adams[118] investigated the adsorption of blood plasma proteins on metallic and anodized tantalum, oxidized and non-oxidized silicon, and polymeric substrates using a recording ellipsometer to follow the rate of adsorption. They have found that oxidized silicon surfaces adsorbed fibrinogen from blood plasma within two seconds, that is subsequently converted by a plasma component[118]. Platelets adhere to unconverted fibrinogen films deposited on glass[118]. Others have observed similar effects[119-121]. On the other hand, albumin-coated surfaces did not seem to attract platelets, whereas γ-globulin coatings caused not only platelet adhesion but also aggregation and the release of platelet constituents[119]. Other investigators have also reported on the interaction of fibrinogen, albumin, and prothrombin with various surfaces using ellipsometry and infra-red bound fraction measurements aimed at elucidating the molecular conformational changes that occur during the adsorption process[122,123]. Apparently, no change occurred in the extension of the proteins for a given surface during the time period while the adsorbance increases, suggesting a lack of molecular re-arrangement. Furthermore, the equilibrium extension values increased with decreasing surface energy, while the quantities of protein adsorbed at physiological concentrations remained approximately constant. These findings indicate that molecular conformation is dependent on surface energy. Other workers are investigating the thermodynamics of the interactions between selected blood plasma proteins and synthetic surfaces using

a sensitive microcalorimeter without an air/protein interface[124,125]. For γ-globulin adsorbed on glass powder, the enthalpy values suggest that the greatest interaction energies are evolved by those molecules which are directly exposed to the surface in the first monolayer of protein. Molecules in the second and successive layers of the protein give rise to exponentially decreasing enthalpy values with increasing molar surface concentrations[125].

Finally, the interaction of platelets with surfaces can be influenced by various agents and drugs. For example, the adherence of platelets to fibrinogen-coated glass surfaces and the release of platelet constituents are inhibited by divalent cations, prostaglandin E_1, and caffeine, all of which increase the level of cyclic AMP (adenosine monophosphate) in platelets[126]. Non-steroidal anti-inflammatory drugs also inhibit platelet adhesion to collagen-coated surfaces[127]. Prostaglandins are unsaturated fatty acids which are synthesized by many types of cells in very small quantities and released upon stimuli to the cell membranes. Prostaglandin E_1 is an especially powerful inhibitor of platelet aggregation[128], while prostaglandin E_2 enhances the second wave of platelet aggregation induced by ADP[129]. Certain antihistamines also inhibit platelet aggregation[130]. Other low molecular weight substances, such as derivatives of benzamidine, phenylguanidine and benzylamine, likewise inhibit platelet aggregation induced by ADP, collagen, and thrombin[131]. Among macromolecules, polyphloretinphosphate (a polyester of phloretin and phosphoric acid) has been shown recently to inhibit platelet adhesion on a polypropylene surface[132].

The above developments substantially widen the horizon for biomaterials research and applications, and emphasize the need for close interactions between the physical, biological, and medical disciplines.

A phenomenological description of the non-linear viscoelastic properties of polymer melts and concentrated solutions

M. G. Brereton

Department of Physics, University of Leeds, Leeds LS2 9JT UK
(Received 12 September 1974; revised 11 November 1974)

The non-linear stress response of molten polymers and concentrated solutions to an applied strain is formulated in terms of a material response function. The response function is considered to depend explicitly on the resulting stress history and it is shown how many of the non-linear features of these systems can be described both qualitatively and quantitatively. The particular equations used involve one non-linear term in addition to the usual linear response terms. Finally the non-linear equation is interpreted in terms of a plausible model process.

INTRODUCTION

For polymer melts and concentrated solutions highly non-linear effects dominate all aspects of both the transient and steady state behaviour. The data shown in *Figure 1*, from Vinogradov and Belkin[1], illustrate this point. It is typical for a whole class of concentrated polymer systems and shows the shear stress response to a suddenly imposed, steady state of simple shear flow. Above a certain strain rate the shear stress shows a characteristic overshoot behaviour where the stress actually decreases with increasing strain.

In the steady state the system exhibits a non-Newtonian viscosity, i.e. the shear stress depends non-linearly on the shear rate. In stress relaxation after the cessation of steady flow a very sudden drop in the stress at high shear rates followed by a comparatively slow relaxation is almost universally observed[2-6]. Also in many systems the stress relaxation after the cessation of a large shear rate can fall below that from small rates[7]. Other modes of testing such as stress relaxation from a constant strain[8] and from a repeated stop-start flow experiment[9] also show quite distinctive non-linear features.

Clearly we might hope to find a common explanation for these features which will enable the results from the different modes of testing to be correlated. It is the object of this paper to suggest in fairly general terms a possible mechanism to account for many of the non-linear features seen in concentrated polymer systems. Our description will be phenomenological in that, in this paper, no attempt will be made to set up a three-dimensional constitutive stress—strain relation. Instead we will aim at describing both qualitatively and quantitatively a wide range of non-linear viscoelastic behaviour in terms of the applied shear rate $\dot{\gamma}$ and resulting shear stress $\sigma(t)$. The equations to be described are, therefore, one-dimensional relations between $\sigma(t)$ and $\gamma(t')$. However, the form of this relation can still be usefully compared to the multiple integral representation for non-linear constitutive relations.

NON-LINEAR STRESS—STRAIN RELATION

There are many approaches used in understanding the rheological properties of polymers, ranging from formal constitutive relations through phenomenological analysis to empirical relations. Useful surveys of these methods have been given by Middleman[10], Christensen[11] and Spriggs[12]. In the linear regime the viscoelastic properties of polymers can be described by expressions of the form:

$$\begin{matrix} \text{stress} \\ \text{strain} \end{matrix} = \int_0^t (\text{response function}) \begin{cases} \text{stress}(t') \\ \text{strain}(t') \end{cases} dt' \qquad (1)$$
Figure 1 Stress relaxation data re-drawn from Vinogradov and Belkin. [Reproduced from *J. Polym. Sci. (A)* 1965, **3**, 917 by permission of John Wiley, New York ©]

For example, the shear stress $\sigma(t)$ response to an applied shear strain can be written as:

$$\sigma(t) = \int_0^t g(t - t')\gamma(t')dt' \tag{2}$$

where $\gamma(t')$ is the shear strain acting between the times 0 and t. (In this paper both σ and γ will be assumed to be zero for negative times.)

The response function $g(t)$ is related to the stress relaxation modulus, G by:

$$G(t) = \int_0^t \dot{g}(t - t')dt' \tag{3}$$

To extend this formulation to non-linear phenomena, we propose that the material response function g should now be dependent on the resulting stress response history $\{\sigma\}$. so that

$$\sigma(t) = \int_0^t g(t - t'; \{\sigma\})\gamma(t')dt' \tag{4}$$

Because the output stress is related to the input strain history $\{\gamma\}$ it might be argued that we could just as well consider g to be dependent on $\{\gamma\}$. At least in this latter case the stress would be expressed as an explicit function of the strain. However, by adopting the original form (4) we introduce the idea that the state of the material is *directly* affected by the resulting output. The stress is now determined by an implicit equation and the situation becomes very analogous to a feedback process. In fact by introducing the simplest form of feedback we can model all the non-linear behaviour described in the introduction. More specifically we will regard the non-linearity as a modification of the linear response function g by some as yet unspecified functional $U(t'; \{\sigma\})$ of the output acting at time t' intermediate between the times t and t_1. The situation is diagrammatically represented in *Figure 2*. As a result of the 'interaction', the linear response function $g(t' - t_1)$ is changed to another form $L(t - t_1')$. Separating out the linear term (2) we can write

$$\sigma(t) = \int_0^t g(t - t')\gamma(t')dt' +$$

$$\int_0^t dt' \int_0^{t'} dt_1 L(t - t')U(t'; \{\sigma\})g(t' - t_1)\gamma(t_1) \tag{5}$$

For the functional term we will choose the simplest form where U is proportional to σ and in order that the second term of equation (5) should act so as to reduce the stress, we take

$$U(t'; \{\sigma\}) = -c\sigma(t') \tag{6}$$
Figure 2 Diagrammatic representation of the proposed non-linearity

By defining the linear response term:

$$\sigma_L(t) = \int_0^t g(t - t')\gamma(t')dt' \tag{7}$$

and absorbing the constant c into the function $L(t)$, we can write equation (5) as:

$$\sigma(t) = \sigma_L(t) - \int_0^t L(t - t')\sigma_L(t')\sigma(t')dt' \tag{8}$$

This equation will form the basis for the rest of the paper. It has the form of an integral equation which if iterated would produce a series expansion similar to a multiple integral representation.

In the next section we will analyse the predictions of this non-linear form for an imposed shear rate.

SHEAR RATE CONTROLLED EXPERIMENT

Non-Newtonian viscosity

Under the action of a constant shear rate $\dot{\gamma}$ the flow reaches, at long times, a steady state stress level and we can define a viscosity η by:

$$\sigma(t \to \infty) \equiv \sigma_\infty = \eta\dot{\gamma} \tag{9}$$

where η will also depend on $\dot{\gamma}$. Using our proposed non-linear relation (8) we can find the long time limit for $\sigma(t)$ by integrating by parts the integral part of equation (8). The result is that:

$$\sigma(\infty) = \sigma_L(\infty) - I\sigma(\infty)\sigma_L(\infty) \tag{10}$$

where

$$I = \int_0^\infty L(t')dt' \tag{}$$

The linear stress response is given in terms of the Newtonian viscosity η_0 as $\sigma_L(\infty) = \eta_0\dot{\gamma}$ and equation (10) can be written as:

$$\sigma(\infty) = \left(\frac{\eta_0}{1 + \tau\dot{\gamma}}\right)\dot{\gamma} \tag{11}$$

where $\tau = I\eta_0$.
Figure 3 Steady state stress data from *Figure 1* plotted according to equation (14). Straight line fit gives $\eta_0 = 9.10 \times 10^5$ dyne/cm^{-2} sec. $\tau = 2.54$ sec

Consequently we can identify the non-Newtonian viscosity, η, as:

$$\eta(\dot\gamma) = \frac{\eta_0}{1 + \tau\dot\gamma} \tag{12}$$

Cross[17] has correlated an extensive amount of literature data on the shear dependence of the viscosity of concentrated polymer systems on the basis of a four parameter equation:

$$\frac{\eta_0 - \eta_\infty}{\eta - \eta_\infty} = 1 + (\tau\dot\gamma)^m \tag{13}$$

where η_0, η_∞, τ and m are the parameters. Briefly his results indicate that for monodisperse systems $m \simeq 1$ and η_∞ is small. Consequently our result (12) gives a reasonable description of the experimental data for monodisperse systems. In particular we can apply the data of Vinogradov and Belkin by writing equation (11) as:

$$\frac{1}{\sigma_\infty} = \frac{1}{\eta_0\dot\gamma} + \frac{\tau}{\eta_0} \tag{14}$$

which predicts a linear relation between $1/\sigma(t \to \infty)$ and $1/\dot\gamma$. *Figure 3* shows the data of Vinogradov plotted in this manner, the result is an excellent straight line from which η_0 and τ where determined as $\eta_0 = 9.10 \times 10^5$ dyne cm^{-2} sec^{-1} and $\tau = 2.54$ sec.

Transient overshoot behaviour

The results of Vinogradov shown in *Figure 1* for Alkathene are typical of the dynamic response for a large class of concentrated polymer systems[3,4,7,13-16]. To describe these data using equation (8) we need to know the linear stress response term $\sigma_L(t)$ and the non-linear function $L(t)$. In the rest of this paper we will tentatively take $L(t)$ to be a simple memory function:

$$L(t) = K\delta(t) + \rho e^{-\mu t} \tag{15}$$

For the linear term $\sigma_L(t)$ we will first consider the effect of

a Newtonian viscosity i.e. $\sigma_L(t) = \eta_0\dot\gamma$. Equation (8) can then be solved analytically for $\sigma(t)$ and the result is:

$$\sigma(t) = \eta_0\dot\gamma \left[\frac{\tau\dot\gamma \exp\{-\mu(1 + \dot\gamma\tau)t\} + 1}{1 + \tau\dot\gamma} \right] \tag{16}$$

where τ defined by equation (11) and for the simple form (15) for $H(t)$ is given by:

$$\tau = \frac{\rho\eta_0}{\mu} \tag{17}$$

We have also put $K = 0$ for further simplicity. This result shows that at $t = 0$, $\sigma(t) = \eta_0\dot\gamma$ which is just the linear response term σ_L, whilst as $t \to \infty$ the stress level drops to $\eta_0\dot\gamma/(1 + \tau\dot\gamma)$ in agreement with the non-Newtonian viscosity result discussed in the previous section. The relaxation of stress is governed by a shear rate dependent relaxation rate $\mu(1 + \tau\dot\gamma)$ which can also be written as $\mu\eta_0/\eta(\dot\gamma)$.

We still, as yet, have not got the short time behaviour correct, as our result (16) does not show the experimentally observed overshoot behaviour. This is because of the over-simplified Newtonian form we adopted for $\sigma_L(t)$. At short times there will be some elastic effects which we can model by putting

$$\sigma_L(t) = \eta_0\dot\gamma(1 - e^{-\lambda t}) \tag{18}$$

Unfortunately with this form for σ_L it is no longer possible to solve equation (8) for $\sigma(t)$ in terms of known functions. However, we can anticipate that there will be a competition between the build up of stress coming from the elastic term in the linear response and the relaxation of stress caused by the non-linear interaction. As the relaxation rate $\mu(1 + \tau\dot\gamma)$ is governed by the applied shear rate $\dot\gamma$, becoming faster as $\dot\gamma$ is increased, then we can anticipate that an overshoot behaviour will appear as $\dot\gamma$ is increased. In fact in the Appendix we have derived a condition on $\dot\gamma$ for the appearance of the overshoot behaviour. Using equation (18) for σ_L and equation (15) for $L(t)$, we find that:

$$\tau\dot\gamma > \frac{\mu - \lambda}{\lambda} \tag{19}$$

A numerical iteration of equation (8) was performed using equation (18) for σ_L and taking $K = 0$, $\rho = 1$, $\mu = 0.2$, $\eta_0 = 10$, $\lambda = 0.1$ as model values for the parameters involved. The results are shown in *Figure 4* and confirm our expectations about the origin of the overshoot behaviour. The next step was to see how well actual experimental data could be modelled by using equation (8). The data chosen, largely because they were the most comprehensive available, were those of Vinogradov and Belkin on Alkathene at 114°C. Using the simple parameterizations (15) and (18) for $L(t)$ and $\sigma_L(t)$ respectively we found, by trial and error, values for the parameters to fit the whole range of data. The result is shown in *Figure 5* together with the actual values of the parameters used. In view of the simple parameterization used the overall fit is quite good.

OTHER PROGRAMMED SHEAR INPUTS

In principle equation (8) can be solved numerically for any shear input behaviour. The choice of inputs considered in
Figure 4 Numerical iteration of equation (8). Parameters used: $\eta_0 = 10$, $\lambda = 0.1$, $K = 0$, $\rho = 1$, $\mu = 0.2$. Shear rates: 1, 0.2; 2, 0.1; 3, 0.05; 4, 0.01; 5, 0.001

$K = 0$, $\rho = 1$, $\mu = 0.2$, $\eta_0 = 10$. The results are shown in *Figure 6* and show a very sudden drop in the stress at high shear rates followed by a comparatively slow relaxation. This kind of behaviour is almost universally observed[2-6].

Another feature frequently observed is the fact that the stress relaxation after the cessation of large shear rates can fall below that from small rates[7]. By decreasing the non-linear relaxation rate μ from 0.2 to 0.1 we can also model this kind of behaviour. *Figure 7* shows the computed results for $\mu = 0.1$.

The reason for the sudden drop in stress can be seen from the structure of equation (8) if we write it as:

$$\sigma(t) = \sigma_L(t) - F(t) \tag{21}$$

where $F(t)$ is the feedback term $\int_0^t L(t - t')\sigma_L(t')\sigma(t')\,dt'$. Basically $\sigma(t)$ is determined through a competition between the linear response term $\sigma_L(t)$ and the feedback term $F(t)$. As the linear term σ_L begins to decrease after the cessation of flow, $F(t)$ still has a 'memory' of the previously high values of σ and σ_L and correspondingly subtracts a greater

Figure 5 Theoretical predictions based on equations (8), (15) and (18) (———). Experimental data from *Figure 1* (--------)

this section has been dictated by the availability of experimental data.

Stress relaxation after the cessation of steady flow

The linear stress response σ_L to a steady imposed flow is taken to be modelled by the viscoelastic form (18). If the flow is stopped at some t_0 then the linear stress relaxation is given for $t > t_0$:

$$\sigma_L(t) = \eta_0\dot{\gamma}(1 - e^{-\lambda t_0})e^{-\lambda(t - t_0)} \tag{20}$$

The full non-linear response $\sigma(t)$ is found by solving equation (8). Using equations (18) and (20) for σ_L and (15) for $H(t)$, we have numerically evaluated this equation using

Figure 6 Theoretical curves of stress relaxation based on equation (8). Parameters used: $\eta_0 = 10$, $\lambda = 0.1$, $\rho = 1$, $\mu = 0.2$
Figure 7 Curves of stress relaxation, after the cessation of steady flow, predicted by equation (8). Parameters used: $\eta_0 = 10$, $\lambda = 0.1$, $K = 0$, $\rho = 1$, $\mu = 0.1$
Figure 8 Data of Stratton and Butcher[9] on the stress relaxation obtained from a 'stop—start' experiment
Figure 9 Stress relaxation predicted from equation (8) using a 'start—stop' flow input. Parameters used: $\eta_0 = 10$, $\lambda = 0.1$, $K = 0$, $\rho = 1$, $\mu = 0.2$ and flow rate $\dot{\gamma} = 0.2$

contribution from σ_L. By increasing the 'memory' of this term, i.e. by decreasing μ we increase further the contribution of $F(t)$ as shown in *Figure 7*. For essentially the same argument we get the overshoot behaviour at the start up of a flow experiment. In this case $F(t)$ has a memory of previously low values of σ and σ_L, correspondingly it is not until the lapse of some time before it can effectively begin to subtract from σ_L.

The existance of this feedback term with a memory of the past stress history can be further demonstrated in a repeated stop—start flow experiment.

Stress relaxation in a repeated stop—start flow experiment

In this kind of experiment, a constant flow rate is imposed for one period of time, then switched off for another period and then switched on again etc. Such an experiment has been performed by Stratton and Butcher[9] on a polyisobutylene solution. The kind of results they obtained are reproduced in *Figure 8*. The main feature is a decreasing maximum with decreasing 'off-time'.

The predictions based on the use of equation (8) are shown in *Figure 9* and qualitatively agree with the experimental results. This behaviour can easily be understood

from the feedback structure of the equation. In an 'off' period the stress is given by:

$$\sigma_{\text{off}}(t) = \sigma_{L\text{off}}(t) - F(t) \qquad (22)$$

But at the start of an 'on' period the driving term $\sigma_{L\text{off}}$ changes rapidly to $\sigma_{L\text{on}}$ which is an increasing function of time. However, the feedback term $F(t)$ cannot change so quickly and continues to subtract from the linear term. Only if the 'off' period has been sufficiently long to allow this term to decay completely, will a full stress maximum be developed on the start up of the experiment.

Stress relaxation from a constant strain

Few measurements have been taken on the stress relaxation of concentrated polymer systems in the non-linear regime. Recently, however, a systematic series of measurements on polystyrene in solution under conditions of large strain were carried out by Einaga *et al.*[8]. Their results are reproduced in *Figure 10*. The relaxation modulus is clearly strain dependent, but the terminal relaxation time remains unaffected. The stress relaxation predicted by equation (8) is shown, for a wide range of strains, in *Figure 11*. The parameters are the same as those previously used. The selection of curves enclosed in the broken square show good qualitative agreement with the experimental ones. Again at long times the curves come together because in this approach only the linear term survives.

A MODEL INTERPRETATION

The approach adopted in this paper has so far avoided any specific molecular or mechanistic models. A non-linear equation has been proposed where the non-linearity comes from a simple feedback scheme. If we adopt very simple
Figure 10 Stress relaxation modulus $G(t) = \sigma(t)/\dot{\gamma}$ for a 20% solution of narrow distribution polystyrene in chlorinated diphenyl. Data taken from Einaga *et al.*[8]

forms for the terms σ_L and L occurring in this equation, then in these circumstances (and only in these circumstances) we can re-interpret our approach in terms of a simple mechanistic model. For example in a constant shear rate test, if we take the linear stress σ_L as given by the Newtonian result $\eta_0\dot{\gamma}$ and $L(t)$ given by equation (15) with $K = 0$, then the full stress response is given by equation (16) i.e.

$$\sigma(t) = \eta_0\dot{\gamma}\left[\frac{\tau\dot{\gamma}e^{-\mu(1+\tau\dot{\gamma})t} + 1}{1 + \tau\dot{\gamma}}\right] \qquad (23)$$

If we write this as:

$$\sigma(t) = \eta_0\dot{\gamma}n(t) \qquad (24)$$

then this suggests that we interpret $n(t)$ as the fraction $N(t)/N_0$ of stress bearing units present at the time t and that the contribution of each of these units to the total stress is $\bar{\eta}\dot{\gamma}$ where $\bar{\eta} = \eta_0/N_0$ and N_0 is the total number of units available in the absence of any external force. If we use a 'switch' to signify whether a unit is contributing to the total stress or not, then this model can be represented by the meachanistic model shown in *Figure 12*. From the solution (23) we have that the fraction of switches closed is:

$$n(t) = \frac{\tau\dot{\gamma}e^{-\mu(1+\tau\dot{\gamma})t} + 1}{1 + \tau\dot{\gamma}} \qquad (25)$$

By differentiating equation (25) we see that $n(t)$ satisfies the following simple rate equation:

$$\frac{dn}{dt} = -\mu(\tau\dot{\gamma})n + \mu(1 - n) \qquad (26)$$

This implies that the activation (opening) of the switches is governed by a shear rate dependent rate constant (first term

Figure 12 Dashpot model representation of the non-linear relation between stress and strain rate

of equation 26), whereas the restoration of the original closed state of the switches is simply governed by the departure from the equilibrium fraction, i.e. the second term $\mu(1 - n)$ in equation (26).

Clearly this particular model could be developed in a more realistic way in terms of the formation and destruction of network bonds[18,19]. The main point of introducing it here was to show how a specific model could be encompassed within the more general formalism described earlier.

CONCLUSION

We have proposed a new approach to the non-linear viscoelastic properties of molten polymers and concentrated solutions. The material response function describing the stress response to an applied strain was considered to depend explicitly on the output stress history $\{\sigma\}$. In this paper we expanded the dependence of the response function on $\{\sigma\}$ to first order in $\{\sigma\}$ and have shown both qualitatively and quantitatively how many of the non-linear features of these systems can be described. The formulation of the non-linear equation was accomplished by the introduction of a further phenomenological response function $L(t)$, in addition to the usual linear response terms. By adopting simple forms for the response functions involved, we could interpret the non-linear equation in terms of a plausible model process.

APPENDIX

Condition on the shear rate for the appearance of the overshoot behaviour

For $L(t)$ given by equation (15) with $K = 0$, the non-linear equation (8) for $\sigma(t)$ can be differentiated to give:

$$\frac{d\sigma}{dt}(t) + \left\{\mu + \rho\sigma_L(t)\right\} = \frac{d\sigma_L}{dt}(t) + \mu\sigma_L(t) \tag{A1}$$

The condition for a maximum in $\sigma(t)$ is that:

$$\frac{d\sigma}{dt} = 0 \text{ and } \frac{d^2\sigma}{dt^2} < 0 \tag{A2}$$

If we write the linear stress term σ_L as:

$$\sigma_L(t) = \dot{\gamma}f(t) \tag{A3}$$

then the condition for the overshoot behaviour (maximum is $\sigma(t)$) can be shown, using equations (A1) and (A2), to be:

$$\dot{\gamma} > \frac{\mu}{\rho} \left\{\frac{\mu\dot{f} + \ddot{f}}{\dot{f}^2 - f\ddot{f}}\right\} \tag{A4}$$

For the simple viscoelastic parameterization (18) we have used for σ_L:

$$f(t) = \eta_0(1 - e^{-\lambda t}) \tag{A5}$$

and consequently the condition on $\dot{\gamma}$ can be written as:

$$\tau\dot{\gamma} > \frac{\mu - \lambda}{\lambda} \tag{A6}$$

where, as usual, $\tau = \eta_0\rho/\mu$.

Studies on poly (iso-butene oxide):
3. Elastic hard fibre of poly (iso-butene oxide)

(Received 30 July 1974)

Poly(iso-butene oxide), a highly crystalline polyether, gives an 'elastic hard fibre', having excellent elastic recovery, on melt-spinning under appropriate drafting conditions. The interrelation between fabricating conditions and elastic recovery has been studied and the mechanism of the appearance of the elastic recovery is discussed. The mechanical, thermal and chemical properties of the fibre have been investigated.

INTRODUCTION

In recent years, it has been found that 'elastic hard fibres', having the property of high elastic recovery, are formed from highly crystalline polymers such as polypropylene[1], polyacetal[2], poly(3-methylbutene-1)[3] and polypivalolactone[4], under special fabricating conditions.

The mechanism of the elastic recovery of these 'elastic hard fibres' has been explained by Quynn and coworkers[5] as due to reversible 'bending' of the stacked crystalline lamellae. Clark[6] who discussed the elastic behaviour in terms of the 'RENKER WEB' model, (similar to network structure) explained the elastic property as arising from the formation of tie molecules in 'row' structure lamellae.

We have found out that poly(iso-butene oxide) (PIBO):

$$\left(\begin{array}{c} CH_3 \\ | \\ C-CH_2-O \\ | \\ CH_3 \end{array}\right)_n$$
a highly crystalline polyether, becomes an excellent 'elastic hard fibre', and a detailed study is underway. In this paper, we discuss mainly the processing and apparent behaviour of the fibre.

PIBO is easier to restrain in the lower degree of crystallinity on quenching than polyacetal, because it has a lower rate of crystallization as shown in *Figure 1*. Moreover, it is characteristic of this polymer that the polymer molecules readily orientate by rolling in the unmelted state (unpublished results).

We discovered that the filaments of PIBO exhibit very excellent elastic recovery when melt extruded, and stretched at the appropriate draft ratio under cooling conditions leading to crystallization. The characteristic mechanical and thermal properties of PIBO fibre, such as high elastic recovery and excellent low temperature properties, as well as the good chemical property compared to those of Spandex elastic fibre are described.

EXPERIMENTAL

Materials

Poly(iso-butene oxide) (PIBO) was prepared, using diethyl zinc, water and cyclohexylamine catalysts system[7] (molar ratio of $ZnEt_2/H_2O/C_6H_{11}NH_2$ was 3:1:1) in hexane at 75°C in a bench-scale reactor.

The residue of catalysts was extracted after polymerization, and the polymer was pelleted after addition of antioxidants such as 0.9 pph tetra-kis[methylene-3-(3,5-di-t-butyl-4-hydroxyl phenyl)propionate] methane and 0.1 pph dibenzildisulphide, and 0.5 pph 2-(2-hydroxy-5-methylphenyl)- benzotriazole as ultra-violet absorber.

The PIBO resin thus obtained has excellent mechanical, chemical and thermal properties, and is highly crystalline with m.p. of 172°C.
Figure 1 Crystallization rate of PIBO (●) and polyacetal (○). The values of half time of overall crystallization, $t_{1/2}$, were calculated from the half area of d.s.c. curves due to polymer crystallization

Table 1 Relationship between fabricating conditions and the elastic recovery of PIBO fibres

Runs	Nozzle (holes)	Temperature of cylinder and die (C_1-C_2-D)* (°C)	Speed of winding (m/min)	Crystallization condition	Elastic recovery
1	12	205–225–250	135	cooled in air	excellent
2	12	215–230–260	125	cooled in air	good
3	1	190–215–235	100–130	cooled in air	fair
4	1	190–200–220	55	cooled in air	poor
5	20	185–210–260	30–50	cooled in air	after heat-treated, fair
6	1	230–240–260	120	quenched in chilled ice-water (−10°C)	poor
7	12	210–230–260	90	treated in warmed cylinder (50°C)	poor

* C = cylinder; D = die

Melt spinning apparatus

The melt spinning die connected to a single hole nozzle having a diameter of 1 mm, or multi-hole nozzle of twelve or twenty holes, was attached to the extruder, the cylinder of which had a diameter of 25 mm, and a length of 420 mm. Single or multi-filaments passed on to a guide-roll and were wound up on a winding-roll placed at a distance of about 2m from the nozzle.

Measurements

Mechanical properties of the PIBO fibre and Spandex fibre were measured with a 'Tensilon UTM-II' (made by Toyo-Bowling Corp., Japan) in elongation–retraction cycles. A uniaxial stretching tool with scale was used to fix the fibre in elongated state for 24 h. Both energy for elongation and energy loss during elongation–retraction cycles were measured with a planimeter on the stress–strain curves.

RESULTS AND DISCUSSION

Relationship between fibre fabricating conditions and elastic recovery

The experimental results summarized in *Table 1* show that the elastic recovery of PIBO filaments is good for higher speeds of winding and crystallizing in ambient air, in comparison with crystallizing in water (run 6) or in a warm cylinder (run 7).

In the melt-spinning process, the draft ratio (DR) of filament is defined as:

$$DR = V_1/V_0 \tag{1}$$

where V_1 is winding speed and V_0 is the extruding speed of filament.

Since the extruded volume per unit time, Q, of the twelve and twenty hole nozzles are the same:

$$V_0 = Q/n \cdot \pi \cdot \phi^2 \tag{2}$$

where n is the number of nozzle holes, and ϕ is the radius of the nozzle hole.

The values of V_0 in both cases are also equal. Thus, the comparison between DR for twelve and twenty hole nozzles, is equivalent to the comparison between the corresponding V_1 values.

According to *Table 1*, the higher the draft ratio the better the elastic recovery in the cases of multi-hole nozzles, and

this indicates that the most important factors controlling the elastic recovery are shear stress and thermal conditions for the crystallization in good agreement with the mechanism of elastic recovery proposed by Quynn and coworkers.

On the other hand, V_0 in the case of a single hole nozzle is about five times larger than in the case of multi-hole nozzles and therefore, V_1 must be about five times larger for the multi-hole nozzles to get the equivalent draft ratio. Thus, the inferior elastic recovery of the filament of run 3 in comparison with that of run 2 could be ascribed to the lower draft ratio of the former.

The other factor influencing elastic recovery is the ratio of length to diameter of the nozzle hole (L/D). The L/D ratio of a single hole nozzle is larger than that of the multi-hole nozzles and it is likely that the smaller the value, the more excellent the elastic recovery.

Although it cannot be concluded from the results in *Table 1* that the temperature of the cylinder and die influence elastic recovery, it is our experience that the elastic recovery of filaments extruded at the slightly higher temperature than the melting point of PIBO is better than that of the filaments extruded at much higher temperatures. These facts may be understood if we consider that the higher 'spinning-stress' results in the superior elastic recovery of the filaments.

Furthermore, as shown in *Table 2*, the elastic recovery of PIBO filaments is very closely related to the orientation of filaments. This indicates that the adequate draft of PIBO filaments during crystallization is a main factor in determining the elastic recovery.

Measurements show that all samples had similar crystal structures.

We also found that PIBO filaments in the stretched state spontaneously lose the elastic recovery, when sprayed with organic solvents such as toluene, acetone, and regain it with

Table 2 Relationship between birefringence and the elastic recovery of PIBO fibres

Samples*	Birefringence, $\Delta n \times 10^{-3}$	Elastic recovery

† Elastic recovery was measured after the filament was fixed in the elongated state for a constant time, and then relaxed for 10 min

evaporation of the solvent. This behaviour is shown in *Figure 2* and suggests that the elastic recovery force could be intimately correlated to the surface energy and presumably interfacial energy of crystal interfaces.

Mechanical properties of PIBO fibre

Physical and mechanical properties of PIBO elastic hard fibre are compared with those of Spandex fibre in *Table 3*. The PIBO fibre has higher tensile strength, higher retracted force, higher energy required for elongation, lower elongation ratio at break and higher energy loss during elongation and retraction cycles. It may be considered that these characteristic properties are due to the mechanism of the elastic recovery of hard fibre which is different from that of 'entropic' elastic recovery of a crosslinked rubber.

Elastic recovery at low temperature

Table 4 shows that PIBO elastic hard fibre has very excellent low temperature properties. On the other hand, Spandex fibre shows an elastic recovery of only about 10% at the temperature of −75°C. These facts also suggest the former has sufficient elastic recovery at a much lower temperature below its glass transition temperature and the mechanism of the elastic recovery of the elastic hard fibre is different from that of rubber elasticity.

Chemical properties of PIBO fibre

In *Table 5*, some chemical properties of PIBO elastic hard fibre are compared with those of Spandex fibre. PIBO has excellent resistivity against chemical reagents and is more resistant against such reagents as sodium hypochlorite, tetrachloroethylene, carbon tetrachloride and dimethyl formamide than Spandex fibre.

Table 4 Mechanical properties at low temperature of PIBO elastic hard fibre

Reagents	PIBO degree of swelling (weight loss) (%)	Spandex weight loss (%)
60 min in boiling aq. H$_2$SO$_4$ (0.5 cm^3/l)	no change	no change 3.3
60 min in boiling aq. acetic acid (0.5 cm^3/l)	no change	no change 3.1
60 min in boiling aq. oxalic acid (1 g/l)	no change	no change 1.6
60 min in boiling aq. sodium hydroxide	no change	no change 3.1
60 min in boiling aq. sodium carbonate (10 g/l)	no change	no change 4.1
sodium hypochlorite (effective chlorine contents: 2 g/l) at 20°C, 24 h	no change 4.9	yellowish, mechanical properties change to worse
tetrachloroethylene (20°C, 24 h)	no change 1.9 (1.9)	slightly yellowish, mechanical properties change to worse
carbon tetrachloride (20°C, 24 h)	no change 0.7 (2.4)	slightly yellowish, mechanical properties change to worse
Soxhlet extraction (3 h):		
benzene	(3.3)	—
methanol	(3.2)	—
benzine	(3.0)	—
Warmed dimethyl formamide	no change	swollen or soluble
Hot dichlorobenzene, or xylene (100—140°C)	swollen or soluble	—

Table 6 Weathering* and thermal stability of PIBO and Spandex
elastic fibres

Tests	PIBO	Spandex fibre
Weathering stability: colour	no change	slightly yellowish
retension percentages of tensile strength	87—100	slightly decreased
retention percentages of elongation	100	—
elastic recovery	no change	—
Thermal stability (120°C, 5 h, in air)	no change	yellowish

* Weathering meter, 60°C, 40 h

Weathering resistivity and thermal stability

As shown in *Table 6*, the weathering resistivity and thermal stability of PIBO is superior to those of Spandex fibre and has excellent properties also from the point of view of practical use.

Some kinetic aspects of radical copolymerization: influence of the reaction medium on the reactivity ratios

Giorgio Bontà, Bianca M. Gallo and Saverio Russo
Istituto di Chimica Industriale, Università Genova, 16132 Genova, Italy
(Received 9 May 1974; revised 30 September 1974)

The reactivity ratios for the free radical copolymerization of styrene and methyl methacrylate at $50°C$ have been evaluated in dioxane, acetone and dimethylformamide solutions. In all these systems there is a marked solvent effect on both r_1 and r_2, which can be correlated to the variation in the dielectric constant of the solvent. The role of solvents in enhancing the polarization of growing chains and the alternation tendency is discussed.

INTRODUCTION

In the past few years we have undertaken a thorough study of the fundamental aspects of the free radical copolymerization reaction. In particular we have proposed[1] a novel approach for interpreting the behaviour of the overall copolymerization rate in place of the older inadequate reaction schemes, and at present we are studying in detail the many still obscure aspects in the kinetics and mechanisms which control the stages of initiation, propagation and termination.

As far as the propagation stage is concerned, we have evaluated[2] the temperature dependence of reactivity ratios for the pair styrene–methyl methacrylate polymerized in bulk at temperatures ranging from $40°$ to $80°C$ [initiator α, α'-azobisisobutyronitrile (AIBN)]. Changes in composition due to temperature variations were found to be not very pronounced, because of the small differences between the activation energies associated with the four rate constants in the propagation stage.

It is well known that, besides temperature and pressure, the reaction medium can affect reactivity ratios. This is clearly evident in systems including ionogenic monomers such as acrylic and methacrylic acids, sodium styrene sulphonate, etc.[3–6] and it has been observed also in the radical copolymerization of non-ionizable monomers, such as acrylamide[7–10], N-monosubstituted acrylamides[11,12], methacrylamide[13], acrylonitrile[14], methacrylonitrile[15]. Moreover, some recent papers[16,17], conflicting with earlier reports in the literature[18,19], show an appreciable effect of the reaction medium on the reactivity ratios for the pair styrene–methyl methacrylate.

Several interpretations have been proposed for the variation of the reactivity ratios as functions of the reaction medium. Monomer solvation, complex formation, stabilization of the growing chains, hydrogen bonding ability, polarization, proton donating tendency of the solvent, microphase separation and hot radical theory are among the most common ones.

In the present paper we refer to the solvent dependence of reactivity ratios for the pair styrene–methyl methacrylate polymerized at $50°C$. The solvents used are acetone, dioxane, and N,N'-dimethylformamide (DMF).

EXPERIMENTAL

Materials

Purification of styrene (S) (Carlo Erba RP) and methyl methacrylate (MMA) (B. H. Shilling) monomers was carried out following previously described techniques[1].

Acetone (Baker) was distilled twice at atmospheric pressure. DMF was purified following the method described by Ritchie et al.[20], i.e., it was dried by molecular sieves and vacuum distilled in a nitrogen stream over phosphorus pentoxide. Dioxane (Baker) was distilled twice at reduced pressure.

AIBN initiator (Merck) was purified as described previously[1].

Procedure

All experiments were performed in glass ampoules covered by aluminium foil to prevent photoinitiation. Sampling of monomers and solvents in the ratio 1 : 2 (v/v) was carried out using conventional techniques. The mixtures were flushed with helium, degassed and vacuum distilled into the ampoule containing a known amount of initiator. The ampoules were sealed under a pressure $\leqslant 10^{-5}$ mmHg. Initiator, monomer and solvent concentrations, temperature of sampling and reaction, polymerization times and yields were carefully determined. The polymerization temperature was $50° \pm 0.05°C$. The maximum monomer conversions were $\leqslant 3\%$.

The copolymers were precipitated twice using benzene or methyl ethyl ketone as solvents and methanol as precipitant.

Copolymer analysis

Copolymer composition was determined by elemental analysis, using a Carlo Erba CHNO automatic analyser model 1102. Monomer reactivity ratios were calculated on the basis of the curve-fitting method recently proposed by Braun et al.[21].

Infra-red spectroscopy

The absorption bands in the region of C=C stretching for styrene and methyl methacrylate were recorded in
Figure 1 Copolymer composition for the copolymerization of S (1) and MMA (2) in dioxane at 50°C

In order to evaluate whether solvent interaction influences the monomer or the growing radicals, we have measured the i.r. absorption of monomer mixtures with the different solvents. The spectroscopic data related to the stretching frequencies of the alkene groups are reported in *Table 2*. The strong absorption bands of DMF in that wavelength region prevented any measure of DMF—monomer interactions.

The above data do not show any change in the stretching frequencies of vinyl and vinylidene groups for the different monomer—solvent mixtures. Even if the above experimental evidence cannot be considered conclusive owing to the contrasting opinions on the validity of this argument[15,22,23], we suggest that interactions with solvents, if any, are not so remarkable as to affect monomer reactivities in an appreciable way.

Figure 4 shows r_1 and r_2 as functions of the solvent dielectric constant, ϵ at 50°C. For evaluating $\epsilon_{50°}$ interpolations and extrapolations of literature values have been used[24,25]. A good correlation between monomer reactivity ratios and ϵ is evident. An increase of solvent dielectric constant corresponds to a decrease of both reactivity ratios, which is more pronounced for r_1 than for r_2. The

sodium chloride microcells (0.075 mm pathlength), using 15% (v/v) solutions. A Perkin-Elmer grating spectrometer Model 225 was employed.

RESULTS AND DISCUSSION

Copolymer composition data as functions of monomer feed are reported in *Figures 1—3* and refer to acetone, dioxane and DMF solutions, respectively. Monomer reactivity ratios are quoted in *Table 1*. For comparison, the values referred to bulk copolymerization at 50°C are also given. The slight discrepancy with previous data in bulk[2] is due to the novel method used for the calculation of r_1 and r_2[21].

From the data of *Table 1* it is evident that all solvents used in the copolymerization experiments affect copolymer composition considerably. Both r_1 and r_2 are significantly changed.

Table 1 Reactivity ratios for the copolymerization of S and MMA at 50°C in various solvents

Solvent	r_1	r_2	$r_1 \cdot r_2$
dioxane	0.56_2	0.53_1	0.29_8
acetone	0.49_2	0.49_6	0.24_4
DMF	0.38_0	0.45_3	0.17_2
bulk	0.47_7	0.45_8	0.21_9

Table 2 Stretching frequencies (in cm^{-1}) of alkene groups from i.r. spectra of S and MMA in various solvents

Solvent	$C{=}C_S$	$C{=}C_{MMA}$
dioxane	1631	1637
acetone	1629	1637
DMF	—	—
bulk	1630	1639
Figure 4 Reactivity ratios and alternation tendency of S—MMA pair as functions of solvent dielectric constant at 50°C. □, r_1; △, r_2; ○, r_1r_2

simultaneous decrease of both monomer reactivity ratios determines a marked increase of the alternating tendency, inversely proportional to the product $r_1 \cdot r_2$.

As has been recently recalled[15], Bamford et al.[26] already foresaw the variation of reactivity ratios by changing the dielectric constant of the reaction medium; the assumption[19] of growing chains almost insensitive to the environment, because of their radical character, has been mainly based on earlier results[18], affected by large experimental errors in the determination of monomer reactivity ratios. Quite recently[27], Joshi has reviewed the various published methods of calculating r_1 and r_2. All the earlier methods are considered inadequate and obsolete, whereas new computer programs[28-30] for minimizing errors lead to the maximum reliable information about monomer reactivity ratios.

Using a very accurate set of analytical data for copolymer composition and a newer computer method[21] we have obtained the values of r_1 and r_2 given in *Table 1*. They do show an unequivocal solvent effect, which seems to be mainly due to changes in the dielectric constant. Variations in the propagation rate constants for the homopolymerization of styrene[31,32] and methyl methacrylate[33-35] in several solvents have been recently discovered. Often, the solvent effects show an opposite trend for the two monomers; a decrease of k_p for styrene polymerization corresponds to an increase of k_p for methyl methacrylate. Such effects are not confined only to aromatic solvents, but seem to be more general. Bamford et al.[33] and later Cameron et al.[32] interpret the above results in terms of stability and reactivity of the complex between growing radical and solvent as compared to the reactivity of the growing chain towards the monomer. This interpretation, supported by indirect evidence[36,37] is an extension of the well known radical complex theory by Henrici-Olivé and Olivé[38-41]. In a more general sense, it has been stated[42] that polymer radical 'complexing' can be regarded as an enhanced form of radical solvation by monomer and/or solvent.

The polarity of the medium would be expected to affect activation energies and entropies of propagation, by enhancing polarized forms of the growing radical in the transition state, although no charged species are directly involved in propagation. The polar character of polymer radicals has been recently reviewed by Jenkins[43].

The growing chains ending with a styrene unit are mainly polarized by the electron-donating phenyl group:

$$\text{\footnotesize} \overset{\delta^-}{\underset{\underset{\delta^+}{\overset{|}{\underset{|}{C_6H_5}}}}{\text{~~~CH}_2\text{—CH}}}$$
whereas the electron-withdrawing ester group gives methyl methacrylate growing ends which are oppositely polarized:

$$\text{~~~CH}_2\text{—}\overset{\overset{\displaystyle CH_3}{|}}{\underset{\underset{\displaystyle \delta^-}{\underset{|}{COOCH_3}}}{C}}\cdot\delta^+$$
On these grounds, the alternation tendency in the copolymerization of styrene and methyl methacrylate can be easily derived. Polar solvents will enhance the role of the polarized forms, resulting in a marked increase of the alternation tendency. The stronger effect on r_1 in comparison to r_2 may be ascribed to an opposite behaviour of k_{11} in solution as compared to k_{22}. The same patterns already discovered for bromobenzene[32,33], diethyl malonate[32,35] and benzonitrile[32,33], which increase k_{22} but decrease k_{11}, has been recently found to be valid also for the solvents considered in other studies of the present work[44].

Also from the results of Ito and Otsu[16], who were the first to point out a solvent effect in the copolymerization of styrene and methyl methacrylate, it is clearly evident that both r_1 and r_2 decrease as the dielectric constant of the solvent increases, although owing to large experimental errors, the data points do not fit a straight line*. Nevertheless, here again r_1 seems to be more solvent-dependent than r_2.

CONCLUSIONS

The solvent effects on the monomer reactivity ratios for the pair styrene–methyl methacrylate appear to be connected mainly with the polarity of the polymerizing medium. The enhancement of polarized forms of the growing radicals by polar solvents can explain the increase of the alternating tendency.

From our results it may be expected that highly polar solvents would give rise to alternating-type copolymers.

Further work in this area seems to be needed in the future.

Synthesis and characterization of some copolycarbonates of 2,2-bis(4-hydroxyphenyl) propane (bisphenol A) and 1,4-bis-(hydroxymethyl) decafluoro-bicyclo(2.2.1) heptane

G. A. Adam, I. W. Parsons and R. N. Haward

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK
(Received 2 December 1974)

The preparation and properties of the copolycarbonates of bisphenol A (I) and 1,4-bis(hydroxmethyl) decafluoro-bicyclo (2.2.1) heptane (II) are described. Most of the copolymers were prepared by reaction with phosgene in a mixture of pyridine and methylene dichloride. Bisphenol A polycarbonate molecular weights could be controlled by the use of small quantities of p-cresol. Increasing quantities of II led to a slight reduction in the glass transition temperature (T_g) of the copolymers and to an increased solubility in, for example, acetone. At the same time the heat stability, as measured thermogravimetrically, increased. Even small quantities of II in the copolymer have a substantial effect in reducing the tendency to crystallize and in limiting annealing effects. When heated at 120–140°C polycarbonate (I) shows an increase in yield strength and develops a substantial peak in the d.s.c. curve at T_g. These changes are much reduced by small amounts of copolymerized II. Dynamic mechanical properties were measured on a Rheovibron dynamic viscoelastometer.

INTRODUCTION

The polymers prepared by the reaction of 2,2-bis(4-hydroxyphenyl) propane (bisphenol A) (I) with phosgene to give 'polycarbonate' plastics have assumed increasing importance in recent years and a number of analogous polymers and copolymers have been prepared and studied[1-4].

(I)
Further, as 'polycarbonate resin' has become commercially available and widely applied, more has been learnt about their valuable properties and also about their limitations. Thus several originally unsuspected characteristics have come to light, many of which are not understood and most of which were not included in early studies of copolymers or analogous polyacrylates.

Among the properties of polycarbonate which have recently become of interest we may include a tendency to slow and partial crystallization and their response to annealing[5-8]. When annealed at elevated temperatures below the glass transition temperature, T_g, polycarbonate develops a nodular structure visible under the electron microscope[5]; this is accompanied by an increase in yield strength and a characteristic peak observable at T_g in a differential scanning calorimeter. These annealing effects are accompanied by a decrease in impact strength[8,9], although there are only very minor changes in low temperature relaxation behaviour[9]. The polymer is also rather sensitive to solvent stress cracking[10,11].

In view of these features we decided to prepare some

polycarbonate copolymers containing fluorine and to study their physical properties and since a new fluorine containing diol had been prepared in this Department we decided to use it in these studies. The compound was 1,4-bis(hydroxymethyl) decafluoro-bicyclo (2.2.1) heptane (II):

(II)
In the present work particular interest was attached to the question of a possible relation between the response to annealing and crystallization properties. Some theories of annealing behaviour propose significant analogies between the two processes[12,13] and if they are correct then both annealing and crystallization should be affected in the same way by the introduction of comonomers.

The preparation and properties of the copolymers are described below.

EXPERIMENTAL

Materials

Bisphenol A was a gift from Shell Chemicals UK Ltd. It was recrystallized to m.p.160°C. Phosgene, nitrogen, dichloromethane, pyridine and tetrahydrofuran (THF) were purified by standard methods before use. p-Cresol (BDH Ltd) was used as supplied. 1,4-Bis(hydroxymethyl) deca-fluoro-bicyclo (2.2.1) heptane was prepared by a modified procedure as follows. To a stirred mixture of 1*H*, 4*H*-deca-fluoro-bicyclo (2.2.1) heptane[14] (20.0 g), 37–41% (w/v) formalin (300 cm³) and dimethylsulphoxide (1 dm³) were

added portionwise 50 g of KOH pellets. The mixture was stirred at room temperature for ~2 h and then for 16 h at 75°C. The cooled mixture was then acidified with concentrated HCl, poured into water (0.5 dm³) and extracted with ether (3 x 0.5 dm³). The ethereal extracts were washed with water and dried (MgSO₄) before removal of the solvent by fractional distillation. The residue was sublimed to give a crude product (21.5 g) which was recrystallized twice from CCl₄ to give 19.0 g of 1,4-bis(hydroxymethyl)decafluoro-bicyclo (2.2.1) heptane, m.p. 210°C (lit. 210–210.5°C[15]) with a correct i.r. spectrum[16].

Polymerization procedures

Homogeneous systems. Some homogeneous polymerizations were carried out in pure pyridine but most polymers, including all the copolymers, were made on a 70 g scale in a mixed solvent system, using CH_2Cl_2/C_5H_5N, which gave higher molecular weights. The techniques employed followed closely those described in ref 17.

Heterogeneous systems. A series of two phase polymerizations were carried out using the procedure described in ref 18. Several batches of homopolymers were prepared in this system both with and without p-cresol as molecular weight modifier. Copolymerizations in this system proved unsuccessful (see text).

Polymer characterization

The following procedures were employed

Viscometry, using Ubbelohde suspended level viscometers at 25 ± 0.01°C. The solvent used was CH_2Cl_2 and the values used in the Mark–Houwink equation[19] are:

$$K = 1.11 \times 10^{-2} \ (\eta \ in \ cm^3/g)$$

$$\alpha = 0.82$$

The results obtained with commercial materials agreed with the values supplied by the manufacturer[20].

Vapour pressure osmometry (v.p.o.), using a Perkin-Elmer Hitachi model 115 instrument, with $CHCl_3$ as solvent at 32 ± 0.2°C.

Gel permeation chromatography (g.p.c.), using a Waters Association analytical instrument fitted with a differential refractometry detector. Solutions of 2.5 g polymer/dm³

THF were employed at 25°C. Calibration was against standard polystyrenes.

Infra-red (i.r.) spectroscopy, using a Perkin-Elmer 257 grating instrument.

^1H n.m.r. spectroscopy, using a Perkin-Elmer R12 instrument, operating at 60 MHz; samples were run as $CDCl_3$ solutions, with an internal TMS standard.

Tensile tests, were performed on an Instron floor model TT-BM or a metric table model Tm-M. The tests were carried out in a controlled environment at 23 ± 1°C and 50 ± 5% relative humidity.

Dynamic mechanical properties of the materials were determined on a Rheovibron Direct Reading Viscoelastometer, Model DDVII.

Differential scanning calorimetry (d.s.c.) was performed on a Perkin-Elmer DSC-2 machine.

Differential thermal gravimetry was performed using a Perkin-Elmer Thermobalance, Model TGS-1.

Preparation of copolymers and homopolymers

Three systems were tried for these polymerizations, viz. two homogeneous systems (one using pure pyridine as solvent, and one with a mixed pyridine/dichloromethane solvent) and a heterogeneous (two phase) system. Initial trials showed that all three of these systems gave efficient homopolymerizations of bisphenol A, with a heterogeneous system giving generally higher molecular weights, but that only the homogeneous system with mixed solvents gave good copolymerizations. The heterogeneous system gave crude 'copolymers' which certainly contained fluorine, as evidenced by elemental analyses, but partial extraction of these materials with dichloromethane gave fractions which differed greatly in their fluorine contents, showing that these copolymers were not uniform. Further efforts at copolymerizations were therefore concentrated on the homogeneous system.

In the homogeneous systems it was found that use of a pure pyridine solvent gave materials of rather low molecular weight, but that the mixed solvent system gave high molecular weight material. The range of materials prepared and used are described in *Table 1*.

The early trials showed the necessity of allowing separately for the effects of molecular weight and fluorocarbon (como-

nomer) content upon some of the physical properties of the polymers. Consequently, efforts were made to prepare a range of bisphenol A polycarbonates of differing molecular weights. Two approaches were made to this problem. First, using both the heterogeneous and homogeneous systems, the rate of phosgenation was varied, particularly towards the end of the reaction. This did vary the molecular weights somewhat, but did not produce a wide enough range; also, the reproducibility of this method was poor. Secondly, *p*-cresol was used as a molecular weight modifier, following the method of Weilgosz *et al.*[21]. This produced an acceptable range of molecular weights, using the heterogeneous system for high molecular weights, and the (pure pyridine) homogeneous system for the lower ones.

Synthesis of the fluorocarbon diol

This compound was prepared by the following (schematic) route:

(III)

(II)
where F in the ring denotes 'all unmarked bonds to fluorine'.

In this sequence the intermediate $1H,4H$-decafluorobicyclo (2.2.1) heptane (III) was available to us[15], but the published method for the second stage proved difficult to scale up. A modified procedure has therefore been developed (see above) which consistently gives large batches of pure product. It should be pointed out that even small deviations from this procedure give much reduced yields.

Simple theory shows that in a closed condensation polymerization system where the molecular weight is determined by adventitious terminating agents, T:

$$\overline{M}_n = \frac{2[W]}{[T]}$$

where [W] is the initial monomer concentration. Thus, when an artificial terminator C is introduced:

$$\overline{M}_n = \frac{2[W]}{[T + C]}$$

Since [T] will be different for the two systems which we have studied, a plot of $\overline{M}_n$, or $\overline{M}_v$ for these polymers against the concentration of *p*-cresol will give two separate curves (*Figure 1*).

Also, for any system:

$$\frac{1}{\overline{M}_n} - \frac{1}{\overline{M}_{n0}} = \frac{[C]}{2[W]}$$

where $\overline{M}_{n0}$ is the number average molecular weight obtained with a given system in the absence of added terminator.

Further we have found from g.p.c. measurements (with homopolymers) that $\overline{M}_v \sim 2.5 \ \overline{M}_n$ so that in this case:

$$\frac{1}{\overline{M}_v} - \frac{1}{\overline{M}_{v0}} = \frac{[C]}{[W]}$$

A plot of results from both systems in this form is given in *Figure 2* where the gradient is found to be 0.23, i.e. it is in good agreement with expectation for simple theory and also suggests that our preparation methods are reasonably satisfactory.

RESULTS AND DISCUSSION

Polymer characterizations

The physical methods employed give the results shown in *Table 1*. Some comments are, however, required. The most
Figure 2 Relation between the reciprocal molecular weight and the concentration of added chain terminator. ● Homogeneous; ○, heterogeneous system

general characterization procedures are of course those of d.s.c. and g.p.c. The g.p.c. results require interpretation, however, since they depend upon the size of the polymer molecules per unit molecular weight, which is a variable from polymer to polymer. In this work the most internally consistent set of all molecular weights is obtained if the molecular weight of the polymer is worked out by calculating the weight per Å of the extended copolymer chain, using the figure for percentage fluorocarbon incorporation calculated from the elemental analysis figures, doing the same for polystyrene, and then assuming that these two (rather different) chains behave similarly with respect to coil volume, degree of extension in the solvent, etc. These results are the ones included in *Table 1*. The intrinsic viscosities of the copolymers are, of course, experimental data, but their conversion into $\bar{M}_v$ numbers is a difficulty. This has been done using values for K and α appropriate to homopolymer. It is realised that inaccuracies will occur here, but this procedure seems to be the best available.

However, since the $\bar{M}_n$ values were directly measured for the copolymers and were generally more relevant to the comparison of physical properties of different polymers the difficulty over $\bar{M}_v$ does not play a very significant part in the subsequent discussion.

Two further points need to be made concerning the copolymers. First, i.r. spectroscopy could be used qualitatively to determine the incorporation of fluorocarbon into the copolymer: a band at 935 cm^{-1} appeared to belong to the fluorocarbon unit, and one at 890 cm^{-1} to belong to the bisphenol A unit. Secondly, the amount of fluorocarbon incorporated could be estimated from ^{1}H n.m.r. spectroscopy, by integrating a band at 4.8—4.95 (CH_2O) against bands at 1.5—1.755 (—CH_3) and/or the aromatic protons. Calculations based on these results suggest lower comonomer contents than do the elemental analyses. Whilst we can offer no proof, we suggest the following reaction sequence as a possible explanation of this:
In this way, there would be less than two CH_2—O units per fluorocarbon unit incorporated into the chain.

Thermal stability of copolymers

It is important that any copolymer of polycarbonate should have an adequate thermal stability, since processing (e.g. moulding) must inevitably take place above the relatively high glass transition temperatures (around 160°C — see below). In order to estimate thermal stability at high temperatures it is convenient to employ thermogravimetric analysis, i.e. the specimen is heated to a high temperature and changes of weight are observed. Although the method is quite simple to apply it is necessary to ensure that the copolymers and homopolymers studied are themselves truly comparable. For this purpose we note that the degradation of polycarbonate has been reported to depend on the active hydrogen present either as water or as end groups[22]. The latter will lead to an influence due to molecular weight, which will be described in detail elsewhere[23], but for the

present purpose it will be enough to ensure that all polymers compared lie within a reasonably narrow band of molecular weight ($\bar{M}_n$).

Four polymers of this type are shown in *Figure 3* where the isothermal weight loss at 410°C is plotted as a function of time. It will be seen that the two copolymers have a thermal stability superior to the homopolymer prepared in the same way. However, the equivalent commercial polymer is better than the laboratory materials, probably indicating the use of a stabilizer or stabilizing treatment. Nevertheless direct comparison of equivalent homopolymers and copolymers shows that no special difficulty need be expected from this source.

Crystallization of polycarbonate copolymers

The polycarbonates studied in the present work were all 100% amorphous (as shown by d.s.c.) unless they were specially treated. However, it is well known that the polycarbonate of 1 may be crystallized in a number of ways. These include heating for long times at temperatures above T_g[24] and treatment with solvents[25]. We found it possible to obtain powdery products with relatively high crystallinity by dissolving the polymers in boiling 1,2-dichloroethane (78°C) and precipitating at 80°C in petroleum ether (b.p. 80—100°C). The fine precipitates were dried under vacuum at 100°C for 8 h. A second method of treatment consisted
Figure 3 Thermogravigrams of polymers and copolymers heated at 410°C. A, Makrolon 5730; B, 10% copolymer; C, 2% copolymer; D, synthetic polycarbonate
Figure 4 Crystallinity of copolymers and homopolymers precipitated from solution. ●, Homopolymers; □, copolymers with number showing percentage II. The homopolymers were synthesized to give a range of molecular weights

of simply heating the polymer at 195°C under vacuum for 8 and 21 days respectively. In each case the percentage crystallinity (T_m 250–260°C) was determined by d.s.c. measurements assuming a heat of fusion of 30.7 cal/g. This value was obtained by averaging our own estimates and those quoted by Wineman[26].

As the amount of crystallization achieved with a particular treatment was shown to depend on the molecular weight of the homopolymers, we have presented our results to show the percentage crystallinity measured for a copolymer of a particular molecular weight in such a way that the value can be related to that of a similar homopolymer (*Figures 4* and *5*). It will be seen that even small quantities of the comonomer (II) have a substantial effect on crystallization and that above 15% comonomer the amount of crystallization is virtually zero.
